Abstract

Introduction: Practice effects (PEs) on cognitive tests obscure decline, thereby delaying detection of mild cognitive impairment (MCI). Importantly, PEs may be present even when there are performance declines, if scores would have been even lower without prior test exposure. We assessed how accounting for PEs using a replacement-participants method impacts incident MCI diagnosis.

Methods: Of 889 baseline cognitively normal (CN) Alzheimer’s Disease Neuroimaging Initiative (ADNI) participants, 722 returned 1 year later (mean age = 74.9 ± 6.8 at baseline). The scores of test-naïve demographically matched “replacement” participants who took tests for the first time were compared to returnee scores at follow-up. PEs—calculated as the difference between returnee follow-up scores and replacement participants scores—were subtracted from follow-up scores of returnees. PE-adjusted cognitive scores were then used to determine if individuals were below the impairment threshold for MCI.
threshold for MCI. Cerebrospinal fluid amyloid beta, phosphorylated tau, and total tau were used for criterion validation. In addition, based on screening and recruitment numbers from a clinical trial of amyloid-positive individuals, we estimated the effect of earlier detection of MCI by accounting for cognitive PEs on a hypothetical clinical trial in which the key outcome was progression to MCI.

Results: In the ADNI sample, PE-adjusted scores increased MCI incidence by 19% ($P < .001$), increased proportion of amyloid-positive MCI cases (+12%), and reduced proportion of amyloid-positive CNs (~5%; $P_s < .04$). Additional calculations showed that the earlier detection and increased MCI incidence would also substantially reduce necessary sample size and study duration for a clinical trial of progression to MCI. Cost savings were estimated at $\approx 5.41$ million.

Discussion: Detecting MCI as early as possible is of obvious importance. Accounting for cognitive PEs with the replacement-participants method leads to earlier detection of MCI, improved diagnostic accuracy, and can lead to multi-million-dollar cost reductions for clinical trials.

Alzheimer’s disease, clinical trials, early diagnosis, longitudinal aging, mild cognitive impairment, practice effects

1 INTRODUCTION
Alzheimer’s disease (AD) is a leading cause of death in adults over age 65 and an estimated 1 in 85 people will be living with the disease by 2050.1,2 Given the protracted AD prodromal period, emphasis is now on clinical trials that begin with cognitively normal (CN) individuals who may progress to mild cognitive impairment (MCI).3–6 Delayed detection of MCI is essentially misdiagnosis, that is, labeling someone as CN when they, in fact, have MCI. Such misdiagnosis impedes identification of meaningful drug effects and may lead to misinterpretation of findings in clinical trials.7,8 Clinically, any effects to slow disease progression require early detection. Detection of MCI as early as possible is thus critical.

Repeat cognitive assessments are necessary for accurately determining transitions from CN to MCI or MCI to dementia. However, repeat assessments are subject to practice effects (PEs) that can inflate follow-up scores via memory of specific stimuli (i.e., content PE) or through increased comfort with test taking (i.e., context PE).9,10 Put simply, someone taking a test for the second time will typically have a higher score than if they were taking it for the first time. PEs have a wide-ranging impact on any study or field involving cognitive testing because they mask true cognitive decline and compromise diagnostic accuracy, impairing the separation of cases (i.e., MCI) and controls (i.e., CN).11,12 Moreover, PEs are pervasive; they have been found across multiple cognitive domains and test–retest intervals as long as 7 years in older adults, including those with MCI and mild AD.9,12–14

A major limitation of most PE methods is that they only consider PEs when scores are higher at follow-up than at baseline.11,14 However, PEs can exist when there is no overall change and when there is decline, as they may still cause underestimation of decline (Figure 1).11,14 In such situations, failure to account for PEs may delay MCI diagnosis because PEs would inflate scores above diagnostic impairment thresholds.11,12,16,17 This is particularly relevant for older adults for whom decline over time may be the norm.

