Abstract

Rationale—Neuroendocrine-immune regulation is essential for maintaining health. Early-life adversity may cause dysregulation in the neuroendocrine-immune network through repeated activation of the stress response, thereby increasing disease risk.

Objective—This paper examined the extent to which maternal psychological well-being moderates neuroendocrine-immune relations in children.

Methods—We used data from a laboratory-based study of mothers and their five-year old children ($n=125$ mother-child pairs) conducted from 2011–2013 in Baltimore, Maryland. Child saliva was assayed for markers of immune function (i.e., cytokines: interleukin [IL]-1 β , IL-6, IL-8, tumor necrosis factor alpha [TNF- α]) and hypothalamic-pituitary-adrenal activity (i.e., cortisol). A composite score for depressive symptoms, anxiety, and parenting stress characterized maternal psychological distress. Multilevel mixed models examined the relationship between maternal psychological well-being and child neuroendocrine-immune relations.

Results—Significant cytokine \times maternal distress interactions indicated that as maternal distress increased, expected inverse cytokine-cortisol relations within children became weaker for IL-1 β , IL-6, and TNF- α . Sex-stratified models revealed that these interactions were only significant

Financial disclosure:

DAG has a financial relationship with Salimetrics LLC (Carlsbad, CA). All other authors have nothing to disclose.

Conflict of interest:

DAG is founder and Chief Scientific and Strategy Advisor at Salimetrics LLC (Carlsbad, CA), and this relationship is managed by the policies of the committees on conflict of interest at the Johns Hopkins University School of Medicine and the Office of Research Integrity and Adherence at Arizona State University. The other authors have no conflicts of interests.

among girls. Among boys, there were inverse cytokine-cortisol relations for all cytokines, and, while in the same direction as observed among girls, the cytokine \times maternal distress interactions were non-significant.

Conclusion—The findings suggest that maternal distress is associated with child neuroendocrine-immune relations in saliva and may alter the sensitivity of inflammatory immune processes to cortisol's inhibitory effects. This desensitization may place the child at risk for inflammatory diseases. The findings support efforts for the early detection and treatment of at-risk mothers to protect maternal and child health and well-being.

Keywords

salivary cortisol; cytokines; children; maternal mental health; acute stress

Introduction

Early-life adversity contributes to poorer mental and physical health throughout life (Danese & McEwen, 2012; J. Shonkoff et al., 2012). Preventing and identifying early-life adversity are increasingly important aspects of social, education, public health and clinical policies and programs aiming to promote healthy development and lifelong well-being (Brent & Silverstein, 2013; Garner et al., 2012). Developing effective interventions, however, requires advanced understanding of the mechanisms linking adversity and disease.

Early-life adversity activates a developing child's stress response. While acute activation of the stress response protects the child in the short-term and helps the child cope with immediate dangers or threats (McEwen, 2005), repeated activation of the stress response, as a consequence of chronic or frequent childhood adversities, may result in physiologic damage or dysfunction in the system of nervous, endocrine and immune processes involved in the body's response to stress (Danese & McEwen, 2012; Hertzman & Boyce, 2009; McEwen, 2005). Coordination within the neuroendocrine-immune (NEI) network is essential for maintaining homeostasis (Johnson, Riley, Granger, & Riis, 2013). Adversity-related NEI disruptions early in life may render the body vulnerable to imbalanced NEI activity, and increase disease risk later in life. For example, adversity may make inflammatory immune processes less sensitive to inhibitory signals from the central nervous system (i.e., cortisol), thereby increasing risk for chronic inflammation (Miller et al., 2009).

Previous research suggests, however, that the negative effects of adversity on health may be buffered by a supportive caregiver (Chen, Miller, Kobor, & Cole, 2011; Miller et al., 2011; J. P. Shonkoff, 2012). A sensitive and attentive adult caregiver is one of the most important protective factors supporting child health (Chen et al., 2011; Miller et al., 2011; J. P. Shonkoff, 2012). Animal studies have shown a potential link between the quality of early-life maternal care and later-life immune functioning with dysfunctional maternal behavior associated with an inflammation-prone immune response in offspring (Coe & Lubach, 2003). While the study of these biologic effects in humans is limited, there is evidence that high levels of social support and maternal care are associated with lower and more regulated inflammatory processes in adults otherwise at risk for stress-related increases in inflammatory processes (Chen et al., 2011; Miller, Cohen, & Ritchey, 2002). These findings

demonstrate the importance of social-emotional supports in NEI network regulation, particularly under high stress conditions.

