We examine coherent active-active channel neutrino flavor evolution in environments where neutrino-neutrino forward scattering can engender large-scale collective flavor transformation. We introduce the concept of neutrino flavor isospin which treats neutrinos and antineutrinos on an equal footing, and which facilitates the analysis of neutrino systems in terms of the spin precession analogy. We point out a key quantity, the “total effective energy,” which is conserved in several important regimes. Using this concept, we analyze collective neutrino and antineutrino flavor oscillation in the synchronized mode and what we term the bi-polar mode. We thereby are able to explain why large collective flavor mixing can develop on short time scales even when vacuum mixing angles are small in, e.g., a dense gas of initially pure ν_e and $\bar{\nu}_e$ with an inverted neutrino mass hierarchy (an example of bi-polar oscillation). In the context of the spin precession analogy, we find that the corotating frame provides insights into more general systems, where either the synchronized or bi-polar mode could arise. For example, we use the corotating frame to demonstrate how large flavor mixing in the bi-polar mode can occur in the presence of a large and dominant matter background. We use the adiabatic condition to derive a simple criterion for determining whether the synchronized or bi-polar mode will occur. Based on this criterion, we predict that neutrinos and antineutrinos emitted from a protoneutron star in a core-collapse supernova event can experience synchronized and bi-polar flavor transformations in sequence before conventional Mikheyev-Smirnov-Wolfenstein flavor evolution takes over. This certainly will affect the analyses of future supernova neutrino signals, and might affect the treatment of shock reheating rates and nucleosynthesis depending on the depth at which collective transformation arises.

I. INTRODUCTION

In both the early universe and in core-collapse supernovae, neutrinos and antineutrinos can dominate energetics and can be instrumental in setting compositions (i.e., the neutron-to-proton ratio). However, the way these particles couple to matter in these environments frequently is flavor specific. Whenever there are differences in the number fluxes or energy distribution functions among the active neutrino species (ν_e , $\bar{\nu}_e$, ν_μ , $\bar{\nu}_\mu$, ν_τ , and $\bar{\nu}_\tau$), flavor mixing and conversion can be important [1–8].

In turn, the flavor conversion process becomes complicated and nonlinear in environments with large effective neutrino and/or antineutrino number densities [1,3,5,9–11]. In these circumstances, neutrino-neutrino forward scattering can become an important determinant of the way in which neutrinos and antineutrinos oscillate among flavor states.

Two of the three vacuum mixing angles for the active neutrinos are now measured. The third angle (θ_{13}) is constrained by experiments and is limited to values such that $\sin^2 2\theta_{13} \lesssim 0.1$ (see, e.g., Ref. [12] for a review). In addition, the differences of the squares of the neutrino mass

eigenvalues are now measured, though the absolute masses and, therefore, the neutrino mass hierarchy remains unknown.

Both the solar and atmospheric neutrino mass-squared differences are small, so small in fact that conventional matter-driven Mikheyev-Smirnov-Wolfenstein (MSW) evolution [13–15] would suggest that neutrino and/or antineutrino flavor conversion occurs only far out in the supernova envelope. On the other hand, it has been shown that plausible conditions of neutrino flux in both the early shock reheating epoch and the later neutrino-driven wind, r -process epoch, could provide the necessary condition for neutrino-neutrino forward scattering induced large-scale flavor conversion deep in the supernova environment [16].

The treatment of the flavor evolution of supernova neutrinos remains a complicated problem, and the exact solution to this problem may only be revealed by full self-consistent numerical simulations. However, physical insights still can be gained by studying somewhat simplified models of the realistic environments. For example, one source of complication is that there are three active flavors of neutrinos in play. As the measured vacuum mass-squared difference for atmospheric neutrino oscillations ($\delta m_{\text{atm}}^2 \approx 3 \times 10^{-3} \text{ eV}^2$) is much larger than that for solar neutrino oscillations ($\delta m_{\odot}^2 \approx 8 \times 10^{-5} \text{ eV}^2$), the general problem of three-neutrino mixing in many cases may be

^{*}Electronic address: hduan@ucsd.edu[†]Electronic address: gfuller@ucsd.edu[‡]Electronic address: qian@physics.umn.edu

reduced to two separate cases of two-neutrino mixing, each involving ν_e ($\bar{\nu}_e$) and some linear combination of ν_μ and ν_τ ($\bar{\nu}_\mu$ and $\bar{\nu}_\tau$). This reduction allows the possibility of visualizing the neutrino flavor transformation as the rotation of a “polarization vector” in a three-dimensional flavor space [17]. Different notations have been developed around this concept (see, e.g., Refs. [3,18]). However, none of these notations fully exhibits the symmetry of particles and antiparticles in the SU(2) group that governs the 2×2 flavor transformation.

The equations of motion (e.o.m.) of a neutrino “polarization vector” are similar to those of a magnetic spin precessing around magnetic fields. One naturally expects that some collective behaviors may exist in dense neutrino gases just as for magnetic spins in crystals. Indeed, it was observed in numerical simulations that neutrinos with different energies in a dense gas act as if they have the same vacuum oscillation frequency [10]. This collective behavior was later explained by drawing analogy to atomic spin-orbit coupling in external fields and termed “synchronization” [6].

Another, more puzzling, type of collective flavor transformation, the “bi-polar” mode, has been observed in the numerical simulations of a dense gas of initially pure ν_e and $\bar{\nu}_e$ [19]. This type of collective flavor transformation usually occurs on time scales much shorter than those of vacuum oscillations. Although the analytical solutions to some simple examples of bi-polar systems have been found [20,21], many aspects of these bi-polar systems still remain to be understood. In particular, it seems counterintuitive that, even for a small mixing angle, large flavor mixing occurs in both the neutrino and antineutrino sectors in a dense gas initially consisting of pure ν_e and $\bar{\nu}_e$ for an inverted mass hierarchy.

Both synchronized and bi-polar flavor transformation were discovered in the numerical simulations aimed at the early universe environment. It has been shown that synchronized oscillation can also occur in the supernova environment [22]. However, it is not clear if supernova neutrinos can also have bi-polar flavor transformation. If supernova neutrinos can have collective synchronized and/or bi-polar oscillations, the questions are then where these collective oscillations would occur and how neutrino energy spectra would be modified.

In this paper we try to answer the above questions. In Sec. II we will give the general equations governing the mixing of two neutrino flavors in the frequently used forms and introduce the notation of neutrino flavor isospin, which treats neutrinos and antineutrinos on an equal footing. We will also point out a key quantity, the “total effective energy,” in analogy to the total energy of magnetic spin systems, which is conserved in some interesting cases. In Secs. III and IV we will analyze the synchronized and bi-polar neutrino systems using the same framework in each case. We will first describe and explain the main features of

these collective modes using the concept of total effective energy. We then generalize these analyses by employing “corotating frames.” We will derive the criteria for the occurrence of these collective modes, and discuss the effects of an ordinary matter background. In Sec. V we will outline the regions in supernovae where the neutrino mixing is dominated by the synchronized, bi-polar, and conventional MSW flavor transformations. We will also describe the typical neutrino mixing scenarios expected with different matter density profiles. In Sec. VI we will summarize our new findings and give our conclusions.

II. GENERAL EQUATIONS GOVERNING NEUTRINO FLAVOR TRANSFORMATION

We consider the mixing of two neutrino flavor eigenstates, say $|\nu_e\rangle$ and $|\nu_\tau\rangle$, which are linear combinations of the vacuum mass eigenstates $|\nu_1\rangle$ and $|\nu_2\rangle$ with eigenvalues m_1 and m_2 , respectively:

$$|\nu_e\rangle = \cos\theta_v |\nu_1\rangle + \sin\theta_v |\nu_2\rangle, \quad (1a)$$

$$|\nu_\tau\rangle = -\sin\theta_v |\nu_1\rangle + \cos\theta_v |\nu_2\rangle, \quad (1b)$$

where θ_v is the vacuum mixing angle. We take $\theta_v < \pi/4$ and refer to $\delta m^2 \equiv m_2^2 - m_1^2 > 0$ as the normal mass hierarchy and $\delta m^2 < 0$ as the inverted mass hierarchy. When a neutrino with energy E_ν propagates in matter, the evolution of its wave function in the flavor basis

$$\psi_\nu \equiv \begin{pmatrix} a_{\nu_e} \\ a_{\nu_\tau} \end{pmatrix} \quad (2)$$

is governed by a Schrödinger-like equation

$$i \frac{d}{dt} \psi_\nu = (\mathcal{H}_v + \mathcal{H}_e) \psi_\nu, \quad (3)$$

where a_{ν_e} and a_{ν_τ} are the amplitudes for the neutrino to be in $|\nu_e\rangle$ and $|\nu_\tau\rangle$ at time t , respectively. (This equation is “Schrödinger-like” because, unlike the Schrödinger equation, we are here concerned with flavor evolution at fixed energy and with relativistic leptons.) The vacuum mass contribution $\mathcal{H}_v$ to the propagation Hamiltonian in the flavor basis is

$$\mathcal{H}_v = \frac{\delta m^2}{4E_\nu} \begin{pmatrix} -\cos 2\theta_v & \sin 2\theta_v \\ \sin 2\theta_v & \cos 2\theta_v \end{pmatrix}, \quad (4)$$

and the contribution $\mathcal{H}_e$ due to forward scattering on electrons in the same basis is

$$\mathcal{H}_e = \frac{A}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad (5)$$

where $A = \sqrt{2} G_F n_e$ with n_e being the net electron number density. Equation (3) also applies to the antineutrino wave function

$$\psi_{\bar{\nu}} \equiv \begin{pmatrix} a_{\bar{\nu}_e} \\ a_{\bar{\nu}_\tau} \end{pmatrix} \quad (6)$$

if A in $\mathcal{H}_e$ is replaced by $-A$.

When a large number of neutrinos and antineutrinos propagate through the same region of matter, their forward scattering on each other makes another contribution to the propagation Hamiltonian for each particle. For the i th neutrino, this contribution is [1,3,5,9,23]

$$\mathcal{H}_{\nu\nu,i} = \frac{1}{2} \begin{pmatrix} B & B_{e\tau} \\ B_{e\tau}^* & -B \end{pmatrix}, \quad (7)$$

where

$$B = \sqrt{2}G_F \sum_j (1 - \cos\Theta_{ij}) \{ n_{\nu,j} [(\rho_{\nu,j})_{ee} - (\rho_{\nu,j})_{\tau\tau}] - n_{\bar{\nu},j} [(\rho_{\bar{\nu},j})_{ee} - (\rho_{\bar{\nu},j})_{\tau\tau}] \}, \quad (8a)$$

$$B_{e\tau} = 2\sqrt{2}G_F \sum_j (1 - \cos\Theta_{ij}) [n_{\nu,j}(\rho_{\nu,j})_{e\tau} - n_{\bar{\nu},j}(\rho_{\bar{\nu},j})_{e\tau}]. \quad (8b)$$

In the above equations, Θ_{ij} is the angle between the propagation directions of the i th neutrino and the j th neutrino or antineutrino, and $n_{\nu,j}$ ($n_{\bar{\nu},j}$) and $\rho_{\nu,j}$ ($\rho_{\bar{\nu},j}$) are the number density and single-particle flavor-basis density matrix of the j th neutrino (antineutrino), respectively. Specifically,

$$\rho_\nu = \begin{pmatrix} |a_{\nu_e}|^2 & a_{\nu_e} a_{\nu_\tau}^* \\ a_{\nu_e}^* a_{\nu_\tau} & |a_{\nu_\tau}|^2 \end{pmatrix}, \quad (9a)$$

and

$$\rho_{\bar{\nu}} = \begin{pmatrix} |a_{\bar{\nu}_e}|^2 & a_{\bar{\nu}_e}^* a_{\bar{\nu}_\tau} \\ a_{\bar{\nu}_e} a_{\bar{\nu}_\tau}^* & |a_{\bar{\nu}_\tau}|^2 \end{pmatrix}, \quad (9b)$$

where we have adopted the convention for the density matrix of an antineutrino in Ref. [3]. The neutrino-neutrino forward scattering contribution for an antineutrino can be obtained by making the substitution $B \rightarrow -B$ and $B_{e\tau} \rightarrow -B_{e\tau}^*$ in $\mathcal{H}_{\nu\nu,i}$.