Despite their importance, PEs are largely ignored in longitudinal studies, clinical trials, and clinical practice, particularly with respect to diagnosis.10,11,14,18,19 A review of PEs in MCI and AD samples noted considerable evidence of PEs (i.e., increased scores) in clinical trials.14 However, despite recognition that accounting for PEs may potentially improve clinical trials and diagnostic accuracy, there are minimal empirical data on PEs in clinical trials.11,14,15,20

One method of PE adjustment, the replacement-participants method, is able to gauge PEs even when performance declines.12,16 This method relies on the recruitment of an additional set of test-naïve participants (i.e., “replacements”) that is similar to returnees in terms of age and other demographic factors. A comparison of replacements’ performance and that of the returnees calculates a PE because score differences are due to the fact that returnees have taken the tests twice, but replacements have taken the tests only once. PE-adjusted scores can then be derived by subtracting PEs from the returnees’ follow-up scores.12,16 Using a replacement-participants method, in what to our knowledge is the only study using PE adjustment to modify diagnosis, we showed that MCI incidence doubled (4.6% vs. 9.0%) when scores were adjusted for PEs in a 6-year follow-up study.12 The increased incidence means earlier detection of MCI, suggesting an important strength of this method. However, as this method lowers all scores, it is crucial to determine if the increased incidence truly represents more accurate diagnosis rather than methodological arti-
RESEARCH IN CONTEXT

1. Systematic Review: We reviewed the literature (e.g., PubMed) and found only one study (by our group) that used practice effects (PEs) for purposes of earlier detection of mild cognitive impairment (MCI). However, the validity or accuracy of the practice-adjusted diagnoses and their potential impact on clinical trials remains unknown.

2. Interpretation: Our novel application of the replacement-participant method of practice effect estimation resulted in a 21% increase in incident MCI at 1-year follow-up. This earlier detection was also more accurate: 20% increase in amyloid-positive MCI cases and 6% decrease in amyloid-positive controls. We then showed that accounting for PEs would substantially increase power and reduce necessary sample size, duration, and cost of AD drug trials.

3. Future Directions: Matched replacement participants should be included in the design of large longitudinal aging studies and AD clinical drug trials to gauge PEs and provide for earlier detection of progression to impairment.

We propose improved correspondence between AD biomarkers and MCI diagnoses as a way of validating the PE-adjusted diagnoses. Other strengths of the method are that returnees and replacements are always well-matched for demographics, and PEs are always calculated based on the specific time interval and for a specific test. A shortcoming of this method is that each test’s PE is the same for all subjects because they are group mean effects.

Here, we used a novel approach by identifying the equivalent of replacement participants in the Alzheimer’s Disease Neuroimaging Initiative (ADNI). In individuals who were CN at baseline, we hypothesized that: (1) we would observe PEs at the 12-month follow-up; and (2) accounting for PEs would increase the number of MCI diagnoses at follow-up. Regarding criterion validity, we hypothesized that: (3) PE-adjusted diagnoses would result in more AD biomarker-positive MCI cases and fewer biomarker-positive CN individuals than PE-unadjusted diagnoses. Finally, we completed power/sample size calculations, hypothesizing that: (4) accounting for PEs would substantially reduce the number of participants needed for clinical trials. We then applied these estimates to a hypothetical drug trial with progression to MCI as a key outcome using recruitment data from a major clinical trial. Earlier and more accurate detection should thus have a substantial impact on clinical trials by reducing study duration, attrition, participant and staff burden, and overall cost.

2 | MATERIALS AND METHODS

2.1 | Participants

Data were obtained from the ADNI database (adni.loni.usc.edu). The ADNI was launched in 2003 as a public–private partnership, led by Principal Investigator Michael W. Weiner, MD. The primary goal of ADNI has been to test whether biological markers, clinical assessment, and neuropsychological measures can be combined to measure the progression of MCI and early AD. For up-to-date information, see www.adni-info.org. Participants from the ADNI-1, ADNI-GO, and ADNI-2 cohorts were included. Informed consent was obtained from all participants.

