Abstract

In this paper we describe some measurements of the neutron-proton scattering cross section at neutron energies of approximately 40 and 90 Mev. Both the total scattering cross section and the differential cross section as a function of the angle of scattering were measured.

The results are condensed in Fig. 10.

Introduction

One of the important experiments that became feasible as soon as the 184-inch cyclotron started to operate was an investigation of the n-p scattering at a neutron energy around 90 Mev. As is well known, n-p scattering at high energy may yield interesting clues to the nuclear forces and data on it constitute important experimental material against which any future theory must be checked. The investigation acquires particular importance if the De Broglie wave length of the neutron in the center of gravity system (c.g. system) is comparable with the range of nuclear forces. The De Broglie wave length is given by $\lambda = \frac{h}{p} = \frac{9.0 \times 10^{-13}}{\sqrt{E}}$ cm (E in Mev in laboratory system) and in the region of E = 100 Mev has a value favorable for investigating n-p scattering.

The deuterons of the cyclotron are stripped in collision with nuclei of the target and produce a beam of neutrons of small angular aperture and of

*A short preliminary report of this work has been given in Phys. Rev. 73, 1114 (1948).

fairly narrow energy distribution^{1,2}. This energy distribution has a maximum at about 90 Mev ($\lambda = 0.95 \times 10^{-13}$ cm).

DECLASSIFIED

In the investigation to be described we have studied

- a), the angular dependence of the scattering cross section
- b). the total cross section³

at neutron energies of 90 Mev and 40 Mev. The angular measurements were extended for a scattering angle in the c.g. system from 36 to 180 degrees.

The main results of the investigations are contained in Tables II, III, and IV, and Fig. 11.

To avoid unnecessary repetitions we shall now define the angles used in this paper (see Fig. 1). We shall call the angle of scattering of the neutron in the c.g. system θ , the angle of scattering of the neutron in the laboratory system Θ ; the angle between the direction of motion of the incoming neutron and the recoil proton in the c.g. system and in the laboratory system ϕ and Φ respectively. Between these angles we have the following relations:

$$(1) \quad \text{tg } \Theta = \sqrt{1 - \beta^2} \text{tg } \frac{\theta}{2}$$

$$(2) \quad \text{tg } \Phi = \sqrt{1 - \beta^2} \text{cotg } \frac{\theta}{2}$$

$$(3) \quad \frac{d \cos \Phi}{d \cos \Theta} = \frac{1}{4} \frac{1}{1 - \beta^2} \frac{(1 - \beta^2 \cos^2 \Phi)^2}{\cos \Phi}$$

$$(4) \quad E_n = Mc^2 \frac{2\beta^2}{1 - \beta^2}$$

$$(5) \quad E_p = \frac{2 \beta^2 Mc^2}{1 - \beta^2 + \text{tg}^2 \Theta}$$

where E_n and E_p are the kinetic energies of neutron and proton in the laboratory system, M is the rest mass of proton or neutron (considered equal), β is the ratio of the velocity of the neutron in the c.g. system to the velocity of light. In our experiments ($E_n = 88$ Mev) β is equal to 0.2124.

³See also L.F. Cook, E.M. McMillan, J.M. Peterson, and D.C. Sewell, Phys. Rev. 72, 1264 (1947).

The principle of our experiment is to measure the number of protons scattered by a hydrogenous target (polyethylene or paraffin) into a fixed solid angle $d\Omega = d\psi d\cos\bar{\Phi}$ at angle $\bar{\Phi}$; this number is proportional to the differential cross section $\sigma(\bar{\Phi})$ and from this we find the differential cross section $\sigma(\theta) = \sigma(\bar{\Phi}) \frac{d\cos\bar{\Phi}}{d\cos\theta}$ in the c.g. system. The direct measurement of $\sigma(\bar{\Phi})$ is not on an absolute scale, but we can normalize it and pass to an absolute scale by requiring that

$$(6) \int \sigma(\bar{\Phi}) d\Omega = \text{total scattering cross section} = \sigma_t$$

This last quantity is obtained by measuring the attenuation of the neutron beam in passing through suitable absorbers.

Angular Distribution Experiments

For angles $\bar{\Phi}$ between 0° and about 60° we have used apparatus A and B whose general arrangement is shown in Fig. 2. For angles $\bar{\Phi} > 55^\circ$ we have used a different apparatus (C) to be described later.

