# RATE EFFECTS ON THE UNDRAINED SHEAR STRENGTH OF COMPACTED CLAY

By W. Mun, Ph.D.<sup>1</sup>, T. Teixeira, B.S.<sup>2</sup>, M.C. Balci, M.S.<sup>3</sup>, J. Svoboda, M.S.<sup>4</sup>,

and J.S. McCartney, Ph.D., P.E.<sup>5</sup>

**Abstract:** Unconsolidated-undrained (UU) triaxial compression tests were performed on low-plasticity clay specimens compacted to the same void ratio but different initial degrees of saturation to evaluate the impact of axial strain rates ranging from 0.1 to 150 %/min on the undrained shear strength. Although an effective stress analysis cannot be performed on the results, they are useful to evaluate the relative roles of initial hydraulic conditions (i.e., matric suction and degree of saturation) and compaction effects (i.e., potential changes in soil structure with compaction water content). This evaluation is relevant due to difficulty in measuring shear-induced pore water and air pressures in consolidated-undrained (CU) compression tests on unsaturated clay. In all tests, the undrained shear strength quantified as the maximum principal stress difference increased log-linearly with axial strain rate, with rates of increase ranging from 4.1 to 9.7% per log cycle of axial strain rate for specimens having initial degrees of saturation ranging from 0.99 to 0.59. The undrained shear strength, rate of increase in undrained shear strength with axial strain rate, and secant moduli all increased nonlinearly with decreasing initial degree of saturation, although compaction effects played an important role in these trends. The increase in undrained shear strength with axial strain rate can be attributed to a reduction in the magnitude of excess pore water pressure, with similar reductions in magnitude for all the degrees of saturation considered. A comparison between the measured undrained shear strength values

21 and the drained shear strength values estimated using the suction stress concept was useful in  
22 delineating the impacts of initial hydraulic conditions and compaction effects on the trends in  
23 measured undrained shear strength.

## 24 **INTRODUCTION**

25 There are many situations in geotechnical engineering systems where the loading rate may be  
26 substantially greater than those employed in standard laboratory tests used to obtain shear  
27 strength properties, including impact loading, blast loading, wave loading, or earthquake loading.  
28 It is well established that the undrained shear strength of saturated clays increases log-linearly  
29 with the axial strain rate due to lower magnitudes of excess pore water pressure generation  
30 during faster tests. However, the impacts of loading rate on the undrained shear strength of  
31 unsaturated soils may be more complicated than in saturated soils due to the effects of matric  
32 suction and degree of saturation on the stress state, effects of compaction, generation of shear-  
33 induced excess pore air and water pressures, hydraulic hysteresis, and lower hydraulic  
34 conductivity than in saturated conditions. While considerable research has been focused on the  
35 shear strength of unsaturated soils in terms of both experimental characterization (Fredlund et al.  
36 1978; Ho and Fredlund 1982; Escario and Saez 1986; Rahardjo et al. 1995; Feuerharmel et al.  
37 2005; Nam et al. 2011) and predictive models (Fredlund et al. 1987; Abramento and Carvalho  
38 1989; Vanapalli et al. 1996), fewer studies have focused on investigating the role of unsaturated  
39 conditions on the undrained shear strength of unsaturated, compacted clays subject to elevated  
40 strain rates (Olson and Parola 1967; Svoboda and McCartney 2014).

41 The behavior of compacted soils sheared at different rates is important as the initial degree of  
42 saturation may influence the undrained shear strength through changes in the initial effective  
43 stress state (Bishop 1959) and the potential magnitudes of excess pore air and pore water

44 pressures generated during shear (Hilf 1948). However, consolidated-undrained (CU) or constant  
45 water content (CW) tests on unsaturated soils are time consuming, and measurements of excess  
46 pore water pressure at the boundary of unsaturated soil specimens in these tests may not be  
47 representative of those near the shear plane. Accordingly, the goal of this study is to assess the  
48 role of elevated axial strain rates on the undrained shear strength of unsaturated, compacted clay  
49 specimens obtained from unconsolidated-undrained (UU) triaxial compression tests. Although  
50 these UU tests do not permit the evaluation of shear-induced excess pore water pressures, they  
51 allow for examination of the relative roles of the initial hydraulic conditions (i.e., the initial  
52 matric suction and degree of saturation) and compaction effects (i.e., potential changes in soil  
53 structure when a soil is compacted wet or dry of optimum) on the undrained shear strength.  
54 Further, UU triaxial compression tests can be performed in a short period of time to facilitate  
55 characterization of variability in undrained shear strength. Furthermore, the air and water  
56 drainage conditions in a UU test also represent the pore fluid drainage conditions expected  
57 during rapid loading.

58       Compaction is expected to have complex effects on the undrained shear strength of  
59 unsaturated soils. Olson and Langfelder (1965) found that compaction of soils at different  
60 gravimetric water contents will lead to a variation in the initial suction, while Mitchell et al.  
61 (1965) found that compaction of clays will lead to a change in behavior from that associated with  
62 a flocculated structure to that associated with a dispersed structure as the compaction water  
63 content passed from being dry of optimum to wet of optimum. The initial suction and degree of  
64 saturation in the specimen may affect the effective stress and thus the shear strength (Bolzon and  
65 Schrefler 1998; Lu et al. 2010), while Mitchell et al. (1965) found that the shear strength and  
hydraulic conductivity were higher for flocculated specimens compacted dry of optimum than

67 for dispersed specimens compacted wet of optimum. Mitchell et al. (1965) hypothesized that  
68 flocculated specimens have greater interlocking between particles while dispersed specimens  
69 have particles aligning parallel to each other. Although changes in compaction-induced soil  
70 structure were not experimentally verified in this study, the effect of soil structure on soil  
71 behavior and in particular the undrained shear strength has been well established in the technical  
72 literature (Mitchell et al. 1965; Seed and Chan 1959; Vanapalli et al. 1999; Cetin and Gököğlü  
73 2013). Accordingly, the potential changes in soil structure for specimens compacted or dry of  
74 optimum are referred to simply as compaction effects in this study, while the degree of saturation  
75 and matric suction were determined independently.

