(Dated: January 22, 2021)

The study of lepton flavor universality violation (LFUV) in semitauonic b -hadron decays has become increasingly important in light of longstanding anomalies in their measured branching fractions, and the very large datasets anticipated from the LHC and Belle II. In this review, we undertake a comprehensive survey of the experimental environments and methodologies for semitauonic LFUV measurements at the B -factories and LHCb, along with a concise overview of the theoretical foundations and predictions for a wide range of semileptonic decay observables. We proceed to examine the future prospects to control systematic uncertainties down to the percent level, matching the precision of Standard Model (SM) predictions. Furthermore, we discuss new perspectives and caveats on combinations of the LFUV data and revisit the world averages for the $\mathcal{R}(D^{(*)})$ ratios. Here we demonstrate that different treatments for the correlations of uncertainties from D^{**} excited states can vary the current 3σ tension with the SM within a 1σ range. Prior experimental overestimates of $D^{**}\tau\nu$ contributions may further exacerbate this. The precision of future measurements is also estimated; their power to exploit full differential information, and solutions to the inherent difficulties in self-consistent new physics interpretations of LFUV observables, are briefly explored.

To be submitted to *Reviews of Modern Physics*.

I. INTRODUCTION

Over the past decade, collider experiments have provided ever-more precise measurements of Standard Model (SM) parameters, while direct collider searches for new interactions or particles have yielded ever-more stringent bounds on New Physics (NP) beyond the SM. This, in turn, has brought renewed attention to the NP discovery potential of indirect searches: measurements that compare the interactions of different species of elementary SM particles to SM expectations.

A key feature of the Standard Model is the universality of the electroweak gauge coupling to the three known fermion generations or families. In the lepton sector, this universality results in an accidental lepton flavor symmetry, that is broken in the SM (without neutrino mass terms) only by Higgs Yukawa interactions responsible for generating the charged lepton masses. A key prediction, then, of the Standard Model is that physical processes involving charged leptons should feature a *lepton flavor universality*: an approximate lepton flavor symmetry among physical observables, such as decay rates or scattering cross-sections, that is broken in the SM only by charged lepton mass terms in the amplitude and phase space. (Effects of additional Dirac or Majorana neutrino mass terms in extensions of the SM are negligible in all contexts we consider.) In the common parlance of the literature, testing for lepton flavor universality violation (LFUV) in any particular process thus refers to measuring deviations in the size of lepton flavor symmetry breaking versus SM predictions.

An observation of LFUV would clearly establish the presence of physics beyond the Standard Model, and could thus provide an indirect window into resolutions of the nature of dark matter, the origins of the matter-antimatter asymmetry, or the dynamics of the electroweak scale itself. Decades of LFUV measurements have yielded results predominantly in agreement with SM predictions. Various strong constraints have been obtained from (semi)leptonic decays of light hadrons, gauge bosons, or leptonic τ decays (see e.g. (Zyla *et al.*, 2020)), among a plethora of many other measurements. A notable recent addition is the measurement of $\mathcal{B}(W \rightarrow \tau\nu)/(W \rightarrow \mu\nu)$ (Aad *et al.*, 2020), resolving a long-standing LFUV anomaly from LEP that deviated from the SM prediction at 2.7σ . Moreover, sources of LFUV that implicate NP interactions with the first two quark generations are typically strongly constrained by e.g. precision $K-\bar{K}$ and $D-\bar{D}$ mixing measurements. Such LFUV bounds involving third generation quarks, however, are typically much weaker (Cerri *et al.*, 2019).

This review focusses on the rich experimental landscape for testing LFUV in semileptonic b -hadron decays. Not only do these decays provide a high statistics laboratory to measure LFUV that is (relatively) theoretically-clean, but results from the last decade of measurements have indicated anomalously high rates for various semitauonic $b \rightarrow c\tau\nu$ decays compared to precision SM predictions. In particular, the ratios

$$\mathcal{R}(D^{(*)}) = \frac{\mathcal{B}(B \rightarrow D^{(*)}\tau\nu)}{\mathcal{B}(B \rightarrow D^{(*)}\ell\nu)}, \quad \ell = e, \mu, \quad (1)$$

where $D^{(*)}$ refers to both D and D^* mesons, deviate from SM predictions at the 3σ level when taken together (Amhis *et al.*, 2019). (We revisit later the construction of these world averages and their degree of tension with the SM.) Apart from these results, there are additional measurements for various other $b \rightarrow c\tau\nu$ decays and other observables, including $\mathcal{R}(J/\psi)$, the τ polarization and D^* longitudinal fractions (see Sec. IV). Some of these measurements presently agree with SM predictions only at the $1.6 - 1.8\sigma$ level, and when combined with $\mathcal{R}(D^{(*)})$ can mildly increase the degree of tension with the SM. Some tensions also currently exist in several $b \rightarrow see$ versus $b \rightarrow s\mu\mu$ transitions, each at the 2.5σ level (Aaij *et al.*, 2017b, 2019c).

Upcoming runs of the LHC, the high-luminosity (HL)-LHC, and Belle II will yield large new datasets for a wide range of $b \rightarrow c\tau\nu$ and $b \rightarrow u\tau\nu$ processes. Given this expected deluge of data, it is important to review and synthesize our understanding of the various strategies and channels through which LFUV might be discovered. To this end, we undertake this review along two different threads. First, in Sec. II we provide a compact yet comprehensive overview of the current theoretical state-of-the-art for the SM (and NP) description of semitauonic

decays. This includes not only a survey of SM predictions in the literature, but also several novel results first calculated for this review.

Second, we provide a substantial review of the various experimental methods and strategies used to measure LFUV. This includes an assessment of the various experimental methods in Sec. III, and a summary of the LFUV measurements published to date in Sec. IV. An effort has been made to synthesize all of the available information from current measurements and, when possible, to make direct comparisons across experiments that provide further context. For instance, we present the various approaches towards reconstructing the momentum of the parent b -hadron in Sec. III.C and provide a comparison between the two hadronic B tag measurements of $\mathcal{R}(D^{(*)})$ by *BABAR* and *Belle* in Sec. IV.A.1.

These two threads of the review are woven in Secs. V and VI into discussions of the main challenges arising from systematic uncertainties, and into discussions of current interpretations and combinations of the data, respectively. In particular, in Sec. V we provide an extended analysis of the main sources of systematic uncertainty in the LFUV measurements, and the prospects to control them in the future down to the percent level. This will be essential for establishing a conclusive tension with the Standard Model. We examine key challenges in computation, the modeling of b -hadron semileptonic decays in signal and background modes, and estimations of other important backgrounds. We also point out the potential sensitivity of $\mathcal{R}(D^{(*)})$ analyses to the assumptions used for the $B \rightarrow D^{**}\tau\nu$ branching fractions (Sec. V.C.2), which are presently overestimated compared to SM predictions.

Section VI begins by examining the $\mathcal{R}(D^{(*)})$ results and other SM tensions for different light-lepton normalization modes or isospin channels, before turning to revisit entirely the world average combinations of the $\mathcal{R}(D^{(*)})$ ratios. We specifically analyze the sensitivity of these combinations to the treatment of the correlation structure assigned to the uncertainties from $B \rightarrow D^{**}l\nu$ decays across different measurements, and show they may vary the degree of their current $\sim 3\sigma$ tension with the SM over approximately a 1σ range. As an illustration, incorporating such correlations as a free fit parameter in the combination, we show that the resulting $\mathcal{R}(D^{(*)})$ world averages would feature a tension of 3.6 standard deviations with respect to the SM. This is 0.5σ higher than the current world average (Amhis *et al.*, 2019). We further explore a comparison of inclusive versus exclusive measurements; caveats and challenges in establishing NP interpretations of the current $\mathcal{R}(D^{(*)})$ anomalies; and possible connections to anomalies in neutral current rare B decays.

Beyond the current state-of-the-art, in Sec. VII we proceed to explore the power of future LFUV ratio measurements for a variety of hadronic states, taking into account

the discussed prospects for the evolution of the systematic uncertainties and the data samples that LHCb and Belle II are expected to collect over the next two decades (Sec. VII.A). The power of future analyses to exploit full differential information is briefly explored (Sec. VII.B), as well as the role of proposed future colliders (Sec. VII.C).

II. THEORY OF SEMILEPTONIC DECAYS

In this section we introduce the foundational theoretical concepts required to describe $b \rightarrow cl\nu$ semileptonic decays. Throughout this review, we adopt the notation

$$l = \tau, \mu, e, \quad \ell = \mu, e. \quad (2)$$

While our focus is the Standard Model (SM) description of $b \rightarrow cl\nu$, in some contexts we shall present a model-independent discussion, in order to accommodate discussion of beyond Standard Model (BSM) physics. We discuss first $B \rightarrow D^{(*)}l\nu$ decays, since they are of predominant experimental importance in current measurements, before turning to processes involving excited states, charm-strange mesons, charmonia, baryons, as well as $b \rightarrow ul\nu$ and inclusive processes. The LFUV observables (anticipating their definitions below) for which predictions are discussed, and their respective sections, comprise:

| | | | |
|--------------------------|-------------|--|-------------|
| $\mathcal{R}(D^{(*)})$: | Sec. II.D.1 | $F_L(D^*), P_\tau(D^{(*)})$: | Sec. II.D.2 |
| $\mathcal{R}(D^{**})$: | Sec. II.E | $\mathcal{R}(D_s^{(*)})$: | Sec. II.E |

A. SM operator and amplitudes

In the SM, $b \rightarrow cl\nu$ processes are mediated by the weak charged current, generating the usual $V - A$ four-Fermi operator

$$\mathcal{O}_{\text{SM}} = 2\sqrt{2}G_F V_{cb} (\bar{c}\gamma^\mu P_L b) (\bar{l}\gamma_\mu P_L \nu_l), \quad (3)$$

at leading electroweak order. Here the projectors $P_{L,R} = (1 \mp \gamma^5)/2$, and $G_F^{-1} = 8m_W^2/(\sqrt{2}g_2^2) = \sqrt{2}v^2$, with $v \simeq 246.22$ GeV and g_2 denoting the $SU(2)$ weak coupling constant. In diagrammatic language, the corresponding amplitude for this charged current process

$$\mathcal{A}_{\text{SM}} = \begin{array}{c} b \\ \swarrow \\ \text{---} g_2 V_{cb}^* / \sqrt{2} \\ \searrow \\ W^- \\ \swarrow \quad \searrow \\ \bar{l} \quad \nu_l \\ \text{---} g_2 / \sqrt{2} \end{array}, \quad (4)$$

Figure 1 Left: Definition of the θ_l and ϕ_l helicity angles in the lepton pair rest frame. Center: Definition of the θ_v and ϕ_v helicity angles in the D^* rest frame. Right: Definition of the θ_h and ϕ_h helicity angles in the τ rest frame, for $B \rightarrow D^{(*)}(\tau \rightarrow h\nu)\bar{\nu}$ decay.

in which the quarks may be ‘dressed’ into various different hadrons. It is conventional to define the momentum $q = p - p' = p_l + p_\nu$ where p (p') is the beauty (charm) hadron momentum.

The leptonic amplitude $W \rightarrow \ell\nu$ always take the form of a Wigner- D function $D_{m_1, m_2}^j(\theta_l, \phi_l)$, with $j = 0$ or 1 , and $|m_{1,2}| \leq j$. The helicity angle θ_l is defined herein as in Fig. 1. We show also in Fig. 1 the definition of helicity angles for subsequent $D^* \rightarrow D\pi$ or $\tau \rightarrow h\nu$ decays, for example, where h is any hadronic system or $\ell\nu$. The helicity angle definition also applies for the case of $D^* \rightarrow D\gamma$, though with a different fully differential rate. Some literature uses the definition $\theta_l \rightarrow \pi - \theta_l$, such that caution must be used in adapting fits to fully differential measurements from one convention to the other. The phase ϕ_l is unphysical unless defined with reference to spin-polarizers of the charm or beauty hadronic system or the lepton, such as the subsequent decay kinematics of the τ or charm hadron, or the spin of the initial b -hadron. For example, in $B \rightarrow (D^* \rightarrow D\pi)\ell\nu$, the only physical phase is $\chi \equiv \phi_l - \phi_v$.

B. Hadronic matrix elements and form factors

The predominant theory uncertainty in $B \rightarrow D^{(*)}\ell\nu$ arises in the description of the hadronic matrix elements $\langle D^{(*)}|\bar{c}\Gamma b|\bar{B}\rangle$,¹ where (anticipating a discussion of New Physics (NP) below) Γ is any Dirac operator. More generally, one seeks a theoretical framework to describe the matrix elements $\langle 2s_c+1(L^c)_{J_c}|\bar{c}\Gamma b|2s_b+1(L^b)_{J_b}\rangle$, using here the spectroscopic notation to describe the hadron

¹ All definitions and sign conventions below apply to $b \rightarrow c$ transitions; they may be extended to $\bar{b} \rightarrow \bar{c}$ with appropriate sign changes. To emphasize this, while we do not typically distinguish between $\bar{B} \rightarrow D^{(*)}$ and $B \rightarrow \bar{D}^{(*)}$ in this discussion, we do retain such notation in the explicit definition of matrix elements or where charge assignments of other particles have been made explicit. Throughout the review, inclusion of charge-conjugate decay modes is implied, unless stated otherwise.

in terms of its quark constituents’ total spin s , their orbital angular momentum $L = S, P, D, \dots$, and the total angular momentum of the hadron J . We focus first on the description for $B \rightarrow D^{(*)}$, i.e. $^1S_0 \rightarrow ^1S_0$ or 3S_1 : The ground state charmed mesons.

For $B \rightarrow D^{(*)}$ SM transitions, the matrix elements are represented by two (four) independent form factors. In terms of three common form factor bases,

$$\begin{aligned} \langle D|\bar{c}\gamma^\mu b|\bar{B}\rangle &= f_+(p+p')^\mu \\ &+ (f_0 - f_+)q^\mu(m_B^2 - m_D^2)/q^2 \end{aligned} \quad (5a)$$

$$\begin{aligned} \langle D^*|\bar{c}\gamma^\mu b|\bar{B}\rangle &= 2i\tilde{g}\varepsilon^{\mu\nu\alpha\beta}\epsilon_\nu^*p'_\alpha p_\beta \\ &= i\sqrt{m_B m_{D^*}}h_V\varepsilon^{\mu\nu\alpha\beta}\epsilon_\nu^*v'_\alpha v_\beta \end{aligned} \quad (5b)$$

$$\begin{aligned} \langle D^*|\bar{c}\gamma^\mu\gamma^5 b|\bar{B}\rangle &= f\epsilon^{*\mu} + a_+\epsilon^*\cdot p(p+p')^\mu + a_-(\epsilon^*\cdot p)q^\mu \\ &= \sqrt{m_B m_{D^*}}[h_{A_1}(w+1)\epsilon^{*\mu} \\ &- h_{A_2}(\epsilon^*\cdot v)v^\mu - h_{A_3}(\epsilon^*\cdot v)v'^\mu], \\ &= A_1(m_B + m_{D^*})\epsilon^{*\mu} - A_2\frac{\epsilon^*\cdot p(p+p')^\mu}{m_B + m_{D^*}} \\ &+ 2m_{D^*}q^\mu(A_0 - A_3)(\epsilon^*\cdot p)/q^2, \end{aligned} \quad (5c)$$

noting $\langle D|\bar{c}\gamma^\mu\gamma^5 b|\bar{B}\rangle = 0$ because of angular momentum and parity conservation. Here we have used the spectroscopic basis $\{f_+, f_0, f, \tilde{g}, a_\pm\}$;² the heavy quark symmetry (HQS) basis $\{h_\pm, h_V, h_{A_{1,2,3}}\}$; and the basis $\{V, A_{0,1,2,3}\}$, in which $2m_{D^*}A_3 = A_1(m_B + m_{D^*}) - A_2(m_B - m_{D^*})$. The velocities $v = p/m_B$ and $v' = p'/m_{D^{(*)}}$, and the recoil parameter

$$w = v \cdot v' = \frac{m_B^2 + m_{D^{(*)}}^2 - q^2}{2m_B m_{D^{(*)}}}. \quad (6)$$

The form factors are functions of q^2 or equivalently w . Their explicit forms may also involve the scheme-dependent parameters m_b/m_c and α_s , though any such scheme-dependency must vanish in physical quantities. In the HQS basis, h_{A_1} , and the three form factor ratios

$$\begin{aligned} R_1(w) &= \frac{h_V}{h_{A_1}}, \quad R_2(w) = \frac{h_{A_3} + r^* h_{A_2}}{h_{A_1}}, \quad \text{and} \quad (7) \\ R_0(w) &= \frac{(w+1)h_{A_1} - (w-r^*)h_{A_3} - (1-wr^*)h_{A_2}}{(1+r^*)h_{A_1}}, \end{aligned}$$

where $r^{(*)} = m_{D^{(*)}}/m_B$, fully describe the $B \rightarrow D^*$ transition, noting R_0 enters only in terms proportional to m_l .

Particular care must be taken with sign conventions in Eqs. (5): For $B \rightarrow D^{(*)}$, the conventional choice in the literature, and here, is such that $\text{Tr}[\gamma^\mu\gamma^\nu\gamma^\sigma\gamma^\rho\gamma^5] =$

² The form factor \tilde{g} is often written as g , but should not be confused with $g = 2\tilde{g}$ in the helicity basis below.

$+4i\varepsilon^{\mu\nu\rho\sigma}$, equivalent to fixing the identity $\sigma^{\mu\nu}\gamma^5 \equiv -(i/2)\varepsilon^{\mu\nu\rho\sigma}\sigma_{\rho\sigma}$, with $\sigma_{\mu\nu} = (i/2)[\gamma^\mu, \gamma^\nu]$. One may further choose either $\varepsilon^{0123} = +1$ or -1 . In $B \rightarrow D^{**}$ literature, as well as $\Lambda_b \rightarrow \Lambda_c$, typically the choice is instead $\text{Tr}[\gamma^\mu\gamma^\nu\gamma^\sigma\gamma^\rho\gamma^5] = -4i\varepsilon^{\mu\nu\rho\sigma}$, equivalent to $\sigma^{\mu\nu}\gamma^5 \equiv +(i/2)\varepsilon^{\mu\nu\rho\sigma}\sigma_{\rho\sigma}$. These sign choices affect the sign of R_1 , but leave physical quantities unchanged provided they are used consistently both in the form factor definitions *and* in the calculation of the amplitudes. Care must be taken in adapting form factor fit results obtained in one convention to expressions defined in the other. In our sign conventions, the form factor ratio $R_1 > 0$.

An additional common choice for $B \rightarrow D^*$ decays is the helicity basis (cf. (Boyd *et al.*, 1996, 1997)), with form factors $\{g, f, F_1, P_1\}$, that are particularly convenient for expressing the $B \rightarrow D^*$ helicity amplitudes. Explicit relations between the HQS and helicity bases are

$$h_{A_1} = \frac{f}{m_B\sqrt{r^*(w+1)}}, \quad h_V = gm_B\sqrt{r^*} \quad (8a)$$

$$h_{A_1}(w - r^* - (w-1)R_2) = \frac{F_1}{m_B^2\sqrt{r^*(w+1)}}, \quad (8b)$$

$$h_{A_1}R_0 = P_1. \quad (8c)$$

The SM differential rate can then be written compactly in terms of Legendre polynomials of $\cos\theta_l$,

$$\begin{aligned} \frac{d^2\Gamma}{dw d\cos\theta_\ell} = & 2\Gamma_0\sqrt{w^2-1}r^{*3}\left[\frac{\bar{q}^2-r_l^2}{\bar{q}^2}\right]^2 \left\{ \right. \\ & \left(1 + \frac{r_l^2}{2\bar{q}^2}\right)(\mathcal{H}_+ + 2\bar{q}^2\mathcal{H}_1) + \frac{3r_l^2}{2\bar{q}^2}\mathcal{H}_0 \\ & \left. + \cos\theta_l\mathcal{H}_{+0} + \frac{3\cos^2\theta_l-1}{2}\left[\frac{\bar{q}^2-r_l^2}{\bar{q}^2}\right](\bar{q}^2\mathcal{H}_1 - \mathcal{H}_+)\right\}, \end{aligned} \quad (9)$$

in which $\Gamma_0 \equiv G_F^2\eta_{\text{EW}}^2|V_{cb}|^2/(192\pi^3)$, $r_l = m_l/m_B$, $\bar{q}^2 = q^2/m_B^2 = 1 - 2r^*w + r^{*2}$, $\eta_{\text{EW}} \simeq 1 + \alpha/\pi \log(m_Z/m_B) \simeq 1.0066$ is an electroweak correction (Sirlin, 1982), and

$$\mathcal{H}_1 = \frac{f^2}{r^*m_B^2} + g^2r^*m_B^2(w^2-1), \quad (10a)$$

$$\mathcal{H}_+ = \frac{F_1^2}{r^*m_B^4}, \quad (10b)$$

$$\mathcal{H}_0 = P_1^2(r^*+1)^2(w^2-1), \quad (10c)$$

$$\mathcal{H}_{+0} = 6\bar{q}^2fg\sqrt{w^2-1} - \frac{3r_l^2}{\bar{q}^2}\sqrt{\mathcal{H}_+\mathcal{H}_0}. \quad (10d)$$

The θ_l -independent term in Eq. (9) is simply $1/2 d\Gamma/dw$. The overall sign of the $\cos\theta_l$ term, and the relative sign of the fg term in \mathcal{H}_{+0} , are sensitive to sign conventions. In the massless lepton limit, it is common to express the differential rate $d\Gamma/dw$ in terms of the single form factor combination

$$\mathcal{F}^2(w) = \frac{\mathcal{H}_+ + 2\bar{q}^2\mathcal{H}_1}{(1-r^*)^2(w+1)^2 + 4w(w+1)\bar{q}^2}, \quad (11)$$

normalized such that $\mathcal{F}(1) = h_{A_1}(1)$.

The $B \rightarrow D$ rate may be expressed similarly. In the form factor basis $\{\mathcal{G} \equiv V_1, S_1\}$,³ defined via

$$\mathcal{G} \equiv V_1 = h_+ - \frac{1-r}{1+r}h_-, \quad (12a)$$

$$S_1 = h_+ - \frac{1+r}{1-r}\frac{w-1}{w+1}h_-, \quad (12b)$$

the SM differential rate has the same form as Eq. (9) and Eqs. (10), but with $r^* \rightarrow r$,

$$\mathcal{H}_+ = V_1^2(1+r)^2(w-1)^2, \quad (13a)$$

$$\mathcal{H}_0 = S_1^2(1-r)^2(w+1)^2, \quad (13b)$$

and, by definition, no f or g terms, i.e. $\mathcal{H}_1 = 0$ and $\mathcal{H}_{+0} = -3r_l^2/\bar{q}^2\sqrt{\mathcal{H}_+\mathcal{H}_0}$.

Note that the expressions of this section apply similarly to any other $^1S_0 \rightarrow ^1S_0$ or 3S_0 transition, such as $B \rightarrow \pi l\nu$ or $B \rightarrow \rho l\nu$ (with the additional replacement of $V_{cb} \rightarrow V_{ub}$).

C. Theoretical frameworks

Various theoretical approaches exist to parametrize the $B \rightarrow D^{(*)}$ or other exclusive decay form factors. Broadly, these fall into four overlapping categories:

1. Use of the functional properties of the hadronic matrix elements – analyticity, unitarity, and dispersion relations – to constrain the form factor structure;
2. Use of heavy quark effective theory (HQET) to generate order-by-order relations in $1/m_{c,b}$ and α_s between form factors;
3. Various quark models, including those that may approximately compute the form factors (in various regimes), such as QCD sum rule (QCDSR) and light cone sum rule (LCSR) approaches; and
4. Lattice QCD (LQCD) calculations, presently available only for a limited subset of form-factors and kinematic regimes.

The details of the various approaches to the form factor parametrization are particularly important for measurements that are sensitive to the differential shape of exclusive semileptonic decays, such as the extraction of the CKM matrix element $|V_{cb}|$. Hadronic uncertainties, however, mostly factor out of observables that consider ratios of $|V_{cb}|$ -dependent quantities, including e.g. measurements that probe lepton universality relations between

³ Some literature uses the notation V_1 , while others \mathcal{G} .

the $B \rightarrow D^{(*)}\ell\nu$ and $B \rightarrow D^{(*)}\tau\nu$ decays or other exclusive processes. Instead, in the latter context, the main role and importance of form factor parametrizations lies in their ability to generate predictions for lepton universality relations, and the precision thereof.

1. Dispersive bounds

A dispersion relations-based approach does not alone generate lepton universality relations between the $B \rightarrow D^{(*)}\ell\nu$ rates or other exclusive processes, but does provide crucial underlying theoretical inputs to approaches that do. The dispersive approach (Boyd *et al.*, 1996, 1997) begins with the observation that the matrix element $\langle H_c|J|H_b\rangle$ for a hadronic transition $H_b \rightarrow H_c$, mediated by current $J = \bar{c}\Gamma b$, may be analytically continued beyond the physical regime $q^2 < (m_{H_b} - m_{H_c})^2 \equiv q_-^2$ into the complex q^2 plane. For $q^2 > (m_{H_b^0} + m_{H_c^0})^2 \equiv q_+^2$, where $H_{c,b}^0$ denote the lightest pair of hadrons that couple to J , the matrix element features a branch cut from the crossed process $H_b^0 H_c^0$ pair production. For $B \rightarrow D^*$ processes, it is typical to take $q_+ \equiv (m_B + m_{D^*})^2$ for both vector and axial vector currents. For e.g. $B_c \rightarrow J/\psi$, the branch points are taken as $(m_{B^{(*)}} + m_D)^2$ for (axial)vector currents. A bc bound state that is created by J but with mass $m^2 < q_+^2$, is a ‘subthreshold’ resonance.

The conformal transformation

$$z(q^2, q_0^2) = \frac{\sqrt{q_+^2 - q^2} - \sqrt{q_+^2 - q_0^2}}{\sqrt{q_+^2 - q^2} + \sqrt{q_+^2 - q_0^2}} \quad (14)$$

maps $|q^2| < q_+^2$ ($|q^2| > q_+^2$) to the interior (exterior) of the unit circle $|z| = 1$, centered at $q^2 = q_0^2$. Two common choices of q_0^2 are q_-^2 , in which case $z(w = 0) = 0$, or $q_+^2(1 - [1 - q_-^2/q_+^2]^{1/2}) \equiv q_{\text{opt}}^2$, which minimizes $|z(q^2 = 0)|$. This allows the matrix element to be written as an analytic function of z on the unit disc $|z| \leq 1$, up to simple poles that are expected at each ‘sub-threshold’ resonance. These poles must fall on the interval $q_-^2 \leq q^2 \leq q_+^2 \Leftrightarrow (0 \geq) z_- \geq z \geq -1$.

The second ingredient is the vacuum polarization $\Pi_J = i \int d^4x e^{iqx} \langle 0|T J^\dagger(x) J(0)|0\rangle$, which obeys a once-subtracted dispersion relation

$$\chi_J(q^2) \equiv \frac{\partial \Pi_J}{\partial q^2} = \frac{1}{\pi} \int \frac{dt}{(t - q^2)^2} \text{Im} \Pi_J. \quad (15)$$

The QCD correlator χ_J can be computed at one-loop in perturbative QCD for $q^2 > q_+^2$, and then analytically continued to $q^2 < q_+^2$. $\text{Im} \Pi_J$ may be re-expressed as a phase-space-integrated sum over a complete set of b - and c -hadronic states $\sim \sum_{X=H_b H_c^\dagger, \dots} |\langle 0|J|X\rangle|^2$ with appropriate parity and spin. E.g. for $J = \bar{c}\gamma^\mu b$, one may have $H_b H_c^\dagger = BD^\dagger, BD^{*\dagger}$ and so on. The positivity of each summand allows the dispersion relation to provide an upper bound—a so-called ‘weak’ unitarity bound—for any

given hadron pair $H_b H_c^\dagger$. (A ‘strong’ unitarity bound would, by contrast, impose the upper bound on a finite sum of hadron pairs coupling to J .) Crossing symmetry permits this bounds to be applied to the transition matrix elements $\langle H_c|J|H_b\rangle$ of interest here.

Making use of the conformal transformation, the unitarity bound can be expressed in the form

$$\int_{|z|=1} \frac{dz}{2\pi i z} \sum_i |P_i^J(z) \phi_i^J(z) F_i^J(z)|^2 \leq 1. \quad (16)$$

in which F_i^J is a basis of form factors and the ‘outer’ functions ϕ_i^J are analytic weight functions that encode both their q^2 -dependent prefactors arising in $\langle H_c|J|H_b\rangle$, as well as incorporating the $1/\sqrt{\pi\chi_J}$ prefactor. The additional Blaschke factors P_i^J satisfy $|P_i^J(|z|=1)| = 1$ by construction, and do not affect the integrand on the $|z| = 1$ contour. However, the choice $P_i^J = \prod_\alpha (z - z_{\alpha,i}) / (1 - z z_{\alpha,i})$ explicitly cancels the (known) poles at $z = z_{\alpha,i}$ on the negative real axis. Each term in the sum must then be analytic, i.e. $P_i^J(z) \phi_i^J(z) F_i^J(z) = \sum_{n=0}^\infty a_n^{Ji} z^n$, so that Eq. (16) requires the a_n^{Ji} coefficients to satisfy a unitarity bound $\sum_{i,n} |a_n^{Ji}|^2 \leq 1$.

The BGL parametrization (Boyd *et al.*, 1996, 1997) uses this approach to express the f, g, F_1 and P_1 form factors in terms of an analytic expansion in $z = z(q^2, q_-^2)$. In particular for the light lepton modes, with $F_A = f, F_1$,

$$g(z) = \frac{1}{P_V(z) \phi_g(z)} \sum_n a_n^g z^n, \quad \sum_n |a_n^g|^2 \leq 1,$$

$$F_A(z) = \frac{1}{P_A(z) \phi_{F_A}(z)} \sum_n a_n^{F_A} z^n, \quad \sum_{F_A, n} |a_n^{F_A}|^2 \leq 1,$$

noting $F_1(q_-^2)/\phi_{F_1}(q_-^2) = f(q_-^2)m_B(1 - r^*)/\phi_f(q_-^2)$ from Eq. (8b). This relatively unconstrained parameterization provides a hadronic model-independent approach to measuring $|V_{cb}|$ from light leptonic $B \rightarrow D^*\ell\nu$ modes, but does not relate $B \rightarrow D^*\tau\nu$ to $B \rightarrow D^*\ell\nu$: E.g. a fit to light lepton data, taking $m_\ell \rightarrow 0$, to determine f, g, F_1 provides no prediction for P_1 , and hence no prediction for the $B \rightarrow D^*\tau\nu$ rate. (The general SM expectation remains, however, that the unitarity bound for P_1 should not be violated in a direct fit to $B \rightarrow D^*\tau\nu$ data.) Instead, additional theoretical inputs are required.

