PART I: AN ANALYSIS OF LIFE CYCLE COSTS OF SOLAR FACILITIES

SUMMARY

The life cycle costs over a range of technological and economic assumptions were compared to investigate the trade offs among solar and renewable energy technologies, and between centralized and decentralized technologies. We looked at these costs under different financial conditions by varying the interest rates, tax rates, and taxable lifetimes. For wood stoves, we varied the fuel price over a wide range. For some technologies cost estimates for alternative designs were compared with the original TASE characterizations.

Life cycle costs under different financial conditions were compared by calculating the derivatives of the fixed charge rate (FCR) with respect to the discount and tax rates for taxable lifetimes ranging from 5 to 30 years. At the upper end of this range (15 years or more) the FCR is not sensitive to the taxable lifetime.

The FCR is most sensitive to changes in the tax rate, especially at high rates. Below tax rates of 30 percent, the dependence is nearly linear, but above 40 percent, the FCR increases rapidly. Tax rates above this level will thus inhibit investment in new capital intensive facilities.

The fixed charge rate is fairly linear with respect to the discount rate over the range 0 to 22 percent. The slope of the linear curve depends strongly on the tax rate.

Fuel costs for wood stoves were varied from zero to \$600 per year. This covers a range of prices from a rural consumer gathering his own wood to an urban consumer who purchases four cords of delivered wood at \$150 per cord. This spread in fuel costs results in the life cycle costs varying over a factor of four from \$2.58 to \$6.33 per million Btu. These costs are much lower than the life cycle costs of other residential space heating systems, including passive solar, because the capital

costs are so low.

Comparing the different TASE facilities that generate electricity, we see that the centralized systems are less expensive than dispersed systems on a life cycle cost basis (see Table 1). Wind systems are the least costly, central solar next, and photovoltaics are the most expensive. For residential space heating, wood stoves are least expensive and active solar the most expensive, with passive solar in between. These differences arise primarily from differences in capital costs.

Comparing the TASE characterizations with the SERI characterizations, we see significant differences in life cycle costs in less than half of the technologies (see Table 2). Except for photovoltaic systems, the largest differences are about a factor of 2-3. This range results from differences in the design and in the geographic location of the system. Since the life cycle costs are dominated by the capital costs, the same system located at a site with low input energy will have higher unit energy costs than if it were located at a site with high energy input. The SERI life-cycle costs for photovoltaic systems are much higher than the corresponding TASE costs. The SERI capital costs amount to about \$10 per peak kilowatt, which is an accepted estimate for current costs. The TASE costs for central photovoltaic systems are about \$1 per peak kilowatt, which corresponds to DOE's design goals for the mid 1980's.

INTRODUCTION

Solar and biomass technologies require more capital than their conventional counterparts. The fuel costs of solar technologies are negligible, while those of biomass technologies are site specific. For example, annual fuel costs for wood stoves can vary from zero in a rural area to \$600 in an urban area. In an earlier report [1], we examined the capital costs and labor requirements and the indirect impacts of constructing solar and biomass energy facilities. The purpose of this paper is to examine the life cycle costs of various solar and biomass technologies and to examine the sensitivity of these costs to variations in financial variables.

In comparing solar and biomass technologies with their conventional alternatives, these technologies are often thought of as a single homogeneous technology. Their diversity is ignored in such comparisons. Solar technologies range from centralized solar thermal electric power plants to dispersed or decentralized residential solar heating. In our analysis we examine the difference in costs of centralized vs. decentralized systems.

Most solar and biomass technologies are at the research and development stage; their performance characteristics are not yet proven. The cost of these prototype technologies are generally high. As the technologies develop and their market shares increase the unit costs will decline until they ultimately match or fall below the costs of conventional alternatives. Because of the uncertainties in cost estimates, we compare the costs for alternative characterizations of technologies with similar designs.

Life cycle costs depend on the capital and operating costs and the fuel cost of each facility. The fixed charge rate, which depends upon the financial conditions (tax and interest rates), the expected lifetime of each facility, and its performance characteristics, determines the capital component of the life cycle costs. We examine the effect of changing these variables on the life cycle costs of solar and biomass facilities.

METHODOLOGY

The levelized cost of energy from each solar facility may be expressed as the sum of three types of costs:

$$c_j = (\text{Levelized Capital Cost})_j \\ + (\text{Operations and Maintenance Cost})_j \\ + (\text{Fuel Cost})_j$$

where j = Solar Technology Type

The levelized capital cost is a function of the initial capital cost (CC), the energy generated each year (E), and the fixed charge rate (FCR). For a specific type of solar facility the levelized capital cost is

$$\text{Levelized Capital Cost} = CC_j \text{ ESC}_j \text{ FCR}_j / E_j$$

The capital costs in our analysis were derived from the technology characterizations previously published as part of the TASE study [2]. The corresponding data for alternative designs were from a SERI study [3]. Capital requirements of solar and biomass power plants are likely to decline according to the SERI study.

The first few renewable power plants will be prototypes of commercial plants to come on line later. Prototypes may cost as much as ten times more than a commercial plant of the same size. Plant costs can be expected to decline because of improved management, more efficient construction practices, competitive bidding on the part of suppliers, mass production of components, and more efficient use of materials. Costs may also increase as a result of unforeseen circumstances, stricter health and safety requirements or environmental regulations, and more expensive on site resources: land, water and labor. Published goals for the cost of renewable facilities indicate that they will decline over the next twenty years. The decline may be fairly rapid during the first 10 to 15 years as the first plants are commercialized, after which it

will slow down as unit costs stabilize.

