Abstract

Rutherford backscattering and particle induced x-ray emission have been utilized to precisely characterize targets used in nuclear fission experiments. The method allows for a fast and non destructive determination of target thickness, homogeneity and element composition.

---

1 Introduction

Many experiments in nuclear physics require targets with a precise characterization. In particular, one needs a precise determination of quantities such as the target thickness, the homogeneity, and the amount and kind of impurities, in order to investigate rare processes or perform high accuracy measurements.

Recently, we have investigated ^{3}He- and ^{4}He-induced nuclear fission of several compound nuclei at bombarding energies between 20 and 145 MeV measured at the 88-Inch Cyclotron of the Lawrence Berkeley National Laboratory [1–4].

23 September 1996

To study the excitation energy dependence of the first chance fission probability, which is determined by subtracting similar cross sections of two neighboring isotopes [4], it is essential to measure the cumulative fission cross sections with high precision. While statistical errors can be minimized by measuring a sufficiently large number of fission events, systematic errors, as for example caused by uncertainties in the target thickness or uniformity, are of particular concern and must be evaluated.

Fig. 1. Schematic excitation functions for the cumulative fission of the compound nuclei ^{209}Po, ^{210}Po, ^{211}Po. The first chance fission probability can be determined by subtracting similar cross sections of the mother (triangle) and daughter nucleus (circle).

To qualitatively illustrate the accuracy needed for our measurements, we schematically show in Fig. 1 the fission excitation functions of three neighboring lead isotopes [4]. The first chance fission probability is determined by the difference in the cross sections of the mother (triangle) and daughter nucleus (circle) separated by the kinetic and the binding energies of the evaporated neutron. Due to the flattening of the curves at large excitation energies, the cross sections become more similar and thus precise cross sections measurements are required.

The presence of contaminations from heavier elements represents another systematic uncertainty in fission cross sections measured from targets made of lighter elements in the rare earth region: Due to their substantially lower fission barriers, even a small contamination from heavy elements ($<$ 1 ppm) can significantly increase the measured fission cross sections [5]. This effect is most prominent at low excitation energies near the fission barrier of the lighter element.

In this paper, we report on the use of Rutherford backscattering and particle induced x-ray emission for a precise off-line characterization of targets used in nuclear physics experiments. Furthermore, we introduce a sensitive method to check the relative accuracy of cross section measurements.

2 The Rutherford backscattering technique

Rutherford scattering was studied at the beginning of the century by Rutherford [6], Geiger and Marsden [7]. Their experiments were purely of nuclear physics interest, i.e. they were designed to confirm the atomic model proposed by Rutherford. The analytical nature of the Rutherford backscattering method (RBS), however, was not fully realized until the late 1950s [8].

For several decades, RBS has been used as a technique to characterize the surface and near surface properties of thin films of thicknesses between $\sim$100Å and 1μm (see e.g. Ref. [9]). The major push to use this method has come from the need to analyze electronic materials like semiconductors [10,11]. The technique has also been used to investigate ion implantations into solids [12].

As in the original experiments by Rutherford, Geiger and Marsden, the RBS technique analyzes the Coulomb interaction between a projectile of charge $Z_1 e$ and a target nucleus of charge $Z_2 e$. As we will briefly discuss in this section, the energy and scattering angle of the scattered particle provide information on the thickness, the nature of constituents, and the profile of the target. A typical experimental setup requires a beam generating device (providing a collimated monoenergetic beam of charged particles), a scattering chamber where the beam interacts with the target, and a detector for the backscattered particles. As mentioned before, the measured quantities are the backscattering angle θ and the energy E of the detected particle. Good energy resolution is obviously an essential quantity for the accuracy of the analysis.

In the following, we give a brief description of the method. More detailed information can be found, e.g., in the book by Chu, Mayer and Nicolet [13].

