Fatty acid synthase

ABSTRACT

Tetrabromobisphenol A (TBBPA) and tetrachlorobisphenol A (TCBPA) – both halogenated bisphenol (BPA) analogues – are suspected ligands of peroxisome proliferator-activated receptor gamma (PPAR γ). While previous studies have shown that TBBPA and TCBPA activate PPAR γ within cell-free assays, the downstream effects of TBBPA- and TCBPA-induced PPAR γ activation on cellular transcription and physiology have not been thoroughly investigated. Therefore, the objective of this study was to determine whether exposure to TBBPA or TCBPA (either alone or in combination) alters levels of neutral lipids and fatty acid synthase (FASN) – an enzyme that catalyzes synthesis of long-chain saturated fatty acids – within intact cells in a PPAR γ -dependent manner. For this study, we relied on human hepatocellular carcinoma (HepG2) cells as a model since these liver cells express basal levels of PPAR γ and have been used to study lipoprotein metabolism and regulation of drug metabolizing enzymes. Although exposure to TBBPA and TCBPA alone did not affect cell viability nor neutral lipid and FASN levels in a concentration-dependent manner, exposure to binary mixtures of TBBPA and TCBPA resulted in a concentration-dependent decrease in cell viability in the absence of concentration-dependent effects on neutral lipid and FASN levels. Interestingly, exposure to TBBPA or TCBPA alone or as a mixture enhanced the effects of a reference PPAR γ agonist (ciglitazone) and antagonist (GW 9662) on cell viability (but not neutral lipid levels), suggesting that these two halogenated BPA analogues may interact synergistically with ciglitazone and GW 9662 to induce cytotoxicity. However, overexpression of PPAR γ did not mitigate nor enhance the effects of TBBPA – a potent PPAR γ ligand predicted by ToxCast's cell-free competitive binding assays – on cell viability, neutral lipid levels, nor the cellular transcriptome. Overall, our findings suggest that halogenated BPA analogues such as TCBPA and TBBPA induce toxicity within HepG2 cells in a PPAR γ -independent manner.

1. Introduction

Although bisphenol A (BPA) is mainly used as a plasticizer in polycarbonate and epoxy resins, tetrabromobisphenol A (TBBPA) and tetrachlorobisphenol A (TCBPA) are two halogenated BPA analogs primarily used as flame retardants in electronic devices. As a result, these two halogenated BPA analogues have the potential to migrate into indoor dust (Leisewitz et al., 2001) and expose humans within the built environment, where levels of TBBPA in house dust have been previously found to range from 1 to 3600 ng/g (Wang et al., 2015). TBBPA-sulfate and TBBPA-glucuronide (Schauer et al., 2006) – the primary metabolites of TBBPA – have been found in both serum and urine samples in humans around the world (Nagayama et al., 2000; Thomsen et al., 2001; Jakobsson et al., 2002; Dirtu et al., 2008; Shi et al., 2013; Ho et al., 2017). While BPA is a weak ligand for the estrogen receptor (Gould

et al., 1998; Liu et al., 2018), neither TBBPA nor TCBPA activate ER to the same magnitude as BPA (Lee et al., 2012; Cao et al., 2017). However, TBBPA and TCBPA have both been shown to activate another member of the nuclear receptor family – peroxisome proliferator activated receptor gamma (PPAR γ) (Riu et al., 2011; Akiyama et al., 2015; Chappell et al., 2018).

PPAR γ is a transcription factor (Issemann and Green, 1990; Tontonoz et al., 1994; Martin et al., 1998) that can be activated by both endogenous ligands such as prostaglandin PGJ2 and eicosapentaenoic acid (Forman et al., 1995; Kliewer et al., 1995; Nagy et al., 1998) or exogenous ligands such as pharmaceutical compounds (e.g., thiazolidinediones) (Nolan et al., 1994; Lehmann et al., 1995). Upon activation by ligand binding, PPAR γ heterodimerizes with retinoid X receptor (RXR) and then binds to PPAR response elements (PPREs), resulting in transcription of genes involved in lipid/glucose metabolism and

Fig. 1. Mean (\pm standard deviation) fluorescence (cell viability) (A), neutral lipid staining normalized to DAPI staining (B), and fatty acid synthase protein levels normalized to DAPI staining (C) of HepG2 cells exposed to vehicle (0.1% DMSO), 10–100 μ M TBBPA, or 10–100 μ M TCBPA for 24 h. Asterisk (*) denotes a significant difference ($p < 0.05$) relative to vehicle-exposed cells.

adipogenesis (Tontonoz et al., 1994; Martin et al., 1998; Chawla et al., 2001). While several thiazolidinediones have been developed to treat Type II diabetes and obesity within human populations, many of these compounds have severe side effects and have been discontinued from use (Nesto et al., 2003; Nissen and Wolski, 2007; Lewis et al., 2011). As several environmental chemicals have been shown to bind and activate PPAR γ , there is concern about human exposure to xenobiotic PPAR γ ligands and potential downstream effects (Hurst and Waxman, 2003; Riu et al., 2011; Wang et al., 2016).