The single-particle density matrices in Eqs. (9a) and (9b) can be written in the form

$$\rho = \frac{1}{2}(1 + \mathbf{P} \cdot \boldsymbol{\sigma}), \quad (10)$$

where $\mathbf{P}$ is the polarization vector in the three-dimensional (Euclidean) flavor space and $\boldsymbol{\sigma}$ represents the Pauli matrices. Explicitly, the polarization vectors in column form are

$$\mathbf{P}_\nu = \begin{pmatrix} 2\text{Re}(a_{\nu_e}^* a_{\nu_\tau}) \\ 2\text{Im}(a_{\nu_e}^* a_{\nu_\tau}) \\ |a_{\nu_e}|^2 - |a_{\nu_\tau}|^2 \end{pmatrix}, \quad (11)$$

and

$$\mathbf{P}_{\bar{\nu}} = \begin{pmatrix} 2\text{Re}(a_{\bar{\nu}_e}^* a_{\bar{\nu}_\tau}) \\ 2\text{Im}(a_{\bar{\nu}_e}^* a_{\bar{\nu}_\tau}) \\ |a_{\bar{\nu}_e}|^2 - |a_{\bar{\nu}_\tau}|^2 \end{pmatrix}. \quad (12)$$

By straightforward algebra, it can be shown that the Schrödinger-like equation

$$i \frac{d}{dt} \psi_{\nu,i} = (\mathcal{H}_\nu + \mathcal{H}_e + \mathcal{H}_{\nu\nu,i}) \psi_{\nu,i} \quad (13)$$

and a similar equation for an antineutrino lead to [3]

$$\begin{aligned} \frac{d}{dt} \mathbf{P}_{\nu,i} = \mathbf{P}_{\nu,i} \times & \left[\frac{\delta m^2}{2E_{\nu,i}} \begin{pmatrix} -\sin 2\theta_\nu \\ 0 \\ \cos 2\theta_\nu \end{pmatrix} - \sqrt{2}G_F n_e \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} \right. \\ & \left. - \sqrt{2}G_F \sum_j (1 - \cos\Theta_{ij}) (n_{\nu,j} \mathbf{P}_{\nu,j} - n_{\bar{\nu},j} \mathbf{P}_{\bar{\nu},j}) \right], \end{aligned} \quad (14a)$$

$$\begin{aligned} \frac{d}{dt} \mathbf{P}_{\bar{\nu},i} = \mathbf{P}_{\bar{\nu},i} \times & \left[-\frac{\delta m^2}{2E_{\bar{\nu},i}} \begin{pmatrix} -\sin 2\theta_\nu \\ 0 \\ \cos 2\theta_\nu \end{pmatrix} - \sqrt{2}G_F n_e \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} \right. \\ & \left. - \sqrt{2}G_F \sum_j (1 - \cos\Theta_{ij}) (n_{\nu,j} \mathbf{P}_{\nu,j} - n_{\bar{\nu},j} \mathbf{P}_{\bar{\nu},j}) \right]. \end{aligned} \quad (14b)$$

The three real components of the polarization vector contain the same information as the two complex amplitudes of the wave function except for an overall phase which is irrelevant for flavor transformation. Therefore, Eqs. (14a) and (14b) are equivalent to the Schrödinger-like equations. Equations (14a) and (14b) appear to suggest a geometric picture of precessing polarization vectors. This picture has been discussed quite extensively in the literature (see, e.g., [6,24,25]) and shown to be especially helpful in understanding flavor transformation when neutrino self-interaction (i.e., neutrino-neutrino forward scattering) is important. To facilitate the use of this picture, we briefly discuss the physics behind it and introduce some notations.

For simplicity, we first consider only the contributions $\mathcal{H}_\nu$ and $\mathcal{H}_e$ to the propagation Hamiltonian $\mathcal{H}$ for a neutrino. In this case, we can write

$$\mathcal{H} = \mathcal{H}_\nu + \mathcal{H}_e = -\frac{\boldsymbol{\sigma}}{2} \cdot (\mu_\nu \mathbf{H}_\nu + \mathbf{H}_e), \quad (15)$$

where

$$\mu_\nu \equiv \frac{\delta m^2}{2E_\nu}, \quad (16)$$

$$\mathbf{H}_\nu \equiv -\hat{\mathbf{e}}_x^f \sin 2\theta_\nu + \hat{\mathbf{e}}_z^f \cos 2\theta_\nu, \quad (17)$$

$$\mathbf{H}_e \equiv -\hat{\mathbf{e}}_z^f \sqrt{2} G_F n_e, \quad (18)$$

with $\hat{\mathbf{e}}_x^f$ and $\hat{\mathbf{e}}_z^f$ being the unit vectors in the x and z directions in the flavor basis, respectively. Equation (15) takes the form of the interaction between the “magnetic moment” $\boldsymbol{\mu} = \gamma \mathbf{s}$ of a spin- $\frac{1}{2}$ particle and an external “magnetic field” $\mathbf{H} = \mathbf{H}^{\text{eff}}/\gamma$ with

$$\mathbf{H}^{\text{eff}} \equiv \mu_V \mathbf{H}_V + \mathbf{H}_e. \quad (19)$$

Here γ is the “gyromagnetic ratio” and can be chosen arbitrarily. Classically, the spin $\mathbf{s}$ would experience a torque $\boldsymbol{\tau} = \boldsymbol{\mu} \times \mathbf{H} = \mathbf{s} \times \mathbf{H}^{\text{eff}}$ and its e.o.m. would be given by the angular momentum theorem:

$$\frac{d}{dt} \mathbf{s} = \boldsymbol{\tau} = \mathbf{s} \times \mathbf{H}^{\text{eff}}. \quad (20)$$

By Ehrenfest’s theorem, the quantum mechanical description of a system has the same form as the classical e.o.m. provided that all physical observables are replaced by the expectation values of their quantum mechanical operators. In the present case, if we replace $\mathbf{s}$ in Eq. (20) by

$$\mathbf{s}_\nu \equiv \psi_\nu^\dagger \frac{\boldsymbol{\sigma}}{2} \psi_\nu = \frac{\mathbf{P}_\nu}{2}, \quad (21)$$

then neutrino flavor transformation governed by $\mathcal{H} = \mathcal{H}_V + \mathcal{H}_e$ can be described quantum mechanically by

$$\frac{d}{dt} \mathbf{s}_\nu = \mathbf{s}_\nu \times \mathbf{H}^{\text{eff}}, \quad (22)$$

which is the same as Eq. (14a) in the absence of neutrino self-interaction. Clearly, the operator $\boldsymbol{\sigma}/2$ in Eqs. (15) and (21) represents a fictitious spin in the neutrino flavor space, which may be appropriately called the neutrino flavor isospin (NFIS). The flavor eigenstates $|\nu_e\rangle$ and $|\nu_\tau\rangle$ correspond to the up and down eigenstates, respectively, of the z -component of $\boldsymbol{\sigma}/2$. We will loosely refer to the expectation value $\mathbf{s}_\nu$ of this operator as the NFIS and use it instead of the polarization vector $\mathbf{P}_\nu$ to describe neutrino flavor transformation. The z -component of a NFIS $\mathbf{s}_\nu$ is of special importance as it determines the probability for the corresponding neutrino to be in $|\nu_e\rangle$:

$$s_{\nu z}^f \equiv \mathbf{s}_\nu \cdot \hat{\mathbf{e}}_z^f = \frac{|a_{\nu_e}|^2 - |a_{\nu_\tau}|^2}{2} = |a_{\nu_e}|^2 - \frac{1}{2}. \quad (23)$$

Therefore, for a neutrino, $s_{\nu z}^f = 1/2$, $-1/2$, and 0 correspond to $|\nu_e\rangle$, $|\nu_\tau\rangle$, and a maximally mixed state, respectively.

Adiabatic MSW flavor conversion has a simple explanation in this “magnetic spin” analogy. For illustrative purposes, we assume $\delta m^2 > 0$ and $\theta_v \ll 1$. As a ν_e propagates from a region with large matter density, e.g., the core of the sun, to a region of very little ordinary matter, $\mathbf{H}^{\text{eff}}$ changes its direction from $\sim -\hat{\mathbf{e}}_z^f$ to $\mathbf{H}_V \sim \hat{\mathbf{e}}_z^f$. If the density of electrons n_e changes only slowly along the way (adiabatic process), $\mathbf{H}^{\text{eff}}$ also changes slowly, and the NFIS

$\mathbf{s}_\nu$ corresponding to the neutrino is always antialigned with $\mathbf{H}^{\text{eff}}$. Therefore, the neutrino originally in the ν_e eigenstate ($\mathbf{s}_\nu = \hat{\mathbf{e}}_z^f/2$) is now mostly in the ν_τ eigenstate ($\mathbf{s}_\nu \approx -\hat{\mathbf{e}}_z^f/2$).

It is useful to illustrate the criterion for adiabaticity of this process in the “magnetic spin” analogy. First, we note that the probabilities for a neutrino to be in instantaneous mass eigenstates ν_L (light) and ν_H (heavy) are

$$|a_{\nu_L}|^2 = \frac{1}{2} + \mathbf{s}_\nu \cdot \hat{\mathbf{e}}_z^m = \frac{1 + \cos 2\theta}{2}, \quad (24a)$$

$$|a_{\nu_H}|^2 = \frac{1}{2} - \mathbf{s}_\nu \cdot \hat{\mathbf{e}}_z^m = \frac{1 - \cos 2\theta}{2}, \quad (24b)$$

respectively, where 2θ is the angle between the directions of $\mathbf{s}_\nu$ and $\hat{\mathbf{e}}_z^m \equiv \mathbf{H}^{\text{eff}}/|\mathbf{H}^{\text{eff}}|$, and $\hat{\mathbf{e}}_i^m$ are the unit vectors for the instantaneous mass basis. In the MSW picture, θ is the instantaneous matter mixing angle. In an adiabatic process, $|a_{\nu_L}|^2$ and $|a_{\nu_H}|^2$ are constant, and so is θ . Using Eq. (22) we have

$$\frac{1}{2} \frac{d}{dt} (\cos 2\theta) = \frac{d}{dt} (\mathbf{s}_\nu \cdot \hat{\mathbf{e}}_z^m) = \mathbf{s}_\nu \cdot \frac{d}{dt} \hat{\mathbf{e}}_z^m. \quad (25)$$

On a time scale $\delta t \gtrsim 2\pi/|\mathbf{H}^{\text{eff}}|$, $\mathbf{s}_\nu$ has rotated by at least one cycle around $\mathbf{H}^{\text{eff}}$. If $\mathbf{H}^{\text{eff}}$ changes its direction only by a small angle $\delta\phi \equiv |d\hat{\mathbf{e}}_z^m/dt|\delta t \ll 2\pi$ during δt , then $\mathbf{s}_\nu$ in Eq. (25) averages to $(\mathbf{s}_\nu \cdot \hat{\mathbf{e}}_z^m)\hat{\mathbf{e}}_z^m$. Noting that $\hat{\mathbf{e}}_z^m \cdot (d\hat{\mathbf{e}}_z^m/dt) = (1/2)d(|\hat{\mathbf{e}}_z^m|^2)/dt = 0$, one can see that the angle θ is unchanged in this process. Therefore, the criterion for a MSW flavor transformation to be adiabatic is

$$\left| \frac{d}{dt} \hat{\mathbf{e}}_z^m \right| = \frac{|\dot{\mathbf{H}}^{\text{eff}} \times \mathbf{H}^{\text{eff}}|}{|\mathbf{H}^{\text{eff}}|^2} \ll |\mathbf{H}^{\text{eff}}|, \quad (26)$$

which is equivalent to saying that the rate of change of the direction of the “magnetic field” $\mathbf{H}^{\text{eff}}$ is much smaller than the rotating rate of the “magnetic spin” $\mathbf{s}_\nu$ around $\mathbf{H}^{\text{eff}}$.