2. Heavy quark effective theory

HQET inputs may be combined with the BGL approach, in order to generate SM (or NP) predictions for lepton universality observables. A ‘heavy’ hadron is defined as containing one heavy valence quark, i.e. $m_Q \gg \Lambda_{\text{QCD}}$, dressed by light quark and gluon degrees of freedom—so-called ‘brown muck’—in a particular spin-state. An HQET (Eichten and Hill, 1990; Georgi, 1990; Isgur and Wise, 1989, 1990) (for a review, see e.g. (Neubert, 1994)) is an effective field theory of the brown

muck, in which interactions with the heavy quark enter at higher orders in $1/m_Q$. An apt analogy arises in atomic physics in which the electronic states are insensitive to the nuclear spin state, up to hyperfine corrections. This provides a hadronic model-independent parametrization of not only the spectroscopy of heavy hadrons but also order-by-order in $1/m_Q$ relations between their transition matrix elements. The form factors of $B \rightarrow D^{(*)}\ell\nu$ are then related to those of $B \rightarrow D^{(*)}\tau\nu$, allowing for lepton universality predictions.

In this language, the spectroscopic 1S_0 and 3S_1 states—e.g. the D and D^* or B and B^* —may instead be considered to belong to a heavy quark (HQ) spin symmetry doublet of a pseudoscalar (P) and vector (V) meson, formed by the tensor product of the light degrees of freedom in a spin-parity $s_\ell^P = 1/2^-$ state, combined with the heavy quark spin: $\frac{1}{2}_{\text{HQ}} \otimes \frac{1}{2}_{\text{light}} = \mathbf{0} \oplus \mathbf{1}$. Their masses can be expressed as

$$m_{P,V} = m_Q + \bar{\Lambda} - \frac{\lambda_1}{2m_Q} \mp \frac{(2J_{V,P} + 1)\lambda_2}{2m_Q} + \dots, \quad (17)$$

where m_Q is the heavy quark mass parameter of HQET, $\bar{\Lambda} = \mathcal{O}(\Lambda_{\text{QCD}})$ is the brown muck kinetic energy for $m_Q \rightarrow \infty$, and $\lambda_{1,2} = \mathcal{O}(\Lambda_{\text{QCD}}^2)$. Furthermore, one expects that in the limit that $m_Q \rightarrow \infty$ (and, $\alpha_s \rightarrow 0$)—the heavy quark limit—the physics of heavy hadron flavor-changing transitions such as $B \rightarrow D^{(*)}$ should be insensitive to—and therefore preserve—the spin of the underlying heavy quarks, while being sensitive to the change in heavy quark velocity.

Following this intuition, the QCD kinetic term $\bar{Q}(i\not{D} - m_Q)Q$ may itself reorganized into an effective theory of brown muck—i.e. an HQET—parametrized by the heavy quark velocity $v = p_Q/m_Q$, featuring an $1/m_Q$ expansion in which the leading order terms conserve heavy quark spin, while higher order terms in $1/m_Q$ do not. A heavy quark flavor violating interaction like $J = \bar{c}\Gamma b$ can be similarly reorganized, such that at leading order, the transition is sensitive only to the difference of the incoming and outgoing heavy hadron velocities v and v' , respectively. It is then natural to express the matrix elements as in Eq. (5), with the natural form factor basis in the SM being $h_\pm, h_V, h_{A_{1,2,3}}$.

When organized in this way, the key result is that any $B \rightarrow D^{(*)}$ matrix element can be written as a spin-trace

$$\frac{\langle D^{(*)} | \bar{c}\Gamma b | \bar{B} \rangle}{\sqrt{m_{D^{(*)}} m_{\bar{B}}}} = -\xi(w) \text{Tr} [\bar{H}_{v'}^{(c)} \Gamma H_v^{(b)}] + \mathcal{O}(\varepsilon_c, \varepsilon_b, \hat{\alpha}_s), \quad (18)$$

where $H^{(c,b)}$ are HQET representations of the HQ doublet and $\xi(w)$ is a leading *Isgur-Wise function*. Higher order terms in $\varepsilon_{c,b} = \bar{\Lambda}/(2m_{c,b})$, can be similarly systematically constructed in terms of universal *subleading* Isgur-Wise functions, while radiative corrections in $\hat{\alpha}_s = \alpha_s/\pi$ can be incorporated at arbitrary fixed order.

Heavy quark flavor symmetry implies that $\xi(1) = 1$, preserved at order $\varepsilon_{c,b}$ by Luke's theorem.

The CLN parametrization (Caprini *et al.*, 1998) applies dispersive bounds to the $B \rightarrow D$ form factor V_1 , expanded up to cubic order as

$$\frac{V_1(w)}{V_1(1)} = 1 - \rho_1^2(w-1) + c_1(w-1)^2 + d_1(w-1)^3 + \dots \quad (19)$$

It thus extracts approximate relations between the parameters ρ^2 , c_1 and d_1 , by saturating the dispersive bounds at (the then) 1σ uncertainty in the QCD correlators χ_J . The parametrization then makes use of heavy quark symmetry to relate this form factor to all other form factors in the $B \rightarrow D^{(*)}$ system, incorporating additional, quark model inputs from QCD sum rules (QCDSR, see below), to constrain the $1/m_{c,b}$ terms. In particular, predictions are obtained for a z expansion of h_{A_1} , with coefficients dependent only on ρ_1^2 , plus predictions for $R_{1,2,0}(w)$ up to a fixed order in $(w-1)$: $R_i(w) = R_i(1) + R'_i(1)(w-1) + 1/2R''_i(1)(w-1)^2 + \dots$

The intercepts $R_i(1)$ are theoretically correlated order-by-order in the HQ expansion with the slope and gradients $R_i^{(',')} (1)$, and therefore must be determined simultaneously when measured. A common experimental fitting practice of floating $R_{1,2}(1)$ while keeping $R_{1,2}^{(',')} (1)$ fixed to their QCDSR predictions is inconsistent with HQET at subleading order, when fits are performed to recent higher precision unfolded datasets, such as the 2017 Belle tagged analysis (Abdesselam *et al.*, 2017). The BLPR parametrization (Bernlochner *et al.*, 2017) removes this inconsistency, and exploits higher precision data-driven fits to the subleading IW functions to obviate the need for QCDSR inputs. It furthermore consistently incorporates the $1/m_{c,b}$ terms for NP currents, important for NP predictions of $B \rightarrow D^{(*)}\tau\nu$.

There has been long-standing debate about the size of the $1/m_c^2$ corrections, partly because quark model-based calculations predicted them to have coefficients somewhat larger than unity. Recent data-driven fits, however, in the baryonic $\Lambda_b \rightarrow \Lambda_c$ system provide good evidence that the $1/m_c^2$ corrections obey power counting expectations (Bernlochner *et al.*, 2018b); see also (Bordone *et al.*, 2020) with regard to $B_{(s)} \rightarrow D_{(s)}^*$.

3. Quark models

Beyond dispersive bounds and HQET, quark model-based approaches have historically played an important role in descriptions of the form factors, and have provided useful constraints in generating lepton universality predictions. The ISGW2 parametrization (Isgur *et al.*, 1989; Scora and Isgur, 1995) implements a non-relativistic constituent quark model, providing estimates of the form factors by expressing the transition matrix elements for

each spectroscopic combination of hadrons in terms of wave-function overlap integrals. In addition, it incorporates leading order and $\mathcal{O}(1/m_{c,b})$ constraints from heavy quark symmetry and higher-order hyperfine corrections.

The ISGW2 parametrization of the form factors is treated as fully predictive, being typically implemented without any undetermined parameters. This amounts to fixed choices for e.g. the heavy and light quark masses or the brown muck kinetic energy $\bar{\Lambda}$. It therefore is not considered to provide state-of-the-art form factors, compared to data-driven fits. Non-relativistic quark models may, however, be useful choices for double heavy hadron transitions such as $B_c \rightarrow J/\psi$ or η_c (for a very recent example see e.g. (Penalva *et al.*, 2020)), where heavy quark symmetry cannot be applied.

QCD sum rules (QCDSR) exploit the analytic properties of three-point correlators constructed by sandwiching an operator of interest with appropriate interpolating hadronic currents. This allows the expression of e.g., an Isgur-Wise function in terms of the Borel transform of the correlator, the latter of which can be computed in perturbation theory via an operator product expansion (OPE). One must further assume quark-hadron duality to estimate the spectral densities of relevant excited states. Renormalization improved results for the $1/m_{c,b}$ Isgur-Wise functions and their gradients at zero recoil are known (Ligeti *et al.*, 1994; Neubert, 1994; Neubert *et al.*, 1993a,b). While theoretical uncertainties associated with the perturbative calculations are well understood, there is no systematic approach to assessing uncertainties arising from quark-hadron duality and scale variations. Rough estimates of the uncertainties are large compared to the precision obtained by more recent data-driven methods.

Light cone sum rules (LCSR) operate in a similar spirit to QCDSR. They describe, however, the regime in which the outgoing hadron kinetic energy is large, by reorganizing the OPE such that one expands in the ‘transverse distance’ of partons from the light cone. LCSR have broad application in exclusive heavy-light quark transitions, such as for $b \rightarrow u$ transitions including $B \rightarrow \rho$, ω , or π , in which the valence parton is highly boosted compared to the spectator.

4. Lattice calculations

Lattice QCD (LQCD) results are available for the form-factors at zero recoil for both $B_{(s)} \rightarrow D_{(s)}$ and $B_{(s)} \rightarrow D_{(s)}^*$, with the most precise $B \rightarrow D^{(*)}$ results (Aoki *et al.*, 2020)

$$\begin{aligned} \mathcal{G}(1) \equiv V_1(1) &= 1.054(4)_{\text{stat}}(8)_{\text{sys}}, \\ \mathcal{F}(1) &= 0.906(4)_{\text{stat}}(12)_{\text{sys}}. \end{aligned} \quad (20)$$

LQCD results for the both the $B_{(s)} \rightarrow D_{(s)}$ form factors $f_{+,0}^{(s)}$ are available beyond zero recoil, with respect to the optimized expansion in $z = z(q^2, q_{\text{opt}}^2)$. Results for $B_{(s)} \rightarrow D_{(s)}^*$ form factors beyond zero recoil are still in progress.

The $B \rightarrow D$ LQCD data allows for lattice predictions for the differential rate of $B \rightarrow D\tau\nu$, and when combined with HQET relations plus QCD sum rule predictions, may also predict $B \rightarrow D^*\tau\nu$, but with slightly poorer precision compared to data-driven approaches (Bernlochner *et al.*, 2017). Beyond zero-recoil LQCD results are also available for $B_c \rightarrow J/\psi l\nu$ (Harrison *et al.*, 2020a) (see Sec. II.E), as well as for the baryonic $\Lambda_b \rightarrow \Lambda_c l\nu$ (Detmold *et al.*, 2015) decays including NP matrix elements.

D. Ground state observables and predictions

1. Lepton universality ratios

Lepton universality in $b \rightarrow cl\nu$ may be probed by comparing the ratios of total rates for $l = e, \mu$ and τ , in particular the ratio of the semitauonic to light semileptonic exclusive decays

$$\mathcal{R}(H_c) = \frac{\Gamma[H_b \rightarrow H_c\tau\nu]}{\Gamma[H_b \rightarrow H_c\ell\nu]}, \quad \ell = e, \mu, \quad (21)$$

where $H_{c,b}$ are any allowed pair of c - and b -hadrons. (The ratios of the electron and muon modes are in agreement with SM predictions, i.e. near unity; see Sec. VI.A. One may also consider ratios $\mathcal{R}(H_u)$ for $H_b \rightarrow H_u\tau\nu$ decays, in which the valence charm quark is replaced by a u quark.) The ratios $R(H_c)$ should differ from unity not only from the reduced phase space as $m_\tau \gg m_{e,\mu}$, but also because of the mass-dependent coupling to the longitudinal W mode. The theory uncertainties entering into the SM predictions for this quantity are then dominated by uncertainties in the form factor contributions coupling exclusively to the lepton mass, such as the form factor ratios S_1/V_1 and $R_0(w)$ in $B \rightarrow D$ and D^* , respectively.

In Table I we show a summary of various predictions as collated by the Heavy Flavor Averaging Group (HFLAV) (Amhis *et al.*, 2019). Before 2017, $\mathcal{R}(D^{(*)})$ predictions based on experimental data used the CLN parametrization, since this was the only experimentally implemented form factor parametrization. An unfolded analysis by Belle (Abdesselam *et al.*, 2017) has since allowed use of other parameterizations, with the different (and more consistent) theoretical inputs as described in Table I. At present, given the different theoretical inputs and correlations in the results of these analyses, the HFLAV SM prediction is a naïve arithmetic average of the $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ predictions and uncertainties, independently.

Table I $\mathcal{R}(D^{(*)})$ predictions as currently collated and arithmetically averaged by HFLAV. Predictions shown below the HFLAV line are not included in the arithmetic average.

On occasion, the phase-space constrained ratio

$$\tilde{\mathcal{R}}(H_c) = \frac{\int_{m_\tau^2}^{Q^2} dq^2 \frac{d\Gamma[H_b \rightarrow H_c \tau \nu]}{dq^2}}{\int_{m_\tau^2}^{Q^2} dq^2 \frac{d\Gamma[H_b \rightarrow H_c \ell \nu]}{dq^2}}, \quad \ell = e, \mu, \quad (22)$$

is also considered, in which the relative phase-space suppression for the tauonic mode is factored out. For instance, the SM predictions are, using the fit results of (Bernlochner *et al.*, 2017)

$$\tilde{\mathcal{R}}(D) = 0.576(3), \quad \tilde{\mathcal{R}}(D^*) = 0.342(2), \quad (23)$$

with a correlation coefficient of 0.53.

2. Longitudinal and polarization fractions

In the helicity basis for the D^* polarization, the $D^* \rightarrow D\pi$ decay amplitudes within $B \rightarrow (D^* \rightarrow D\pi)l\nu$ decays are simply $L = 1$ spherical harmonics $e^{i\lambda\phi_v} Y_{1,\lambda}(\theta_v)$, with respect to the helicity angles defined in Fig. 1. That is, the $B \rightarrow (D^* \rightarrow D\pi)l\nu$ amplitudes may be expressed in the schematic form $\sum_\lambda A_\lambda [B \rightarrow D^* l\nu](\theta_l, \phi_l - \phi_v) \times Y_{1,\lambda}(\theta_v)$. The D^* longitudinal polarization fraction⁴

$$F_{L,l}(D^*) = \frac{\Gamma_{\lambda=0}[B \rightarrow D^* l\nu]}{\Gamma[B \rightarrow D^* l\nu]}, \quad (24)$$

⁴ Another common notation is $F_{L,\tau}(D^*) = F_L^{D^*}$.

Table II SM predictions for the D^* longitudinal fraction and the τ polarization in $B \rightarrow D^{(*)}$. We also show simple arithmetic averages of the predictions and uncertainties. The CLN-based predictions shown below the line is not included in the arithmetic average.

^a (Huang *et al.*, 2018), using the fit of (Jung and Straub, 2019)

^b (Jaiswal *et al.*, 2020), using Belle 2019 data

^c Using the fit of (Bernlochner *et al.*, 2017). The correlation between $P_\tau(D^*)$ and $P_\tau(D)$ is $\rho = 0.33$

^d (Alok *et al.*, 2017)

thus arises as a physical quantity in $B \rightarrow (D^* \rightarrow D\pi)l\nu$ decays, via the marginal differential rate

$$\frac{1}{\Gamma} \frac{d\Gamma_{B \rightarrow (D^* \rightarrow D\pi)l\nu}}{d \cos \theta_v} = \frac{3}{2} \left[F_{L,l} \cos^2 \theta_v + (1 - F_{L,l}) \frac{\sin^2 \theta_v}{2} \right]. \quad (25)$$

The interference terms between amplitudes with different λ vanish under integration over $\phi_l - \phi_v$. Similar to $\mathcal{R}(D^{(*)})$, theory uncertainties in $|V_{cb}|$ are factored out of $F_{L,l}$. Some recent (and new) SM predictions for $F_{L,\tau}(D^*)$ are provided in Table II, using a variety theoretical inputs. We also include an SM prediction for $F_{L,\ell}(D^*)$.

A similar analysis may be applied to $\tau \rightarrow h\nu$ decay amplitudes within $B \rightarrow D^{(*)}(\tau \rightarrow h\nu)\bar{\nu}$. For example, in the helicity basis for the τ , the $\tau \rightarrow \pi\nu$ amplitudes are the $j = \frac{1}{2}$ Wigner- D functions $e^{i\phi_h/2} \sin(\theta_h/2)$ or $e^{-i\phi_h/2} \cos(\theta_h/2)$, for $\lambda_\tau = \mp$, respectively, where the helicity angles θ_h and ϕ_h are defined in Fig. 1. The τ polarization

$$P_\tau(D^{(*)}) = \frac{(\Gamma_{\lambda_\tau=+} - \Gamma_{\lambda_\tau=-})[B \rightarrow D^{(*)}\tau\nu]}{\Gamma[B \rightarrow D^{(*)}\tau\nu]}, \quad (26)$$

is a physical quantity in $B \rightarrow D^{(*)}(\tau \rightarrow \pi\nu)\bar{\nu}$ decays, via the marginal differential rate

$$\frac{1}{\Gamma} \frac{d\Gamma_{B \rightarrow D^{(*)}(\tau \rightarrow \pi\nu)\bar{\nu}}}{d \cos \theta_h} = \frac{1}{2} \left[1 + P_\tau(D^{(*)}) \cos \theta_h \right]. \quad (27)$$

The interference terms between amplitudes with different λ_τ vanish under integration over $\phi_\tau - \phi_h$. This generalizes to other final states, such as $h = \rho, 3\pi$ as

$$\frac{1}{\Gamma} \frac{d\Gamma_{B \rightarrow D^{(*)}(\tau \rightarrow h\nu)\bar{\nu}}}{d \cos \theta_h} = \frac{1}{2} \left[1 + \alpha_h P_\tau(D^{(*)}) \cos \theta_h \right], \quad (28)$$

in which α_h is the analyzing power, that depends on the final state h . In particular the pion is a perfect polarizer,

$\alpha_\pi = 1$, while $\alpha_\rho = (1 - 2m_\rho^2/m_\tau^2)/(1 + 2m_\rho^2/m_\tau^2)$. Just as for $F_{L,\tau}(D^*)$, some recent (and new) SM predictions for $P_\tau(D^{(*)})$ are provided in Table II, using a variety of different theoretical inputs. The missing energy in the τ decay means that θ_h is reconstructible only up to 2-fold ambiguities in present experimental frameworks.

E. Excited and other states

So far we have mainly discussed the ground state meson transitions $B \rightarrow D^{(*)}l\nu$. However, much of the above discussion can be extended to excited charm states, baryons, charm-strange hadrons, or double heavy hadrons. Several of these process exhibit fewer HQ symmetry constraints or greater theoretical cleanliness compared to the ground states. This may be exploited to gain higher sensitivity to NP effects or better insight or control over theoretical uncertainties, such as $1/m_c^2$ contributions.

Four orbitally excited charm mesons, collectively labelled as the D^{**} , comprise in spectroscopic notation, the states $D_0^* \sim {}^3P_0$, $D_1' \sim {}^3P_1$, $D_2^* \sim {}^3P_2$ and the $D_1 \sim {}^1P_1$.⁵ In the language of HQ symmetry, the D_0^* and D_1' (D_1 and D_2^*) furnish a heavy quark doublet whose dynamics is described by the $s_\ell^P = 1/2^+$ ($s_\ell^P = 3/2^+$) HQET. The $1/2^+$ doublet is quite broad, with widths ~ 0.2 and 0.4 GeV, while the $3/2^+$ states are an order of magnitude narrower. The $B \rightarrow D^{**}l\nu$ decays produce important feed-down backgrounds to $B \rightarrow D^{(*)}l\nu$.

Several of the $B \rightarrow D^{**}$ form factors vanish at leading order in the heavy-quark limit at zero recoil, so that the higher-order $\mathcal{O}(1/m_{c,b})$ corrections become important, as included in the LLSW parametrization (Leibovich *et al.*, 1997, 1998). This can lead to higher sensitivities to various NP currents, compared to the ground states, such that these decays must be incorporated consistently, especially for LFUV analyses with beyond the SM contributions. The current SM predictions for all four modes, from fits to Belle data including NLO HQET contributions at $\mathcal{O}(\alpha_s, 1/m_{c,b})$, are (Bernlochner and Ligeti, 2017; Bernlochner *et al.*, 2018a)

$$\begin{aligned} \mathcal{R}(D_0^*) &= 0.08(3), & \mathcal{R}(D_1') &= 0.05(2), \\ \mathcal{R}(D_1) &= 0.10(2), & \mathcal{R}(D_2^*) &= 0.07(1). \end{aligned} \quad (29)$$

These are smaller than $\mathcal{R}(D^{(*)})$ because of the smaller phase space and reduced w range. An additional useful quantity is the ratio for the sum of the four D^{**} states

$$\mathcal{R}(D^{**}) = \frac{\sum_{X \in D^{**}} \Gamma[B \rightarrow X\tau\bar{\nu}]}{\sum_{X \in D^{**}} \Gamma[B \rightarrow X\ell\bar{\nu}]} = 0.08(1), \quad (30)$$

⁵ The D_1' is also often denoted by D_1^* .

taking into account correlations in the SM predictions.

An identical discussion proceeds for $B_s \rightarrow D_s^{(*)}l\nu$ decays, with the light spectator quark replaced by a strange quark. The typical size of flavor $SU(3)$ breaking suggests $\sim 20\%$ corrections compared to the predictions for $B \rightarrow D^{(*)}$. Lattice studies are available for $B_s \rightarrow D_s$ (McLean *et al.*, 2020) beyond zero-recoil, with the prediction

$$\mathcal{R}(D_s) = 0.2987(46), \quad (31)$$

and there is some evidence of relative insensitivity of the matrix elements to the (light) spectator quark (McLean *et al.*, 2019). A recent analysis for $B_{(s)} \rightarrow D_{(s)}^{(*)}$ (Bordone *et al.*, 2020) combines model-dependent QCDSR and LCSR inputs, even though the charm hadron is not ultra-relativistic. This analysis predicts

$$\begin{aligned} \mathcal{R}(D) &= 0.298(3), & \mathcal{R}(D_s) &= 0.297(3) \\ \mathcal{R}(D^*) &= 0.250(3), & \mathcal{R}(D_s^*) &= 0.247(8), \end{aligned} \quad (32)$$

though the resulting $\mathcal{R}(D^*)$ prediction is notably in tension with the prior predictions in Table I. At the LHC, or on the Z peak, non-negligible feed-downs to $\mathcal{R}(D^*)$ arise from $B_s \rightarrow D_{s1}'\tau\nu$ decays, because of their subsequent decay to $D^{(*)}\tau\nu X$, that must be taken into account. Likewise $B_s \rightarrow D_{s2}^*\tau\nu$ decays may feed-down to $\mathcal{R}(D)$: see Sec. IV.C.

The light degrees of freedom in the ground state baryons $\Lambda_{b,c}$ have spin-parity $s_\ell^P = 0^+$, corresponding to the simplest, and therefore most constrained, HQET. In particular, the $\Lambda_b \rightarrow \Lambda_c$ form factors receive hadronic corrections to the leading order IW function only at $1/m_{c,b}^2$. Beyond zero-recoil lattice data is available for both SM and NP form factors (Detmold *et al.*, 2015). Predictions for $\Lambda_b \rightarrow \Lambda_c\tau\nu$, however, are at present more precise when LQCD results are combined with data-driven fits for $\Lambda_b \rightarrow \Lambda_c\ell\nu$ plus HQET relations. In particular, a data-driven HQET-based form factor parametrization, when combined with the lattice data, provides the currently most precise prediction (Bernlochner *et al.*, 2018b)

$$\mathcal{R}(\Lambda_c) = 0.324(4), \quad (33)$$

as well as the ability to directly extract or constrain the $1/m_c^2$ corrections. The latter are found to be consistent with HQ symmetry power counting expectations. Similar techniques will be applicable to the two Λ_c^* excited states with $s_\ell^P = 1^-$ (Böer *et al.*, 2018; Leibovich and Stewart, 1998), once data is available. At present, predictions for $\mathcal{R}(\Lambda_c^*)$ may be derived using a constituent quark model approach (Pervin *et al.*, 2005) similar to ISGW2, yielding $\mathcal{R}(\Lambda_c^*(2595)) \simeq 0.16$ and $\mathcal{R}(\Lambda_c^*(2625)) \simeq 0.11$.

Finally, the semileptonic decay $B_c \rightarrow J/\psi(\rightarrow \ell\ell)l\nu$ provides an extremely clean signature to test LFUV. The

above HQ symmetry arguments, however, cannot be applied to double heavy quark mesons such as B_c and J/ψ (or the pseudoscalar η_c): They cannot be thought of as a single heavy quark dressed by brown muck, nor do we expect approximate conservation of the spin of the heavy quarks in the underlying $b \rightarrow c$ transition. Hence an HQET description cannot be used for these modes. A variety of quark model based analyses and predictions have been conducted, with wide-ranging predictions for $\mathcal{R}(J/\psi) \sim 0.2\text{--}0.4$. A recent model-independent combined analysis for $B_{(s)} \rightarrow D_{(s)}^{(*)}$ and $B_c \rightarrow J/\psi$ and η_c , making use of a combination of dispersive bounds, lattice results and HQET where applicable, provided a prediction $\mathcal{R}(J/\psi) = 0.25(3)$ (Cohen *et al.*, 2019). A subsequent LQCD result provides the high precision prediction (Harrison *et al.*, 2020b)

$$\mathcal{R}(J/\psi) = 0.2582(38). \quad (34)$$

Preliminary lattice results for the $B_c \rightarrow \eta_c$ form factors beyond zero recoil are also available (Colquhoun *et al.*, 2016).

F. $b \rightarrow ul\nu$ processes

The dispersive analysis used in Sec. II.C.1 to parametrize the form factors for $B \rightarrow D^{(*)}$ may also be employed for the light hadron $b \rightarrow ul\nu$ processes. For $B \rightarrow \pi l\nu$ in particular, significant simplifications arise because there is only a single possible subthreshold resonance—the B^* —for the f_+ form factor, and no subthreshold resonance for f_0 . Combining this with general analyticity properties of the $B \rightarrow \pi$ matrix element, leads to the BCL parametrization (Bourrely *et al.*, 2009). Expanding in $z = z(q^2, q_{\text{opt}}^2)$

$$\begin{aligned} f_+(q^2) &= \frac{1}{1 - q^2/m_{B^*}^2} \sum_{j=0}^N b_j^+ \left[z^j - (-1)^{j-N} \frac{j}{N} z^N \right], \\ f_0(q^2) &= \sum_{j=0}^N b_j^0 z^j, \end{aligned} \quad (35)$$

where N is the truncation order. Lattice results beyond zero recoil are available for all $B \rightarrow \pi$ form factors (Bailey *et al.*, 2015a,b), that can be incorporated into global fits to available experimental data. The SM prediction is (Bernlochner, 2015)

$$\mathcal{R}(\pi) = 0.641(16). \quad (36)$$

Higher-twist LCSR results are available for the $B \rightarrow \rho$ and $B \rightarrow \omega$ SM and NP form factors, parametrized by the optimized $z = z(q^2, q_{\text{opt}}^2)$ expansion (Bharucha *et al.*, 2016). These results may be applied to obtain a correlated, beyond zero recoil fit between the SM and NP form

factors and the measured q^2 spectra of the corresponding light-lepton modes. The SM predictions from this fit are (Prim *et al.*, 2020)

$$\mathcal{R}(\rho) = 0.535(8), \quad \mathcal{R}(\omega) = 0.546(15). \quad (37)$$

G. Inclusive processes

The inclusive process $B \rightarrow X_c l\nu$, where X_c is a single-charm (multi)hadron final state of any invariant mass, admits a different, cleaner theoretical description compared with the above exclusive processes. For instance, in the limit $m_b \rightarrow \infty$, the inclusive process is described simply by the underlying $b \rightarrow cl\nu$ free quark decay, rather than in terms of an unknown Isgur-Wise function.

The square of the inclusive matrix element $|\langle X_c | J | \bar{B} \rangle|^2$ can be re-expressed in terms of the time-ordered forward matrix element $\langle \bar{B} | T(J^\dagger J) | \bar{B} \rangle$. The latter can be computed via an OPE order-by-order in $1/m_b$ and α_s , yielding theoretically clean predictions. State-of-the-art predictions include $1/m_b^2$ terms (Ligeti and Tackmann, 2014) and two-loop QCD corrections (Biswas and Melnikov, 2010), that may be combined to generate the precision prediction (Freytsis *et al.*, 2015)

$$\mathcal{R}(X_c) = 0.223(4), \quad (38)$$

as well as precision predictions for the dilepton invariant mass and lepton energy distributions. Because the theoretical uncertainties in $B \rightarrow X_c l\nu$ are of a different origin to the exclusive modes, the measurement of $B \rightarrow X_c \tau\nu$ would provide a hadronic-model independent cross-check of lepton flavor universality (see Sec. VI.C).

H. New Physics operators

New Physics (NP) may enter the $b \rightarrow cl\nu$ processes via a heavy mediator, such that the semileptonic decay is generated by four-Fermi operators of the form

$$\mathcal{O}_{XY} = \frac{c_{XY}}{\Lambda_{\text{eff}}^2} (\bar{c} \Gamma_X b) (\bar{\tau} \Gamma_Y \nu_\tau), \quad (39)$$

where $\Gamma_{X(Y)}$ is any Dirac matrix with X (Y) labeling the chiral structure of the quark (lepton) current, and c_{XY} is a Wilson coefficient defined at scale $\mu \sim m_{c,b}$. The Wilson coefficient is normalized against the SM such that $\Lambda_{\text{eff}} = (2\sqrt{2}G_F V_{cb})^{-1/2} \simeq 870 \text{ GeV}$. If we denote by M the characteristic scale of an ultraviolet (UV) completion that matches onto the effective NP operators in Eq. (39), then order 10–20% variations in $\mathcal{R}(D^{(*)})$ or other observables from SM predictions typically probe $M \sim \Lambda_{\text{eff}}/\sqrt{c_{XY}} \sim \text{few TeV}$. This is tantalizingly in range of direct collider measurements and nearby the natural scale for UV completions of electroweak dynamics.

A common basis choice for Γ_X is the set of chiral scalar, vector and tensor currents: $P_{R,L}$, $\gamma^\mu P_{R,L}$, and $\sigma^{\mu\nu} P_{R,L}$, respectively. Assuming only SM left-handed neutrinos, the lepton current is always left-handed, and the tensor current may only be left-handed. It is common to write the five remaining Wilson Coefficients as $c_{XY} = c_{SR}$, c_{SL} , c_{VR} , c_{VL} and c_T . We use this notation for the Wilson coefficients hereafter. As for the SM, the NP leptonic amplitude still takes the form $D_{m_1, m_2}^j(\theta_l, \phi_l)$, with $j = 0$ or 1, and $|m_{1,2}| \leq j$, and the structure of the differential decay rate resembles Eq. (9), but with additional dependencies on NP Wilson coefficients, w , and r .