Although TBBPA and TCBPA have nearly identical chemical structures (TBBPA is brominated whereas TCBPA is chlorinated), TBBPA binds to the ligand binding domain of human PPAR γ with greater affinity than TCBPA (Riu et al., 2011). For example, TBBPA induces neurotoxic effects within mouse primary neuronal cells that is partially PPAR γ -dependent (Wojtowicz et al., 2014). While previous studies have investigated the ability of TBBPA and TCBPA to bind to PPAR γ within reporter and ligand binding assays, to our knowledge no prior studies have linked TBBPA or TCBPA exposure to PPAR γ activation and subsequent downstream effects within a human liver cell model. Therefore, the overall objective of this study was to determine whether exposure of human liver cells to non-cytotoxic concentrations of TBBPA or TCBPA results in effects on transcription and other endpoints that are consistent with the known mechanism of action for PPAR γ activation, such as neutral lipid staining (Wakabayashi et al., 2009). We also utilized

immunohistochemical staining of fatty acid synthase (FASN) protein *in situ*, as FASN catalyzes synthesis of long-chain saturated fatty acids and is correlated with PPAR γ expression in adipocytes (Zhao et al., 2011).

For this study, we relied on human hepatocellular carcinoma (HepG2) cells as a model since these liver cells express basal levels of PPAR γ and have previously been used to study lipoprotein metabolism (Meex et al., 2011) and regulation of drug metabolizing enzymes (Wilkening et al., 2003). We also utilized a human PPAR γ expression plasmid to overexpress PPAR γ and determine whether the effects of halogenated BPA analogues were mitigated or enhanced in the presence of increased PPAR γ levels. Our overall hypothesis was that TBBPA- and TCBPA-induced effects on cell viability, lipid homeostasis, and FASN protein levels were associated with PPAR γ -mediated alterations to the cellular transcriptome. Therefore, our study is timely and significant to the field of environmental toxicology, as it 1) helps us further understand the mechanisms of action of two widely used flame retardants (TBBPA and TCBPA) within human cells and 2) challenges a long-standing assumption that PPAR γ activation by environmental chemicals leads to downstream effects on cellular transcription and physiology.

2. Materials and methods

2.1. Chemicals

TBBPA (>97% purity) and TCBPA (>98% purity) were purchased from Millipore Sigma (St. Louis, MO, USA). Ciglitazone (>99.4% purity) was purchased from Tocris Biosciences (Bristol, UK) and GW 9662 (>98% purity) was purchased from Enzo Life Sciences (Farmingdale, NY, USA). For all chemicals, stock solutions were prepared in high-performance liquid chromatography (HPLC)-grade dimethyl sulfoxide (DMSO) and stored in 2-mL amber glass vials with polytetrafluoroethylene-lined caps. Working solutions were prepared by spiking stock solutions into sterile cell culture media immediately prior to each experiment, resulting in 0.1% DMSO (single chemical exposures) or 0.2% DMSO (binary mixture exposures) within all treatment groups. For binary mixture exposures, the final concentration of DMSO used was 0.2% since an equal volume of two different stock solutions were added to working solutions, resulting in twice the volume of DMSO relative to single chemical exposures. As shown in Figs. 1 and 2, exposure to 0.2% DMSO had no effect on cell viability relative to exposure to 0.1% DMSO.

2.2. PPAR γ ligand exposures and cell viability assays

HepG2 cells were purchased from American Type Culture Collection (ATCC) (Manassas, VA, USA) and grown within T75 cell culture flasks (MilliporeSigma, St. Louis, MO, USA) containing 15 mL of Eagle's Minimum Essential Medium supplemented with 10% fetal bovine serum (FBS) (ATCC, Manassas, VA, USA) at 37 °C and 5% CO $_2$. Media was changed within each flask every other day and cells were split every four days using 0.25% Trypsin/0.53 mM EDTA (ATCC, Manassas, VA, USA) after reaching ~70–90% confluency.

HepG2 cells were plated at a concentration of 0.5×10^4 cells per well in a clear, polystyrene 96-well plate (Thermo Fisher Scientific, Waltham, MA, USA) and allowed to adhere overnight. Media was removed and replaced with 200 μ L media spiked with either vehicle (0.1% DMSO for single chemical exposures), TBBPA (10–100 μ M), or TCBPA (10–100 μ M) and incubated at 37 °C and 5% CO $_2$ for 24 h (4 replicate wells per treatment). To assess whether TBBPA and TCBPA resulted in additive or synergistic effects on cell viability and FASN levels, cells were also exposed to either vehicle (0.2% DMSO for binary mixture exposures), 60 or 80 μ M TBBPA alone, 60 or 80 μ M TCBPA alone, or binary mixtures of 30–100 μ M TBBPA and 30–100 μ M TCBPA and then incubated at 37 °C and 5% CO $_2$ for 24 h; rather than using a combination index design, we simply tested binary mixtures that reflected combinations of treatments that were tested for TBBPA and TCBPA alone. At the end of the exposure