76 This study involved the evaluation of the undrained shear strength of compacted clay  
77 specimens prepared at the same initial void ratio but different initial degrees of saturation.  
78 Assuming that the optimum water content occurs at a degree of saturation of 0.9 for a given  
79 compaction water content, initial degrees of saturation of 0.99 and 0.90 were selected to  
80 represent the behavior of soils compacted wet of optimum, while initial degrees of saturation of  
81 0.70 and 0.60 were selected to represent the behavior of soils compacted dry of optimum. To  
82 assess the impact of the initial hydraulic conditions, the suction stress concept of Lu et al. (2010)  
83 was employed to estimate the impact of suction on the shear strength of the clay specimens under  
84 drained conditions. A comparison between drained and undrained shear strength values permits  
85 assessment of the relative effects of initial hydraulic conditions (and associated effective stress  
86 state), the potential for shear-induced excess pore water pressure generation, as well as  
87 compaction effects.

88 **BACKGROUND**

89 Most studies on strain rate effects on shearing behavior of saturated clay have employed  
90 quasi-static triaxial compression tests under strain-controlled conditions, potentially with either  
91 pore water pressure measurements, or impulse loading compression tests which were under  
92 stress-controlled conditions. As most low-permeability soils will not have sufficient time for  
93 drainage during fast shearing, most studies have focused on understanding axial strain rate  
94 effects on the undrained shear strength. A summary of the results from several studies on the  
95 impact of axial strain rates on the undrained shear strength of saturated and unsaturated clay  
96 specimens having different mineralogies, stress states, and stress histories is presented in Table  
97 1. Although Olson and Parola (1967) found that there may be more curvature in the relationship  
98 between undrained shear strength and the rate of loading at very high axial strain rates (i.e.,  
99 greater than 1000 %/min), most of the studies summarized in Table 1 reported that most clay  
100 soils experience an average increase in undrained shear strength of 10% per log cycle of axial  
101 strain rate.

102 Most researchers have hypothesized that rate effects on the undrained shear strength of clays  
103 results from changes in the tendency for shear-induced volume change, resulting in lower  
104 magnitudes of excess pore water pressures at faster rates. Richardson and Whitman (1963)  
105 observed a decrease in the excess pore water pressure measured at the center of a saturated clay  
106 specimen sheared under an axial strain rate that was 500 times faster than the rate that would  
107 correspond to 90% equalization of pore water pressure, which led to a greater mean effective  
108 stress at failure for the faster test. They also observed that shear planes did not tend to form in the  
109 specimen until reaching relatively large strains and that pore water pressure was not strain rate  
110 dependent at strains less than 0.5%. Other studies have observed that soils become stiffer as the

111 axial strain rate is increased, leading to a smaller axial strain at failure (Casagrande and Shannon  
112 1948; Richardson and Whitman 1963; Olson and Parola 1967; Zhu and Yin 2000). This increase  
113 in stiffness with axial strain rate may correspond to the lower tendency to change in volume  
114 during shear. This is consistent with the hypothesis of Soga and Mitchell (1996), who assumed  
115 that pore water pressure generation is more related to the magnitude of strain rather than the  
116 strain rate. The shear strength of dry sands under relatively low confining stresses experience  
117 negligible rate effects, indicating that the axial strain rate may not affect the friction angle of  
118 soils (Svoboda and McCartney 2013).

119 Although unsaturated conditions may have an important effect on the shear strength of clays,  
120 it is difficult to evaluate rate effects due to challenges in instrumentation, low permeability, and  
121 compression of the air phase. Nonetheless, there are several relevant lessons that can be learned  
122 from drained and undrained shear strength tests on unsaturated soils under conventional loading  
123 rates. Escario and Saez (1986) performed drained shear strength tests on unsaturated soils and  
124 observed that the shear strength increases with suction and net normal stress. Lu and Likos  
125 (2006) reinterpreted their data in terms of effective stress, and found that there the matric suction  
126 does not affect the slope of the failure envelope. Matric suction does affect the shear strength  
127 through variations in the stress state (Bishop 1959; Bolzon and Schrefler 1995; Lu et al. 2010),  
128 and several experimental studies observed that the variation of shear strength with matric suction  
129 is nonlinear (Escario and Saez 1986; Gan et al. 1988; Rassam and Williams 1999; Nam et al.  
130 2011). The soil-water retention curve (SWRC) has been used as a tool in the prediction of the  
131 shear strength along with the saturated shear strength parameters (Vanapalli et al. 1996;  
132 Vanapalli and Fredlund 2000). Although there are several formulations for quantifying the  
133 effects of matric suction on the effective stress state and the shear strength of unsaturated soils,

134 Bolzon and Schrefler (1995) and Lu et al. (2010) developed linkages between the effective stress  
135 and SWRC models.