The (pseudo)scalar and tensor operators run under the Renormalization Group (RG) evolution of QCD, while the vector and axial vector operators correspond to conserved currents and do not (for this reason the normalization of Eq. (3) is well-defined). At one-loop order in the leading-log approximation, the running of $c_{SR,SL,T}$ is dominated by contributions below the top quark mass m_t , and only weakly affected by variations in $M \sim \Lambda_{\text{eff}}$. Electroweak interactions, however, may induce mixing between $c_{SR,SL,T}$, that can become non-negligible for RG evolution above the weak scale (González-Alonso *et al.*, 2017). RG evolution from $M \simeq \Lambda_{\text{eff}} > m_t$ to $\mu \simeq \sqrt{\bar{m}_c \bar{m}_b}$ generates at leading-log order

$$c_{SR,SL}(\mu)/c_{SR,SL}(M) \simeq 1.7, \quad c_T(\mu)/c_T(M) \simeq 0.84. \quad (40)$$

These running effects are particularly important in translating the low scale effective field theory (EFT) implications of $b \rightarrow c\tau\nu$ measurements to collider measurements at high scales.

I. Connection to other processes

LFUV in $b \rightarrow c\nu$ necessarily implies violation in the crossed process $B_c \rightarrow l\nu$. The latter decays are extremely theoretically clean: Their tauonic versus leptonic LFUV ratios are simply the ratios of chiral suppression and 2-body phase space factors, i.e. $m_\tau^2(1 - r_\tau^2)^2/m_\ell^2(1 - r_\ell^2)^2$, in which $r_l = m_l/m_{B_c}$. These ratios are precisely known.

In the SM, the branching ratio

$$\mathcal{B}[B_c \rightarrow l\nu] = \tau_{B_c} G_F^2 |V_{cb}|^2 m_{B_c}^3 f_{B_c}^2 r_l^2 (1 - r_l^2)^2 / 8\pi, \quad (41)$$

in which the decay constant $f_{B_c} \simeq 0.434(15)$ GeV from lattice data (Colquhoun *et al.*, 2015), and the B_c lifetime, $\tau_{B_c} = 0.510(9) \times 10^{-12}$ s is well-measured (Zyla *et al.*, 2020). In particular, in the SM one predicts $\mathcal{B}[B_c \rightarrow \tau\nu] \simeq 2.2(2)\% \times (|V_{cb}|/0.04)^2$.

In the presence of NP, the NP Wilson coefficients generate an additional factor

$$\mathcal{B}[B_c \rightarrow \tau\nu] = \mathcal{B}_{SM} \left| 1 + c_{VL} - c_{VR} + \frac{m_{B_c}^2 (c_{SR} - c_{SL})}{m_\tau (\bar{m}_b + \bar{m}_c)} \right|^2, \quad (42)$$

where $\bar{m}_{c,b}$ are $\overline{\text{MS}}$ quark masses arising from equations of motion. Because the NP pseudoscalar current induces a chiral flip, its chiral suppression is lifted by a factor of $m_{B_c}/m_\tau \sim 3.5$ versus the $V - A$ current. This leads to large tauonic branching ratio enhancements, that may then be in tension with naive expectations that the B_c hadronic branching ratios ~ 70 –90% (Akeroyd and Chen, 2017; Alonso *et al.*, 2017; Bardhan and Ghosh, 2019; Li *et al.*, 2016). A corollary is that a future measurement or bounds of $\mathcal{B}[B_c \rightarrow \tau\nu]$ alone would tightly constrain the NP pseudoscalar contributions.

In the absence of any NP below the electroweak scale, the NP effective operators in Eq. (39) must match onto an electroweak-consistent EFT constructed from SM quark and lepton doublets and singlets under $SU(2)_L \times U(1)_Y$. In particular, because the SM neutrino belongs to an electroweak lepton doublet, L_L , then electroweak symmetry requires the presence of at least two electroweak doublets in any operator that generates the $b \rightarrow c\tau\nu$ decay. (An exception applies if right-handed sterile neutrinos are present.) In any given NP scenario, this may generate relations between $b \rightarrow c\tau\nu$ and other processes, that arise when at least one of the four fermions is replaced by its electroweak partner. For example, various minimal NP models, depending on their flavor structure, may be subject to tight bounds from the rare $b \rightarrow s\nu\nu$ or $b \rightarrow s\tau\tau$ decays or bounds on $Z \rightarrow \tau\tau$ or $W \rightarrow \tau\nu$ branching ratios (Freytsis *et al.*, 2015; Sakaki *et al.*, 2013), or the high- p_T scattering $pp \rightarrow \tau\tau$ or $\tau\nu$ (Greljo *et al.*, 2019; Greljo and Marzocca, 2017). Ultraviolet completions with non-trivial flavor structures may further generate relations to charm decay processes, or $b \rightarrow s\ell\ell$. The latter is particularly intriguing, because of an indication for *light* lepton universality violation in the ratios (Aaij *et al.*, 2017b, 2019c)

$$\mathcal{R}_{K^{(*)}} \equiv \frac{\Gamma[B \rightarrow K^{(*)}\mu\mu]}{\Gamma[B \rightarrow K^{(*)}ee]}, \quad (43)$$

at approximately the 2.5σ level in each mode (see Sec. VI.E). Extensive literature considers possible common origins of LFUV in semitauonic processes with LFUV in these rare decays. See e.g. (Bhattacharya *et al.*, 2015; Buttazzo *et al.*, 2017; Calibbi *et al.*, 2015; Kumar *et al.*, 2019), among many others, for extensive discussions of combined explanations for semileptonic and rare decay LFUV anomalies.

III. EXPERIMENTAL METHODS

A. Production and detection of b -hadrons

Since the discovery of the b quark in 1977 (Herb *et al.*, 1977), large samples of b -hadrons have been produced at colliders such as CESR, LEP, or Tevatron. However, it was not until the advent of the B factories and the LHC,

Table III Approximate number of b -hadrons produced and expected at the B factories (Altmannshofer *et al.*, 2019; Bevan *et al.*, 2014) and at the LHCb experiment (Albrecht *et al.*, 2019), including some of the latest developments (Béjar Alonso *et al.*, 2020). The LHCb numbers take into account an average geometrical acceptance of about 25% for $2 < \eta < 5$. Note that the overall B reconstruction efficiencies are usually quite different between B factories and LHCb (see text). The two values of integrated luminosities and center-of-mass energies shown for Belle and Belle II correspond to data taking at the $\Upsilon(4S)$ and $\Upsilon(5S)$ resonances, respectively. The B -factory experiments also recorded data sets at lower center-of-mass energies (below the open beauty threshold) that are not included in this table.

| Experiment | BABAR | Belle | Belle II | LHCb | | | |
|--|-----------|-----------------|----------------------|------------------------|-------------------|-------------------|-------------------|
| | | | | Run 1 | Run 2 | Runs 3–4 | Runs 5–6 |
| Completion date | 2008 | 2010 | 2031 | 2012 | 2018 | 2031 | 2041 |
| Center-of-mass energy | 10.58 GeV | 10.58/10.87 GeV | 10.58/10.87 GeV | 7/8 TeV | 13 TeV | 14 TeV | 14 TeV |
| $b\bar{b}$ cross section [nb] | 1.05 | 1.05/0.34 | 1.05/0.34 | $(3.0/3.4)\times 10^5$ | 5.6×10^5 | 6.0×10^5 | 6.0×10^5 |
| Integrated luminosity [fb^{-1}] | 424 | 711/121 | $(40/4) \times 10^3$ | 3 | 6 | 40 | 300 |
| B^0 mesons [10^9] | 0.47 | 0.77 | 40 | 170 | 580 | 4,200 | 32,000 |
| B^+ mesons [10^9] | 0.47 | 0.77 | 40 | 170 | 580 | 4,200 | 32,000 |
| B_s mesons [10^9] | - | 0.01 | 0.5 | 40 | 140 | 1,000 | 7,600 |
| Λ_b baryons [10^9] | - | - | - | 90 | 300 | 2,200 | 16,000 |
| B_c mesons [10^9] | - | - | - | 1.3 | 4.4 | 32 | 240 |

with their even larger samples and specialized detectors, that the study of third generation LFUV in B mesons became feasible. This is because of the stringent analysis selections that are required to achieve adequate signal purity when reconstructing final states that include multiple unreconstructed neutrinos. The B factories (Bevan *et al.*, 2014), KEKB in Japan and PEP-II in the United States, took data from 1999 to 2010. Their detectors, Belle (Abashian *et al.*, 2002) and BABAR (Aubert *et al.*, 2013), recorded over a billion of $B\bar{B}$ events originating from clean e^+e^- collisions. The LHCb detector (Aaij *et al.*, 2015a; Alves *et al.*, 2008) at the CERN LHC, which started taking data in 2010, has recorded an unprecedented trillion $b\bar{b}$ pairs as of 2020, which allows it to compensate for the more challenging environment of pp collisions. The recently commissioned Belle II experiment and the LHCb detector, to be upgraded in 2019–21 and 2031, are expected to continue taking data over the next decade and a half, surpassing the current data samples by more than an order of magnitude. In the following, we describe how b -hadrons are produced and detected at these facilities.⁶ Table III summarizes the number of b -hadrons produced and expected at the B factories and at the LHCb experiment.

⁶ Other current experiments might also be able to make contributions to semitauonic LFUV measurements in the future. For instance, the CMS experiment at the LHC recorded in 2018 a large (parked) sample of unbiased b -hadron decays, with the primary goal of measuring the $\mathcal{R}_{K^{(*)}}$ ratios. This sample could conceivably also be used to measure semitauonic decays if, e.g., the challenges arising from the multiple neutrinos in the final state can be overcome.

1. The B factories

KEKB and PEP-II produced B mesons by colliding electron and positron beams at a center-of-mass energy of 10.579 GeV. At this energy, e^+ and e^- annihilation produces $\Upsilon(4S)$ mesons in about 24% of the hadronic collision processes, with the production of $c\bar{c}$ and other light quark pairs accounting for the remaining 76%. Together with other processes producing pairs of fermions, the latter form the so-called continuum background.

The $\Upsilon(4S)$ meson is a $b\bar{b}$ bound state which, as a result of having a mass only about 20 MeV above the $B\bar{B}$ production threshold, decays almost exclusively to B^+B^- or $B^0\bar{B}^0$ pairs. Some limited running away from the $\Upsilon(4S)$ resonance was performed in order to study the continuum background and the properties of the bottomonium resonances $\Upsilon(1S)$ – $\Upsilon(5S)$. The largest data set produced by KEKB was used to study B_s mesons obtained from $\Upsilon(5S)$ decays. However, the resulting $B_s^{(*)}\bar{B}_s^{(*)}$ data sample was small, about 3% of the total $B\bar{B}$ sample as shown in Table III.

On the one hand, compared to hadron colliders, the $b\bar{b}$ production cross section in lepton colliders such as the B factories is much smaller: even at the (so far) highest instantaneous luminosity of $2.4 \times 10^{34} \text{ cm}^{-2}\text{s}^{-1}$ achieved by SuperKEKB in the Summer of 2020, $B\bar{B}$ pairs were produced only at a rate of about 25 Hz. On the other hand, one of the significant advantages of colliding fundamental particles like electrons and positrons is that the initial state is fully known, i.e., nearly 100% of the e^+e^- energy is transferred to the $B\bar{B}$ pair. This feature can be exploited by tagging techniques (Sec. III.C.1) that reconstruct the full collision event and can determine the momenta of missing particles such as neutrinos, so long

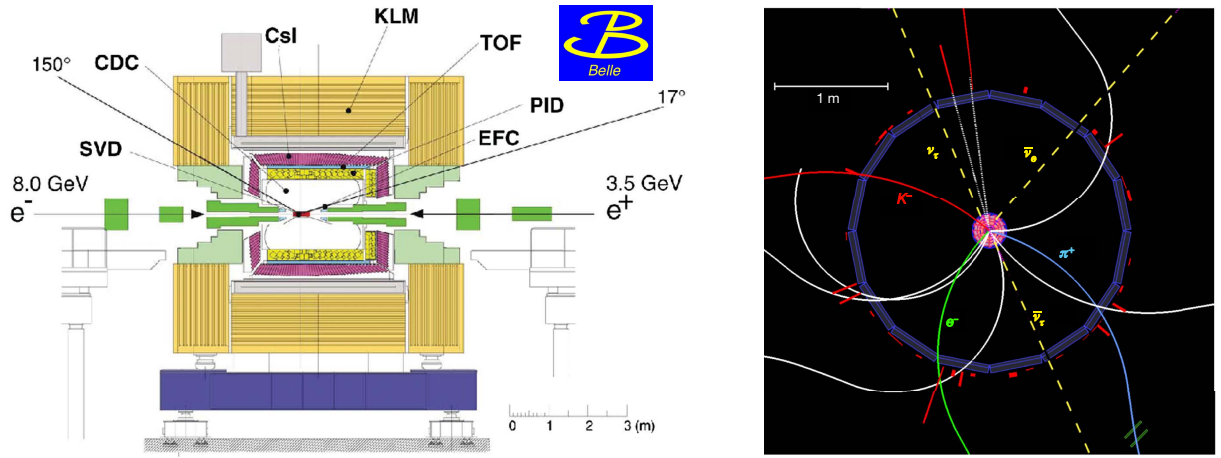

Figure 2 Left: Side view of the Belle detector. See (Abashian *et al.*, 2002) for further detail on the subdetectors and their acronyms. The BABAR detector has a similar configuration. Right: view perpendicular to the beam axis. The displayed event is reconstructed as a $\Upsilon(4S) \rightarrow B^+ B^-$ candidate, with $B^- \rightarrow D^0 \tau^- \bar{\nu}_\tau$, $D^0 \rightarrow K^- \pi^+$ and $\tau^- \rightarrow e^- \nu_\tau \bar{\nu}_e$, and the B^+ decaying to five charged particles (white solid lines) and two photons. The directions of undetected neutrinos are indicated as dashed yellow lines. From (Abashian *et al.*, 2002; Ciezarek *et al.*, 2017).

as the detectors are capable of reliably reconstructing all of the visible particles. The BABAR and Belle detectors managed to cover close to 90% of the total solid angle by placing a series of cylindrical subdetectors around the interaction point and complementing them by endcaps that reconstructed the particles that were ejected almost parallel to the beam pipe. This is sketched in Fig. 2.

The specific technologies employed in both B -factory detectors have been described in detail in (Bevan *et al.*, 2014). Four or five layers of precision silicon sensors placed close to the interaction point reconstruct the decay vertices of long-lived particles, as well as the first ≈ 10 cm of the tracks left by charged particles. Forty to fifty layers of low-material drift chambers measure the trajectories and ionization energy loss as a function of distance (dE/dx) of charged particles. Time-of-flight and Cherenkov systems provide particle identification (PID) that allow kaon/pion discrimination. Crystal calorimeters measure the electromagnetic showers created by electrons and photons. A solenoid magnet generates the 1.5 T magnetic field parallel to the beam pipe that bends the trajectories of charged particles, to allow for determination of their momenta. A series of steel layers instrumented with muon chambers guide the return of the magnetic flux and provide muon and K_L^0 PID.

Between 1998 and 2008–10, the BABAR and Belle detectors recorded a total of 471 and 772 million $B\bar{B}$ pairs, respectively. These large samples, still being analyzed at the time of this writing, allowed for the first measurement of CP violation in the B system, the observation of B mixing, as well as many other novel results (Bevan *et al.*, 2014). These further included the first observations of $B \rightarrow D^{(*)} \tau \nu$ decays (see Sec. IV), which in turn began the study of third generation LFUV: the focus of

this review. The success of the B factories has led to the upgrade of the accelerator facilities at KEKB, so called SuperKEKB (Akai *et al.*, 2018), such that it will be capable of delivering instantaneous luminosities 30 times higher than before. The upgraded Belle detector, Belle II (Abe, 2010), started taking data in 2018 with the aim of recording a total of over 40 billion $B\bar{B}$ pairs. The LFUV prospects for Belle II are discussed in Sec. VII.A.2.

2. The LHCb experiment

At hadron colliders such as the LHC, b quarks are predominantly pair-produced in pp collisions via the gluon fusion process $gg \rightarrow b\bar{b}$ plus subleading quark fusion contributions, with an approximate production cross-section $\sigma(b\bar{b}) \sim 560 \mu\text{b}$ at $\sqrt{s} = 13 \text{ TeV}$, scaling approximately linearly in \sqrt{s} (Aaij *et al.*, 2017a). Electroweak production cross-sections for single or pairs of b quarks via Drell-Yan processes, Higgs or top quark decays are five or more orders of magnitude smaller, with the largest such cross-section $\sigma(Z \rightarrow b\bar{b}) \sim 10 \text{ nb}$. As a result, b quarks are effectively always accompanied in LHC collisions by a companion \bar{b} quark. This feature is extremely important for unbiased trigger strategies and for CP violation studies, as it can be exploited to establish the beauty content at the production vertex of neutral B mesons.

At leading order, the hadronization of a b quark at the LHC is quite similar to the one observed in detail by the LEP experiments. For instance, the momentum distribution of the non- b -hadron fragments, which is relevant for same-side tagging studies, is well described by LEP-inspired Monte Carlo simulations (Sjöstrand *et al.*, 2015). More important is the relative production of the various

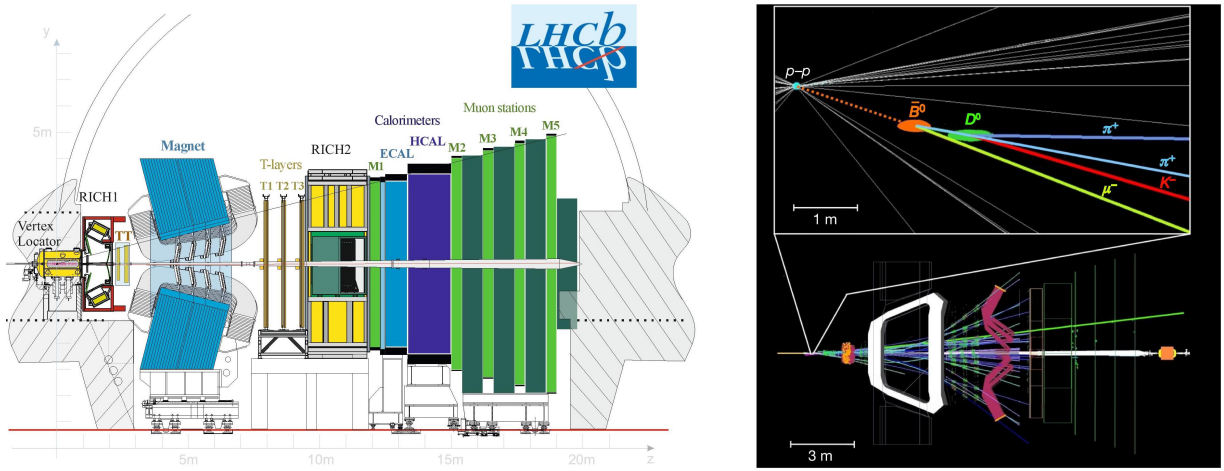

Figure 3 Left: Side view of the LHCb detector. See (Aaij *et al.*, 2015a; Augusto Alves Jr *et al.*, 2008) for further details on the subdetectors and their acronyms. Right: side view of an event display for a $B^0 \rightarrow D^{*+} \tau^- \bar{\nu}_\tau$ decay. The area around the interaction point is enlarged in the inset at the top. The trajectory of the B^0 meson is indicated with a dotted orange line, and the trajectories of the particles from the subsequent $D^{*+} \rightarrow D^0 \pi^+$, $D^0 \rightarrow K^- \pi^+$, and $\tau^- \rightarrow \mu^- \bar{\nu}_\mu \nu_\tau$ decays are illustrated with thick colored lines. Adapted from (Aaij *et al.*, 2015a; Ciezarek *et al.*, 2017).

b -hadron species: the main features—dominant production of B^0 and B^+ mesons, and sizeable production fraction of B_s and Λ_b —are the same, except that a much larger Λ_b production fraction is observed for p_T (momentum transverse to the beam axis) below 10 GeV (Aaij *et al.*, 2019a). LHCb can also study the decays of B_c mesons, in spite of its very low production rate, approximately 0.6% of the B^+ production cross-section (Aaij *et al.*, 2015b). As discussed in Secs. II.E and III.I, B_c mesons provide a very interesting laboratory for testing LFUV in $B_c \rightarrow J/\psi \tau \nu$ or $B_c \rightarrow \tau \nu$ decays.

The parton center-of-mass energy required to produce a b -hadron pair at threshold is far smaller than the total available collision energy in the pp system, leading to the production of a significant fraction of $b\bar{b}$ pairs with very large forward or backward boosts. This characteristic is the basis of the LHCb experimental concept, which studies the $b\bar{b}$ pairs produced within a 400 mrad cone covering the forward region, corresponding to a pseudorapidity $2 \leq \eta \leq 5$. Despite this very small solid angle, the LHCb detector captures $\sim 15\%$ of the full $b\bar{b}$ cross-section.

Within this acceptance, the b -hadrons have a typical transverse momentum, p_T , of 10 GeV, corresponding to an overall energy of ~ 200 GeV. This in turn corresponds to a typical boost factor of about 50, resulting in a mean flight distance of over 2 cm for each electroweakly-decaying ground-state b -hadron: namely $B^{0,+}$, B_s , B_c , or Λ_b . The sophisticated silicon trackers used in the LHCb detector provide a typical position resolution of 300 μm for the B vertex along its flight direction, resulting in flight distance significances between the b -hadron decay vertex and its primary vertex (PV) of over 100σ . This precision leads to extremely clean signals even for

high-multiplicity decay channels, provided the primary production vertex can be identified.

The LHCb luminosity is kept low enough so that the mean number of primary vertices per event until 2018 was between 1 and 2. This number is expected to rise to about 5 after the 2019–21 upgrade and possibly 50 after the 2031 upgrade. The longitudinal size of the LHCb luminous region is 20 cm, so that with only a handful of pp interactions in a given event, the primary vertex misconstruction is kept to a very low level. The ATLAS and CMS experiments typically accumulate 50 primary vertices in a given event (rising to 200 after 2027) and face therefore a very different challenge. Nevertheless, they are capable of cleanly reconstructing low multiplicity b -hadron decays thanks to their large coverage and high-granularity subdetectors. It should be stressed, however, that for semitauonic b -hadron decays the goal is not just to isolate a decay vertex from a primary vertex, but rather to identify a chain of vertices comprising the PV, the b -hadron decay, and, in the case of hadronic- τ measurements, the τ decay. At the LHC, this is currently only feasible at LHCb.

As in the B factories, PID capabilities are critical to properly identify b -hadron decays. For instance, at a hadron collider, misidentifying a pion as a kaon could lead to confusing a B_s meson for a B^0 meson, and identifying a pion as a proton can lead to a Λ_b baryon impersonating a B^0 meson. PID information is provided by the two ring-imaging Cherenkov (RICH) detectors shown in Fig. 3 left.

Table III lists the known production rates for all ground-state b -hadron species, at both LHCb and B factories. While the geometrical acceptance is included for

the LHCb values, the average trigger and analysis requirements must be taken into account as well in order to compare LHCb with the B factories. These requirements limit the useful yield to about 0.1% or less of the available sample. As an example, LHCb can reconstruct 5×10^4 events per fb^{-1} for modes having a total branching fraction into stable hadrons of $\sim 10^{-4}$.

Another feature of LHCb physics is the large production rate of excited b -hadron states: B^{**} , B_s^{**} , Λ_b^{**} can be studied in detail, as well as baryons containing both b and s quarks, such as Ξ_b , Ω_b , and their excited states. These can be useful to study semitauonic decays because, as described in Sec. III.C.3, the decay $B_{s2}^{**} \rightarrow BK$ can provide access to kinematic variables in the B center-of-mass frame via B tagging.

B. Particle reconstruction

Ground state b -hadrons—i.e. hadrons decaying only through flavor changing electroweak currents—have lifetimes of the order of one picosecond. Thus, they decay fast enough that they must all be reconstructed from their more stable decay products. At the same time, they live and fly long enough so that their decay vertices can be separated from the vertex of the primary collision (e^+e^- in the case of the B factories and pp in the case of LHCb). The reconstruction of these stable decay products proceeds in a similar fashion for the B factories and the LHCb experiment, with some key differences.

1. Charged particle reconstruction

The trajectories of charged particles—‘tracks’—are reconstructed based on the energy deposits left in the trackers—‘hits’. The momenta of these particles are determined based on the bending of these trajectories induced by the magnetic fields in each detector. As shown in Figs. 2 and 3, charged particles follow helical trajectories in the B factories due to their solenoidal magnetic fields, while in LHCb the particles are simply deflected by the dipole magnet. In either case, charged track reconstruction proceeds with efficiencies of over 95%—for $p > 300$ MeV at the B factories (Bevan *et al.*, 2014) and $p > 5$ GeV at LHCb (Aaij *et al.*, 2015a)—and the momentum determination is achieved with a typical resolution of 0.5-1%.

The reconstruction of the b -hadron secondary vertices is of primary importance to distinguish signal from background decays, especially in LHCb. In the B factories (Bevan *et al.*, 2014), the decay vertices of the short-lived B and D mesons were reconstructed with a resolution of 60 – 100 μm when they decayed inside the vertex trackers (about 80% of the time), and 100 – 400 μm when decaying outside. LHCb reconstructs the impact param-

eter of the tracks, that is, their distance to the primary vertex in the plane transverse to the beam line, with an impressive resolution of 45 μm for $p_T = 1$ GeV, and down to 15 μm for very high momenta tracks. As discussed in Sec. III.A.2, the vertex resolution along the beam line is of the order of 250 μm which, given the large boost of most particles at LHCb, is sufficient to suppress prompt background processes by multiple orders of magnitude (Sec. IV.C.2).

For both the B factories and LHCb, charged leptons have generically clean signatures that can be differentiated from other types of particles with high efficiency. Electrons are reconstructed from tracks that match a cluster in the electromagnetic calorimeter with the appropriate shape and energy; muons are generally identified as tracks that leave hits in the outer muon detectors, with some additional inputs from the other subdetectors. However, the performance of the two kinds of experiments diverges substantially in the details.

At the B factories, both electrons and muons are reconstructed with efficiencies over 90% and with low misidentification rates, though the performance is generally better for electrons (see Fig. 4). For instance, a typical 2 GeV electron is reconstructed with 96% efficiency and 0.3% pion misidentification probability, whereas a 2 GeV muon would have 92% efficiency and 2.5% pion misidentification probability. In contrast, at LHCb the electron reconstruction is much more challenging because of the lower granularity of the electromagnetic calorimeter and the larger amount of material before it, compared to the B factories. A 20 GeV electron is reconstructed with about 90% efficiency for a misidentification rate of 2.5%, while a muon with the same momentum would be reconstructed with 98% efficiency for a 1% misidentification rate (Fig. 5). Additionally, the first level of the LHCb trigger during 2010–18 is implemented on hardware and does not use information from the trackers, resulting in trigger efficiencies much lower for electrons than muons. This limitation will be overcome during the 2019–21 upgrade by a software-only trigger.

Finally, charged (light) hadrons are identified primarily by their signatures in the Cherenkov detectors, as well as the energy deposition in the drift chamber for low momentum particles in the B factories. The right panels of Figs. 4 and 5 show the separation achieved for several species of charged hadrons in some of the Cherenkov detectors for BABAR and LHCb, respectively.

2. Neutral particle reconstruction

Another key difference between B factories and LHCb lies in the ability to efficiently reconstruct neutral particles: primarily photons in the case of LFUV measurements. The low material in front of the B -factory calorimeters, as well as their good resolution and granu-

Figure 4 Examples of particle reconstruction performance for the *BABAR* detector; the performance for the Belle detector is similar. Left: electron reconstruction efficiency. larities, allows them to fully reconstruct final states that contain π^0 mesons decaying to two photons—present, for instance, via the copious $D^0 \rightarrow K^-\pi^+\pi^0$ decay—as well as photons, such as those coming from $D^{*0} \rightarrow D^0\gamma$ decays. At LHCb, the granularity and detector material challenges discussed above, as well as the high number of b -hadrons, have led its LFUV measurements to (so far) avoid of the reconstruction of final states with π^0 mesons or photons.

C. Kinematic reconstruction: The b -hadron momentum

One of the major challenges in the reconstruction of semitauonic $H_b \rightarrow H_c\tau\nu$ decays is the determination of the parent b -hadron momentum. This momentum is necessary to measure important kinematic variables such as the momentum transfer $q^2 = (p_{H_b} - p_{H_c})^2 \equiv (p_\tau + p_\nu)^2$, that is not directly accessible because of the undetected neutrinos in the final state. In measurements involving the $\tau \rightarrow \ell\nu\bar{\nu}$ decay, the momentum of the parent b -hadron is further employed to reconstruct other invariants, such

as the invariant mass of the unreconstructed particles

$$m_{\text{miss}}^2 = (p_{H_b} - p_{H_c} - p_\ell)^2, \quad (44)$$

or the energy of the charged lepton in the H_b rest frame,

$$E_\ell^* = (p_\ell \cdot p_{H_b})/m_{H_b}. \quad (45)$$

In these leptonic- τ measurements, the signal and normalization modes ($H_b \rightarrow H_c\tau\nu$ and $H_b \rightarrow H_c\ell\nu$, respectively) are reconstructed in the same exact final state, differing only in the number of undetected neutrinos. Since normalization events only have one neutrino, their reconstructed m_{miss}^2 distribution is sharply peaked at zero, in contrast to the broad m_{miss}^2 distribution of signal events. Additionally, charged leptons in the signal events are generated in the secondary τ decay and thus have a lower maximum E_ℓ^* than those arising from normalization $H_b \rightarrow H_c\ell\nu$ decays.

In Sec. III.C.1 we describe how the B factories take advantage of their precisely known e^+e^- beam energies to determine the momentum of the signal B in a $B\bar{B}$ event by reconstructing the accompanying tag \bar{B} . This procedure is not available in the busier hadronic environment of pp collisions. Instead, LHCb employs the

Table IV Reconstruction efficiencies of some of the B tagging algorithms employed by the B factories. FEI stands for “Full event interpretation”, FR for “Full reconstruction”, and SER for “Semi-exclusive reconstruction”. The numbers are extracted from (Keck *et al.*, 2019; Lees *et al.*, 2013)

| B tagging | Experiment | Algorithm | B^\pm | B^0 |
|--------------|------------|-------------------|---------|-------|
| Hadronic | Belle II | FEI | 0.76% | 0.46% |
| | Belle II | FEI (FR channels) | 0.53% | 0.33% |
| | Belle | FR | 0.28% | 0.18% |
| | BABAR | SER | 0.4% | 0.2% |
| Semileptonic | Belle II | FEI | 1.80% | 2.04% |
| | Belle | FR | 0.31% | 0.34% |
| | BABAR | SER | 0.3% | 0.6% |

untagged methods detailed in Secs. III.C.2 and III.C.3. These methods have much higher efficiency than B tagging, but at the cost of significantly worse p_{H_b} resolution.

