## 19 Summary

20 In many vertebrate species, early social experience generates long-term effects on later-life social behaviour.  
21 These effects are accompanied by persistent modifications in the expression of genes implicated in the  
22 stress axis. It is unknown, however, whether stress axis programming can affect the development of social  
23 competence, and if so, by which mechanism(s). Here we used pharmacological manipulations to  
24 persistently reprogram the hypothalamic-pituitary-interrenal (HPI) axis of juvenile cooperatively breeding  
25 cichlids, *Neolamprologus pulcher*. During the first two months of life, juveniles were repeatedly treated with  
26 cortisol, mifepristone or control treatments. Three months after the last manipulation, we tested for  
27 treatment effects on (i) social competence, (ii) the expression of corticotropin-releasing factor (*crf*),  
28 glucocorticoid receptor (*gr1*) and mineralocorticoid receptor (*mr*) in the telencephalon and hypothalamus  
29 and (iii) cortisol levels. Social competence in a social challenge was reduced in cortisol-treated juveniles,  
30 which is in accordance with previous work applying early-life manipulations using different social  
31 experiences. During early life, both cortisol and mifepristone treatments induced a persistent down-  
32 regulation of *crf* and upregulation of *mr* in the telencephalon. We suggest that these persistent changes in  
33 stress gene expression may represent an effective physiological mechanism for stress coping.

34

## 35 Introduction

36 Through developmental plasticity, the early social environment can strongly influence animal social  
37 behaviour and social competence in later life stages [1,2]. Social competence, the ability of animals to  
38 optimise their social behaviour as function of the available social information[3,4], can be shaped by the  
39 quantity, quality and diversity of social interactions young animals are exposed to during early life [2]. For  
40 example, laboratory mice reared in communal nests that received more intensive maternal care and tactile  
41 stimulation [5] or encountered more peer-to-peer interactions [6] before weaning, later in life established  
42 social hierarchies faster and behaved more adequately with respect to their social rank compared to mice  
43 reared by single mothers. Similar patterns have been reported in young zebra finch (*Taeniopygia guttata*)  
44 males [7] and in teleost fish. In the cooperatively-breeding cichlid fish *Neolamprologus pulcher*, individuals  
45 reared in larger [8] or more complex [9,10] social groups had an improved social competence both as  
46 juveniles and adults compared to individuals that reared in small groups or in groups consisting of a single  
47 age class. Improved social competence was indicated by the ability to defend a resource more efficiently [9]  
48 and to integrate more easily into a new social group [10].

49 In vertebrates, differential programming of the stress axis has repeatedly been shown to accompany long-  
50 term effects of the early social environment on social behaviour [11–13]. The hypothalamic-pituitary-  
51 adrenal (HPA) axis of mammals and birds or its homolog, the hypothalamic-pituitary-interrenal (HPI) axis  
52 of fish, is the main physiological mechanism responsible (i) for eliciting and terminating stress responses  
53 [14] and, in turn, (ii) for responding and adapting to environmental changes [15]. The presence or absence  
54 of *N. pulcher* parents during early life has been shown to affect the expression of genes implicated in the  
55 HPI stress axis [16,17]. Early life experience can shape neurobiological pathways involved in stress  
56 responsiveness through organizational effects on tissue sensitivity for glucocorticoids [18,19].  
57 Glucocorticoids, such as cortisol (in fish and most mammals) or corticosterone (in rodents and birds) are  
58 the major vertebrate stress hormones and are responsible for the regulation of the stress axis [20]. Evidence  
59 suggests that the early social environment may generate a cascade of neurobiological changes involving the  
60 vertebrate stress axis, which has implications for social behavioural [12].

61 Following the perception of a stressor, a stress responses is elicited by an endocrine cascade, where the  
62 primary steps include the release of catecholamines in the sympathetic nervous system, followed by the  
63 hypothalamic release of corticotropin-releasing factor (CRF) [20]; this eventually leads to the secretion of  
64 glucocorticoids from the adrenal or interrenal glands into the bloodstream [21]. The control of stress  
65 responses is mediated by cortisol signalling through two types of intracellular receptors that act as ligand-  
66 dependent transcription factors [22,23]. These receptors mediate the activation or repression of different  
67 genes in the target cells [24]. Elevated concentrations of cortisol activate the glucocorticoid receptors (GR)  
68 in the nucleus preopticus [25], the hypothalamus and the pituitary gland [18], which attenuate and  
69 eventually terminate the stress response via negative feedback loops that lead to suppression of further  
70 cortisol release. This suppression happens by blocking further CRF production [25]. The second  
71 intracellular receptor type, the mineralocorticoid receptor (MR) in teleost fish [26] and in the nonepithelial  
72 limbic neurons of other vertebrates [23], has a high-affinity to cortisol and is activated at basal levels [22,23].  
73 Nuclear MR maintains the integrity and stability of the limbic circuit, determining the threshold or

1 74 sensibility of the limbic stress response system [27]. In contrast, low-affinity MR in membranes boosts the  
2 75 initial stress response [27].  
3  
4

5 76 Although early social experience alters both stress axis programming and social competence, it is as yet  
6 77 unknown whether stress axis programming in early life *causally* determines the development of social  
7 78 competence, and if so, by which mechanism. Few studies have pharmacologically manipulated the stress  
8 79 axis prenatally or in early life to test for causal links between this axis and behaviour (neophobia [28,29];  
9 80 aggression [30]; defence against an intruder [31]; migration [32]; predator avoidance [33]; exploration [34]).  
10 81 A well-developed social competence should be particularly important for highly social species, such as  
11 82 cooperative breeders, in which almost all aspects of life include social interactions [4]. Here we aimed to  
12 83 manipulate early-life programming of the principal pathway that regulates the stress axis by  
13 84 pharmacological application of either cortisol or GR blocker in the highly-social cichlid *N. pulcher*. We  
14 85 predicted that our treatments would generate long-term effects on later life social competence, social  
15 86 performance, gene expression in the brain, and fluctuating cortisol.  
16  
17  
18  
19  
20  
21

22 87 Mifepristone has been successfully used to block GR1 (see [35] and references therein), which is the teleost  
23 88 homolog of the mammalian GR. Besides its function as GR blocker, it binds also to progesterone receptors,  
24 89 and therefore may have an additional function in reproduction [35]. However, this second function is  
25 90 unlikely to play a role in this study, as the fish were in their earliest juvenile stages when they were treated  
26 91 with mifepristone (i.e., > 6 months before sexual maturity). Previous work revealed contrasting behavioural  
27 92 effects of pharmacological administrations of cortisol and mifepristone. Blocking GR1 by mifepristone in  
28 93 *adult N. pulcher* induced a higher expression of submissive behaviours in intruders aiming to take over the  
29 94 territory from a resident, but nevertheless led to a higher success monopolization of territory [36]. The  
30 95 authors concluded that this increased success in territory acquisition resulted from an enhanced expression  
31 96 of adequate behaviours (social competence) after mifepristone treatment. Adult rainbow trout  
32 97 (*Oncorhynchus mykiss*) decreased aggression levels towards territory intruders [37] after being treated with  
33 98 mifepristone. In contrast, rainbow trout that were exposed to cortisol exhibited increased aggression, both  
34 99 when treated as adults [37] or during early ontogeny [30]. Based on these findings, we hypothesized that  
35 100 mifepristone treatment would increase submission and decrease aggression, but nevertheless lead to a  
36 101 higher success in obtaining or retaining resources (see [36]). Conversely, cortisol treatment was  
37 102 hypothesized to enhance aggression in *N. pulcher* facing a territory intrusion, but not necessarily lead to a  
38 103 higher success in aggressive contests over a resource.

43  
44  
45  
46  
47  
48

49 104 In vertebrates, elevations of cortisol levels generate a negative feedback via GR that eventually blocks  
50 105 further corticotropin-releasing factor (CRF) release (e.g. [24,38,39]). Therefore, we predicted that early-life  
51 106 cortisol treatment would up-regulate *gr1* gene expression, thereby enhancing the negative feedback loop on  
52 107 further cortisol release by decreasing *crf* mRNA levels. Additionally, we predicted up-regulation of *mr* gene  
53 108 expression, as early-life corticosteroid treatment has been shown to up-regulate *mr* expression in Japanese  
54 109 quail (*Coturnix coturnix japonica*) [40]. Conversely, the GR blocker mifepristone has been shown to induce  
55 110 down-regulation of *crf* and *gr* genes in different tissues of the fish brain; for example, in the hypothalamic  
56 111 preoptic area of rainbow trout, *O. mykiss*, [41], telencephalon-preoptic brain region of goldfish, *Carassius*

1 112 *auratus* [42] and in whole body samples of juvenile zebrafish, *Danio rerio* [43]. Consequently, we predicted a  
2 113 decrease of the *gr1* and *crf* expression after early-life GR blocker treatment. However, these predictions are  
3 114 based on studies measuring the immediate effects of mifepristone administration as studies of early-life  
4 115 exposure to mifepristone are not available, and should therefore be considered with caution.