The neutron beam coming from the cyclotron was produced by stripping 180 Mev deuterons on 1.25 cm thickness of beryllium. It was collimated through a hole in the 10 feet thick concrete walls of the cyclotron shield and emerged through an aperture of a diameter that has been varied in the different experiments from 7.5 cm to 1 cm. This aperture consisted of holes in two 50 cm long copper plugs, one on each side of the concrete shield. The beam was accurately centered either by obtaining a photographic image on an x-ray film in front of which we had put some paraffin or by looking with a cathetometer at the beryllium probe in the cyclotron.

The primary neutron beam was monitored either by protons scattered from an auxiliary paraffin target or by a bismuth fission chamber⁴.

⁴C. Wiegand, R.S.I. in press.

The scattered protons were detected with a telescope of three proportional counters pointing at the scatterer. The counters were brass cylinders 5 cm in diameter about 13 cm long with a 5 mil wire on the axis, filled at atmospheric pressure with a mixture of argon and carbon dioxide in the ratio 25 to 1 by volume. The front windows were 45 mg cm^{-2} copper or 7 mg cm^{-2} aluminum. The telescope was made insensitive to protons generated by primary neutrons having an energy smaller than 66 Mev by interposing between the last two counters an aluminum absorber (absorber A of Fig. 2) of a thickness such that it would stop all protons of an energy smaller than $66 \text{ Mev} \cos^2 \Phi$.

The energy distribution of the neutrons to be expected in the primary beam is given by Serber's theory. It is desirable however to have a direct experimental confirmation of the distribution because although the excellent agreement with the angular distribution of neutrons as measured in ref. 2 is good proof of the soundness of the picture, we want to know also if there are many neutrons of lower energy arising from other effects. We have, for this reason, taken a curve of coincidence counting rate, keeping Φ constant at 15° , as a function of the thickness of the absorber A. From this curve it is possible to calculate by differentiation the energy distribution of the neutrons in the primary beam. The same distribution has been investigated also by lowering the voltage in the counter behind absorber A in the telescope in such a way that it was sensitive only to protons near the end of their range. The results are shown in Fig. 3 together with Serber's theoretical curve. Agreement with Serber's diagram is good for the high energy region, but we have some indications of an appreciable number of neutrons of lower energy. This subject has not been further investigated because all our detectors were operated in such a way as to be insensitive to protons generated by primary neutrons of energy lower than 66 Mev.

For this reason, as we have said above, the absorber A placed in the coincidence telescope was chosen so that the minimum energy a neutron must have in order to give a detectable scattered proton was 66 Mev. This condition was exactly fulfilled only for an infinitesimal layer at half the depth of the scatterer. The energy loss of the protons in the scatterer make this condition for a thick scatterer only approximate and since the thickness of the scatterer in terms of energy loss becomes greater as Φ increases the error increases with Φ . However even in the case of the widest angles measured a neutron must have $(66 + 7)$ Mev in order to give a detectable proton from the side of the scatterer farther from the detector, and $(66 - 7)$ Mev in the case of the side nearer to the detector. The neutron energy distribution as measured by us, when multiplied by $\sigma(E) \approx \frac{A}{E}$, shows that the correction necessitated by the effect of the thickness of the scatterer is negligible ($\pm 2\%$), because the number of protons originating at the far side of the scatterer and lost due to absorption, is almost exactly compensated for by the excess of low energy protons originating at the near side of the scatterer.

The apparatus schematically drawn in Fig. 2 was used for angles Φ between 0 and 60° . At larger angles the thickness of the scatterer itself, the air, windows etc., make this type of apparatus inadequate. A new apparatus shown in Fig. 4 was built in an evacuated box and the scattering cross section for $35^\circ \leq \Phi \leq 71.6^\circ$ was measured with it. At angles larger than 71° all the difficulties introduced by matter in the path of the scattered beam and by the thickness of the scatterer became critical and the rapidly increasing difficulty of the experiment made it impractical to exceed the angle of 71.6° by our methods.