The most important quantity determined in RBS is the kinematic scattering

factor k, defined by the ratio of the energy of the backscattered particle E and the incident energy of the projectile E_0:

$$k = \frac{E}{E_0} = \left(\frac{\sqrt{M_2^2 - M_1^2 \sin^2 \theta} + M_1 \cos \theta}{M_1 + M_2} \right)^2 . \qquad (1)$$

Here, M_1 and M_2 are the masses of the projectile and the target, respectively. The knowledge of the mass and energy of the projectile and the measurement of the energy E and the angle θ of the backscattered particle allows the identification of the elementary constituents of the sample.

The thickness t of the sample can be derived from the energy loss dE/dx, i.e. by determining the energy of the backscattered particles E_1 and E_2 at both edges of the sample [13].

Fig. 2. Schematic RBS spectrum of a sample which contains three different constituents (A, B, and C). The individual contributions are shown as a dashed-dotted (A), a dotted (B), and a dashed line (C). The sum spectrum is displayed with a full line.

Due to the specific energy loss in different materials, contaminations in the sample show up as distortions of the RBS spectrum. This is schematically shown in Fig. 2 for a sample which contains three different constituents. Since the amount of backscattered particles from any given element is proportional to its concentration, RBS can be used to investigate quantitatively the depth profile of individual elements in the sample.

We note that due to the strong Z dependence of the scattering cross section,

4

the RBS technique shows a lack of sensitivity for low Z contaminants imbedded in high Z materials. RBS spectrometers using heavy ions as projectiles have been designed and utilized to improve the sensitivity to low Z constituents [14].

The advantages of the RBS method are many. It provides precise information about the sample without employing physical or chemical sectioning techniques and gives a quantitative analysis without references or standards. Furthermore, this technique is fast and non destructive.

3 Target thickness and homogeneity

We have utilized an RBS spectrometer at Lawrence Berkeley National Laboratory using monoenergetic $^4He^+$ particles of $E_0 = 1.95$ MeV generated by a 2.5 MeV van der Graaf accelerator. The diameter of the beam size was 0.75 mm. A silicon surface barrier detector was positioned at 165° with respect to the ion beam to collect and analyze the scattered helium particles [15].

Four different targets made of natural and isotopic lead ($^{nat,206,207,208}Pb$) have been investigated. The free standing targets were mounted on a thin aluminum target frame with a circular opening of 19 mm. The target thicknesses were ~0.5 mg/cm². The commercially made targets were manufactured using an evaporation method [16].