The full version of Eq. (14a) can be obtained by extending the Hamiltonian in Eq. (4) to include

$$\mathcal{H}_{\nu\nu,i} = -\frac{\boldsymbol{\sigma}}{2} \sum_j \mu_{ij} \left(n_{\nu,j} \frac{\mathbf{P}_{\nu,j}}{2} - n_{\bar{\nu},j} \frac{\mathbf{P}_{\bar{\nu},j}}{2} \right), \quad (27)$$

where

$$\mu_{ij} \equiv -2\sqrt{2} G_F (1 - \cos \Theta_{ij}). \quad (28)$$

We define the NFIS for an antineutrino as¹

$$\mathbf{s}_{\bar{\nu}} \equiv -\frac{\mathbf{P}_{\bar{\nu}}}{2}, \quad (29)$$

so that the terms related to neutrinos and antineutrinos

¹The two fundamental representations $\mathbf{2}$ and $\bar{\mathbf{2}}$ of the SU(2) group generated by the Pauli matrices are equivalent. These representations are related to each other by the transformation σ_y , and $\bar{\psi}_{\bar{\nu}} \equiv \sigma_y \psi_{\bar{\nu}}$ transforms in exactly the same way as does $\psi_{\bar{\nu}}$ under rotation. Defining $\mathbf{s}_{\bar{\nu}} \equiv \bar{\psi}_{\bar{\nu}}^\dagger (\boldsymbol{\sigma}/2) \bar{\psi}_{\bar{\nu}}$, one naturally obtains the minus sign in Eq. (29).

appear symmetrically in $\mathcal{H}_{\nu\nu,i}$. The probability for an antineutrino to be in $|\bar{\nu}_e\rangle$ is determined from

$$s_{\bar{\nu}_e}^f \equiv \mathbf{s}_{\bar{\nu}} \cdot \hat{\mathbf{e}}_z^f = \frac{|a_{\bar{\nu}_\tau}| - |a_{\bar{\nu}_e}|^2}{2} = \frac{1}{2} - |a_{\bar{\nu}_e}|^2. \quad (30)$$

For an antineutrino, $s_{\bar{\nu}_e}^f = 1/2, -1/2$, and 0 correspond to $|\bar{\nu}_\tau\rangle$, $|\bar{\nu}_e\rangle$, and a maximally mixed state, respectively.

Now Eqs. (14a) and (14b) can be rewritten in terms of the NFIS's in a more compact way:

$$\frac{d}{dt}\mathbf{s}_i = \mathbf{s}_i \times \left(\mu_{\nu,i}\mathbf{H}_V + \mathbf{H}_e + \sum_j \mu_{ij}n_{\nu,j}\mathbf{s}_j \right), \quad (31)$$

with the understanding that

$$\mu_{\nu,i} \equiv \begin{cases} \delta m^2/(2E_{\nu,i}) & \text{for a neutrino,} \\ -\delta m^2/(2E_{\bar{\nu},i}) & \text{for an antineutrino,} \end{cases} \quad (32)$$

and that the sum runs over both neutrinos and antineutrinos. We also define a total effective energy (density) $\mathcal{E}$ for a system of neutrinos and antineutrinos that interact with a matter background as well as among themselves through forward scattering:

$$\mathcal{E} \equiv -\sum_i n_{\nu,i}\mathbf{s}_i \cdot \mathbf{H}_i^{\text{eff}} - \frac{1}{2}\sum_{i,j} \mu_{ij}n_{\nu,i}n_{\nu,j}\mathbf{s}_i \cdot \mathbf{s}_j, \quad (33)$$

where

$$\mathbf{H}_i^{\text{eff}} \equiv \mu_{\nu,i}\mathbf{H}_V + \mathbf{H}_e. \quad (34)$$

We note that this effective energy should not be confused with the physical energies of neutrinos and antineutrinos. It can be shown from Eq. (31) that $\mathcal{E}$ is constant if n_e and all the $n_{\nu,i}$'s and μ_{ij} 's are also constant. The concept of the total effective energy will prove useful in understanding collective flavor transformation in a dense neutrino gas.

In the early universe the neutrino gas is isotropic, and

$$\mu_{ij} \rightarrow \mu_\nu \equiv -2\sqrt{2}G_F. \quad (35)$$

For illustrative purposes we will assume this isotropy condition in most of what follows. We will discuss the effects of the anisotropic supernova neutrino distributions in Sec. V.

III. SYNCHRONIZED FLAVOR TRANSFORMATION

In a dense neutrino gas, NFIS's are coupled to each other through self-interaction and may exhibit collective behaviors. As discovered in the numerical simulations of Ref. [10], neutrinos with different energies in a dense gas act as if they are oscillating with the same frequency. This collective behavior was referred to as ‘‘synchronized’’ flavor oscillations in the literature and explained in Ref. [6] by drawing analogy to atomic spin-orbit coupling in external magnetic fields. In this section we will first review the characteristics of a simple synchronized NFIS

system from the perspective of the conservation of the total energy $\mathcal{E}$ of the NFIS system. We will then extend the discussion to more general synchronized NFIS systems using the concept of a ‘‘corotating frame’’ and demonstrate the criteria for a NFIS system to be in the synchronized mode. We will show that the stability of a synchronized system is secured by the conservation of the total effective energy. In the last part of the section, we will look into the problem of synchronized flavor transformation in the presence of ordinary matter, which is relevant for the supernova environment.

A. A simple example of synchronized flavor transformation

We start with a simple case of a uniform and isotropic neutrino gas with no matter background ($n_e = 0$). The gas initially consists of pure neutrinos with a finite energy range corresponding to $|\mu_{\nu,i}| \leq |\mu_{\nu,i}|_{\text{max}}$, and all the $n_{\nu,i}$'s stay constant. The e.o.m. of a single NFIS is

$$\frac{d}{dt}\mathbf{s}_i = \mathbf{s}_i \times (\mu_{\nu,i}\mathbf{H}_V + \mu_\nu\mathbf{S}), \quad (36)$$

where

$$\mathbf{S} \equiv \sum_j n_{\nu,j}\mathbf{s}_j \quad (37)$$

is the total NFIS (density) of the gas. (The NFIS density for an individual ‘‘spin’’ $\mathbf{s}_j$ is just $n_{\nu,j}\mathbf{s}_j$.) Summing Eq. (36) over all neutrinos, we obtain

$$\frac{d}{dt}\mathbf{S} = \sum_i \mu_{\nu,i}n_{\nu,i}\mathbf{s}_i \times \mathbf{H}_V. \quad (38)$$

Following the discussion at the end of the preceding section, the evolution of the individual ($\mathbf{s}_i$) and the total ($\mathbf{S}$) NFIS obeys conservation of the total effective energy

$$\mathcal{E} = -\sum_i \mu_{\nu,i}n_{\nu,i}\mathbf{s}_i \cdot \mathbf{H}_V - \frac{1}{2}\sum_{i,j} \mu_{ij}n_{\nu,i}n_{\nu,j}\mathbf{s}_i \cdot \mathbf{s}_j \quad (39a)$$

$$= -\sum_i \mu_{\nu,i}n_{\nu,i}\mathbf{s}_i \cdot \mathbf{H}_V - \frac{\mu_\nu}{2}\mathbf{S}^2. \quad (39b)$$

An interesting limit is

$$|\mu_\nu\mathbf{S}| \gg |\mu_{\nu,i}|_{\text{max}}. \quad (40)$$

Noting that each $\mathbf{s}_i$ has a magnitude of $1/2$ and $\mathbf{H}_V$ has a magnitude of unity, we see that

$$\mathcal{E} \simeq -\frac{\mu_\nu}{2}\mathbf{S}^2 \simeq \text{const} \quad (41)$$

in the above limit. Therefore, a gas with a large initial total NFIS $\mathbf{S}$ evolves in such a way that it roughly maintains the magnitude of its $\mathbf{S}$. For such a gas, Eq. (36) reduces to

$$\frac{d}{dt}\mathbf{s}_i \simeq \mu_\nu\mathbf{s}_i \times \mathbf{S}, \quad (42)$$

which means that each $\mathbf{s}_i$ precesses around the total NFIS with a fixed common (angular) frequency

$$\omega_\nu \equiv |\mu_\nu \mathbf{S}|. \quad (43)$$

Equation (38) shows that $\mathbf{S}$ evolves on a time scale $\geq 2\pi/|\mu_{V,i}|_{\max}$. Consequently, over a period δt satisfying

$$\frac{2\pi}{\omega_\nu} \ll \delta t \ll \frac{2\pi}{|\mu_{V,i}|_{\max}}, \quad (44)$$

$\mathbf{s}_i$ averages out to be $(\mathbf{s}_i \cdot \mathbf{S})\mathbf{S}/\mathbf{S}^2$ and Eq. (38) effectively becomes

$$\frac{d}{dt}\mathbf{S} \simeq \omega_{\text{sync}}\mathbf{S} \times \mathbf{H}_V, \quad (45)$$

where

$$\omega_{\text{sync}} = \langle \mu_V \rangle \equiv \sum_i \frac{\mu_{V,i} n_{\nu,i} \mathbf{s}_i \cdot \mathbf{S}}{\mathbf{S}^2}. \quad (46)$$

It can be shown from Eqs. (38), (41), and (42) that $\omega_{\text{sync}} \simeq \text{const.}$ Therefore, $\mathbf{S}$ precesses around $\mathbf{H}_V$ with a fixed frequency ω_{sync} while the individual $\mathbf{s}_i$'s precess around $\mathbf{S}$ with a fixed common frequency ω_ν . This collective behavior of a dense neutrino gas is usually referred to as synchronized flavor oscillations [6].

B. General synchronized systems

Synchronization can occur not only in dense neutrino gases but also in dense antineutrino gases and gases including both neutrinos and antineutrinos. Noting that the NFIS's for neutrinos and antineutrinos essentially only differ by the signs in $\mu_{V,i}$'s [see Eq. (32)], one can repeat the same arguments in Sec. III A for these more generalized cases. Instead of doing so, we want to proceed from a new perspective, which demonstrates some of the benefits of the NFIS notation.

We consider a reference frame rotating with an angular velocity of $-\Omega\mathbf{H}_V$. In this corotating frame, Eqs. (36) and (38) take the form

$$\dot{\tilde{\mathbf{s}}}_i = \tilde{\mathbf{s}}_i \times (\tilde{\mu}_{V,i}\mathbf{H}_V + \mu_\nu \tilde{\mathbf{S}}), \quad (47a)$$

$$\dot{\tilde{\mathbf{S}}} = \sum_i \tilde{\mu}_{V,i} n_{\nu,i} \tilde{\mathbf{s}}_i \times \mathbf{H}_V, \quad (47b)$$

where $\tilde{\mathbf{s}}_i$ ($\tilde{\mathbf{S}}$) and $\dot{\tilde{\mathbf{s}}}_i$ ($\dot{\tilde{\mathbf{S}}}$) are $\mathbf{s}_i$ ($\mathbf{S}$) and its time derivative in terms of their x -, y -, and z -components in the corotating frame, and

$$\tilde{\mu}_{V,i} \equiv \mu_{V,i} - \Omega. \quad (48)$$

It is clear that one can set $\tilde{\mu}_V$ of a NFIS to any value by choosing an appropriate corotating frame, and a NFIS for an antineutrino in the lab frame becomes a neutrino in some corotating frame. For example, the NFIS in the lab frame with $\mathbf{s} = -\hat{\mathbf{e}}_z^f/2$ and $\mu_V = -\delta m^2/2E$ corresponds to a $\bar{\nu}_e$ with energy E . In a corotating frame with $\Omega =$

$-\delta m^2/E$, the NFIS has $\tilde{\mathbf{s}} = -\hat{\mathbf{e}}_z^f/2$ and $\tilde{\mu}_V = \delta m^2/2E$, which corresponds to a ν_τ with energy E . Therefore, the NFIS notation really treats neutrinos and antineutrinos on an equal footing.

Because $\tilde{\mathbf{S}}$ and $\mathbf{S}$ are the same vector in two different frames, the synchronization of the NFIS's in one frame means the synchronization in any frame. Consequently, synchronization can occur in dense antineutrino gases and gases of both neutrinos and antineutrinos just as it can occur in pure neutrino gases as long as Eq. (40) is satisfied in some corotating frame.