The fixed charge rate used in computing the cost of capital is based on the following equation [4]:

$$FCR = \frac{1}{1 - \text{Tax}} \left[C_r (1 - \text{ITC}) - \frac{\text{Tax}}{n} \right] + B_1 + B_2 \quad (1)$$

where

$$C_r = \frac{r}{1 - (1+r)^{-n}}$$

n = taxable life (20 years)

r = cost of capital (13%)

tax = tax rate (40%)

ITC = investment tax credit (25%)

B_1 = other taxes (2%)

B_2 = insurance (0.25%)

The fixed charge rate amounts to 0.226 using these values for the variables. The cost of capital is based on constant 1978 dollars.

To examine the sensitivity of the fixed charge rate to the economic conditions under which the solar and renewable energy facilities would be built, we calculated the derivative of the FCR with respect to the tax rate and the discount rate (cost of capital). The resulting expressions are:

$$\frac{dFCR}{d\text{Tax}} = \frac{C_r (1 - \text{ITC}) - 1/n}{(1 - \text{Tax})^2} \quad (2)$$

$$\frac{dFCR}{dr} = \frac{1 - \text{ITC}}{1 - \text{Tax}} \frac{1 - (1+r)^{-n} - nr(1+r)^{-n-1}}{\left[1 - (1+r)^{-n} \right]^2} \quad (3)$$

The FCR and its derivatives were calculated for taxable lifetimes ranging from 5 to 30 years using a broad range of discount and tax rates.

The capital, operating and fuel costs were derived from the technology characterizations previously published as part of the TASE study [2]. The corresponding data for alternative designs were taken from a SERI study [3]. The alternative designs were analysed since there are widely varying designs, and expectations of future costs of solar technologies. Analysis of alternative designs permits us to assess the sensitivity of costs to design changes. Estimates of fuel costs for wood stoves came from an informal survey by Lipfert [5] and from Lucarelli [6].

RESULTS

Fixed Charge Rate

In calculating the life cycle costs of an energy facility, the initial capital costs are distributed over the lifetime of the system. The factor used to distribute the capital costs, the fixed charge rate (FCR), is defined as the annualized life cycle cost per dollar of capital investment. As can be seen from equation (1), the FCR depends mainly on the taxable life of the facility, the income tax rate, and the cost of capital or discount rate. To investigate the effect of these parameters, we calculated the fixed charge rate and its derivatives over a wide range of these variables. The results are shown in Figures 1 through 3.

In Figure 1, we plot the fixed charge rate as a function of taxable lifetime for several tax rates. For facilities with relatively long lifetimes (greater than 15 years), the FCR is nearly independent of the lifetime. This is especially true as the discount rate gets larger. The taxable lifetime is therefore of less consideration for centralized facilities which have long lifetimes than for dispersed facilities such as wood stoves or residential solar or wind systems which may have a much shorter lifetime.

Of these three parameters, the FCR shows the strongest dependence on the income tax rate. The curves shown in Figure 2 are nearly linear for tax rates less than about 30 percent. Above this level the FCR increases more rapidly than the tax rate. High tax rates, over 30 percent, therefore disproportionately discourage investment in capital intensive energy facilities.

The FCR in our formulation decreases with increasing facility lifetime. However, beyond a tax rate of approximately 40 percent, this trend is reversed. With increasing lifetimes, the tax rate increases slightly. Figure 3 illustrates this anomaly for 30, 40 and 50 year lifetimes.