6 116 Finally, we predicted that our treatments would translate into different mechanisms of stress response  
7 117 regulation, that is, the response of an individual to a stressor by cortisol release, which in turn gives rise to  
8 118 physiological pathways that aid in returning to a homeostatic state [44,45]. Mifepristone treatment  
9 119 increased endogenous cortisol levels in the fish *Opsanus beta* [46] but, importantly, it suppressed the  
10 120 amplitude of cortisol responses in both fish and rats [41,47]. After a post-natal corticosterone treatment,  
11 121 juvenile Japanese quail (*C. c. japonica*) showed a shorter stress response after a stressful stimulus than  
12 122 control birds [48]. Therefore, we predicted that both mifepristone and cortisol treatment would decrease  
13 123 stress responsiveness. Specifically, mifepristone would reduce the amplitude of the stress response and  
14 124 cortisol reduces the duration of the response.

15 125

## 16 126 **Materials and methods**

### 17 127 **Study species**

18 128 *N. pulcher* is a cooperatively breeding cichlid fish endemic to Lake Tanganyika, East Africa. Social groups  
19 129 consist of a dominant breeding pair, related and unrelated helpers ranging from 1 up to 25 individuals and  
20 130 the offspring of the current breeding pair. A group will inhabit a joint territory of up to 1 m<sup>2</sup> [49,50].  
21 131 Helpers stay in the natal territory even after reaching sexual maturity (at a size of  $\geq 3.5$  cm SL (standard  
22 132 length)) [51] at about 10 and 12 months of age [36]. In natural populations, reproductive success of the  
23 133 dominant breeding pair increases with the number of helpers due to improved offspring survival [52]. In  
24 134 turn helpers pay-to-stay with breeders by contributing to territory defence and maintenance [53,54].

25 135 Offspring start performing social behaviour towards other siblings at about 5 weeks post hatching and  
26 136 frequencies of these behaviours increase over time [9]. At a size of 1.5 to 2 cm, offspring start to join in  
27 137 helping tasks. These duties include the cleaning and fanning of eggs produced by dominants, removing  
28 138 sand from the breeding cavity, and defending the breeder's territory against predators and intruders [55].  
29 139 Helper task specialization is size dependent [56]. Small helpers usually perform alloparental care in form of  
30 140 egg cleaning and fanning [57], while large helpers engage in territory defence and territory maintenance  
31 141 [56]. The composition and size of social groups during the first months of life strongly affects social  
32 142 behaviours (helping behaviours, social competence, life history decisions and the expression of stress axis  
33 143 genes) [4,9,16,17,58,59].

### 34 144 **Animal housing**

35 145 The experiments were conducted at the Hasli Ethological Station of the Institute of Ecology and Evolution,  
36 146 University of Bern, Switzerland, under license BE 74/15 of the Veterinary Office of Kanton Bern. The

1 147 parents of our experimental fish were laboratory-reared 2<sup>nd</sup> and 3<sup>rd</sup> generation offspring of wild caught fish  
2 148 from Kasakalawe Point, Mpulungu, Zambia. We created 31 breeding pairs from haphazardly chosen adult  
3 149 males and females from our laboratory stock. Each breeding pair was randomly assigned to produce  
4 150 offspring to be exposed to one of three treatments: (i) the stress hormone cortisol (cor; n= 11), (ii) the  
5 151 glucocorticoid receptor blocker mifepristone (mif; n= 10) and (iii) a blank control treatment (control; n= 10).  
6 152 The breeding pairs were housed in individual 60-L tanks equipped with 2 cm of fine sand, a biological  
7 153 filter, two flowerpot halves serving as potential breeding cavities, and a half-transparent PET bottle  
8 154 mounted near the water surface to serve as refuge. The water temperature was kept at  $27 \pm 1$  °C with a light  
9 155 dark regime of 13:11 h and a dimmed-light phase of 10 min. The breeding pairs were fed commercial adult  
10 156 flake food (JBL Novo Tanganyika®) 5 days a week and frozen zooplankton 1 day a week. Additionally,  
11 157 frozen krill and *Artemia spp.* nauplia (Artemix, Dohse Aquaristik, Germany) were provided twice a week to  
12 158 stimulate egg production. We waited until the pairs produced a clutch and the larvae had developed into  
13 159 free-swimming fry. The first day of free-swimming was defined as the experimental 'Day 0' (e.g.  $10 \pm 2$  days  
14 160 post-fertilization). After Day 0, each rearing group was fed TetraMin Baby® food the amount of which was  
15 161 adjusted to the number of fry and their age by following the feeding regime describe in [59]. Additional  
16 162 adult flake food was provided for the breeders This feeding regime was adopted to ensure homogeneous  
17 163 growth rates among siblings within and across rearing groups.

## 164 Experience phase

### 165 Cortisol treatment

166 For the cortisol treatment, we used a concentration that was half of the cortisol plasma levels reported from  
167 stressed *N. pulcher* adults [60]. When this concentration was applied to developing rainbow trout eggs, it  
168 generated transitional (<1 day) elevations of cortisol levels and induced a long-term effect on stress  
169 sensitivity [61]. To prepare the treatment solution, hydrocortisone (Product number H4001, Sigma-Aldrich,  
170 Switzerland) was dissolved in Dimethylsulfoxid (DMSO) to get a stock solution of 1 mg/ml cortisol  
171 concentration. The final concentration of 200 ng/ml was obtained by adding 100 µl of cortisol stock  
172 solution to 500 ml of tap water. Local tap water had ideal water parameters to hold Tanganyika cichlids  
173 and needed no further processing.

### 174 Mifepristone treatment

175 For the mifepristone treatment, we used a concentration that had been previously shown to generate short-  
176 term effects on *N. pulcher* social performance [36]. We dissolved mifepristone (RU486; Product number  
177 M8046 Sigma-Aldrich, Switzerland) following the modified protocol of [62]. Briefly, a mifepristone stock  
178 solution (50 ng/µl) was used to obtain a final concentration of 400 ng/L by adding 4 µl of mifepristone  
179 stock solution to 500 ml of water.

### 180 Control treatment

181 In the control treatment we applied the same solvents in the same concentration used to dilute mifepristone  
182 (DMSO, PBS, BSA), but without adding mifepristone.

**183 Application of water baths**

184 At experimental Days 10, 20, 30, 40, 50 and 60 (Fig. 1) the assigned treatment was applied to all offspring of  
185 a rearing group. Treatments were assigned to rearing groups randomly, on the condition that the same  
186 treatment was never assigned to two neighbouring tanks and all treatments were represented equally in the  
187 different rows of the tank-rack. The treatments were applied as water baths; this non-invasive method  
188 allows repeated applications of hormones at very low manipulation stress levels [62–64]. For the water  
189 bath, a maximum of 20 juveniles were placed inside a 2-L glass beaker filled with 500 ml of tap water. All  
190 beakers were supplied with oxygen using glass Pasteur pipettes connected to an air stream. The beakers  
191 were kept in complete darkness and were isolated against noise during the entire exposure procedure  
192 which consisted of (1) a 30 min acclimatization period, (2) 1 hour of exposure to the respective treatment,  
193 (3) a first recovery period of 30 min in a beaker with home tank water and (4) a second recovery period of  
194 30 min inside a mesh cage (14.5 x 8.5 x 7 cm) hanging in the home tank. Finally, the juveniles were gently  
195 released from the mesh cage into the home tank. The breeder pair always immediately reaccepted their  
196 offspring.

197 We kept the repeated exposure to the drugs short to generate a pulsed exposure (1 hour) followed by a  
198 long unexposed period (10 days), because we wanted that the exposure to cortisol to have similar effects to  
199 short stressful situations in a natural context. The application of short exposures to cortisol and  
200 mifepristone is expected to lead to a temporary increase in the cortisol of juveniles once they developed  
201 full functionality of their HPI axis [62]. Veillete et al. 2007 reported that in summer flounders the HPI axis  
202 was fully developed at an age of 3 weeks, which is even slightly earlier than the age when we exposed our  
203 fish to mifepristone (30 days of age, that is, 20 days after free swimming). Thus, we can assume that the HPI  
204 axis in *N. pulcher* was fully functional at first exposure. In 21-d old summer flounders the administration of  
205 mifepristone resulted in a rapid (within a few hours) increase of cortisol, and we assume that the same  
206 happened in *N. pulcher*.