As we have seen, $|\mu_{V,i}|_{\max}$ is not uniquely determined and can have different values in different corotating frames. However, we note that the relative spread of the individual values of the $\mu_{V,i}$'s of the NFIS's is an intrinsic property of a NFIS system and is corotating frame invariant. For a corotating frame with

$$\Omega = \frac{(\mu_{V,i})_{\min} + (\mu_{V,i})_{\max}}{2}, \quad (49)$$

one has

$$|\tilde{\mu}_{V,i}|_{\max} = \Delta\mu_V, \quad (50)$$

where

$$\Delta\mu_V \equiv \frac{(\mu_{V,i})_{\max} - (\mu_{V,i})_{\min}}{2} \quad (51)$$

measures the spread of the $\mu_{V,i}$'s in the NFIS system. Synchronization can be obtained if

$$|\mu_\nu \mathbf{S}| \gg \Delta\mu_V. \quad (52)$$

When applying this condition to astrophysical environments such as the early universe and supernovae, we must consider the meaning of $\Delta\mu_V$ as neutrinos in these environments formally have an infinite energy range. One interesting scenario is where the distribution of NFIS density as a function of μ_V has a single dominant peak. An example is the neutronization burst in a core-collapse supernova event where the neutrinos emitted are dominantly ν_e with a Fermi-Dirac-like energy distribution $f_{\nu_e}(E)$. For this case a natural estimate of $\Delta\mu_V$ is the half-width of the distribution function $f_{\nu_e}(\mu_V)$, where $f_{\nu_e}(\mu_V)$ is obtained from $f_{\nu_e}(E)$ using the relation $\mu_V(E) = \delta m^2/2E$.

Another interesting scenario is where the distribution of NFIS density as a function of μ_V has two dominant peaks. An example of this scenario is the Kelvin-Helmholtz cooling phase of a protoneutron star in a core-collapse supernova event where the neutrinos emitted are mostly (in number) ν_e and $\bar{\nu}_e$. For this scenario one can take

$$\Delta\mu_V \simeq \left| \frac{\delta m^2}{2E_{\nu_e}} + \frac{\delta m^2}{2E_{\bar{\nu}_e}} \right|, \quad (53)$$

where E_{ν_e} and $E_{\bar{\nu}_e}$ are the peak energies of the ν_e and $\bar{\nu}_e$ energy spectra, respectively.

For more complicated scenarios, the criterion to obtain synchronized flavor oscillations can be compared to the criterion for an adiabatic MSW flavor conversion. If a NFIS system has been tested to be in a synchronized mode using the analyses in Sec. III A in some corotating frame, each individual NFIS $\tilde{\mathbf{s}}$ should precess around the total NFIS $\tilde{\mathbf{S}}$ with a fixed angle. This is the same “tracking” behavior as in the adiabatic MSW flavor transformation process discussed in Sec. II except that $\tilde{\mathbf{S}}$ now takes the place of $\mathbf{H}^{\text{eff}}$ in Eq. (26). Because $\tilde{\mathbf{S}}$ slowly rotates around $\mathbf{H}_V$ with angular frequency $\tilde{\omega}_{\text{sync}} = \langle \tilde{\mu}_V \rangle$, the adiabatic criterion yields

$$|\mu_\nu \tilde{\mathbf{S}}| \geq |\langle \tilde{\mu}_V \rangle| \cdot |\sin \xi|, \quad (54)$$

where ξ is the angle between the directions of $\tilde{\mathbf{S}}$ and $\mathbf{H}_V$. Equation (54) provides a necessary condition for synchronization. Practically one may use

$$|\mu_\nu \mathbf{S}| \geq |\langle \mu_V \rangle| \quad (55)$$

as the criterion for synchronization, where $\langle \mu_V \rangle$ is evaluated using Eq. (46) with all the relevant neutrino and antineutrino energy distributions.

We now make some comments on the stability of the synchronized mode. Because neutrinos with different energies have different vacuum oscillation frequencies, one may think that the NFIS's will develop relative phases and that the resulting destructive interference will break the synchronization, i.e., reducing $\mathbf{S}$ to approximately 0. Indeed, using Eq. (38) one can see that

$$\frac{d}{dt} \mathbf{S}^2 = 2\mathbf{S} \cdot \dot{\mathbf{S}} \quad (56a)$$

$$= \sum_{ij} n_{\nu,i} n_{\nu,j} (\mu_{V,i} - \mu_{V,j}) (\mathbf{s}_j \times \mathbf{s}_i) \cdot \mathbf{H}_V \quad (56b)$$

is generally not zero, and therefore, $|\mathbf{S}|$ varies with time. However, Eq. (36), from which Eq. (38) is derived, can be used to show that the total effective energy $\mathcal{E}$ is conserved and the total NFIS $\mathbf{S}$ roughly maintains constant magnitude if the $n_{\nu,i}$'s do not vary with time [see Eq. (41)]. In this case, destructive interference stemming from the relative phases of different NFIS's cannot completely destroy synchronized flavor oscillations. On the other hand, if $|\mathbf{S}| \approx 0$ initially, no significant synchronization of NFIS's can occur spontaneously. This result is in accord with the lengthy study in Ref. [26].

C. Synchronized flavor transformation with a matter background

We now discuss the effects of a matter background on synchronized flavor transformation in dense gases of neutrinos and/or antineutrinos. The relevant evolution equations are

$$\frac{d}{dt} \mathbf{s}_i = \mathbf{s}_i \times (\mu_{V,i} \mathbf{H}_V + \mathbf{H}_e + \mu_\nu \mathbf{S}), \quad (57a)$$

$$\frac{d}{dt} \mathbf{S} = \sum_i \mu_{V,i} n_{\nu,i} \mathbf{s}_i \times \mathbf{H}_V + \mathbf{S} \times \mathbf{H}_e. \quad (57b)$$

First, we assume a fixed matter background with net electron number density n_e . For high n_e , corresponding to $|\mathbf{H}_e| \gg |\langle \mu_V \rangle|$, Eqs. (57a) and (57b) reduce to

$$\frac{d}{dt} \mathbf{s}_i \approx \mathbf{s}_i \times (\mathbf{H}_e + \mu_\nu \mathbf{S}), \quad (58a)$$

$$\frac{d}{dt} \mathbf{S} \approx \mathbf{S} \times \mathbf{H}_e. \quad (58b)$$

The above equations correspond to perfectly synchronized flavor oscillations: in a frame rotating with an angular velocity of $-\mathbf{H}_e$, the total NFIS stays fixed and the individual NFIS's precess around it with a common frequency $|\mu_\nu \mathbf{S}|$. However, for neutrinos and antineutrinos initially in pure flavor eigenstates, $\mathbf{s}_i$ and $\mathbf{S}$ start out aligned or anti-aligned with $\mathbf{H}_e = -\hat{\mathbf{e}}_z \sqrt{2} G_F n_e$. Therefore, the above perfect synchronized flavor oscillations reduce to a trivial case where all $\mathbf{s}_i$'s remain in the initial state (i.e., all neutrinos stay in their initial flavor states). This trivial case is of no interest to us and will not be discussed further.

For $|\mathbf{H}_e| \sim |\langle \mu_V \rangle|$ and $|\mu_\nu \mathbf{S}| \gg |\langle \mu_V \rangle|$, the discussion is similar to the case with no matter background. All $\mathbf{s}_i$'s precess around $\mathbf{S}$ with a frequency $|\mu_\nu \mathbf{S}|$ and Eq. (57b) becomes

$$\frac{d}{dt} \mathbf{S} \approx \mathbf{S} \times (\langle \mu_V \rangle \mathbf{H}_V + \mathbf{H}_e). \quad (59)$$

Therefore, the total NFIS of the gas precesses around the effective field $\mathbf{H}^{\text{eff}} = \langle \mu_V \rangle \mathbf{H}_V + \mathbf{H}_e$ and behaves just as does a single NFIS with $\mathbf{s} = \mathbf{S}/(2|\mathbf{S}|)$ and $\mu_V = \langle \mu_V \rangle$ in the same matter background [see Eq. (22)]. For the cases with $\delta m^2 > 0$ and $\langle \mu_V \rangle > 0$ or with $\delta m^2 < 0$ and $\langle \mu_V \rangle < 0$, this representative NFIS corresponds to a neutrino with energy

$$E_{\text{sync}} \equiv \left| \frac{\delta m^2}{2\langle \mu_V \rangle} \right|. \quad (60)$$

For the other cases, this representative NFIS corresponds to an antineutrino with energy E_{sync} . For an initially pure ν_e neutrino gas, E_{sync}^{-1} is simply the neutrino energy distribution-averaged value of $E_{\nu_e}^{-1}$:

$$E_{\text{sync}}^{-1} = \int \frac{f_{\nu_e}(E)}{E} dE, \quad (61)$$

where $f_{\nu_e}(E)$ is the energy distribution of ν_e . For more general cases, E_{sync} is evaluated using Eqs. (46) and (60) with all the relevant neutrino and antineutrino energy distributions.

The above discussion can be extended to the case of a slowly varying matter background in a straightforward

manner. We note that this is again an adiabatic process as discussed in Sec. II except that $\mathbf{S}$ takes the place of $\mathbf{s}_\nu$ this time. The angle between $\mathbf{S}$ and $\mathbf{H}^{\text{eff}}$ is therefore constant. A gas of initially dominantly ν_e with $|\mu_\nu \mathbf{S}| \gg |\langle \mu_\nu \rangle|$ acts just like a single neutrino with energy E_{sync} propagating in this matter background. For a normal mass hierarchy ($\delta m^2 > 0$), there may be an MSW resonance that can enhance flavor transformation. In contrast, no MSW resonance exists and flavor transformation is suppressed by the matter effect for an inverted mass hierarchy ($\delta m^2 < 0$).

Obviously, for a neutrino and/or antineutrino gas with $|\mu_\nu \mathbf{S}| \ll |\langle \mu_\nu \rangle|$, there is no synchronized flavor transformation.

IV. BI-POLAR FLAVOR TRANSFORMATION

The astrophysical environments where neutrino flavor transformation is of interest do not always provide conditions which are favorable for synchronization. For a neutrino gas to be in the synchronized mode, the neutrinos have to be prepared in such a way that the corresponding NFIS's are strongly aligned in one direction. There are important regimes where this does not occur.

For example, consider the 2×2 mixing channels $\nu_e \rightleftharpoons \nu_\tau$ and $\bar{\nu}_e \rightleftharpoons \bar{\nu}_\tau$ in the late-time, shocked region above the protoneutron star. By definition, $\mathbf{s}_i = \hat{\mathbf{e}}_z^f/2$ for a ν_e or $\bar{\nu}_\tau$ and $\mathbf{s}_i = -\hat{\mathbf{e}}_z^f/2$ for a $\bar{\nu}_e$ or ν_τ . Therefore ν_e , $\bar{\nu}_e$, ν_τ , and $\bar{\nu}_\tau$ form two NFIS blocks pointing in opposite directions when they leave the neutrino sphere. The subsequent behavior of these neutrinos is interesting. We show below that under the right conditions large-scale collective “swapping” of flavors $\nu_e \rightleftharpoons \nu_\tau$ and $\bar{\nu}_e \rightleftharpoons \bar{\nu}_\tau$ can occur in a mode in which the NFIS blocks remain more or less oppositely-directed. This is an example of the bi-polar mode.

In Ref. [19], numerical simulations of a homogeneous, dense neutrino-antineutrino gas in the absence of a matter background showed that the flavor swapping in the bi-polar mode occurred at a higher frequency than would vacuum oscillations. Reference [20] gave an analytical solution to a simple bi-polar system, a gas initially consisting of equal numbers of monoenergetic ν_e and $\bar{\nu}_e$, for a normal mass hierarchy. Reference [21] generalized the solution to a gas of unequal numbers of ν_e and $\bar{\nu}_e$ with different energies, again for a normal mass hierarchy scenario, and found that the system exhibits bimodal features (dual frequencies).

In this section we again adopt a physical, analytical approach and use a simple example to illustrate neutrino flavor transformation in bi-polar systems from the energy conservation perspective. For the first time, we explain why large flavor mixing can develop in some bi-polar systems even with a small mixing angle. We will then extend the discussion to more general bi-polar systems using the corotating frame, and discuss how bimodal features can appear in such systems. We will propose criteria under which a NFIS system can be in the bi-polar mode, and show that a bi-polar system is at least semistable. We

will conclude this section with some discussion on the effects of the matter background on bi-polar flavor transformation.