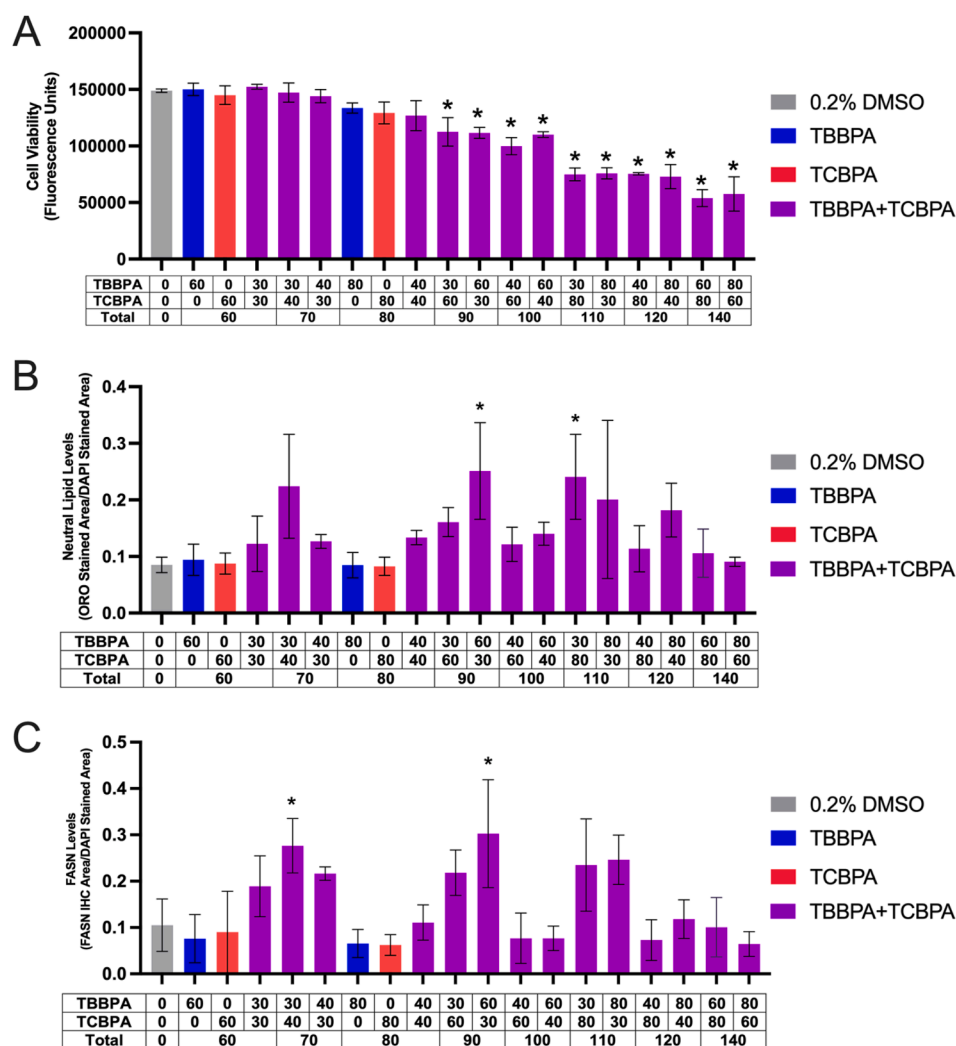

Fig. 2. Mean (\pm standard deviation) fluorescence (cell viability) (A), Oil Red O neutral lipid-stained area divided by DAPI stained area (B), or FASN immunofluorescence area divided by DAPI stained area of HepG2 cells exposed to vehicle (0.2% DMSO) or TBBPA and/or TCBPA for 24 h. Asterisk (*) denotes a significant difference ($p < 0.05$) in cell viability, neutral lipid staining, or FASN immunofluorescence relative to vehicle-exposed cells.

duration, treatment solution was removed and replaced with 100 μ L of clean cell culture media and 20 μ L of CellTiter-Blue (Promega, Madison, WI, USA), and then allowed to incubate for 2 h at 37 $^{\circ}$ C and 5% CO₂. Fluorescence was then quantified using a GloMax Multi+ Detection System (Promega, Madison, WI, USA).

2.3. Oil Red O staining

To determine whether exposure to TBBPA or TCBPA affected neutral lipid abundance, HepG2 cells were exposed to vehicle (0.1% DMSO), TBBPA, or TCBPA as described above and then stained for neutral lipids using Oil Red O (ORO) (MilliporeSigma, St. Louis, MO, USA) as previously described (Cheng et al., 2021). Briefly, cells were fixed using 4% paraformaldehyde for 20 min at room temperature. Cells were then rinsed with 60% isopropanol and stained with ORO working solution (1.8 mg ORO per 1 mL 60% isopropanol) for 10 min at room temperature. Cells were then rinsed four times with molecular biology-grade water for 5 min at room temperature. After the final wash, cells were counterstained with a 1:4 solution of DAPI Fluoromount-G (SouthernBiotech, Birmingham, AL, USA) for 5 min at room temperature. Cells were washed three more times with molecular biology-grade water and then imaged (at 10 \times magnification) and analyzed using our ImageXpress Micro XLS Widefield High-Content Screening System (Molecular Devices, Sunnyvale, CA, USA).

2.4. FASN immunohistochemistry

To quantify FASN protein levels *in situ*, cells were exposed to either vehicle (0.1% DMSO), TBBPA, or TCBPA as described above for 24 h. At exposure termination, cells were fixed with 4% formaldehyde at room temperature for 10 min. Cells were then rinsed three times with 1 \times phosphate-buffered saline (PBS) and incubated in blocking buffer [1 \times PBS + 0.1% Tween-20 (PBST), 2 mg/mL bovine serum albumin, and 2% sheep serum] at room temperature for 1 h by shaking gently. Blocking buffer was then replaced with a 1:500 dilution of a human FASN-specific antibody (G-11, sc-48357; Santa Cruz Biotechnology, Dallas, TX, USA) in blocking buffer and allowed to incubate overnight at 4 $^{\circ}$ C. Cells were then incubated with a 1:500 dilution of Alexa Fluor 488-conjugated goat anti-mouse IgG₁ antibody (Thermo Fisher Scientific, Waltman, MA, USA) overnight at 4 $^{\circ}$ C. Cells were then counterstained with a 1:4 solution of DAPI Fluoromount-G (SouthernBiotech, Birmingham, AL, USA) for 5 min, rinsed with 1 \times PBS three times, and then imaged (at 10 \times magnification) and analyzed using our ImageXpress Micro XLS Widefield High-Content Screening System (Molecular Devices, Sunnyvale, CA, USA).