**207 Behavioural recordings**

208 During the experience phase, which lasted until Day 60, we performed repeated recordings of all  
209 spontaneous social behaviours and the general activity of the experimental juveniles in their home tanks.  
210 During this time the juveniles were still co-housed with the breeder pair (see 'Animal housing conditions').  
211 The recordings were conducted 9 days after an application of a pharmacological or control treatment (Fig.  
212 1) following the observation methods and ethogram used by [9]; (see ethogram in Supplement, Table S1).  
213 Thus, recording took place on days 29, 39, 49, 59 and 69, but not on Day 19, as at this age fish were still very  
214 small and did not show noticeable social behaviour. Before each recording, a transparent acetate grid of 14  
215 x 10 cells (4 x 4 cm each cell) was attached to the front wall of the tank, which was used to randomly select  
216 the first juvenile for a recording using a random number table, and for estimating its activity. All  
217 behavioural recordings were done by an observer who was blind to the treatment. Before starting a  
218 recording, juveniles were allowed to acclimatize for 5 min to the presence of the observer, who sat

1 219 motionless in front of the tank. A total of three juveniles per rearing were recorded for 5 min each,  
2 220 amounting to a total recording time of 15 min per tank [9].  
3  
4

### 5 221 **Recorded behaviours**

6  
7 222 The recorded behaviours (cf. [9] see Ethogram in Supporting Information, SI) were grouped according to  
8 223 their function for statistical analyses: (1) Restrained aggression, which comprises all threat behaviours not  
9 224 involving physical contact. (2) Overt aggression, which involves physical contact or attempted physical  
10 225 contact (*i.e.* chasing). While overt aggression by larger specimens can have a strong impact and inflict  
11 226 injuries in the receiver, we never observed injuries in the interactions between our experimental juveniles.  
12 227 Overt aggression was rare and thus could not be statistically analysed. (3) Submissive displays, which can  
13 228 be shown spontaneously towards dominant individuals or in response to received aggression, most often  
14 229 consists of a strong vibration of tail and body. (4) Affiliative behaviour, includes swimming in close  
15 230 proximity without showing signs of aggression, and soft body touches ('bumping'; see ethogram in SI),  
16 231 which is mostly performed by subordinates towards dominants. (5) General activity was measured as the  
17 232 amount of locomotion by an individual estimated by the number of lines of the acetate grid a focal  
18 233 individual crossed during a 5 min observation period. All behaviours were recorded as frequencies. The  
19 234 sum of the behaviours shown by the three juveniles per rearing group was used for statistical analyses [9].  
20  
21  
22  
23  
24  
25  
26

### 27 235 **Neutral phase**

28  
29 236 At the end of the 2-months experience phase breeder pairs were removed and returned to the laboratory  
30 237 stock. The experimental juvenile groups were left in their home tanks under the same housing conditions  
31 238 describe above and without any treatment for the next 95 days. At the beginning of the neutral phase,  
32 239 juvenile groups in the home tanks had a mean size of 44.1 ( $\pm$  3.14 SE).  
33  
34  
35  
36

37 240 Two month old *N. pulcher* juveniles are independent of parental care [4]. When living in a family group, at  
38 241 this age they start to act as brood care helpers [57]. They can specialise in direct brood care, defence or  
39 242 territory maintenance, or develop a submissive non-helper type [59,65,66]. For our study, introducing a  
40 243 neutral phase was therefore critically necessary to prevent individual task specialisation, which would have  
41 244 confounded the effect of the pharmacological manipulation.  
42  
43  
44  
45

46 245

### 48 246 **Test phase**

#### 50 247 **Selection of focal individuals**

51  
52  
53 248 At Day 157 individuals were selected for hormone measurement and the social challenge test. We  
54 249 determined the median standard length (SL) for each rearing group and selected four focal individuals that  
55 250 were closest to the mean SL of their rearing group. These focal fish were later used in a social challenge test  
56 251 (see Fig. 1) where they acted in one of two social roles, owners (Ow.) and intruders (Int.; see below). When  
57  
58  
59  
60

1 252 selecting the focal fish (*i.e.* two replicate fish per social role), we preassigned them to their role and marked  
2 253 each individual with a fin clip according to social role for later identification. The SL of focal individuals  
3  
4 254 was  $3.035 \pm 0.34$  cm (mean  $\pm$  SE; Int.) and  $2.995$  cm  $\pm$  0.25 (Ow.). Until and between the manipulations for  
5 255 hormone sampling and behavioural testing (see Fig. 1) the focal juveniles were kept in individual,  
6 256 transparent isolation boxes (10.5 x 10 x 17 cm) floating at the surface of the home tank, which allowed for  
7  
8 257 exchange of visual and olfactory cues with the other siblings housed in the tank. It facilitated repeated,  
9 258 quick catching of the focal individuals to reduce catching stress.

### 12 259 **Hormone sampling**

14 260 During three consecutive days (Days 160-162) at 10:00 h, focal individuals were placed for 30 min each in a  
15 261 separate 2-L glass beaker containing 500 ml of clean tap water. This procedure has been shown to lead to  
16 262 habituation to the handling procedure in other cichlids [67], including *N. pulcher*, thereby minimizing the  
17 263 effect of handling stress on our stress measurements.

21 264 At Day 163 we measured basal cortisol of all focal fish using the same manipulations and procedures used  
22 265 during the habituation phase. In a total of 93 individuals (cortisol, Ow.: n=20, Int.: n= 16; mifepristone, Ow.:  
23 266 n=19 Int.: n=10; control, Ow.: n=19, Int.: n=9) we sampled baseline cortisol using the 'fish-holding water  
24 267 method', a non-invasive technique to sample waterborne steroid hormones in small fishes [67–69]. Finally,  
25 268 on Day 164 we sampled cortisol responses after fish had experienced an acute stressor in the same 93  
26 269 individuals and following the procedure described above. The acute stressor consisted of placing the focal  
27 270 individuals gently in a mesh and exposing them to air for 1 min [70,71] before placing them into the glass  
28 271 beaker to sample their cortisol.

34 272 All cortisol samples were obtained between 10:00-11:00 h to minimize variation due to diurnal fluctuations  
35 273 of cortisol excretion [45]. The preparation of hormone samples followed a protocol developed by Neuchâtel  
36 274 Platform of Analytical Chemistry, University of Neuchâtel (see details in the SI). Cortisol content was  
37 275 analysed by ultrahigh performance liquid chromatography-tandem mass spectrometry (UHPLC-MS/MS).

### 40 276 **Social challenge test**

43 277 We staged an asymmetric contest over a shelter, which is a vital resource for *N. pulcher* in nature, to test the  
44 278 ability of fish to express adequate behaviour according to their preassigned social role. Thus, this test  
45 279 evaluated the social competence of fish in a biologically meaningful context. Preassigned owners should  
46 280 defend the shelter against an intruder and are in a favourable position to maintain the shelter. Therefore a  
47 281 restrained, non-escalated form of aggression (threat display) should suffice for a successful defence [9].  
48 282 Preassigned intruders are usually not able to take over the shelter, but should aim to achieve tolerance from  
49 283 the resident owner when near the shelter [9,16]. In nature, each subordinate group member defends a  
50 284 private shelter for hiding from predator attacks within the group territory [52] and these shelters are crucial  
51 285 for survival of subordinates [10,72].

57 286 A total of 58 individuals were tested in the social challenge test (mif. n=19, cort. n=20, control n=19) in the  
58 287 role of owners, and a total of 46 individuals (mif. n=12, cort. n= 21, control n=13) as intruders. Different

1 288 sample sizes between treatments within a social role were caused by the death of some individuals between  
2 289 hormone sampling and behavioural testing due to a temporary deterioration of water conditions in some  
3 290 rearing tanks. Further, more fish were tested in the owner role than in the intruder role; for logistical  
4 291 reasons we could not perform tests in the intruder role for all rearing groups. This is because in *N. pulcher*  
5 292 larger individuals are dominant over smaller ones, so we size-matched the focal fish and their respective  
6 293 opponents to the nearest millimetre (difference mean  $\pm$  SE, between focal individual and opponent  $0.16 \pm$   
7 294  $0.075$  mm SL). Opponents were unrelated, unfamiliar fish from a laboratory stock tank, which had never  
8 295 received any hormonal treatment. Each opponent was used only once, and after the contest it was  
9 296 immediately returned to its home tank.