136       Olson and Parola (1967) performed one of the few studies on the impact of strain rate on the  
137 undrained shear strength of unsaturated, compacted soils. They performed UU triaxial tests on  
138 compacted Goose Lake clay at different initial gravimetric water contents at axial strain rates  
139 ranging from approximately 0.2 to  $4.0 \times 10^5$  %/min. For tests at the same strain rate, specimens  
140 with the lowest water content had the greatest undrained shear strength at failure. As the  
141 compaction water content increased, the undrained shear strength of the clay decreased.  
142 However, they only considered the effect of axial strain rate on the undrained shear strength by  
143 differentiating between the initial compaction water contents but did not consider the role of  
144 initial suction. Further, the specimens had different initial void ratios. Consistent with the  
145 observations of Mitchell et al. (1965), they found that soil structure also plays an important role  
146 in the rate effects on compacted soils, where the undrained shear strength of soils compacted wet  
147 of optimum was much lower than that of soils compacted dry of optimum. Also similar to the  
148 observations of Mitchell et al. (1965), Olson and Parola (1967) did not see a significant  
149 difference in undrained shear strength with different initial water contents dryer than optimum  
150 for tests performed at relatively low confining stresses (690 kPa), indicating that soil structure  
151 may play the greatest role in changing soil behavior near the optimal compaction water content.  
152 Olson and Parola (1967) also observed that the confining stress used in the unconsolidated  
153 undrained shear strength tests at different rates on unsaturated, compacted soils can have a  
154 significant impact on the magnitude of undrained shear strength, especially at high confining  
155 stresses (6900 kPa), contrary to the role of confining stress in UU tests on water-saturated soils.

Svoboda and McCartney (2014) observed that the undrained shear strength of compacted Boulder clay in both saturated and unsaturated conditions increases log-linearly with increasing strain rate from a series of consolidated-undrained (CU) triaxial compression tests. In their research, the excess pore water pressure at the bottom boundary of the specimen was consistently positive for both the saturated and unsaturated specimens at failure. Cunningham et al. (2003) observed that the pore water pressures measured at a specimen boundary may not be representative of those on the failure plane in unsaturated soils. In particular, this occurs when the pore water phase is not connected across the length of the specimen (i.e., when the soil specimen has a relatively low degree of saturation).

## **MATERIAL**

The soil evaluated in this study was obtained from a stockpile at a construction site on the University of Colorado Boulder campus, and is referred to as Boulder clay. The clay was ground in air-dry conditions then processed to remove all particles with a diameter greater than 2 mm (retained on the #10 sieve), which provided a more homogeneous and consistent material for experimental testing. The processed Boulder clay is classified as a low plasticity clay (CL) according to the Unified Soil Classification System (USCS). Some of the geotechnical characteristics of Boulder clay are listed in Table 2.

The standard Proctor compaction curve for Boulder clay is shown in Figure 1(a), along with the initial compaction points for the different UU test specimens. A compaction water content of 17.5% and a dry unit weight of  $17.4 \text{ kN/m}^3$  correspond to optimum conditions for the standard Proctor compaction effort. The shape of the compaction curve supports the assumption that the line of optimums corresponds to a line of constant degree of saturation of 0.9, so the arrows in this figure define which specimens can be considered wet or dry of optimum. As one of the goals

179 of this study is to evaluate the role of the initial suction on rate effects on the undrained shear  
180 strength, the initial suction values in several of the compacted specimens having different initial  
181 degrees of saturation were assessed using a carefully de-aired UMS T5 tensiometer, with the  
182 time series of suction equilibration shown in Figure 1(b). In order to prevent cavitation during  
183 suction measurement, the tensiometer was saturated using de-aired water by applying positive  
184 pressure of 140 kPa and a negative pressure of 80 kPa before each test. After equilibration of the  
185 tensiometer, an increasing initial suction is observed with decreasing initial degree of saturation,  
186 as shown in Figure 1(b). The Transient Water Release and Imbibition Method (TRIM) of  
187 Wayllace and Lu (2012) was used to infer the drying and wetting paths of the SWRC for a  
188 Boulder clay specimen having the same initial void ratio as that used in the undrained triaxial  
189 tests (0.52) under unconfined conditions, as shown in Figure 1(c). This approach permitted  
190 inverse estimation of the van Genuchten (1980) SWRC model parameters  $\alpha$  and  $n$  for the drying  
191 and wetting paths, which are shown in the figure. The air entry suction for the drying path is  
192 approximately 40 kPa. The equilibrium suction-saturation points for the specimens evaluated  
193 using the tensiometer in Figure 1(b) are also shown in Figure 1(c), which correspond well with  
194 the drying path of the SWRC from the TRIM analysis.

## 195 **EXPERIMENTAL APPROACH**

196 A series of UU triaxial compression tests was performed on compacted specimens of Boulder  
197 clay to investigate the effects of strain rate, initial hydraulic conditions, and compaction effects  
198 on the undrained shear strength. Although the tests focused on compacted specimens with  
199 varying initial degrees of saturation and different axial strain rates, the general testing procedures  
200 followed the standard for UU triaxial compression testing described in ASTM D2850 (ASTM  
201 2007).