We identified 889 individuals who were CN at baseline; 722 of them returned for a 12-month follow-up. Mean educational level of returnees was 16 years (standard deviation [SD] = 2.7), 47% were female, and mean baseline age was 74.9 years (SD = 6.8). All participants completed neuropsychological testing at baseline and 12-month follow-up. After accounting for PEs, we re-diagnosed returnees at their 12-month follow-up as CN or MCI.

FIGURE 1  Practice effects (PEs) with and without true decline. The solid line represents true cognitive ability. The dashed line represents observed performance, which is inflated due to a practice effect (vertical arrow). A, Typically observed practice effect: an individual’s observed score increases from baseline to follow-up, demonstrating a typical practice effect. B, Practice effect in the context of cognitive decline. In this scenario, an individual’s ability is decreasing over time. A practice effect still exists but is masked by cognitive decline. As a result, the individual’s performance appears to be stable but is actually better than it would have been without previous exposure to the test. C, PEs impair detection of mild cognitive impairment (MCI). In this situation, an individual has declined below an MCI cutoff. However, PEs are inflating their score so that they now fall above the MCI cutoff and will be diagnosed as cognitively normal at follow-up.
2.2 | Procedures

Six cognitive tests were examined at both baseline and follow-up (mean = 12.21 months; SD = 0.97): memory (Wechsler Memory Scaled-Revised, Logical Memory Story A delayed recall; Rey Auditory Verbal Learning Test [AVLT] delayed recall); language (Boston Auditory Verbal Learning Test; Animal Fluency); attention-executive function (Trail Making Test Parts A and B). The American National Adult Reading Test provided an estimate of premorbid IQ. Participants completed the same version of tests at baseline and 12-month visits.

PE-adjusted and PE-unadjusted scores were converted to z-scores based on external norms that accounted for age, sex, and education for all tests except the AVLT.21 Having found no external norms for the AVLT that were appropriate for this sample and accounted for age, sex, and education, the AVLT was z-scored based on ADNI participants who were CN at baseline (n = 889). AVLT demographic corrections were based on a regression model that followed the same approach as the other normative adjustments.21

We focused primarily on MCI diagnosed according to the Jak-Bondi approach, requiring scores on ≥ 2 tests within the same cognitive domain to be ≥ 1 SD below normative means.7,8,22 To test whether the results were specific to a particular diagnostic approach, we repeated analyses using Petersen MCI criteria.22

Biomarkers included cerebrospinal fluid amyloid beta (Aβ), phosphorylated tau (p-tau), and total tau (t-tau) collected at baseline. The ADNI biomarker core (University of Pennsylvania) used the fully automated Elexys immunoassay (Roche Diagnostics). Sample collection and processing have been described previously.23 Cutoffs for biomarker positivity were: Aβ+: Aβ < 977 pg/mL; p-tau+: p-tau > 21.8 pg/mL; t-tau+: t-tau > 270 pg/mL (http://adni.loni.usc.edu/methods).24,25 There were 521 returnees with Aβ, 518 with p-tau, and 519 with t-tau data.

2.3 | Practice effect calculation and statistical analysis

PEs were calculated using a modified version of a replacement-participants method.12 Reviews and meta-analysis have noted that almost all studies of PEs considered only observed performance increases (Figure 1A), and recommended replacement-participant methods in situations in which decline is expected.11,14,16 In some situations PEs will not necessarily manifest as improvements for middle-aged and older adults, particularly for individuals on an AD trajectory.26 The replacement-participants approach involves recruiting participants for testing at follow-up who are demographically matched to returnees. The only difference between groups is that replacements are taking the tests for the first time whereas returnees are retaking the tests. Comparing scores at follow-up between returnees and replacement participants (with additional adjustment for attrition effects) allows for detection of PEs when observed scores remain stable (Figure 1B) and even when they decline (Figure 1C). In both scenarios, scores would have been lower with prior exposure. Thus, the goal is to create follow-up scores over retest intervals that are free of PEs and comparable to general normative data. By design, this method is equally applicable for any sample and any test because returnees and replacements are always matched on demographic characteristics, test, and retest interval.