14 297 One day before the social challenge, at Day 167, focal individuals and opponents were acclimatized to the  
15 298 experimental set up, which was a 20-L tank (20 x 20 x 30 cm) equipped with a 2 cm layer of sand divided  
16 299 into two compartments by an opaque partition. The owner's compartment was equipped with a flowerpot  
17 300 halve (5.5 cm outer diameter) and a biological filter. The intruder's compartment only contained an air  
18 301 stone.

23 302 At Day 168 we removed the opaque partition to start the asymmetric competition test. The behavioural  
24 303 recording started when one of the individuals crossed the virtual border between the two compartments  
25 304 (*i.e.* where the partition had previously been) and lasted for 20 min. All social behaviours performed by  
26 305 both individuals were recorded using the program Solomon Coder (Copyright © 2017, András Péter). The  
27 306 observer, who was blind to the treatments, was hidden behind a black curtain. After the recording, we  
28 307 determined the time point when the contest had been decided ('end of contest'), and who won or lost the  
29 308 contest following the criteria used by Nyman and colleagues [36]. Briefly, an individual lost when it was  
30 309 evicted from the vicinity of the shelter and did not attempt to gain access to it anymore; an individual was  
31 310 the winner when it had unrestricted access to the shelter and was not attacked by the other fish; contests  
32 311 were rated as 'undecided' when no clear winner or loser existed at the end of the recording. Contests were  
33 312 classified as 'alternative outcome' if the owner chose the aquarium filter as shelter so that the intruder  
34 313 could use the flowerpot without being threatened or attacked by the opponent.

## 41 314 Gene expression

42 315 To assess whether the constitutive expression of stress axis genes was altered by our early-life  
43 316 pharmacological manipulations we measured the expression of three key genes of the stress axis, *crf*, *gr1*  
44 317 and *mr*. As outlined above, the products of these three genes play a central role in regulating stress  
45 318 responses.

49 319 Between days 171 and 173, we sacrificed two randomly-selected replicate individuals from each rearing  
50 320 group by an overdose of tricaine methanesulfonate (MS-222; Sandoz, Switzerland). None of these fish had  
51 321 taken part in hormone sampling and/or the social challenge test beforehand. Following the procedures  
52 322 described in [16], we dissected the brains with a scalpel under a stereomicroscope, and stored the  
53 323 telencephalon and the hypothalamus of each brain separately in RNAlater® (Qiagen, The Netherlands) and  
54 324 kept the vials at  $-20^{\circ}\text{C}$  for up to 7 months until RNA extraction. Only one individual from each rearing

1 325 group was used for genetic analysis (sample size per treatment and brain area: cortisol n = 11; mifepristone  
2 326 n = 10; control n = 10; size:  $2.99 \pm 0.26$  cm SL) and the other was kept as backup. The two brain regions were  
3  
4 327 chosen because they contain the brain tissues involved in stress regulation, namely the limbic forebrain  
5 328 neurons (telencephalon) and the parvocellular CRH-producing neurons in the paraventricular nucleus  
6 329 (PVN) of the hypothalamus [73]. Gene expression was measured by a standard reverse-transcriptase  
7  
8 330 quantitative polymerase chain reaction (RT-qPCR) protocol (details in SI).  
9

10  
11 331

## 12 332 Statistical analyses

13  
14 333 We analysed treatment effect by GLMMs and LMMs (see details below). If models had non-significant  
15 334 interaction terms they were excluded stepwise [74,75]. Poisson distributed generalized linear-mixed effect  
16 335 models (GLMMs) were corrected in case of over-dispersion by including an observation level random  
17 336 factor. For each factor of the model, estimates and their standard errors, and t or z-values according to the  
18 337 type of model are given in Tables 2-5 of the SI. Significance testing was based on deviance when removing  
19 338 respective terms from the model. The change in likelihood was compared to a chi-square distribution  
20 339 (likelihood ratio test [LRT], see reference [76], therefore  $\chi^2$ -values are given in the main text and SI tables.  
21 340 Normality assumptions for all linear-mixed effect models (LMMs) were tested by visual inspection of  
22 341 Quantile-Quantile plots and by Shapiro-Wilks and Lilliefors (Kolmogorov-Smirnov) normality tests. If  
23 342 necessary, the dependent variable was boxcox-transformed to achieve normality of the error terms. We  
24 343 checked for potential outliers of model residuals by visual inspection of the Cook's distance score [77],  
25 344 excluding values with a Cook's distance  $>0.5$ . In addition we assessed the influence of those values with the  
26 345 Grubb's test [78]. Only in one data set (*crf* in the telencephalon), one high-leverage data point had to be  
27 346 excluded based on these criteria. Post-hoc analyses were done in cases of significant interaction terms in  
28 347 models. Data were analysed using R 3.1.2. and the packages 'lme4' [79], 'car' [80], 'nortest' [81], 'MASS'  
29 348 [82], 'multcomp' [83], and "outliers" [78].

33  
34  
35  
36  
37

## 38 349 Experience phase

39  
40 350 The sums of behavioural frequencies of the three individuals recorded from each rearing group at a given  
41 351 developmental time point, and the sums of line crosses (our estimate of locomotory activity; see section  
42 352 'Behavioural recordings above), were included as dependent variables of Poisson-distributed GLMMs,  
43 353 which were fitted with a log-link function. 'Treatment', 'Experimental Day' and their interaction term were  
44 354 included as fixed effects, and 'Rearing group of origin' was included as a random effect.  
45  
46  
47  
48

## 49 355 Contest outcome

50  
51 356 Contest outcome was analysed by fitting a binomial GLMM with logit link function. The binary outcome  
52 357 refers to either winning or losing the contest over the shelter. The categories 'undecided' and 'alternative  
53 358 outcome' were excluded from this analysis. Because social performance [84], in our case contest outcome,  
54 359 and social status [85] can depend on individual cortisol levels, we included waterborne cortisol levels in the  
55 360 models of contest outcome. We included 'stress responsiveness' as covariate in the models; it was  
56 361 calculated as the difference between cortisol content in the holding water after the acute stressor (Stress  
57  
58  
59

1 362 level cortisol) and cortisol content in the water sample of the same individual when not stressed (Basal  
2 363 cortisol level) [44,45]. Note that waterborne cortisol, both basal levels and stress responsiveness, *per se* did  
3 364 not differ between treatments and we do not present these results. They did, however, influence the  
4 365 outcome of fights (see 'Results'). Individuals in both social roles can take over the resource therefore 'Social  
5 366 role' (*i.e.* owner or intruder) was included as a covariate. Furthermore, 'Treatment' was included as fixed  
6 367 factor and 'Rearing group of origin' was included as random factor.

### 10 368 **Social behaviour during contest**

13 369 We only included behaviours performed until the end of the contest in our analysis. While after the end of  
14 370 a contest, social behaviour may still occur, these behaviours would not occur after natural contests, where a  
15 371 loser would either leave the territory or get out of reach of the winner. To account for contest duration, we  
16 372 analysed the behavioural data until the end of contests as rates per minute [9,16] and fitted LMMs for  
17 373 analysis. 'Treatment' was included as a fixed factor and 'Rearing group of origin' as a random factor in all  
18 374 LMMs. 'Total aggression of opponent' was included as a covariate since the conflict can escalate and extend  
19 375 if both opponents behave aggressively, and neither shows submissive behaviour.

24 376 We analysed the two social roles of owners and intruders separately, since they afford different appropriate  
25 377 behavioural responses. For owners, we analysed restrained aggression, an appropriate type of behaviour  
26 378 expected in individuals that already own a resource in a competitive situation [9]; we included 'Submissive  
27 379 behaviour of opponent' as covariate as the submissive tendencies of conspecifics in *N. pulcher* influence  
28 380 aggression, and *vice versa* [9,16]. For intruders, submissive behaviour is the most adequate social behaviour  
29 381 in an asymmetric situation to achieve being tolerated near the shelter, because an aggressive takeover of the  
30 382 shelter is nearly impossible [9,16]; we included 'Total aggression of opponent' as covariate because of the  
31 383 above mentioned mutual dependence between submission and aggression. None of the behaviours  
32 384 expressed in the two social roles were influenced by cortisol levels (*i.e.* basal or acute stress levels or stress  
33 385 responsiveness; data no shown).

### 39 386 **Gene expression**

42 387 In order to test the effect of treatment on the expression of the candidate genes (*crf*, *gr1*, and *mr*) we fitted  
43 388 LMs with the factors 'Treatment' and 'Size' (SL in cm). Size was included as a covariate only if it  
44 389 significantly predicted gene expression, which was only true for *mr*. 'Plate number', that is, the  
45 390 identification number of each plate used for quantification of each gene's transcript copy number was  
46 391 included in the models, because the enzyme mixture used for each plate was prepared separately and  
47 392 could potentially affect the measurement of gene expression.