1. B tagging at the B factories

As described in Sec. III.A.1, the B factories produce B mesons via $e^+e^- \rightarrow \Upsilon(4S) \rightarrow B\bar{B}$ decays. Since the momenta of the colliding electron-positron beams are known with high precision, the complete reconstruction of one of the two B mesons (the tag B or B_{tag}) can be used to fully determine the momentum of the other B meson (the signal B or B_{sig}), simply via $p_{B_{\text{sig}}} = p_{e^+e^-} - p_{B_{\text{tag}}}$.

This “tagging” has been implemented by the B factories (Bevan *et al.*, 2014) in the following ways:

- *Hadronic B tagging*: the B_{tag} is fully reconstructed in final states that contain a charm hadron plus a number of pions and kaons. The full reconstruction of the decay results in the best possible $p_{B_{\text{sig}}}$ resolution (11% as shown in Fig. 6) at the price of a lower 0.2–0.8% efficiency (Table IV).
- *Semileptonic B tagging*: the B_{tag} is reconstructed in its $\bar{B}_{\text{tag}} \rightarrow D^{(*)}\ell\bar{\nu}$ decays. This leads to efficiencies as high as 2% thanks to the large values of the semileptonic branching fractions. The presence of an unreconstructed neutrino, however, results in a poor resolution of $p_{B_{\text{sig}}}$. To mitigate this effect, analyses employing this technique exploit the full reconstruction of the collision event and require that no unassigned charged or neutral particles should be present. They further avoid the direct use of $p_{B_{\text{sig}}}$.
- *Inclusive B tagging*: no attempt is made to explicitly reconstruct the B decay chain. Instead, a specific B_{sig} candidate is first reconstructed. The tag side is then reconstructed using all remaining charged and neutral particles. This leads to a high efficiency, but also poor resolution of the tag-side momentum.

Figure 6 Resolution on the q^2 reconstruction in simulated $B \rightarrow D^* \tau \nu$ decays for the different methods of estimating the $p_{B_{\text{sig}}}$ momentum. The values in parentheses correspond to the RMS of each distribution. The various curves are extracted from (Aaij *et al.*, 2015c, 2018b; Lees *et al.*, 2013).

Table IV summarizes the performance of the most efficient algorithms employed by BABAR, Belle, and Belle II. The Belle II numbers are based on simulations.

The hadronic B tagging algorithm of BABAR is based on the reconstruction of a charmed seed-state of a $B \rightarrow H_c X$ cascade. Here H_c can either be a charmed meson or a J/ψ particle and X is a number of charged and neutral pions or a single kaon. Combinations of seed mesons with different X constituents are selected based on the purity obtained from simulated samples.

Belle uses a similar Ansatz, but relies on multivariate methods (either neural networks or boosted decision trees) to distinguish correctly-reconstructed versus wrongly-reconstructed tag candidates in a staged approach. Figure 7 illustrates this procedure for the Full Event Interpretation (FEI) algorithm described in (Keck *et al.*, 2019). This algorithm reconstructs one of the B mesons produced in the collision event using either hadronic or semileptonic decay channels. Instead of attempting to reconstruct as many B meson decay cascades as possible, the FEI algorithm employs a hierarchical reconstruction Ansatz in several stages: at the initial stage, boosted decision trees are trained to identify charged tracks and neutral energy depositions as detector stable particles (e^+ , μ^+ , K^+ , π^+ , K_L^0 , γ). At the following stages, these candidate particles are combined into composite particles (π^0 , K_S^0) and later heavier meson candidates (J/ψ , D^0 , D^+ , D_s). For each target final state, a boosted decision tree is trained to identify probable candidates. The input features are the classifier outputs of the previous stages, vertex fit probabilities, and the four-momenta. Similarly candidates for D^{*0} , D^{*+} , and D_s^* mesons are formed. At the final stage, all the information of the previous stages is combined to assess the viability of a B_{tag} candidate. The FR algorithm uses a very similar approach with neural networks. A more

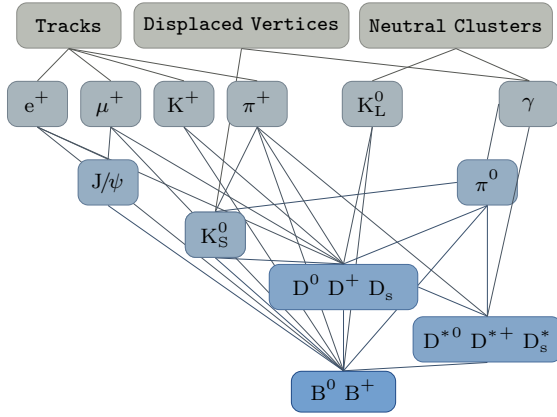

Figure 7 Schematic illustration of the FEI algorithm. From (Keck *et al.*, 2019).

detailed description can be found in (Feindt *et al.*, 2011). The performance of the FEI algorithm on early Belle II data is discussed in (Abudinén *et al.*, 2020).

In the future deep learning or graph-based network approaches might allow further increases in the reconstruction efficiency of algorithms like the FEI at Belle II (Boeckh, 2020; Keck, 2017).

2. $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$ vertex reconstruction at LHCb

At the LHC, the energies of the partons whose collisions produce the $b\bar{b}$ pairs are not known, so B tagging cannot be employed. However, by taking advantage of the excellent vertexing capabilities of LHCb, in the case that the τ lepton decays to at least three charged particles, the momentum of the parent b -hadron in $H_b \rightarrow H_{c,u} \tau \nu$ events can still be precisely determined up to a discrete ambiguity. This procedure was established in 2018 by the hadronic- τ measurement of $\mathcal{R}(D^{*+})$ with $\tau \rightarrow \pi^+ \pi^+ \pi^- \nu$ (Aaij *et al.*, 2018b).⁷

In general, about 100 tracks arise from a primary vertex (PV) within a pp collision at LHCb, such that the location of this vertex can be measured to an excellent precision of around 10 μm . In $\bar{B}^0 \rightarrow D^{*+} \tau^- \bar{\nu}_\tau$ events with the D^{*+} meson decaying promptly via the $D^{*+} \rightarrow D^0 \pi^+$ strong decay, the D^0 vertex can be reconstructed as the intersection of its kaon and pion daughters with a 150 μm precision along the z direction (see Fig. 8 top). The vertex for the $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$ decay can be measured to a 200 μm precision. Due to the very small angle between the directions of the bachelor pion produced in the D^{*+} decay and the reconstructed D^0 , their intersection has poor precision and is not used in the determination of

Figure 8 Reconstructed topologies for the $B \rightarrow D^* \tau \nu$ decays in the hadronic- τ (top) and muonic- τ (bottom) measurements of $\mathcal{R}(D^{*+})$ at LHCb (Aaij *et al.*, 2015c, 2018b). The filled circles correspond to the reconstructed vertices, and solid lines to reconstructed particles. “PV” refers to the primary vertex, Δz the distance in the z -direction between the \bar{B}^0 (or D^{*+}) and the τ^- vertices, and α to the angle between the beam axis and the momentum of the \bar{B}^0 meson.

the position of the \bar{B}^0 vertex. Instead, this position is estimated with a ~ 1 mm resolution as the intersection of the D^{*+} and τ trajectories, where the τ line of flight is approximated by the $\pi^- \pi^+ \pi^-$ direction. Thanks to the large boost of b -hadrons at LHCb, $\beta\gamma \sim 50$, these three vertices are well separated and determine the directions of flight of the \bar{B}^0 meson and τ lepton momenta—the unit vectors \hat{p}_B and \hat{p}_τ , respectively—with fairly good precision.

With \hat{p}_τ known and the $\pi^- \pi^+ \pi^-$ hadronic state fully reconstructed, the τ energy can be determined up to a two-fold ambiguity, arising from the solution of the quadratic relation $(p_\tau - p_{\pi\pi\pi})^2 = 0$. This result, when further combined with \hat{p}_B and the full reconstruction of the D^{*+} , in turn allows the determination of the B momentum up to a four-fold ambiguity from the quadratic $(p_B - p_{D^*} - p_\tau)^2 = 0$. The resulting overall q^2 resolution is around 19%.

3. Rest frame approximation with $\tau \rightarrow \mu \nu \bar{\nu}$ at LHCb

It is not possible to reconstruct the τ vertex when the τ lepton is identified by its 1-prong $\tau \rightarrow \mu \nu \bar{\nu}$ decay (Fig. 8 bottom). Thus, semitauonic measurements at LHCb that make use of this decay mode estimate the momentum of the b -hadron via the *rest frame approximation* (RFA) instead. This procedure assumes that the proper velocity of the H_b hadron along the z -axis—the beam axis—is the same for as for the reconstructed charm-muon system, μH_c . This leads to the relationship $(p_{H_b})_z/m_{H_b} = (p_{\mu H_c})_z/m_{\mu H_c}$. Since the direction of

⁷ The channel $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$ always includes contributions from the $\tau \rightarrow \pi^- \pi^+ \pi^- \pi^0 (\pi^0) \nu$ channels, unless specified otherwise.

flight of the b -hadron can be determined by the displacement of the H_b decay vertex from the primary vertex, the H_b momentum can then be estimated via

$$|p_{H_b}| = \frac{m_{H_b}}{m_{\mu H_c}} (p_{\mu H_c})_z \sqrt{1 + \tan^2 \alpha}, \quad (46)$$

where α is the angle between the H_b direction of flight and the z axis, as shown in Fig. 8.

In the highly boosted regime of LHCb, the RFA is a fairly good approximation that leads to an adequate overall q^2 resolution of about 22% (see Fig. 6), albeit with a long tail on the positive side and some bias. It is worth noting that this resolution is highly q^2 -dependent, varying between 34% for $q^2 < 5 \text{ GeV}^2$ to 7% at $q^2 > 9 \text{ GeV}^2$.

In general, semitauonic measurements at LHCb that make use of the hadronic- τ reconstruction (Aaij *et al.*, 2018b) will have better precision for the reconstruction of kinematic distributions than muonic- τ measurements (Aaij *et al.*, 2015c). In contrast, the latter may have a better ultimate precision in the determination of the ratios $\mathcal{R}(H_c)$ because they do not depend on external branching fractions in the normalization of the signal $H_b \rightarrow H_c \tau \nu$ decays, such as those used in Eq. (53) below.

In the future, LHCb may be able to improve the precision on the b -hadron momentum reconstruction by taking advantage of the large samples of b -hadrons that will be collected over the next decade and a half. For instance, the reconstruction of B^+ mesons arising from $B_{s2}^* \rightarrow B^+ K^-$ decays allows for a higher-precision determination of the B^+ kinematics by constraining the invariant mass of the $B^+ K^-$ system to the known B_{s2}^* mass, but it comes at the price of a less than 1% reconstruction efficiency. This technique has already been successfully employed to reconstruct $B^- \rightarrow D^{(*,**)0} \mu^- \bar{\nu}_\mu$ decays (Aaij *et al.*, 2019b), and could be in the future applied to semitauonic decays as well.

IV. EXPERIMENTAL TESTS OF LEPTON FLAVOR UNIVERSALITY

The decay $B \rightarrow D^* \tau \nu$ was first observed in 2007 by the Belle collaboration (Matyja *et al.*, 2007), and subsequent measurements by BABAR (Aubert *et al.*, 2008) and Belle (Adachi *et al.*, 2009; Bozek *et al.*, 2010) found evidence for $B \rightarrow D \tau \nu$ decays as well. These measurements all saw values of $\mathcal{R}(D^{(*)})$ that exceeded the SM expectations, but the significance of these excesses was low due to the large uncertainties involved in these early results: above 20% for $\mathcal{R}(D^*)$ and over 30% for $\mathcal{R}(D)$. All of these measurements have now been superseded, so they will not be further discussed in this review.

The first evidence for an excess of $B \rightarrow D^{(*)} \tau \nu$ decays was reported by BABAR in 2012 (Lees *et al.*, 2012), a measurement that also included the first observation of

$B \rightarrow D \tau \nu$ decays. Similar excesses have been reported since by the Belle (Caria *et al.*, 2020; Hirose *et al.*, 2018; Huschle *et al.*, 2015; Sato *et al.*, 2016) and LHCb experiments (Aaij *et al.*, 2015c, 2018b), and the first measurements of the polarization of some of the decay products have been reported by Belle (Abdesselam *et al.*, 2019; Sato *et al.*, 2016) as well. The persistent nature of these anomalies has spurred wide interest in semitauonic decays and, as a result, other channels that proceed via $b \rightarrow u \tau \nu$ or different $b \rightarrow c \tau \nu$ transitions are being studied. Two such results have been published so far: Belle's search for $B \rightarrow \pi \tau \nu$ decays (Hamer *et al.*, 2016) and LHCb's measurement of $\mathcal{R}(J/\psi)$ (Aaij *et al.*, 2018a).

In this section we describe the key features of all of these measurements regarding their event selection, background determination, main uncertainties, and signal extraction. The following subsections group the various results according to their b -hadron *tagging* method which, as we saw in Sec. III.C, can be employed to determine the momentum of the parent b -hadron and has a substantial

impact on the approach to determine the signal yields and on the composition of the background contributions. Table V shows an overview of the results and the subsections where they are discussed. Additionally, the section following this one (Sec. V) offers a deeper dive into the various sources of systematic uncertainty to which these measurements are subject as well the prospects for its reduction, and Sec. VI provides combinations of the various $\mathcal{R}(D^{(*)})$ results and comparisons of all the observables with their respective SM predictions.

There exist, in addition, measurements of the inclusive $B \rightarrow X_c \tau \nu$ rate, that we will not cover in this review. These comprise LEP measurements of $b \rightarrow X \tau \nu$ (Abbiendi *et al.*, 2001; Abreu *et al.*, 2000; Acciarri *et al.*, 1994, 1996; Barate *et al.*, 2001), that require assumptions about cancellation of hadronization effects in order to be interpreted as $B \rightarrow X \tau \nu$ measurements, and a recent result (Hasenbusch, 2018) that is unpublished.

A. B -factory measurements with hadronic tags

This section describes some of the most recent semi-tauonic results involving hadronic B tags: the measurements of $B \rightarrow D^{(*)} \tau \nu$ decays by BABAR (Lees *et al.*, 2012, 2013) and Belle (Huschle *et al.*, 2015) in Sec. IV.A.1, as well as a 2015 search for $B \rightarrow \pi \tau \nu$ decays by Belle (Hamer *et al.*, 2016) in Sec. IV.A.2. An additional measurement of $B \rightarrow D^{(*)} \tau \nu$ decays by Belle involving hadronic tags focused on the polarization of the τ lepton (Hirose *et al.*, 2017, 2018), and is described in Sec. IV.D.

1. $\mathcal{R}(D^{(*)})$ with $\tau \rightarrow \ell \nu \bar{\nu}$

The BABAR experiment published the first high-precision measurement of $\mathcal{R}(D^{(*)})$ based on their full dataset of $471 \times 10^6 B\bar{B}$ pairs in 2012 (Lees *et al.*, 2012, 2013). The Belle experiment followed in 2015 with an analysis of their $772 \times 10^6 B\bar{B}$ pair dataset (Huschle *et al.*, 2015), employing a similar strategy. In both cases, signal $B \rightarrow D^{(*)} \tau \nu$ and normalization $B \rightarrow D^{(*)} \ell \nu$ decays are selected by the same particles in the final state: a D or D^* meson, and a charged light lepton $\ell = e$ or μ . In the case of signal events, the light lepton ℓ comes from the secondary $\tau \rightarrow \ell \nu \bar{\nu}$ decay, which leads to two additional neutrinos in the final state and a typically lower lepton momentum. The D mesons are reconstructed by combinations of K^+ , K_S^0 , π^+ , and π^0 mesons with invariant masses close to the nominal D^0 and D^+ masses, covering 25–35% of the total D branching fractions. The heavier D^* mesons are identified by the $D^{*+} \rightarrow D^0 \pi^+$, $D^{*0} \pi^+$ and $D^{*0} \rightarrow D^0 \pi^0$, $D^{*0} \gamma$ decays.

In order to separate signal from normalization decays as well as to reduce background contributions, the event

is also required to have a fully reconstructed hadronic B_{tag} and no additional tracks; see Sec. III.C.1. As described there, the reconstruction efficiency of the B_{tag} is only $\approx 0.3\%$, but it allows these measurements to accurately determine the 4-momentum of the signal B , which in turn is used to calculate the momentum transfer $q^2 = (p_{B_{\text{sig}}} - p_{D^{(*)}})^2$ and the missing momentum of the unreconstructed neutrinos $p_{\text{miss}} = p_{B_{\text{sig}}} - p_{D^{(*)}} - p_{\ell} = p_{e^+e^-} - p_{B_{\text{tag}}} - p_{D^{(*)}} - p_{\ell}$. The invariant missing mass $m_{\text{miss}}^2 = p_{\text{miss}}^2$ peaks at zero for the one-neutrino normalization events, but has a broad distribution at positive values for signal events with three neutrinos in the final state.

A key variable to further reduce background contributions is E_{ECL} : the sum of the energy deposits in the calorimeter which are not associated with the tag or signal B decays. Events involving signal and normalization decays have all their visible final state particles reconstructed, but background decays to D^{**} mesons (among others) can enter the signal selection when their daughter π^0 mesons or photons are unassigned. Both BABAR and Belle feed E_{ECL} to multivariate classifiers that are trained to reject these background contributions. In the case of BABAR, the output of the classifier, a boosted decision tree, is required to have a minimum value for the event to be selected. As we describe below, Belle fits the output distributions of the classifier (from a neural network) directly. Finally, only events with $q^2 > 4 \text{ GeV}^2$ are selected, a requirement that takes advantage of the momentum transfer of signal events being kinematically constrained to lie above $m_{\tau}^2 = 3.16 \text{ GeV}^2$.

The number of signal, normalization, and background events in each of the $D^0 \ell$, $D^+ \ell$, $D^{*0} \ell$, and $D^{*+} \ell$ data samples is determined by maximum likelihood fits to the observed data distributions. The ratios of yields for the isospin-related contributions—e.g., $D^0 \ell$ versus $D^+ \ell$ or $D^{*0} \ell$ versus $D^{*+} \ell$ —are constrained by the known branching fractions and simulated relative efficiencies. BABAR employs an additional fit without these constraints that checks the consistency with the expected percent-level degree of isospin breaking. The probability distribution functions (PDFs) that describe each of the contributions are taken from Monte Carlo simulations that make use of the CLN form factor parametrization (Sec. II.C.2) for the signal and normalization modes, LLSW (Leibovich *et al.*, 1997) for $B \rightarrow D^{**} \ell \nu$ decays,⁸ and other (phase-space based) models augmented with corrections from data control samples for the rest of the background contributions. Additional assumptions on the D^{**} branching fractions are described in Sec. V.C.2.

The BABAR analysis employs a two-dimensional fit to the m_{miss}^2 and the charged lepton energy in the B

⁸ As a reminder, throughout this review l stands for e , μ , or τ , and ℓ for e or μ .

| | Other bkg. | 1033 | 2005 | 1.18 |
| $D^*\ell$ | $B \rightarrow D^*\tau\nu$ | 888 | 503 | 0.35 |
| | $B \rightarrow D^*\ell\nu$ | 11953 | 12045 | 0.61 |
| | $B \rightarrow D^{**}\ell\nu$ | 261 | 153 | 0.36 |
| | Other bkg. | 404 | 2477 | 3.74 |

rest frame, E_ℓ^* , while Belle fits the m_{miss}^2 distribution for $m_{\text{miss}}^2 < 0.85 \text{ GeV}^2$ and the output of the classifier at high m_{miss}^2 . Figure 9 shows some of the relevant projections for both fits. The narrow peaks in Fig. 9(a-b), including that of the *feed-down* $B \rightarrow D^*\ell\nu$ decays reconstructed in the $D\ell$ sample with a broader m_{miss}^2 distribution, illustrate the power of hadronic tagging in discriminating signal from normalization decays. Table VI shows a comparison of their fitted yields. Although the Belle dataset is 64% larger, the signal yields are about 40% smaller due to the lower reconstruction efficiency. The differences in the background yields are primarily due to *BABAR* placing a requirement on the multivariate classifier and Belle fitting its output instead.

The most challenging background contribution arises from $B \rightarrow D^{**}\ell\nu$ and $B \rightarrow D^{**}\tau\nu$ decays. The $B \rightarrow$

$D^{**}\ell\nu$ processes are estimated in control samples with the same selection as the signal samples, except for the addition of a π^0 meson. In these control samples, decays of the form $\bar{B} \rightarrow D^{(*)}\pi^0\ell^-\bar{\nu}_\ell$ have values of m_{miss}^2 close to zero, so that their yields are easily determined with fits to this variable. This fit is performed simultaneously with the fits to the signal samples, and the $B \rightarrow D^{**}\ell\nu$ contribution to both is linked by the ratio of expected yields taken from the simulation. Additional backgrounds from continuum and combinatorial B processes are estimated from data control samples, and are fixed in the fits.

Table VII summarizes all the sources of uncertainty in the measured $\mathcal{R}(D^{(*)})$ ratios by both analyses. The largest uncertainties come from the $B \rightarrow D^{**}\ell\nu$ contributions and the limited size of the simulated samples (“MC stats”). The latter uncertainty affects primarily the PDFs describing the kinematic distributions of all the components in the fit. The branching fraction ratios are calculated as

$$\mathcal{R}(D^{(*)}) = \frac{N_{\text{sig}}}{N_{\text{norm}}} \frac{\epsilon_{\text{norm}}}{\epsilon_{\text{sig}}}, \quad (47)$$

where N_{sig} and N_{norm} are the number of signal and normalization events determined by the fit, respectively, and $\epsilon_{\text{sig}}/\epsilon_{\text{norm}}$ is the ratio of efficiencies taken from simulation. Since the signal and normalization decays are reconstructed with the same particles in the final state, many uncertainties cancel in the ratio leading to a relatively small 2–3% overall uncertainty on this quantity.

Table VIII shows the results from the *BABAR* and Belle analyses, which are compatible within uncertainties. The isospin-unconstrained results from *BABAR* (Table XIX in Sec. VI.A) show good agreement with the expected percent-level degree of isospin breaking. The total uncertainty on $\mathcal{R}(D^{(*)})$ in these measurements is dominated by

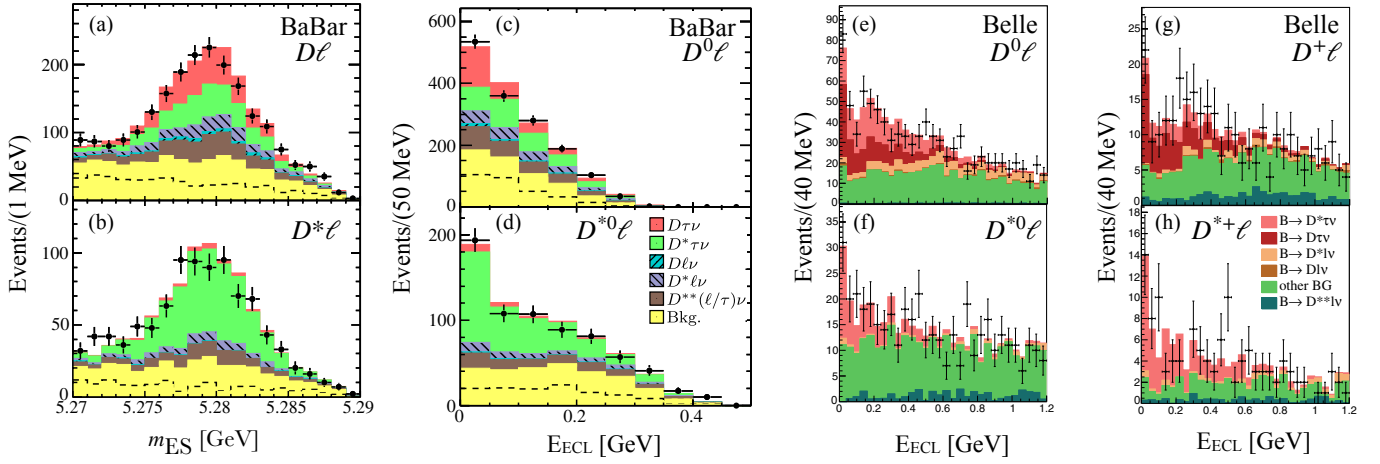

Figure 10 Checks on the kinematic distributions for events in the signal enhanced high m_{miss}^2 region [$m_{\text{miss}}^2 > 1.5 \text{ GeV}^2$ for (a-d) and $m_{\text{miss}}^2 > 2 \text{ GeV}^2$ for (e-h)]. The solid histogram correspond to the simulation scaled to the fit results. Adapted from (Huschle *et al.*, 2015; Lees *et al.*, 2013).

Table VII Summary of the relative uncertainties for the BABAR (Lees *et al.*, 2012) and Belle (Huschle *et al.*, 2015) measurements of $\mathcal{R}(D^{(*)})$ with hadronic tagging.

Table VIII Results of the BABAR (Lees *et al.*, 2012) and Belle (Huschle *et al.*, 2015) measurements of $\mathcal{R}(D^{(*)})$ with hadronic tagging. The first uncertainty is statistical and the second systematic.

| Result | BABAR | Belle |
|--------------------|-----------------------------|-----------------------------|
| $\mathcal{R}(D)$ | $0.440 \pm 0.058 \pm 0.042$ | $0.375 \pm 0.064 \pm 0.026$ |
| $\mathcal{R}(D^*)$ | $0.332 \pm 0.024 \pm 0.018$ | $0.293 \pm 0.038 \pm 0.015$ |

the statistical uncertainty, so the much larger data samples expected to be collected by Belle II should improve these results significantly.

Thorough checks of the stability of these results were performed, including separate fits to the muon and electron samples, to the various running periods, and to samples modified selection requirements varying the signal over background ratio, S/B , from 1.27 to 0.27. In all cases, results were compatible with the nominal result. Additionally, a number of kinematic distributions of signal-enriched samples were compared with the fitted SM signal plus background model and found good agreement overall. Figure 10 shows the distributions for the energy substituted mass $m_{\text{ES}} = \sqrt{E_{\text{beam}}^2 - \mathbf{p}_{\text{tag}}^2}$, which peaks at the B mass for correctly reconstructed events, and E_{ECL} . In both cases, the distributions are consistent with the fitted signal events to be coming from B mesons with no additional unreconstructed particles in the event.

Finally, Fig. 11 shows the measured efficiency-corrected q^2 distributions for $B \rightarrow D^{(*)}\tau\nu$ decays and finds good agreement with the SM expectations. The measured distributions are also compared in panels (e-f) with the expectations from the Type-II two-Higgs doublet model (2HDM) with $\tan\beta/m_{H^\pm} = 0.45 \text{ GeV}^{-1}$, which proceeds primarily via a scalar mediator. The BABAR analysis recalculates the signal PDFs, reweighting the light lepton momentum to approximately account for the changes in helicity, for each value of $\tan\beta/m_{H^\pm}$ and fits the data again, so the data points in Fig. 11 (c-d) are somewhat different from those in panels (e-f) due to the slightly different background and signal cross-feed subtraction. Including systematic uncertainties, this benchmark model is excluded at greater than 95% confidence level.

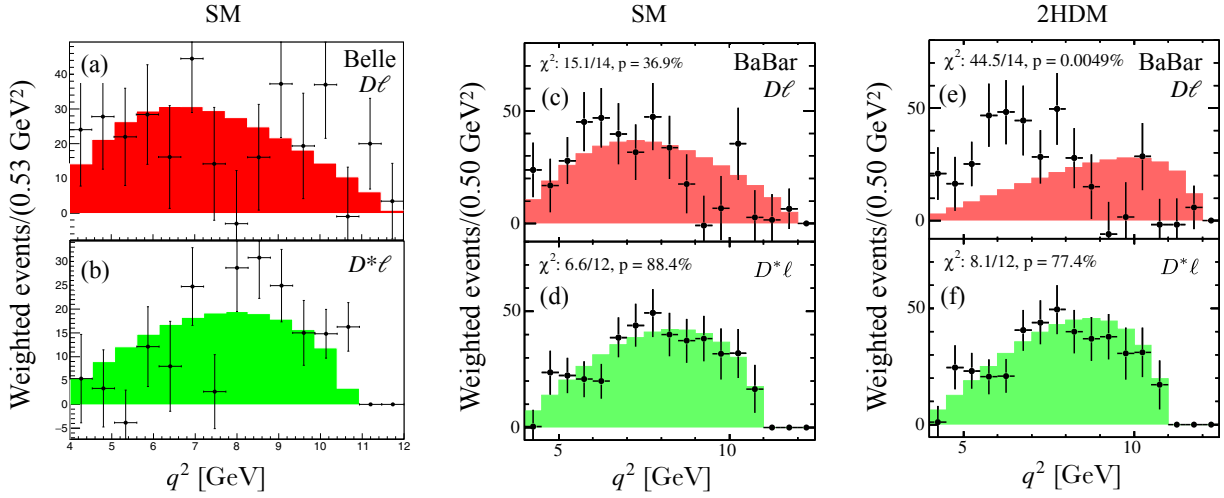

Figure 11 Efficiency corrected q^2 distributions for $B \rightarrow D\tau\nu$ (top) and $B \rightarrow D^*\tau\nu$ (bottom) events with $m_{\text{miss}}^2 > 0.85 \text{ GeV}^2$ (a-b) and $m_{\text{miss}}^2 > 1.5 \text{ GeV}^2$ (c-f). The shaded distributions correspond to the SM expectations in (a-d) and a Type-II 2HDM with $\tan\beta/m_{H^\pm} = 0.45 \text{ GeV}^{-1}$ in (e-f). The χ^2 values are calculated based on the statistical uncertainties only. Adapted from (Huschle *et al.*, 2015; Lees *et al.*, 2013).

2. Search for $B \rightarrow \pi\tau\nu$ decays

Charmless semitauonic decays offer an interesting, independent probe of LFUV to complement the excesses observed in various $\mathcal{R}(D^{(*)})$ measurements. Although they involve different four-Fermi operators, and are CKM suppressed, they also offer access to third generation semileptonic decays in an experimental setting with very different background composition. The most promising candidate for a first observation is the $B \rightarrow \pi\tau\nu$ channel. Further, even modest precision could already strongly constrain new physics models involving scalar mediators such as the Type-II 2HDM (Bernlochner, 2015).