202 The clay specimens were prepared using static compaction with a mechanical loading press  
203 to reach the same initial void ratio of 0.52, but with different initial degrees of saturation. Lines  
204 of constant degree of saturation are shown in Figure 1(a) to put these initial conditions into  
205 perspective with the standard Proctor compaction curve. Each specimen was compacted into a  
206 cylindrical mold that is 71.1 mm high with a 35.6 mm diameter. To ensure uniformity throughout  
207 the sample, each specimen was compacted using three lifts of equal mass at gravimetric water  
208 contents of 11.5, 13.5, 17.5, and 19.5% to reach the same target dry unit weight of  $17.4 \text{ kN/m}^3$   
209 (i.e., a target void ratio of 0.52). A conventional triaxial testing setup with no drainage ports in  
210 the top and bottom platens was used, and the specimens were encased within a latex membrane.  
211 For each of the specimens, a total confining stress of 207 kPa was immediately applied after  
212 assembly of the cell without permitting drainage or air or water, after which the specimen was  
213 allowed to rest without drainage for a minimum of 10 minutes. This magnitude of confining  
214 stress is not expected to lead to pressurized saturation of the specimens based on the results from  
215 undrained compression tests on this soil reported by Mun and McCartney (2015). For each set of  
216 specimens having a different initial degree of saturation, UU tests were performed at four  
217 different axial strain rates under displacement control conditions: 0.1, 1.5, 15.0, and

218 150.0%/minute, with each combination repeated three times for variability characterization.  
219 These axial strain rates correspond to shearing times (i.e., the time required to reach 15% axial  
220 strain) of 150, 10, 1 and 0.1 minutes. A motor-driven load frame manufactured by ELE  
221 International (model Digital Tritest 50) was used to shear the specimens for displacement rates  
222 up to 10 mm/min (axial strain rates less than 15.0 %/min), while a hydraulic press manufactured  
223 by Wille Geotechnik (model LO 70XX/DYN-SH) was used for the tests with an axial strain rate  
224 of 150 %/min. In both cases, the axial displacement as well as the axial load were monitored  
225 independently by using a linearly-variable deformation transformer (LVDT) and the load cell  
226 mounted on the cross head of the load frame. All tests for a given strain rate and initial degree of  
227 saturation were repeated three times in order to assess variability. The gravimetric water content  
228 at failure was measured at the shear plane of the specimen for each test, and were found to be  
229 nearly identical to the compaction water content values, confirming a negligible change in water  
230 content during shearing in the UU tests. Summaries of the average values of compaction water  
231 content, degree of saturation and initial void ratio for the UU tests are listed in Table 3.

**232 EXPERIMENTAL RESULTS**

233 The principal stress difference ( $\sigma_1 - \sigma_3$ ), where  $\sigma_1$  is the major principal total stress equal to  
234 the axial stress and  $\sigma_3$  is the minor principal total stress equal to the cell pressure, is plotted as a  
235 function of axial strain for specimens under different water contents and axial strain rates in  
236 Figure 2. The curves in this figure are the average of three curves performed under the same  
237 conditions, with excellent repeatability observed under each combination. The undrained shear  
238 strength in this study is presented in terms of the principal stress difference at failure  $(\sigma_1 - \sigma_3)_f$ ,  
239 which is equivalent to twice the undrained shear strength. When evaluating the stress-strain  
240 curves, the principal stress difference at failure  $(\sigma_1 - \sigma_3)_f$  was defined as either the maximum value

241 of the principal stress difference from the stress-strain curve in the case that a peak value was  
242 observed, or the value of principal stress difference at an axial strain of 15% in the case that no  
243 peak value was observed. A summary of the test results is presented in Table 4, which provides  
244 all of the values including average values with standard deviations from repeated tests.  
245 Regardless of the compaction water content, an increase in  $(\sigma_1 - \sigma_3)_f$  with increasing strain rate is  
246 observed in the stress strain curves in Figure 3. Further,  $(\sigma_1 - \sigma_3)_f$  increases with decreasing  
247 compaction water content regardless of the applied strain rate. A transition in the shapes of the  
248 stress-strain curves is also observed. The specimens with the two lower compaction water  
249 contents show a peak value at an axial of approximately 3-6% followed by strain softening,  
250 while the specimens with the two greater compaction water content show strain hardening  
251 throughout shearing.

252 The values of  $(\sigma_1 - \sigma_3)_f$  from the UU triaxial tests on specimens compacted at different water  
253 contents as a function of the axial strain rate are shown in Figure 3(a). The data points signify the  
254 average of the three tests at each testing condition, while the error bars denote the range of the  
255 principal stress differences measured in the repeated tests. Consistent with observations from the  
256 literature, the results indicate that  $(\sigma_1 - \sigma_3)_f$  increases log-linearly with axial strain rate. The  
257 following equation was fit to each data set shown in Figure 3(a):

$$(\sigma_1 - \sigma_3)_f = A \log(\dot{\varepsilon}) + B \tag{1}$$

258 where  $\dot{\varepsilon}$  is the axial strain rate and A and B are the slope and intercept values of the semi-  
259 logarithmic relationship, respectively.

260 The average axial strains at failure corresponding to the points in Figure 3(a) are plotted as a  
261 function of axial strain rate in Figure 3(b). Specimens with lower compaction water contents  
262 failed at an axial strain less than 15%, with a decrease in the axial strain at failure with increasing

263 axial strain rate. This indicates that stiff soils will behave in an even stiffer manner when sheared  
264 at faster rates. The greater strength of the specimens sheared at faster rates supports the  
265 hypothesis of Soga and Mitchell (1996) that lower excess pore water pressures may be induced  
266 in the specimens that fail at a smaller axial strain. The axial strain at failure is greater for  
267 specimens with higher initial water contents. All of the specimens with water contents wet of  
268 optimum (17.6 and 19.3%) reached an axial strain of 15% without exhibiting a peak value,  
269 irrespective of the axial strain rate.