Infancy and early childhood, when the hypothalamic-pituitary-adrenal (HPA) axis and immune system are undergoing developmental change, represent sensitive periods during which stress, and a supportive caregiver, may have profound, and possibly lasting, impacts on NEI network functioning (Coe & Lubach, 2003; Miller, Chen, & Zhou, 2007). Studying NEI relations in children, however, has traditionally been limited by the need for blood-based biomeasures. Blood collection can be especially difficult for studies involving children (Djuric et al., 2008). In contrast, saliva collection is minimally-invasive, low-cost and generally more socially acceptable (Djuric et al., 2008; Marques, Silverman, & Sternberg, 2010). Research focused on salivary immune markers in healthy young children is limited; however, there is a growing body of literature, especially examining interleukin-1 beta (IL-1 β) and interleukin-6 (IL-6) (El-Sheikh, Buckhalt, Granger, Erath, & Acebo, 2007; Keller, El-Sheikh, Vaughn, & Granger, 2010; Riis, Granger, DiPietro, Bandeen-Roche, & Johnson, 2015). These salivary inflammatory biomarkers open up new opportunities to gain a better understanding of NEI functioning in children and the role caregivers play in moderating stress-related damage within the NEI network. This emerging line of inquiry may help illuminate a link between early-life adversity and health, which, in turn, may contribute to more effective screening tools and interventions.

This study uses salivary biomeasures to examine whether coordination between HPA axis and inflammatory immune system functioning varies by level of maternal distress in five-year old children from diverse socioeconomic backgrounds. This paper addresses two gaps in current knowledge. First, unlike prior studies that do not adequately parse financial and psychosocial aspects of adversity (Slopen, Koenen, & Kubzansky, 2012), we used several markers of maternal psychological well-being and socioeconomic status (SES) to separate the effects of caregivers from SES. Second, rather than examining a single biologic system, we assessed relations between the HPA and immune systems to gain a nuanced understanding of the biologic consequences of early-life adversity. We hypothesized that maternal psychological well-being would moderate HPA-immune system relations regardless of SES.

Methods

This study used data from the Fetus to Five study, supplemented with data collected from a community sample (DiPietro et al., 2010; Riis et al., 2015).

Participants

Mother-child pairs were recruited in 2011–2013 as detailed previously (DiPietro et al., 2010; Riis et al., 2015). Approximately a third of the sample (58 pairs) was recruited from mothers who participated in a fetal development study in 2006–2007. Enrollment in the fetal development study was limited to low-risk, healthy women (DiPietro et al., 2010). To increase the diversity of the sample, an additional 93 participant pairs were enrolled from Baltimore, Maryland via community postings. English fluency was required, and child participants had to be five-years old. Mother-child pairs were excluded if mothers reported

that the child had health or developmental conditions impairing cognitive, motor, or regulatory functioning.

Procedures

The Johns Hopkins Bloomberg School of Public Health Institutional Review Board approved the study protocol. Mothers provided written consent. During a 90-minute study visit, five-year old children (Mean [M]=5.45 years, standard deviation [SD]=0.29) completed neuropsychological and behavioral assessments and participated in emotional stressor tasks. Four saliva samples were collected from children; two before and two after the stressor tasks (M [SD] minutes from sample 1–2=12.15 [2.87]; 2–3=14.58 [2.94]; 3–4=23.36 [6.06]). Mothers provided sociodemographic and child health information, and completed a battery of psychological assessments.

Emotional stressor tasks—Children participated in three age-appropriate emotional stressor tasks including: the Disappointing Gift Game, the Not Sharing Game, and Mischel's Delay of Gratification Task (Mischel & Mischel, 1983). These tasks elicit negative emotions and challenge behavioral and emotional regulation (Cole, Zahn-Waxler, & Smith, 1994; Gagne, Hulle, Aksan, Essex, & Goldsmith, 2011; Jahromi & Stifter, 2008; Kieras, Tobin, Graziano, & Rothbart, 2005; Mischel & Mischel, 1983; Spinrad et al., 2009). The Not Sharing Game also elicits an increase in salivary cortisol in young children (Spinrad et al., 2009). Detailed descriptions of the tasks were previously published (Riis et al., 2015).

Family sociodemographic data—Sociodemographic data included: family income, maternal education, marital status, and the number of moves during the child's life. Financial stress was measured using a six-item instrument adapted from Essex and colleagues (Essex, Klein, Cho, & Kalin, 2002) assessing the frequency of financial stressors in the last three months (e.g., difficulty paying bills, fears of losing home/job).

Maternal psychological measures—Maternal psychological well-being was measured using three commonly-used, validated instruments. Maternal depressive symptoms in the last week were measured using the Center for Epidemiologic Studies Depression Scale (CESD-20; Radloff, 1977). Trait-anxiety was assessed using the Spielberger State-Trait Anxiety Inventory-Form Y2 (STAI; Spielberger, Gorsuch, Lushene, Vagg, & Jacobs, 1983). Maternal parenting and life stress were measured using the Parenting Stress Index-Short Form (PSI; Aibidin, 1995).