51 393

## 54 394 **Results**

### 57 395 **Experience phase**

1 396 Treatment and age (*i.e.* experimental Day) interactively influenced affiliative behaviour performed in the  
2 397 home tank (GLMM,  $n=121$ ,  $\chi^2=16.22$ ,  $p=0.0003$ ). This effect is mainly due to an interaction between cortisol  
3 398 treatment and age (Cortisol  $\times$  Day: Estimate=  $0.0429 \pm 0.0134$  SE,  $z=3.19$ ,  $p=0.0014$ ; Mifepristone  $\times$  Day:  
4 399 Estimate=  $0.00611 \pm 0.0141$  SE,  $z=-0.44$ ,  $p=0.66$ ; Table S2, Fig. 2). This interaction is unlikely to be explained  
5 400 by locomotory activity of the fish, because activity was not affected by treatment (Table S2) or its  
6 401 interaction with age (non-significant interaction term was dropped from the model). No other social  
7 402 behaviour was affected by treatment or its interaction with age during the experience phase (results not  
8 403 shown).

## 404 Social challenge

### 405 Contest outcome

18 406 Contest outcome (winning or losing) was interactively influenced by treatment and cortisol stress  
19 407 responsiveness (binomial GLMM,  $n = 44$ , Treatment  $\times$  Stress responsiveness:  $\chi^2= 13.71$ ,  $p=0.0012$ ). This  
20 408 interaction was mostly caused by an interaction between mifepristone and stress responsiveness (Cortisol  $\times$   
21 409 Stress responsiveness: Estimate=  $1.729 \pm 1.321$ ,  $z=1.31$ ,  $p=0.19$ ; Mifepristone  $\times$  Stress responsiveness:  
22 410 Estimate=  $5.679 \pm 2.262$ ,  $z=2.51$ ,  $p=0.012$ ; Table S3). The likelihood of winning a contest increased with  
23 411 stress responsiveness in the mifepristone, whereas in the control treatment fish with a lower stress  
24 412 responsiveness were more likely to win (Fig. 3).

### 413 Social behaviour during contest

31 414 Treatment significantly affected the amount of restrained aggression shown during a contest by focal  
32 415 owner fish (LMM,  $n=58$ ,  $\chi^2=13.49$ ,  $p=0.0012$ ) as well as contest duration (LMM,  $n= 58$ ,  $\chi^2= 8.49$ ,  $p=0.014$ ).  
33 416 Focal owner fish, which received the cortisol treatment in early life, showed more restrained aggression  
34 417 during contests (Estimate=  $1.441 \pm 0.418$ ,  $z$ -value =  $8.12$ ,  $p = 0.0019$ ; Fig. 4a, Table S4) and contests lasted  
35 418 longer in these fish (Estimate=  $3.867 \pm 1.828$ ,  $t$ -value =  $2.12$ ,  $p = 0.039$ ; Fig. 4b, Table S4). In contrast,  
36 419 behaviour and contest duration were unaffected in owner fish that had received the mifepristone treatment  
37 420 (Table S4). Both treatments had no effect on intruder behaviour (results not shown).

## 421 Gene expression

42 422 In the telencephalon the expression of both *crf* and *mr* was affected by treatment (*crf*: LMM,  $n = 31$ ,  $\chi^2= -$   
43 423  $780.11$ ,  $p=0.012$ ; *mr*: LMM,  $n = 21$ ,  $\chi^2= -240.28$ ,  $p=0.027$ ). Cortisol (Estimate =  $-2.175e-06 \pm 8.480e-07$ ,  $t$ -value =  
44 424  $-2.57$ ,  $p=0.017$ ; Table S5, Fig. 5a) and mifepristone (Estimate =  $-2.237e-06 \pm 9.005e-07$ ,  $t$ -value =  $-2.48$ ,  $p =$   
45 425  $0.02$ ) treated fish had a down-regulated *crf* expression. In contrast, *mr* was upregulated by both treatments  
46 426 (Cortisol treatment: Estimate =  $0.018 \pm 0.009$ ,  $t$ -value =  $2.06$ ,  $p = 0.04973$ ; Table S5, Fig. 5b. Mifepristone  
47 427 treatment: Estimate =  $0.021 \pm 0.009$ ,  $t$ -value =  $2.33$ ,  $p = 0.028$ ; Table S5, Fig. 5b). Body size was negatively  
48 428 correlated with *mr* expression (Spearman's rank correlation,  $\rho= -0.36$ ,  $p=0.046$ ) but not with the other two  
49 429 genes in the telencephalon. In the hypothalamus, early-life treatment did not significantly affect the  
50 430 expression of *crf* and *mr* (Table S5). *Gr1* expression was not affected by either treatment (results not  
51 431 shown).

1 432

2  
3  
4 433 **Discussion**

5 434

6 435 Our experiment showed that social behaviour and social performance, here winning or losing a contest  
7  
8 436 over an important resource, is causally evoked by early life stress axis programming in the cooperatively  
9  
10 437 breeding cichlid *N. pulcher*. Our pharmacological manipulations persistently altered two key players in the  
11  
12 438 regulation of the vertebrate stress axis, (i) the mineralocorticoid receptor and (ii) the corticotropin-releasing  
13  
14 439 factor. The behavioural effects of the manipulations became apparent only over the long-term and only in  
15  
16 440 fish assigned to the role of territory owners. Interestingly, social behaviour was little affected by treatment  
17  
18 441 *during* the phase of drug application. Early cortisol application had several long-term effects. Fish showed  
19  
20 442 more aggressive behaviour and contests took longer to be resolved, *crf* gene expression was downregulated  
21  
22 443 and *mr* gene expression was upregulated in the telencephalon compared to control individuals.  
23  
24 444 Interestingly, mifepristone application affected gene expression in the same way as the cortisol treatment.  
25  
26 445 Moreover, it influenced the likelihood of winning a contest in interaction with stress responsiveness.

27 446

28 447 **Effects of early-life treatments on behaviour**

29 448

30 449 Early-life treatment and developmental day interactively influenced affiliative behaviour during the  
31  
32 450 experience phase. The interactive effect during the first weeks of life it is difficult to interpret as Fig. 2  
33  
34 451 suggests that the changes of affiliative behaviour change non-linearly with age in the different treatments.  
35  
36 452 Affiliative behaviours and glucocorticoid levels have been shown to be related in other vertebrates [86]. For  
37  
38 453 example, in bonobos (*Pan paniscus*) aggressive conflicts increase HPA axis activity and promote affiliative  
39  
40 454 behaviours between victims of the conflict and conspecifics [86]. Furthermore, in rhesus macaques playful  
41  
42 455 behaviours in young males correlate with lower cortisol levels [87]. The interactive effect on affiliative  
43  
44 456 behaviour was the only effect of treatment on behaviour during the experience phase, whereas all other  
45  
46 457 behavioural effects became apparent only during the late juvenile period.

47 458

48 459 For the social test performed during later life, we predicted aggression to increase in cortisol treated fish.  
49  
50 460 For instance, juvenile rainbow trout given a cortisol treatment during the egg stage increased their  
51  
52 461 frequency of bites and lateral displays performed towards their mirror image [30]. Accordingly, we found  
53  
54 462 that cortisol treated fish showed higher rates of restrained aggression. If this type of low-level aggressive  
55  
56 463 behaviour, which does not include physical contact with opponents, tends to resolve contests faster, it can  
57  
58 464 be viewed as being the most appropriate behaviour in a contest situation [9]. However, if high rates of  
59  
60 465 aggression go along with longer contest durations, as was the case in our cortisol treated fish, it suggests  
61  
62 466 that cortisol evoked in a decrease of social competence and consequently, decreased social performance.  
63  
64 467 Longer contests should increase energy expenditure, because agonistic interactions and submissive  
65  
66 468 behaviours are energetically demanding [88], and being involved in distracting, aggressive contests reduces  
67  
68 469 vigilance and thereby the chance to detect dangerous predator [89]. Evidence from zebrafish and laboratory  
69  
70 470 rodents suggests that our cortisol treatment had a very similar effect to that of natural stressors. After  
71  
72 471 dyadic interactions of dominant and subordinate zebrafish endogenous cortisol levels increased to levels

1 472 sufficiently high to elicit changes in *mrr* mRNA levels [90]. Furthermore, in young rodents, early exposure  
2 473 (between postnatal day 28 and 42) to non-social stressors or to social deprivation increased aggressiveness  
3 474 in adulthood [91].  
4  
5