## 270 ANALYSIS

### 271 *Overview*

272 One of the goals of this study is to discern the relative impacts of the initial hydraulic  
273 conditions and compaction effects on the undrained shear strength of compacted clays. The  
274 initial values of suction and degree of saturation may affect both the initial effective stress in the  
275 specimen, and compaction of specimens wet or dry of optimum may lead to changes in soil  
276 behavior. Although it is not possible to evaluate shear-induced excess pore water pressures in the  
277 UU tests, the compaction effects may affect the magnitude of excess pore water pressures  
278 generated during shearing at different rates due to the relative amounts of each fluid within the  
279 soil. Two analyses are performed in this study to investigate the relative effects of other factors  
280 affecting undrained shear strength. First, the rate of increase in  $(\sigma_1 - \sigma_3)_f$  with axial strain rate, the  
281 magnitude of  $(\sigma_1 - \sigma_3)_f$ , and the secant modulus are plotted as function of the initial degree of  
282 saturation and suction. However, as the trends in these figures may mask the effects of  
283 compaction effects, a second analysis is performed to compare the measured undrained shear  
284 strength values with the drained shear strength values that would be expected for a similar initial  
285 effective stress. This comparison involves the assessment of two expected behaviors: (1) does the

286 increase in undrained shear strength with initial suction follow a similar trend; and (2) is the  
287 magnitude of the undrained shear strength less than that of the drained shear strength due to  
288 positive excess pore water pressures expected during faster shearing tests (Svoboda and  
289 McCartney 2014). Deviations from the expected behaviors may reveal the role of the specimen  
290 being compacted wet or dry of optimum. The challenge of this comparison is to select the same  
291 initial effective stress for the drained tests, which requires an estimate of the impact of suction on  
292 the effective stress and an estimate of the impact of the change air pressure generated by the  
293 application of the cell pressure.

**Impact of Initial Hydraulic Conditions and Compaction Effects**

Although it is clear that the initial suction and degree of saturation have an effect on the  
undrained shear strength, it is possible that compaction effects may be superimposed on these  
trends. As the results in Figure 1(b) indicate that the initial suction ( $\psi_i$ ) values measured using  
the tensiometer match well with those from the drying-path SWRC, the initial suction values  
were estimated using the SWRC model of van Genuchten (1980), expressed as follows:

$$\psi = \frac{1}{\alpha} \left\{ S_e^{-\frac{n}{n-1}} - 1 \right\}^{\frac{1}{n}} \tag{1}$$

where  $S_e$  is the effective saturation [i.e.,  $S_e=(S_r-S_{res})/(1-S_{res})$ , where  $S_r$  is the degree of saturation  
and  $S_{res}$  is the residual saturation] and  $\alpha$  and  $n$  are fitting parameters.

The log-linear slopes of the relationship between  $(\sigma_1-\sigma_3)_f$  and axial strain rate (Parameter A  
from Eq. 1) for each different water content are plotted against initial the degrees of saturation  
and estimated initial suction in Figures 4(a) and 4(b), respectively. The magnitudes of log-linear  
slopes increase with decreasing initial degree of saturation and with increasing initial suction.  
The rate of increase in  $(\sigma_1-\sigma_3)_f$  tends to decay with decreasing degree of saturation, indicating

307 that the amount of pore water plays a role in the rate effects. The values of  $(\sigma_1 - \sigma_3)_f$  are plotted  
308 against the initial degree of saturation and estimated initial suction in Figures 5(a) and 5(b),  
309 respectively. An interesting observation from the results in Figure 5 is that the rate effects are  
310 similar regardless of the initial degree of saturation (i.e., a uniform shift upward). This indicates  
311 that the excess pore air and pore water pressures at different initial degrees of saturation have the  
312 same net effect on the effective stress state. The value of  $(\sigma_1 - \sigma_3)_f$  increases with decreasing  
313 initial degree of saturation and increasing initial suction. Although Mitchell et al. (1965)  
314 observed that the undrained shear strength was relatively constant for specimens compacted dry  
315 of optimum, this may be because their specimens were all prepared using the same compaction  
316 effort and had different void ratios as well as initial suction values. It is possible that the effects  
317 of compaction wet or dry of optimum and the initial effective stress associated with the initial  
318 suction and initial degree of saturation offset in their tests. Although partially due to the log  
319 scale, a different trend in the increase in  $(\sigma_1 - \sigma_3)_f$  with initial suction is observed for the  
320 specimens compacted at or less than optimum (i.e., the two lower suction values) than those  
321 compacted dry of optimum. The large jump in  $(\sigma_1 - \sigma_3)_f$  between the two middle suction values is  
322 an indicator that the impact of compacting the specimen wet or dry of optimum may be  
323 superimposed atop the initial suction effects for specimens compacted to the same void ratio.

324 Not only is the secant modulus from the stress strain curves linked with the magnitude of the  
325 principal stress at failure, but it also may reflect the tendency for volume change during the  
326 undrained tests. The average secant modulus at an axial strain of 1% as a function of the axial  
327 strain rate for specimens with different initial hydraulic conditions is shown in Figure 6, along  
328 with the error bars. The secant modulus clearly increases with axial strain rate, albeit with a  
329 greater rate of increase for the specimens compacted dry of optimum. The average secant

330 modulus was plotted as a function of the initial degree of saturation and estimated initial suction  
331 in Figures 7(a) and 7(b), respectively. Similar to the trends observed for  $(\sigma_1 - \sigma_3)_f$ , the secant  
332 modulus increases with decreasing initial degree of saturation and increasing initial suction.  
333 Although a relatively uniform upward shift with axial strain was observed in the data regardless  
334 of the initial degree of saturation, a significant upward shift in secant modulus was observed for  
335 the fastest axial strain rate. Similar increases in the secant modulus with decreasing compaction  
336 water content were observed by Olson and Parola (1967).