2.5. Pretreatment with reference PPAR γ ligands

To determine whether TBBPA- or TCBPA-induced effects were

Fig. 3. Mean (\pm standard deviation) fluorescence (cell viability) (A, B) or Oil Red O neutral lipid staining normalized to DAPI stained area (C, D) of HepG2 cells after 24 h pretreatment with ciglitazone or GW 9662 followed by exposure to vehicle (0.2% DMSO), 30 μ M TBBPA, 60 μ M TCBPA, or 30 μ M TBBPA + 60 μ M TCBPA for 24 h. Asterisk (*) denotes a significant PPAR γ ligand-driven difference ($p < 0.05$) in cell viability or neutral lipid staining relative to vehicle (0.1% DMSO)-pretreated cells. Cross (†) denotes a significant TBBPA- and/or TCBPA-driven difference ($p < 0.05$) in cell viability or neutral lipid staining relative to vehicle (0.2% DMSO)-exposed cells pretreated with the same PPAR γ ligand concentration.

mitigated or enhanced by a reference PPAR γ agonist (ciglitazone) or antagonist (GW 9662), HepG2 cells were plated in 96-well plates as described above. As shown in our prior study (Cheng et al., 2021), exposure to GW 9662 resulted in decreased PPAR γ protein levels after 24 h; therefore, we relied on a 24-h pretreatment with either ciglitazone or GW 9662. Following pretreatment with either vehicle (0.1% DMSO), 30–100 μ M ciglitazone, or 10–100 μ M GW 9662, cells were then exposed to either vehicle (0.2% DMSO), 30 μ M TBBPA, 60 μ M TCBPA, or 30 μ M TBBPA + 60 μ M TCBPA for 24 h and collected for cell viability, neutral lipid staining, and FASN protein IHC as described above.

2.6. ToxCast data mining

ToxCast assay endpoint data for TBBPA and TCBPA were downloaded from the U.S. Environmental Protection Agency's website (<https://www.epa.gov/nct/toxcast/data/html>). Half-maximal activity concentrations (AC₅₀) for TBBPA and TCBPA were used to calculate assay hit rates and develop overall summary statistics. Since the number of assay endpoints for TBBPA and TCBPA were not identical, the percent assay hit rate for each chemical was defined as the number of assay endpoints with an AC₅₀ of <1000 μ M – the maximal concentration tested and the basis for an “inactive” activity call – relative to the total number of assay endpoints per chemical. Assays were then sorted by “Intended_Target_Family” for “Nuclear Receptor” to determine the hit rate for nuclear receptor assays. Finally, “Gene_Name” was sorted by “PPAR γ ” to determine the hit rate for PPAR γ -specific assay endpoints.

2.7. Overexpression of PPAR γ within HepG2 cells

To determine whether overexpression of PPAR γ modified the effects of TBBPA (a potent PPAR γ ligand based on ToxCast data), HepG2 cells were plated and transfected with either a negative control (NC) cloning plasmid (pCMV6-XL4, OriGene, Rockville, MD, USA) or an expression plasmid containing human untagged PPAR γ clone (SC124177, OriGene,

Rockville, MD, USA) following the manufacturer's protocol. Briefly, 100 ng/well of either NC plasmid or PPAR γ expression plasmid were diluted in Opti-MEM reduced serum media (Thermo Fisher Scientific, Waltham, MA, USA). TurboFectin 8.0 (OriGene, Rockville, MD USA) (0.3 μ L/well) was added to plasmids diluted in Opti-MEM and incubated for 15 min at room temperature to form complexes. Following incubation, plasmid: TurboFectin 8.0 complexes were added to each well and gently shaken to distribute evenly. Transfected HepG2 cells were then allowed to incubate for 48 h followed by exposure to either vehicle (0.1% DMSO) or 30 μ M TBBPA for 24 h as described above. PPAR γ protein levels *in situ* across transfections and treatments were then quantified using a 1:150 dilution of a human PPAR γ -specific antibody (E-8, sc-7273; Santa Cruz Biotechnology, Dallas, TX, USA) following previously described protocols (Cheng et al., 2021). Transfected cells were also collected for cell viability, ORO neutral lipid staining, and FASN IHC as described above.

2.8. mRNA-sequencing

HepG2 cells were plated, transfected with either NC plasmid or PPAR γ expression plasmid, and exposed to either vehicle (0.1% DMSO) or 30 μ M TBBPA (3 wells pooled per replicate; 3 replicates per treatment) as described above. After 24 h, total RNA from each replicate was isolated using a Promega SV Total RNA Isolation System (Promega, Madison, WI, USA) following the manufacturer's protocol. RNA quantity and quality were confirmed using a Qubit 4.0 Fluorometer and Bioanalyzer 2100 system, respectively. Based on sample-specific Bioanalyzer traces, the RNA Integrity Number (RIN) was > 8.5 for all RNA samples used for library preparations.