Figure 1 - Fixed Charge Rate as a Function of Facility Lifetime

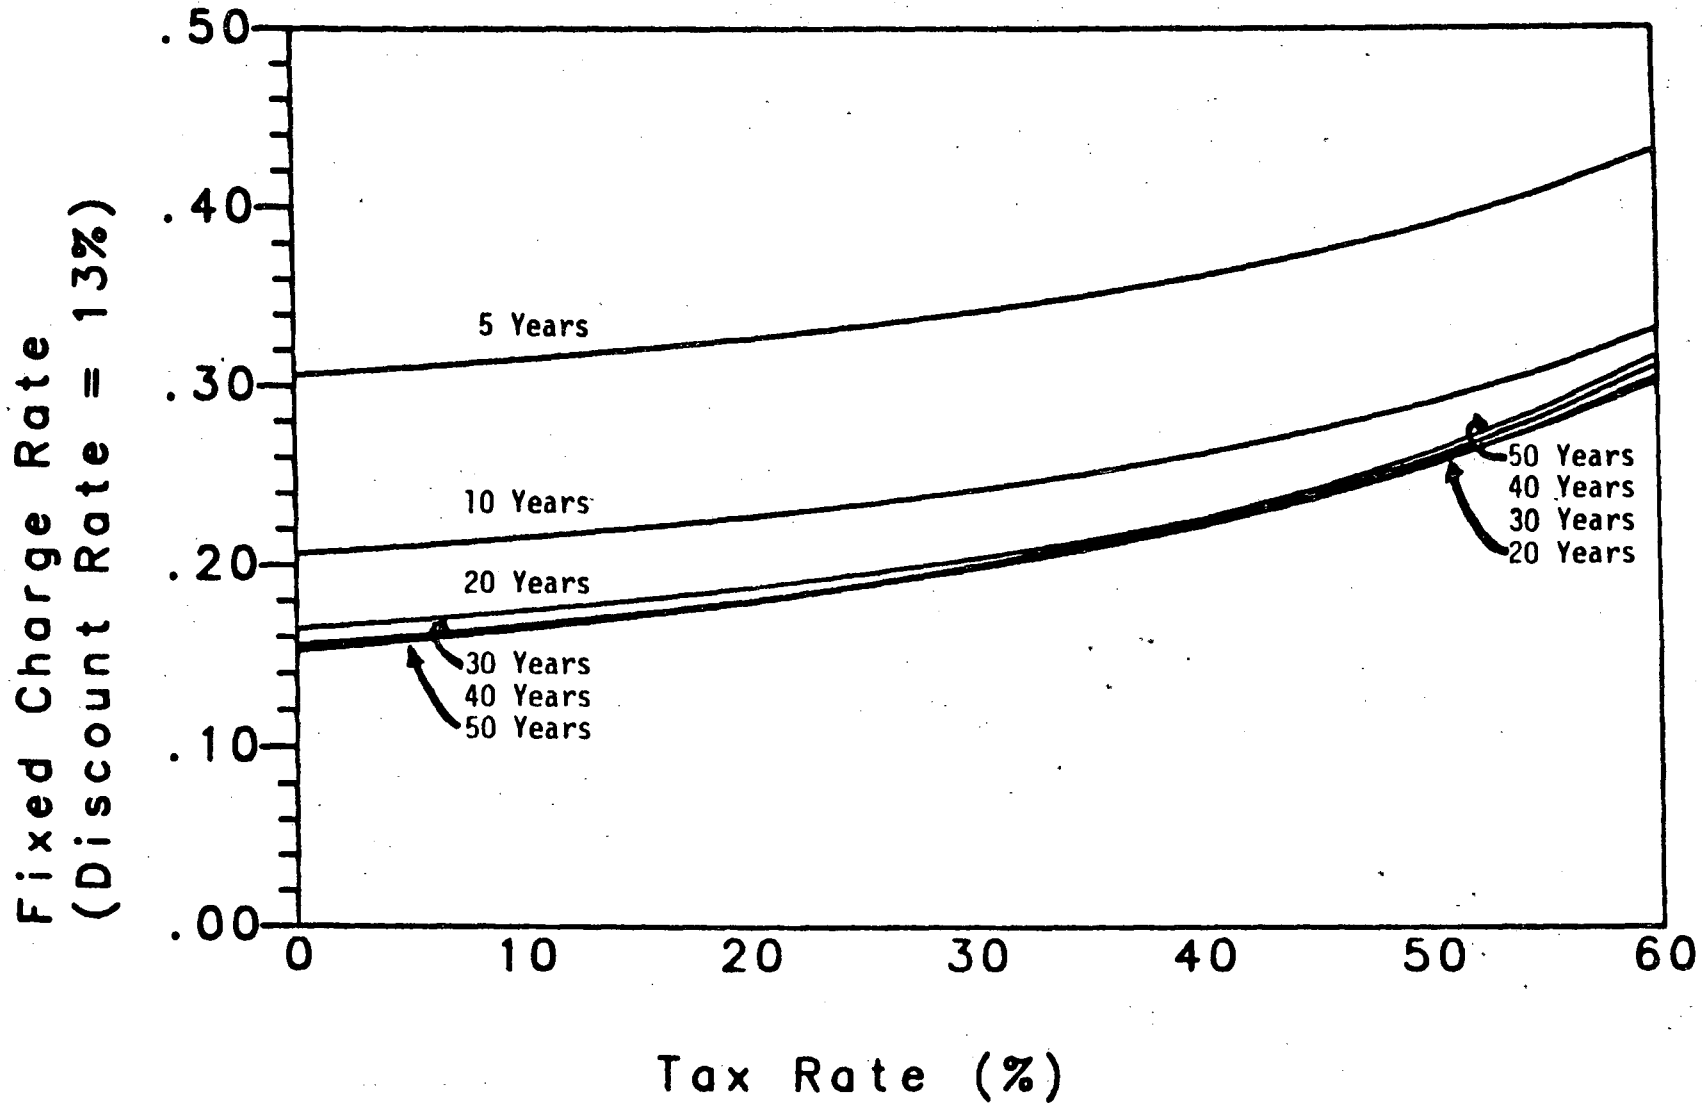

Figure 2 - Fixed Charge Rate as a Function of Tax Rate

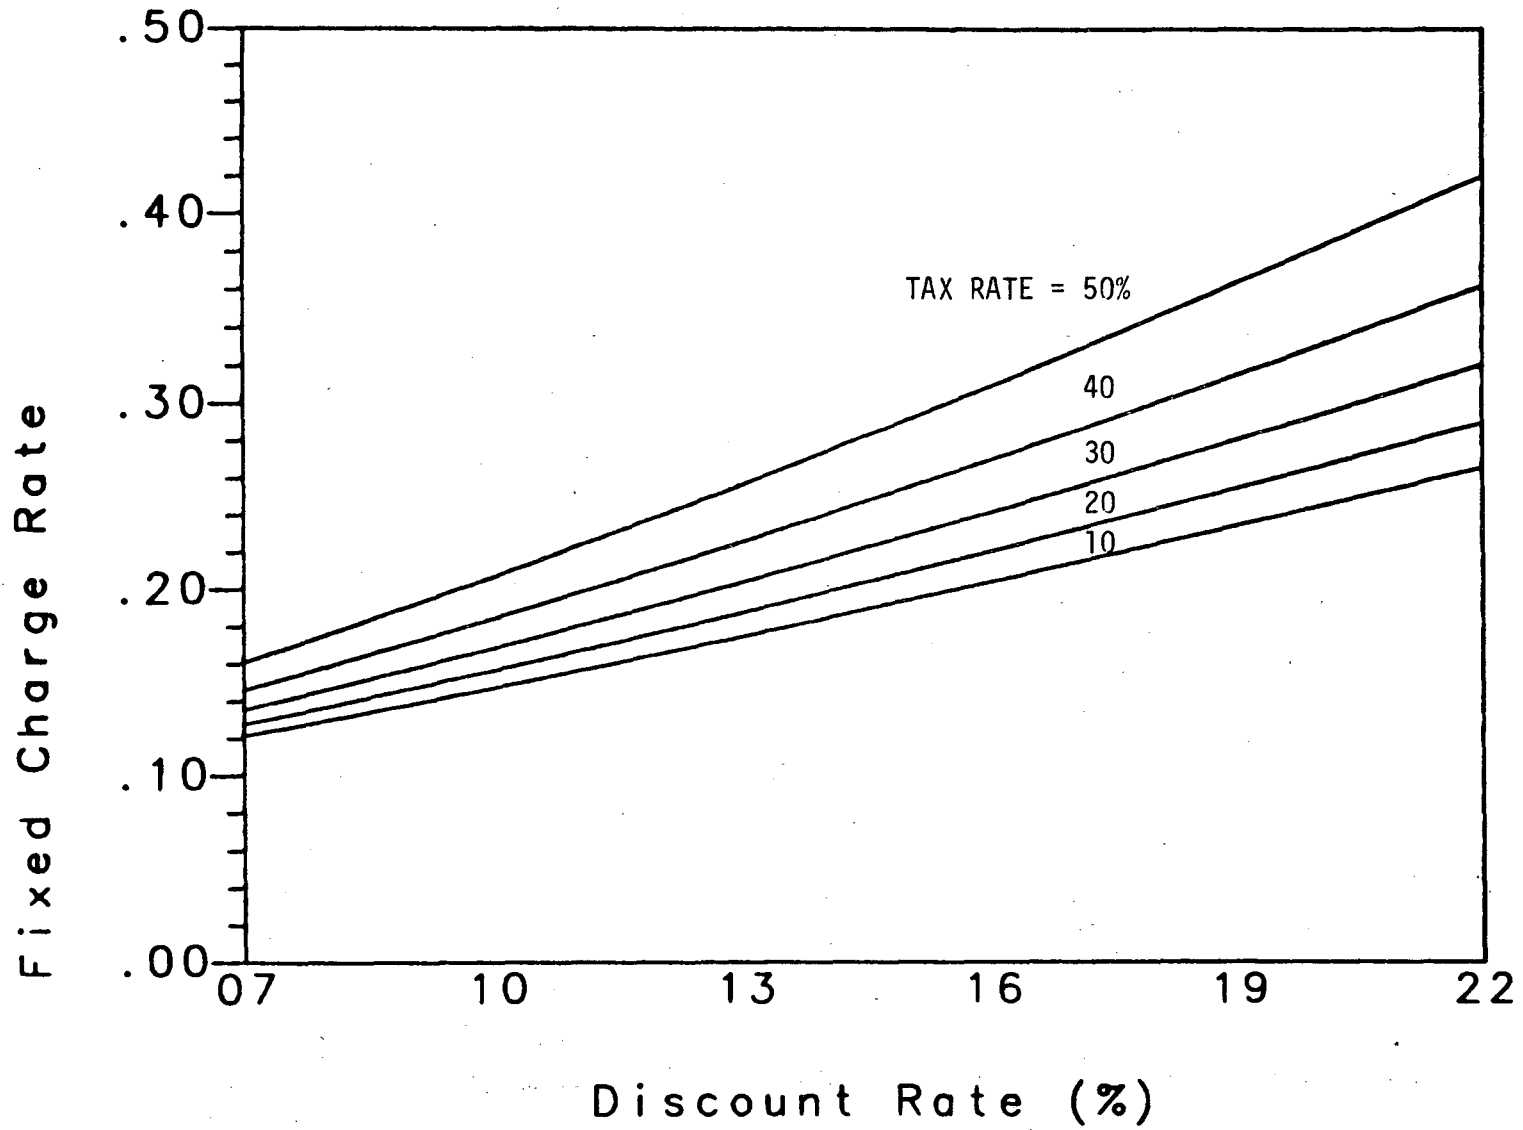

Figure 3 - Fixed Charge Rate as a Function of Discount Rate

The FCR increases nearly linearly with the discount rate over a range of 0 to 22 percent. As shown in Figure 3, the slope of this curve increases with increasing tax rate. The combination of high interest rates and high tax rates that we have been experiencing over the past few years result in a very high fixed charge rate which drives up the cost of energy from new sources and inhibits investment in them.

Life Cycle Costs of TASE Facilities

Life cycles costs for 16 facilities characterized as part of the TASE study [2] were calculated under the following financial conditions:

| | |
|-----------------------|--------------|
| Taxable life | 20 years |
| Cost of capital | 13 percent |
| Tax rate | 40 percent |
| Investment tax credit | 0.25 percent |
| Other taxes | 2 percent |
| Insurance | 0.25 percent |

The results per million Btu of input energy are presented in Table 1.

Except for wood stoves, no fuel costs are involved for the biomass facilities because they are assumed to have a captive source of fuel. For this reason and because they have lower capital and operating costs, biomass facilities are in general less expensive per Btu than solar facilities (see Table 1). The only exceptions are the Industrial Process Heat systems which have high capital costs; for these, the levelized energy costs are comparable to those for solar facilities.