337 ***Comparison of Undrained and Drained Shear Strength Values***

338 As mentioned, the difference between the undrained and drained shear strength values is  
339 expected to reflect the magnitude of excess pore water pressure conditions, the impact of suction  
340 on the shear strength, and the role of compaction effects. The shear strength of soil under drained  
341 conditions, quantified using the maximum principal stress difference  $(\sigma_1 - \sigma_3)_f$ , can be estimated  
342 from the Mohr-Coulomb failure criterion, as follows:

$$(\sigma_1 - \sigma_3)_f = \frac{2\sigma_3' \sin \phi'}{1 - \sin \phi'} \tag{3}$$

343 where  $\phi'$  is the friction angle (assumed to be constant with suction), and  $\sigma_3'$  is the effective minor  
344 principal stress equal to the effective confining stress. The effective stress can be estimated using  
345 the effective stress definition of Bishop (1959), given as follows:

$$\sigma' = (\sigma - u_a) + \chi(u_a - u_w) \tag{4}$$

346 where the difference between total stress  $\sigma$  and the pore-air pressure  $u_a$  is referred to as the net  
347 stress  $\sigma_{net}$ , and  $\chi$  is the effective stress parameter. Lu and Likos (2006) hypothesized that the term  
348  $\chi(u_a - u_w)$  could be replaced by the suction stress  $\sigma_s$  to up-scale the effects of capillarity and other  
349 inter-particle forces that may vary with degree of saturation or suction, as follows:

$$\sigma' = (\sigma - u_a) - \sigma_s \quad (5)$$

Lu et al. (2010) referred to the functional relationship between suction stress and suction for a given soil under a certain stress state as the suction stress characteristic curve (SSCC). In order to define the SSCC, Lu et al. (2010) made a similar assumption to Bolzon and Schrefler (1995) that the effective stress parameter in Equation (4) is equal to the effective saturation  $S_e$ , which permits a SWRC model such that that of van Genuchten (1980) to be incorporated into the definition of  $\sigma_s$  as follows:

$$\sigma_s = -\frac{S_e}{\alpha} \left\{ S_e^{\frac{n}{n-1}} - 1 \right\}^{\frac{1}{n}} \quad (6)$$

The drying path SWRC for Boulder clay along with the SSCC estimated using Equation (6) are shown in Figure 8(a). Consistent with the silty soil evaluated by Lu et al. (2010) and for soils with a van Genuchten (1980) SWRC when  $n$  parameter is greater than 2.5, the SSCC exhibits a peak value at a mid-range of suction. This indicates that suction has an optimal effect on the effective stress at mid-range values of effective saturation.

One of the challenges in applying Equation (5) in a comparison between the drained and undrained shear strength values is the selection of the air pressure to use in the definition of the net stress  $(\sigma - u_a)$ . This may be obtained using the pore pressure analysis of Hilf (1948), who combined Boyle's law and a simplified form of Henry's law to estimate the change in pore air pressure expectation during changes in porosity of unsaturated soils under undrained conditions. He assumed that the matric suction does not significantly change during undrained compression, which was later confirmed by Bishop and Donald (1961) and Rahardjo (1990). In this case, the change in pore air pressure  $(\Delta u_a)$  is equal to the change in pore water pressure  $(\Delta u_w)$ . Considering the volumetric strain of the unsaturated soil under undrained compression [i.e.,

370  $\Delta n = m_v(\Delta p - \Delta u_a)$ , the change in pore air pressure ( $\Delta u_a$ ) with a change in total cell pressure ( $\Delta \sigma_3$ )  
371 can be expressed as follows:

$$\Delta u_a = \left[ \frac{1}{1 + \frac{(1 - S_{r,0} + hS_{r,0})n_0}{(u_{a0} + \Delta u_a)m_v}} \right] \Delta \sigma_3 \quad (7)$$

372 where  $S_{r,0}$  is the initial degree of saturation,  $n_0$  is the initial porosity,  $h$  is the volumetric  
373 coefficient of solubility assumed to be 0.02,  $u_{a0}$  is the initial absolute pore-air pressure which  
374 assumed to be atmospheric (i.e., 101.3 kPa), and  $m_v$  is the coefficient of volume compressibility  
375 of soil obtained from undrained compression tests on this clay performed by Mun and  
376 McCartney (2015). An iterative approach is needed to solve for the change in air pressure ( $\Delta u_a$ )  
377 to satisfy Equation (7) because the unknown term ( $\Delta u_a$ ) appears on both sides of the equation.  
378 The relationship between pore-air pressure and total stress estimated by using Equation (7) using  
379 the input values summarized in Table 5 is shown in Figure 8(b). For the change in total stress  
380 during application of the cell pressure (207 kPa), the difference in the change in pore air pressure  
381 was not significant for the specimens having different initial degrees of saturation. For  
382 simplicity, an average change in pore air pressure of 6.3 kPa was incorporated in Equation (5) to  
383 define the initial effective stress in the UU tests.

