Lactic acidosis results from the accumulation of lactate and protons in the body fluids and is often associated with poor clinical outcomes. The effect of lactic acidosis is governed by its severity and the clinical context. Mortality is increased by a factor of nearly three when lactic acidosis accompanies low-flow states or sepsis, and the higher the lactate level, the worse the outcome. Although hyperlactatemia is often attributed to tissue hypoxia, it can result from other mechanisms. Control of the triggering conditions is the only effective means of treatment. However, advances in understanding its pathophysiological features and the factors causing cellular dysfunction in the condition could lead to new therapies. This overview of lactic acidosis emphasizes its pathophysiological aspects, as well as diagnosis and management. We confine our discussion to disorders associated with accumulation of the \( l \)-optical isomer of lactate, which represent the vast majority of cases of lactic acidosis encountered clinically.

**Pathophysiological Features**

### Normal Lactate Metabolism

The reaction integral to the generation or consumption of lactate is shown below:

\[
\text{pyruvate} + \text{NADH} + \text{H}^+ \leftrightarrow \text{lactate} + \text{NAD}^+.
\]

Pyrurate is generated largely by anaerobic glycolysis (Embden–Meyerhof pathway). The redox-coupled interconversion of pyruvate and lactate occurs in the cytosol and is catalyzed by lactate dehydrogenase (LDH), a tetramer with five isoforms, each made up of different combinations of two subunits, LDHA and LDHB. The LDHA subunit has a higher affinity for pyruvate and its reduction than does LDHB; thus, the nature of the LDH isoforms in tissues affects lactate metabolism. The blood lactate:pyruvate ratio is normally 10:1, but it rises with an increased ratio of NADH concentration ([NADH]) to NAD+ concentration ([NAD+]) (redox state).

Approximately 20 mmol of lactate per kilogram of body weight is produced in the human body daily, primarily by highly glycolytic tissues containing LDHA-rich LDH, such as skeletal muscle. Lactate is reconverted to pyruvate and consumed in the mitochondria of the liver, kidney, and other tissues, which have LDHB-rich LDH. The pathways include the Cori cycle, which generates glucose but consumes ATP in the liver and kidney (gluconeogenesis), as well as the tricarboxylic acid cycle and oxidative phosphorylation in the liver, kidney, muscle, heart, brain, and other tissues, which generate ATP when pyruvate is oxidized to carbon dioxide and water. Lactate consumption is subserved by intraorgan and interorgan lactate shuttles facilitated by monocarboxylic acid transporters (MCTs), which mediate the influx and efflux of lactate and accompanying protons. Normally, the generation and consump-
tion of lactate are equivalent, which results in a stable concentration of lactate in the blood.\textsuperscript{4,6} Lactate production can rise markedly, as exemplified by its increase by a factor of several hundred during maximal exercise,\textsuperscript{5} but it can also be rapidly consumed, as seen after cessation of exercise, seizures, or exogenous lactate loads.\textsuperscript{5,7}

The bioenergetics of lactate generation can be summarized as follows:

\[
\text{glucose} + 2(\text{ADP} + \text{inorganic phosphate}) \rightarrow 2 \text{lactate} + 2 \text{H}^+ + 2 \text{ATP}.
\]

Production of lactate ions by means of glycolysis is accompanied by the release of an equivalent number of protons from the hydrolysis of the generated ATP. Conversely, lactate consumption removes an equivalent number of protons, thereby maintaining the internal acid–base balance.\textsuperscript{4}

**HYPERLACTATEMIA**

Hyperlactatemia occurs when lactate production exceeds lactate consumption. It also signifies the addition of a number of protons equivalent to the number of excess lactate ions, regardless of the prevailing acid–base status. Establishing the pathogenesis of hyperlactatemia can be a valuable guide to therapy.