The apparatus shown in Fig. 4 relieved some of the difficulties mentioned above by providing for the evacuation of a space surrounding the scatterer and extending almost to the counter tube. Two benefits were obtained

from this: First, the direct replacement of a 33 cm air column (equivalent to about $50 \text{ mg cm}^{-2} \text{ Al}$) by an $11 \text{ mg cm}^{-2} \text{ Al}$ window; and second, the removal of the air from the beam path, which greatly decreased the background radiation. This fact in turn made it possible to use thinner scatterers ($25 \text{ mg cm}^{-2} \text{ CH}_2$), thus decreasing absorption within the scatterer.

The apparatus was made in the form of an aluminum alloy box, with 38 mg cm^{-2} rectangular stainless steel windows on opposite sides to allow passage of the beam. The arrangement provided for minimum production of protons by interaction of the beam with the box walls. On a third side was fixed an 11 mg/cm^2 aluminum window, through which the protons scattered by the target pass to reach the counting tubes. The carbon and polyethylene scatterers inside of the box were mounted on a rack which could be rotated from the outside to place either scatterer at a point within the beam and perpendicular to the axis of the counting tubes, or to place both out of the beam. A scale calibrated in degrees was attached to the rack, and a transparent window placed in the top of the box, so that the scatterers could be accurately placed for a run. The telescope of counting tubes was fixed permanently to the vacuum box, and adjustment to various scattering angles was made by rotating the entire apparatus on a pivot directly under the point occupied by the scatterer when in place for a run. The beam windows were made long enough to allow for this shifting of beam position with respect to the box. A removable cover was placed over the scatterers to provide access to them. Since there was no need to attain a very high degree of vacuum, no special precautions were necessary in making the box vacuum tight. It was evacuated by a small mechanical pump, which ran continuously during the course of an experiment.

In order to decrease the amount of material in the path of the scattered protons, all four tubes of the counting telescope were built into

one envelope, with resultant elimination of the windows between the individual units as indicated in Fig. 4a. With this arrangement, of course, it was impossible to place absorbers between the last two tubes of the counting telescope. Consequently they had to be put in front of the whole telescope and the effect of Rutherford scattering by the absorber was somewhat more serious than in the other apparatus. This effect will be discussed later.

The angular resolution of our apparatus was approximately given by the diameter d of the counter farthest from the scatterer divided by its distance D from the scatterer, i.e., $2/50$ radians. Since the target itself was extended, the resolution was perhaps 3° . If one wishes to take into account the resolution, it is easily shown that the finite resolving power introduces a negligible correction unless the curve has very sharp irregularities. Only near $\Phi = 0^\circ$ may this correction be of any significance; at that point we estimate that it will raise the true cross section above the observed one by at least 10^{-27} cm² for the 90 Mev case.

The value of the cross section at $\Phi = 0^\circ$ i.e., in the direction of the primary neutron beam was obtained with apparatus A using the same procedure as that used in measuring at $\Phi \neq 0^\circ$ but with some added precautions due to the fact that the primary neutron beam passed directly through the counters. The beam was stopped down to an aperture 1.25 cm in diameter at the concrete shield and the intensity was reduced to about 3 percent of the usual operating intensity. The loss in intensity was partially compensated by using a thicker scattering target. The results obtained at 0° are also given in Table II.

The amplifiers used were conventional ones with times of rise varying from 0.2 microsecond in some of the sets to 0.5 microsecond in others. The scaling circuits were also quite conventional and allowed the recording of individual counts in each of the counter tubes. The coincidence circuits

were of two types: in one model, delay lines were used to obtain the gate-open times; in the other model, multivibrators were used to form the gates. Gate times ran from about 0.5 to 12 microseconds and will be discussed later on.

The scattering target which was of different thickness in different runs, was always kept perpendicular to the direction of the scattered protons. The neutrons thus traversed an effective target thickness equal to $t/\cos \Phi$ where t is the true target thickness. At constant beam, the number of neutrons crossing the target per unit time multiplied by the effective target thickness was independent of Φ if the beam always filled the whole scatterer, because on varying Φ the change of effective area was exactly compensated by the change of effective thickness. On the other hand, if the beam was smaller than the target area the number of neutrons crossing the target per unit time multiplied by the effective target thickness was proportional to $t/\cos \Phi$. Both modes of operation were used.