A first limit on the branching fraction of this decay was obtained by Belle in 2015 (Hamer *et al.*, 2016), which followed a similar strategy to that employed by Belle’s hadronic tag measurement of $\mathcal{R}(D^{(*)})$. For the $B \rightarrow \pi\tau\nu$ analysis, B_{tag} mesons are selected only when the best candidate is compatible with the decay of a neutral B meson. In order to boost the reconstructed number of $B \rightarrow \pi\tau\nu$ signal decays, both electronic $\tau \rightarrow e\nu\bar{\nu}$ as well as hadronic one-prong $\tau \rightarrow \pi\nu$ and $\tau \rightarrow \rho\nu$ decays were included in the reconstruction. The signal side is thus required to have at most two oppositely charged tracks, with one of those tracks having a particle identification compatible with an electron in the case of $\tau \rightarrow e\nu\bar{\nu}$ decays. For the $\rho^+ \rightarrow \pi^+\pi^0$ reconstruction, neutral pion candidates, which are not used in the tag-reconstruction, are constructed from neutral energy depositions in the calorimeter. If multiple ρ candidates exist, the one with a mass closest to the nominal ρ mass is kept. In order to reduce background from $B \rightarrow X_c\ell\nu$ decays, events with K_L candidates are vetoed. Such candidates are identified as a cluster in the outer K_L and muon detector with

no energy depositions in the electromagnetic calorimeter near the flight path of the K_L candidate.

With all particles assigned to either the tag or signal side, E_{ECL} can be reconstructed from the remaining neutral clusters in the collision event. To further reduce backgrounds, three boosted decision trees are trained: one for each probed τ decay mode. The input variables are:

- The four-momenta of all signal particles
- q^2 as calculated from the tag-side B meson four-momentum and the signal-side pion with the highest momentum; for signal decays $q^2 \geq m_\tau^2$, whereas for backgrounds lower values are possible.
- m_{miss}^2 ; for signal decays we expect a higher missing mass because of the additional neutrinos in the final state.

Requirements on the classifier outputs are chosen to select signal events such that each channel has an optimal statistical sensitivity. The resulting number of signal events is then extracted via a simultaneous fit of the respective E_{ECL} distributions. The post-fit distributions are shown in Fig. 12. The measurement quotes an upper limit of $\mathcal{B}(B \rightarrow \pi\tau\nu) < 2.5 \times 10^{-4}$ at 90% CL. This can be converted to a value of

$$\mathcal{R}(\pi) = 1.05 \pm 0.51, \quad (48)$$

which can be compared to the SM expectation of $\mathcal{R}(\pi)_{\text{SM}} = 0.641 \pm 0.016$ (Bernlochner, 2015).

Table IX shows an overview of the systematic uncertainties of the result. The largest systematic uncertainties stem from the tagging calibration, as the measurement was not carried out as a ratio with respect to the

Figure 12 Signal fit for the Belle measurement of $B \rightarrow \pi\tau\nu$ decays, adapted from (Hamer *et al.*, 2016). The E_{ECL} distributions for the three reconstructed τ decay modes are shown: (left) $\tau \rightarrow e\nu\bar{\nu}$, (middle) $\tau \rightarrow \pi\nu$, and (right) $\tau \rightarrow \rho\nu$.

Table IX Summary of the relative uncertainties for the measurement of $B \rightarrow \pi\tau\nu$ decays by Belle (Hamer *et al.*, 2016).

| Contribution | Uncertainty [%] | |

light-lepton mode. The K_L veto, used to reduce the background from CKM favored semileptonic decays, introduces a large uncertainty due to the poorly known K_L reconstruction efficiency.

B. Belle measurements with semileptonic tags

1. $\mathcal{R}(D^{(*)})$ with $\tau \rightarrow \ell\nu\bar{\nu}$

The first measurement of $\mathcal{R}(D^*)$ using semileptonic tagging was performed by Belle (Sato *et al.*, 2016), a result that was subsequently superseded by Belle's combined measurement of $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ in 2020 (Caria *et al.*, 2020). This analysis employs the FEI algorithm (described in Sec. III.C.1) to efficiently identify semileptonic B meson decays of the second B meson (B_{tag}) in the event. This allows for the full identification of all particles and decay cascades in the collision event and the reliable reconstruction of E_{ECL} , the unassigned energy in the calorimeter, as already defined in Sec. IV.A. Tag-side $B \rightarrow D^{(*)}\ell\nu$ decays are selected by exploiting the observable

$$\cos\theta_{B,D^{(*)}\ell} \equiv \frac{2E_{\text{beam}}E_{D^{(*)}\ell} - m_B^2 - m_{D^{(*)}\ell}^2}{2|\mathbf{p}_B||\mathbf{p}_{D^{(*)}\ell}|}, \quad (49)$$

in which the energies and momenta, E and \mathbf{p} , are all defined in the centre-of-mass (CM) frame—the $\Upsilon(4S)$ rest frame—of the colliding beams. In particular, note that $E_{D^{(*)}\ell}$ and $\mathbf{p}_{D^{(*)}\ell}$ are the energy and momentum of the $D^{(*)}\ell$ system, respectively, and that in this frame $E_{\text{beam}} = E_B$. For $B \rightarrow D^{(*)}\ell\nu$ decays with a single final state neutrino, which satisfy $(p_B - p_{D^{(*)}\ell})^2 = m_\nu^2 \simeq 0$, the definition of $\cos\theta_{B,D^{(*)}\ell}$ corresponds to the cosine of the angle between the tag B meson and $D^{(*)}\ell$ system in the CM frame. Thus, for correctly reconstructed tag-side $B \rightarrow D^{(*)}\ell\nu$ decays, the right hand side of Eq. (49) falls in the physical region such that $-1 \leq \cos\theta_{B,D^{(*)}\ell} \leq 1$ (with a tail towards negative values due to final state radiation). However, for incorrectly reconstructed tag-side decays such as $B \rightarrow D^{**}\ell\nu$ or semitauonic $B \rightarrow D^{(*)}\tau(\rightarrow \ell\nu\nu)\nu$ decays, the right hand side of Eq. (49) will typically produce large negative values due to the absent term $(p_B - p_{D^{(*)}\ell})^2/2|\mathbf{p}_B||\mathbf{p}_{D^{(*)}\ell}| > 0$, needed for $\cos\theta_{B,D^{(*)}\ell}$ to represent a physical cosine. Including finite resolution effects, a requirement of $\cos\theta_{B,D^{(*)}\ell} \in [-2, 1]$ thus captures most tag $B \rightarrow D^{(*)}\ell\nu$ decays, while strongly suppressing $B \rightarrow D^{**}\ell\nu$ and $B \rightarrow D^{(*)}\tau(\rightarrow \ell\nu\bar{\nu})\nu$ decays.

On the signal side, lepton candidates are combined with D and D^* meson candidates. The decay modes used for the D^0 and D^+ account for about 30% and 22%, respectively, of the overall decay branching fractions. To further improve the reconstruction, a decay vertex fit of the D daughter particles is carried out. The D^{*+} is reconstructed using both charged and neutral slow pion candidates, and for the D^{*0} neutral slow pion candidates and photons are used. The selection is refined by applying requirements on the masses of these candidates and other variables that are optimized to maximize the statistical significance of the final result. In case several tag and signal-side candidates can be reconstructed, the candidate combination with the highest tagging classifier output from the FEI, and on the signal side with the best D vertex fit probability, is selected. Events with additional unassigned charged particles or displaced tracks are rejected. At this stage, all signal and tag-side parti-

cles are identified and E_{ECL} can be reconstructed. Here, only clusters in the barrel, forward region and backward region with energies greater than 50, 100, and 150 MeV, respectively are included. For correctly reconstructed normalization and signal decays, one expects no unassigned neutral depositions in the detector and that E_{ECL} peaks at zero with a tail towards positive values due to reconstruction mistakes on the tag-side, and to a lesser extent due to beam-background depositions and noise in the calorimeter.

To separate signal and normalization mode decays, a boosted decision tree is trained with the following distinguishing features ranked in order of importance:

- Signal side $\cos\theta_{B,D^*\ell}$: for normalization mode decays this variable will be in the physical range of $[-1, 1]$, whereas for the signal mode large negative values are expected.
- Approximate missing mass squared, m_{miss}^2 (more details in Sec. III.C): the additional two neutrinos from the τ decay will produce on average a larger missing invariant mass than the normalization mode.
- The total visible energy $E_{\text{vis}} = \sum_i E_i$ of all reconstructed particles i in the event: the two additional neutrinos from the signal mode also will reduce the visible energy observed in the detector in contrast to the normalization mode.

The classifier output \mathcal{O}_{sig} is then directly fitted along with the E_{ECL} of the event to disentangle signal, normalization, and background contributions. This is done by exploiting the isospin relations between the charged and neutral final states for the normalization and signal contributions, i.e. fixing $\mathcal{R}(D^{(*)0}) = \mathcal{R}(D^{(*)+})$. The free parameters of the fit are the yields for the signal, normalization, $B \rightarrow D^{**}l\nu$, and feed-down from $D^{(*)}\ell$ components. The yields of other background contributions from continuum and B meson decays are kept fixed to their expectation values.

Figure 13 shows the full post-fit projections of E_{ECL} as well as those in the signal enriched region of $\mathcal{O}_{\text{sig}} > 0.9$. The final results are

$$\mathcal{R}(D) = 0.307 \pm 0.037 (\text{stat}) \pm 0.016 (\text{syst}), \quad (50)$$

$$\mathcal{R}(D^*) = 0.283 \pm 0.018 (\text{stat}) \pm 0.014 (\text{syst}), \quad (51)$$

with the first error being statistical and the second from systematic uncertainties, and an anti-correlation of $\rho = -0.52$ between both values. The measurement is the most precise determination of these ratios to date and shows a good compatibility with the SM expectation.

Table X summarizes the relative systematic and statistical uncertainties on $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$. The limited size of the simulated sample, used to define the fit templates and to train the multivariate selection, results in

Table X Summary of the relative uncertainties for the Belle measurement of $\mathcal{R}(D^{(*)})$ using semileptonic tagging (Caria *et al.*, 2020).

the dominant systematic uncertainty. Uncertainties from lepton efficiencies and fake rates cancel only to some extent in the measured ratios because of the large differences in the momentum spectra of signal and normalization decays. This leads to a sizeable uncertainty of the efficiency ratios $\epsilon_{\text{sig}}/\epsilon_{\text{norm}}$. Uncertainties from the $B \rightarrow D^{**}l\nu$ background are less dominant.

C. LHCb untagged measurements

The measurement of decays with multiple neutrinos in the final state is especially challenging at hadron colliders given the typically smaller signal-to-background ratios compared to the B -factories and the inability to effectively reconstruct a tag b -hadron to constrain the kinematics of the signal decay. These difficulties have been overcome by taking advantage of the large data samples of b -hadrons produced in high-energy pp collisions and by cleverly estimating the kinematics of the signal b -hadron based on the particles that can be reconstructed. The measurements described in Secs. IV.C.1 and IV.C.3 make use of the relatively clean muonic decays of the τ lepton to limit the background contributions and estimate the B or B_c kinematics with the so-called rest frame approximation (see Sec. III.C.3). The measurement detailed in Sec. IV.C.2 takes advantage of the additional vertex that can be reconstructed from $\tau \rightarrow \pi^-\pi^+\pi^-\nu$ hadronic decays to not only reduce hadronic backgrounds by four orders of magnitude, but also to estimate the momentum of the signal B meson relatively precisely (see Sec. III.C.2).

Figure 13 Projection of the signal fit for the Belle measurement of $\mathcal{R}(D^{(*)})$ using semileptonic tagging, adapted from (Caria *et al.*, 2020). The four panels correspond to the four reconstruction categories: (top left) $D^+\ell$, (top right) $D^0\ell$, (bottom left) $D^{*+}\ell$, (bottom right) $D^{*0}\ell$. The signal enriched regions, obtained by a cut on a multivariate classifier, are shown in the inset figures. The uncertainties are only statistical.

1. $\mathcal{R}(D^{*+})$ with $\tau \rightarrow \mu\nu\bar{\nu}$

The LHCb experiment published the first measurement of a $b \rightarrow c\tau\nu$ transition in a hadron collider environment in 2015 (Aaij *et al.*, 2015c). This result was based on a 3 fb^{-1} sample of pp collision data and measured $\mathcal{R}(D^{*+})$, which under isospin symmetry has the same value as $\mathcal{R}(D^{*0})$ to a very good approximation. This first analysis chose to focus on $\mathcal{R}(D^*)$ over $\mathcal{R}(D)$ because the lower $B \rightarrow D\tau\nu$ branching fraction, the lack of the D^* mass constraint, and the larger contributions from feed-down processes make $\mathcal{R}(D)$ a significantly more challenging observable to measure at a hadron collider. A combined $\mathcal{R}(D)$ – $\mathcal{R}(D^*)$ measurement from LHCb is expected in 2021.

Signal $\bar{B}^0 \rightarrow D^{*+}\tau^-\bar{\nu}_\tau$ and normalization $\bar{B}^0 \rightarrow D^{*+}\mu^-\bar{\nu}_\mu$ decays are selected by requiring that the trajectories of a μ^- and an oppositely charged D^{*+} candidate, reconstructed exclusively via the decay chain $D^{*+} \rightarrow D^0 (\rightarrow K^-\pi^+) \pi^+$, are consistent with a common vertex that is separated from the pp primary vertex (PV). Events with an electron in the final state are not included because of the trigger and calorimeter limitations described in Sec. III.B. Compared to the B -factories, the reduction in signal reconstruction efficiency due to the exclusive use of muons and a single D^0 decay chain is compensated by the far larger production cross-section for B mesons at LHCb.

An isolation boosted decision tree (BDT) is trained to reject events arising from partially reconstructed B

decays. For each additional track in the event this algorithm evaluates the possibility that the track originates from the same vertex as the $D^{*+}\mu^-$ candidate based on quantities such as the track separation from the decay vertex and the angle between the track and the candidate momentum vector. The signal sample is made up of events where the $D^{*+}\mu^-$ candidate is found to be isolated from all other tracks in the event.

The isolation BDT is employed to further select three data control samples: a $D^{*+}\mu^-K^\pm$ sample that includes an additional kaon coming from the $D^{*+}\mu^-$ vertex, as well as the $D^{*+}\mu^-\pi^-\pi^-$ and $D^{*+}\mu^-\pi^-\pi^+\pi^+$ samples with an additional pion and pion pair, respectively. The $D^{*+}\mu^-K^\pm$ sample is enriched in double-charm decays of the type $\bar{B} \rightarrow D^{*+}H_cX$, where H_c is a charmed hadron that decays semileptonically and X refers to unreconstructed particles, while the samples with additional pions are enriched in $B \rightarrow D^{*+}l\nu$ decays. Additional data control samples based on wrong charge combinations of the D^{*+} , D^{*+} decay products and muon are used to measure the combinatorial background. The misidentified muon background is estimated in a $D^{*+}h^\pm$ sample where h^\pm is a track that fails the muon identification requirements.

A three-dimensional binned maximum likelihood fit to the q^2 , m_{miss}^2 (Eq. (44)), and E_ℓ^* (Eq. (45)) variables is performed to determine the signal, normalization, and background yields, as well as several parameters describing the shapes of the different distributions. The momentum of the B meson, necessary to calculate the three fit

Figure 14 Projections of the control sample fits in the highest q^2 bin for the LHCb measurement of $\mathcal{R}(D^{*+})$ involving muonic τ decays, adapted from (Aaij *et al.*, 2015c). (a-b) $D^{*+}\mu^-K^{\pm}$ sample enriched in $\bar{B} \rightarrow D^{*+}H_c X$ decays and (c-d) $D^{*+}\mu^-\pi^-$ sample enriched in $B \rightarrow D^{**}l\nu$ decays.

Figure 15 Projections of the signal fit for the LHCb measurement of $\mathcal{R}(D^{*+})$ involving muonic τ decays (Aaij *et al.*, 2015c). Left: full q^2 projection; Middle: m_{miss}^2 projection in the highest q^2 bin; and Right: E_{ℓ}^* projection in the highest q^2 bin.

variables, is estimated via the rest frame approximation, detailed in Sec. III.C.3.

The templates for the combinatorial and misidentified muon backgrounds are taken directly from the data control samples described above, while the templates for the $\bar{B} \rightarrow D^{*+}H_c X$ and $B \rightarrow D^{**}l\nu$ backgrounds are based on Monte Carlo simulations with corrections extracted from a fit to the $D^{*+}\mu^-K^{\pm}$ and $D^{*+}\mu^-\pi^-$ (π^+) samples. Figure 14 shows the excellent agreement between the data and the resulting background model that is achieved.

The templates for the signal and normalization contributions are parameterized by CLN form factors (Sec. II.C.2) extracted from the fit to the signal sample. Figure 15 shows the fit projection of the q^2 variable in the full range, as well as the m_{miss}^2 and E_{ℓ}^* projections in the q^2 bin with the highest signal-to-background ratio.

As Table XI shows, the limited size of the simulated samples is the main source of systematic uncertainty in

Table XI Summary of the relative uncertainties for the LHCb measurement of $\mathcal{R}(D^{*+})$ involving muonic τ decays (Aaij *et al.*, 2015c).

| Contribution | Uncertainty [%] | |
|---------------------------------|-----------------|-------------|
| | Sys. | Stat. |
| Simulated sample size | 6.2 | |
| Misidentified μ bkg. | 4.8 | |
| $B \rightarrow D^{**}l\nu$ bkg. | 2.1 | |
| $B \rightarrow D^*l\nu$ FFs | 1.9 | |
| Hardware trigger | 1.8 | |
| Double-charm bkg. | 1.5 | |
| MC/data correction | 1.2 | |
| Combinatorial bkg. | 0.9 | |
| Particle ID | 0.9 | |
| Total systematic | 8.9 | |
| Total statistical | | 8.0 |
| Total | | 12.0 |

this analysis, followed by the uncertainty in the background contributions and $B \rightarrow D^* l \nu$ templates. The overall systematic uncertainty is slightly larger than the statistical uncertainty but, as discussed in Sec. V, many of the systematic uncertainties are expected to decrease commensurately with larger data samples. The result of this measurement is

$$\mathcal{R}(D^{*+}) = 0.336 \pm 0.027 \text{ (stat)} \pm 0.030 \text{ (syst)}, \quad (52)$$

in good agreement with the previous measurements by the B -factories.

2. $\mathcal{R}(D^{*+})$ with $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$

Instead of a leptonic τ decay, the 2018 measurement of $\mathcal{R}(D^{*+})$ by LHCb (Aaij *et al.*, 2018b) employed the 3-prong $\tau^- \rightarrow \pi^- \pi^+ \pi^- \nu_\tau$ decay. This channel is interesting *a priori* because it is presently the only τ decay for which it is practical to reconstruct the τ decay vertex. This in turn provides good precision on the reconstruction of the \bar{B}^0 momentum as described in Sec. III.C. Moreover, when aggregated with the $\tau^- \rightarrow \pi^- \pi^+ \pi^- \pi^0 \nu_\tau$ channel, the 3-prong decays have a total branching fraction of 13.5%, comparable to that of the muonic decay channel, and the pion-triplet dynamics provides very useful discrimination against the largest background contributions.

In this measurement, signal $\bar{B}^0 \rightarrow D^{*+} \tau^- \bar{\nu}_\tau$ decays are selected by requiring that the trajectories of a τ^- lepton and an oppositely charged D^{*+} candidate, reconstructed exclusively via the decay chain $D^{*+} \rightarrow D^0 (\rightarrow K^- \pi^+) \pi^+$, are consistent with a common vertex separated from the PV. The τ lepton is reconstructed by requiring that the tracks of three pions with the appropriate charges share a common vertex (Fig. 8 top). Since the final state does not contain any charged lepton, fully hadronic $\bar{B}^0 \rightarrow D^{*+} \pi^- \pi^+ \pi^- X$ decays initially dominate the selected event sample. However, this background contribution may be reduced by four orders of magnitude by taking advantage of the long τ lifetime: the $\pi\pi\pi$ vertex in a signal decay is typically *displaced* downstream of the B vertex. This allows one to distinguish such from the prompt topology of $\bar{B}^0 \rightarrow D^{*+} \pi^- \pi^+ \pi^- X$ decays, in which the $\pi\pi\pi$ and the \bar{B}^0 vertices overlap, by requiring that the distance between the τ and the B vertex positions along the beam-axis is larger than four times its reconstructed uncertainty (Fig. 16). Additionally, strict isolation from other charged particles is required to reject charm decays with more than three charged daughters, as well as fake detached vertices where the D^* meson and the three pions come from other b -hadrons present in the event.

One of the major challenges in hadronic- τ measurements is that the normalization $\bar{B}^0 \rightarrow D^{*+} \mu^- \bar{\nu}_\mu$ decays are not measured simultaneously with the signal

Figure 16 Distribution of the distance between the \bar{B}^0 vertex and the τ vertex along the beam direction (Fig. 8 top) divided by its uncertainty in simulated events for the LHCb measurement of $\mathcal{R}(D^{*+})$ involving $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$ decays (Aaij *et al.*, 2018b). The vertical line shows the 4σ requirement used in the analysis to separate signal events in red from the prompt background component in grey.

$\bar{B}^0 \rightarrow D^{*+} \tau^- \bar{\nu}_\tau$ decays. Since absolute branching fraction measurements are exceedingly difficult at LHCb, this analysis normalizes the signal yield against that of the prompt $\bar{B}^0 \rightarrow D^{*+} \pi^- \pi^+ \pi^-$ decay, which has the same particle content as the signal, and then relies on two *external branching fractions* to calculate $\mathcal{R}(D^*)$ via

$$\mathcal{R}(D^*) = \frac{\mathcal{B}(\bar{B} \rightarrow D^* \tau \nu_\tau)}{\mathcal{B}(\bar{B} \rightarrow D^* \pi \pi \pi)} \Big|_{\text{fit}} \times \frac{\mathcal{B}(\bar{B} \rightarrow D^* \pi \pi \pi)}{\mathcal{B}(\bar{B} \rightarrow D^* \mu \nu_\mu)} \Big|_{\text{ext}}. \quad (53)$$

After selecting events with large τ flight significance as described above, the dominant remaining background contributions consist of double-charm $B \rightarrow D^{*+} D_s^{(*,**)}$ decays. These decays were also the largest background contributions to the muonic- τ measurement of $\mathcal{R}(D^{*+})$, but their relative amount in D and D_s^+ mesons are very different. Due to the large inclusive branching fraction of the D_s^+ meson to final states with three pions (about 30%) and small rate to semileptonic final states, the double-charm background in the hadronic- τ sample contains ten times more D_s^+ mesons than that for the muonic- τ sample. Interestingly, the D_s^+ inclusive three-pion modes proceed mainly from two-body and quasi two-body decay channels involving η , η' , ω , and ϕ mesons, which leads to very different three-pion kinematics with respect to those of the signal. That is, the $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$ decay is well-described within resonance chiral theory (Ecker *et al.*, 1989a,b), featuring chiral terms as well as single-resonance ρ and double-resonance $a_1 \rightarrow \rho$ contributions (Nugent *et al.*, 2013; Shekhovtsova *et al.*, 2012), leading to prominent ρ peaks in the distribution of both the minimum and maximum masses to the two $\pi^+ \pi^-$ mass combinations— $\min(m_{\pi^+ \pi^-})$ and $\max(m_{\pi^+ \pi^-})$, respectively.

These kinematic differences are effectively exploited by

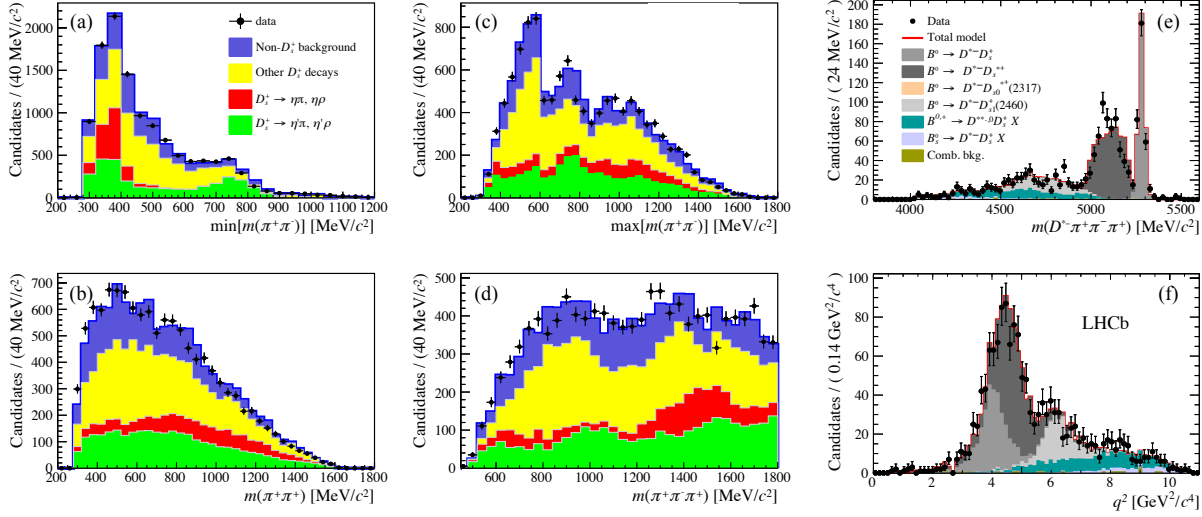

Figure 17 Control sample fits for the LHCb measurement of $\mathcal{R}(D^{*+})$ involving $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$ decays (Aaij *et al.*, 2018b) employed to evaluate the composition of the various double-charm background contributions. (a-d) low-BDT sample and (e-f) $B \rightarrow D^{*+} D_s^- (\rightarrow \pi^- \pi^+ \pi^-) X$ sample.

a BDT that also includes other variables such as the energy measured in the electromagnetic calorimeter in a cone whose axis is defined by the three-pion momentum. The kinematics of the three-pion system in background D^0 and D^+ decays is more similar to that in signal decays because the inclusive $\pi\pi\pi$ final state from these two mesons is dominated by the Ka_1 channel (Zyla *et al.*, 2020). Some discrimination is still possible, however, due to the restricted phase space of this virtual a_1 meson.

Many of the B branching fractions to double-charm final states are known with poor precision or have not been measured yet. The following data control samples are used to reduce the uncertainty due to the composition of these background contributions:

- A low-BDT sample enriched with inclusive D_s^+ decays constrains the composition of $B \rightarrow D^{*+} D_s^- X$ decays. The simulation is reweighted to match a fit to the $\min(m_{\pi^+\pi^-})$, $\max(m_{\pi^+\pi^-})$, $m_{\pi^+\pi^-\pi^+}$, and $m_{\pi^+\pi^+}$ distributions. These variables capture the combined dynamics of the various inclusive D_s^+ decay channels to three pions (Fig. 17 a-d).
- A highly pure $B \rightarrow D^{*+} D_s^- (\rightarrow \pi^- \pi^+ \pi^-) X$ sample selected by imposing a requirement on $m_{\pi^+\pi^-\pi^+}$ around the D_s^+ mass. A template fit to the $m_{\pi^+\pi^-\pi^+}$ distribution is used to measure the relative fractions of D_s^+ mesons produced directly and from D_s^* or D_s^{**} decays. The shape of the D_s^* broad peak depends on the degree of longitudinal polarization of the D_s^* and was adjusted in the simulation to reproduce the data. These measurements

are important since the q^2 distributions of these decays are very different from each other, as shown in Fig. 17 (f).

- Clean $B \rightarrow D^{*+} D^0 (\rightarrow K^- \pi^+ \pi^- \pi^+) X$ and $B \rightarrow D^{*+} D^- (\rightarrow K^- \pi^+ \pi^-) X$ samples selected by explicitly reconstructing the D^0 and D^- mesons. These samples are used to monitor and understand the non- D_s^+ background composition.

A three-dimensional binned maximum likelihood fit to q^2 , the BDT output, and the decay time of the reconstructed τ is performed to determine the signal and background yields. The calculation of q^2 relies on the B momentum determination described in Sec. III.C.2. The decay time of the reconstructed τ , t_τ , is computed from its flight distance and momentum obtained by the partial kinematic reconstruction. This variable is useful to separate τ from D^- decays, since the lifetime of the D^- meson is 3.5 times longer than that of the τ lepton. The fit results for the LHC Run 1 data sample, corresponding to a luminosity of 3 fb^{-1} , are displayed in Fig. 18. An interesting feature of this method compared to the muonic- τ measurement is that the highest BDT output bin provides a fairly clean sample of signal decays with a purity of about 40%.

As shown in Table XII, the uncertainties related to the double-charm background and the limited size of the simulated samples are the dominant systematic uncertainties in this measurement. The uncertainties due to the limited knowledge of external branching fractions in Eq. (53), currently 4.6%, are worth mentioning because, unlike many of the other systematic uncertainties, these

Figure 18 Projections of the signal fit for the LHCb measurement of $\mathcal{R}(D^{*+})$ involving $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$ decays (Aaij *et al.*, 2018b). The four rows correspond to the four BDT bins for increasing values of the BDT response.

Table XII Summary of the relative uncertainties for the LHCb measurement of $\mathcal{R}(D^{*+})$ involving $\tau \rightarrow \pi^- \pi^+ \pi^- \nu$ decays (Aaij *et al.*, 2018b).

will not be reduced with the increasing LHCb data samples that will be collected. Instead, additional measurements from Belle II will be needed (Sec. V.E).

The result of this measurement was reported as $\mathcal{R}(D^{*+}) = 0.291 \pm 0.019 \pm 0.026 \pm 0.013$ in 2018. Taking into account the latest HFLAV average of $\mathcal{B}(B^0 \rightarrow D^{*+} l \nu) = 5.08 \pm 0.02 \pm 0.12\%$ (Amhis *et al.*, 2019), the result is

$$\mathcal{R}(D^{*+}) = 0.280 \pm 0.018 \text{ (stat)} \pm 0.025 \text{ (syst)} \pm 0.013, \quad (54)$$

where the third uncertainty is due to the external branching fractions described above.

3. $\mathcal{R}(J/\psi)$ with $\tau \rightarrow \mu\nu\bar{\nu}$

The ratio $\mathcal{R}(J/\psi)$ was measured for the first time in 2018 by the LHCb experiment (Aaij *et al.*, 2018a), thus opening the possibility for the exploration of LFUV in decays subject to very different sources of both experimental and theoretical uncertainties compared to those in $\mathcal{R}(D^{(*)})$. This measurement leverages two of the key techniques developed for the muonic $\mathcal{R}(D^{*+})$ analysis described in Sec. IV.C.1: the isolation BDT and the rest frame approximation. Just as for the $\mathcal{R}(D^{*+})$ measurement, the τ lepton is reconstructed via $\tau \rightarrow \mu\nu\bar{\nu}$, so that signal $B_c \rightarrow J/\psi \tau \nu$ and normalization $B_c \rightarrow J/\psi \mu \nu$ decays share the same final state. The event is selected if the only additional tracks close to the muon coming from the τ decay are a pair of oppositely charged muons that form a vertex separated from the PV and whose invariant mass is compatible with the $J/\psi \rightarrow \mu\mu$ decay.