Centralized solar systems shown in Table 1 appear to be less expensive than decentralized ones. This is especially true for photovoltaic systems, but in this case the capital costs for the central system is quite low while the operating cost for the residential system provided in Reference 3 seems high. The capital costs correspond to approximately \$1 per peak watt, whereas current estimates are closer to \$10 per peak watt. The \$1 figure represents DOE's goals for the cost of photovoltaics in 1985 [7]. The operating costs for residential photovoltaics

come to nearly \$2,000 per year which seems unreasonably high.

Wood stoves are the least expensive way to supply residential heating. Passive solar heating costs about twice as much, and active heating is another factor of two higher. These cost figures should only be considered as rough estimates of the actual cost of a real system in a given location. The cost per million Btu depends to a large extent on the details of the technical design of the system and, for a solar system, on its geographic location. The latter factor determines the amount of energy incident on the system annually.

Comparison of TASE and SERI Facilities.

To investigate the sensitivity of the life cycle costs of solar and biomass energy systems to differences in design and location, we compared our results with a similar cost calculation we performed using the data in a recent report by the Solar Energy Research Institute [3]. We chose the SERI systems that fulfilled the same end-use demand as the TASE systems. In some cases the SERI systems were given for two locations in the country.

Comparing the data in Tables 1 and 2, we see that for almost all systems the life cycle costs differ by a factor of 2 to 3. The major exceptions are centralized photovoltaic systems. The difference arises because the SERI life cycle costs are based on estimates of the current system costs whereas the TASE results are based on estimates of future costs. As discussed in the previous section, current installed costs for photovoltaic systems are ten times the estimates for systems installed in 1985.

The life cycle cost for centralized facilities are consistently larger for the SERI systems than for the TASE systems. For residential wind and solar systems they are nearly the same. The costs for the SERI residential solar space and water heating system are about twice as large as that gotten by combining the two corresponding TASE facilities (Solar Space Heating and Active Solar Domestic Water Heating).

*Cost at a less favorable location.

Wood Stoves

Our results indicate that wood stoves are the least expensive source of energy for residential space heating because of their low capital costs. We investigated the life cycle cost of wood stoves for a range of fuel costs. According to Lipfert [5] and Lucarelli [6] the price of wood can range from essentially zero for a rural consumer who collects his own to \$150 per cord for an urban consumer who has it trucked in. Assuming that up to four cords of wood per year would be burned, we calculated life cycle costs for an fuel bill of zero to \$600 per year. The results are plotted in Figure 4. This range of wood prices results in the life cycle costs for wood stoves varying over a factor of four from \$2.58 to \$6.33 per million Btu.

Comparison of Low and High Solar Scenarios

The solar and biomass share of primary energy supply varies by a factor of two between the two scenarios. All the consuming sectors have a larger supply of energy from renewable sources in the high solar scenario. The fraction of total solar and biomass energy used in industry is 63 percent in the low scenario and 51 percent in the high scenario (see Table 3). The fractions of renewable energy consumed in the electric utility and residential sectors are 13 and 22 percent in the low solar scenario and 21 and 27 percent respectively in the high scenario.

The life cycle costs of biomass systems are the lowest among the technologies we considered. Centralized utility systems are somewhat more expensive, followed by residential heating, industrial process heat, and residential wind and photovoltaics.

For the low and high solar scenarios, the annualized life cycle cost for each consuming sector is shown in Table 4. Unit costs for supplying energy in the electric utility sector and in the industrial sector are nearly identical between the two scenarios. In the residential sector there is a significant difference in costs due to a different mix of technologies in the two cases. In this sector, passive solar designs

| Total | 158.6 | 11.2 | 61.8 | 10.3 |

account for a larger fraction of energy use for space heating in the high scenario, hence the unit cost is lower. Residential electricity is less expensive in the high solar scenario than in the low because a larger proportion of the electricity is generated by cheaper wind systems.

The overall unit cost of supplying energy is nine percent higher in the high solar scenario. The total capital cost for the high solar scenario between 1976 and 2000 will amount to \$690 billion in constant 1978 dollars, while for the low solar scenario it will amount to \$270 billion. This is not surprising since the fuel costs for all biomass technologies except for wood stoves are negligible since we assumed a captive fuel source. It also implies that operating costs vary in proportion to capital costs for all the technologies.

PART II: MINERALS CRITICAL TO THE DEVELOPMENT OF FUTURE
ENERGY TECHNOLOGIES IN HIGH AND LOW SOLAR SCENARIOS

SUMMARY

Solar and renewable technologies account for most of the increase in material requirements for energy technologies. Our analysis identified 20 minerals where domestic reserves are inadequate to meet the demand. Domestic mine capacity is inadequate for 23 minerals. However, the world wide mine production capacity is adequate to meet the U.S. demand for all the minerals. Energy related demand can therefore provide a potential market for some of these 23 minerals provided the U.S. has deposits that can be exploited at worldwide competitive prices.

For some critical and strategic minerals such as chromium the U.S. demand peaks during a time period different than the period during which world demand peaks. The time period differences will help smooth market fluctuations and reduce the U.S. vulnerability.

Alternative technology designs can help mitigate adverse supply disruptions or sharp price increases. Alternatives may not always be available for a specific strategic and critical mineral. Each mineral may have to be analyzed and evaluated on its own merits before comparative options can be completely analyzed.

INTRODUCTION

The next 20 to 30 years are expected to be a period of transition from major dependence on conventional energy sources such as oil and natural gas to an era heavily dependent on nonconventional renewable and virtually inexhaustible sources of energy. The viability of these future alternative energy sources is contingent, in part, on future materials and minerals availability.