A. A simple example of bi-polar flavor transformation

We start with a simple bi-polar system initially consisting of monoenergetic ν_e and $\bar{\nu}_e$ with an equal number density n_ν , which form two NFIS blocks $\mathbf{S}_1(0) = n_\nu \mathbf{s}_{\nu_e} = \hat{\mathbf{e}}_z^f n_\nu/2$ and $\mathbf{S}_2(0) = n_\nu \mathbf{s}_{\bar{\nu}_e} = -\hat{\mathbf{e}}_z^f n_\nu/2$. This system is uniform and isotropic and has no matter background. The evolution of $\mathbf{S}_1$ and $\mathbf{S}_2$ is governed by [see Eq. (31)]

$$\frac{d}{dt} \mathbf{S}_1 = \mathbf{S}_1 \times (\mu_{\nu,1} \mathbf{H}_V + \mu_\nu \mathbf{S}_2), \quad (62a)$$

$$\frac{d}{dt} \mathbf{S}_2 = \mathbf{S}_2 \times (\mu_{\nu,2} \mathbf{H}_V + \mu_\nu \mathbf{S}_1), \quad (62b)$$

where $\mu_{\nu,1} = -\mu_{\nu,2} = \mu_\nu$. With the definition of

$$\mathbf{S}_+ \equiv \mathbf{S}_1 + \mathbf{S}_2 \quad \text{and} \quad \mathbf{S}_- \equiv \mathbf{S}_1 - \mathbf{S}_2, \quad (63)$$

we find

$$\frac{d}{dt} \mathbf{S}_+ = \mu_\nu \mathbf{S}_- \times \mathbf{H}_V, \quad (64a)$$

$$\frac{d}{dt} \mathbf{S}_- = \mu_\nu \mathbf{S}_+ \times \mathbf{H}_V + \mu_\nu \mathbf{S}_- \times \mathbf{S}_+. \quad (64b)$$

The initial conditions are

$$\mathbf{S}_+(0) = 0, \quad (65a)$$

$$\mathbf{S}_-(0) = n_\nu \hat{\mathbf{e}}_z^f = n_\nu (\hat{\mathbf{e}}_x^v \sin 2\theta_v + \hat{\mathbf{e}}_z^v \cos 2\theta_v), \quad (65b)$$

where $\hat{\mathbf{e}}_x^v$ and $\hat{\mathbf{e}}_z^v$ are the unit vectors in the x - and z -directions, respectively, in the vacuum mass basis ($\hat{\mathbf{e}}_z^v \equiv \mathbf{H}_V$). Using these conditions and Eq. (64), we can show that

$$\mathbf{S}_+ \cdot \hat{\mathbf{e}}_x^v = \mathbf{S}_+ \cdot \hat{\mathbf{e}}_z^v = \mathbf{S}_- \cdot \hat{\mathbf{e}}_y^v = 0. \quad (66)$$

In other words, $\mathbf{S}_+$ can only move parallel to $\hat{\mathbf{e}}_y^v$ while $\mathbf{S}_-$ is confined to move in the plane defined by $\hat{\mathbf{e}}_x^v$ and $\hat{\mathbf{e}}_z^v$.

The evolution of $\mathbf{S}_+$ and $\mathbf{S}_-$ obeys conservation of the total effective energy

$$\mathcal{E} = -\mu_{\nu,1} \mathbf{S}_1 \cdot \mathbf{H}_V - \mu_{\nu,2} \mathbf{S}_2 \cdot \mathbf{H}_V - \frac{\mu_\nu}{2} (\mathbf{S}_1 + \mathbf{S}_2)^2 \quad (67a)$$

$$= -\mu_\nu \mathbf{S}_- \cdot \mathbf{H}_V - \frac{\mu_\nu}{2} \mathbf{S}_+^2 = -\mu_\nu n_\nu \cos 2\theta_v, \quad (67b)$$

which gives

$$|\mathbf{S}_-| \cos \vartheta = n_\nu \cos 2\theta_v - \frac{\mu_\nu}{2\mu_\nu} \mathbf{S}_+^2 \quad (68)$$

with ϑ being the angle between $\mathbf{S}_-$ and $\hat{\mathbf{e}}_z^v$. Further, it can be shown from Eq. (63) that

$$\mathbf{S}_+^2 + \mathbf{S}_-^2 = n_\nu^2. \quad (69)$$

Combining Eqs. (68) and (69), we obtain

$$\cos \vartheta = \frac{\cos 2\theta_v}{s_-} - \frac{\mu_\nu n_\nu}{2\mu_\nu} \left(\frac{1}{s_-} - s_- \right), \quad (70)$$

where

$$s_- \equiv |\mathbf{S}_-|/n_\nu. \quad (71)$$

Noting that $\mu_\nu = -2\sqrt{2}G_F < 0$ and $s_- \leq 1$, we see that for a normal mass hierarchy ($\mu_\nu > 0$), $\cos 2\theta_\nu \leq \cos \vartheta \leq 1$ and $\mathbf{S}_-$ is constrained to oscillate around $\hat{\mathbf{e}}_z^\nu$ with $-2\theta_\nu \leq \vartheta \leq 2\theta_\nu$. For $\theta_\nu \ll 1$, the system stays close to the initial state and there is very little flavor mixing.

The situation for an inverted mass hierarchy ($\mu_\nu < 0$) is more complicated. We proceed by first rewriting Eq. (70) as

$$\cos \vartheta = \left(\cos 2\theta_\nu - \frac{\mu_\nu n_\nu}{2\mu_\nu} \right) \frac{1}{s_-} + \left(\frac{\mu_\nu n_\nu}{2\mu_\nu} \right) s_- \quad (72a)$$

$$= \cos 2\theta_\nu \left[\left(1 - \frac{n_\nu}{n_\nu^{\text{cri}}} \right) \frac{1}{s_-} + \left(\frac{n_\nu}{n_\nu^{\text{cri}}} \right) s_- \right], \quad (72b)$$

where

$$n_\nu^{\text{cri}} \equiv \frac{2\mu_\nu}{\mu_\nu} \cos 2\theta_\nu \quad (73)$$

is a positive characteristic neutrino number density for $\mu_\nu < 0$. The evolution of the bi-polar system under consideration falls into the following three categories depending on the parameter n_ν/n_ν^{cri} . For $n_\nu/n_\nu^{\text{cri}} \leq 1/2$, $d \cos \vartheta / ds_- \leq 0$ and $\mathbf{S}_-$ is constrained to oscillate around $\hat{\mathbf{e}}_z^\nu$ with $-2\theta_\nu \leq \vartheta \leq 2\theta_\nu$ just as in the case of a normal mass hierarchy. In this case, the difference between $\mu_{\nu,1}$ and $\mu_{\nu,2}$ is too large for the two NFIS blocks to maintain strong correlation, and neutrinos and antineutrinos oscillate as two separate sectors. For $1/2 < n_\nu/n_\nu^{\text{cri}} < 1$, $d \cos \vartheta / ds_-$ is positive for $s_- \sim 1$ but becomes 0 and then negative for smaller s_- , and the maximum value ϑ_{max} corresponding to $d \cos \vartheta / ds_- = 0$ is given by

$$\cos \vartheta_{\text{max}} = 2 \cos 2\theta_\nu \sqrt{\frac{n_\nu}{n_\nu^{\text{cri}}} \left(1 - \frac{n_\nu}{n_\nu^{\text{cri}}} \right)}. \quad (74)$$

In this case, ϑ first increases from $2\theta_\nu$ for the initial state to ϑ_{max} as s_- decreases and then decreases to 0 as s_- further decreases to its minimum value. Subsequently, the motion of $\mathbf{S}_-$ is mirrored in the other half of the plane defined by $\hat{\mathbf{e}}_x^\nu$ and $\hat{\mathbf{e}}_z^\nu$. Note that for each complete cycle $\mathbf{S}_-$ reaches the position at $\vartheta = 2\theta_\nu$ ($-2\theta_\nu$) twice but with $s_- = 1$ and a smaller value, respectively. For $n_\nu/n_\nu^{\text{cri}} \geq 1$, Eq. (72) shows that $d \cos \vartheta / ds_-$ is always positive, $-1 \leq \cos \vartheta \leq \cos 2\theta_\nu$, and $\mathbf{S}_-$ oscillates around $\hat{\mathbf{e}}_z^\nu$ with $2\theta_\nu \leq \vartheta \leq 2\pi - 2\theta_\nu$ (note that for $n_\nu/n_\nu^{\text{cri}} = 1$, $\mathbf{S}_-$ shrinks to 0 at $\vartheta = \pi/2$ and $3\pi/2$, therefore appearing to skip the range $\pi/2 < \vartheta < 3\pi/2$). In the limit $n_\nu/n_\nu^{\text{cri}} \gg 1$, s_- stays ~ 1 as $\mathbf{S}_-$ rotates in the plane defined by $\hat{\mathbf{e}}_x^\nu$ and $\hat{\mathbf{e}}_z^\nu$. This is particularly interesting because the two NFIS blocks remain antialigned and can completely reverse their initial directions, which means that full conversion of the initial ν_e and $\bar{\nu}_e$ occurs even for $\theta_\nu \ll 1$.

The above results on the evolution of $\mathbf{S}_-$ and $\mathbf{S}_+$ can be adapted easily to describe the evolution of the individual

NFIS's $\mathbf{s}_1$ and $\mathbf{s}_2$ of an initial ν_e and $\bar{\nu}_e$, respectively. Using Eqs. (63) and (66), we find

$$s_{1x}^\nu = -s_{2x}^\nu = \frac{\mathbf{S}_- \cdot \hat{\mathbf{e}}_x^\nu}{2n_\nu} = \frac{s_- \sin \vartheta}{2}, \quad (75a)$$

$$s_{1y}^\nu = s_{2y}^\nu = \frac{\mathbf{S}_+ \cdot \hat{\mathbf{e}}_y^\nu}{2n_\nu}, \quad (75b)$$

$$s_{1z}^\nu = -s_{2z}^\nu = \frac{\mathbf{S}_- \cdot \hat{\mathbf{e}}_z^\nu}{2n_\nu} = \frac{s_- \cos \vartheta}{2}, \quad (75c)$$

where, for example, s_{1x}^ν is the x -component of $\mathbf{s}_1$ in the vacuum mass basis. As a visual illustration, we show in Fig. 1 the evolution of $\mathbf{s}_1$ in the vacuum mass basis for the case of a normal mass hierarchy (solid curve) and for the case of an inverted mass hierarchy with $n_\nu/n_\nu^{\text{cri}} > 1$ (dashed curve). The trajectory of $\mathbf{s}_1$ for each case marks the intersection between the parabolic surface representing

$$\mu_\nu \left(s_{1z}^\nu - \frac{\cos 2\theta_\nu}{2} \right) + \mu_\nu n_\nu (s_{1y}^\nu)^2 = 0, \quad (76)$$

which is equivalent to Eq. (68), and the spherical surface representing

$$(s_{1x}^\nu)^2 + (s_{1y}^\nu)^2 + (s_{1z}^\nu)^2 = \left(\frac{1}{2} \right)^2, \quad (77)$$

which follows from the fixed magnitude of $\mathbf{s}_1^2 = (1/2)^2$. The evolution of $\mathbf{s}_2$ can be obtained from that of $\mathbf{s}_1$ based on Eq. (75).