Biomeasure data—Whole saliva was collected using passive drool. Samples were stored at -20 degrees Celsius until assayed. Saliva was assayed for cortisol, a marker of HPA activity, and for four proinflammatory cytokines: IL- 1β , IL-6, interleukin-8 (IL-8) and tumor necrosis factor alpha (TNF- α). IL- 1β , IL-6, IL-8 and TNF- α are critical signaling molecules involved in initiating and maintaining inflammation (Clough & Roth, 1998; Owen, Punt, & Stranford, 2012). Although limited, prior studies have found associations between inflammatory cytokines and HPA activity in the oral cavity (including previously reported data from the current study) (Izawa et al., 2013; Moons, Eisenberger, & Taylor, 2010; Riis et al., 2015). While salivary cytokine activity likely reflects local immune processes,

interactions between inflammatory cytokine and HPA activity in the oral cavity have been found to mirror immune-HPA relations previously identified in serum (Riis et al., 2015). Furthermore, in studies of adults, salivary IL-1 β , IL-6 and TNF- α have exhibited acute stress sensitivity (Slavish, Graham-Engeland, Smyth, & Engeland, 2015).

Determination of salivary analytes—Saliva assays were performed at the Center for Interdisciplinary Salivary Bioscience Research at the Johns Hopkins School of Nursing. Cortisol was analyzed in duplicate using a commercially available enzyme immunoassay (Salimetrics, Carlsbad, California). Cortisol assay sensitivity ranged from 0.007 to 3.0 $\mu\text{g/dL}$. The intra-assay coefficient of variation was less than 5%, and the inter-assay coefficient of variation was less than 10%. Eight percent of cortisol concentrations were below the lower limit of detection; these values were substituted with half the lower limit of detection (0.0035 $\mu\text{g/dL}$).

Salivary cytokines were measured following Riis and colleagues (Riis et al., 2013) using proinflammatory cytokine 4-plex electrochemiluminescence immunoassays by Meso Scale Discovery (Gaithersburg, Maryland). Cytokine concentrations (pg/mL) were determined with MSD Discovery Workbench Software (v. 3.0.17) using curve fit models (4-PL with a weighting function option of 1/y²). Lower limits of detection and intra-assay coefficients of variation were: IL-1 β : 0.06 pg/mL, 4.4%; IL-6: 0.09 pg/mL, 4.8%; IL-8: 0.05 pg/mL, 2.1%; and TNF- α : 0.11 pg/mL, 6.6%. All IL-1 β and IL-8 concentrations were measureable above the lower limit of detection. A small number of non-detects for IL-6 (<1%) and TNF- α (5%) were replaced with laboratory-estimated concentrations. Associations between cytokine concentrations and flow rate were tested using Spearman's rank correlations and regression analyses with robust variance. No consistent relations were found, so data were not adjusted for salivary flow rate.

Descriptive statistics of raw salivary cortisol data by saliva sample are shown in Supplemental Table 1; descriptive statistics of salivary cytokine data were previously published (Riis et al., 2015). All analyte data were positively skewed. Data were log-transformed and Winsorized (Tabachnik & Fidell, 2001) to bring values within three standard deviations of sample means and improve the normality of the distributions. For each analyte, 1% of concentrations were Winsorized. Transformed and Winsorized data were used in all statistical analyses.

Key covariates—Salivary biomarkers may be affected by illness and contamination with blood. Thus, mothers provided information on whether children were currently experiencing symptoms of illness and/or whether they had loose or recently shed teeth, or other dental issues. Information about other potential confounders of cortisol and cytokine concentrations, including child age, sex, and maternal smoking status (smoking/non-smoking), was based on maternal report. In addition, because body mass index (BMI) may influence neuroendocrine and inflammatory functioning, BMI was determined using evaluators' measurements of child height and weight (Centers for Disease Control and Prevention, 2001). Weight status (underweight/healthy weight versus overweight/obese) was assigned to each child using the Centers for Disease Control and Prevention's BMI percentile ranks by age and sex (Centers for Disease Control and Prevention, 2011).

The impact of diurnal patterns in cortisol was adjusted for using elapsed time from child waking to study appointment using maternal report. To account for the differential timing of stressor tasks relative to saliva samples across children, a task timing variable, defined as the time between the beginning of the stressor tasks and each sample, was calculated.

Statistical Analyses

Maternal psychological measures—Cronbach's alpha (α) was used to assess the internal consistency of the CES-D, STAI and PSI in the sample. Correlations between the scale scores were also examined using Spearman's rho.

Factor analyses—The first step in data analysis was to determine whether the eight SES indicators and maternal psychological scale scores (Table 1) could be combined into distinct measures. This was achieved by polychoric exploratory factor analysis with maximum likelihood estimation and robust standard errors (*SEs*), oblique rotation, and one to four factors. A two factor solution was selected based on information criteria, factor loadings, and residual variances; one factor represented financial hardship and one represented maternal distress (Table 1; Supplemental Table 2). Oblique rotation resulted in two factors with correlation=0.57 ($p<.001$). Greater financial hardship was associated with greater maternal distress. Factor scores, derived using the posterior mode method, provided a score for financial hardship and maternal distress for each child.