In tissue hypoxia, whether global or localized, lactate is overproduced and underutilized as a result of impaired mitochondrial oxidation (see Fig. S1A and S1B in the Supplementary Appendix, available with the full text of this article at NEJM.org).\textsuperscript{4} Even if systemic oxygen delivery is not low enough to cause generalized hypoxia, microcirculatory dysfunction can cause regional tissue hypoxia and hyperlactatemia.\textsuperscript{8} Coexisting acidemia contributes to decreased lactate removal by the liver; severe hypoxia and acidemia can convert the liver into a net lactate-producing organ.\textsuperscript{4}

Hyperlactatemia can also result from aerobic glycolysis, a term denoting stimulated glycolysis that depends on factors other than tissue hypoxia. Activated in response to stress, aerobic glycolysis is an effective, albeit inefficient, mechanism for rapid generation of ATP. In the hyperdynamic stage of sepsis, epinephrine-dependent stimulation of the $\beta_2$-adrenoceptor augments the glycolytic flux both directly and through enhancement of the sarcolemmal Na\textsuperscript{+},K\textsuperscript{+}-ATPase (which consumes large quantities of ATP)\textsuperscript{9} (Fig. S1C in the Supplementary Appendix). Other disorders associated with elevated epinephrine levels, such as severe asthma (especially with overuse of $\beta_1$-adrenergic agonists), extensive trauma, cardiogenic or hemorrhagic shock, and pheochromocytoma, can cause hyperlactatemia through this mechanism.\textsuperscript{9} In inflammatory states, aerobic glycolysis can also be driven by cytokine-dependent stimulation of cellular glucose uptake\textsuperscript{10}; in alkaline disorders, it can be driven by stimulation of 6-phosphofructokinase.\textsuperscript{4} Aerobic glycolysis and tissue hypoxia are not mutually exclusive; under certain circumstances, both can contribute to hyperlactatemia.\textsuperscript{4,9}

Drugs that impair oxidative phosphorylation, such as antiretroviral agents and propofol, can augment lactic acid production and on rare occasions cause severe lactic acidosis. Patients receiving these drugs should be monitored carefully.

The liver accounts for up to 70% of whole-body lactate clearance.\textsuperscript{11} In patients with sepsis, even when they are hemodynamically stable and have normal liver function, lactate clearance can be reduced, possibly through inhibition of pyruvate dehydrogenase.\textsuperscript{12} Chronic liver disease exacerbates hyperlactatemia due to sepsis or other disorders,\textsuperscript{7,11} but in the absence of such disorders, even severe cirrhosis rarely generates blood lactate levels that are more than minimally elevated. However, hyperlactatemia is common in acute fulminant liver disease, reflecting both reduced clearance and increased production of lactate by the liver,\textsuperscript{13} and is an important prognostic factor.

**EFFECTS ON CELLULAR FUNCTION**

The cellular dysfunction in hyperlactatemia is complex. Tissue hypoxia, if present, is a major factor. If the cellular milieu is also severely acidic, cellular dysfunction is likely to be exacerbated. The latter factor alone can decrease cardiac contractility, cardiac output, blood pressure, and tissue perfusion; can sensitize the myocardium to cardiac arrhythmias; and can attenuate the cardiovascular responsiveness to catecholamines.\textsuperscript{14}

In some studies, the severity of the acidemia was a better predictor of cellular dysfunction and clinical outcomes than the hyperlactatemia.\textsuperscript{15} However, acidemia is often absent as a result of coexisting acid–base disorders.\textsuperscript{7,14} The interaction of systemic acidity and blood lactate and their effect on clinical outcomes require further study.
Whether hyperlactatemia itself has an effect on cellular function remains unclear. In vitro studies suggest that lactate can depress cardiac contractility, yet sodium lactate infusions that raised blood lactate to levels as high as 15 mmol per liter did not depress hemodynamic measures in patients after cardiac surgery.

**CAUSES**

The major causes of lactic acidosis and their presumed mechanisms are listed in Table 1. Typically, they have been divided into disorders associated with tissue hypoxia (type A) and disorders in which tissue hypoxia is absent (type B). However, the evidence of tissue hypoxia can be subtle, and hyperlactatemia can be of both hypoxic and nonhypoxic origin.

Cardiogenic or hypovolemic shock, severe heart failure, severe trauma, and sepsis are the most common causes of lactic acidosis, accounting for the vast majority of cases.

**DIAGNOSIS**

Evidence of severe cardiopulmonary disease, the systemic inflammatory response syndrome, sepsis, severe trauma, or volume depletion offers important clues for diagnosing lactic acidosis. An elevated serum anion gap, particularly a value higher than 30 mmol per liter, can provide supportive evidence. However, other causes of a raised anion gap, such as ketoacidosis and toxic alcohol ingestion, should always be considered.