Of course, the flavor evolution of an initial ν_e is described most directly by the z -component s_{1z}^f of $\mathbf{s}_1$ in the flavor basis. The unit vectors in this basis are related to those in the vacuum mass basis as

$$\hat{\mathbf{e}}_x^f = \hat{\mathbf{e}}_x^\nu \cos 2\theta_\nu - \hat{\mathbf{e}}_z^\nu \sin 2\theta_\nu, \quad (78a)$$

$$\hat{\mathbf{e}}_y^f = \hat{\mathbf{e}}_y^\nu, \quad (78b)$$

$$\hat{\mathbf{e}}_z^f = \hat{\mathbf{e}}_x^\nu \sin 2\theta_\nu + \hat{\mathbf{e}}_z^\nu \cos 2\theta_\nu. \quad (78c)$$

From the above equations and Eq. (75), we obtain

FIG. 1. The solution of $\mathbf{s}_1$ for a simple bi-polar system in the vacuum mass basis for a normal (solid line) and an inverted (dashed line) mass hierarchy, respectively. The solution of $\mathbf{s}_2$ can be obtained from that of $\mathbf{s}_1$ using Eq. (75).

$$s_{1z}^f = s_{1x}^v \sin 2\theta_v + s_{1z}^v \cos 2\theta_v = \left(\frac{s_-}{2}\right) \cos(\vartheta - 2\theta_v). \quad (79)$$

As $\mathbf{S}_-$ evolves very little from the initial state for $\theta_v \ll 1$ in the case of a normal mass hierarchy and in the case of an inverted mass hierarchy with $n_\nu/n_\nu^{\text{cri}} \leq 1/2$, there is little flavor evolution in these cases. In contrast, for the case of an inverted mass hierarchy with $n_\nu/n_\nu^{\text{cri}} \gg 1$, we have $s_- \sim 1$ and $2\theta_v \leq \vartheta \leq 2\pi - 2\theta_v$, so an initial ν_e can be converted essentially fully into a ν_τ even for $\theta_v \ll 1$.

Taking $\theta_v = 0.1$ and $|\mu_\nu|n_\nu/|\mu_v| = 10$ ($n_\nu/n_\nu^{\text{cri}} = 5.1$ for $\mu_v < 0$), we show the time evolution of s_{1z}^f as the solid lines in Figs. 2(a) and 2(b) for a normal and an inverted mass hierarchy, respectively. The cases with the same θ_v but $|\mu_\nu|n_\nu/|\mu_v| = 40$ ($n_\nu/n_\nu^{\text{cri}} = 20.4$ for $\mu_v < 0$) are shown as the dashed lines. [In order to show the small evolution in the case of a normal mass hierarchy, we have greatly expanded the vertical scale in Fig. 2(a).]

We note that the period of vacuum oscillations in these numerical examples is $T_{\text{vac}} = 2\pi/|\mu_v|$. This is longer than the bi-polar oscillation periods T_{bi} shown in Fig. 2. In addition, the bi-polar oscillation periods decrease by a factor of 2 when the neutrino density n_ν is increased by a factor of 4. These observations can be understood from Eq. (64), even without an outright solution of this equation. In the limit $|\mu_\nu|n_\nu/|\mu_v| \gg 1$, the second term on the right-hand side of Eq. (64b) dominates, and $\mathbf{S}_-$ simply rotates around $\mathbf{S}_+$ with roughly a constant magnitude n_ν and frequency

$$T_{\text{bi}}^{-1} \sim |\mu_\nu| |\langle \mathbf{S}_+ \rangle|. \quad (80)$$

The average value of $|\mathbf{S}_+|$ in the above equation can be estimated from Eq. (64a):

$$\frac{|\langle \mathbf{S}_+ \rangle|}{T_{\text{bi}}} \sim |\mu_v \mathbf{S}_-| \approx |\mu_v| n_\nu. \quad (81)$$

Combining Eqs. (80) and (81), we obtain

$$T_{\text{bi}} \sim \frac{1}{\sqrt{|\mu_v \mu_\nu| n_\nu}}. \quad (82)$$

This simple dimensional analysis agrees with the exact expression for the bi-polar period in the normal mass hierarchy case [20]. Therefore, for a large neutrino density $n_\nu \gg |\mu_v/\mu_\nu|$, the bi-polar oscillation period T_{bi} is much smaller than T_{vac} and decreases as $\sim 1/\sqrt{n_\nu}$.

B. General bi-polar systems

We next look at a slightly more complicated neutrino-antineutrino system. In particular, we consider a system which is the same as that discussed in Sec. IVA except that ν_e and $\bar{\nu}_e$ have different energies. We again define $\mathbf{S}_+$ and $\mathbf{S}_-$ as in Eq. (63). Using Eq. (62), we find

$$\frac{d}{dt} \mathbf{S}_+ = \mathbf{S}_+ \times \mathbf{H}_+ + \mathbf{S}_- \times \mathbf{H}_-, \quad (83a)$$

$$\frac{d}{dt} \mathbf{S}_- = \mathbf{S}_- \times \mathbf{H}_+ + \mathbf{S}_+ \times \mathbf{H}_- + \mu_\nu \mathbf{S}_- \times \mathbf{S}_+, \quad (83b)$$

where

$$\mathbf{H}_\pm \equiv \frac{\mu_{v,1} \pm \mu_{v,2}}{2} \mathbf{H}_v. \quad (84)$$

When viewed in the reference frame rotating with angular velocity $-\mathbf{H}_+$, the e.o.m. of $\tilde{\mathbf{S}}_+$ and $\tilde{\mathbf{S}}_-$ derived from Eq. (83) are exactly the same as that in Eq. (64) and must, therefore, have the same solution. When viewed in the lab frame, this NFIS system not only demonstrates the bi-polar oscillation as discussed in Sec. IVA, but also rotates around $\mathbf{H}_v$ at the same time. We regard this kind

FIG. 2 (color online). The evolution of the z -component of $\mathbf{s}_1$ in the flavor basis for the simple bi-polar system with (a) a normal and (b) an inverted mass hierarchy. The solid lines are for $|\mu_{v,1}|/|\mu_\nu n_\nu| = 1/10$, and the dashed lines are for $|\mu_{v,1}|/|\mu_\nu n_\nu| = 1/40$. The vacuum mixing angle θ_v is taken to be 0.1.

TABLE I. The conditions for a dense neutrino gas starting as two groups of monoenergetic neutrino species with equal number to develop large flavor mixing in the small mixing angle scenario. Combinations of neutrino species other than those shown here will not develop large flavor mixing in this case.

	$\nu_e - \bar{\nu}_e$	$\bar{\nu}_\tau - \nu_\tau$	$\nu_e - \nu_\tau$	$\bar{\nu}_\tau - \bar{\nu}_e$
$\delta m^2 > 0$	Never	Always	$E_{\nu_e} > E_{\nu_\tau}$	$E_{\bar{\nu}_\tau} < E_{\bar{\nu}_e}$
$\delta m^2 < 0$	Always	Never	$E_{\nu_e} < E_{\nu_\tau}$	$E_{\bar{\nu}_\tau} > E_{\bar{\nu}_e}$

of flavor transformation as also being of bi-polar type. Note that this bi-polar system has two intrinsic periods, i.e., T_{bi} and $2\pi/|\mathbf{H}_+|$. This bimodal feature of the neutrino-antineutrino system was first discussed in Ref. [21].

Note that the above arguments employing corotating frames apply not only to systems consisting of $\nu_e - \bar{\nu}_e$, but also to systems of $\bar{\nu}_\tau - \nu_\tau$, $\nu_e - \nu_\tau$, or $\bar{\nu}_\tau - \bar{\nu}_e$. Because $\nu_e - \bar{\nu}_e$ systems can develop large flavor mixing in the case of a small mixing angle and an inverted mass hierarchy, the other systems also can exhibit the same phenomenon as long as

$$\mu_{V,1} < \mu_{V,2}, \quad (85)$$

where $\mu_{V,1}$ and $\mu_{V,2}$ are the vacuum coupling coefficients of the “spin-up” and “spin-down” NFIS’s, respectively. For convenience, we have listed these conditions in Table I.

From the simple examples discussed above, we can infer a general description of a system possessing bi-polar oscillations: a system composed of two groups of neutrinos and/or antineutrinos of roughly equal numbers, where the corresponding NFIS’s point in two roughly opposite directions and have different characteristic values of μ_V .

In Fig. 3 (the solid lines) we illustrate two nonideal bi-polar systems. These examples consist of gases of initially pure ν_e and $\bar{\nu}_e$ with $n_{\nu_e} \neq n_{\bar{\nu}_e}$ and $E_{\nu_e} \neq E_{\bar{\nu}_e}$. One of the examples [Fig. 3(a)] illustrates neutrino mixing with a large mixing angle and $\delta m^2 \simeq \delta m_\odot^2$, and the other [Fig. 3(b)] uses a small mixing angle and $\delta m^2 \simeq -\delta m_{\text{atm}}^2$.

As the difference between the densities of the two NFIS blocks becomes larger and larger, one of the NFIS blocks will eventually dominate the other, and the system will become synchronized rather than bi-polar. This can be seen from Eq. (83). For simplicity, we work in the frame rotating with angular velocity $-\mathbf{H}_+$ where the e.o.m. of $\tilde{\mathbf{S}}_\pm$ take the same form as Eq. (64). We note that a key characteristic of any bi-polar system is a configuration in which a large and near constant magnitude $\tilde{\mathbf{S}}_-$ vector rotates about $\tilde{\mathbf{S}}_+$ [Eq. (64b)]. In this configuration, $\tilde{\mathbf{S}}_+$ typically has a small, variable magnitude. If one of the NFIS blocks dominates, it is possible that $|\mu_V \tilde{\mathbf{S}}_+|$ will be bigger than $|\tilde{\mathbf{S}}_+ \times \tilde{\mathbf{S}}_-|/|\tilde{\mathbf{S}}_-|^2$, and the adiabatic condition can be satisfied. (Note that the rate of change of $\tilde{\mathbf{S}}_+$ is bounded by the intrinsic frequency of the bi-polar oscillation.) If the adiabatic condition is satisfied, then $\tilde{\mathbf{S}}_-$ will precess rapidly around $\tilde{\mathbf{S}}_+$, with a constant relative angle between them. In this case, $\tilde{\mathbf{S}}_-$ will average out to be $(\tilde{\mathbf{S}}_- \cdot \tilde{\mathbf{S}}_+) \tilde{\mathbf{S}}_+ / |\tilde{\mathbf{S}}_-|^2$. At the same time, $\tilde{\mathbf{S}}_+$ will have roughly constant magnitude and will rotate around $\mathbf{H}_V$ with an angular frequency [Eq. (64a)]

$$\tilde{\omega}_+ \equiv \left(\frac{\mu_{V,1} - \mu_{V,2}}{2} \right) \frac{\tilde{\mathbf{S}}_- \cdot \tilde{\mathbf{S}}_+}{|\tilde{\mathbf{S}}_-|^2}. \quad (86)$$

Clearly, the dominant oscillation behavior of the NFIS system is the slow rotation around $\mathbf{H}_V$ and the synchro-

FIG. 3 (color online). The evolution of the z -component of $\mathbf{s}_1$ (in the flavor basis) for representative bi-polar systems. These systems consist of monoenergetic neutrinos in initially pure ν_e and $\bar{\nu}_e$ flavor states. The mixing parameters θ_V and δm^2 are 0.56 and $8 \times 10^{-5} \text{ eV}^2$, respectively, for the calculations in panel (a), and are 0.1 and $-3 \times 10^{-3} \text{ eV}^2$, respectively, for panel (b). The energies of ν_e and $\bar{\nu}_e$ are taken to be 11 and 16 MeV, respectively. The (effective) number densities of ν_e and $\bar{\nu}_e$ are 10^{28} and $6.9 \times 10^{27} \text{ cm}^{-3}$, respectively. The solid, dashed, and dot-dashed lines are plotted with electron number density taken to be 0, 10^{26} , and 10^{29} cm^{-3} , respectively.

nized mode obtains in this case. Indeed, one can explicitly show that $\tilde{\omega}_+$ is the synchronization frequency $\tilde{\omega}_{\text{sync}}$ of the system in the corotating frame.