In this analysis we have estimated the amounts of 46 non-fuel minerals needed to construct the new energy facilities called for in a high and a low solar scenario. Twenty-five of these 46 minerals were selected for a careful analysis of demand and supply. The other 21 minerals, for which the U.S. is a net exporter with adequate reserves and for which resources are readily available, geographically dispersed, and virtually inexhaustible, were excluded from this analysis. Table 1 lists all the sectors which were included in our analysis.

Energy-related and total U.S. and world primary demand for minerals, and U.S. and world mine production capacity, were projected in five-year periods to the year 2000. The percent of U.S. and world demand and capacity needed for both the alternative and conventional energy technologies were calculated under each scenario. The primary demand for the 25 minerals was also projected in the five-year periods to the year 2000 for each group of technologies--coal, oil, gas, solar and other renewables, nuclear, and synfuels.

Since the results from our analysis were limited to the energy-related demand for non fuel minerals, the Department of the Interior's Bureau of Mines was requested to provide projections of total U.S. and world primary demand, mine production capacity, and level of production for each mineral evaluated. The Bureau's projections were based on both statistical and contingency analyses.

METHODOLOGY

The high and low scenarios provide the basic data for the chain of models--an Energy Supply Model and a U.S. Input-Output Model (see Figure 1). The scenarios specify the amount of energy supplied by oil, gas, coal, nuclear, solar, wind, ocean, and biomass sources, disaggregated to give geographic and technological detail (see Tables 2 and 3).

The Energy Supply Model (ESPM) [1] translates this data into the number of energy facilities of each type which have to be constructed to meet the specified levels of energy supply. The 122 types of facilities in the model include coal mines, oil wells, various types of power plants, solar and wind generators, etc. The ESPM also includes algorithms for determining the number of transportation facilities required to move coal, oil, gas and other fuels. The number of trains, pipelines, trucks, etc., are estimated on the basis of projected energy supply and demand by origin and destination for each federal region of the country.

The capital and labor needed to construct and operate each type of facility are subdivided into 140 categories. On the basis of these data, the direct capital costs and labor required to meet the prescribed energy supply scenario are computed. The 1978 ESPM data base was modified to include data on solar and other renewable technologies. The detail for the 20 solar and renewable technologies was constructed at the four-digit SIC level as part of the solar characterizations [2].

| Total Primary Energy Supply | 72901.1 | 92233.3 | 100932.5 | 123862.5 |
| Total Primary Energy Consumption | 67326.6 | 86916.7 | 95499.9 | 117862.4 |

Note: Primary energy consumption does not include coal exports and synthetic fuel losses.

The capital costs include expenditures on manpower, equipment, and materials. The equipment and materials costs are presented by two-digit I-0 sectors. These capital expenditures are treated as final demand vectors in the I-0 model. Two final demand vectors are created to match the I-0 table sectors, one representing expenditures on materials and equipment, and the other expenditures on construction manpower. The output of each industry over the next twenty years required to meet these demands is calculated by the model.

The U.S. Input-Output Model was derived from the 496-sector national table for 1972 prepared by the Bureau of Economic Analysis. The disaggregation of the minerals from 7 to 46 sectors was based on data from the Bureau of Mines and Bureau of Economic Analysis worksheets for 1972. This table was aggregated to 178 sectors keeping the detail in the mineral producing and using sectors (see Table 1).

The industrial outputs from the input-output table in dollar units were converted to physical quantities of minerals. These outputs are the direct and indirect demand for each mineral required for construction of energy facilities called for in the scenario.

RESULTS AND CONCLUSIONS

The methodology provided detailed demand for 46 nonfuel mineral sectors in five year intervals to the year 2000 for the two scenarios. Twenty of these mineral sectors were excluded from detailed analysis because: (1) The United States is a net exporter with adequate reserves and resources, (2) there are readily available geographically dispersed and virtually inexhaustible world resources, (3) the mineral sector included two or more minerals or (4) the sector was not applicable to any given mineral (see Table 4).

Domestic energy-related and total U.S. and world primary demand, together with U.S. and world mine production capacity, were projected in 5-year periods to the year 2000. Percent of U.S. and world demand and capacity were calculated for both the alternative and conventional energy technologies under each scenario. The primary demand for the 26 minerals was also projected in 5-year periods to the year 2000 for each

group of technologies--coal, oil, gas, solar and other renewables, nuclear, and synfuels. A similar analysis was conducted substituting a different technological design for the solar heating and cooling of building facilities.

Mineral Demand

Our analysis indicated that implementation of either of the national energy scenarios to replace or supplement conventional oil, natural gas, and coal with energy sources that are either renewable or available on a scale sufficient for centuries would require large increases in the supply and availability of certain nonfuel minerals.

Energy related demand for the 26 minerals is shown in Table 5. Demand for minerals is highest in the high solar scenario primarily due to the large component of solar and other renewable energy technologies.

Tables 6 and 7 exhibit the percentage of mineral demanded by each group of energy facilities. The 122 types of energy and transportation facilities were combined into eight groups or industries for convenient presentation. Solar facilities dominate the mineral requirements in each scenario. The lowest mineral demand for solar facilities occurs in the low solar scenario. Among the minerals required for other industrial groups, vanadium use in the coal industry, copper in electric power transmission, and asbestos in the nuclear industry account for over 20 percent of the total energy related demand for the respective mineral.

The oil industry is expected to be a major consumer of minerals, second only to the solar industry. Thirty percent of the barite will be used for drilling muds. Fluorspar, iron ore, manganese and molybdenum use exceeds 20 percent of their total demand. These minerals are not directly used in large quantities in the oil industry, but their indirect demand is large because they are used in iron and steel products used by the oil industry. Coal, gas, nuclear and energy transportation account for roughly 10 percent of the demand for each of these four minerals.