Because ADNI did not have replacements, we used individuals who at baseline were demographically matched to returnees at follow-up. We refer to them as pseudo-replacements. Bootstrapping (5000 resamples, with replacement) was used to calculate PE values for each cognitive test. Figure 2 demonstrates how participants were matched at each iteration of the bootstrap. Propensity scores (R package: MatchIt) calculated via one-to-one matching were used to identify pseudo-replacements that were similar to returnees, and an additional constraint confirmed that the returnees and pseudo-replacements were matched at a group level (P’s > .8).27 PEs were calculated by comparing the mean scores of these subsamples at each bootstrapping iteration using equations displayed in Figure 2. The difference score represents the sum of the practice effect and the attrition effect. With actual replacements, the attrition effect accounts for the fact that returnees are often higher-performing or healthier than those who drop out. However, because the pseudo-replacements are similar to returnees, their removal from the baseline sample lowers the mean baseline score among those not chosen to be returnees at that iteration, resulting in an artificially high attrition effect. To ensure a more accurate attrition effect, we calculated the true attrition and retention rates for each test (>16% and 84%, respectively). We then multiplied the mean score of returnees at baseline by the retention rate and the mean score of the remaining baseline participants (i.e., those not chosen as returnees or pseudo-replacements) by the attrition rate. The sum of these values provides a weighted mean for each iteration, which we refer to as the proportional baseline. Finally, the PE for each test equals the difference score minus the attrition effect.12,17 The PE for each test was then subtracted from each individual’s observed (unadjusted) follow-up test score to provide PE-adjusted raw scores.

In summary, this method identifies a comparison sample (pseudo-replacements) who are matched for age and other demographic characteristics to the returnees. The only difference is that returnees have taken the test before and pseudo-replacements have not. Because this analysis uses completed data, creating pseudo-replacements allowed for application of a replacement method of PE adjustment to an already completed study without requiring new participant recruitment.

Adjusted raw scores at follow-up were converted to z-scores, which were used to determine PE-adjusted diagnoses. In other words, determination of whether an individual was below the impairment threshold was now based on the PE-adjusted scores. McNemar χ² tests were used to compare differences in the proportion of individuals classified as having MCI before versus after adjusting for PEs, and to determine if PE-adjusted diagnoses changed the proportions of biomarker-positive MCI and CN participants. Cohen’s d was calculated for each PE by comparing unadjusted and adjusted scores.

To determine the impact of PE adjustment in a clinical trial, we calculated sample size requirements for a hypothetical clinical trial aimed at reducing progression to MCI at 1-year follow-up in amyloid-positive
FIGURE 2  Sample matching and practice effect calculations. Practice effect calculations are based on bootstrapped analyses. Participants with valid baseline data were identified \( (n = 889) \). (1) Participants who also had 12-month follow-up data comprised the returnees \( (n = 722) \). (2) A subsample \( (n = 25\% \text{ total sample}) \) of returnees was selected; this was \( \approx 220 \) participants. (3) Baseline data for these participants were labeled as Returnees\(_{T1}\). Follow-up data for these participants were labeled Returnees\(_{T2}\). (4) The 220 Returnees\(_{T1}\) participants were removed from the pool of baseline data, leaving \( \approx 670 \) remaining baseline participants. (5) Using propensity score matching with an additional age restriction \( (< 0.1 \text{ years}) \), the potential pseudo-replacements were matched to the Returnees\(_{T2}\) participants using one-to-one matching. The pseudo-replacements were drawn from the 670 remaining baseline participant pool. Matching parameters were age, birth sex, education, and premorbid IQ. Additionally, comparisons of age, birth sex, education, and premorbid IQ were completed to confirm groups were similar \( (p’s > .80) \). (6) Once matching was complete, the sample was labeled Pseudo-Replacements\(_{T1}\), and this sample ranged in size from 200 to 240 participants. Thus, the Pseudo-Replacements\(_{T1}\) sample and the Returnees\(_{T2}\) sample were demographically matched and only differed in that the Returnees\(_{T2}\) had taken the test before while Pseudo-Replacements\(_{T1}\) had taken the tests only once. After the—on average—220 Pseudo-Replacements\(_{T1}\) were removed from the pool of baseline data, there were 450 remaining unchosen baseline participants, or 50% of the total sample. The previous steps were completed at each of the 5000 iterations. Practice effects were calculated by comparing the mean scores of these subsamples using the equations provided below the flowchart. The difference between the mean of Returnees\(_{T2}\) scores and the mean of the matched Pseudo-Replacements\(_{T1}\) scores equates to the sum of practice effect and attrition effect. The attrition effect accounts for the fact that individuals who return for follow-up may be higher performing or healthier than the full baseline sample. (7–9) To retain the proportion of returnees to attritors we had in the original sample, we then created a weighted mean of the baseline data cognitive score by multiplying the mean test score of the remaining baseline subject pool by the attrition rate \( (\approx 16\%) \) and the Returnees\(_{T1}\) pool by the retention rate \( (84\%) \); this is referred to as the Proportional Baseline in the text. The practice effect for each test equals the difference score minus the attrition effect.

