Individualized genetic therapies—medicines that precisely target a genetic variant that may only be found in a small number of individuals, as few as only one—offer promise for addressing unmet needs in genetic disease, but present unique challenges for trial design. By nature these new individualized medicines require testing in individualized N-of-1 trials. Here, we provide a framework for maintaining scientific rigor in N-of-1 trials. Building upon best practices from traditional clinical trial design, recent guidance from the United States Food and Drug Administration, and our own clinical research experience, we suggest key considerations including comprehensive baseline natural history, selection of appropriate clinical outcome assessments (COAs) individualized to the patient genotype-phenotype for safety and efficacy assessment over time, and specific statistical considerations. Standardization of N-of-1 trial designs in this fashion will maximize efficient learning from this next generation of targeted individualized therapeutics.

Maturing platforms for targeted cell and gene-based therapies—including but not limited to antisense oligonucleotides (ASOs), siRNA, mRNA, DNA/RNA editing—are offering great hope for treatment of the over 8000 rare genetic diseases (defined as those affecting less than 1:200,000 individuals). The promise of these therapeutic approaches stems from their ability to directly target the underlying root causes of genetic disease at the level of the RNA or DNA—correcting the impact of genetic mutations, or even the mutations themselves. These technologies have been used under existing regulatory and drug development frameworks to support successful commercial drug development for several of the most prevalent rare genetic diseases[1]. However, commercial incentives have largely failed to support development of treatments for the "long tail" of the rarest genetic conditions, 85% of which have an estimated prevalence of less than 1:1,000,000.

Recent examples demonstrate that it is possible to use genetically-targeted technologies to develop therapies tailored to an individual's unique genetic pathology[2–7]. Because of their precise

targeting, the resulting drugs are often applicable to vanishingly small "markets" of only a handful of patients (or even just one), turning many facets of traditional drug development on their head[2]. A series of FDA guidances have been recently drafted to govern the development and investigational clinical deployment of such individualized therapies ("Individualized Antisense Oligonucleotide Drug Products for Severely Debilitating or Life-Threatening Diseases")[8], but specialized approaches to trial design and clinical outcome measures will be required to evaluate them rigorously. Here, we discuss design challenges associated with N-of-1 trials, and propose a clinical framework with which to begin to address them.

N-of-1 trials of individualized, genetically targeted therapies

We refer here to a specific type of N-of-1 trial design involving investigational therapies for which the therapeutic itself is individualized: targeting genetic variants that may be found in only one or a few individuals. We note that these fall in the specific subcategory of single case experimental design (SCED) studies, in which drug and trial design are designed for a single patient. We further note that this is distinct from the traditional concept of N-of-1 trials, a term which has been used to refer to studies involving single patients who are treated with (non-individualized) therapeutics in a repeat cycle of treatment challenge and withdrawal (A-B-A-B)—where non-individualized refers to interventions not specifically designed based on a patient's unique genetic makeup[9]. Furthermore, the genetically targeted modalities discussed in this perspective do not naturally lend themselves to crossover clinical trial designs (for instance, due to their long half-life of ASOs, or the single dose nature of AAV or CRISPR therapies).

Challenges of clinical protocol development for N-of-1 clinical trials of individualized, genetically targeted therapies

Protocol development for N-of-1 trials of individualized, genetically targeted therapies involves many careful considerations that are common to the design of any clinical trial (Table 1). These include, but are not limited to, an in-depth understanding of the genotype and phenotype of the patient to be treated, the mechanism of action and tissue distribution of the investigational drug, the development of treatment goals relevant to the patient/caregiver, and the setting of realistic expectations of what may be attainable. However, N-of-1 trials also involve clinical trial design considerations that are more unique to N-of-1 trials, especially as relates to rigorously assessing clinical efficacy, as discussed below.

Clinical outcome assessments

For many of the rare diseases that are the subject of N-of-1 trials, there are no pre-established disease-relevant clinical outcome assessments (COAs), and formal development of such a measure may not be possible in advance due to the small number of patients, the heterogeneity in symptoms, limited characterization of the natural history, and the global distribution of the patients. N-of-1 clinical trials can follow many of the principles outlined in the FDAs Patient-Focused Drug Development (PFDD) Guidance documents for selection of Clinical Outcome Assessments (COAs)[10]. COAs should be selected based on the patient's lived experience and reflect the current state of their condition. While traditional clinical trial design often utilizes focus groups and exit interviews in early phase trials to determine the appropriateness of COAs, N-of-1 trials only have to account for one or a small number of patient symptoms. Rigorous qualitative interview structures may be deployed at the drug development stage to ensure there is a comprehensive disease concept model that identifies the main areas of impairment and represents each patient's experience. COAs may be identified to capture the identified symptoms and structured data collection can begin ideally well before the intervention. It is essential that clinical investigators treating patients with ultra-rare disease have a deep understanding of disease pathophysiology and the patients'

unmet treatment needs to therefore identify the most appropriate outcome measures to track safety and efficacy of investigational individualized therapies.