384 A comparison between the measured (undrained) values of  $(\sigma_1 - \sigma_3)_f$  obtained from the UU  
385 tests and the estimated (drained) value of  $(\sigma_1 - \sigma_3)_f$  using Equation (3) as a function of the initial  
386 suction is shown in Figure 8(c). The range of average undrained shear strength  $(\sigma_1 - \sigma_3)_{f,ave}$  values  
387 measured under the different axial strain rates is also shown in this figure. In order to calculate  
388 the effective confining stress ( $\sigma'_3$ ) as part of the estimate of the drained shear strength in  
389 Equation (3), the suction stress ( $\sigma_s$ ) estimated using Equation (6) was subtracted from the applied

390 net stress ( $\sigma_{net}$ ) following Equation (5). The drained friction angle ( $\phi'$ ) was assumed to be  
391 constant with suction for this calculation. Similar to the shape of the SSCC, the suction has the  
392 greatest effect on the drained value of  $(\sigma_1 - \sigma_3)_f$  at intermediate suction values near or above the  
393 air entry suction but below the suction at the inflection point of the SWRC. This indicates that  
394 the initial suction should not play a significant role in the shear strength of soils under high  
395 suctions due to the lower availability of water in the pores to hold the particles together via  
396 capillarity or adhesion. Several interesting conclusions can be drawn when comparing the values  
397 of  $(\sigma_1 - \sigma_3)_f$  for drained and undrained conditions. The values of  $(\sigma_1 - \sigma_3)_f$  from the UU tests are  
398 lower than those expected in drained conditions for the specimens compacted wet of optimum  
399 (compaction water contents of 17.6 and 19.3%). As the degree of saturation in these tests is 0.9  
400 or greater, it is likely that the pore water phase is continuous throughout the soil specimens and  
401 the pore air phase is occluded. In this case, the comparison between the values of  $(\sigma_1 - \sigma_3)_f$  for  
402 drained and undrained conditions indicates that positive excess pore water and pore air pressures  
403 were likely generated during undrained shear, leading to a reduction in effective stress and  
404 potentially a reduction in suction. This explanation of the behavior at low initial suctions is  
405 consistent with the observations of Svoboda and McCartney (2014), who measured positive  
406 excess pore water pressures during CU tests on Boulder clay regardless of the initial suction  
407 value. However, the values of  $(\sigma_1 - \sigma_3)_f$  from the UU tests are greater than those in drained  
408 conditions for the specimens compacted dry of optimum (compaction water contents of 11.5 and  
409 13.5%). At these lower initial degrees of saturation (approximately 0.6 to 0.7), it is likely that the  
410 pore air phase is continuous throughout the specimen and the pore water phase is occluded.  
411 Although it is possible that negative excess pore water pressures could be generated in drier  
412 conditions leading to an increase in effective stress, it is more likely that positive pore air

413 pressure would be generated due to the compression of air voids leading to a decrease in  
414 effective stress. Accordingly, it is believed that the difference in  $(\sigma_1 - \sigma_3)_f$  for the specimens  
415 compacted wet of optimum (low suctions) and dry of optimum (high suctions) is due to  
416 dispersed or flocculated soil structures (Mitchell et al. 1965). However, the greater values of  
417  $(\sigma_1 - \sigma_3)_f$  for the specimens compacted at a water content of 13.5% than those compacted at a  
418 water content of 11.5% is due to the impact of initial suction, as suction still has an impact on the  
419 drained shear strength at this range of suction values. Accordingly, the similar trends between the  
420 measured (undrained) and the estimated (drained) shear strength with suction can be expected  
421 regardless of the impact of compacting wet or dry of optimum.

**422 CONCLUSIONS**

423 Unconsolidated undrained (UU) triaxial tests were performed at increased loading rates to  
424 investigate the effects of strain rate on the undrained shear strength quantified using the  
425 maximum principal stress difference  $(\sigma_1 - \sigma_3)_f$  of a low plasticity clay at different initial  
426 compaction water contents. The following specific conclusions can be drawn from this study:

- 427 • The value of  $(\sigma_1 - \sigma_3)_f$  for compacted Boulder clay increases by approximately 4.1 to 9.7%  
428 per log cycle of axial strain rate, with a greater rate for specimens that are compacted dry of  
429 optimum.
- 430 • The increase in undrained shear strength with increasing strain rate can be associated with  
431 less excess pore air or pore water pressure during shearing at faster rates. A corresponding  
432 increase in secant modulus with strain rate indicates that specimens sheared at faster rates  
433 should undergo less deformation than the one that contributes to excess pore water pressure  
434 generation.

- 435 • The rate effects were observed to be similar regardless of the initial degree of saturation,  
436 indicating that although the excess pore air and pore water pressures at different initial  
437 degrees of saturation may differ they offset and have the same net effect on the effective  
438 stress state.
- 439 • Clays compacted at or above the line of optimums are expected to experience positive excess  
440 pore water pressure generation during shear similar to the saturated soils under the same  
441 stress state, and have lower undrained shear strength than drained shear strength.
- 442 • Clays compacted below the line of optimums are also expected to experience positive excess  
443 pore water pressure generation during shear similar to saturated soils under the same stress  
444 state, but will have a greater undrained shear strength than drained shear strength due to  
445 flocculated conditions associated with compaction.
- 446 • If the compaction effects on the soil structure are neglected, the trends in undrained shear  
447 strength with initial suction are similar to trends in drained shear strength with initial suction.