6 475 Contrary to our predictions, mifepristone had no detectable influence on social behaviour during the  
7 476 experimental contest. Our predictions were based on findings of immediate effects of mifepristone  
8 477 treatment in adult *N. pulcher*, which have been shown to gain access to a resource by increasing their  
9 478 submissive behaviour when being attacked [36]. The lack of direct effects of mifepristone on behaviour in  
10 479 our study clearly indicates that long-term effects of early-life administration and immediate effects are not  
11 480 directly comparable. As discussed above, this is probably due to the possibility to compensate for early-life  
12 481 impacts on the stress axis by re-programming of this axis. Interestingly, we found a striking interactive  
13 482 effect of mifepristone and stress responsiveness on contest outcome; control fish had an enhanced  
14 483 likelihood of winning a contest if they had a reduced stress response. Nyman and colleagues [36] argued  
15 484 that the likelihood of winning a contest is enhanced by low stress responsiveness, which may explain these  
16 485 results. However, the opposite effect occurred in fish treated with mifepristone in early life. Although this  
17 486 reversal of the relationship between stress responsiveness and winning is difficult to explain, we propose  
18 487 that it was caused by the differential programming of the stress axis of mifepristone-treated fish, which  
19 488 likely qualitatively altered the link between stress axis regulation and behavioural regulation.  
20

22  
23  
24  
25  
26

27 489 Contrary to our findings for owners, we found that early-life treatment did not influence the contest  
28 490 duration or social behaviours for intruders. This finding contrasts previous work in *N. pulcher*, which  
29 491 showed a significant influence of early-life social experience on stress gene expression [17,36] and on the  
30 492 behaviour of both owners and intruders in the same asymmetric competition paradigm [9,16]. In these  
31 493 studies, *N. pulcher* reared with parents and other older group members (helpers) (i) had a higher expression  
32 494 of the *gr1* gene in the telencephalon, (ii) when in the role of intruders they showed more submissive  
33 495 behaviour per received opponent aggression and (iii) they were less neophobic [92] compared to juveniles  
34 496 reared in a socially deprived setting with same aged siblings only; thus also these previous findings  
35 497 involved a re-programming of the stress axis, but with significant differences from the current study. Here,  
36 498 different genes, behaviours and social roles were affected, which suggests that different components of the  
37 499 stress axis were affected by social factors [16,17] and direct application of cortisol and mifepristone. This is  
38 500 perhaps not so surprising, given that during a social challenge social cues and experiences accompany the  
39 501 stress response. In the case of cortisol administration salient cues that can be learned and memorized are  
40 502 absent, and these learning processes are one important function of adaptive stress responses [91].

#### 50 504 **Effects of early-life treatments on stress axis programming**

51  
52 505 Early exposure to cortisol and to mifepristone induced persistent changes of the expression of two main  
53 506 stress genes in the telencephalon, suggesting that glucocorticoid signalling in this brain area during later  
54 507 life will differ compared to control treatment fish [91]. The telencephalon is central for behavioural  
55 508 expression as it is involved in social decision making [93,94] and cognitive processing of information [95].  
56 509 In the following paragraphs we discuss the long-term effects of cortisol and mifepristone, which suggest  
57  
58  
59  
60

1 510 that both drugs may have temporarily increased fluctuating cortisol levels after the applications during  
2 511 early life. Therefore, both drugs may have induced similar changes in the telencephalon.

3  
4  
5 512 In line with our hypothesis, repeated exposure to cortisol during early development caused a persistently  
6 513 lower constitutive gene expression of *crf* in the telencephalon. In contrast to mammals, in which cortisol  
7 514 regulates CRF release in the hypothalamus [38,39,96], in fish the *crf* gene is also expressed in other brain  
8 515 areas, including the telencephalon. In adult goldfish (*C. auratus*) cortisol implants down-regulate *crf* mRNA  
9 516 levels in the telencephalon [25]. In the cichlid *Oreochromis mossambicus* the principal source of plasma CRF  
10 517 is the ventral telencephalon [97], and these authors suggested that the self-inhibiting negative feedback of  
11 518 cortisol by blocking the secretion of further CRF acts predominantly in this brain region. CRF is related to  
12 519 stress-coping style, which is defined as the physiological and behavioural response to stress [98]. A  
13 520 proactive coping style is characterized by low stress axis activity, whereas the opposite is true for reactive  
14 521 individuals [98,99]. Accordingly, we hypothesize that repeated exposure to cortisol early in life generated  
15 522 fish with an attenuated cortisol response that produce lower levels of CRF under stressful conditions.  
16 523 Possibly these effects on the cortisol response were too subtle to be detected by our rather coarse, non-  
17 524 invasive measurement of waterborne cortisol [69].

18  
19  
20  
21  
22  
23  
24 525 The mineralocorticoid receptor gene (*mr*) was up-regulated in cortisol treated-fish. Nuclear MR determines  
25 526 the sensitivity of the limbic stress response system [73]. MR signalling is important for coordinating the  
26 527 initial stress response [21,100] and preparing animals for coping with a stressor (e.g. lower sensory  
27 528 detection thresholds, higher alertness) [101], but MRs are also thought to be involved in the negative  
28 529 feedback on cortisol [102]. In Japanese quail, corticosteroid exposure before or after hatching results in *mr*  
29 530 up-regulation in the hippocampus [40], which is part of the telencephalon. In line with our predictions,  
30 531 cortisol treatment up-regulated *mr* gene expression in experimental fish. We speculate that a higher  
31 532 sensitivity to cortisol in the presence of more MR may help these fish to mount a stress response at a  
32 533 normal speed (*i.e.* a rapid response to a stressor despite their lowered CRF response; discussed above),  
33 534 which is then followed by an attenuated response with lower peak values of cortisol due to lower *crf*  
34 535 expression.

35  
36  
37  
38  
39  
40  
41 536 The fact that a similar change of *crf* expression was caused by mifepristone treatment in the telencephalon  
42 537 is in accordance with our hypothesis that the mifepristone applications generated increases of endogenous  
43 538 cortisol [46]. Furthermore, early mifepristone application induced a higher constitutive expression of *mr* in  
44 539 the telencephalon. Although, this finding is opposite to our initial predictions, we speculate that the early  
45 540 mifepristone treatment generated a compensatory effect in the stress axis similar to the one by cortisol.  
46 541 Mifepristone blocks GRs, which are involved in the clearance of cortisol and blocking of further cortisol  
47 542 production. Correspondingly, juvenile *N. pulcher* exposed to mifepristone can be assumed to have  
48 543 experienced temporarily enhanced cortisol concentrations. In fish temporary cortisol increases after  
49 544 application of mifepristone can last 2 (larval summer flounders, *Paralichthys dentatus*, [62]; adult gulf  
50 545 toadfish, *Opsanus beta*, [46]) or 3 days [adult goldfish, *Carassius auratus*, [25]). In our mifepristone treated *N.*  
51 546 *pulcher*, persistent programming of higher *mr* expression may have developed as a compensatory  
52 547 mechanism to mediate the effects of high plasma cortisol concentrations as previously shown in mice [103].

1 548 Socially challenging interactions are known to induce elevations of fluctuating glucocorticoid levels in  
2 549 several vertebrates including fish [90,98] and mammals [104]. In cooperatively breeding species or other  
3 550 species with hierarchical social organization, individuals are exposed to frequent social interactions  
4 551 including repeated challenges of their social rank. For instance, subordinate members of cooperative  
5 552 breeders, both in highly social vertebrate and invertebrate species, recurrently challenged their position in  
6 553 the queue for a breeding position by lower ranking individuals [105]. Moreover subordinate group  
7 554 members have to mediate conflicts with dominants over group membership [56,106] by appeasement  
8 555 behaviours in the form of subordination and helping [54,59,107]. Social challenges will induce frequent  
9 556 stress responses and thus elevations of glucocorticoid levels in the involved social partners [90]. If  
10 557 individuals experience frequent social stressors early in life, a reprogramming of the stress axis involving  
11 558 altered *mr* and *crf* expression might be a mechanism allowing animals to mount normal cortisol responses  
12 559 even in socially stressful situations later in life. However, the potential benefits of programming depend  
13 560 strongly on the later-life social environment. Moreover, programming of the stress axis by early cortisol  
14 561 surges and does not come without cost, as it can negatively affect emotionality and behavioural  
15 562 performance in the long run as shown in laboratory rats [19,108]. Such negative behavioural impact of  
16 563 glucocorticoids might explain why *N. pulcher* had impaired social competence and social performance  
17 564 following early-life cortisol exposure. Finally, further research would have to confirm whether multiple  
18 565 social stressors during early life have comparable effects to multiple pharmacologically induced cortisol  
19 566 surges.