Multilevel mixed models—The next step was to examine the effect of cytokine concentrations, maternal distress, and cytokine \times maternal distress interactions on cortisol values. To do this, cortisol was modeled as an outcome using multilevel mixed models with a random intercept and a random slope to account for repeated sampling within individuals and varying cortisol trajectories between individuals. Robust variance and an independent covariance and residual errors structure were specified. Residual variance was modeled separately for each sample to allow for unequal variance across samples.

First, bivariate analyses explored relations between cortisol and each independent variable. Next, four separate fully-adjusted models for cortisol were performed, each with only one cytokine predictor. The independent variables in fully-adjusted models included: the cytokine of interest, the maternal distress score, the cytokine \times maternal distress interaction, all key covariates, and the financial hardship score. Fully-adjusted models also included a time since waking \times saliva sample interaction based on literature showing blunted cortisol responses to acute stress in the morning versus afternoon (Dickerson & Kemeny, 2004). We previously reported sex differences in cytokine-cortisol relations (Riis et al., 2015), so a sex \times cytokine interaction was also included in fully-adjusted models. The main independent variables in fully-adjusted models were the cytokine of interest, the maternal distress score, and the cytokine \times maternal distress interaction. Four parsimonious final models were created by subjecting fully-adjusted models to backwards stepwise selection of covariates using a $p<.05$ retention criterion. The main independent variables were retained for final models and not subjected to the backwards stepwise selection. Model fit was assessed for each final model using residual and added variable plots.

In addition to including financial hardship as a covariate, *post-hoc* models examined the specificity of the moderating effect of maternal distress on cytokine-cortisol relations by testing the significance of cytokine \times financial hardship interaction terms in final models with maternal distress included as a covariate.

All analyses, except factor analyses, were conducted in Stata/SE 12.1 (StataCorp LP, College Station, Texas). Factor analyses were conducted in MPlus Version 7.11 (Muthen and Muthen, Los Angeles, California). Sensitivity analyses tested the robustness of the interaction between cytokine concentrations and maternal distress by using a three-level categorical maternal distress variable (created using tertiles) instead of a continuous factor score. In the final models, sensitivity analyses also examined the association between individual maternal distress and family financial variables, rather than factor scores.

Results

Data were collected from 151 mother-child pairs. Three children were unable to complete the appointment, and 23 children had insufficient salivary data. Analyses were performed on the remaining 125 pairs. Sociodemographic and health measures did not differ between children with and without full salivary data. All children were five-years old, approximately half were female, and slightly more than a third were overweight (Table 2). On average, children were awake for seven hours when the study appointment began (Table 2). The families in our sample represented a wide range in SES families; annual incomes ranged from less than \$5,000 to greater than \$100,000 (Table 1). There was also a wide range of maternal psychological distress among our sample, as assessed by the CES-D, STAI and PSI (Table 1).

Maternal Psychological Measures

There was strong internal consistency for the CES-D, STAI and PSI in the sample (Cronbach's $\alpha = .90, .85, .90$, respectively). Scores on the psychological assessments were also positively correlated: CES-D with STAI: $\rho(123) = .84$; CES-D with PSI: $\rho(123) = .53$; STAI with PSI $\rho(123) = .60$ (all p 's $< .001$).

Multilevel Mixed Models for Cortisol

Backward stepwise selection of covariates—Seven covariates were retained in each of the four final models (i.e., saliva sample, child sex, sex \times cytokine, current illness, financial hardship, time since waking, time since waking \times sample). In addition to these covariates, child BMI category was significantly associated with cortisol in models with TNF- α as the main cytokine predictor. Thus, BMI category was included in this final model. In all models, there were significant inverse relations between financial hardship and cortisol indicating that as financial hardship increased, cortisol levels decreased (Table 3).

Neuroendocrine-immune relations and moderation by maternal distress—IL-6 and IL-8 were inversely associated with cortisol (Table 3). While there was no main effect of maternal distress on cortisol in any model, there were significant interactions between cytokines and maternal distress for IL-1 β , IL-6 and TNF- α (Table 3). Inverse relations

between cortisol and IL-1 β , IL-6 and TNF- α became less strong with increasing maternal distress (these relationships are illustrated in Figure 1 using the three-category maternal distress variable created using tertiles).

Post-hoc analyses tested the specificity of cytokine \times maternal distress interaction effects on cortisol by examining the significance of cytokine \times financial hardship in the final models with maternal distress included as a covariate. The cytokine \times financial hardship interaction term did not significantly predict cortisol for IL-6, IL-8 and TNF- α . The interaction between IL-1 β and financial hardship was significantly and positively associated with cortisol ($\beta=0.03$, $SE=0.01$, $p=.02$), indicating that the inverse relation between IL-1 β and cortisol became less strong as financial hardship increased, a similar pattern to the relation observed for maternal distress.

