Cycloheptatrienyl (tropyli) radical, C_7H_7 , was cleanly produced in the gas-phase, entrained in He or Ne carrier gas, and subjected to a set of flash-pyrolysis micro-reactors. The pyrolysis products resulting from C_7H_7 were detected and identified by vacuum ultraviolet photoionization mass spectrometry. Complementary product identification was provided by infrared absorption spectroscopy. Pyrolysis pressures in the micro-reactor were roughly 200 Torr and residence times were approximately 100 μ s. Thermal cracking of tropyli radical begins at 1100 K and the products from pyrolysis of C_7H_7 are only acetylene and cyclopentadienyl radicals. Tropyli radicals do not isomerize to benzyl radicals at reactor temperatures up to 1600 K. Heating samples of either cycloheptatriene or norbornadiene never produced tropyli (C_7H_7) radicals but rather only benzyl ($C_6H_5CH_2$). The thermal decomposition of benzyl radicals has been reconsidered without participation of tropyli radicals. There are at least three distinct pathways for pyrolysis of benzyl radical: the Benson fragmentation, the methyl-phenyl radical, and the bridgehead norbornadienyl radical. These three pathways account for the majority of the products detected following pyrolysis of all of the isotopomers: $C_6H_5CH_2$, $C_6H_5CD_2$, $C_6D_5CH_2$, and $C_6H_5^{13}CH_2$. Analysis of the temperature dependence for the pyrolysis of the isotopic species ($C_6H_5CD_2$, $C_6D_5CH_2$, and $C_6H_5^{13}CH_2$) suggests the Benson fragmentation and the norbornadienyl pathways open at reactor temperatures of 1300 K while the methyl-phenyl radical channel becomes active at slightly higher temperatures (1500 K). *Published by AIP Publishing*. I. INTRODUCTION

Resonance stabilized radicals are important in combustion processes because they are precursors to soot formation.¹ Modern transportation fuels include a large fraction^{2,3} of aromatics (benzene, toluene, xylenes, alkylbenzenes, and the like); see Fig. 3 of Ref. 4. Consequently, benzyl radicals ($C_6H_5CH_2$) are important intermediates in the high-temperature oxidation of these fuels. The pyrolysis of the benzyl radical has recently been examined^{5–7} and evidence was found for several complex decomposition pathways. Fig. 1 is an overview⁷ of the products that were detected following the pyrolysis of the $C_6H_5CH_2$ radical. A pathway for fragmentation of benzyl radical to fulvenallene and the fulvenallenyl radical was suggested⁸ by Benson in 1986. An isomer of the benzyl radical is the cycloheptatrienyl (or tropyli) radical, C_7H_7 . The relationship of tropyli to the benzyl radical is shown in Fig. 1. In the early literature, the interconversion of benzyl to tropyli ($C_6H_5CH_2 \rightleftharpoons C_7H_7$) was considered by several groups.^{9–15} However, all recent theoretical studies^{16–18} find no pathways below 2000 K for the isomerization of benzyl to tropyli. A photoionization search for the isomerization of the $C_6H_5CD_2$ benzyl radical to the $C_7H_5D_2$ tropyli radical with

tunable VUV radiation found no evidence for tropyli radical formation.⁷ To date, there are no experimental studies of the thermal decomposition of the tropyli radical, $C_7H_7 (+ M) \rightarrow$ products.

The focus of this paper is to generate authentic samples of the tropyli radical and to examine the pyrolysis pathways: $C_7H_7 (+ M) \rightarrow$ products. Earlier photoionization studies¹⁹ of the C_7H_7 radical found bitropyli, $C_7H_7-C_7H_7$, to be a convenient thermal precursor for tropyli. As sources of tropyli radicals, we have investigated the flash-pyrolysis of bitropyli, cycloheptatriene, and norbornadiene. The hydrocarbon samples were diluted in a carrier gas of He or Ne and subjected to pyrolysis in a heated silicon carbide (SiC) micro-reactor. The micro-reactor was resistively heated to temperatures up to 1600 K and operated at pressures of roughly 200 Torr. Approximate residence times²⁰ in the reactor are 100 μ s after which the gas mixture exits into a vacuum chamber at a pressure of 10^{-6} Torr. The resulting pyrolysis products are entrained in a molecular beam and are analyzed by a combination of photoionization mass spectrometry (PIMS) and matrix infrared (IR) absorption spectroscopy.

Because of its importance in organic chemistry, atmospheric chemistry, and combustion processes, the benzyl

FIG. 1. The Benson pathway⁸ for the pyrolysis of benzyl radical⁷ is shown. A possible link of the $\text{C}_6\text{H}_5\text{CH}_2$ radical to the C_7H_7 radical is indicated.

radical ($\text{C}_6\text{H}_5\text{CH}_2$, $\tilde{X}^2\text{B}_1$) has been extensively studied and a list of its properties is collected in Table 1 of Ref. 7. The tropylium radical (C_7H_7 , $\tilde{X}^2\text{E}_2''$) is not as well characterized experimentally. Because the tropylium radical has no electric dipole moment, there are no microwave spectra. To date, there are published laser induced fluorescence (LIF) spectra^{11,12} of the tropylium radical, an IR-UV double resonance study with a free electron laser,¹⁵ and preliminary helium nanodroplet IR absorption spectra.²¹ There is no definitive analysis of the infrared spectrum of C_7H_7 . Some of the available experimental properties of the tropylium radical are summarized in Table I.