Table 4. Mineral sectors excluded from projection.

| Reason for Exclusion | Mineral Sector |
|---|--|
| Net exporter, adequate reserves and resources | Construction sand and gravel gravel Industrial sand Bentonite Fire clay Fuller's earth Kaolin and ball clay Other clay, ceramic, and refractory minerals except feldspar Phosphate rock Talc, soapstone, and pyrophyllite |
| Inexhaustible world resources | Dimension stone Limestone Granite Other stone (marble, sandstone, etc.) Rock salt |
| Could not be disaggregated | Potash, soda, and borate minerals Other chemical and fertilizer minerals (lithium, strontium, etc.) Ferroalloys, including cobalt, except chromium, columbium, manganese, molybdenum, nickel, tantalum, tungsten, and vanadium Other metallic minerals including beryllium, ilmenite, rare earths, rutile, thorium, tin, and zirconium Other nonmetallic minerals including corundum, industrial diamonds, gem and precious stones, graphite, mica, and pumice |
| Not applicable to any given mineral | Metal mining services Nonmetallic minerals services |

The two scenarios evaluated required an average of between 17 percent and 23 percent of total projected U.S. demand for the 26 minerals to the year 2000 (Table 8). However, the percentage of each mineral varied sharply from a low of 3 percent for molybdenum to a high of 75 percent for tantalum.

Demand for the 26 nonfuel minerals by the conventional oil, gas, and coal technologies remained relatively constant between the two energy scenarios averaging between 8 percent and 9 percent of total projected U.S. demand. However, demand by the alternative solar, synfuel, and nuclear technologies varied from 8 percent to 15 percent depending primarily on the amount of energy in the scenario provided by the solar and other renewable technologies.

Average demand under the energy technology scenarios comprised between 5 percent and 7 percent of total projected world demand for the 26 minerals to the year 2000. Again, the amount of energy in the scenario provided by the solar and other renewable technologies was the primary driver for any increase in average demand.

Mineral Supply-Demand Comparison

Different technological designs can reduce dependence on critical and strategic minerals. For example, a substitute design for the solar heating and cooling of buildings having the same life expectancy reduced the amount of chromium required for the solar group by over 50 percent.

The consensus among most of the scientific community supported by current geologic, economic, and demographic evidence is that physical or "crustal" exhaustion of world mineral resources is not likely to be a problem through the remainder of this century. Also, world reserves of most minerals, defined as that portion of resources which are located in identified deposits and can be economically extracted given current technology and mineral prices, are also expected to be adequate. Our analysis resulted in similar findings, despite the increased demand generated by the alternative energy technologies.

Schedule of Demand by the Conventional and
Alternative Energy Technologies as a Percent
Of Total U.S. and World demand (1976-2000)

Table 8

| Mineral | Percentage of U.S. Demand | | | | | | Percentage of World Demand | | | | | |
|----------------|---------------------------|-----|--------------------------|-----|-------|-----|----------------------------|-----|--------------------------|-----|-------|-----|

| Cumulative | | | | | | | | | | | | |
| Average | 8 | 9 | 15 | 8 | 23 | 17 | 3 | 2 | 5 | 2 | 7 | 5 |

The Bureau of Mines' estimates of reserves and resources for the minerals included in our analysis have been historically very conservative. Increases over the 20-year period 1960 to 1980 ranging between 200 percent and 300 percent were not uncommon for the minerals we analyzed due to discoveries of major new deposits technological advances in recovery processing permitting inclusion of lower grade ores, and an upward movement in prices.

Of the 26 minerals analyzed, copper, feldspar, iron ore, lead, molybdenum, and sulfur presented no long-range supply problems in the form of either U.S. or world mineral exhaustion. Demand for these minerals is less than projected U.S. reserves. Demand for gypsum and titanium will exceed projected U.S. reserves by 30 and 17 percent respectively. Judging from historical errors of 200 to 300 percent in projected reserves, the excess demand for gypsum and titanium is no cause for concern.

Further, of the remaining minerals for which the U.S. has no or inadequate reserves or resources, world reserves and resources appear adequate (see Table 9). Energy related demand for aluminum, antimony, chromium, cobalt, fluorspar, manganese, nickel, and the platinum group metals exceeds projected U.S. mine capacity of the next 25 year period. Total demand for all minerals except feldspar, molybdenum, and sulfur exceeds U.S. mine capacity over the same period (see Table 10). This indicates that there is potential for domestic expansion of the U.S. industry for 23 minerals provided these minerals can be extracted at worldwide competitive prices.

a Demand by the alternative synfuel, nuclear, solar, and other renewable technologies was added to Bureau of Mines total projected demand. Since demand by these alternative technologies varied between energy scenarios, the highest demand was used for analytical purposes.

b Analyzed separately.

c The U.S. has no known reserves.

Table 10. Schedule of maximum U.S. total and energy-related demand as a percent of projected U.S. mine capacity (1976-2000)^a

| Zinc | 232 | 228 | 40 | 30 |

a Demand by the alternative syrfuel, nuclear, and solar and other renewable technologies was added to Bureau of Mines total projected demand. Since demand by these alternative technologies varied in each of the four energy scenarios, the highest demand was used for analytical purposes.

b The U.S. has no mine capacity.

c Not available.