The role of child sex—There were significant sex \times cytokine interactions in every model that indicated stronger, inverse cytokine-cortisol relations among boys than girls (Table 3). To explore these sex-specific relations, we performed stratified analyses for each final model using a homogeneous, independent residual structure and regular variance (i.e., not robust) given the smaller sample sizes.

Cytokine-cortisol relations varied by sex with significant inverse relations between cortisol and all cytokines among boys ($\beta=-0.18$ to -0.34 , $SE=0.05$ to 0.08 , $p<.001$ to $.004$), but not girls. Among girls, IL-1 β , IL-6 and IL-8 were positively related to cortisol, although these relations were only marginally significant ($\beta=0.09$ to 0.12 , $SE=0.05$ to 0.07 , $p=.06$ to $.07$). Similarly, cytokine by maternal distress interactions varied by sex for IL-1 β , IL-6 and TNF- α with significant positive interactions among girls ($\beta=0.18-0.27$, $SE=0.07$, $p<.001-.009$), but not boys, despite the fact *t*-tests of model coefficients revealed no significant differences between the interaction effects for boys and girls. Among girls, as maternal distress increased, the positive cytokine-cortisol relations became stronger, mirroring the relations in the full sample. Again, we tested the specificity of cytokine \times maternal distress interactions in boys and girls separately in *post-hoc* analyses. No significant cytokine \times financial hardship interactions were found among boys. Among girls, the only significant cytokine \times financial hardship interaction was seen for IL-1 β ($\beta=0.03$, $SE=0.01$, $p=.02$) and the direction of this effect was the same as that observed in the full sample.

Discussion

Findings from this study provide insight into the sensitivity of child NEI relations to adversity. In our sample of young children from varied SES families, relations between inflammatory immune and HPA activity in saliva varied by maternal distress. Regardless of SES, as maternal distress increased, inverse relations between salivary cytokine and cortisol activity in children became weaker. Systemically, cortisol regulates inflammation by inhibiting the activity of inflammatory cytokines (Irwin & Cole, 2011). This regulatory mechanism is important for preventing excessive and potentially dangerous inflammation (Dantzer, O'Connor, Freund, Johnson, & Kelley, 2008; Irwin & Cole, 2011). Our findings suggest that maternal distress is associated with less efficient regulation of salivary inflammatory mechanisms in children. These findings are consistent with the notion that

adversity can result in a “defensive phenotype” characterized by an over-active inflammatory response (Miller et al., 2009; Zhang et al., 2006). While potentially adaptive in the short-term, prolonged up-regulation of inflammatory mechanisms damages cells and increases disease risk (Dantzer et al., 2008).

Interestingly, the significant interactions between cytokines and maternal distress were driven by significant interactions among girls. While cytokine \times maternal distress interactions among boys were in the same direction as those in girls, and there were no significant differences in interaction effects by sex, all interaction terms were non-significant among boys. These differences may be related to sex differences in cytokine-cortisol relations. As previously reported (Riis et al., 2015), there were inverse relations between cortisol and every cytokine for boys but not girls. Among girls, cytokines were positively associated with cortisol (although relations were non-significant). Similar sex differences in serum cytokine-cortisol relations have been reported in adults (Dickerson, Gable, Irwin, Aziz, & Kemeny, 2009; Prather et al., 2009; Rohleder, Kudielka, Hellhammer, Wolf, & Kirschbaum, 2002; Rohleder, Schommer, Hellhammer, Engel, & Kirschbaum, 2001). These studies suggest that inflammatory cytokines in males show increased sensitivity to the inhibitory effects of cortisol after acute stress, while the same cytokines in females show no change or decreased sensitivity (Dickerson et al., 2009; Rohleder et al., 2002, 2001). The findings are also consistent with animal studies, which have found the anti-inflammatory effects of glucocorticoids to be less potent in female rats compared to males (Duma, Collins, Chou, & Cidlowski, 2010; Quinn, Ramamoorthy, & Cidlowski, 2014). Studies in mice have also found similar sex differences in the effects of early-life stress on NEI relations. In a series of experiments, Avitsur and colleagues found that postnatal stress was associated with increased production of IL-1 β and TNF- α in response to immune challenge in female mice, but not males (Avitsur, Hunzeker, & Sheridan, 2006). Furthermore, enhanced cytokine responses were related to reduced glucocorticoid production, suggesting postnatal stress altered NEI relations in the mice (Avitsur et al., 2006). Taken together, these findings support the notion that females may be more vulnerable to the effects of maternal distress on NEI regulation. If cytokines are predisposed to exhibit decreased sensitivity to cortisol, the desensitization of inflammatory mechanisms associated with adversity may be magnified or observed at lower levels of adversity or earlier in the lifecourse among females.