In Fig. 3, we show the measured energy spectra from the RBS analysis for four lead targets. The thicknesses of the foils are deduced from the widths of the RBS spectra using the energy loss data of the ions in Pb. The high energy edge reflects the front and the low energy edge the back of the sample. Small inhomogeneities in the target thickness can clearly be seen in the figure. In general, the spectral edges are sharply defined indicating well defined surfaces. In Table 1, we compare the thicknesses determined by direct weighing, using a geometric correction factor to account for evaporation nonuniformity [16], with thicknesses determined by the RBS method. Note that the thickness measured by RBS is given in areal density (atoms/cm²), i.e. the amount of materials present to scatter the incident He ions. This areal density can be directly compared to the data obtained by the direct weighing method using Avogadro's number and the known isotopic weight of the Pb isotope. To determine the overall homogeneity of the target, we have measured the thickness at 3 different points (center, lower left and upper right edge). The distance between the different points was 6 mm. The standard weighing technique provides only an average thickness and does not provide any information on the homogeneity of the target foils. We have also calculated an average thickness using the results from the RBS measurements according to $< t^{RBS} >= (t^{RBS}_{center} + t^{RBS}_{low} + t^{RBS}_{up})/3$.
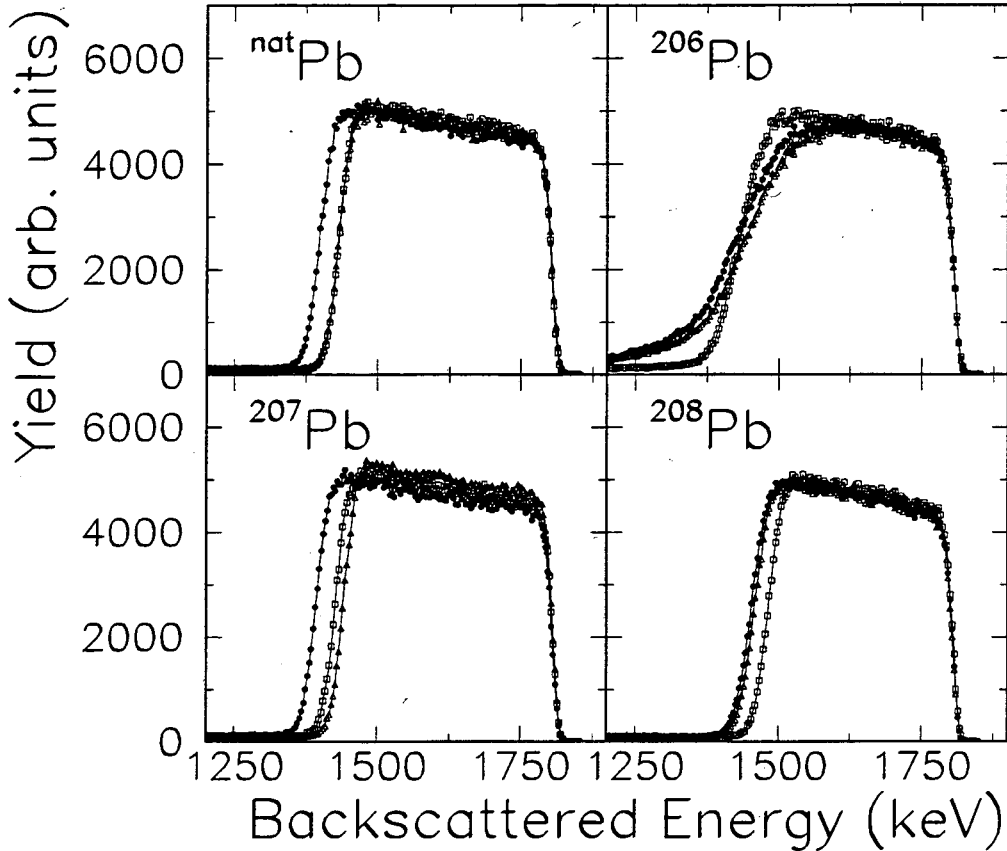

Fig. 3. RBS energy spectra for four lead targets (^{nat}Pb, ^{206}Pb, ^{207}Pb, ^{208}Pb). The different symbols correspond to different positions on the target: center (full circles), upper (open squares) and lower edge (open triangles).

The observed agreement between the average thicknesses determined by the two methods is good.

In Fig. 4, we show the thickness as a function of the distance from the center on the surface for the ^{207}Pb target. Measurements were made in 2 mm steps to determine the homogeneity. Within the central 8-10 mm, the thickness fluctuation is small. However, the sides are not symmetric. A systematic decrease of the target thickness from the center to the edges is found which is due to the evaporation process used to produce the target. In our fission experiments, the diameter of the beam spot on the target was less than 5 mm and the accuracy of the center focus was ~1 mm. Therefore, the differences in the target thickness given in Table 1 represent an upper limit for the uncertainty in the homogeneity.

We note that the relative uncertainty of the RBS target thickness measurement is below 1% and thus provides the necessary accuracy to minimize systematic errors in cross section measurements and associated quantities like, in our
Fig. 4. Target thickness determined by RBS as a function of position on the target surface for ^{207}Pb. The error bars show the absolute uncertainty of the measurement.