CN individuals using MCI incidence rates from the present study. We performed logistic regressions with drug/placebo as the predictor and diagnosis at follow-up as the outcome. Sample size estimates were determined across a range of drug effects (10% to 40% reduction in MCI diagnoses) with \( \alpha = 0.05 \) and power = 0.80. We then used this information to estimate the effects on required sample size and cost for a variant of the Anti-Amyloid Treatment in Asymptomatic Alzheimer’s Disease (A4) study given \( \alpha = 0.05 \), and power = 0.80. The A4 study recruited amyloid-positive CN individuals to investigate whether anti-amyloid therapy can delay cognitive decline.\(^6\) Progression to disease is a common and meaningful outcome for clinical trials. For our hypothesis, the variation of the A4 study, the outcome of interest was progression to MCI at 1 year rather than just comparing cognitive decline. These analyses were completed within the powerMediation package in R v3.6.1.\(^{28,29}\)

3 RESULTS

PE magnitudes varied within and between cognitive domains (Table 1). PE-adjusted scores resulted in 124 (17%) converters to MCI; unadjusted scores resulted in 104 (14%) converters (Table 2A). Thus, there
were 19% (P < .001) more individuals diagnosed with MCI after one year using PE-adjusted scores (Table 2A). Table 2B shows that adjusting for PEs significantly increased the number of biomarker-positive participants who progressed to MCI (+13% to +15%) and decreased the number of biomarker-positive participants who remained CN (-5%). In particular, there was a 12% increase in amyloid-positive MCI cases and a 5% decrease in amyloid-positive CNs. Tables S1-S2 in supporting information show results for diagnoses based on Petersen criteria. The pattern is the same as for the Jak-Bondi criteria, and all significant differences remained significant regardless of diagnostic approach.

Next, we showed that the number of participants necessary to determine a significant drug effect was substantially reduced by accounting for PEs across all effect sizes (Figure 3). On average, adjusting for PEs reduced the number of participants required by 15.9% (321 participants) across effect sizes (range = 68 to 1377 participants). The inset within Figure 3 focuses on differences for hypothetical PE-adjusted and unadjusted samples of ≈1000.

We then applied our findings to recruitment data from the A4 study (Figure 4A).30 Obtaining the CN, amyloid-positive A4 sample of 1323 required the recruitment of 5.11 times as many people for initial screening (n = 6763) and 3.39 times as many people to undergo amyloid positron emission tomography (PET) imaging (4486).30 Our calculations showed that this sample size of 1323 would be powered to detect a 24.7% drug effect on incident MCI outcomes, which should lead to substantial cost reductions.