In an actual run we measured the relative number of protons scattered by a polyethylene target per impinging neutron by registering the ratio R_1 between the coincidence counts obtained in the telescope and the counts of the monitor. Subsequently, the polyethylene target was replaced by a graphite target having the same stopping power for protons as the polyethylene target and the ratio R_2 similar to R_1 was measured. Finally without any target we obtained the ratio R_3 . The effect H due to the hydrogen is obtained by

$$\begin{aligned} (7) \quad H &= (R_1 - R_3) - 0.713 (R_2 - R_3) \\ &= R_1 - 0.713 R_2 - 0.287 R_3 \end{aligned}$$

Where the coefficient 0.713 is the ratio between the number of atoms per cm^2 of carbon in the polyethylene target and the graphite target

having the same stopping power for protons. $\frac{H}{t}$ is proportional to the cross section for n-p scattering. The statistical standard deviation of H, δH , is given by

$$(8) \left[(\delta R_1)^2 + (0.713 \delta R_2)^2 + (0.287 \delta R_3)^2 \right]^{\frac{1}{2}} = \delta H$$

where δR_1 is the standard deviation of R_1 etc.

We describe now the tests that we have performed on the apparatus. The first point is to ascertain that we count all the protons of energy larger than $66 \text{ Mev} \cos^2 \Phi$ coming from the target and nothing else. For this purpose we first studied the counter response versus voltage. With the telescope set at 10° , in order to be dealing with protons of practically maximum energy and hence minimum specific ionization, the coincidence counting rate versus the collection voltage of the counters was studied. Plateaus extending over about 300 volts were quite readily obtainable as shown in Fig. 5. When the counters were adjusted to detect protons the energy of which was about 100 Mev we found that the counters were also sensitive to the recoil electrons produced when a source of radium was brought near the counter. This was to be expected on the basis of the ionization produced by high energy protons and the ionization made by electrons. The sensitivity to these electrons provided a means of rough preliminary adjustment of the counters. Although the voltage plateau would indicate that all of the protons were being counted, more certainty can be obtained from the following experiment: With the counters in operation at a fixed angle, e. g. 10° , the triple coincidence counting ratio R_1 was obtained. Then the middle counter was disconnected (this procedure leaves the geometry unchanged) and a double coincidence count was obtained with the first and third counters in coincidence. If the number of protons recorded from the scatterer is the same as with the triple coincidence set-up we feel justified in

assuming that the efficiency is practically 100 percent, because if it were not, the use of only two counters would increase the number of coincidences obtained. This experiment was done also using 4 counters in coincidence and in any case only the suppression of the counter farthest from the target, which obviously changes the geometry, had any effect on R_1 . The reason for using triple coincidence rather than double coincidence is that a better ratio of R_1 to R_3 is obtained, and that accidental coincidences are practically zero.

Another test is to determine the accidental coincidences. This was done by again setting the telescope at 10° , and obtaining the triple coincidence ratio R_1 . Then the middle counter was removed physically from the telescope and placed just adjacent to its regular position. In this position the coincidence counts were reduced by a factor of about 1000, which makes them negligible. This is what one should expect if the apparatus were working properly. The latter test is also important because it is easy to overload the counters due to the fact that the neutrons are emitted by the cyclotron in short bursts. The last test described shows conclusively that this is not the case, because spurious coincidences which are unaffected if we put the counters out of line with the target, were not present. This point was further confirmed by showing that $\frac{H}{t}$ was independent of the target thickness t and of the beam intensity in the region of operation, as shown in Fig. 6.

Experiments on the counting of protons with various gate times of the coincidence circuits showed that approximately the same counting efficiency was obtained with gate widths from about 2 to 10 microseconds. Appropriate settings for the gate times amounted to 2 to 3 microseconds, as shown in Fig. 7.

At the neutron energies used in this experiment, the absorbers A, which fix the minimum energy a proton must have in order to be counted, are so thick (several grams/cm²) that some protons which would otherwise pass through are removed either by Rutherford scattering or nuclear absorption.

In the case of apparatus A, where the absorber was placed immediately in front of the last counter, Rutherford scattering was negligible, and only the nuclear absorption produced any effect.