The increase in the anion gap (ΔAG) can mirror the blood lactate level, but a close relationship might not always be found, since anions other than lactate often contribute to the ΔAG.

A normal anion gap does not rule out lactic acidosis. In one study, 50% of patients with a serum lactate level of 5 to 10 mmol per liter did not have an elevated anion gap. Correction of the anion gap for the effect of serum albumin can improve its sensitivity, but many cases will still escape detection. Therefore, the serum anion gap lacks sufficient sensitivity or specificity to serve as a screening tool for lactic acidosis.

Because a 1:1 relationship between the ΔAG and the decrease in serum bicarbonate concentration ([HCO₃⁻]), ΔHCO₃⁻, is often found in ketoacidosis, deviations from this ratio suggest coexisting acid–base disturbances. In lactic acidosis, the ΔAG:ΔHCO₃⁻ ratio is often greater than 1, in part because the apparent space of distribution of protons exceeds that of lactate; therefore, an increased ratio might not always suggest a coexisting acid–base disorder.

An elevated blood lactate level is essential for confirmation of the diagnosis. The lower limit of the normal range for the blood lactate level, 0.5 mmol per liter, is consistent among clinical laboratories, but the upper limit can vary substantially, from as low as 1.0 mmol per liter to as high as 2.2 mmol per liter. Therefore, the cutoff for abnormal values often differs among laboratories. Levels at the upper tier of normal values have been associated with increased mortality among seriously ill patients. Thus, blood lactate concentrations at the upper tier of normal values or slightly increased from a previous baseline value, although remaining within the normal range, can augur a poor outcome and call for monitoring of the patient.

Previously, the definition of lactic acidosis included a blood pH of 7.35 or lower and a serum [HCO₃⁻] of 20 mmol per liter or lower. However, the absence of one or both of these features because of coexisting acid–base disorders does not rule out lactic acidosis. For example, coexisting respiratory alkalosis can increase the blood pH into the alkalemic range, whereas coexisting metabolic alkalosis can result in both hyperbicarbonatemia and alkalalemia (Fig. 1 and 2). In contrast, coexisting respiratory alkalosis can cause severe acidemia (Fig. 2).

Lactic acidosis due to grand mal seizures is associated with normokalemia, because the concurrent entry of lactate and protons into cells negates the need for potassium exit from cells to maintain electroneutrality. However, hyperkalemia is commonly observed in critically ill patients, because they often have renal failure. In addition, potassium is released from damaged tissues. However, hypokalemia can occur when β₂-adrenoceptor stimulation drives potassium into cells.

A serum osmolal gap of more than 20 mOsm per kilogram of water has been reported in some cases, probably reflecting the release of osmotically active solute from ischemic tissues. However, other disorders characterized by an increased osmolar gap and hyperlactatemia (e.g., exposure to toxic alcohols) should be ruled out.

* PaO<sub>2</sub> denotes partial pressure of arterial oxygen.
Supporting the Circulation and Ventilation

Restoring tissue perfusion after hemodynamic compromise is essential in the treatment of patients with lactic acidosis. Vasopressors and inotropic agents should be administered as needed.\textsuperscript{26,27} Acidemia blunts the response to catecholamines, thereby increasing the required dose.\textsuperscript{14} High doses of catecholamines can aggravate hyperlactatemia by reducing tissue perfusion or overstimulating the $\beta_2$-adrenoceptor; therefore, the dose should be adjusted carefully.

Crystalloid and colloid solutions are both effective in restoring tissue perfusion in patients with sepsis or hypovolemia.\textsuperscript{29} However, reports of acute kidney injury, bleeding, and increased mortality in association with hydroxyethyl starch synthetic-colloid solutions provide evidence against their use. If a colloid solution is indicated, albumin should be used. Saline administration can generate or exacerbate a non–anion gap metabolic acidosis\textsuperscript{29} and reduce ionized calcium levels, factors that could depress cardiac function.\textsuperscript{30,31} Also, chloride-rich solutions have been linked to acute kidney injury.\textsuperscript{32} Crystalloids containing bicarbonate or its precursors (balanced salt solutions), such as Ringer’s solution with lactate and Plasma-Lyte (Baxter International) with acetate and gluconate, will not cause non–anion gap metabolic acidosis and may reduce the risk of acute kidney injury, but they can occasionally cause metabolic alkalosis.\textsuperscript{31,33}