Library preps were performed using a QuantSeq 3' mRNA-Seq Library Prep Kit FWD for Illumina (Lexogen, Vienna, Austria) and indexed by treatment replicate per manufacturer's instructions. Library quantity and quality were confirmed using a Qubit 4.0 Fluorometer and 2100 BioAnalyzer system, respectively. Raw Illumina (fastq.gz) sequencing files (12 total) are available via NCBI's BioProject database under

BioProject ID PRJNA752134, and a summary of sequencing run metrics are provided in Table S1. All 12 raw and indexed Illumina (fastq.gz) sequencing files were downloaded from Illumina's BaseSpace and uploaded to Bluebee's genomics analysis platform (<https://www.bluebee.com>) to align reads against the human genome (GRCh38/hg38). After combining treatment replicate files, a DESeq2 application within Bluebee (Lexogen Quantseq DE1.4) was used to identify significant treatment-related effects on transcript abundance (relative to vehicle) based on a false discovery rate (FDR) p -adjusted value ≤ 0.05 . To determine whether differentially expressed genes contained PPREs, we searched for PPRE consensus half-site sequences (AGGTCA) (Chawla et al., 2001) up to 5000 bases upstream of the transcription start site (TSS) using the sequence text view tool within NCBI (<https://www.ncbi.nlm.nih.gov>).

2.9. Statistical analyses

For cell viability, ORO staining, and immunohistochemistry data, a general linear model (GLM) analysis of variance (ANOVA) ($\alpha = 0.05$) was performed using SPSS Statistics 27 (IBM, Armonk, NY, USA), as data did not meet the equal variance assumption for non-GLM ANOVAs. Treatment groups were compared with vehicle controls using pair-wise Tukey based multiple comparisons of least square means to identify significant treatment-specific differences.

3. Results

3.1. Exposure to TBBPA and TCBPA alone or as binary mixtures decreases cell viability in the absence of effects on neutral lipid and FASN levels

Relative to cells exposed to vehicle (0.1% DMSO) for 24 h, cells exposed to 100 μM TBBPA for 24 h resulted in a significant decrease in cell viability (Fig. 1A), whereas exposure to concentrations of TBBPA and TCBPA between 40 and 100 μM resulted in a slight (albeit non-significant) increase in neutral lipid staining (Fig. 1B) and decrease in FASN protein levels (Fig. 1C). Following exposure to binary mixtures of TBBPA and TCBPA, cell viability decreased in a concentration-dependent manner (based on the total sum concentration of TBBPA and TCBPA), with significant decreases in cell viability occurring at 90 μM and higher (Fig. 2A). However, effects on cell viability occurred in the absence of consistent, concentration-dependent effects on neutral lipid (Fig. 2B) and FASN levels (Fig. 2C). Since neutral lipid staining has previously been used as a readout for PPAR γ activation (Wakabayashi et al., 2009), ORO was used in subsequent experiments. However, since FASN is not a downstream PPAR γ -activated protein, FASN was not used as an endpoint for subsequent experiments.

3.2. Exposure to TBBPA or TCBPA alone or as a mixture enhances the effects of reference PPAR γ ligands on cell viability

Pretreatment with ciglitazone alone at 80 μM or higher resulted in a significant decrease in cell viability within all treatment groups (Fig. 3A). Interestingly, pretreatment with increasing ciglitazone concentrations followed by exposure to 60 μM TCBPA or 30 μM TBBPA + 60 μM TCBPA resulted in a concentration-dependent decrease in cell viability (Fig. 3A), whereas this concentration-dependent effect was not observed following pretreatment with ciglitazone and exposure to 0.2% DMSO or 30 μM TBBPA alone. Following pretreatment with 100 μM ciglitazone, exposure to 60 μM TCBPA or 30 μM TBBPA + 60 μM TCBPA resulted in a significant decrease in cell viability relative to vehicle (0.2% DMSO) and 100 μM ciglitazone alone even though exposure to 60 μM TCBPA or 30 μM TBBPA + 60 μM TCBPA alone (i.e., in the absence of ciglitazone pretreatment) did not affect cell viability relative to vehicle-treated cells (Fig. 3A).