### DISCUSSION

Delayed detection of MCI is extremely costly from a public health perspective. In 2018, the Alzheimer’s Association projected an estimated US national savings of $231 billion by 2050 if those on the AD trajectory were diagnosed during the MCI, rather than the dementia, stage.1 In clinical practice, the MCI stage represents a critical time for preparation and intervention for individuals who will progress to AD-related dementia. If PEs delay detection of MCI, clinicians may also be providing inadequate care to those most at risk.

Results of the present study confirm our hypothesis that adjusting for PEs using the replacement-participants method does lead to earlier detection of MCI. Accounting for cognitive PEs resulted in a 26% increase in 12-month MCI incidence. The increase in biomarker-positive MCI (+20% amyloid-positive) and reduction in biomarker-negative CN participants (~6% amyloid-positive) supports diagnostic validity. Failure to account for PEs led to a substantial number of false negatives as 18% of biomarker-positive MCI cases were labeled as CN at follow-up. Accounting for PEs improved accuracy, reducing false positives by 5%. Individuals diagnosed with MCI based on PE-adjusted scores—who would otherwise have been considered CN—would be expected to progress to AD dementia sooner than true CN participants. Progression at later follow-ups was consistent with this hypothesis, but sample sizes were too small for statistical comparisons (see Table S3 in supporting information). Taken together, these results demonstr-

Abbreviations: Aβ, amyloid beta; CN, cognitively normal; MCI, mild cognitive impairment; PE, practice effects; p-tau, phosphorylated tau; t-tau, total tau.

Notes: Follow-up diagnoses were made with practice effect-unadjusted (PE-unadjusted) or practice effect-adjusted (PE-adjusted) scores. The difference in the number of cases is calculated by subtracting the number of cases, based on PE-unadjusted scores, from the number of cases based on PE-adjusted scores. The percent difference (%) in number of cases is the differences in number of cases divided by the number of cases based on PE-unadjusted cognitive scores (eg., 19% = 20/104). $\chi^2$ is McNemar $\chi^2$. Individuals could be impaired in more than one domain. Consequently, the sum of impaired individuals within each domain is greater than the total number of MCI cases. The MCI diagnosis row counts an individual only once, even if they are impaired in more than one domain.

To quantify how clinical trials would be improved by PE adjustment, we estimated sample sizes necessary to power a simulated clinical drug trial. Our PE adjustment increased the base rate of MCI at 12-month follow-up and, other things being equal, detecting differences or making predictions is less accurate for low base rate events. Progression to disease is the most common outcome of interest in clinical trials, and smaller samples would be needed for clinical trials with a PE-adjusted diagnostic endpoint. Across effect sizes, there was an average reduction of 16% in necessary sample size using PE-adjusted diagnoses; sample size reductions were greater with smaller treatment effect sizes (Figures 3, 4A). Based on screening/recruitment numbers in the A4 study, Figure 4A showed that determining progression to MCI using PE-adjusted scores would mean 1060 fewer initial screenings and 703 fewer amyloid PET scans. At $5000 per scan, cost savings for that alone would be $3.52 million. Initial screening—which included cognitive testing, clinical assessments, and apolipoprotein E genotyping—for 1060 individuals would result in considerable additional cost savings, estimated at $2.50 million. Cost savings would be partially offset by needing to add replacement participants. In prior work, 150 to 200 replacement participants were sufficient. With replacements for three follow-up cognitive assessment sessions with 200 participants each, we estimated additional costs of $615,000. Estimated overall savings would be $5.41 million. Moreover, PE-adjusted diagnoses result in earlier detection, which means shorter follow-up periods. Reduced study duration would lead to still further cost reductions and benefits including lower participant and staff burden, fewer invasive procedures, and likely reduced attrition.