20 567 In the past years, evidence is rapidly accumulating that the stress axis of vertebrates can be re-programmed  
21 568 early in life by social [11,16,93] and ecological [94,95] stressors in mammals, birds and fish. Understanding  
22 569 the physiological and behavioural mechanisms of stress coping should greatly increase our understanding  
23 570 of individual life history trajectories and behavioural strategies, both in natural and perturbed  
24 571 environments. Vertebrates, including humans, are increasingly exposed to environmental stressors, be it  
25 572 because of competition for increasingly limited resources or human-made problems such as pollution. Here  
26 573 we uncover a potentially general mechanism that may be involved in stress axis re-programming and stress  
27 574 coping, which regulates stress by increasing the sensitivity of limbic stress response and decreasing stress  
28 575 axis reactivity. Further research is necessary to reveal, which type of environmental social and ecological  
29 576 stressors will elicit this programming mechanism in vertebrates, and whether there are certain sensitive  
30 577 periods when it can happen [112]

## 31 578 Conclusions

32 579 The altered programming of the stress axis induced by our pharmacological treatments during early  
33 580 development suggests the generation of a mechanism to cope with stressors. The down-regulation of *crf*  
34 581 and the up-regulation of *mr* in the telencephalon both by early-life mifepristone and cortisol have two  
35 582 potential implications: First, the increase of mineralocorticoid receptor expression could increase the  
36 583 sensitivity of the limbic stress response and result in a faster initial response to stress that is mediated by  
37 584 MR [66]. Second, lower levels of *crf* expression could lower HPI axis activity following the encounter of a  
38 585 stressor [98], which means that it may need stronger stress stimuli to mount a stress response compared to

1 586 control fish. This suggests that individuals have developed a physiological mechanism that allows them to  
2 587 better cope with stressors. This may help them to avoid physiological damage caused by increases of  
3  
4 588 allostatic load [113], which is the amount of energy required to maintain homeostasis [113]. However, the  
5 589 stress axis programming by cortisol and mifepristone comes with some costs, as these fish exhibit reduced  
6 590 social competence. Whether or not this stress axis programming results in net fitness benefits depends on  
7  
8 591 the frequency and strength of stressors present in the environment and whether the costs are smaller than  
9 592 the benefits. Our results suggest that early life exposure to stimuli known to trigger elevations in cortisol  
10 593 levels such as social defeat [114] or social deprivation [91] may lead to programming of stress axis genes  
11 594 such that this protective mechanism is implemented.

12 595

## 17 596 Additional Information

### 20 597 Acknowledgements

21 598 The authors thank Albert F.H. Ros and Corinna von Kuerthy for helpful comments on experimental design,  
22 599 Danielle Bonfils, Eva Zwygart, Laurence Lachat, Beat Suter, Paula Vazquez Pianzola, and Gerald Heckel for  
23 600 technical laboratory support, Leif Engqvist, Mattia Maldonado and the late Hirokazu Tanaka for providing  
24 601 statistical advice.

25 602

### 31 603 Author's Contributions

32 604 MR and BT designed the study, MR collected behavioural data and biological samples, MR and GG did the  
33 605 hormone analyses, MR and DR did the gene expression analyses, MR, BT and DR did the statistical  
34 606 analyses, MR and BT wrote the manuscript, all authors edited and approved the manuscript.

### 39 607 Competing Interests

40 608 The authors do not declare competing interests

### 44 609 Funding

45 610 BT acknowledges financial support by the Swiss National Science Foundation (SNSF; grant  
46 611 31003A\_156881).

1 915 **Figure Captions**

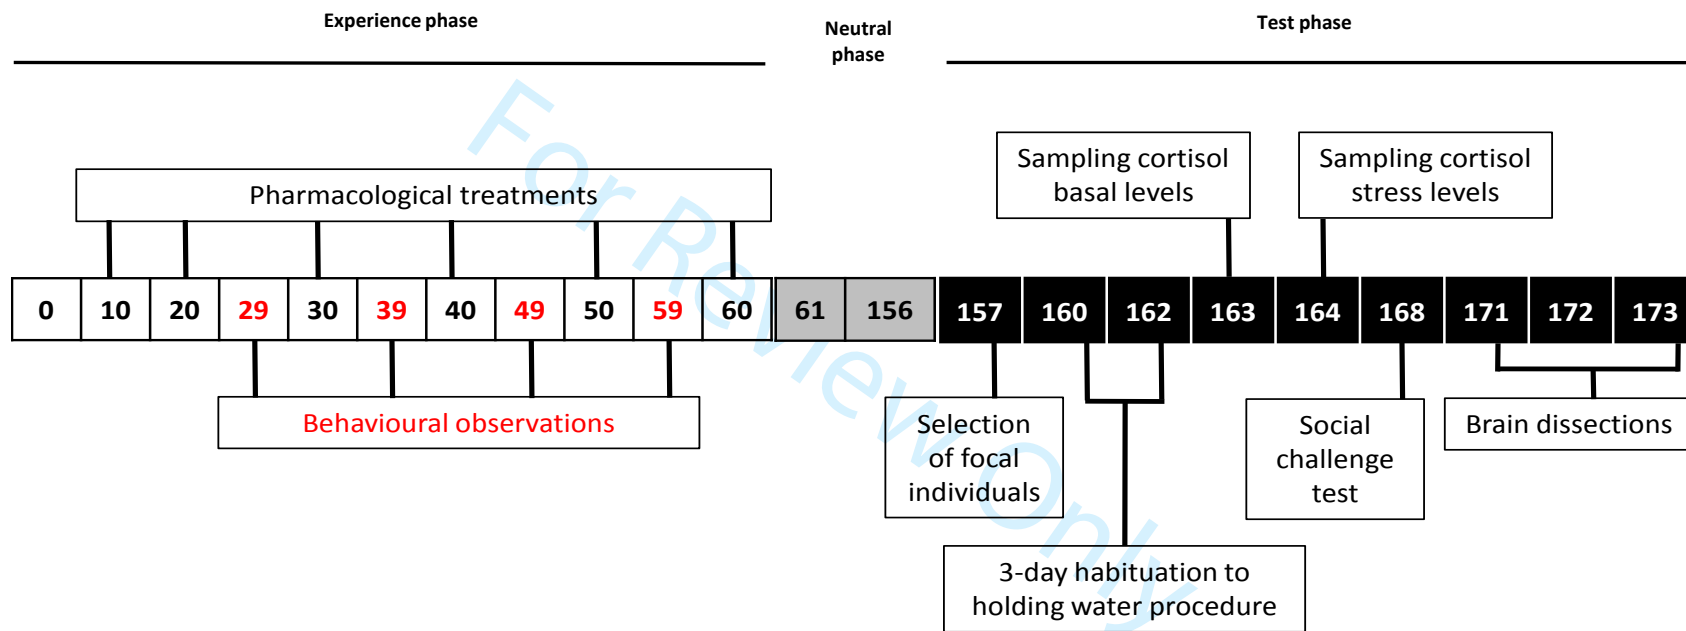

2  
3 916 **Figure 1.** Timeline of experimental manipulations between developmental Day 0 (first day of free swimming)  
4 and Day 173. White boxes: experience phase; individuals received pharmacological treatments and their  
5 behaviour was recorded. Grey boxes: neutral phase; broods were kept under identical conditions without their  
6 parents. Black boxes: test phase; experimental individuals were selected for hormonal measurements and  
7 social challenge tests; brain were dissected of 'naïve' individuals, i.e. individuals which had not taken part in  
8 either hormone measurements or social challenge test.  
9  
10  
11  
12

13  
14 922 **Figure 2.** Frequency of spontaneous affiliative behaviour performed by juveniles towards their siblings  
15 (medians  $\pm$  interquartile ranges are shown). Behaviours were recorded in the home tanks of rearing groups (3  
16 times 5 min per group, see 'Materials and Methods') during the experience phase 9 days after the application  
17 of each treatment starting on developmental day 29 until day 59. Treatments: control (black), cortisol (white)  
18 and mifepristone (grey).  
19  
20  
21  
22