Defining relevant changes

Once COAs are selected, clinical trials for individualized drugs still face the challenge of defining meaningful change. Traditionally this is captured via the concept of the trial's minimal clinically important difference (MCID)—the smallest response that would be considered clinical impactful—which can be then used in an objective and quantifiable way to classify patients into responders or non-responders[11]. With sufficient patient population data, statistical methods can be applied to establish a *standardized* MCID[12]—e.g., for Duchenne Muscular Dystrophy, a threshold of 30 meters on the 6-min walk test, as determined by assessing more than 150 patients in a Phase 2B clinical trial[13]. However, it is often challenging or impossible to implement this approach to current individualized N-of-1 trials. This is due to the fact that current individualized N-of-1 trials involve ultra-rare diseases for which this data typically does not exist. Furthermore, even if a standardized MCID has been established for the disease population in question, its applicability may be limited by clinical heterogeneity, since an individualized drug may only target a small subset of patients (or a single patient) with a specific mutation, whose clinical trajectories may differ from the group.

While a standard statistical approach to the determination of MCID is not possible in an N-of-1 trial as discussed here, the diligent collection of individualized 'natural history data' prior to treatment may allow for determination of test-retest and longitudinal stability of measures with longer baseline data collection providing more data points. One of the methods of determination of MCID outlined by the PFDD Guidance document four is to use hypothetical scenarios measured within a particular set of COAs to understand a group of patients assessment of meaningfulness through qualitative interviews. This could be a useful method for determining an "a priori" categorization of what a meaningful outcome would be for an individual patient prior to initiating an N-of-1 trial[14].

This general approach of collecting "individual natural history" data also usefully addresses several inherent challenges to N-of-1 trials, namely genotype-phenotype heterogeneity[15] and the scarcity of characterized and validated biomarkers[16]. For instance, among individuals diagnosed with the same disease, there may be great variability in the manifestation of symptoms, amplifying the challenge of selecting relevant COAs. As an example, patients with pathogenic SCN2A variant related disorders and developmental epileptic encephalopathies (DEEs) can exhibit variable symptoms ranging across the phenotypic spectrum, with differing symptoms and ages of onset depending on the genetic variant (i.e., gain of function, loss of function, etc.), including infantile spasms, neonatal onset medically refractory seizures, neurodevelopmental delay, choreoathetosis, intellectual disability, autism, ataxia, and significant gastrointestinal and autonomic dysfunction[17]. Genetic diseases often impact multiple domains, and the heterogeneity within and between these domains adds another layer of complexity[18,19] which further requires N-of-1 trial design tailored to the individual with appropriate outcome and endpoint measures.

A suggested approach to N-of-1 trial design

Implementing this strategy, we suggest that designing N-of-1 trials is usefully subdivided into consideration of markers of target engagement, clinical biomarkers, and outcome assessments that can reliably measure aspects of function, development and behavior relevant and individualized to the patient and underlying disease. These assessments should be informed by what is known about the toxicity profiles for the investigational agent or class of agent deployed. Objective and quantitative clinical assessments are of special value, but qualitative tools remain imperative for capturing clinical impacts and tracking

Table 1 | A framework of fundamental elements in rare disease N-of-1 trials

Introduction	Background Information Nonclinical and clinical data Rationale Risk-Benefit Assessment
Objectives and Endpoints	Primary Secondary Exploratory
Study Design and Dose Rationale	Overall design Treatment goals Dose rationale End of study definition
Study Population	Inclusion criteria Exclusion criteria
Treatment	Study drug information Route of administration Dose escalation Dose modifications Stopping rules
Study drug	Preparation, handling, storage, accountability Product storage and stability Preparation of study drug
Study Procedures	Procedures for screening and enrollment - Study assessments and procedures (include all assessments with description)
Safety	Definition of adverse events and serious adverse events Assessment of severity of adverse events Assessment of AE relationship to study drug Reporting responsibilities
Statistical considerations	Pre-specify frequency of outcomes measures and select appropriate time-series methods Pre-design any composite outcome measures Consider combining data across similar N-of-1 trials
Data handling and record keeping	Source documents/case reports forms Study records retention Data sharing

No datasets were generated during the construction of the fundamental elements framework.

meaningfulness to the patient in terms of disease morbidity and quality of life. We highlight several subdomains of special relevance to current N-of-1 trials in the discussion below.