The signal and normalization yields are extracted from a four-dimensional binned maximum likelihood fit to q^2 , m_{miss}^2 , E_ℓ^* , and the proper time elapsed between the production and decay of the B_c meson: the decay time. The first three variables are calculated with the same techniques as used in the muonic $\mathcal{R}(D^{*+})$ analysis (Sec. IV.C.1). The inclusion of the decay time among the fit variables improves the separation of B_c decays from $B_{u,d,s}$ decays, because the B_c lifetime is almost three times shorter than that of $B_{u,d,s}$ mesons.

A key difference with respect to the $\mathcal{R}(D^{(*)})$ measurements is that background contributions from partially reconstructed B_c decays are significantly reduced thanks to the narrow invariant mass of the J/ψ meson and its clean dimuon final state. As a result of this reduction and the overall small B_c production rate, the main sources of background in the $\mathcal{R}(J/\psi)$ analysis are misidentified $H_b \rightarrow J/\psi h^+$ decays, where H_b is a more abundant b -hadron and h^+ is a hadron incorrectly identified as a muon, as well as random combinations of muons.

The template for the $J/\psi h^+$ contribution is estimated by applying the the misidentification probabilities for different hadron species, as determined in high-purity samples of identified hadrons, to a control sample with a

Figure 19 Projections of the signal fit for the LHCb muonic measurement of $\mathcal{R}(J/\psi)$ (Aaij *et al.*, 2018a). | Combinatorial bkg. | 6.5 | |
| $\epsilon_{\text{sig}}/\epsilon_{\text{norm}}$ | 0.9 | |
| Total systematic | 25.4 | |
| Total statistical | | 23.9 |
| Total | | 34.9 |

J/ψ and an additional track that fails the muon identification. This template is treated as free-floating in the signal fit. The combinatorial backgrounds are estimated in the sidebands of the B_c mass and the J/ψ masses, $m(J/\psi\mu) > 6.4$ GeV and $3150 < m(\mu^+\mu^-) < 3190$ MeV, respectively. The small contributions from higher-mass $B_c^- \rightarrow \psi(2S)\ell^-\bar{\nu}_\ell$ and $B_c^- \rightarrow \chi_c(1P)\ell^-\bar{\nu}_\ell$ are extracted from the fit with templates taken from MC simulation.

Figure 19 shows the fit projections for m_{miss}^2 over the full range, as well as m_{miss}^2 and the B_c decay time in the E_ℓ^* and q^2 ranges with the highest signal-to-background ratio. The agreement is good overall and a small but significant signal contribution at high m_{miss}^2 and low decay times can be observed.

Table XIII summarizes the sources of uncertainty in this measurement. The leading contribution comes from the $B_c \rightarrow J/\psi l\nu$ decay form factors, which have not been measured yet and had to be determined in the signal fit itself. As discussed in Sec. II.E, HQET cannot be used to describe a decay with a heavy spectator quark, so that at the time of publication of this measurement only quark model predictions, untested by experiment, were available. The recent results of lattice calculations will reduce

this uncertainty substantially. Sizeable uncertainties also arise due to the limited size of the simulated samples and the fit model. These are also expected to be reduced in future measurements.

The result of this measurement is

$$\mathcal{R}(J/\psi) = 0.71 \pm 0.17 (\text{stat}) \pm 0.18 (\text{syst}), \quad (55)$$

which lies within 2 standard deviations of the SM prediction in Eq. (34).

D. Belle polarization measurements

1. τ polarization with $\tau \rightarrow \pi\nu$ and $\tau \rightarrow \rho\nu$

The Belle experiment measured in (Hirose *et al.*, 2017, 2018) the τ polarization fraction $P_\tau(D^*)$ introduced in Sec. II.D.2. The analysis strategy is similar to that of the hadronic tag measurements of $B \rightarrow D^*\tau\nu$ decays (Huschle *et al.*, 2015; Lees *et al.*, 2012, 2013), but reconstructs the τ lepton in the hadronic one-prong $\tau \rightarrow \pi\nu$ and $\tau \rightarrow \rho\nu$ modes. For these final states, the helicity angle $\cos\theta_h$ can be explicitly reconstructed by taking advantage of the fully reconstructed tag-side B meson to boost the visible τ daughter particles into the rest frame of the $\tau\nu$ lepton system with the 4-momentum

$$q = p_{e^+e^-} - p_{B_{\text{tag}}} - p_{D^*}. \quad (56)$$

The terms on the right hand side are the momenta of the colliding e^+e^- pair, the reconstructed tag-side B meson, and the reconstructed D^* candidate, respectively. In the lepton system frame, the τ energy and momentum magnitude are fully determined by q^2 and the τ lepton mass m_τ ,

$$E_\tau = \frac{q^2 + m_\tau^2}{2\sqrt{q^2}}, \quad |\vec{p}_\tau| = \frac{q^2 - m_\tau^2}{2\sqrt{q^2}}. \quad (57)$$

In this frame, the cosine of the angle between the spatial momenta of the τ lepton and its daughter meson, h , is

$$\cos\theta_{\tau h} = \frac{2E_\tau E_h - m_\tau^2 - m_h^2}{2|\vec{p}_\tau||\vec{p}_h|}, \quad (58)$$

Figure 20 Signal fit for the measurement of the τ polarization fraction $P_\tau(D^*)$ by Belle (Hirose *et al.*, 2017). The fits to the neutral and charged B candidates as well as the $\tau \rightarrow \pi\nu$ and $\tau \rightarrow \rho\nu$ decay modes and the two $\cos\theta_h$ bins are all combined together.

in which E_h and $|\vec{p}_h|$ are the daughter meson energy and absolute spatial momentum, respectively. By applying a boost into the τ rest frame, one can then express the cosine of the helicity angle as

$$\cos\theta_h = \frac{1}{|\vec{p}_h^\tau|} (\gamma|\vec{p}_h| \cos\theta_{\tau h} - \gamma\beta E_h). \quad (59)$$

Here, $\gamma = E_\tau/m_\tau$, $\beta = |\vec{p}_\tau|/E_\tau$, and $|\vec{p}_h^\tau| = (m_\tau^2 - m_h^2)/(2m_\tau)$ denotes the absolute daughter meson spatial momentum in the τ rest frame.

To reduce backgrounds, only candidates with $q^2 > 4 \text{ GeV}^2$ and with a physical value of $\cos\theta_h \in [-1, 1]$ are retained. Unassigned neutral energy depositions fulfilling photon-energy reconstruction criteria are summed to reconstruct E_{ECL} and only candidates with $E_{\text{ECL}} < 1.5 \text{ GeV}$ are retained. In order to not be dependent on the B_{tag} reconstruction, whose efficiency likely differs between data and simulation, the measured signal event yields are normalized to $B \rightarrow D^*\ell\nu$ events. These can be identified and separated from background processes using m_{miss}^2 (cf. Sec. III.C). For both signal and normalization candidates, events with additional charged tracks or π^0 candidates are rejected.

The observables $\mathcal{R}(D^*)$ and $P_\tau(D^*)$ are extracted from a fit to the E_{ECL} distribution in two bins of $\cos\theta_h$: $[-1, 0]$ and $[0, 1]$. This fit is performed simultaneously to the two τ decay samples, $\tau \rightarrow \pi\nu$ and $\tau \rightarrow \rho\nu$. The free parameters in the fit include the yields for the $B \rightarrow D^*\tau\nu$, $B \rightarrow D^*\ell\nu$, $B \rightarrow D^{**}\ell\nu$, continuum, and fake D^* contributions, among others. Figure 20 shows the fitted E_{ECL} distribution for all the reconstructed modes combined together. The fitted signal yields are then converted into measurements of $\mathcal{R}(D^*)$ and $P_\tau(D^*)$ with

$$\mathcal{R}(D^*) = \frac{1}{\mathcal{B}(\tau \rightarrow h\nu)} \times \frac{\epsilon_{\text{norm}}}{\epsilon_{\text{sig}}} \times \frac{N_{\text{sig}}}{N_{\text{norm}}}, \quad (60)$$

Figure 21 The values of $\mathcal{R}(D^*)$ and $P_\tau(D^*)$ (white star) and the 1σ , 2σ , and 3σ contours as measured by Belle (Hirose *et al.*, 2017). The SM expectations (Amhis *et al.*, 2019; Tanaka and Watanabe, 2013) are shown by the white triangle. The gray band shows the (then) world average measurement of $\mathcal{R}(D^*)$.

$$P_\tau(D^*) = \frac{2}{\alpha} \frac{N_{\text{sig}}^{\cos\theta_h > 0} - N_{\text{sig}}^{\cos\theta_h < 0}}{N_{\text{sig}}^{\cos\theta_h > 0} + N_{\text{sig}}^{\cos\theta_h < 0}}, \quad (61)$$

with α being a factor that accounts for the sensitivity on the polarization and efficiency differences of both channels. The obtained values are

$$\mathcal{R}(D^*) = 0.270 \pm 0.035(\text{stat})_{-0.025}^{+0.028}(\text{syst}), \quad (62)$$

$$P_\tau(D^*) = -0.38 \pm 0.51(\text{stat})_{-0.16}^{+0.21}(\text{syst}), \quad (63)$$

with a total correlation including systematic uncertainties of $\rho = 0.33$. These results are in good agreement with the SM expectations, as shown in Fig. 21. A summary of the uncertainties on these measurements can be found in Table XIV. The largest systematic uncertainties stem from the composition of the hadronic B meson background and the limited size of the simulated samples used to determine the fit PDFs.

2. D^* polarization with inclusive tagging

The Belle experiment reported in (Abdesselam *et al.*, 2019) a first, preliminary, measurement of the longitudinal D^* polarization fraction $F_{L,l}(D^*)$ (see Sec. II.D.2) based on inclusively tagged events (Sec. III.C.1). First, a viable $B^0 \rightarrow D^{*-}\tau^+\nu_\tau$ signal candidate with $\tau \rightarrow \ell\nu\bar{\nu}$ or $\tau \rightarrow \pi\nu$ and $D^{*-} \rightarrow \bar{D}^0\pi^-$ is reconstructed. The \bar{D}^0 meson is reconstructed in $\bar{D}^0 \rightarrow K^+\pi^-$, $\bar{D}^0 \rightarrow K^+\pi^-\pi^0$, and $\bar{D}^0 \rightarrow K^+\pi^+\pi^-\pi^-$ modes. Thereafter, no explicit reconstruction is attempted of the other (tag) B meson produced in the e^+e^- collision. Instead, an inclusive reconstruction approach that sums over all unassigned charged particles and neutral energy depositions above a certain energy threshold in the calorimeter is employed.

Table XIV Summary of the relative uncertainties for Belle’s hadronic tag measurement of $\mathcal{R}(D^*)$ and $P_\tau(D^*)$ (Hirose *et al.*, 2017, 2018).

| Result | Contribution | Uncertainty [%] | |
|--------------------|--|-----------------|-------------|
| | | sys. | stat. |
| $\mathcal{R}(D^*)$ | $B \rightarrow D^{**}\ell\bar{\nu}_\ell$ | 2.4 | |
| | PDF modeling | 3.4 | |
| | Other bkg. | 8.4 | |
| | $\epsilon_{\text{sig}}/\epsilon_{\text{norm}}$ | 3.2 | |
| | Total systematic | 9.9 | |
| | Total statistical | | 12.9 |
| Total | | 16.3 | |
| $P_\tau(D^*)$ | PDF modeling | 33 | |
| | Other bkg. | 31 | |
| | Total systematic | 48 | |
| | Total statistical | | 134 |
| Total | | 143 | |

Compared to hadronic or semileptonic tagging, this approach has the benefit of a higher reconstructions efficiency, as it does not rely on identifying decay cascades correctly, but results in a poorer B momentum resolution.

The tag side is required to be compatible with a well-reconstructed B meson by requiring

$$M_{\text{tag}} = \sqrt{(E_{\text{beam}}^2 - |\mathbf{p}_{\text{tag}}|^2)} > 5.2 \text{ GeV}, \quad (64)$$

and $-0.30 < E_{\text{tag}} - E_{\text{beam}} < 0.05$ GeV, where $E_{\text{beam}} = \sqrt{s}/2$ is the energy of each of the colliding e^+e^- beams in the CM frame.

The sizeable background contributions are suppressed with the signal-side normalized variable

$$X_{\text{miss}} = \frac{E_{\text{miss}} - |\mathbf{p}_{D^*} + \mathbf{p}_{d_\tau}|}{\sqrt{E_{\text{beam}}^2 - m_{B^0}^2}}, \quad (65)$$

where $E_{\text{miss}} = E_{\text{beam}} - (E_{D^*} + E_{d_\tau})$ and d_τ refers to the visible τ daughter. Events with one neutrino have values of X_{miss} in the range $[-1, 1]$, while events with multiple undetected particles tend to take larger values. The analysis optimizes the signal significance by requiring that X_{miss} be larger than 1.5 or 1 for the $\tau \rightarrow \ell\nu\bar{\nu}$ and $\tau \rightarrow \pi\nu$ decay modes, respectively.

The helicity angle θ_v is defined as the angle between the reconstructed \bar{D}^0 and the direction opposite to the B^0 meson in the D^{*-} frame (see definition in Fig. 1; the Belle analysis uses the notation θ_{hel}). Because of the low D^* reconstruction efficiency for $\cos\theta_v > 0$, the analysis focuses on the $-1 \leq \cos\theta_v \leq 0$ range. The signal yields are extracted in three bins of $\cos\theta_v$ from fits to the M_{tag} distribution, see Fig. 22 for an example. Most backgrounds do not peak in this variable, with the exception of semileptonic decays into light leptons. The

Figure 22 Signal fit to the lowest $\cos\theta_v$ bin, $[-1, -0.67]$, in the $\bar{D}^0 \rightarrow K^+\pi^-\pi^0$ channel for the measurement of the longitudinal D^* polarization fraction by Belle (Abdesselam *et al.*, 2019). The red curve corresponds to the signal contribution, and the blue and green curves display the non-resonant and resonant background contributions, respectively.

yields for these peaking contributions are determined in the side bands of kinematic variables. The D^* polarization fraction is determined by a fit to the signal yields as a function of $\cos\theta_v$. Given the size of the $\cos\theta_v$ bins, resolution effects are assumed to be negligible. Figure 23 shows the measured helicity angle distribution, corrected for acceptance effects. The resulting fitted value for the longitudinal D^* polarization fraction is

$$F_{L,\tau}(D^*) = 0.60 \pm 0.08(\text{stat}) \pm 0.04(\text{sys}), \quad (66)$$

with its uncertainty dominated by the limited size of the data sample. The largest systematic uncertainty in this measurement stems from the signal and non-resonant background shapes used in the M_{tag} fits, followed by the uncertainty on the modeling of $B \rightarrow D^{**}\tau\nu$ decays.

This result agrees with the SM prediction of $F_{L,\tau}(D^*)_{\text{SM}} = 0.455(6)$ (Sec. II.D.2, from an arithmetic average of the various SM predictions) at the 1.6σ level. An important control measurement is the D^* polarization of the light-lepton states, $F_{L,\ell}(D^*) = 0.56 \pm 0.02$, which is in agreement with the prediction of $F_{L,\ell}(D^*)_{\text{SM}}^{\text{BLPR}} = 0.517(5)$ within 2.1 standard deviations.

V. COMMON SYSTEMATIC UNCERTAINTIES AND FUTURE PROSPECTS

The different measurements of $\mathcal{R}(D^{(*)})$ so far are fairly independent of each other because their uncertainties are dominated by the limited size of the data and the simulation samples. However, over the next decade and half, Belle II and LHCb will collect data samples 50 to 200 times larger than those used for the present measurements of $\mathcal{R}(D^{(*)})$ (Table III), so the relative impact

Figure 23 Measured $\cos\theta_v$ distribution in $B^0 \rightarrow D^{*-}\tau^+\nu_\tau$ decays for the determination of the longitudinal D^* polarization fraction by Belle, adapted from (Abdesselam *et al.*, 2019). The red curve shows the best fit of the longitudinal polarization fraction and the yellow band corresponds to the SM expectation (Huang *et al.*, 2018).

of other systematic uncertainties will increase. Some of these uncertainties are due to aspects of the experimental analysis that are shared among all measurements and can therefore lead to common systematic uncertainties. As a result, the combination of the measurements will entail a more complex treatment of these uncertainties. Table XV and the following subsections describe the main sources of systematic uncertainty in the measurement of $\mathcal{R}(D^{(*)})$, and the level of commonality among the various approaches.⁹

We also discuss in the following subsections the future prospects to reduce the total uncertainty in $\mathcal{R}(D^{(*)})$, as well as on LFUV ratios in many other decay modes, down to a few percent or less. In particular, reducing the systematic uncertainties commensurately with the statistical uncertainties will require meeting key challenges in computation, the modeling of b -hadron semileptonic decays, and background estimation in the years to come.

A. Monte Carlo simulation samples

Table XV shows that one of the principal sources of uncertainty in the $\mathcal{R}(D^{(*)})$ measurements arises from the

⁹ It is worth noting that, while some uncertainties are *multiplicative*, i.e. they scale with the resulting central value (e.g., uncertainties on the signal efficiency), the majority of the uncertainty is *additive* (e.g., uncertainties associated to the background subtraction or signal shapes). As a result, changes in the central values would alter the value of the uncertainty when expressed in percentage. However, given that the overall uncertainty has become smaller than 20% and the central values are starting to converge (see Fig. 25), the presentation of uncertainties in percentages should give a broadly accurate representation of the uncertainties and allow for comparisons across different measurements.

limited size of the simulation samples. This limitation results in large uncertainties through two different, but parallel, considerations: First, $B \rightarrow D^{(*)}l\nu$ decays have some of the largest B branching fractions, necessitating very large simulation samples to acceptably model the data. Such uncertainties, however, are statistical in nature and thus independent among different experimental analyses.

Second, semitauconic decays involve final states with multiple neutrinos, which escape detection. As a result, the reconstructed kinematic distributions employed to separate signal from background events are broad and difficult to describe analytically. Instead, experiments rely upon Monte Carlo simulation to derive the templates that are used in the signal extraction fit. Because of the broad nature of these distributions, multiple dimensions are necessary to disentangle the various contributions, which results in the simulated events being widely distributed among the numerous bins in the templates.

Of course, Monte Carlo-based uncertainties can be reduced simply by producing more simulated events. However, given the size of future data samples, it will be both a time and cost challenge to continue producing simulated events in sufficient numbers such that these uncertainties remain controlled. Thus, different solutions will need to be considered. At present the most promising approaches are:

(i) *Hardware*: The High Energy Physics (HEP) community has historically relied upon the exponential increase in computing throughput for relatively stable investments. As this exponential growth slows, either greater funding will have to be found or new avenues will need to be explored to keep up. Monte Carlo simulations are highly parallelizable, which makes them a favorable target for graphics processing unit (GPU) computation. Efforts to make increasing use of GPUs are underway, and expertise and appropriate tools will have to be further developed by the HEP community to ensure the widespread adoption of GPUs and reap their benefits.

(ii) *Fast simulation (FastSim)*: the most resource intensive step in the generation of simulated events is the simulation of the detector response. Several procedures have been developed and are in use already that accelerate this step by simulating only parts of the detectors, or parameterizing its response. New machine learning techniques such as generative adversarial networks may be able to further optimize this aspect of event simulation. See e.g. (Erdmann *et al.*, 2019; Vallecorsa, 2018) for proof-of-concept studies of this.

(iii) *Aggressive generator-level selections*: these can help reduce the number of events that need to be fully simulated. Fiducial selections are already widely applied, but as data becomes abundant and the computing resources are stretched thin, analyses may have to start focusing on reduced regions of phase space with an even better signal-to-noise ratio. The generator-level

Table XV Summary of the uncertainties on the $\mathcal{R}(D^{(*)})$ measurements. The “Other bkg.” column includes primarily contributions from DD and combinatorial backgrounds. The “Other sources” column is dominated by particle identification and external branching fraction uncertainties.

| Result | Experiment | τ decay | Tag | Systematic uncertainty [%] | | | | | Total uncert. [%] | | |

^a(Lees *et al.*, 2012, 2013)

^b(Caria *et al.*, 2020) ^c(Huschle *et al.*, 2015) ^d(Hirose *et al.*, 2018) ^e(Aaij *et al.*, 2015c) ^f(Aaij *et al.*, 2018b)

selections would then have to be adjusted as closely as possible to these reduced areas to maximize the physics output of the simulation. For Belle II an attractive option to increase the size of simulated samples in analyses that use hadronic tagging would be to only generate the low branching fraction modes actually targeted by the tagging algorithms. See e.g. (Kahn, 2019) for a proof-of-concept implementation using generative adversarial networks.

It is important to note that each of these approaches alone will not be sufficient to cover all future needs. For instance, the FastSim implementations currently being employed at LHCb allow for simulated events to be produced with about ten times fewer resources than with full simulation. However, this order of magnitude improvement only covers the increased needs from Run 1 (3.1 fb^{-1}) to Run 2 (6 fb^{-1} , twice the $b\bar{b}$ cross section, and higher efficiency than in Run 1). Meeting the needs for the 50 ab^{-1} that will be collected by Belle II, or the 300 fb^{-1} by LHCb, will probably involve the combined use of the approaches listed above and perhaps others.

B. Modeling of $B \rightarrow D^{(*)}\ell\nu$

As discussed at length in Sec. II, the predominant theory uncertainties in the modeling of $b \rightarrow c\tau\nu$ decays arises in the description of their hadronic matrix elements. Precision parametrizations of these matrix elements are currently achieved by either data-driven model-independent approaches, such as fits to HQET-based parametrizations (Sec. II.C.2), or by lattice QCD results (Sec. II.C.4), or a combination of both. This applies to predictions both for the ground states as well as the excited states (Sec. II.E) that often dominate background contributions. In the case of $B \rightarrow D^{(*)}\ell\nu$, these approaches have led to form factors determinations whose uncertainties

only contribute at the 1–2% level in the measurements of $\mathcal{R}(D^{(*)})$.

Especially for semitauonic analyses using the electronic or muonic τ decay channels, a reliable description of $B \rightarrow D^{(*)}\ell\nu$ semileptonic decays is a critical input, in order to control lepton cross-feed backgrounds. The hadronic τ decay analyses also rely on these light semileptonic inputs, but to a lesser extent. Finally, there is some additional uncertainty in the modeling of the detector resolution for the kinematic variables that these analyses depend upon, that can be shared across results from the same experiment.

C. $B \rightarrow D^{**}\ell\nu$ and $B \rightarrow D^{**}\tau\nu$ backgrounds

1. Systematic uncertainties evaluation and control

Excited D^{**} states decay to D^* , D^0 , or D^\pm mesons plus additional photons or pions, which can escape detection. As a result, both $B \rightarrow D^{**}\ell\nu$ and $B \rightarrow D^{**}\tau\nu$ decays can easily lead to extraneous candidates in $\mathcal{R}(D^{(*)})$ analyses, though the former contributes only to measurements that employ the leptonic decays of the τ lepton. In hadronic analyses, the corresponding background is formed by $B \rightarrow D^{**}D_s^{(*,**)}$ decays. While all analyses exploit dedicated D^{**} control samples where some of the parameters describing these contributions are measured, a number of assumptions are shared among the various measurements, namely the form factor parameterization of the $B \rightarrow D^{**}\ell\nu$ decays (Sec. II.E) and the D^{**} decay branching fractions.

First data-driven fits of the $B \rightarrow D^{**}$ form factors have been performed (Bernlochner and Ligeti, 2017; Bernlochner *et al.*, 2018a), but the resulting parameters—especially for the broad states—are not yet well constrained. The chosen approach is, however, improvable

with future data. Just as for the $B \rightarrow D^{(*)}$ modes, data-driven predictions for $B \rightarrow D^{**}$ (Eq. (29)) are thus likely to improve in precision until they reach the naive order of $1/m_c^2$ contributions—i.e. a few percent—beyond which the number of nuisance parameters becomes large. Combination with future LQCD results (see e.g. (Bailas *et al.*, 2019)), however, may permit even more precise predictions. Additionally, the $\mathcal{R}(D^{**})$ ratios have not yet been measured, so the various experiments have relied on theoretical predictions, assigning a relatively large uncertainty. The size of this uncertainty is however arbitrary and could lead to a common underestimate of the systematic uncertainty from the D^{**} feed-down (cf. Sec. V.C.2). With the latest theoretical predictions (Eq. (29)), this uncertainty should be reduced in the future.

Dedicated experimental efforts are also presently ongoing to further address these issues. In particular:

(i) Improved measurements are anticipated for the $B \rightarrow D^{**}\ell\nu$ relative branching fractions and kinematic distributions such as the four-momentum transfer squared or further angular relations. This is especially important for the broad D'_1 and D_0^* states, that are still poorly known compared to the narrow D_1 and D_2^* states. Such measurements can in principle already be carried out with currently available data sets.

(ii) Measurements involving a hadronized $W \rightarrow D_s^+$, i.e. $B \rightarrow (D^{**} \rightarrow D^{(*)}\pi)D_s^+$ (Aaij *et al.*, 2020a; LHCb Collaboration, 2020). This approach offers much better sensitivity to decays involving the wide D^{**} states because the $D^{(*)}\pi$ spectrum can be cleanly measured via the sideband subtraction on the narrow B mass peak. Additionally, the presence of a D_s^+ meson in the final state offers two unique features: (a) in contrast to decays where the virtual W produces a single pion, the q^2 range for production of a D_s^+ meson is in the range of interest for semitaonic decays; and (b) the relative rates of the various D^{**} states can be measured when associated to both spin-0 (D_s) and spin-1 (D_s^*) states.

(iii) The direct measurement of $B \rightarrow D^{**}\tau\nu$ decays for the narrow states $D^{**} = D_1$ or D_2^* . When combined with the estimated branching fractions for the narrow D^{**} versus the total D^{**} rate, and expectations from isospin symmetry (the feed-down is dominated by $D^{**\pm}$ states while much better experimental precision will be achieved for D^{**0}), these $B \rightarrow D^{**}\tau\nu$ results might be used to control the D^{**} feed-down rate into the $\mathcal{R}(D^{(*)})$ signal regions.

Significant progress can therefore be expected in the control of this important common systematic uncertainty in the near term, such that the systematic uncertainty due to $B \rightarrow D^{**}\ell\nu$ decays is likely to be reduced to the percent level or less.

Table XVI Estimates for D^{**} strong decay branching fractions to exclusive two body decays, and the sum of non- D^* -resonant three body decays, $\sum D\pi\pi$. Based on the approach of (Bernlochner and Ligeti, 2017) and measurements from (Aaij *et al.*, 2011; Zyla *et al.*, 2020).

| Parent | Final State | | | | |
|---------|-------------|------------|----------|----------|----------------|
| | $D^*\pi^+$ | $D^*\pi^0$ | $D\pi^+$ | $D\pi^0$ | $\sum D\pi\pi$ |
| D_2^* | 0.26 | 0.13 | 0.40 | 0.20 | — |
| D_1 | 0.42 | 0.21 | — | — | 0.36 |
| D'_1 | 0.67 | 0.33 | — | — | — |
| D_0 | — | — | 0.67 | 0.33 | — |

2. D^{**} branching fraction assumptions in $\mathcal{R}(D^{(*)})$ analyses

While the estimation of the normalization of the contributions from background $B \rightarrow D^{**}\ell\nu$ decays is largely data-driven, a number of assumptions in the various branching fractions involved can have a significant impact in the measurement of $\mathcal{R}(D^{(*)})$. These are:

(i) $\mathcal{B}(D^{**} \rightarrow D^{(*)}\pi(\pi))$: These branching fractions are primary inputs to all the $B \rightarrow D^{**}\ell\nu$ templates employed in the signal extraction fits. Using the approach of (Bernlochner and Ligeti, 2017), $\mathcal{B}(D^{**} \rightarrow D^{(*)}\pi)$ can be estimated by combining data for the ratios $\mathcal{B}(D^{**} \rightarrow D^*\pi)/\mathcal{B}(D^{**} \rightarrow D\pi)$ (Zyla *et al.*, 2020), isospin relations, and measurements of ratios of non- D^* -resonant three body D_1^0 and D_2^0 decays to $D^0\pi^+\pi^-$ versus two body decays to $D^{*+}\pi^-$ (Aaij *et al.*, 2011). The latter are used to estimate the total non- D^* -resonant branching fraction to all possible $D\pi\pi$ final states with an isospin correction factor $\simeq 2$. The resulting estimates for exclusive two body decays, and sum of non- D^* -resonant three body decays, are shown in Tab. XVI. The experimental analyses, however, have used various other sets of different numbers, which is worth being revisited.

(ii) $\mathcal{B}(B \rightarrow D^{**}\ell\nu)$: As mentioned above, the hadronic- τ measurements are not sensitive to this contribution. The leptonic- τ analyses have some sensitivity to these branching fractions, but it is small because the total contribution from $B \rightarrow D^{**}\ell\nu$ decays for the four D^{**} states is floated in the various fits. Since the four contributions are combined together in the same fit template, the relative $B \rightarrow D^{**}\ell\nu$ branching fractions—typically taken from (Zyla *et al.*, 2020)—impact the measured $\mathcal{R}(D^{(*)})$ values at the 0.3–0.8% level (Lees *et al.*, 2013).

(iii) $\mathcal{B}(B \rightarrow D^{**}\tau\nu)$: All $\mathcal{R}(D^{(*)})$ measurements are rather sensitive to this contribution because the kinematics of the final state particles in these decays are similar to those in signal decays. Some leptonic- τ measurements tie this contribution to the fitted $B \rightarrow D^{**}\ell\nu$ yields via $\mathcal{R}(D^{**})$ or merge it with other background contributions. The BABAR analysis (Lees *et al.*, 2013) assumes $\mathcal{R}(D^{**}) = 0.18$ for all D^{**} states. Investigation

of the numerical simulation inputs used by Belle analyses (Caria *et al.*, 2020; Huschle *et al.*, 2015) suggests they assumed an average of $\mathcal{R}(D^{**}) = 0.15$, while the LHCb result (Aaij *et al.*, 2015c) uses $\mathcal{R}(D^{**}) = 0.12$. The hadronic- τ $\mathcal{R}(D^*)$ measurement from LHCb (Aaij *et al.*, 2018b) ties the $B \rightarrow D^{**}\tau\nu$ yield to be 11% of the fitted $B \rightarrow D^*\tau\nu$ yield, and further decreases the value of $\mathcal{R}(D^*)$ by 3% to take into account an additional contribution from $B_s \rightarrow D_{s1}^*\tau\nu$ decays. Notably, all these assumed values for $\mathcal{R}(D^{**})$ are significantly above the predicted central values (Eq. (29)), by about 50%. The impact on the measured values can be estimated from the $\mathcal{R}(D^{**})$ systematic uncertainty estimated in (Lees *et al.*, 2013). A 50% downwards variation of the assumed $\mathcal{R}(D^{**}) = 0.18$ value results in $\mathcal{R}(D^{(*)})$ increasing by 1.7–1.8%. A shift of this magnitude would result in an increase of the tension of the $\mathcal{R}(D^{(*)})$ world average with the SM predictions by more than 0.5σ . For future measurements, we therefore advocate that experiments revisit their assumptions regarding the D^{**} feed-down in light of available data-driven predictions.