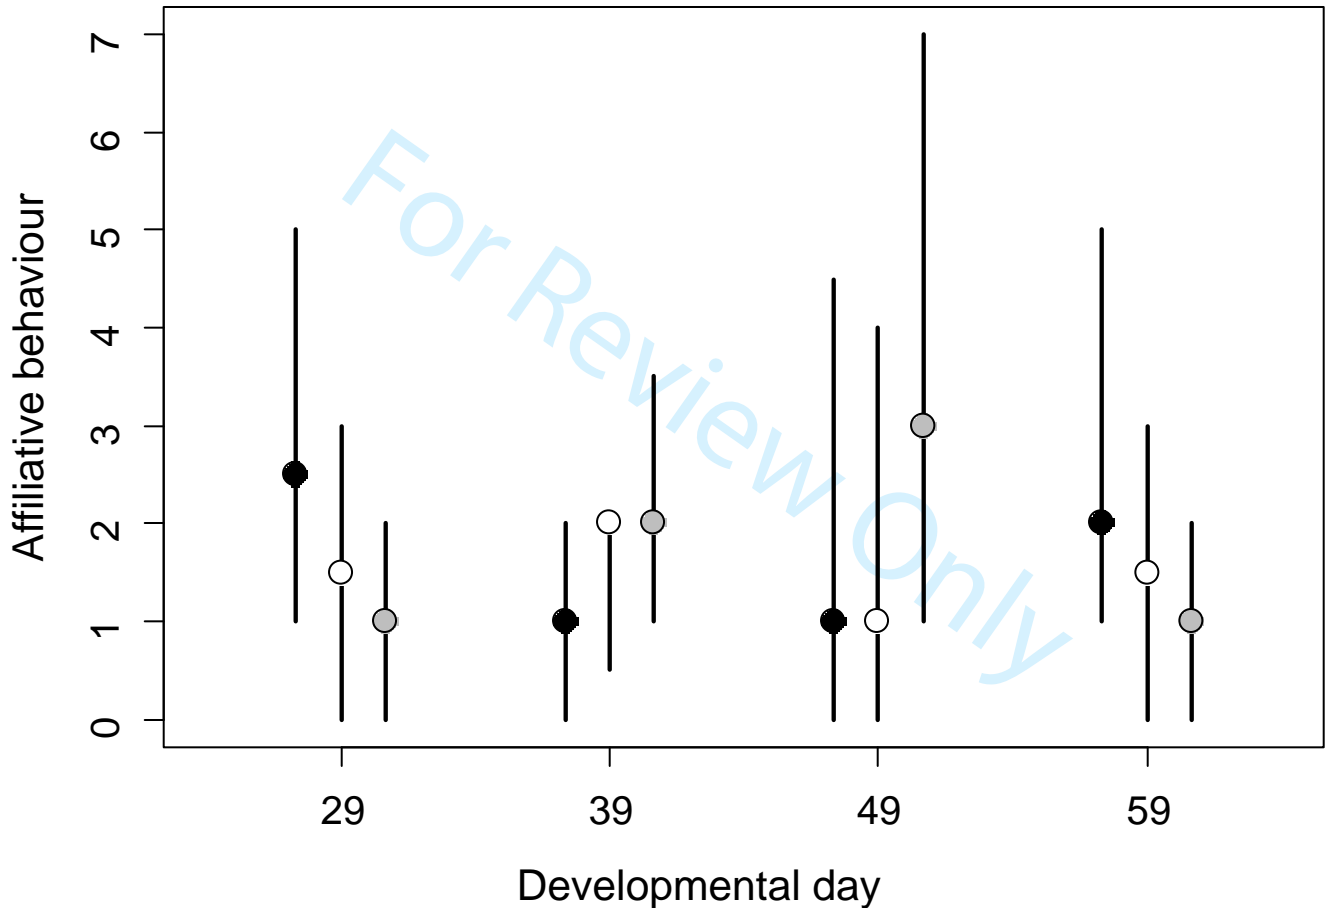

23 927 **Figure 3.** Interactive effect of mifepristone treatment and stress responsiveness on the likelihood of winning  
24 (outcome = 1) or losing (outcome = 0) a contest. Mifepristone treatment (n=20, grey line and triangles) and  
25 control treatment (n=22, black line and circles).  
26  
27  
28

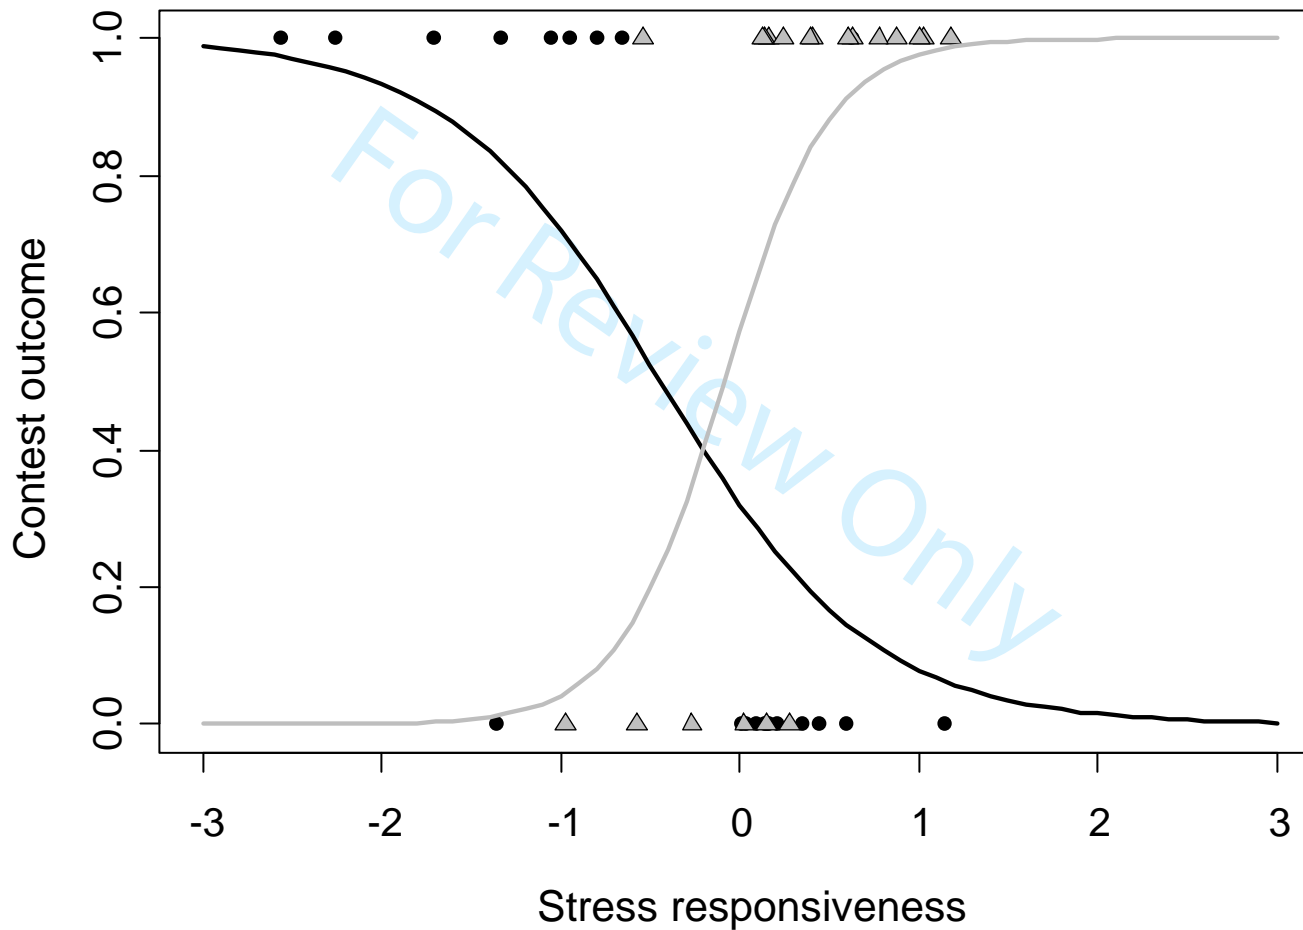

29 930 **Figure 4.** Social behaviours in asymmetric contest over a shelter. (a) Total duration (min) of contests when  
30 owners were the focal individuals. (b) Rate of restrained aggression per min performed by owners. In both  
31 panes control n=19 (black), cortisol n=20 (white) and mifepristone n=19 (grey). Medians and  $\pm$  interquartile  
32 range are shown.  
33  
34  
35

36 934 **Figure 5.** Expression of candidate genes in the telencephalon relative to the reference gene 18s. (a) Expression  
37 of *crf* gene. (b) Expression of *mr* gene. In both panels control n= 10 (black), cortisol n=11 (white) and  
38 mifepristone n=10 (Black). Means  $\pm$  S.E. are shown.