We observed that financial hardship was inversely associated with cortisol, indicating that as financial hardship increased cortisol levels decreased. These results are consistent with studies showing blunted physiologic stress responses among low-SES children (Blair, Berry, Mills-koonce, Granger, & The FLP Investigators, 2013; Evans & Kim, 2007). SES-related differences in cortisol likely reflect a combination of psychosocial and environmental effects. While we accounted for the distinct effects of maternal distress, other unmeasured SES-related factors likely contributed to the observed financial hardship relations.

Importantly, the moderating effect of maternal distress on cytokine-cortisol relations was significant after adjusting for financial hardship. Also, financial hardship did not moderate NEI relations for IL-6, IL-8 or TNF- α . The only cytokine-cortisol relation moderated by financial hardship was the IL-1 β -cortisol relation, and the IL-1 β \times financial hardship

interaction was in the same direction as the cytokine by maternal distress interactions. Additional research is needed to fully understand the role of financial, psychosocial, and environmental factors in modifying NEI relations in children. However, these results suggest that maternal psychological well-being plays a unique role in moderating child NEI relations in saliva and these effects cannot be explained by SES.

Strengths and Limitations

There are several strengths to our study. First, the sample size is large and includes children with diverse SES backgrounds. Also, we measured and adjusted for several aspects of SES, and we examined the discrete effects of maternal psychological well-being using validated instruments. The findings are further strengthened by repeated within-subject sampling and tightly controlled laboratory procedures. Finally, our use of salivary biomeasures represents a novel approach to studying the effects of adversity which allowed us to examine several measures of NEI activity. By examining immune and HPA activity simultaneously, we gained a new, more complex understanding of the physiologic effects of adversity. This study demonstrates the potential of using minimally-invasive methods to study, detect, and treat the physiologic effects of early-life adversity.

Despite these strengths, limitations of the study warrant discussion. While the order of study tasks was constant, the time between saliva samples and stressor tasks depended on the speed at which the child completed the tasks. Therefore, changes in analytes across the visit are considered cumulative responses to all tasks. Variation in cortisol trajectories after acute stressors is typical for young children (Gunnar, Talge, & Herrera, 2009), and our statistical models accounted for varying cortisol trajectories across the visit. We also tested the effect of task timing on cortisol and found non-significant relations in every model. Preliminary models also explored the effects of three-way interactions for cytokine \times maternal distress \times saliva sample and found no evidence that the interaction between cytokine and maternal distress changed across the study visit.

Our sample included families that represented a wide range in SES, however, income and maternal education were not evenly distributed. There were large proportions of low- and high-income families and fewer middle-income families. Studies with equal representation across socioeconomic strata are needed to fully understand relations between SES and child NEI functioning. Also, we used a maternal distress factor score to examine the combined effect of various dimensions of functioning without overloading models with covariates. This approach, however, limits the clinical significance of the findings as accepted cut-offs for individual instruments are not distinguished. Sensitivity analyses that examined the effect of individual maternal psychological well-being and family SES variables, rather than factor scores, found similar results to those reported here. In addition, all measures, with the exception of biomeasure and BMI data, were based on maternal report and could have introduced the possibility of reporter bias. Finally, longitudinal studies are needed to clarify the direction of the observed relations and the meaning of altered NEI relations in saliva for health and disease risk. Additional research of salivary cytokines, including serum-saliva studies, is also needed to increase our understanding of the meaning of salivary cytokines in healthy children. Furthermore, our findings suggest that maternal distress is related to

differences in some, but not all, salivary inflammatory mechanisms examined; further research is needed to understand the sensitivity of specific NEI relations to psychosocial factors. Future research should investigate NEI relations using other markers of inflammation, such as C-reactive protein, which has been found to have stronger serum-saliva correlations than other inflammatory markers (Slavish et al., 2015).

Conclusion

This study advances understanding of potential mechanisms linking early-life adversity and later-life disease and aids in the identification of adversity risk factors. While prior studies reported significant relations between maternal mental health and altered HPA activity in children (Essex et al., 2002; Fernald, Burke, & Gunnar, 2008; Palmer et al., 2013), to our knowledge, this is the first study examining the moderating effect of maternal distress on cross-system NEI relations. The findings suggest that maternal distress can impact child NEI functioning in saliva by altering the sensitivity of inflammatory immune processes to the inhibitory effects of cortisol. While additional research on salivary NEI functioning is needed, this desensitization may indicate increased risk for chronic inflammation and disease (Danese & McEwen, 2012). Currently little is known about the meaning of salivary markers of immune and NEI relations in children for overall health, however, higher levels of salivary inflammatory activity have been associated with sleep disruptions (El-Sheikh et al., 2007) and behavioral and mood disorders in young children (Keller et al., 2010). If left unchecked, poorly regulated inflammatory activity in adulthood is associated with a range of health conditions including depression, obesity, and heart disease (Barnes & Adcock, 2009; Danese & McEwen, 2012; Dantzer et al., 2008).