From the above arguments, one can see that the condition for a bi-polar system to degrade into a synchronized mode is the same as that for $\tilde{\mathbf{S}}_-$ to adiabatically precess around $\tilde{\mathbf{S}}_+$. Therefore, the criterion for a NFIS system to be bi-polar is that

$$|\mu_\nu \tilde{\mathbf{S}}_+| \lesssim \frac{|\dot{\tilde{\mathbf{S}}}_+ \times \tilde{\mathbf{S}}_+|}{|\tilde{\mathbf{S}}_+|^2} = |\tilde{\omega}_{\text{sync}}| \cdot |\sin \xi|, \quad (87)$$

where ξ is the angle between the directions of $\tilde{\mathbf{S}}_+$ and $\mathbf{H}_V$. We note that this criterion is exactly the opposite of the synchronization criterion given in Eq. (54). In many cases, the criterion for bi-polar flavor transformation can be expressed as

$$|\mu_\nu \mathbf{S}| \lesssim |\langle \mu_V \rangle|. \quad (88)$$

We now comment on the stability of the bi-polar mode. Realistic systems of interest usually consist of neutrinos and/or antineutrinos with continuous energy distributions. Because neutrinos (antineutrinos) of different energies have different vacuum oscillation frequencies, one might suspect that the bi-polar mode eventually collapses as a result of destructive interference. We have argued above (Sec. III B) that the conservation of total effective energy $\mathcal{E}$ essentially guarantees the stability of the synchronized mode. This conclusion does not extend directly to the bi-polar mode. However, this energy conservation condition *does* provide some shielding of the two-oppositely-directed-NFIS-block configuration against rapid destructive interference-driven breakdown. This is because the effective energies of the two NFIS blocks ($-\mu_\nu \mathbf{S}_1^2/2 \approx -\mu_\nu n_{\nu,1}^2/8$ and $-\mu_\nu \mathbf{S}_2^2/2 \approx -\mu_\nu n_{\nu,2}^2/8$) and the interaction energy of these blocks ($-\mu_\nu \mathbf{S}_1 \cdot \mathbf{S}_2 \approx \mu_\nu n_{\nu,1} n_{\nu,2}/4$) sum to almost zero, and because each of these ingredient energies are large in magnitude and not easily altered. If the bi-polar configuration is ever to break down, the two NFIS blocks must disassemble simultaneously in a symmetric way in order to conserve the total effective energy. As a result, the bi-polar mode is at least semistable. It has been observed that the two-oppositely-directed-NFIS-block configuration is roughly maintained in example numerical simulations [18,27].

C. Bi-polar flavor transformation with a matter background

In Fig. 3 we present results of numerical solutions to the e.o.m. for two NFIS blocks [Eq. (31)]. In this figure, we show examples (the dashed and dot-dashed lines) of flavor oscillations in gases of initially pure ν_e and $\bar{\nu}_e$ in the presence of various matter backgrounds. It can be seen that flavor transformation is suppressed for the scenario with a large mixing angle and a normal mass hierarchy if

$n_e \gtrsim n_\nu$. On the other hand, large flavor mixing still occurs in these systems with small mixing angles and an inverted mass hierarchy even if the electron density dominates, although the flavor oscillation period is somewhat longer than in the case with no matter background.

This phenomenon can be understood qualitatively by using the concept of corotating frames. In the presence of a matter background, the motions of $\mathbf{S}_\pm$ still are governed by Eq. (83) except that $\mathbf{H}_+$ is in this case defined as

$$\mathbf{H}_+ = \frac{\mu_{V,1} + \mu_{V,2}}{2} \mathbf{H}_V + \mathbf{H}_e. \quad (89)$$

We decompose $\mathbf{H}_-$ into two components: $\mathbf{H}_{-,\perp}$ and $\mathbf{H}_{-,\parallel}$. These vectors are perpendicular and parallel to $\mathbf{H}_+$, respectively. In the reference frame rotating with angular velocity $-\mathbf{H}_+$, we have

$$\dot{\tilde{\mathbf{H}}}_{-,\perp} = -\tilde{\mathbf{H}}_{-,\perp} \times \mathbf{H}_+, \quad (90a)$$

$$\dot{\tilde{\mathbf{H}}}_{-,\parallel} = 0. \quad (90b)$$

This configuration is illustrated in Fig. 4. If n_e is very large, $\tilde{\mathbf{H}}_{-,\perp}$ will rotate very rapidly and the NFIS's are not able to follow it. In this limit, $\tilde{\mathbf{H}}_{-,\perp}$ will have on average negligible influence on the overall evolution of the system, at least so long as $\mathbf{S}_1$ and $\mathbf{S}_2$ are not aligned with $\tilde{\mathbf{H}}_{-,\parallel}$. Note that this scenario is similar to the simple small mixing angle bi-polar example discussed in Sec. IV A. However, one difference is that here $\tilde{\mathbf{H}}_{-,\parallel}$ takes the place of $\mu_V \mathbf{H}_V$ in the simple case. Bi-polar systems with matter backgrounds, therefore, behave similarly to those without.

Consider the simple $\nu_e - \bar{\nu}_e$ system discussed in Sec. IV A but now with a large matter background. The two NFIS blocks formed by neutrinos and antineutrinos are

FIG. 4. A bi-polar system in the presence of a large electron background. (a) $\mathbf{H}_-$ can be decomposed into two components, $\mathbf{H}_{-,\perp}$ and $\mathbf{H}_{-,\parallel}$, which are perpendicular and parallel to $\mathbf{H}_+$, respectively. (b) Component $\tilde{\mathbf{H}}_{-,\perp}$ will rotate very rapidly and will have little net effect in the frame rotating with angular velocity $-\mathbf{H}_+$. In the same corotating frame, $\tilde{\mathbf{H}}_{-,\parallel}$ is static. This component drives the bi-polar motion of the system.

initially aligned or antialigned with $\mathbf{H}_e = \mathbf{H}_+$. The field component $\tilde{\mathbf{H}}_{-, \perp}$ will perturb the system to break this alignment. The perturbation by $\tilde{\mathbf{H}}_{-, \perp}$ is not enough to cause $\tilde{\mathbf{S}}_1$ and $\tilde{\mathbf{S}}_2$ to deviate much from their original directions. This is because $\tilde{\mathbf{H}}_{-, \perp}$ has negligible net effects once the angle between $\tilde{\mathbf{S}}_1$ ($\tilde{\mathbf{S}}_2$) and $\tilde{\mathbf{H}}_{-, \parallel}$ is significant. However, the configuration with a misalignment of $\tilde{\mathbf{S}}_1$ and $\tilde{\mathbf{S}}_2$ relative to $\tilde{\mathbf{H}}_{-, \parallel}$ is just like the initial configuration of the simple $\nu_e - \bar{\nu}_e$ system discussed in Sec. IV A. Therefore, for the normal mass hierarchy ($\delta m^2 > 0$), $\tilde{\mathbf{S}}_1$ and $\tilde{\mathbf{S}}_2$ will oscillate around $\hat{\mathbf{e}}_z^f = \mathbf{H}_e/|\mathbf{H}_e| = \tilde{\mathbf{H}}_{-, \parallel}/|\tilde{\mathbf{H}}_{-, \parallel}|$, and no significant flavor mixing occurs. For the inverted mass hierarchy ($\delta m^2 < 0$), $\tilde{\mathbf{S}}_1$ and $\tilde{\mathbf{S}}_2$ could completely swap their directions and large flavor mixing will result.

Dynamically, the configuration with $\tilde{\mathbf{S}}_-$ aligned with $\tilde{\mathbf{H}}_{-, \parallel}$ is “stable” because $\tilde{\mathbf{H}}_{-, \parallel}$ acts as a restoring “force” which prevents $\tilde{\mathbf{S}}_-$ from becoming significantly misaligned with it. This is why neutrino-antineutrino gases of initially pure ν_e and $\bar{\nu}_e$ do not have large flavor mixing if $\delta m^2 > 0$ and $\theta_v \ll 1$. On the other hand, the configuration with $\tilde{\mathbf{S}}_-$ antialigned with $\tilde{\mathbf{H}}_{-, \parallel}$ is “unstable” because $\tilde{\mathbf{H}}_{-, \parallel}$ acts as a force which drives $\tilde{\mathbf{S}}_-$ toward the (stable) position of alignment with $\tilde{\mathbf{H}}_{-, \parallel}$ and then drives it back to the original (unstable) position. This is why neutrino-antineutrino gases of initially pure ν_e and $\bar{\nu}_e$ can have large flavor mixing if $\delta m^2 < 0$ and $\theta_v \ll 1$.

V. COLLECTIVE NEUTRINO FLAVOR TRANSFORMATION IN SUPERNOVAE

To treat neutrino and antineutrino flavor transformation in a core-collapse supernova event, we must account for nonuniformity and anisotropy in the neutrino density distribution. At a radius r which is larger than the neutrino sphere radius R_ν , the neutrino number density distribution is

$$\frac{d^2 n_\nu}{dE_\nu d\Omega_\nu} = \begin{cases} [L_\nu f_\nu(E_\nu)]/(4\pi^2 R_\nu^2 \langle E_\nu \rangle), & 0 \leq \Theta \leq \Theta_0, \\ 0 & \text{otherwise,} \end{cases} \quad (91)$$

where L_ν is the neutrino (energy) luminosity, $f_\nu(E_\nu)$ is the normalized neutrino energy distribution, $\langle E_\nu \rangle$ is the average neutrino energy, $d\Omega_\nu$ is the differential solid angle around the radial direction with Θ being the polar angle, and

$$\cos \Theta_0 = \sqrt{1 - (R_\nu/r)^2}. \quad (92)$$

In general, flavor evolution of neutrinos traveling in different directions above the neutrino sphere will be different due to the anisotropy of the neutrino density distribution. For a qualitative discussion, we will assume the “single-angle approximation” (see, e.g., Ref. [16]) that the

flavor evolution history of a radially propagating neutrino is representative of all neutrinos. Under this approximation,

$$\mu_{ij} n_{\nu, i} \rightarrow \mu_\nu n_\nu^{\text{eff}} f_\nu(E_\nu) dE_\nu, \quad (93)$$

where

$$n_\nu^{\text{eff}} \equiv \int (1 - \cos \Theta) \frac{d^2 n_\nu}{dE_\nu d\Omega_\nu} d\Omega_\nu dE_\nu \quad (94a)$$

$$= \frac{L_\nu}{4\pi R_\nu^2 \langle E_\nu \rangle} [1 - \sqrt{1 - (R_\nu/r)^2}]^2. \quad (94b)$$

We will comment on the validity of the single-angle approximation at the end of the section.

When they leave the neutrino sphere, the neutrinos and antineutrinos form two oppositely directed NFIS blocks. For illustrative purposes we assume that ν_e and $\bar{\nu}_e$ dominate the neutrino species emitted from the protoneutron star. We will also assume that ν_e and $\bar{\nu}_e$ have the same luminosity L_ν , and that the vacuum coupling coefficients of the two corresponding NFIS blocks are

$$\mu_{\nu, 1} \simeq \frac{\delta m^2}{2\langle E_{\nu_e} \rangle} \quad \text{and} \quad \mu_{\nu, 2} \simeq -\frac{\delta m^2}{2\langle E_{\bar{\nu}_e} \rangle}, \quad (95)$$

respectively.