Exposure to 30 μM TBBPA or 60 μM TCBPA resulted in a significant

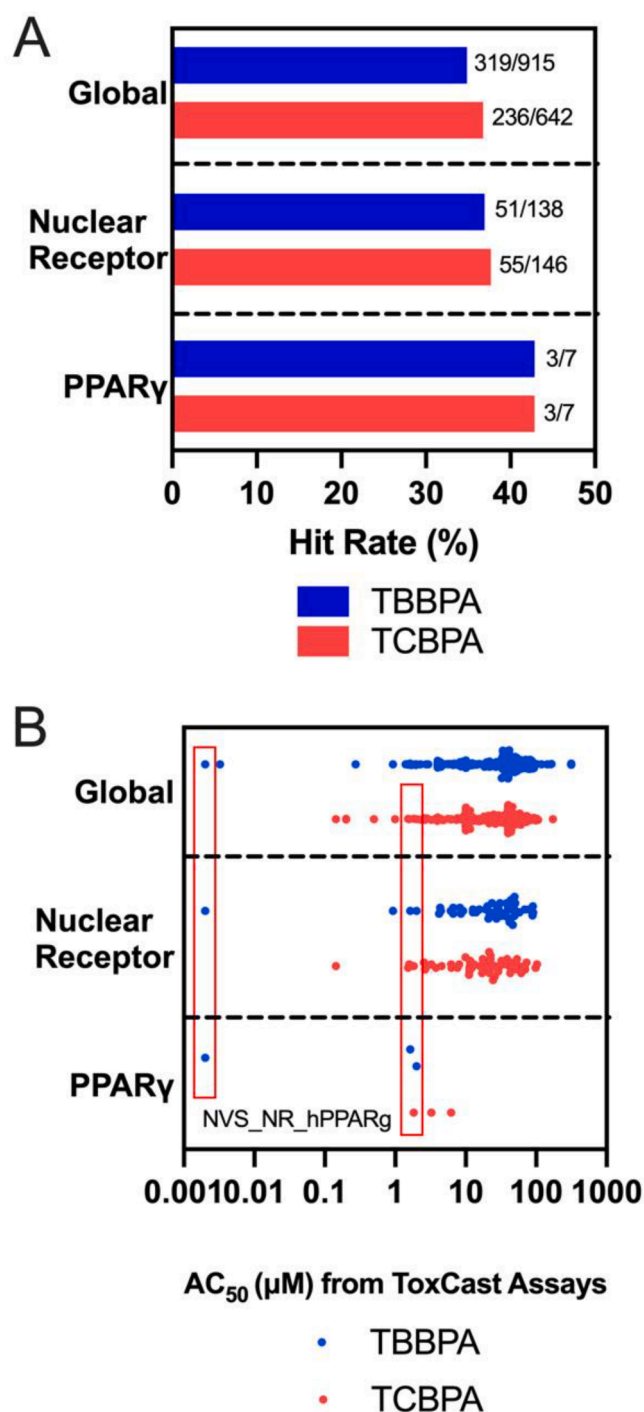

Fig. 4. Hit rate (A) and summary statistics (B) based on AC₅₀ values for TBBPA and TCBPA screened within ToxCast. AC₅₀ values based on a cell-free, human-specific PPAR γ ligand binding assay (NVS_NR_hPPAR γ) are boxed in red for both TBBPA and TCBPA.

decrease in cell viability relative to vehicle (0.2% DMSO) and GW 9662 alone even though GW 9662 alone did not affect cell viability at all concentrations tested (Fig. 3B). Similar to ciglitazone, pretreatment with increasing GW 9662 concentrations followed by exposure to 30 μM TBBPA + 60 μM TCBPA resulted in a concentration-dependent decrease in cell viability (Fig. 3B), whereas this concentration-dependent effect was not as significant following pretreatment with GW 9662 and exposure to 0.2% DMSO, 30 μM TBBPA, or 60 μM TCBPA alone. However, pretreatment with ciglitazone or GW 9662 did not consistently

Fig. 5. Mean (\pm standard deviation) PPAR γ immunofluorescence area divided by DAPI stained area (A), cell viability (fluorescence) (B), and Oil Red O neutral lipid staining divided by DAPI stained area (C) of HepG2 cells transfected with either no TurboFectin 8.0 or plasmid, TurboFectin 8.0 only, negative control plasmid, or PPAR γ expression plasmid and then exposed to either vehicle (0.1% DMSO), 30, 60, or 100 μ M TBBPA for 24 h. Asterisk (*) denotes a significant difference ($p < 0.05$) in cell viability or neutral lipid staining relative to no TurboFectin or plasmid-transfected cells. Cross (†) denotes a significant difference ($p < 0.05$) in cell viability or neutral lipid staining relative to vehicle-exposed cells.

enhance nor mitigate the effects on neutral lipid levels after TBBPA or TCBP exposure (Fig. 3C and 3D).

3.3. Overexpression of PPAR γ does not mitigate nor enhance the effects of TBBPA on cell viability, neutral lipid levels, nor the cellular transcriptome

When comparing available ToxCast assays for TBBPA and TCBP, both compounds had similar hit rates (active assay endpoint divided by total available assays) within the global, nuclear receptor, and PPAR γ data sets (Fig. 4A). When comparing the range of AC₅₀ values across active assays, TBBPA and TCBP also had very similar distributions (Fig. 4B). Of all ToxCast assays, TBBPA was the most potent (AC₅₀ = 0.002 μ M) within a cell-free, human-specific PPAR γ ligand binding assay (NV_S_NR_hPPAR γ), whereas the AC₅₀ for TCBP was 1.83 μ M based on the same assay. Therefore, as a ToxCast-based human-specific PPAR γ ligand binding assay predicted TBBPA to be \sim 900 \times more potent relative to TCBP, we focused on the potential effects of PPAR γ overexpression on TBBPA-induced toxicity.

A human PPAR γ -specific antibody was used to determine whether cells transfected with a PPAR γ expression plasmid increased PPAR γ

protein *in situ* within HepG2 cells. Relative to cells transfected to NC plasmid, PPAR γ levels were approximately doubled within PPAR γ -transfected cells exposed to either vehicle (0.1% DMSO) or 30 μ M TBBPA (Fig. 5A). While transfection with Turbofectin 8.0 alone decreased cell viability, the viability of cells transfected with either NC or PPAR γ expression plasmid was not affected across all treatment groups. As expected, exposure to 100 μ M TBBPA resulted in significant decrease in cell viability across all transfection groups (Fig. 5B). Interestingly, within the vehicle (0.1% DMSO) or 100 μ M TBBPA treatment groups, cells transfected with PPAR γ expression plasmid slightly increased neutral lipid levels relative to non-transfected cells; however, this effect was not observed following exposure to 30 μ M nor 60 μ M TBBPA (Fig. 5C).