D. Modeling other signal modes

Some insight into the precision of future form factor predictions, and their role in LFUV analyses, can be obtained from considering the case of $B_c \rightarrow J/\psi\tau\nu$. As can be seen in Tab. XIII, a dominant systematic uncertainty—17%—in the 2018 LHCb analysis (Aaij *et al.*, 2018a) arose from the poorly-known description of the $B_c \rightarrow J/\psi$ form factors. At the time, the prediction for $\mathcal{R}(J/\psi)$ was known only at the 10% level, or worse. However, very recent LQCD results for the $B_c \rightarrow J/\psi$ form factors (34) now permit percent level predictions, such that one might expect the corresponding systematic uncertainty to similarly drop by an order of magnitude in a future analysis.

With regard to $\Lambda_b \rightarrow \Lambda_c^{(*)}$ decays, while the ground state form factors are known to high precision already, a combination of anticipated LQCD results and future data may similarly permit the excited state form factors to be constrained at or beyond the $1/m_c^2$ level. Finally, future LQCD studies may be expected to improve predictions for $B_s \rightarrow D_s^{(*,**)}$ form-factors to a comparable level as for $B \rightarrow D^{(*,**)}$, well beyond the $\sim 20\%$ uncertainties from flavor symmetry arguments.

E. Other background contributions

Double charm decays of the form $B \rightarrow D^{(*,**)}D_s^{(*,**)}$ and $B \rightarrow D^{(*,**)}D^{(*,**)}K^{(*)}$ can lead to final state topologies very similar to those of semitaonic processes, whenever the decay of one of the charm mesons mimics that of a τ lepton. Examples are $D_s^{(*,**)} \rightarrow$

$X\tau\nu$, $X\pi^+\pi^-\pi^+$ or $D^{(*,**)} \rightarrow X\ell\nu$ with X referring to unreconstructed particles. Such processes are very significant background modes for $\mathcal{R}(D^{(*)})$ measurements at LHCb, and to a somewhat lesser extent, for B -factory measurements. While several of these analyses estimate the overall double-charm contribution using data control samples, all measurements rely on averages of previously measured branching fractions of B and D decays from the Particle Data Group compilation (Zyla *et al.*, 2020). These averages are used as an input to produce the right mixture of decay modes for background templates. Additionally, the extrapolations into the signal regions often rely on simulations whose models for the decay dynamics might not reflect the full resonance structure of such transitions. This set of assumptions can be common to several experiments.

Although a wealth of branching fraction determinations regarding these and other relevant decays have been accumulated by BESIII, BaBar, Belle, and LHCb, there are significant areas where measurements that are in principle feasible have not been carried out or are not precise enough to provide useful constraints. Instances of these are double charm decays with excited kaons in the final state or hadronic and double charm processes involving D^{**} states. These are especially important because they cover the high q^2 range that has the highest signal purity in $\mathcal{R}(D^{(*)})$ measurements. In the near future, Belle II and LHCb will provide new results of branching fractions for such decays that will alleviate the reliance on common assumptions for the various double-charm decay modes. Additionally, more precise information about the semileptonic and $\pi^+\pi^-\pi^+$ decays of charm mesons will be needed, which can be provided by BESIII in the near future.

F. Other systematic uncertainties

The remaining uncertainties in Table XV are dominated by particle identification and external branching fraction uncertainties. The latter are especially relevant for measurements that utilize the hadronic decays of the τ lepton. The final state for the signal decays in these measurements does not correspond to that of the $B \rightarrow D^{(*)}\ell\nu$ decays needed for the $\mathcal{R}(D^{(*)})$ denominator and, as a result, intermediate normalization modes are employed. For instance, the current precision on the normalization decays for the $\tau \rightarrow \pi^-\pi^+\pi^-\nu$ analysis from LHCb (Aaij *et al.*, 2018b), $B \rightarrow D^*\pi^+\pi^-\pi^+$ and $B \rightarrow D^*\mu\nu$ as shown in Eq. (53), is limited to 3–4%, so new measurements of these branching fractions are necessary to reduce the overall uncertainty beyond that level. In fact, what is required is the ratio of these two quantities, which can be measured more precisely than each branching ratio separately, a measurement that Belle II may be able to perform relatively easily.

Additionally, the treatment of radiative corrections, and other subtle effects in event generation such as polarization effects, are shared in the event generators employed by many experiments. This can be a source of common systematic uncertainties, albeit negligible compared to the precision of the current measurements.

VI. COMBINATION AND INTERPRETATION OF THE RESULTS

The semitauonic measurements described in Sec. IV exhibit various levels of disagreement with the SM predictions. In this section, we further examine these results and explore these tensions. To briefly resummarize, at the time of the publication of this review, the following recent measurements were available (see also Table V):

1. In $B \rightarrow D^{(*)}\tau\nu$ decays
 - (a) Six measurements of $\mathcal{R}(D^*)$ and three of $\mathcal{R}(D)$. For convenience we resummarize here these results in Table XVII.
 - (b) One measurement of the τ polarization fraction, $P_\tau(D^*) = -0.38 \pm 0.51_{-0.16}^{+0.21}$.
 - (c) One measurement of the D^* longitudinal polarization fraction, $F_{L,\tau}(D^*) = 0.60 \pm 0.08 \pm 0.04$.
 - (d) Two measurements of the efficiency corrected q^2 distributions shown in Fig. 11.
2. One measurement of a $b \rightarrow c\tau\nu$ transition using B_c decays, $\mathcal{R}(J/\psi) = 0.71 \pm 0.17 \pm 0.18$.
3. One measurement of a $b \rightarrow u\tau\nu$ transition, $\mathcal{R}(\pi) = 1.05 \pm 0.51$.

In Sec. VI.A, we inspect the measurements of $\mathcal{R}(D^{(*)})$ in terms of the light-lepton normalization modes, the isospin-conjugated modes, and their measured values as a function of time. Thereafter we revisit in Sec. VI.B the combination of the measured $\mathcal{R}(D^{(*)})$ values. In particular, we discuss the role of non-trivial correlation effects on such averages and point out that with more precise measurements on the horizon these effects will need to be revisited. In Sec. VI.C we discuss the saturation of the measured inclusive rate by exclusive contributions as implied by the current world averages of $\mathcal{R}(D^*)$ and $\mathcal{R}(D)$ together with the expected $B \rightarrow D^{*}\tau\nu$ rates. Finally, Secs. VI.D and VI.E discuss the challenges in developing self-consistent new physics interpretations of the observed tensions with the SM and possible connections to the present-day FCNC anomalies, respectively.

A. Dissection of $\mathcal{R}(D^{(*)})$ results and SM tensions

The current status of LFUV measurements versus SM predictions, and the significance of their respective ten-

Table XVII Summary of $\mathcal{R}(D^{(*)})$ measurements and world averages. The hadronic- τ LHCb result (Aaij *et al.*, 2018b) has been updated taking into account the latest HFLAV average of $\mathcal{B}(B^0 \rightarrow D^{*+}\ell\nu) = 5.08 \pm 0.02 \pm 0.12\%$. The values for ‘‘Average ($\hat{\rho}_{D^{**}}$)’’ are calculated by profiling the unknown $B \rightarrow D^{*}\ell\nu$ correlation and obtaining $\hat{\rho}_{D^{**}} = -0.88$ as described in Sec. VI.B.

| Experiment | τ decay | Tag | $\mathcal{R}(D)$ | $\mathcal{R}(D^*)$ | ρ_{tot} |
|--|-----------------------|--------|------------------|---|---------------------|
| BABAR ^a | $\mu\nu$ | Had. | 0.440(58)(42) | 0.332(24)(18) | -0.31 |
| Belle ^b | $\mu\nu$ | Semil. | 0.307(37)(16) | 0.283(18)(14) | -0.52 |
| Belle ^c | $\mu\nu$ | Had. | 0.375(64)(26) | 0.293(38)(15) | -0.50 |
| Belle ^d | $\pi\nu, \rho\nu$ | Had. | | 0.270(35) ⁽⁺²⁸⁾ ₍₋₂₅₎ | - |
| LHCb ^e | $\pi\pi\pi(\pi^0)\nu$ | - | - | 0.280(18)(25)(13) | - |

Table XVIII Current status of LFUV measurements (see Sec. IV) versus SM predictions in Sec. II, and their respective agreements or tensions. For $P_\tau(D^*)$ and $F_{L,\tau}(D^*)$ we show a naïve arithmetic average of the SM predictions (Tab. II) as done for $\mathcal{R}(D^{(*)})$. For $\mathcal{R}(D^{(*)})$ we show the world average from the HFLAV combination (Amhis *et al.*, 2019); below the line we show for comparison the results of the $\mathcal{R}(D^{(*)})$ world average obtained in this work (see Sec. VI.B).

| Obs. | Current World Av./Data | Current SM Prediction | Significance |
|-----------------------|-------------------------------------|-----------------------|--------------|
| $\mathcal{R}(D)$ | 0.340 ± 0.030 | 0.299 ± 0.003 | 1.2σ |
| $\mathcal{R}(D^*)$ | 0.295 ± 0.014 | 0.258 ± 0.005 | 2.5σ |
| $P_\tau(D^*)$ | $-0.38 \pm 0.51_{-0.16}^{+0.21}$ | -0.501 ± 0.011 | 0.2σ |
| $F_{L,\tau}(D^*)$ | $0.60 \pm 0.08 \pm 0.04$ | 0.455 ± 0.006 | 1.6σ |
| $\mathcal{R}(J/\psi)$ | $0.71 \pm 0.17 \pm 0.18$ | 0.2582 ± 0.0038 | 1.8σ |
| $\mathcal{R}(\pi)$ | 1.05 ± 0.51 | 0.641 ± 0.016 | 0.8σ |
| $\mathcal{R}(D)$ | 0.337 ± 0.030 | 0.299 ± 0.003 | 1.3σ |
| $\mathcal{R}(D^*)$ | 0.298 ± 0.014 | 0.258 ± 0.005 | 2.5σ |

sions or agreements, is summarized in Tab. XVIII, including the current HFLAV combination of the $\mathcal{R}(D^{(*)})$ data. For the SM predictions the arithmetic averages discussed in Section II are quoted. The individual tensions of all LFUV measurements with the SM expectations range from 0.2–2.5 σ . The combined value of $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ is in tension with the SM expectation by 3.1 σ because of their anti-correlation. Also note that the value of $P_\tau(D^*)$ is slightly correlated with both averages.

A subset of the existing measurements provide values

Table XIX Results of the isospin-unconstrained fits for the BABAR analysis (Lees *et al.*, 2012, 2013). The first uncertainty is statistical and the second systematic.

| Result | BABAR |
|-----------------------|-----------------------------|
| $\mathcal{R}(D^0)$ | $0.429 \pm 0.082 \pm 0.052$ |
| $\mathcal{R}(D^+)$ | $0.469 \pm 0.084 \pm 0.053$ |
| $\mathcal{R}(D^{*0})$ | $0.322 \pm 0.032 \pm 0.022$ |
| $\mathcal{R}(D^{*+})$ | $0.355 \pm 0.039 \pm 0.021$ |

of $\mathcal{R}(D^{(*)})$ normalized to either electron or muon final states. These results present an important check because the values reported for the semitauonic ratios are typically an average for the electron and muon normalizations, assuming

$$\mathcal{R}(D^{(*)}) = \mathcal{R}(D^{(*)})_e = \mathcal{R}(D^{(*)})_\mu \quad (67)$$

with

$$\mathcal{R}(D^{(*)})_e \equiv \frac{\mathcal{B}(\bar{B} \rightarrow D^{(*)}\tau^-\bar{\nu}_\tau)}{\mathcal{B}(\bar{B} \rightarrow D^{(*)}e^-\bar{\nu}_e)}, \quad (68)$$

$$\mathcal{R}(D^{(*)})_\mu \equiv \frac{\mathcal{B}(\bar{B} \rightarrow D^{(*)}\tau^-\bar{\nu}_\tau)}{\mathcal{B}(\bar{B} \rightarrow D^{(*)}\mu^-\bar{\nu}_\mu)}. \quad (69)$$

LHCb only measures $\mathcal{R}(D^{(*)})_\mu$, but the B -factories have access to the electron normalization as well. Figure 24 compares $\mathcal{R}(D^{(*)})_e$ and $\mathcal{R}(D^{(*)})_\mu$ and no systematic deviation between both ratios is observed. It should be noted that these results were released as stability checks that compare the compatibility of the electron and muon channels, not as optimized measurements of $\mathcal{R}(D^{(*)})_{e/\mu}$. For instance, (Franco Sevilla, 2012) does not include the full systematic uncertainties and correlation for the electron and muon $\mathcal{R}(D^{(*)})$, so the values from the full $\mathcal{R}(D^{(*)})$ results are used in Fig. 24, increasing the correlation to account for the larger statistical uncertainty of the $\mathcal{R}(D^{(*)})_e$ and $\mathcal{R}(D^{(*)})_\mu$ results. Additionally, the double ratio

$$\mathcal{R}(D^{(*)})_{\text{light}} = \frac{\mathcal{R}(D^{(*)})_\mu}{\mathcal{R}(D^{(*)})_e} = \frac{\mathcal{B}(\bar{B} \rightarrow D^{*}e^-\bar{\nu}_e)}{\mathcal{B}(\bar{B} \rightarrow D^{*}\mu^-\bar{\nu}_\mu)}, \quad (70)$$

that would be obtained from dividing these results, would have unnecessarily large uncertainties because the common $\mathcal{B}(B \rightarrow D^{(*)}\tau\nu)$ factor is obtained with $\tau \rightarrow e\nu\bar{\nu}$ decays in the case of $\mathcal{R}(D^{(*)})_e$ and $\tau \rightarrow \mu\nu\bar{\nu}$ decays for $\mathcal{R}(D^{(*)})_\mu$. A high precision measurement of $\mathcal{R}(D^{(*)})_{\text{light}}$ was released recently by the Belle collaboration (Waheed *et al.*, 2019)

$$\mathcal{R}(D^{(*)})_{\text{light}} = 1.01 \pm 0.01 \pm 0.03 \quad (71)$$

and is compatible with unity.

Table XIX shows the results of the isospin-unconstrained fits of the BABAR $\mathcal{R}(D^{(*)})$ analysis, exhibiting good compatibility between charged and neutral

Figure 24 Measurements of $\mathcal{R}(D^{(*)})$, $\mathcal{R}(D^{(*)})_e$, and $\mathcal{R}(D^{(*)})_\mu$ from BABAR (Franco Sevilla, 2012) and Belle (Caria, 2019).

Figure 25 Measurements of $\mathcal{R}(D^{(*)})$ as a function of paper submission time. Green refers to BABAR, dark blue to Belle, light blue to LHCb, and violet to the SM predictions. Circular markers refer to hadronic tagging, triangles to semileptonic tagging, rombsuses to inclusive tagging, and squares to untagged measurements. Filled markers refer to measurements using muonic decays of the τ lepton while hollow to hadronic decays.

D and D^* modes. Such measurements might be particularly interesting in the context of obtaining data-driven insight into the size of semiclassical radiative corrections, expected to enter at the subpercent level.

Another interesting comparison is to examine the measurements of $\mathcal{R}(D^{(*)})$ as a function of time: more precise knowledge of normalization and background processes often leads to shifts. Figure 25 displays the measured value as a function of paper submission time. Notably the most precise measurements were produced recently and show overall a better agreement with the SM expectation.

B. Revisiting $\mathcal{R}(D^{(*)})$ world averages

To further investigate the tension of the measured values of $\mathcal{R}(D^{(*)})$ with the SM, we examine and update their averages. We note that the systematic uncertainties of all measurements have significant correlations (see Sec. V) that need to be taken into account properly.

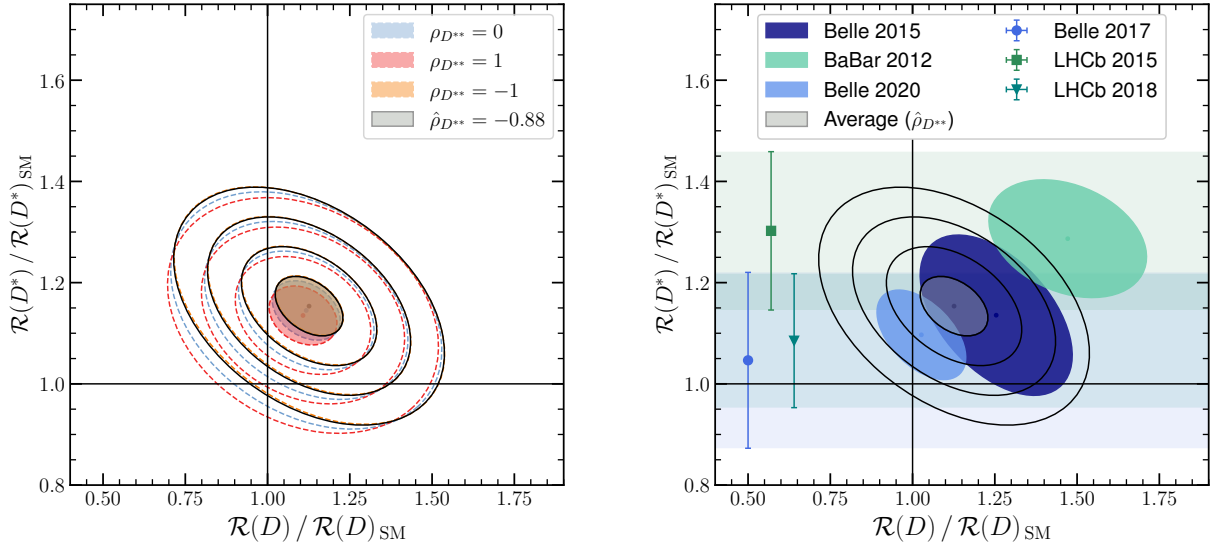

Figure 26 Left: $\mathcal{R}(D^{(*)})$ world averages with different assumptions for the unknown correlation $\rho_{D^{**}}$: The average with $\rho_{D^{**}} = 0$ (light blue) is based on similar assumptions as (Amhis *et al.*, 2019) and shows a compatibility with the SM expectation of 3.2 standard deviations taking into account the small uncertainties of the theoretical predictions; $\rho_{D^{**}} = \pm 1$ (light red or orange) agrees with the SM expectation within 2.9 and 3.7 standard deviations, respectively. In our quoted average we profile the unknown correlation and obtain $\hat{\rho}_{D^{**}} = -0.88$ (heather gray) with a compatibility with the SM of 3.6 standard deviations. Right: Our world average of $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ (black curves), compared to the various measurements of $\mathcal{R}(D^{(*)})$. The unknown correlation $\rho_{D^{**}}$ is treated as a free, but constrained, parameter of the average (see main text for more details).

The most important ones stem from the modeling of the $B \rightarrow D^{**}l\nu$ processes, which comprise a significant background source in all measurements to date. The manner in which the uncertainties of these background contributions are estimated varies considerably. As discussed in Sec. V.C.1, the normalization or shape uncertainties from the hadronic form factors are, in some measurements, validated or constrained by control regions. Thus, a simple correlation model will not be able to properly quantify such correlations.

One particularly important point here is the treatment of the correlations of these systematics between $\mathcal{R}(D^*)$ and $\mathcal{R}(D)$ measurements. In individual measurements that measure both quantities simultaneously, this treatment is straightforward. However, it becomes unclear how to relate systematic uncertainties between e.g. $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ in two separate measurements. To provide a concrete example, consider the BABAR measurement of $\mathcal{R}(D)$ (in the context of the combined $\mathcal{R}(D^{(*)})$ determination of (Lees *et al.*, 2012, 2013)) and the Belle measurement of $\mathcal{R}(D^*)$ (in the combined $\mathcal{R}(D^{(*)})$ analysis of (Huschle *et al.*, 2015)). In the individual measurements, the systematic uncertainty associated with $B \rightarrow D^{**}l\bar{\nu}_\ell$ is 45% and -15% correlated between $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$, respectively. From this information alone it is impossible to derive the correct correlation structure between $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ across measurements.

We further investigate the dependence of the world average on the $B \rightarrow D^{**}l\bar{\nu}_\ell$ correlation structure across $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ measurements by parametrizing them with a single factor $\rho_{D^{**}}$. In Fig. 26 (left) we show the world average assuming such correlation effects are negligible (labeled as $\rho_{D^{**}} = 0$) and we reproduce a world average very similar to HFLAV (Amhis *et al.*, 2019). The numerical values, normalized to the arithmetic average of the SM predictions (cf. Tab. I in Sec. II.D.1), are

$$\mathcal{R}(D)/\mathcal{R}(D)_{\text{SM}} = 1.12 \pm 0.10, \quad (72)$$

$$\mathcal{R}(D^*)/\mathcal{R}(D^*)_{\text{SM}} = 1.15 \pm 0.06, \quad (73)$$

with an overall correlation of $\rho = -0.33$. In addition to the $B \rightarrow D^{**}l\bar{\nu}_\ell$ uncertainties, the uncertainties in the leptonic τ branching fractions and the $B \rightarrow D^{(*)}l\nu$ FFs are fully correlated across measurements. The compatibility with the SM expectation is within 3.2 standard deviations (close to the value quoted by (Amhis *et al.*, 2019) of 3.1σ). Figure 26 (left) also shows the impact of setting this unknown correlation to either $\rho_{D^{**}} = 1$ or $\rho_{D^{**}} = -1$, resulting in compatibilities with the SM predictions of 2.9 or 3.7 standard deviations, respectively.

A possible way to deal with an unknown parameter such as $\rho_{D^{**}}$ in this type of problem is outlined in (Cowan, 2019). Instead of neglecting the value, we can incorporate it as a free parameter of the problem

and constrain it within its probable range. A possible choice that limits this missing correlation to fall between $[-1, 1]$ is to assign it a double Fermi Dirac distribution¹⁰ with a large shape parameter, e.g. $w = 50$. Carrying out our average with such a setup results in

$$\mathcal{R}(D)/\mathcal{R}(D)_{\text{SM}} = 1.13 \pm 0.10, \quad (74)$$

$$\mathcal{R}(D^*)/\mathcal{R}(D^*)_{\text{SM}} = 1.15 \pm 0.06, \quad (75)$$

with $\hat{\rho}_{D^{**}} = -0.88$ and an overall correlation of $\rho = -0.40$. This results in an increased tension of about 3.6σ with respect to the SM.

Although neither of these world averages are based on completely correct assumptions, they illustrate the need for future $\mathcal{R}(D^{(*)})$ measurements to provide more detailed breakdowns of their uncertainties. It is intriguing that introducing an additional correlation structure of a systematic uncertainty can shift the agreement with the SM expectation over a range of 0.8 standard deviations. Table XVII lists the numerical values of this average—denoted as “Average ($\hat{\rho}_{D^{**}}$)”—and the HFLAV average (Amhis *et al.*, 2019); see also Tab XVIII. We show this world average for $\mathcal{R}(D^{(*)})$ compared to the various measurements in Fig 26 (right).

C. Inclusive versus exclusive saturation

The SM prediction for the semitauconic inclusive branching ratio is

$$\mathcal{B}(B \rightarrow X_c \tau \nu) = 2.37(6) \times 10^{-2}, \quad (76)$$

obtained by combining the SM prediction in Eq. (38) with the data for the flavor-averaged light lepton branching ratio $\mathcal{B}(B \rightarrow X_c \ell \nu)$ (Zyla *et al.*, 2020). The saturation of the inclusive SM prediction by the sum of SM predictions for the exclusive decay modes can be explored by comparing the inclusive branching ratio to that for the sum of $D^{(*)}$ and D^{**} . For simplicity, in the following we treat the uncertainties for each mode as independent. Using the HFLAV-averaged SM prediction for $\mathcal{R}(D^{(*)})$ (Table I) together with the average branching ratio for $\mathcal{B}(B^0 \rightarrow D^{(*)} \ell \nu)$ and $\mathcal{B}(B^- \rightarrow D^{(*)} \ell \nu)$, one finds

$$\mathcal{B}(B \rightarrow D \tau \nu) = 0.72(4) \times 10^{-2}, \quad (77a)$$

$$\mathcal{B}(B \rightarrow D^* \tau \nu) = 1.28(4) \times 10^{-2}, \quad (77b)$$

and similarly one may use the combined D^{**} SM prediction in Eq. (30) with world averages for $\mathcal{B}(B^- \rightarrow D^{**} \ell \nu)$ (Bernlochner and Ligeti, 2017), yielding

$$\sum_{X_c \in D^{**}} \mathcal{B}(B \rightarrow X_c \tau \nu) = 0.14(2) \times 10^{-2}. \quad (78)$$

¹⁰ $f(x, w) = 1/(2(1 + \exp(w(x-1)))(1 + \exp(-w(x-1))))$

Figure 27 Saturation of the inclusive SM prediction (red band) for $\mathcal{B}(B \rightarrow X_c \tau \nu)$ by the sum of measured exclusive branching fractions implied by the $\mathcal{R}(D)$ and $\mathcal{R}(D^{(*)})$ world averages (blue square). By comparison, the SM prediction for the sum of $B \rightarrow D^{(*)} \tau \nu$ exclusive branching fractions (blue band), is compatible with, and does not saturate, the inclusive prediction. Also shown is: (i) the measured inclusive branching fraction measurements for $b \rightarrow X \tau \nu$ from LEP (Zyla *et al.*, 2020) (open red square), normalized against total number of tagged $b\bar{b}$ events. Assuming hadronization effects cancel, it can be interpreted as $\mathcal{B}(B \rightarrow X \tau \nu)$; and (ii) the unpublished inclusive measurement of (Hasenbusch, 2018) using Belle data (red filled square), that shows a large excess.

Adding these contributions, one obtains the SM prediction $\sum_{X_c \in D^{(*)}} \mathcal{B}(B \rightarrow X_c \tau \nu) = 2.14(6) \times 10^{-2}$, which is compatible with, and does not saturate, the inclusive SM prediction in Eq. (76), as shown in Fig. 27.

One can characterize the degree of LFUV in the semitauconic system by comparing the inclusive SM prediction with the sum of measured branching ratios for $\mathcal{B}(B \rightarrow D^{(*)} \tau \nu)$. In this case the SM prediction in Eq. (76) arises from theory inputs, and features theory uncertainties, that are independent of the inputs used for predictions of $\mathcal{R}(D^{(*)})$ (see Sec. II.G). Figure 27 compares the inclusive SM prediction with the sum of the $B \rightarrow D^{(*)} \tau \nu$ branching fractions arising from the $\mathcal{R}(D^{(*)})$ world averages, as well as with the measured inclusive $b \rightarrow X \tau \nu$ branching fraction from LEP (Zyla *et al.*, 2020), and the result for $B \rightarrow X \tau \nu$ from the PhD thesis (Hasenbusch, 2018) using Belle data. One sees that the $\mathcal{R}(D^{(*)})$ world averages already imply near-saturation of the inclusive SM prediction, while the unpublished result from the Belle data is more than 3σ in tension with it.

D. New Physics interpretations

1. Parametrization of SM tensions

The measured lepton universality ratios $\mathcal{R}(D^{(*)})$ naively express tensions with respect to SM predictions in terms of the overall decay rates or branching ratios. As

Figure 28 Top: Typical variation of experimental acceptances for the 2HDM, the leptoquark models R_2 and S_1 , and a pure tensor current, normalized with respect to the SM acceptance ε_{SM} , for $B \rightarrow D\tau\nu$ (blue) and $B \rightarrow (D^* \rightarrow D\pi)\tau\nu$ (red), with $\tau \rightarrow e\nu\nu$. The dotted, solid and dashed lines show the resulting acceptances for q^2 resolutions (see text) of 0.8, 1.2 and 1.6 GeV^2 , respectively. Bottom: Variation in $\mathcal{R}(D^{(*)})/\mathcal{R}(D^{(*)})_{\text{SM}}$ for the same models.

such, typically many phenomenological interpretations of these results simply require that any New Physics (NP) accounts for the measured ratios (or other observables such as polarization fractions) within quoted uncertainties. However, this naive approach may lead to biases in NP interpretations.

The reason for this is that in practice, as discussed in Sec. IV, the $\mathcal{R}(D^{(*)})$ ratios are recovered from fits in multiple reconstructed observables. In these fits, the signal $B \rightarrow D^{(*)}\tau\nu$ decay distributions (as well as backgrounds) are assumed to have SM shapes—their reconstructed observables are assumed to have an *SM template*—while their normalization is allowed to float independently. In the SM, the ratio of $\mathcal{R}(D)/\mathcal{R}(D^*)$ is itself tightly predicted up to small form factor uncertainties. Thus, the current experimental approach can be thought of introducing a *NP fit template*, that is parametrized by variation in the double ratio $\mathcal{R}(D)/\mathcal{R}(D^*)$ as well as, say, the overall size of $\mathcal{R}(D^*)$.

Variation of $\mathcal{R}(D^*)$, while keeping $\mathcal{R}(D)/\mathcal{R}(D^*)$ fixed to its SM prediction, is consistent with NP contributions from the c_{VL} Wilson coefficient. This Wilson coefficient by definition still generates SM-like distributions: so that incorporating c_{VL} contributions is self-consistent with the fit template assumptions from which the measured $\mathcal{R}(D^{(*)})$ values were recovered.

However, to explain the variation in $\mathcal{R}(D)/\mathcal{R}(D^*)$ from the SM prediction requires further NP contributions, that generically also alter the $B \rightarrow D^{(*)}\tau\nu$ sig-

nal (and some background) decay distributions and acceptances. (It is possible that there exist NP contributions which only modify the neutrino distributions. Because the experiments marginalize over missing energy, this particular NP could permit $\mathcal{R}(D)/\mathcal{R}(D^*)$ to simultaneously float from the SM prediction while preserving the SM template for reconstructed observables.) These NP contributions are thus generically inconsistent with the assumed SM template in the current measurement and fit, and may affect the recovered values of $\mathcal{R}(D^{(*)})$ themselves. As a result, while the current world-average for $\mathcal{R}(D)-\mathcal{R}(D^*)$ unambiguously indicates a tension with the SM, it does not *a priori* allow for a self-consistent NP interpretation or explanation. A self-consistent BSM measurement of any recovered observable instead requires e.g. dedicated fit templates for each BSM point of interest, which we discuss further below.

A similar tension with the SM can be established when additional observables such as asymmetries, longitudinal fractions, or polarization fractions are compared to SM predictions (see Sec. II.D.2), and there is much literature studying their in-principle NP discrimination power. However, the same caveat with regard to NP interpretations applies: NP contributions may alter the recovered values of these parameters.

Figure 29 Top: Color map of the percent variation per bin in the reconstructed m_{miss}^2 normalized distribution for $\bar{B} \rightarrow D\tau\nu$, comparing the SM to a range of couplings for the 2HDM, the leptoquark models R_2 and S_1 , and a pure tensor current. Variations for $B \rightarrow D^*\tau\nu$ are similar but somewhat smaller, ranging up to the 1-2% level. Bottom: Example normalized m_{miss}^2 distributions for the SM (solid) versus NP (dashed) for $B \rightarrow D\tau\nu$ (blue) and $B \rightarrow D^*\tau\nu$ (red). The chosen NP coupling for each model is shown by a dashed line in the corresponding top row figures.