We define a dimensionless quantity

$$\kappa \equiv \frac{|\delta m^2|/2\langle E_\nu \rangle}{|\mu_\nu| n_\nu^{\text{eff}}} \quad (96a)$$

$$= \frac{|\delta m^2| \pi R_\nu^2}{\sqrt{2} G_F L_\nu} [1 - \sqrt{1 - (R_\nu/r)^2}]^{-2} \quad (96b)$$

$$\simeq 3.6 \times 10^{-6} \left(\frac{|\delta m^2|}{3 \times 10^{-3} \text{ eV}^2} \right) \left(\frac{R_\nu}{10 \text{ km}} \right)^2 \left(\frac{10^{51} \text{ erg/s}}{L_\nu} \right) \times [1 - \sqrt{1 - (R_\nu/r)^2}]^{-2}. \quad (96c)$$

This quantity gives a measure of the inverse of the number density of either neutrino species. Using Eqs. (88), (94b), (95), and (96), we find that the rough boundary condition for supernova neutrinos to transition from the synchronized mode to the bi-polar mode is

$$\kappa \gtrsim \epsilon, \quad (97)$$

where the dimensionless quantity

$$\epsilon \equiv \frac{(\langle E_{\nu_e} \rangle - \langle E_{\bar{\nu}_e} \rangle)^2}{2(\langle E_{\nu_e} \rangle^2 + \langle E_{\bar{\nu}_e} \rangle^2)} \quad (98)$$

measures the disparity between the energy spectra of ν_e and $\bar{\nu}_e$. If R_ν is much smaller than the boundary radius r_{BS} (Bi-polar Starting) of the two collective modes, we can estimate

$$r_{\text{BS}} \approx (51 \text{ km}) \left(\frac{|\delta m^2|}{3 \times 10^{-3} \text{ eV}^2} \right)^{-1/4} \left(\frac{L_\nu}{10^{51} \text{ erg/s}} \right)^{1/4} \times \left(\frac{R_\nu}{10 \text{ km}} \right)^{1/2} \left(\frac{\epsilon}{0.01} \right)^{1/4}. \quad (99)$$

As neutrinos propagate away from the protoneutron star, the local neutrino density decreases. Beyond some radius the neutrino density is so low that the collectivity of neutrino flavor transformation breaks down and neutrinos undergo conventional MSW flavor evolution. This occurs if

$$\Delta\mu_{\nu 1(2)} \gtrsim |\mu_\nu \mathbf{S}_{1(2)}|, \quad (100)$$

where $\Delta\mu_{\nu 1(2)}$ is the half-width of the distribution $f_{\nu_e(\bar{\nu}_e)}(\mu_\nu)$ (see the discussion in Sec. III B). We estimate that

$$\Delta\mu_{\nu 1(2)} \approx \frac{|\delta m^2|}{2\langle E_{\nu_e(\bar{\nu}_e)} \rangle^2} \Delta E_{\nu_e(\bar{\nu}_e)}, \quad (101)$$

where $\Delta E_{\nu_e(\bar{\nu}_e)}$ is the half-width of the ν_e ($\bar{\nu}_e$) energy spectra. Using Eqs. (94b), (96), (100), and (101), we can obtain a condition for where collectivity of neutrino flavor oscillations will break down:

$$\kappa \gtrsim \frac{\langle E_\nu \rangle}{2\Delta E_\nu}. \quad (102)$$

If R_ν is much smaller than the boundary radius where collectivity breaks down, r_{BE} (Bi-polar Ending), we can show that

$$r_{\text{BE}} \approx (193 \text{ km}) \left(\frac{|\delta m^2|}{3 \times 10^{-3} \text{ eV}^2} \right)^{-1/4} \left(\frac{L_\nu}{10^{51} \text{ erg/s}} \right)^{1/4} \times \left(\frac{R_\nu}{10 \text{ km}} \right)^{1/2} \left(\frac{\Delta E_\nu / \langle E_\nu \rangle}{0.25} \right)^{-1/4}. \quad (103)$$

Taking $|\delta m^2| = 3 \times 10^{-3} \text{ eV}^2$, $R_\nu = 10 \text{ km}$, $L_\nu = 10^{51} \text{ erg/s}$, and $\Delta E_\nu / \langle E_\nu \rangle = 1/4$, we can calculate the boundary radius between the two collective modes and the radius of the boundary separating the collective modes from the regime where conventional MSW evolution dominates. These boundaries are shown in Fig. 5. It is clear that supernova neutrinos are in the synchronized mode near the protoneutron star (region I in Fig. 5), but could experience bi-polar flavor transformation at a moderate distance (region II). It is only in the region far from the protoneutron star that neutrinos will undergo conventional MSW transformation (region III). This is very different from the solar neutrino oscillation case, where neutrinos experience only MSW flavor transformation. We note that there are actually no sharp boundaries between these flavor transformation regions. There will be neutrinos and antineutrinos with many different energies in any region above the protoneutron star. As a result, a particular region in general could host superpositions of various neutrino and antineutrino oscillation modes. Therefore, regions I, II, and III should be understood as where synchronized, bi-polar, and con-

FIG. 5. The regions where the neutrino oscillations in the supernova environment are dominated by synchronized (I), bi-polar (II), and conventional MSW (III) flavor evolution. In the calculations for this figure we have taken $|\delta m^2| = 3 \times 10^{-3} \text{ eV}^2$, $R_\nu = 10 \text{ km}$, $L_\nu = 10^{51} \text{ erg/s}$, and $\Delta E_\nu / \langle E_\nu \rangle = 0.25$.

ventional MSW-type flavor transformations, respectively, *dominate*.

In broad brush, the mixing parameters (θ_ν and δm^2), the neutrino and antineutrino energy spectra and luminosities, and r and R_ν are the principal determinants of the dominant oscillation mode at a particular location. Of course, the actual detailed form of flavor oscillation at any point is also affected by the matter density and electron fraction. For example, if ν_e number flux dominates over that for $\bar{\nu}_e$ and $\delta m^2 > 0$, neutrinos and antineutrinos in the synchronized mode will evolve as if they were one neutrino with energy E_{sync} [Eq. (60)]. As a result, neutrinos and antineutrinos in this case will experience flavor conversion at radius $\sim r_{\text{MSW}}(E_{\text{sync}})$, where $r_{\text{MSW}}(E_\nu)$ is the MSW resonance radius for a neutrino with energy E_ν . This radius is determined by the standard MSW resonance condition,

$$\frac{\delta m^2}{2E_\nu} \cos 2\theta_\nu = \sqrt{2} G_F n_e(r_{\text{MSW}}(E_\nu)). \quad (104)$$

Governed by the density run in the supernova envelope, neutrinos and antineutrinos may experience the following collective flavor mixing scenarios:

- (i) If the protoneutron star has a very “thick” envelope, n_e is very large throughout regions I and II and $r_{\text{MSW}}(E_{\text{sync}}) \gtrsim r_{\text{BE}}$. In this case no significant flavor conversion will occur when neutrinos are in region I. For $\delta m^2 > 0$ flavor conversion is also suppressed in region II. For $\delta m^2 < 0$, however, large flavor mixing can occur in region II.
- (ii) If the envelope of the protoneutron star is “thin,” n_e is very small in regions II and III, and $r_{\text{MSW}}(E_{\text{sync}}) \lesssim r_{\text{BS}}$. For $\delta m^2 > 0$, almost complete flavor conversion ($\nu_e \rightarrow \nu_\tau$ and $\bar{\nu}_e \rightarrow \bar{\nu}_\tau$) occurs around radius

$r_{\text{MSW}}(E_{\text{sync}})$ in region I. Entering region II, neutrinos and antineutrinos are now dominantly ν_τ and $\bar{\nu}_\tau$, and large flavor mixing will occur (see Table I). For $\delta m^2 < 0$, flavor conversion is suppressed in region I, and large flavor mixing can occur in region II.

- (iii) If the protoneutron star has an envelope of a moderate thickness, n_e is large in region I and part of region II and $r_{\text{BS}} \lesssim r_{\text{MSW}}(E_{\text{sync}}) \lesssim r_{\text{BE}}$. In this case, flavor mixing is always suppressed in region I. For $\delta m^2 < 0$, large flavor mixing can occur in region II. The exact flavor oscillation form is not clear for the $\delta m^2 > 0$ case in region II. However, some resonancelike behavior around radius $r_{\text{MSW}}(E_{\text{sync}})$ could be expected.

The typical collective oscillations described above are idealized. In particular, we have assumed that the gradient of n_e is not so large that the adiabatic condition is violated. If the adiabatic condition is violated, other interesting phenomena may occur. For example, the NFIS's of neutrinos and antineutrinos may be kicked into a configuration where they are aligned or antialigned with $\hat{\mathbf{e}}_x^f$ at some instant. This corresponds to a maximally mixed state. If this occurs in region I and the adiabatic condition holds from this point on, the NFIS's will rotate collectively around $\mathbf{H}^{\text{eff}} = \langle \mu_V \rangle \mathbf{H}_V + \mathbf{H}_e$. This nearly maximal mixing will last until radius r_{BS} or $r_{\text{MSW}}(E_{\text{sync}})$, whichever is smaller. This is the background dominant solution described in Ref. [16].

Our analysis of collective flavor transformation assumed isotropy of the neutrino gases. This is appropriate for the early universe scenario. In the supernova environment the neutrino gas is not isotropic. The anisotropy of the supernova neutrinos has two major effects. One effect is that the neutrinos scattering at some particular point have traveled different distances from the neutrino sphere before they interact. We note that the propagation distances along various trajectories are most different near the neutrino sphere. Close to the protoneutron star, the electron density is so large that $n_e \gg n_\nu^{\text{eff}}$, and $\mathbf{H}_e$ breaks the correlation of the NFIS's on different trajectories. As a result, the NFIS's on different trajectories develop relative phases. This effect, however, does not compromise our analysis because neutrinos and antineutrinos are essentially kept in their flavor eigenstates by $\mathbf{H}_e$, and the effects of destructive interference are small. After neutrinos propagate away from the protoneutron star, the distance difference between any two trajectories becomes small.

The other effect of the anisotropy of supernova neutrinos is that the neutrino-neutrino forward scattering potential, and therefore μ_{ij} , depends on the angle between the directions of the neutrino momenta [Eq. (28)]. As a result, the effective total NFIS

$$\mathbf{S}_i^{\text{eff}} \equiv \mu_\nu^{-1} \sum_j \mu_{ij} n_{\nu,j} \mathbf{s}_j \quad (105)$$

is different for NFIS's on different trajectories, and one cannot define a universal total NFIS $\mathbf{S}$ in the original isotropic sense. However, we note that the NFIS's on different trajectories are still strongly coupled as a result of large neutrino density. This is why collective neutrino flavor oscillations can arise in the first place. Although the exact neutrino oscillation behavior can only be shown by the numerical simulations which treat the trajectory issue self-consistently, we expect that qualitatively similar flavor oscillations, e.g., large flavor mixing in the $\delta m^2 < 0$ and $\theta_v \ll 1$ scenario, may occur in the real supernova environment.

VI. CONCLUSIONS

We have introduced a notation for neutrino flavor isospin which explicitly exhibits symmetry between flavor transformation of neutrinos and antineutrinos. We have pointed out a key quantity in dense gases of neutrinos and/or antineutrinos, the total effective energy, which is conserved in some interesting cases. Using the conservation of the total effective energy, we have proved the stability of synchronized flavor transformation in a simple and intuitive fashion. We have also demonstrated how corotating frames can be useful in analyzing collective oscillation in more general cases.

With the concept of total effective energy, we have for the first time explained why large flavor mixing occurs for a dense gas of initially pure ν_e and $\bar{\nu}_e$ with a small mixing angle and an inverted mass hierarchy. We have estimated the oscillation periods of bi-polar systems using simple dimensional analysis. Additionally, we have studied more complicated and more general bi-polar systems by using corotating frames. We have also for the first time demonstrated that a dense gas initially consisting of pure ν_e and $\bar{\nu}_e$ with an inverted mass hierarchy can develop large flavor mixing, even in the presence of a dominant matter background.

We have derived a convenient criterion for determining whether the synchronized or bi-polar type of collective oscillations may arise in a dense neutrino and/or antineutrino gas. Based on this criterion, we have estimated the regions where various modes of flavor oscillation may occur in the supernova environment. We have found that neutrinos emitted from the protoneutron star in a core-collapse supernova event generally experience synchronized and bi-polar flavor transformations in sequence before the conventional MSW flavor transformation takes over. We have also described the typical flavor oscillation behaviors according to different density runs in the supernova envelope.

Although our analysis of neutrino flavor transformation in the supernova environment is based on crude estimates, it does suggest a picture of neutrino flavor transformations dramatically different from that in the solar case. In par-

ticular, because of the large neutrino luminosities, both synchronized and bi-polar types of collective flavor transformations are involved in the supernova scenario.

To go beyond this work we would need to drop a number of the approximations made here and go over to a detailed numerical simulation starting from realistic conditions of neutrino and antineutrino luminosity and spectral distribution. Chief among the requirements of a detailed numerical model would be a self-consistent treatment of flavor evolution on different trajectories from the neutrino sphere. This could be especially important for regions near the neutrino sphere. Even when such detailed numerical simulations are accomplished, the collective behavior of neutrino flavors will remain a complicated phenomenon. This is where our simple physical pictures may be most useful: delineating the expected qualitative behavior of the self-interacting neutrino system in various supernova conditions.

In any case, our results have probably overturned some of the existing paradigms related to the supernova neutrino flavor oscillation problem. Among these, the analyses of future supernova neutrino signals are certainly affected, because most if not all current analyses are based on the assumption that the conventional MSW transformation is valid throughout the supernova environment. Depending on how deep the collective large-scale flavor mixing of neutrinos and antineutrinos may occur, the treatment of shock reheating and nucleosynthesis might also be affected.