A reduced need for renal replacement therapy...
has been reported in seriously ill patients receiving balanced salt solutions rather than saline, but opinions differ regarding which solution should be favored. Solutions containing a racemic mixture of \( \text{d}-\text{lactic acid} \) and \( \text{l}-\text{lactic acid} \) generate as much base as do solutions with an equimolar concentration of only \( \text{l}-\text{lactic acid} \). Infusion of large quantities of Ringer’s lactate can increase blood lactate levels, but the increment is often small in the absence of abnormalities in lactate clearance. Citrate-containing solutions can lead to the generation of microthrombi. Randomized, controlled studies are needed to determine the most effective and safe crystalloid.

Oxygen delivery to tissues depends on the cardiac output, regional blood flow, hemoglobin concentration, and partial pressure of oxygen (\( \text{PaO}_2 \)). Red-cell transfusions should be administered to maintain the hemoglobin concentration at a level above 7 g per deciliter. An adequate \( \text{PaO}_2 \) should be maintained by ensuring an appropriate inspired oxygen concentration, with endotracheal intubation and mechanical ventilation as needed. Invasive ventilation may also be required to prevent hypercapnia, particularly if acidemia persists or worsens.

### IMPROVING THE MICROCIRCULATION

Abnormalities of the microcirculation, if persistent, can augur clinical deterioration and death. Several agents, including dobutamine, acetylcholine, and nitroglycerin, have been shown to improve microvascular perfusion independently of systemic hemodynamics, to reduce hyperlactatemia, and even to improve the outcome. Measures to rescue the microcirculation are likely to become a high priority in the future.

### INITIATING CAUSE-SPECIFIC MEASURES

Resuscitative efforts should be complemented by measures targeting the cause or causes of lactic acidosis. Such measures can include treatment of sepsis with the appropriate antibiotic agents; management of arrhythmias, resynchronization therapy, and left-ventricular assist devices for advanced heart failure; coronary intervention for acute myo-
cardiac infarction; surgery for trauma, tissue ischemia, or toxic megacolon; dialysis for removal of toxins or drugs; discontinuation of certain drugs; and reduction of tumor mass for cancer.

**BASE ADMINISTRATION**

Given the potentially deleterious effects of an acidic environment, some clinicians recommend therapy with intravenous sodium bicarbonate for severe acidemia (blood pH, <7.2). However, the value of bicarbonate therapy in reducing mortality or improving hemodynamics remains unproven. This absence of evidence that bicarbonate therapy is beneficial has been attributed primarily to two adverse events that occur with its administration: intracellular acidification due to the accumulation of carbon dioxide after bicarbonate infusion and a pH-dependent decrease in levels of ionized calcium, a modulator of cardiac contractility. Intracellular acidification is presumed to be more frequent and severe when large quantities of bicarbonate are administered rapidly in patients with severe circulatory failure, which impedes the removal of carbon dioxide from tissues and its excretion by the lungs. Circumvention of these complications might allow the putative benefits of bicarbonate to be manifested.

Using dialysis to provide bicarbonate can prevent a decrease in ionized calcium, prevent volume overload and hyperosmolality (potential complications of bicarbonate infusion), and remove substances associated with lactic acidosis, such as metformin. Through an alkalinizing effect, base administration, whether by means of infusion or dialysis, increases net lactic acid production. Substantial clearance of lactate can be achieved with dialysis, although the quantity cleared is much lower than the quantity of lactate produced in severe lactic acidosis. Continuous dialysis is often favored over intermittent dialysis because it delivers bicarbonate at a lower rate and is associated with fewer adverse events in patients with hemodynamic instability. Controlled studies of the effect of dialysis on lactic acidosis are warranted.

Other buffers have been developed to minimize carbon dioxide generation, including THAM (tris-hydroxymethyl aminomethane) and Carbicarb (a 1:1 mixture of sodium carbonate and sodium bicarbonate). Only THAM is currently available for clinical use, but further study of these and other, novel compounds that buffer acid without increasing carbon dioxide — or, even better, that are capable of consuming carbon dioxide — is warranted to determine their potential role in the treatment of metabolic acidosis.