2. Sensitivity and biases in recovered observables

To gain a sense of the size of these effects, we consider an approximate mock-up of an e^+e^- experimental environment and examine the variation in acceptances, ε , for $B \rightarrow D\tau\nu$ and $B \rightarrow (D^* \rightarrow D\pi)\tau\nu$, with $\tau \rightarrow e\nu\nu$ in the presence of NP. In this mock-up, the beam energies are fixed to 7 and 4 GeV, and we require visible final state particles to fall within an angular acceptance $20^\circ - 150^\circ$. We impose a minimum electron energy threshold of $E_e > 300$ MeV, and an approximate turn-on efficiency is included to account for the slow pion reconstruction efficiencies in $D^* \rightarrow D\pi$ decays. We further include a Gaussian smearing added to the truth level q^2 with a width of 1.2 GeV², in order to account for detector resolution and tag- B reconstruction, and require the reconstructed $q^2 > 4$ GeV².

For this mock-up, we show in Fig. 28 the ratio of the NP experimental acceptance compared to the SM, $\varepsilon/\varepsilon_{\text{SM}}$, for several different simplified models (cf. (Lees *et al.*, 2013) which studied this effect for the Type-II 2HDM). To characterize the sensitivity to the q^2 cut and smearing, we also show acceptances for better and poorer q^2 resolutions, with widths of 0.8 and 1.6 GeV² for the Gaussian smearing, respectively. To provide further insight into the NP variability of the differential distributions, in Fig. 29 we show the percent variation per bin in the reconstructed m_{miss}^2 normalized distribution for $\bar{B} \rightarrow D\tau\nu$ for the same set of simplified models, over the identical

range of NP couplings, as well as example $\bar{B} \rightarrow D^{(*)}\tau\nu$ distributions in the reconstructed m_{miss}^2 for particular NP coupling values.

One sees typically a few percent variation in the acceptances as well as in the differential m_{miss}^2 distribution, with up to 5% or so variations in some cases. Although this might seem small in comparison to the typical 15–20% size of currently measured LFUV in $\mathcal{R}(D^{(*)})$, such variations are already comparable to the typical size of systematic uncertainties in current analyses, such as those shown in Table X. It is then not surprising that mismatches between SM and NP signal template can introduce significant biases into analyses. This was observed in the BaBar analysis (Lees *et al.*, 2013). A similar, but more detailed, mock-up analysis in an e^+e^- collider environment suggests biases at greater than the 4σ level may be expected to typically arise with 5 ab^{-1} of data (Bernlochner *et al.*, 2020a). This effect may also be important in the extraction of the CKM parameter $|V_{cb}|$, which is sensitive to the assumed form factor parametrization used to generate the fit templates.

Future semileptonic analyses may address these biases through a variety of approaches. We discuss these below in Sec. VII.B.

E. Connection to FCNCs

Measurements of the $b \rightarrow s\ell\ell$ ratios $\mathcal{R}_{K^{(*)}}$ (Eq. (43)) in various ranges of the dilepton invariant mass have produced an indication of lepton flavor universality violation. For instance, the current world-average ratios in the range $q^2 = m^2(\ell\ell) \in [1.1, 6.0] \text{ GeV}^2$ are (Amhis *et al.*, 2019)

$$\mathcal{R}_{K^+} = 0.846_{-0.056}^{+0.062}, \quad \mathcal{R}_{K^{*0}} = 0.71_{-0.09}^{+0.12}, \quad (79)$$

but are expected to be unity to the sub-percent level. The deviations are driven dominantly by LHCb measurements (Aaij *et al.*, 2017b, 2019c). Angular analyses of $B \rightarrow K^*\mu\mu$ decays exhibit components that are in similar tension with theoretical predictions, but subject to potentially large theory uncertainties. However, various other less precise measurements of $\mathcal{R}_{K^{(*)}}$ from Belle and BABAR are consistent with unity (Amhis *et al.*, 2019); see also the recent $\Lambda_b \rightarrow pK\ell\ell$ analysis by LHCb (Aaij *et al.*, 2020b). As discussed in Sec. II.I, because the neutrino belongs to an electroweak doublet, non-trivial (model-dependent) connections may arise between $b \rightarrow c\ell\nu$ and $b \rightarrow s\ell\ell$ or $b \rightarrow s\nu\nu$ operators. Studies of possible connections between the $\mathcal{R}(D^{(*)})$ and $\mathcal{R}_{K^{(*)}}$ anomalies thus explore common origins of NP in $b \rightarrow c\tau\nu$ versus $b \rightarrow s\ell\ell$, such as various leptoquark mediators and flavor models, that are not also excluded by other precision measurements (see Sec. II.I). See e.g. (Bhattacharya *et al.*, 2015; Buttazzo *et al.*, 2017; Calibbi *et al.*, 2015; Kumar *et al.*, 2019), as several representatives of an extensive literature.

In light of these results, it is also interesting to consider how much LFUV can be tolerated in the electron versus muon couplings from $b \rightarrow c\ell\nu$ measurements alone. As above, the Belle direct measurement (Eq. (71)) constrains LFUV to no more than percent level deviations between the electron and muon semileptonic modes.

An additional constraint arises from exclusive measurements of $|V_{cb}|$ and associated q^2 distributions from $B \rightarrow D^{(*)}\ell\nu$ decays. Though not a focus of this review, these measurements are presently quite sensitive to the $B \rightarrow D^{(*)}$ form factor parametrization: Precision fits leave little room for the presence of additional form factors beyond those of the $V-A$ interactions, because introducing such form factors would significantly distort the well-measured q^2 distributions for these decays. Moreover, shape fits to the electron and muon modes separately are in good agreement (see e.g. (Aubert *et al.*, 2009; Glattauer *et al.*, 2016; Waheed *et al.*, 2019)). These results suggest that in the $b \rightarrow ce\nu$ and $b \rightarrow c\mu\nu$ systems, one can plausibly introduce NP only via $V-A$ NP currents, and one can plausibly produce electron-muon LFUV at most at the percent level. Based on this qualitative discussion we eagerly anticipate further quantitative studies of bounds on LFUV in $B \rightarrow D^{(*)}\ell\nu$.

VII. PROSPECTS AND OUTLOOK

As detailed in Sec. VI, the world averages for $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ currently exceed their SM predictions by about 14% each. While the theory uncertainties on the $\mathcal{R}(D^{(*)})$ SM predictions are already 1–2% (see Tab. I), the uncertainties on the corresponding measurements are 5–10 times larger. If key challenges in computation, the modeling of b -hadron semileptonic decays, and background estimation are met in the years to come, as discussed in Sec. V, the large amount of data that LHCb and Belle II will collect over the next two decades will bring down the experimental uncertainties to the 1% level. At the present level of discrepancy with the SM, this degree of precision would nominally be sufficient to either establish an observation of LFUV or resolve the present anomalies.

However, highly significant but isolated results will arguably not be sufficient to fully establish the presence of NP in this manner, given the vast number of experimental and theoretical effects that can influence the interpretation of these indirect searches for BSM physics. Spurred on by the $\mathcal{R}(D^{(*)})$ anomalies, a wide program of LFUV measurements and calculations, that encompasses several experimental and theoretical communities across particle physics, will likely be the key to disentangling potential BSM signals from sources of uncertainty that may not be fully understood.

To this end, in this last section we discuss various aspects of this program, including: efforts underway to measure other important ratios such as $\mathcal{R}(J/\psi)$, $\mathcal{R}(\pi)$, $\mathcal{R}(D_{(s)}^{(*)})$ and $\mathcal{R}(\Lambda_c)$ (Sec. VII.A); analyses that exploit the fully differential information measured in semitauonic b -hadron decays to complement and enhance the sensitivity to NP (Sec. VII.B); and should these indirect searches end up establishing the presence of NP, the role of proposed future colliders, that may be able to either directly observe NP mediators, or further characterize established anomalies with related measurements (Sec. VII.C).

A. Measurement of the ratios $\mathcal{R}(H_{c,u})$

As described throughout this review, the ratios $\mathcal{R}(H_{c,u})$ defined in Eq. (21) are powerful probes of LFUV and NP, in part because of the significant cancelation of theoretical and experimental uncertainties in the ratios. The SM predictions for $\mathcal{R}(D_{(s)}^{(*)})$, $\mathcal{R}(J/\psi)$, and $\mathcal{R}(\Lambda_c)$ now have uncertainties in the 1–3% range (see Sec. II), and improvements in lattice QCD together with new experimental measurements are expected to further bring these down. Over the next two decades, LHCb and Belle II will collect enough data to reduce the statistical uncertainty on the $\mathcal{R}(H_{c,u})$ measurements down to a few percent or less. However, the systematic uncertainties on the best known ratios, $\mathcal{R}(D^{(*)})$, are currently significantly higher than that, as shown in Tab. XV. Thus, quantifying the

achievable precision on $\mathcal{R}(H_{c,u})$ as a probe of NP after LHCb and Belle II complete their data taking rests primarily on estimating the extent to which the associated experimental systematic uncertainties can be reduced.

As detailed in Sec. V, if already ongoing theoretical and experimental efforts are sustained in the following years, the majority of the systematic uncertainty on $\mathcal{R}(H_{c,u})$ is expected to decrease commensurately with the increasing size of the data samples being collected. For instance, the uncertainty from the background contributions will decrease as the data control samples grow, and the size of the simulated data samples will continue increasing proportionately if the power of GPUs and fast simulation algorithms is appropriately harnessed. Of course, these improvements are likely to have their own limitations, and a certain level of irreducible systematic uncertainty will be reached. Based on the considerations described in Sec. V, one may estimate that floors of ~ 1 –2% uncertainty in $\mathcal{R}(D^{(*)})$ are achievable, while a floor of ~ 3 –4% is plausible for other $\mathcal{R}(H_{c,u})$ ratios, in which the form factor parameterization cannot be measured as precisely. To illustrate the variability of these estimations, we present extrapolations for the anticipated $\mathcal{R}(H_{c,u})$ precision that LHCb and Belle II are likely to reach under two scenarios: (i) a *pessimistic* scenario, with irreducible systematic uncertainties of 2% for $\mathcal{R}(D^{(*)})$ and 5% for the other $\mathcal{R}(H_{c,u})$ ratios; and (ii) an *optimistic* scenario, with uncertainty floors of 0.5% for $\mathcal{R}(D^{(*)})$ and 3% for the other $\mathcal{R}(H_{c,u})$ ratios. Further assumptions included in these extrapolations are detailed below.

1. Prospects for $\mathcal{R}(H_{c,u})$ at LHCb

As described in Sec. III.A, the high center-of-mass energy at the LHC gives LHCb access to large samples of many b -hadron species. So far, LHCb has published results on $\mathcal{R}(D^*)$ and $\mathcal{R}(J/\psi)$ (see Sec. IV), and measurements of $\mathcal{R}(D)$, $\mathcal{R}(D^{**})$, $\mathcal{R}(D_s)$, $\mathcal{R}(D_s^*)$, $\mathcal{R}(\Lambda_c)$, $\mathcal{R}(\Lambda_c^*)$ as well as the non-semitauonic ratios $\mathcal{R}(D^{(*)})_{\text{light}}$ are underway. We can project the sensitivity to some of these ratios based on the b -hadron samples expected in the next two decades (Tab. III), the reduction of the systematic uncertainty described above, and the following broad assumptions:¹¹

(i) $\mathcal{R}(D^*)$: The current Run 1 results for $\mathcal{R}(D^{*+})$ have a total uncertainty of 12%, but this value should be reduced by about $\sqrt{2}$ when $\mathcal{R}(D^{*0})$ is also included in the measurement. This can be done by inclusively reconstructing $B^- \rightarrow D^{*0}\tau^-\bar{\nu}_\tau$ decays via their feed-down

to $D^0\mu^-$ samples in combined $\mathcal{R}(D)$ – $\mathcal{R}(D^*)$ measurements. Starting in Run 2, a dedicated trigger achieved 50% higher efficiency and the $b\bar{b}$ cross section increased by a factor of around two. Another factor of two will be gained when the hardware trigger is replaced by a software-only trigger starting in the next data taking period (Run 3).

(ii) $\mathcal{R}(D)$: The same assumptions apply as for the measurement of $\mathcal{R}(D^*)$ in terms of triggers and the combination of D^0 and D^+ , but data samples are expected to be about 50% smaller due to the difference in branching fractions and $\mathcal{R}(D)$.

(iii) $\mathcal{R}(D^{**})$: The projections are specifically for $\mathcal{R}(D_1^0)$ which provides the most accessible final state. The projections are based on the expected uncertainty of about 15% for a combined analysis of Run 1 and 2 data, and include a factor of two efficiency increase starting in Run 3 thanks to the software-only trigger.

(iv) $\mathcal{R}(D_s^{(*)})$: Data samples are expected to be about 16 times smaller than for $\mathcal{R}(D^*)$, because of both the smaller B_s production fraction as well as the requirement to reconstruct an additional track in the $D_s^+ \rightarrow K^+K^-\pi^+$ decay (resulting in about a factor of two lower efficiency).

(v) $\mathcal{R}(\Lambda_c)$: Data samples are expected to be six times smaller than for $\mathcal{R}(D^*)$, according to the smaller Λ_b production fraction, as well as the requirement to reconstruct an additional track in the $\Lambda_c^+ \rightarrow pK^-\pi^+$ decay.

(vi) $\mathcal{R}(\Lambda_c^*)$: The projections are specifically for $\mathcal{R}(\Lambda_c^*(2625))$ and follow the same assumptions as for $\mathcal{R}(\Lambda_c)$ but with 33 times smaller data samples due to the smaller $\Lambda_b \rightarrow \Lambda_c^*$ branching fraction and the lower efficiency of the $\Lambda_c^* \rightarrow \Lambda_c\pi\pi$ reconstruction. This is estimated in a preliminary LHCb study of $\Lambda_b \rightarrow \Lambda_c^{(*)}\pi\pi\pi$ events assuming that the ratio of $\Lambda_b \rightarrow \Lambda_c^{(*)}\pi\pi\pi$ branching fractions is the same as that for $\Lambda_b \rightarrow \Lambda_c^{(*)}\tau\nu$. The projections for $\mathcal{R}(\Lambda_c^*(2595))$ would be similar but with data samples a factor of two smaller than those for $\mathcal{R}(\Lambda_c^*(2625))$.

(vii) $\mathcal{R}(J/\psi)$: We scale the 2018 result based on the expected data samples.

Figure 30 shows the results of these projections. The years on the horizontal axis refer to the dates at which data samples become available, that would eventually result in the plotted total uncertainties once analyses are completed. For instance, the 8.5% uncertainty on $\mathcal{R}(D^*)$ shown at the beginning of 2015 corresponds to the eventual precision achievable for the combined measurement of $\mathcal{R}(D^{*+})$ and $\mathcal{R}(D^{*0})$ with the Run 1 data sample, but the analysis is not expected to be completed until 2021. These projections illustrate the enormous benefit that the data samples collected after the ongoing LHCb *Upgrade I* will have on the measurement of $\mathcal{R}(H_c)$. The proposed LHCb *Upgrade II*, which would take place in 2031, would allow LHCb to further improve the precision

¹¹ These projections are for the measurements that employ the muonic decays of the τ lepton. The projections for the hadronic measurements would be similar except that the irreducible systematic uncertainty would be asymptotically higher because of the external branching fractions used to normalize the result.

Figure 30 Projections for the expected precision on the measurement of selected $\mathcal{R}(H_c)$ ratios at LHCb as a function of the year in which the corresponding data sample becomes available. Left: pessimistic scenario for an irreducible systematic uncertainty of 3% on $\mathcal{R}(D^{(*)})$ and 5% on the other ratios. Right: optimistic scenario for an irreducible systematic uncertainty of 0.5% on $\mathcal{R}(D^{(*)})$ and 2% on the other ratios. These extrapolations are based on the current muonic- τ measurements of $\mathcal{R}(D^{(*)})$ and $\mathcal{R}(J/\psi)$, as well as the forthcoming hadronic- τ measurement of $\mathcal{R}(D_1^0)$ for the $\mathcal{R}(D^{**})$ curve. The $\mathcal{R}(\Lambda_c^*)$ entry in the legend refers to $\mathcal{R}(\Lambda_c^*(2625))$. The shaded regions correspond to the long shutdowns during which there is no data taking at the LHC and have been updated including the latest estimates (Béjar Alonso *et al.*, 2020).

on these ratios down to the 0.5–2% level, if the irreducible systematic uncertainties can be reduced accordingly.

Finally, the measurement of $B \rightarrow p\bar{p}\tau\nu$ decays is underway and LHCb also has plans to measure $\Lambda_b \rightarrow p\tau\nu$. As described in Sec. II.F, these $b \rightarrow u\tau\nu$ transitions are especially interesting because their potential NP couplings could be in principle quite different from those potentially involved in $b \rightarrow c\tau\nu$ transitions.

2. Prospects for $\mathcal{R}(H_{c,u})$ at Belle II

Belle II will profit from the much cleaner environment of B meson pair production in electron-positron annihilations, i.e. even with its smaller data samples with respect to LHCb, highly competitive results will emerge. One of the major challenges will be to retain this clean environment at high luminosities and reduce the impact of beam and other backgrounds as much as possible. In addition, several orthogonal data sets can be obtained leveraging different analysis or tagging approaches (see Section III.C.1). The most important results will be:

(i) $\mathcal{R}(D^{(*)})$ with exclusive tagging: In principle four statistically independent measurements can be carried out this way, namely either with hadronic or semileptonic tagging and with the focus on either leptonic or hadronic τ -lepton decays. The results with the best control of the systematic uncertainty will be obtained from the combination of hadronic tagging and leptonic or hadronic τ decays. For these, the B -rest frame will be accessible and, in the case of hadronic single-prong τ decays, the τ

polarization will also be accessible. These results will suffer, however, from the low overall efficiency of hadronic tagging caused by the small branching fractions of such processes.

Semileptonically tagged events will retain much higher numbers of semitauonic decays, but these will in principle suffer from higher systematic uncertainties. Nonetheless, all reconstructed particles in such signatures can still be assigned to either the signal or tag side, which will allow for reliable measurements. It is worth noting that additional energy depositions from beam background processes will lead to more challenging conditions than the present-day results. Further, only measurements with leptonic τ decays have been realized to date, so it will be an exciting challenge for Belle II to establish measurements with hadronic τ decays using this technique.

(ii) $\mathcal{R}(D^{(*)})$ with inclusive or semi-inclusive tagging: Compared to hadronic or semileptonic tagging, inclusive tagging offers much higher reconstruction efficiency at the cost of higher backgrounds and lower precision in the reconstruction of B -frame kinematic variables. Nonetheless, such measurements will offer additional orthogonal data sets that can be analyzed. A particularly interesting option might involve the use of semi-inclusive tagging via a charmed seed meson (D , D^* , J/ψ , D_s , or D_s^*). Such an approach could offer more experimental control than purely inclusive tagging, while still retaining a high reconstruction efficiency. It is unclear at present how precise such measurements will be, as no detailed studies have been carried out, and we therefore do not include

Figure 31 Projections for the expected precision on the measurements of $\mathcal{R}(D^{(*)})$, $\mathcal{R}(X)$, and $\mathcal{R}(\pi)$ at Belle II as a function of the year in which the corresponding data sample becomes available. An irreducible systematic uncertainty of (left) 3% for the pessimistic scenario and (right) 0.5% for the optimistic one is assumed. The optimistic scenario also assumes a 50% increase in the reconstruction efficiency of the exclusive tagging algorithms. The shaded regions indicate years in which significant down-time is expected due to upgrades of the detector and/or the accelerator.

these in our projections.

(iii) $\mathcal{R}(\pi/\rho/\omega)$: Belle II will have a unique opportunity to further investigate semitauonic processes involving $b \rightarrow u$ transitions. The existing search (detailed in Sec. IV.A.2) focused on charged pion final states. Interesting additional channels with higher branching fractions are decays to ρ and ω mesons, although the large width of the ρ is a challenge. Nonetheless, Belle II will improve the existing limits and with a substantial data set of $10\text{--}15 \text{ ab}^{-1}$ the discovery of these decays, assuming their branching fraction is of the size of the SM expectation, is feasible.

(iv) $\mathcal{R}(D_s^{(*)})$: Belle II anticipates collecting a clean sample of $e^+e^- \rightarrow \Upsilon(5S) \rightarrow B_s^{(*)}\bar{B}_s^{(*)}$ events. The experimental methodology applied to the study of semitauonic B meson decays can also be applied to these data sets. For instance, future measurements of $\mathcal{R}(D_s^{(*)})$ can be done based on hadronic or semileptonic tagging in a similar fashion to the $\mathcal{R}(D^{(*)})$ measurements. It is unclear, however, whether a precision can be reached that would rival LHCb, because of the much smaller number of produced B_s mesons.

(v) $\mathcal{R}(X_{(c)})$ with hadronic tagging: Belle II will further be able to produce measurements of fully inclusive or semi-inclusive semitauonic final states. These will allow measurements of $\mathcal{R}(X_{(c)})$. We use the preliminary measurement of (Hasenbusch, 2018) to estimate the sensitivity for $\mathcal{R}(X)$.

Figure 31 displays the expected sensitivity as a function over time. The left panel displays our pessimistic scenario based on the statistical and systematic uncertainties of existing measurements and an irreducible sys-

tematic uncertainty of 3% as described above. The right panel shows the same progression for the optimistic scenario, that includes an irreducible systematic uncertainty of 0.5% and an increase in the efficiency of the exclusive tagging algorithms of 50%. Such an improvement is not completely unexpected since novel ideas, such as the use of deep learning concepts and attention maps, have already shown promising efficiency gains in simulated events (Tsaklidis, 2020). However, it remains to be seen if such efficiency gains are also retained in the analysis of actual collision events, and if the identified events are clean enough to provide an actual gain in sensitivity. In both scenarios the uncertainties are expected to decrease with luminosity until the systematic uncertainty floor is reached.

The grey bands indicate years in which significant down-time is expected due to upgrades of the detector and/or the accelerator. In 2022, the Belle II pixel detector will be replaced with its final version, and more radiation-hard photomultipliers for the time-of-propagation-detector will be integrated as well. In 2026, the Belle II interaction region will be upgraded to allow for the increase of the instantaneous luminosity to its design value: The superconducting magnets that perform the final focusing will be placed further away from the beam crossing point to reduce the chance of quenches. Measurements of $\mathcal{R}(D^{(*)})$ will be somewhat more precise because of their cleaner signature and lack of feed-down contributions, compared to $\mathcal{R}(D)$ measurements, but in both cases a precision of 4–5% and about 3% will be reached by 2026 in the pessimistic and optimistic scenarios, respectively. Inclusive $\mathcal{R}(D^{(*)})$ measurements and

measurements of $\mathcal{R}(D^*)$ with hadronic τ final states will reach 3.5% precision in the pessimistic scenario and below 2% in the optimistic case. All measurements, except for the ones explicitly probing $b \rightarrow u$ transitions, will reach precisions close to their irreducible systematic uncertainties by 2031.

B. Exploiting full differential information

1. Angular analyses and recovered observables

A 2–3% systematic floor for LFUV ratio measurements might be reached quickly given the high statistical power provided by LHCb and Belle II experiments together. This, combined with the fact that the ratios $\mathcal{R}(H_{c,u})$ are recovered observables from template fits to differential distributions, suggests that attention might increasingly turn towards other measurable properties. These include angular correlations, longitudinal and polarization fractions of the D^* and τ (see Sec. II.D.2), or asymmetries and so on.

Many such observables using angular correlations have been put forward by a wide range of phenomenological studies, in particular as a means to distinguish SM from NP interactions in $b \rightarrow c\tau\nu$ transitions. On the experimental side, the most accessible of these is the D^* longitudinal fraction, $F_{L,\tau}(D^*)$, which can be easily reconstructed. As discussed in Sec. IV.D.2, Belle has already provided a preliminary measurement for this variable based on $B \rightarrow D^*\tau\nu$ decays. This result is compatible with the SM expectations within 2σ . LHCb is expected to soon publish a similar analysis with slightly improved sensitivity.

The τ polarization (Sec. IV.D.1) has also been measured for the first time by Belle, using the $\tau \rightarrow \pi\nu$ single-prong decay channel, though with limited precision. Preliminary studies in LHCb have demonstrated that the measurement of the τ polarization is possible using the $\tau \rightarrow \pi^-\pi^+\pi^-\nu$ decay mode, recycling techniques developed at LEP times involving the optimized variable ω (Davier *et al.*, 1993). This analysis is much more complex than the single-prong mode, in which the pion momentum in the τ rest frame acts as an in-principle perfect polarizer, because the analyzing power of the $\pi\pi\pi$ final state is comparatively small (see Eq. (28)): The analyzing power of the dominant a_1 resonance in $\tau \rightarrow \pi^-\pi^+\pi^-\nu$ features a numerical cancellation on-shell, $\alpha_{a_1} = (1 - 2m_{a_1}^2/m_\tau^2)/(1 + 2m_{a_1}^2/m_\tau^2) \simeq 0.02$. The expected LHCb sensitivity to $P_\tau(D^{(*)})$ in the three-prong mode is not yet known.

A recent study (Hill *et al.*, 2019) has shown that LHCb may be able to reliably recover the angular coefficients describing the $B \rightarrow (D^* \rightarrow D\pi)(\tau \rightarrow h\nu)\nu$ decay, assuming a sample around 10^5 signal events. A dataset of this size is expected to be available at the end of Run 3 of the

LHC; first attempts along these lines may be performed using the full Run 2 dataset.

2. Future strategies

However, as discussed in Sec. VI.D.2, mismatches between SM and NP signal templates can introduce significant biases into analyses that consider recovered observables, such that one cannot consistently determine the compatibility of the data with any particular NP model. Future semileptonic analyses may address these biases through a variety of approaches: One possibility is to attempt to carefully control the size of these biases when experiments quote their results. A different, more robust, approach is for experiments to adapt their analyses such that instead of reporting recovered observables, they instead perform fits directly in the multidimensional space of the NP couplings—the Wilson coefficients—themselves. This approach has the additional advantage of making it more straightforward to combine results from different experiments.

The latter approach is sometimes referred to as ‘forward-folding’. A key obstacle is that generating sufficient simulated data for the SM analysis alone is challenging (see Sec. V.A); generating enough to study a space of NP models is naively computationally prohibitive. This difficulty can be resolved, however, with matrix element reweighting, which allows for large MC samples to be converted from the SM to any desired NP template, or to any description of the hadronic matrix elements, without regenerating the underlying MC data. In recent years, new software tools, such as the `Hammer` library (Bernlochner *et al.*, 2020b), have been developed by experimental-theory collaborations to permit fast and efficient MC reweighting of this type.

As an example, one can consider the mock-up reweighting analysis of (Bernlochner *et al.*, 2020a), that uses the differential information in the missing invariant mass m_{miss}^2 and lepton momentum $|\mathbf{p}_\ell|$, including an approximation of the effects of various backgrounds and reconstruction effects. In Fig. 32 we show the potential recovered CLs from this analysis for the (complex) NP Wilson coefficients of the R_2 simplified model, defined by $c_{SL} \simeq 8c_T$, compared to the ‘truth’ value $c_{SL}(= 8c_T) = 0.25(1+i)$. This mock-up forecasts that with 5 ab^{-1} of future data, one would be able to not only exclude the SM, but also recover the ‘true’ NP Wilson coefficient up to a mild two-fold degeneracy in its imaginary part. Because the forward folding approach can use all differential information by construction, it may supersede approaches based on measuring recovered observables.

Figure 32 The 68%, 95% and 99% CL allowed regions for the R_2 simplified model coupling $c_{SL} = 8c_T$ fitting to an Asimov data set with $c_{SL} = 8c_T = 0.25(1 + i)$. The best fit recovered points are shown by grey dots.

C. Outlook for future colliders

If NP were to be discovered through indirect LFUV searches, future colliders could be instrumental in further characterizing the nature of the new interactions. In some scenarios, NP mediators can escape the discovery reach of the High Luminosity (HL)-LHC while still giving rise to the observation of LFUV in semitauonic b -hadron decays. Future hadron machines such as the FCC- hh collider (Mangano *et al.*, 2018), presently under study at CERN, would extend the reach for direct observation of NP mediators into the multi-TeV range, covering most of these scenarios. An indirect NP observation could also be possible at FCC- hh by, e.g., detecting deviations from the predicted inclusive $\tau\tau$ production rate in the SM (Mangano *et al.*, 2018).

High luminosity e^+e^- colliders may also play a crucial role because the characteristics of b -hadron production on the Z pole combines several of the advantages enjoyed by B -factory experiments with those of hadron colliders. In particular, the advantages of the former include: a very favourable ratio of B production divided by total cross section (22%); a low multiplicity environment (perfect separation of the two B mesons); and good knowledge of the B center-of-mass frame by exploiting jet direction measurements and the peaked fragmentation function. The advantages of the latter include large production of all b -hadron species, and the large boost of the hadrons themselves, which allows one to more easily separate their decay products from primary fragments, and to fully reconstruct secondary and tertiary vertices.

The ‘TeraZ’ class of proposed e^+e^- colliders—either the FCC- ee (Abada, 2019) or CEPC (Dong *et al.*, 2018a,b)—could provide enough B mesons produced in this very favorable Z -pole environment to measure very

complex decays such as $B^+ \rightarrow K^+\tau^+\tau^-$, that are very difficult to probe otherwise (Kamenik *et al.*, 2017). A precise measurement of this branching ratio and its angular distributions would provide a critical test of LFUV in the neutral current decays involving the τ lepton. This might in turn provide evidence of a link between the LFUV hints from $\mathcal{R}(H_{c,u})$, involving charged current decays to τ leptons, and those of $\mathcal{R}_{K^{(*)}}$, involving neutral current decays to the first two lepton families only (see Sec. II.I). In a similar vein, rare B_c decays such as $B_c \rightarrow \tau\nu$ could also be studied at a TeraZ factory (Zheng *et al.*, 2020). A precision of 1% of this branching fraction could be reached providing strong constraints on many NP models.

D. Parting thoughts

In this review we have provided an in-depth look into the theoretical and experimental foundations for semitauonic LFUV measurements. This comprised a detailed overview of the theoretical state-of-the-art and an extensive survey of the experimental environments and measurement methodologies at the B factories and LHCb. We further reexamined the current combinations and NP interpretations of the data as well as their limitations, and the future prospects to control systematic uncertainties, all of which will be crucial for not only establishing a tension with the SM, should one exist, but also understanding the nature of the New Physics responsible for it.

Driven by the intriguing and persistent anomalies in $\mathcal{R}(D^{(*)})$, the host of planned and ongoing measurements of lepton flavor universality violation in semitauonic b -hadron decays will provide new data-driven insights, if not resolutions, for these current LFUV puzzles. A golden era in flavor physics is just ahead of us.