In the case of apparatus C, which was used principally for large Φ , it was necessary to place the absorber in front of all three counters. In the experimental arrangement used, about one-half of the protons scattered by more than 3° would not be counted by the coincidence counter telescope. The fraction of protons lost due to this scattering is proportional to $N \sigma_\alpha$, where N is the number of atoms per cm² in the absorber, of atomic number Z , and σ_α is the cross section for Rutherford scattering of the absorber through an angle greater than α . σ_α is proportional to $Z^2 / \alpha^2 E_p^2$ and since at each angle Φ , N is varied approximately proportionately to E_p^2 , the fraction of protons lost is independent of Φ . To check this point, and to find out what fraction was lost, we counted the number of protons going through various absorbers with the same stopping power but with differing Z . For this purpose C, Al, Cu, and Pb were used. By plotting counting rate versus $N \frac{Z^2}{E_p^2}$, and extrapolating to $Z = 0$, we found that at $\Phi = 10^\circ, 45^\circ$ and 65° the fraction lost was about constant and equal to 4% for carbon, which was the absorber actually used with apparatus C. At the largest angle used, there was no carbon absorber in front of the counters, the principal part of the absorber being the gas in the counters themselves. Any Rutherford scattering which occurred would have taken place in the counters, and essentially no protons would

have been lost due to this effect. Therefore, a correction of -4% has been applied to the value of $\sigma(\Phi)$ at 71.6° in order to bring it in line with the rest of the data.

An estimate of nuclear scattering and absorption, originating from nuclear interaction, by the absorber A shows that it will not exceed about 4% in the worst conditions. Moreover the difference between the magnitude of these effects at various angles is about half this absolute value. For this reason this effect has been neglected.

An actual run started by a check of the gain of the amplifying systems effected by placing a radium source in a standard position with respect to the counter tubes and observing with an oscillograph the maximum height of the pulses produced by recoil electrons from the walls of the counters. This was done with a collection voltage on the counter tubes which was found to be on the plateau of the coincidence counting rate versus voltage curve, at the time of the previous run. The observed pulses were synchronized one on top of the other so that the pulse shape was shown. Pulses from the three proportional counter tubes were checked to make sure that the rise and decay times respectively were approximately equal in the three counters. These were rather qualitative checks but were capable of showing immediately any large changes in the characteristics of the counting system.

A standard size pulse was applied in turn to the inputs of each of the scaling circuits to check that the minimum pulse height to trip the discriminators had not changed.

The coincidence circuit gate length was checked on a calibrated sweep. After these checks the measurements started and we report in the following some typical examples. The data in Table I were taken with the following set-up:

Diameter of neutron beam exit hole was 2.22 cm.

Distance from exit hole to scatterer was approximately 350 cm.

Distance from scatterer to first counter was 85 cm.

Distance from scatterer to monitor was 140 cm.

Triple coincidence was used.

The scatterers measured 11 by 11 cm and were made of polyethylene and graphite.

The thickness of the scatterers and absorbers is indicated in the table.

The measurement for different $\bar{\phi}$ in a single run were made in such an order that the various values of $\bar{\phi}$ alternated in order to minimize possible trends in systematic errors, e.g., the following order was used in a run; $\bar{\phi} = 10^\circ, 45^\circ, 30^\circ, 20^\circ, 50, 15^\circ, 40^\circ, 25^\circ, 35^\circ, 5^\circ, 55^\circ$ (February 4, 1948). (See Table I)

To fit the data obtained in different runs we proceeded as follows: Runs no. 1, 2, 12 (see Table II) have 8 values of $\bar{\phi}$ in common. For these values the geometrical mean of the H values was calculated and a curve drawn. The other runs have one or more points in common with runs 1, 2, 12. These points were used to normalize the run in such a way that for the values of $\bar{\phi}$ common to the run in question and to the curve obtained from runs 1, 2, 12 the value of H would be the same, or, in case of more points in common, make a best fit. In doing this we added to the statistical error of the measurement of H a fitting error equal to $H \times \delta\rho$, where $\delta\rho$ is the error in the normalization factor ρ . This can be estimated from the variation of ρ for various values of $\bar{\phi}$ or from the statistical errors of the single measurements. The statistical error of the single measurements and $H \delta\rho$ add by the usual rule.

$$(9) \quad \left[(\delta H)^2 + (H \delta \rho)^2 \right]^{\frac{1}{2}}$$

Having thus obtained H/t as a function of ϕ we have at once on a relative scale the n-p scattering cross section as a function of ϕ . To show the results obtained we report in Table II the values of H obtained in all runs and treated as described above to bring them all to the same scale. The errors listed are the standard deviations calculated from statistics on the single measurements. No account has been taken of the effect of \sqrt{p} .