**POTENTIAL FUTURE THERAPIES**

The sodium–hydrogen (Na⁺–H⁺) exchanger NHE1 is activated during lactic acidosis, leading to deleterious sodium and calcium overload in the heart; its inhibition reduces cellular injury. In experimental models of lactic acidosis due to sepsis, hypoxia, hemorrhagic shock, or cardiac arrest, NHE1 inhibitors attenuated the lactic acidosis and hypotension, improved myocardial performance and tissue oxygen delivery, enabled resuscitation, and reduced mortality. These promising results in animals call for controlled studies in humans.

Cancer cells are programmed to use aerobic glycolysis and lactate production as their main energy source (the Warburg effect). The export of lactate and protons in the tumor microenvironment has emerged as a critical regulator of cancer development, maintenance, and metastasis. Inhibitors of LDH and MCT lactate transporters are being investigated as promising cancer therapies. These compounds might also prove effective in the management of tumor-induced and other types of systemic lactic acidosis.

**MONITORING OF PATIENTS, GOALS OF THERAPY, AND PROGNOSIS**

Measures to monitor and recommended goals of therapy are shown in Table 2. Close assessment of hemodynamic, oxygenation, and acid–base status is paramount.

The detection of tissue hypoxia is important for assessing the effectiveness of resuscitation and the need for other procedures to match oxygen delivery and demand. Although measurement of the blood lactate level is often used for this purpose, hyperlactatemia does not always signify tissue hypoxia. Central venous oxygen saturation has been suggested as a replacement or complementary measure, with the goal being a value greater than 70%. A recent study of septic shock indicated that the use of this measure provided no additional benefit as compared with the usual therapy without central hemodynamic targets. Further study of this issue is needed. New methods of detecting tissue hypoxia,

such as monitoring the concentration of hypoxia-inducing factor in body fluids, could prove useful.53

Measurement of the blood lactate level remains the cornerstone of monitoring for lactic acidosis. Lactate can be measured in arterial or venous blood, since the values are virtually interchangeable.6 Devices for point-of-care measurement are available. Although a single elevated blood lactate level often predicts an adverse outcome are available. Although a single elevated blood lactate level often predicts an adverse outcome, sustained hyperlactatemia is associated with even worse prognoses. Transient hyperlactatemia does not necessarily predict a poor clinical outcome.6,49 An interval of 2 to 6 hours has been suggested for repeat lactate measurements,6 but this issue has not been examined rigorously. Sustained hyperlactatemia in hospitalized patients with diverse disorders is associated with a large increase in mortality, regardless of status with respect to shock or hypotension.6,47,49,54-57 Also, there is a dose–response relationship between lactate levels and mortality: the higher the level, the greater the risk of death.2,6,7,56,57 Some studies have indicated that acidemia accompanying hyperlactatemia increases mortality,15 but the role of systemic acidity in affecting clinical outcomes remains to be elucidated.

Changes in levels of blood lactate have been used to guide therapy.47,49-51,58,59 In a randomized, controlled study, a reduction of at least 20% in serum lactate levels every 2 hours was targeted for the first 8 hours of resuscitation; achievement of this target of lactate clearance was associated with decreased morbidity and mortality.9 Evidence that in seriously ill patients even lactate levels at the upper end of the normal range are associated with poor clinical outcomes argues for the normalization of blood lactate as a primary goal of therapy.2,47,54 The usefulness of lactate-guided therapy and the level of lactate to target remain under investigation.

Given the central role of the microcirculation in lactic acidosis,37 its evaluation both before and after various interventions can be useful. Hand-held devices allowing direct visualization of the microcirculation have been developed, and their clinical role is undergoing study.26,60 In patients with severe circulatory compromise, central venous blood more accurately reflects the acid–base status of tissues than does arterial or peripheral venous blood.14,61 However, it remains unproven whether monitoring central venous blood gases in patients with severe hypoperfusion improves clinical outcomes. Monitoring of arterial blood gases is, of course, required for assessing pulmonary gas exchange.

Dr. Kraut reports holding pending patents related to the use of selective NHE1 inhibitors in the treatment of metabolic acidosis (lapsed without the filing of a nonprovisional application) and systems, methods, and compositions for improved treatment of acidosis. No other potential conflict of interest relevant to this article was reported. Disclosure forms provided by the authors are available with the full text of this article at NEJM.org.