Table 1
Target thicknesses t determined from weighing in comparison to the results of the RBS technique. The thickness has been measured at three different points on the target (center, upper edge, lower edge). Furthermore, an average thickness $< t^{RBS} >$ has been calculated from these values.

Target	$t^{weighing}$	$< t^{RBS} >$	t^{RBS}_{center}	t^{RBS}_{low}	t^{RBS}_{up}
	$(\mu g/cm^2)$	$(\mu g/cm^2)$	$(\mu g/cm^2)$	$(\mu g/cm^2)$	$(\mu g/cm^2)$
^{nat}Pb	544	553	582	538	538
^{206}Pb	555	543	558	531	541
^{207}Pb	560	548	550	534	561
^{208}Pb	500	490	503	496	472

experiment, the first chance fission probability.

The sharpness of the low energy edges of the RBS energy spectra shown in Fig. 3 provides information on the surface condition, surface contaminations, and foil roughness. Non uniformities of the surface or significant contaminations will broaden the energy of the backscattered ^{4}He particle. For all targets the front edges are very sharp and for three targets the back edges are also quite sharp. However, for the ^{206}Pb case, the back edge is significantly washed out compared to other targets. In Fig. 5, we show ^{206}Pb data in comparison to the simulated sum spectrum obtained from the RBS analysis [17]. While the agreement is good for the front edge and inside the target material, a large
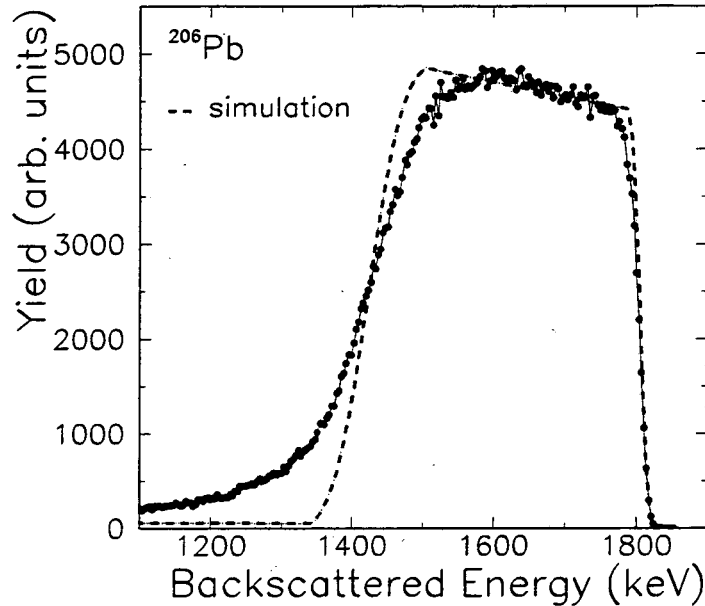

Fig. 5. RBS energy spectra for ^{206}Pb (center of target). The dashed line shows the results of the simulated spectrum. The deviations indicate surface contaminations and/or surface inhomogeneities.

deviation is observed at the back edge. This is most likely caused by either a significant surface inhomogeneity or the presence of large particles in the foil.

4 Target impurities

In order to determine whether any significant target impurities were present, particle induced x-ray emission (PIXE) has been measured simultaneously during the RBS experiments. PIXE is an analytical method which relies on the spectrometry of characteristic x-rays emitted by the target atoms due to the irradiation with a high energy ion beam. The method can identify various constituents in a compound target via their characteristic x-rays. To measure the x-rays, we have used a lithium drifted silicon detector which was located at 30° with respect to the incident beam. Under the most favorable conditions, a detection limit of ~ 1 ppm for thin foils can be achieved [15]. Compared to RBS, this method is significantly more sensitive to determine target impurities [15].