Relative to cells transfected with NC plasmid, exposure of cells transfected with PPAR γ expression plasmid to vehicle (0.1% DMSO) or 30 μ M TBBPA resulted in significant effects on the abundance of four and two transcripts, respectively. Interestingly, growth hormone 1 (GH1) and PPAR γ were significantly decreased and increased, respectively, in both groups (Fig. 6A and B; Tables S2 and S3). Relative to vehicle-treated cells, exposure of cells transfected with NC plasmid to 30 μ M

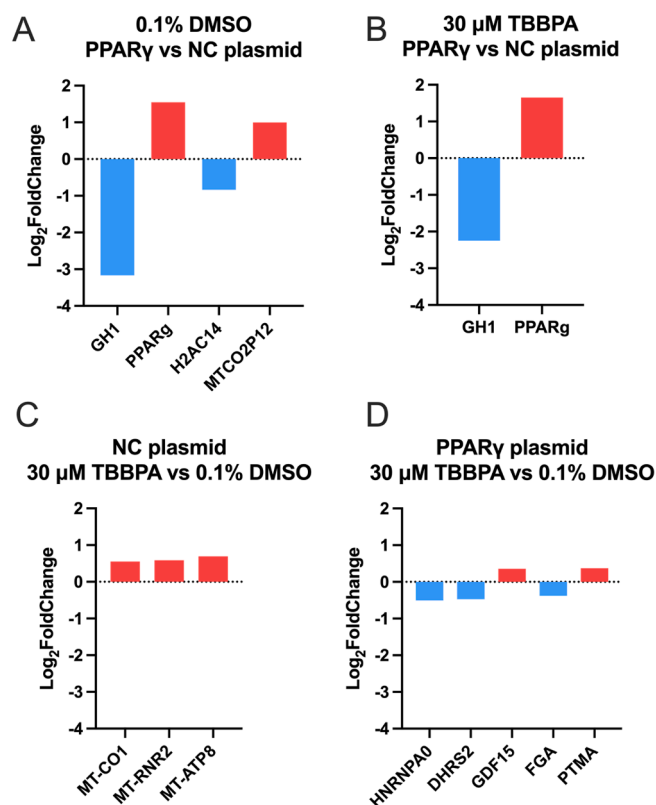

Fig. 6. Significantly affected transcripts for cells transfected with negative control (NC) plasmid transfected cells or PPAR γ plasmid transfected cells and then exposed to vehicle (0.1% DMSO) or 30 μ M TBBPA. Panels A and B are based on within-treatment group comparisons relative to NC plasmid, whereas Panels C and D are based on within-transfection group comparisons relative to vehicle-exposed cells.

TBBPA – a concentration that did not affect cell viability – resulted in a significant increase in the abundance of three transcripts (MT-CO1, MT-RNR2, and MT-ATP8), all of which were mitochondrially encoded genes (Fig. 6C; Table S4). Relative to vehicle-treated cells, exposure of cells transfected with PPAR γ expression plasmid to 30 μ M TBBPA resulted in significant effects on the abundance of five transcripts – HNRNPA0, DHRS2, GDF15, FGA, and PTMA (Fig. 6D; Table S5). Of the transcripts that were significantly affected across all four comparisons, there were 1–4 PPRE consensus half-site sequences within 5000 bases upstream of the respective TSS within corresponding genes, whereas mitochondrially encoded genes did not have any PPRE consensus half-site sequences within 5000 bases upstream of the respective TSS (Table 1).

4. Discussion

Within this study, we found that TBBPA and TCBPA (either alone or as binary mixtures) induce cytotoxicity within HepG2 cells at high μ M (ppm) concentrations that are well above environmentally relevant human exposures (ng/g or ppb concentrations in house dust) (Wang et al., 2015). In part, this may be driven by the sensitivity of HepG2 cells (an immortalized cell line) to chemically-induced toxicity, as overexpression of PPAR γ did not alter the toxicity of TBBPA within HepG2 cells. When cells were exposed to binary mixtures of TBBPA and TCBPA, cell viability decreased in a concentration-dependent manner based on the total sum concentration of TBBPA and TCBPA, suggesting that these effects were driven by simple additive toxicity. Similarly, cell-based studies using TBBPA have previously identified cytotoxic (LC₅₀) concentrations ranging from 21 μ M in mouse TM4 Sertoli cells (Ogunbayo et al., 2008) to 200 μ M in Cal-62 human thyroid cells (Strack et al.,

Table 1

Number of PPRE consensus half-site sequences (AGGTCA) within 5000 base pairs upstream of the transcription start site for differentially expressed genes.

Gene Name	Gene Symbol	GO Annotations*	# of PPRE consensus half-site sequences
Mitochondrially encoded cytochrome c oxidase 1	MT-CO1	Iron ion binding; electron transfer activity	0
Mitochondrially encoded 16s rRNA	MT-RNR2	Not available	0
Mitochondrially encoded ATP synthase membrane subunit 8	MT-ATP8	ATP hydrolysis activity; proton transmembrane transporter activity	0
Heterogeneous nuclear ribonucleoprotein A0	HNRNPA0	Nucleic acid binding; RNA binding	4
Dehydrogenase reductase 2	DHRS2	Oxidoreductase activity; carbonyl reductase activity	4
Growth differentiation factor 15	GDF15	Cytokine activity; transforming growth factor beta receptor binding	3

2007). Likewise, following a 24-h exposure, TBBPA and TCBPA are cytotoxic in mouse embryonic stem cells at 150 and 200 μ M, respectively (Yin et al., 2018). Interestingly, based on pretreatment experiments with reference PPAR γ ligands (ciglitazone and GW 9662), we found that TCBPA enhanced the cytotoxic effects of ciglitazone whereas exposure to GW 9662 and TBBPA or TCBPA resulted in synergistic toxicity (based on cell viability) relative to cells exposed to GW 9662, TBBPA or TCBPA alone. However, overexpression of PPAR γ did not alter TBBPA-induced cytotoxicity, suggesting that the cytotoxic effects of halogenated BPA analogues within HepG2 cells may be PPAR γ -independent and driven by other mechanisms such as oxidative stress.