Our findings add to a large body of research indicating the critical role of caregivers in child health (e.g., Goodman et al., 2011; Halligan, Herbert, Goodyer, & Murray, 2004; Shankardass et al., 2009; Surkan, Kennedy, Hurley, & Black, 2011; Wright, 2007). Our finding that maternal distress is associated with changes in child NEI relations regardless of family SES highlights the importance of identifying and treating maternal mental health problems in families of all socioeconomic strata. The American Academy of Pediatrics recommends screening for post-partum depression as part of standard well child care (Tanski, Garfunkel, Duncan, & Weitzman, 2010). However, recently, pediatricians have been called upon to play a larger role in identifying and treating maternal mental health issues (Chemtob, Gudiño, & Laraque, 2013; Garner et al., 2012). Our findings support screening for maternal depression, and underscore the potential benefit of clinical, family and community-based programs and policies that support mothers and help protect maternal as well as child health and well-being.

Research highlights

- Stress may alter child neuroendocrine-immune (NEI) function, increasing disease risk.
- We examined whether maternal psychological distress moderates child NEI relations.
- Child NEI functioning was measured using salivary biomarkers.
- Maternal distress moderated child NEI relations in saliva.
- The effects of maternal distress on NEI relations were stronger in girls than boys.

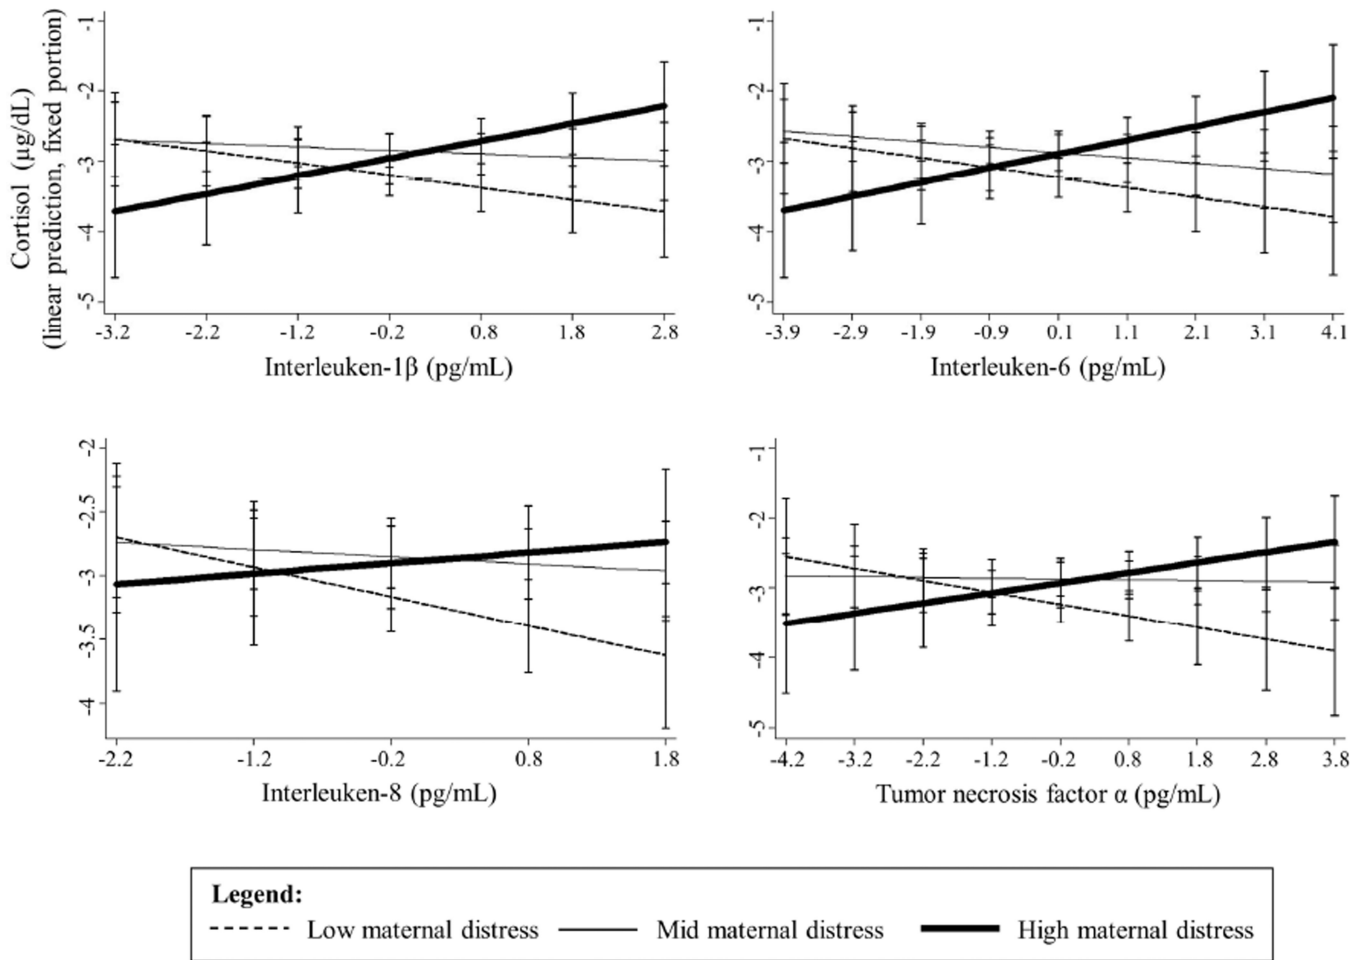

Figure 1.
 Maternal distress moderates salivary cytokine-cortisol relations in five-year old children (n=125).^a
^aCortisol and cytokines are Winsorized and log-transformed. Cytokines are centered.
 Models were adjusted for child health and demographic factors and family socioeconomic status. Maternal distress categorized using tertiles.

Table 1Family sociodemographic and maternal psychological characteristics ($n=125$)

Sociodemographic Characteristics ^a	Number (%)/ Mean \pm SD	Range
Family income in last 12 months		
<\$5,000–\$11,999	30 (24)	
\$12,000–\$24,999	29 (23)	
\$25,000–\$49,999	11 (9)	
\$50,000–\$99,999	14 (11)	
\$100,000	41 (33)	
Maternal education		
<High school	8 (6)	
High school degree/GED	33 (26)	
Some college	31 (25)	
2-Year degree	7 (6)	
4-Year degree	20 (16)	
Master's degree	11 (9)	
Doctoral/professional degree	15 (12)	
Maternal marital status		
Married	56 (45)	
Moves during child's life		
0	35 (28)	
1	38 (30)	
2	17 (14)	
3	21 (17)	
4	7 (6)	
5	2 (2)	
6+	5 (4)	
Maternal financial stress	14.62 \pm 6.87	6–30
<i>Maternal Psychological Characteristics ^b</i>		
Maternal depressive symptoms	13.62 \pm 10.91	0–47
Maternal anxiety	37.39 \pm 9.62	20–62
Maternal parenting and life stress	67.67 \pm 17.26	36–113