In Fig. 6, we show the accumulated x-ray spectrum for one of the targets (^{207}Pb). The spectrum is dominated by the various M and L x-ray peaks of Pb confirming that Pb is the major constituent. In addition, a small peak from the carbon backing of the target is seen. No sizable contribution of other contaminations has been detected. We note that for the present experimental
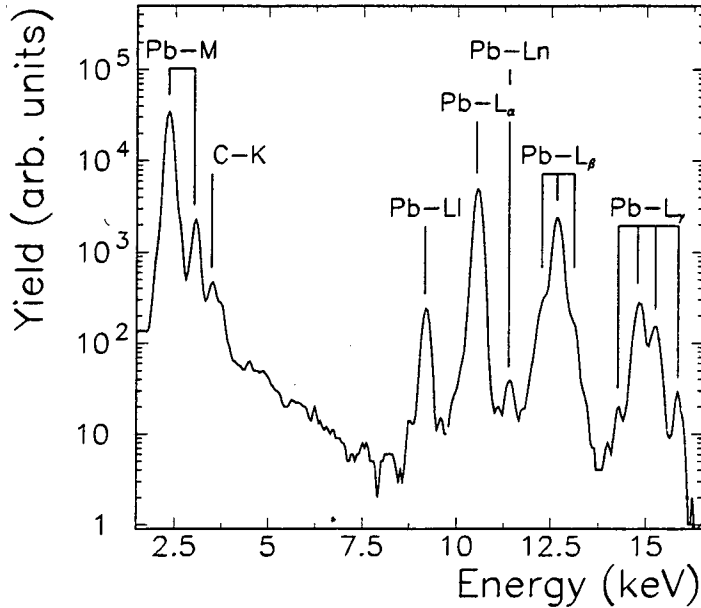

Fig. 6. Particle induced x-ray emission (PIXE) spectrum for ^{207}Pb (center of target).

conditions the detectable limit for most transition metals is 10-50 ppm.

5 Relative cross sections

A good relative accuracy of the measured fission cross sections of the neighboring compound nuclei is very important to minimize the associated error in measurements of first chance fission cross sections. To check this quantity for several separated isotopic targets, we have applied an independent method based on the measurement of the cross section of the corresponding natural target.

In our experiment, we have measured the fission cross sections of four different lead targets (^{206,207,208}Pb and ^{nat}Pb). The composition of natural lead is: 52.4% of ^{208}Pb, 22.1% of ^{207}Pb, 24.1% of ^{206}Pb, and 1.4% of ^{204}Pb. Unfortunately, we have not measured the fission cross section of the latter isotope and had to estimate it from the ratio of the cross sections for ^{208}Pb and ^{206}Pb. This estimate is in agreement with measured fission cross sections for all three isotopes [18]. We have calculated the "natural" cross section by adding up the relative isotopic cross sections using the target thicknesses determined by RBS:

$$\sigma_{nat}^{calc} = \sum_{i=204}^{208} p_i \sigma_i. \tag{2}$$

Here, p represents the contribution of the isotope i to the natural composition.

Fig. 7. Ratio of the calculated fission cross section for natural lead using the individually measured cross sections of the lead isotopes and the measured cross section using a natural lead target. The projectile is ^{3}He.

In Fig. 7, we show the results of this analysis; the calculated cross sections from Eq. 2 have been normalized by the cross section measured for the natural lead target. A rather constant value close to unity has been found. This good agreement allows us to conclude that the relative cross sections are known to $\pm 2\%$. This accuracy is a substantial improvement over previous experiments [18] and is sufficiently good to allow extraction of first chance fission probabilities from our data [4].

6 Summary

In this paper, we have presented results of a method that allows precise characterization of thin target foils used in nuclear physics experiments. The applied Rutherford backscattering and particle induced x-ray emission techniques provide information on the thickness, homogeneity, and constituents of a target material. Furthermore, this method is fast and – more importantly – non-destructive.

The information allows one to minimize systematic errors due to uncertainties in the target thickness and homogeneity. The technique described in this paper thus provides a powerful tool to determine the purity of a target and is especially useful if it is applied in advance of an experiment.