Safety

Safety outcome measures for N-of-1 trials need to be matched for potential modes of toxicity that may be possibly associated with the therapeutic in question. This includes both the toxicity profiles of the specific investigational agent in question (as established in the course of either preclinical testing or prior clinical experience), as well as known or suspected class effects associated with the therapeutic modality. For example, typical safety-related clinical biomarkers for intrathecal ASO trials may include CSF sampling for cell count, protein, glucose, microbial culture, surveillance neuroimaging and symptom screening for ventricular changes, blood testing for basic chemistries platelets/liver function tests, and urinalysis for proteinuria. What safety assessments are most appropriate for a particular class of therapeutic intervention would be expected to evolve as we learn more about the safety profile of that class from traditional clinical trials as well as N-of-1 trials.

Clinical outcome measures

For central nervous system disorders, relevant clinical outcome measures may include seizure logs, quantitative or qualitative electroencephalograms (EEGs), electromyography/nerve conduction studies (EMG/NCVs), qualitative and/or quantitative volumetric neuroimaging, MR spectroscopy, quantitative sensory testing, neurodevelopmental assessments, and other structured neurologic rating scales. Of

particular interest are wearable biometric sensors capable of capturing longitudinal data relevant to symptoms such as motor strength, coordination, sleep, or seizures. Validated devices may prove preferable when assessing an individual with significant cognitive impairment or developmental delays as they acquire data passively and do not depend upon patient understanding or cooperation with testing, such as inertial sensors for ataxic gait measurement.

Many current N-of-1 trials target central nervous system diseases for which neurodevelopmental delays are an especially prominent disease feature impacting quality of life. Neurodevelopmental COAs can include specific assessments of cognitive, academic, adaptive behavior, executive function, sensorimotor, and other behavioral, mood and social concerns. These assessments need to be tailored to individual patients' specific diagnoses and needs and be developmentally age-appropriate. Curation of the patient's neurodevelopmental test battery should incorporate consideration of test validity and reliability (demonstrated in neurotypical and if available, similar disease cohorts). Although these assessments are typically ordinal, many have still been shown to reflect an MCID or MDD during serial assessment in larger trials[20]. Since these instruments will at best be validated only for disease groups with shared clinical features to the N-of-1 trial subject, multiple scales and perspectives (e.g., patient, caregiver, clinician) may be required to test the same domain in order to reduce bias and optimize objectivity.

Fluid/tissue biomarkers

In a perfect world, an interventional trial would ideally incorporate measurement of fluid and tissue biomarkers that demonstrate target engagement of the investigational drug (example: Huntington protein lowering in response to treatment with a *HTT* knockdown ASO), but these do not exist and are not feasible for the majority of N-of-1 trials. This is unsurprising given the rarity of the conditions studied in these trials, combined with the fact that currently, most N-of-1 trials target the CNS where tissue sampling is not possible. Furthermore, some N-of-1 trials employ drugs that may act in a mutation- or allele-specific manner, requiring correspondingly mutation- or allele-specific measures of target engagement. Nonetheless, other fluid and tissue biomarkers may provide helpful guidance to investigators managing patients enrolled in N-of-1 trials when available. For neurodegenerative diseases, plasma or CSF neurofilament levels may correlate with rates of neuronal injury, potentially informing clinical decision making. In addition, electrophysiologic biomarkers on EEG or EMG/NCV studies, if identified, may provide an objective metric of disease course and progression as it relates to the biological underpinnings of the genetic disease. Ideally, a reliable and informative biomarker can serve in a predictive and/or prognostic capacity.

Future statistical study design considerations

Statistical analyses are a seeming challenge given the nature of an individualized intervention, as traditional methods may not readily apply. These challenges are not entirely new, however, as structured approaches towards these issues have been developed in other fields such as oncology[21,22]. There are various statistical methods available for analyzing individual data from N-of-1 trials and other single-case designs. While full discussion is beyond the scope of this paper, we suggest that the clinical design considerations outlined here may serve as a first step towards meeting this challenge for rare genetic disease, paving the way towards the development of master clinical protocols to allow data sharing and aggregation of signals for meta-analyses across multiple N-of-1 interventions[23–26].

Regulatory considerations

The current regulatory landscape allows for the development of individualized investigational drugs for ultra-rare diseases via the submission of N-of-1 research INDs[10,14]. While pathways to approval or

reimbursement of individualized drugs have not yet been established, incorporating the clinical trial design principles discussed here will support the rigorous clinical science necessary to meet these standards[27].

Discussion

Individualized interventions, made possible through recent advances in genetically targeted therapeutic technologies, are now a reality. They represent opportunities to meet unmet medical needs while also posing interesting challenges to clinical trial designs as traditionally implemented. These challenges specifically require collaborative engagement across entities, including manufacturers, investigators, regulatory bodies, institutional review boards, patient advocacy organizations, funding grant agencies and other relevant stakeholders. Tackling the N-of-1 trial design within the framework discussed herein is critical to unlocking the path forward, for the potential benefit of those with rare genetic disease.