Note. SD=Standard deviation. GED=General equivalency diploma.

^aVariables included in financial hardship factor. There were no missing data for maternal education, marital status, or moves during child's life. Family income data were missing or classified as "don't know" for 10% of the sample; incomplete data were substituted with the mean of the sample group. Financial stress data were missing for 6% of the sample, but no participant was missing more than one item. Missing items were imputed with the mean score of the completed items.

^bVariables included in maternal distress factor. Missing data on psychological measures ranged from 10–18%, but only six participants were missing more than one item per instrument. Missing data were imputed with mean scores of completed items in the scale (or subscale for the Parenting Stress Index-Short Form).

Table 2Child health and demographic characteristics ($n=125$)

Characteristics ^a	Number (%) / Mean \pm SD
Age (years)	5.45 \pm 0.29
Female	64 (51)
Current illness ^b	24 (19)
Recent periodontal/dental issues ^c	14 (11)
Mother smokes	28 (22)
Weight status category ^d	
Underweight	5 (4)
Body mass index (kg/m ²)	13.28 \pm 0.51
Healthy weight	76 (61)
Body mass index (kg/m ²)	15.75 \pm 0.82
Overweight	25 (20)
Body mass index (kg/m ²)	17.56 \pm 0.44
Obese	19 (15)
Body mass index (kg/m ²)	20.19 \pm 2.84
Time from waking to study appointment (hours)	7.05 \pm 2.41

Note. SD=Standard deviation.

^a Missing data were <3% for all variables except for child age. All children were five years old, however, age in months was missing for 9% of the sample; missing data were imputed with mean values.

^b Current illness based on maternal response to the question: "Is your child currently feeling sick or ill (i.e., runny nose, fever, cough aching, etc)? (yes/no)"

^c Child periodontal/dental issues based on maternal response to the question: "Does your child have any current dental problems such as cuts or sores in his or her mouth, very loose teeth, a tooth lost in the last 48 hours, bleeding gums while brushing, or untreated cavities? (yes/no)"

^d Weight status categories were determined using the Centers for Disease Control and Prevention's standards for body mass index percentile ranges by age and sex; underweight= < 5th percentile; normal/healthy weight= 5th-85th percentile; overweight= 85th-<95th percentile; obese= 95th percentile.

Adjusted relations between cortisol, cytokines, and maternal distress among five-year old children ($n=125$)

Table 3

	Cytokine Main Independent Variable							
	IL-1 β	IL-6	IL-8	TNF α				
<i>Fixed Effects^a</i>	Parameter (SE)	p	Parameter (SE)	p	Parameter(SE)	p		
Intercept	-3.00 (0.13)	<.001	-3.00 (0.13)	<.001	-2.97 (0.13)	<.001	-2.88 (0.13)	<.001
<i>Main Independent Variables</i>