The availability of each mineral is a function of both U.S. and world mine capacity and reserves. As compared to world mine capacity the energy related U.S. demand is a small fraction for every mineral except tantalum, gypsum, columbium, chromium, antimony, and silver. The total U.S. demand for 18 minerals is well over 20 percent of world production capacity. The demand for tantalum accounts for 95 percent of peak mine capacity. Demand for eight of the 26 minerals exceeds 30 percent of world production capacity (see Table 11).

The peak demand for these minerals occurs during different 5-year time periods. World wide demand projected by the Bureau of Mines peaks during the 1976-1985 period for all the minerals except for aluminum, columbium, molybdenum, nickel, and tantalum. Demand for these minerals peaks during the 1996-2000 period. Often the peak demand in the U.S. occurs during a time period different than the period during which the world demand reaches a peak. Chromium is one such mineral; U.S. demand peaks during 1996-2000 period while world demand peaks during 1976-1985 period. The difference in peaks would help smooth market fluctuation and also deter formation of cartels or sudden price increases in such commodities.

While world supplies appeared adequate to meet U.S. energy-related demand, the uncertain availability of some minerals pose potential constraints to a smooth transition from major dependence on oil and natural gas to alternative sources of energy. This uncertainty stems primarily from the possibility that there might be either a serious disruption in supplies or a sharp increase in prices of certain minerals. Either could delay implementing a national energy program. In this sense, "strategic" refers to the relative availability of a mineral, while "critical" refers to its essentiality for energy-related uses.

Based on our analysis of energy-related demand for minerals presented above and additional research at the General Accounting Office, we have identified nine minerals which may be "energy-critical" and "strategic" (see Table 12).

Table 11. Schedule of maximum U.S. energy-related demand and total demand as a percent of projected world mine capacity (1976-2000)^a

| Mineral | Highest Energy Related Demand as Percentage of World Capacity | | Highest Total U.S. Demand as Percentage of World Capacity | | 5-year period during which demand peaks | |
|----------------|---|-----------------------------|---|---------------------------|---|--------------------------|
| | For any 5-year period to 2000 | For entire 25-year scenario | For any 5-year period to 2000 | For entire 25-year period | U.S. Demand Peak Period | World Demand Peak Period |
| Aluminum ores | 4 | 3 | 29 | 23 | 1996-2000 | 1996-2000 |
| Antimony | 11 | 8 | 31 | 25 | 1996-2000 | 1976-1985 |
| Asbestos | 2 | 2 | 9 | 10 | 1976-1985 | 1976-1985 |
| Barite | 5 | 4 | 40 | 37 | 1976-1985 | 1976-1985 |
| Chromium | 12 | 10 | 23 | 22 | 1996-2000 | 1976-1985 |
| Cobalt | - | - | - | - | - | - |
| Columbium | 18 | 13 | 35 | 31 | 1996-2000 | 1996-2000 |
| Copper | 2 | 2 | 20 | 18 | 1976-1985 | 1976-1985 |
| Feldspar | 4 | 3 | 22 | 21 | 1976-1985 | 1976-1985 |
| Flourspar | 4 | 4 | 25 | 23 | 1976-1985 | 1976-1985 |
| Gold | 5 | 4 | 14 | 12 | 1996-2000 | 1976-1985 |
| Gypsum | 19 | 11 | 42 | 32 | 1996-2000 | 1976-1985 |
| Iron ore | 3 | 2 | 16 | 13 | 1976-1985 | 1976-1985 |
| Lead | 6 | 4 | 22 | 20 | 1976-1985 | 1976-1985 |
| Manganese | 9 | 8 | 13 | 15 | 1976-1985 | 1976-1985 |
| Mercury | 3 | 2 | 11 | 13 | 1976-1985 | 1976-1985 |
| Molybdenum | 1 | 2 | 23 | 28 | 1996-2000 | 1996-2000 |
| Nickel | 5 | 5 | 22 | 19 | 1996-2000 | 1996-2000 |
| Platinum group | 3 | 3 | 20 | 23 | 1976-1985 | 1976-1985 |
| Silver | 10 | 7 | 41 | 36 | 1976-1985 | 1976-1985 |
| Sulfur | 2 | 2 | 19 | 19 | 1976-1985 | 1976-1985 |
| Tantalum | 81 | 63 | 95 | 84 | 1996-2000 | 1996-2000 |
| Titanium | 4 | 3 | 23 | 25 | 1976-1985 | 1976-1985 |
| Tungsten | 3 | 2 | 32 | 23 | 1996-2000 | 1976-1985 |
| Vanadium | 5 | 5 | 21 | 18 | 1976-1985 | 1976-1985 |
| Zinc | 3 | 3 | 17 | 17 | 1976-1985 | 1976-1985 |

^a Demand by the alternative synfuel, nuclear, and solar and other renewable technologies was added to Bureau of Mines total projected demand. Since demand by these alternative technologies varied between energy scenarios, the highest demand was used for analytical purposes.

- Not available.

Table 12. -- Strategic and Critical Minerals

| Mineral | U.S. import dependence | Potentially unreliable foreign source(s) | Few foreign sources | Inadequate domestic mine capacity | Energy intensified U.S. vulnerability | Energy essential |
|----------------|------------------------|--|---------------------|-----------------------------------|---------------------------------------|------------------|
| Aluminum Ores | x | | x | x | | x |
| Chromium | x | x | x | x | x | x |
| Cobalt | x | x | x | x | | x |
| Columbium | x | x | x | x | x | x |
| Gold | x | | x | x | x | x |
| Manganese | x | x | x | x | x | x |
| Nickel | x | | x | x | x | x |
| Platinum Group | x | x | x | x | | x |
| Tantalum | x | x | x | x | x | |