**LIST OF TABLE AND FIGURE CAPTIONS**

**Table 1:** Summary of strain rate effects on undrained shear strength of cohesive soils

**Table 2:** Properties of Boulder clay

**Table 3:** Initial specimen information for UU tests on Boulder clay

**Table 4:** Summary of UU test results

**Table 5:** Summary of the input values for the application of Hilf's analysis (1948)

**Fig. 1:** Boulder clay properties: (a) Standard Proctor compaction curve with initial compaction conditions of tested specimens; (b) Evaluation of typical initial suction values in compacted specimens; (c) Wetting- and drying-path soil water retention curves along with the

**Fig. 2:** Results from UU triaxial compression tests on compacted clay with different gravimetric water contents but the same initial void ratio of 0.52 (Each curve is an average of 3 curves): (a)  $w=11.5\%$ ; (b)  $w=13.5\%$ ; (c)  $w=17.6\%$ ; (d)  $w=19.3\%$

**Fig. 3:** (a) Principal stress difference at failure for specimens having different initial water contents plotted as a function of axial strain rate; (b) Strains at failure as a function of different axial strain rates

**Fig. 4:** Trends in the log-linear slope of the undrained shear strength vs. axial strain rate: (a) Impact of initial degree of saturation  $S_{r,i}$ ; (b) Impact of initial  $\psi_i$

**Fig. 5:** Axial strain rate effects on the principal stress difference at failure for compacted clay specimens having different: (a) Initial degrees of saturation  $S_{r,i}$ ; (b) Initial suction  $\psi_i$  values

**Fig. 6:** Impact of axial strain rate on the secant modulus

586 **Fig. 7:** Strain rate effects on the secant modulus of compacted clay specimens having different:  
587 (a) Initial degrees of saturation  $S_{r,i}$ ; (b) initial suction  $\psi_i$  values

588 **Fig. 8:** (a) Suction stress characteristic curve for Boulder clay estimated from the drying path  
589 SWRC; (b) Predicted pore air pressure development for Boulder clay during total stress  
590 application using the analysis of Hilf (1948); (c) Comparison between all values of  
591  $(\sigma_1 - \sigma_3)_f$  measured in the UU triaxial compression tests with those expected in drained  
592 triaxial compression tests

593 **Table 1: Summary of strain rate effects on undrained shear strength of cohesive soils**

Reference	Soil description	Ave. LL	Ave. PI	Specimen type and stress history	Shearing approach	Specimen height (mm)	Max. axial strain rate (%/min) or min. time to "failure" (s)	Approx. % increase in undrained shear strength per log cycle of axial strain rate
Casagrande & Shannon (1948)	Saturated Cambridge clay (CL)	41	19	Intact and remolded, NC	Stress (fast) and strain (slow) controlled	90	0.01 s	15.0
Casagrande & Shannon (1948)	Saturated Boston clay (CL)	42	22	Intact and remolded, NC	Stress (fast) and strain (slow) controlled	90	0.1 s	13.0
Casagrande & Shannon (1948)	Saturated Stockton clay (CH)	62	40	Intact and remolded, OC	Stress (fast) and strain (slow) controlled	90	0.1 s	8.0
Richardson & Whitman (1963)	Saturated Mississippi River Clay (CH)	62	38	Remolded, NC and OC	Strain controlled with PWP	80	1 %/min	3.7
Olson & Parola (1967)	Unsaturated Goose Lake clay (CL)	31	14	Compacted	Stress (fast) and strain (slow) controlled	76	0.002-1s (fast) 1s – 100min (slow)	$\sigma_3=690$ kPa: 5.7-23.8 (fast), 1.3-5.4 (slow); $\sigma_3=6900$ kPa: 13.3-27.6 (fast), 1.4-8.2 (slow)
Vaid & Campanella (1977)	Saturated Haney clay (CL)	44	18	Intact, NC	Strain controlled with PWP	NR	10 %/min	7.0
Lew (1981)	Winnipeg clay (CH)	80	56	Intact, OC	Strain controlled with PWP	152	0.167 %/min	11.0-12.0
Graham et al. (1983)	Saturated Belfast clay (CH)	93	60	Intact, OC	Strain controlled with PWP	NR	0.167 %/min	9.7-13.4
Nakase et al. (1986)	Saturated sand-clay mixtures (M30 - CH)	55	29	Remolded, anisotropic	Strain controlled with PWP	NR	0.7 %/min	10.6
Nakase et al. (1986)	Saturated sand-clay mixtures (M15 - CL)	35	15	Remolded, anisotropic	Strain controlled with PWP	NR	0.7 %/min	6.5
Nakase et al. (1986)	Saturated sand-clay mixtures (M10 - CL)	28	11	Remolded, anisotropic	Strain controlled with pore water pressure	NR	0.7 %/min	5.0
Lefebvre & LeBoeuf (1987)	Saturated Grande Baleine clay (CL)	34	12	Intact, isotropic, anisotropic	Stress (fast) and strain (slow) controlled	71	100 %/min	7.0-9.0
Lefebvre & LeBoeuf (1987)	Saturated Olga clay (CH)	68	40	Intact, isotropic, anisotropic	Stress (fast) and strain (slow) controlled	71	100 %/min	12.0-13.0
Penumadu et al. (1998)	Saturated Kaolin (CH)	63	30	Remolded, NC	Strain controlled with PWP	102	5 %/min	14.3
Penumadu et al. (1998)	Saturated Kaolin-silica mix (CH)	63	30	Remolded, NC	Strain controlled with PWP	102	5 %/min	15.3
Zhu & Yin (2000)	Saturated Hong Kong Marine clay (CH)	60	32	Remolded, NC and OC	Strain controlled with PWP	100	0.25 %/min	3.0-6.0
Svoboda & McCartney (2014)	Compacted Boulder clay (CL)	43	22	Compacted	Strain controlled with PWP	142	14.5 %/min	14.1 (saturated) 6.2-15.2 (unsaturated)