To determine whether TBBPA or TCBPA exposure resulted in effects on lipid homeostasis, ORO neutral lipid staining was used to quantify potential changes in neutral lipid abundance. Neutral lipid staining by ORO has previously been linked to PPAR γ activation and activity during 3T3-L1 adipocyte differentiation (Wakabayashi et al., 2009). While reliable and reproducible within adipocytes that express higher levels of PPAR γ relative to hepatocytes (Elbrecht et al., 1996), neutral lipid staining by ORO appears to lack sensitivity in HepG2 cells, as PPAR γ reference ligands (ciglitazone and GW 9662) only alter neutral lipid abundance at higher concentrations (>100 μ M) (Cheng et al., 2021). As a result, pretreatment with ciglitazone and GW 9662 did not enhance nor mitigate TBBPA- or TCBPA-induced effects on neutral lipid abundance. However, we found that overexpression of PPAR γ within HepG2 cells increased neutral lipid staining, suggesting that PPAR γ transfection in combination with ORO staining may enable HepG2 cells to be a more sensitive model system for PPAR γ activation using neutral lipid

abundance as a readout.

While FASN activity has been shown to be strongly correlated to PPAR γ mRNA levels in adipocytes (Schmid et al., 2005), exposure to TBBPA and TCBPA (either alone or as binary mixtures) did not increase FASN protein levels in a concentration-dependent manner within HepG2 cells. Additionally, TBBPA did not result in differential expression of the FASN transcript based on our mRNA-seq data, further confirming that FASN transcription was not affected by exposure to TBBPA and TCBPA. Since FASN inhibitors are able to reduce PPAR γ mRNA levels (Schmid et al., 2005), this suggests that FASN activity is upstream of PPAR γ and, as such, may explain the lack of response of TBBPA and TCBPA on FASN transcript and protein levels within HepG2 cells. If FASN activity is upstream of PPAR γ , future studies should focus on whether pretreatment with FASN inhibitors decreases PPAR γ mRNA levels and alters the toxicity of TBBPA and TCBPA within HepG2 cells.

While TBBPA has been shown in several ToxCast assays to activate PPAR γ with relatively strong potency, we found no evidence of PPAR γ activation and transcription of target genes following TBBPA exposure. Despite using a non-cytotoxic concentration of TBBPA (30 μ M) to minimize possible off-target effects, we were unable to detect significant PPAR γ -related transcriptional effects even after overexpression of PPAR γ . Instead, we found that three mitochondrially encoded genes (MT-CO1, MT-RNR2, and MT-ATP8) – none of which have PPRE consensus half-site sequences within 5000 bases upstream of the TSS – were the only significantly altered transcripts within TBBPA- vs. vehicle-exposed cells transfected with the NC plasmid, suggesting that exposure to 30 μ M TBBPA resulted in a mitochondrial-specific stress response (Zhao et al., 2002) in the absence of PPAR γ -mediated transcription. These findings are consistent with previous studies that have shown that TBBPA exposure to L02 human hepatocytes increased reactive oxygen species, induced mitochondrial apoptosis, and altered transcripts related to oxidative stress within the Nrf2 pathway (Zhang et al., 2019). Within cells transfected with PPAR γ expression plasmid, exposure to TBBPA resulted in significant effects on the abundance of five transcripts (HNRNPA0, DHRS2, GDF15, FGA, and PTMA), all of which have at least one PPRE consensus half-site sequence within 5000 bases upstream of the TSS. Of these transcripts, DHRS2 is part of the short-chain dehydrogenase reductase enzyme family involved in the metabolism of steroids, prostaglandins, lipids, and xenobiotics (Gabielli et al., 1995). However, no studies have found any of these transcripts to be directly regulated by PPAR γ .

5. Conclusions

Overall, our study found that, while TBBPA and TCBPA affected cell viability at a similar magnitude and in an additive manner, non-cytotoxic concentrations of TBBPA and TCBPA did not significantly affect FASN protein levels nor neutral lipid abundance in a PPAR γ -dependent manner. Moreover, TBBPA and TCBPA enhanced the adverse effects of reference PPAR γ ligands on cell viability, but non-cytotoxic concentrations of TBBPA and TCBPA did not consistently affect downstream neutral lipid abundance after reference PPAR γ ligand pretreatment. Although ToxCast assays identified PPAR γ as a target for TBBPA and previous studies have confirmed TBBPA binding within cell-free assays, we were unable to link TBBPA-induced effects on the transcriptome to PPAR γ -dependent downstream effects even after overexpression of PPAR γ . However, there is a possibility that TBBPA-induced effects may have been PPAR γ -dependent since we did not knock down PPAR γ (e.g., using siRNAs) within cells overexpressing PPAR γ . Nevertheless, our findings suggest that halogenated BPA analogues such as TBBPA and TCBPA induce toxicity within HepG2 cells in a PPAR γ -independent manner, and further studies are needed to 1) identify other targets or mechanisms of action for TBBPA and TCBPA within HepG2 cells and 2) determine whether TBBPA and TCBPA induce PPAR γ -dependent toxicity with human cells (e.g., adipocytes) that express higher baseline levels of PPAR γ .