Total Cross Section Experiments

In order to place the measured cross sections on an absolute scale it is necessary to determine the total scattering cross section. This can be accomplished by an attenuation measurement of the neutron beam using good geometry. Actually in the experiments we measured

$$(10) \int N(E) D(E) dE$$

and

$$(11) \int N(E) D(E) e^{-\sigma_t(E) s} dE$$

where $N(E) dE$ is the number of neutrons between energies E and $E + dE$ impinging on the absorber, $D(E)$ is the probability that one of these neutrons is counted by the special detector used, $\sigma_t(E)$ is the total cross section of the attenuator nuclei, and s is the number of nuclei per cm^2 of the attenuator. If the neutrons employed were monochromatic ($N(E)$ a delta function) or if $D(E)$ were a delta function, the ratio of (11) to (10) would immediately give $\sigma_t(E)$. Unfortunately this is not the case and there is appreciable uncertainty in the interpretation of the attenuation measurements.

The experiments were performed using as attenuator a column of hydrocarbon (pentane, polyethylene, etc.) and also a column of graphite containing approximately the same amount of carbon as the hydrocarbon. The attenuation produced by each absorber under good geometry conditions was measured and from it the hydrogen cross section was deduced.

Typical geometrical conditions were:

Diameter of neutron beam, 1.9 cm.

Length of absorber, 58 cm, cross section, 5 x 5 cm.

Distance between closest end of absorber and detector,
50 cm.

Diameter of detector, 4.4 cm.

See Fig. 8

In Table III we report the main results thus far obtained.

We can estimate an effective average energy for the neutrons used and calculate also $E_{\text{eff}} \sigma_t(E_{\text{eff}})$; we may expect the last quantity to be nearly constant. This is roughly the case if we assume a primary neutron distribution similar to that predicted by Serber plus a low energy tail of an amplitude of about 20% of the maximum extending down to 20 Mev, reasonable functions $D(E)$, and $\sigma_t(E)$ inversely proportional to E_n . The E_{eff} of Table III have been calculated under these hypotheses.

In conclusion we can assume $\sigma_t = \frac{6.85}{E}$ (E in Mev, σ_t in 10^{-24} cm²) with about 10% incertitude. This value does not match too well with the approximate values of $\sigma_t = \frac{9.8}{E}$ reported by Sleator⁵ on the basis of measurements in the 20-24 Mev energy interval; there is however no reason why $E \sigma_t(E)$ should be constant over such large energy intervals.

Lower Energies Experiments

By reducing the radius at which the beryllium probe is hit by the deuteron beam it is possible to obtain, by the stripping process, neutrons of lower energy. Unfortunately the width of the energy distribution in the forward direction does not decrease as much as the

(5) W. Sleator Jr., Phys. Rev. 72, 207 (1947). See there also for further bibliography.

most probable energy, so that poorer energy resolution is obtained. This is borne out in Fig. 9 where the theoretical neutron energy distribution is plotted for $E_D = 98$ Mev and a target of 1 cm beryllium. Be this as it may, we have repeated the experiments with the same apparatus at a lower energy. The results are reported in Table IV and in Fig. 10.

Conclusion

In Tables III and IV we give $\sigma(\theta)$. In order to find the corresponding $\sigma(\phi)$ we have to multiply $\sigma(\theta)$ by $\frac{d \cos \theta}{d \cos \phi}$ and put this value of σ at the angle ϕ corresponding to the θ considered. Table III gives also θ and $\frac{d \cos \theta}{d \cos \phi}$ as a function of ϕ for 88 Mev. For 40 we have used the non relativistic formulae

$$\theta = \pi - 2\phi; \quad \frac{d \cos \theta}{d \cos \phi} = -\frac{1}{4 \cos \phi}$$

The normalization of the curves is done as explained before by having $\int \sigma(\theta) d\omega = \sigma_0 = \begin{cases} 0.076 \times 10^{-24} \text{ cm}^2 & \text{for 90 Mev} \\ 0.170 \times 10^{-24} \text{ cm}^2 & \text{for 40 Mev.} \end{cases}$