The present study may raise the question of how the replacement-participants method compares with other approaches to PEs, but that is likely to be the wrong question because different approaches may be for different purposes. A 2012 meta-analysis and 2015 review...
described several approaches to estimating PEs. Almost all non-replacement approaches—including more commonly used regression-based approaches—are only informative about relative differences, including predicting future change. One interesting paradigm is to retest participants after a short interval using a regression-based approach, and then have a much longer follow-up. Individuals with smaller PEs at 1 week are more likely to have worse baseline biomarker profiles, experience steeper 1-year decline, and progress to MCI/AD compared to other participants. Thus, this approach may be useful for participant selection in clinical trials. Other studies have found that additional baseline tests improve prediction of progression to MCI. Whether complete 1-week retesting of the entire sample improves prediction over the less burdensome and less costly inclusion of additional measures at baseline testing remains to be determined. Also, regression-based methods require a large, normative change sample, and would require new, large normative samples for each study if the specific tests, retest intervals, or sample demographics are different. Change is assessed relative to the normative sample, but PEs are still unknown in the normative sample. Importantly, regression-based approaches cannot be used for absolute diagnostic cutoff thresholds because, unlike the replacement-participant method, they do not produce stand-alone follow-up scores adjusted for PEs. Thus, they cannot have any effect on when a person crosses an impairment threshold and cannot lead to earlier detection of conversion to MCI. Nor can they calculate PEs in the presence of a mean-level decline over time, which is expected in older adults. The replacement-participants method requires a small number of additional participants relative to an entire study sample, and it generates adjusted scores at follow-up that are not obscured by age-related decline. The other methods can compare trajectories of people already diagnosed as MCI or CN, but only the replacement method—which generates absolute PE-adjusted scores—can alter when MCI is detected. Although the replacement-participants method reduces all scores, it does not change individual differences in any way. Thus, it also allows for comparison of trajectories. More thorough discussions of PE methods can be found in a systematic review by Calamia et al., the position paper on PEs by the American Academy of Clinical Neuropsychology, and a study that directly compares three regression-based PE approaches.

We acknowledge some limitations of the study. ADNI is not a population-based study and is not representative of the general population in terms of sociodemographic factors. However, replacement methods have been shown to be effective in other studies, including population-based samples. The method currently only examines PEs across two time points. As PEs persist over time, their magnitude may differ with additional assessments. Future studies should explore PEs in cases with multiple follow-up visits. As noted, including matched replacements for third and fourth visits would still be cost-effective. Some participants who do not qualify after initial screening or those who do not agree to biomarker assessment might still qualify to serve as replacement participants. Importantly, the PE magnitudes in the present study should not be directly used in other studies. PEs are often sample specific and need to be calculated with appropriate replacement participants for each study. Ultimately, the field may benefit from the development of PE norms for standard neuropsychological tests at some clinically meaningful intervals (e.g., 6 and 12 months). This could reduce the need for replacement participants. Similarly, sample size estimations for our hypothetical clinical trial may not be the same for other studies, but do provide more empirical evidence supporting the use of PE-adjustment.

Surprisingly, we found no practice effect on the AVLT. This may have occurred because, despite receiving the same version at the 12-month visit, some participants also completed an alternate version of the AVLT.
A: 24.7% Drug effect, alpha=.05, power=.80