Since, however, $\sigma(\theta)$ is known only in a limited range, we have arbitrarily extrapolated $\sigma(\theta)$ in the unknown part. The contribution of this part of the curve to the total cross section is 15% of the total for the 90 Mev curve and we have assumed the 40 Mev curve to be symmetrical around 90° . The extrapolated part of the curve is consistent with data obtained in the cloud chamber investigation of n-p scattering by W. Powell, Bruckner, etc. ⁶

The values of $\sigma(\theta)$ obtained in all runs are reproduced in Fig. 10. The stars are, in our judgment, the best average of the measurements we have at the present date; in drawing them we have weighted the

⁶ We thank Dr. Powell and his associates for communicating their data to us.

experimental runs; For clarity it has been impossible to give the statistical errors which can be easily read out of Table II and IV. The spread of the points gives a fair overall impression of the accuracy of the measurements.

Messrs. R. Christian and E. Hart of the theoretical group of the Radiation Laboratory have calculated the n-p cross sections under various assumptions. ⁷ One of the simplest used, which agrees fairly well with the experimental results, is the following:

The n-p scattering depends on a potential

$$V(r) = g^2 \frac{e^{-Kz}}{r} \left(\frac{1+P}{2} \right)$$

where the constant g^2 has two values: One for scattering with parallel and the other with antiparallel spins. These values $g^2/\hbar c = 0.405$ and 0.280 respectively, are chosen so as to fit the scattering cross section for epithermal neutrons and the binding energy of the deuteron. The constant $1/K$ is $1.2 \cdot 10^{-13}$ cm. If we interpret it as the "Compton wave length" of a particle, this particle has the mass of 326 electronic masses, not far from the π meson mass; moreover it is also the value used by Breit in interpreting p-p scattering and fits the coherent scattering observed in neutron scattering by ortho and para hydrogen. P is an exchange operator.

The above potential gives an angular distribution as shown in Fig. 11 and a total cross section at 90 Mev of 0.090×10^{-24} cm². The agreement is fairly good and the simplicity of the hypotheses make this result attractive.

7. A review of the subject is given in Rosenfeld - Nuclear Forces - Amsterdam (1948)

Other calculations on n-p high energy scattering:

M. Connac, H. A. Bethe, Phys. Rev. 73, 191 (1948)

J. Ashkin and Ta-Yon Wu, Phys. Rev. 73, 973 (1948)

On the other hand tensor forces must be present to account for the electric quadrupole moment of the deuteron and they are introduced by changing the potential to

$$V(r) = g^2 \left[\frac{e^{-Kr}}{r} + \gamma \left(\frac{3(\mathbf{S}_1 \cdot \mathbf{r})(\mathbf{S}_2 \cdot \mathbf{r}) - \mathbf{S}_1 \cdot \mathbf{S}_2}{r^3} - K^2 r \right) \right] \left(\frac{1+P}{2} \right)$$

where $\mathbf{S}_1, \mathbf{S}_2$ are the spin operators, γ is a constant fixing the amount of tensor force and K^2 is the range of the tensor forces. Choosing $\gamma = 0.16$ and K^2 about $1/3 K$ it is possible to account also for the electric quadrupole moment of the deuteron without completely destroying the agreement with the other experimental data. However the total cross section becomes 0.104×10^{-24} , a value which seems to be in disagreement with the experimental results. But it must be remembered that in all this, relativistic effects have been neglected and they may be of the order of 20%.

More detailed theoretical studies to bring out the separate influence of the single factors involved in the n-p cross section are in progress.

The authors wish to thank Professor E. O. Lawrence for his interest in this work, the cyclotron operating crew for their valuable assistance in making the runs.

This paper is based on work performed under the auspices of the Atomic Energy Commission.

Notes: R* is the reading of a "radiation" meter near the yoke of the cyclotron magnet.

It is just a check on the operation of the cyclotron and not suitable as a beam monitor.

The first three readings were taken to check the counter voltage vs. coincidence/monitor plateau.

The results of the above two runs give: $H_{100} = 0.420 \pm 0.03$

$H_{450} = 0.139 \pm 0.01_4$

$\sigma(\Phi)$ in 10^{-27} cm² per steradian

All runs have been fitted to the average of runs 2, 3 and 5