**A4 trial without PE-adjustment**

- Screening 1: N=6763
- Screening 2: Amyloid PET N=4486
- Aβ+ CN N=1323

**A4 trial with PE-adjustment**

- Screening 1: N=5704
- Screening 2: Amyloid PET N=3784
- Aβ+ CN N=1116

**Reduction in Sample size**

- Screening 1: N=1060
- Screening 2: Amyloid PET N=703
- Aβ+ CN N=207

**FIGURE 4** Comparison of recruitment designs for detection of a drug effect based on Anti-Amyloid Treatment in Asymptomatic Alzheimer’s Disease (A4) study recruitment. Using sample size estimates from Figure 3, we present how planning to adjust for practice effects (PEs) would alter a clinical drug trial, using A4 study recruitment as an example. The A4 study had a total sample of 1323 participants after recruitment as shown in the top row of gray boxes (based on Figure 1 in Sperling et al.). A, Based on sample size estimates from Figure 3, a sample of 1323 would enable a study to detect a significant drug effect of 24.7% at an alpha of 0.05 and 0.80 power. The top row of the flowchart presents the recruitment for the A4 study. This study reported an initial screening (6763 participants) followed by amyloid positron emission tomography (PET; 4486 participants) imaging to achieve their sample of 1323 amyloid-positive (Aβ+), cognitively normal (CN) participants. Achieving the final sample size thus required an n for the initial screening that was 5.11 times as large as the final sample size, and an n for amyloid PET imaging that was 3.39 times as large as the final sample. Our power analyses suggest that the same effect size is achieved with only 1116 participants if a trial adjusted follow-up scores for PEs. That, along with the reductions in initial screening and PET scans, is shown in the middle row of the flowchart. The bottom row shows the sample size reductions for initial screening, PET screening, and the initial biomarker-positive and CN sample. B, The figure presents the reduction in recruitment sample size (Y-axis) across effect sizes ranging from 10% to 40% (X-axis). The orange line represents how many fewer participants would be necessary at initial screening if a study had planned to adjust for practice effects (PEs) at follow-up at a 6-month visit. The reduced 12-month practice effect for AVLT is consistent with the well-known phenomenon of retroactive interference, that is, the different 6-month version interfering with the PE from exposure to the baseline/follow-up version. Prior studies, including our own, have consistently found PEs on the AVLT or similar episodic memory measures. Thus, the present estimate of the impact of PEs may be a conservative one. It is also noteworthy that despite the lack of an apparent AVLT practice effect in the current study, we still found an increase in amnestic MCI cases after adjusting for PEs. This highlights the importance of including more than one test in each cognitive domain as specified in the Jak-Bondi approach. Finally, we note that use of alternate forms is considered suboptimal as even well-matched forms are not equivalent and add an additional source of test-retest variance.

In summary, adjusting for PEs results in earlier and more accurate detection of MCI. Reluctance to include additional replacement-participant testing is understandable as it increases cost and participant burden. In the end, however, it would substantially reduce the necessary sample size, follow-up time, participant and staff burden, and cost for clinical trials or other longitudinal studies. Although the magnitude of PEs may not be generalized from one sample to another, the replacement-participant method is appropriate for all ages, tests, and retest intervals because replacements are always matched on these features. The method is also not dependent on any specific approach to the diagnosis of MCI. Additionally, we have shown that the replacement-participant method can be adapted for ongoing or already completed studies that did not recruit matched-replacement participants in advance. Given the public health importance of the earliest possible identification of AD pathology, we strongly recommend that accounting for PEs be a planned component of clinical trials, routine clinical work, and longitudinal studies of aging and aging-related cognitive disorders.

CONFLICTS OF INTEREST
Dr. Bondi receives royalties from Oxford University Press, consulting fees from Roche and Novartis, and honorarium from the International Neuropsychological Society. He is also associated with a clinical trial at the Cleveland Clinic and is the vice chair of the Cognition Professional Interest Area (iSTAART/Alzheimer's Association). Dr. Gross is on the data safety monitory Board for a NIA-funded trial let by Pennington Labs. Dr. Jak receives payments from the Ohio Council on Aging. All other authors declare no competing interests.

AUTHOR CONTRIBUTIONS
The study was conceived by Mark Sanderson-Cimino and William S. Kremen. Guidance on statistical analysis was provided by Xin M. Tu and Alden L. Gross. Determination of MCI diagnoses was made by Emily C. Edmonds, Mark W. Bondi, Joel S. Eppig, and Kelsey R. Thomas. Mark Sanderson-Cimino, William S. Kremen, Jeremy A. Elman, Matthew S. Panizzon, and Daniel E. Gustavson contributed to the practice effects methodology. Primary funding to support this work was obtained by William S. Kremen, Carol E. Franz, Michael J. Lyons, and Mark Sanderson-Cimino. All authors provided critical review and commentary on the manuscript.