This paper will demonstrate that pyrolysis of the tropylium radical only produces acetylene and the cyclopentadienyl radical. The tropylium radical does not isomerize to benzyl radical under any conditions observed in this work. As part of the final discussion, we will reconsider the thermal cracking of the $\text{C}_6\text{H}_5\text{CH}_2$ radical in the absence of C_7H_7 . We present three separate pathways for the pyrolysis of the benzyl radical that

seem to account for all of the current experimental findings, $\text{C}_6\text{H}_5\text{CH}_2 (+\text{M}) \rightarrow \text{products}$.

II. EXPERIMENTAL METHODS

A. Heated micro-reactor pyrolysis source

To carry out flash-pyrolysis of target molecules, we employ a resistively heated silicon carbide (SiC) reactor with an inner diameter (I.D.) of either 1.0 mm or 0.6 mm and a relatively short heated length, 10–15 mm. This geometry along with the present flow conditions allows²⁰ for short residence times of around 100 μs . At the exit of the reactor the gas is cooled as it expands into a vacuum chamber pumped to 10^{-4} – 10^{-6} Torr, where reactive collisions cease. To monitor the temperature of the reactor, a type-C thermocouple is attached to the reactor's outer wall using tantalum wire as described previously.²² The fluid mechanics of the heated micro-reactors were the subject of a recent detailed computational fluid dynamics investigation²⁰ that

modeled the pressure and temperature in the reactor at wall temperatures up to 1600 K. The findings in this study show that for a given set of reactor conditions and kinetic parameters, decomposition occurs within a small “sweet-spot” that can be as small as only a few mm of the total heated length. Another important finding was that the temperature, pressure, and thus decomposition rates can vary dramatically upon varying the experimental parameters, including: (1) carrier gas (argon, neon, and helium are all commonly used), (2) upstream and downstream pressure, and (3) mass flow rate, which can be controlled either by use of commercial mass flow controllers or with a pulsed valve. Therefore when comparing results from different experimental techniques, some variation is expected for the onset temperature of decomposition and/or the product ratios of competing decomposition pathways.

B. Photoionization mass spectroscopy

1. Pulsed VUV radiation

The 355 nm output light of a commercial Nd:YAG laser (Spectra Physics Pro-230-10) is focused into a tripling cell filled to 150 Torr with a 9:1 mixture of argon:xenon, which produces 118.2 nm (10.487 eV) photons. At the exit of the tripling cell is a MgF₂ lens used to focus the 118.2 nm

light into the interaction region of the Jordan time-of-flight spectrometer. This tripling process has been well-studied²³ and has an efficiency^{24,25} of around 1×10^{-5} . Additional losses are introduced by incomplete transmission of 118.2 nm light through the Mg₂F lens and intentional off-axis alignment through the lens to spatially separate 118.2 nm light from the remaining 355 nm light that exits the tripling cell, which can cause unwanted multiphoton ionization. As a result, laser powers of 10 mJ pulse⁻¹ at 355 nm yield roughly 10 nJ pulse⁻¹ of 118.2 nm. The region where the ionizing radiation and molecular beam are intersected is maintained at 10⁻⁷ Torr by a turbomolecular pump. Any molecule with ionization energy less than 10.487 eV is ionized and the resulting ions are accelerated into a reflectron time-of-flight spectrometer. In order to sustain sufficiently low pressure to maintain collisionless conditions, the gas flow must be pulsed with a Parker general valve operating at 10 Hz with 1 ms opening time. Backing pressures behind the pulsed valve are typically 2000 Torr of helium carrier gas and the pressure downstream of the reactor is typically 10⁻⁶ Torr, maintained by an 11-in. diffusion pump. Spectra shown in this work are the result of signal averaging of 1000 scans.

2. Continuous VUV radiation

A similar experimental setup for the micro-reactor scheme is used at the Chemical Dynamics Beamline endstation 9.0.2 at the advanced light source (ALS) in the Lawrence Berkeley National Laboratory. Using synchrotron light for PIMS adds a new experimental degree of freedom: tunable photon energy.²⁶ The energy of the synchrotron photons can be tuned between 7.4 eV and 30 eV, sufficiently high to ionize all species produced in the heated reactor. By measuring ion current at a single mass-to-charge ratio (*m/z*) while varying the photon energy and normalizing to the measured VUV power, it is possible to record photoionization spectra, which can be used to identify individual isomers that may be present. Signal averaging is used to increase signal-to-noise ratio; typical spectra are the composite of between 5×10^4 and 2×10^5 sweeps. To control the flow of gas through the reactor, an MKS mass flow controller is used along with a slightly smaller SiC reactor with an I.D. of 0.6 mm. Typical flow conditions include setting the flow controller to 200 standard cm³ min⁻¹ (sccm) backed by 5 atm of He. This yields pressures of 100 Torr between the mass flow controller and entrance of the reactor and roughly 10⁻⁴ Torr at the exit of the nozzle. With a 1 mm skimmer, the pressure in the ionization chamber can be maintained at roughly 5×10^{-6} Torr by a large turbomolecular pump.

C. Matrix isolation Fourier transform infrared spectroscopy

Since all polyatomic molecules possess characteristic vibrational spectra, IR spectroscopy is an excellent technique for identifying molecular species and serves as valuable complement to the PIMS experiments. The matrix IR spectrometer has been described before.^{27,28} Briefly, a 1 mm I.D. SiC reactor is coupled to a pulsed valve assembly very

similar to the PIMS system described above. The upstream pressure is between 800 and 1000 Torr, and with the pulsed valve operating with a roughly 1 ms opening time and 15 Hz repetition rate, the pressure at the reactor exit is typically 10^{-6} Torr, which is maintained with a small turbomolecular pump. The output of the reactor impinges on a cryogenically cooled CsI window 4 cm downstream that is maintained at 5 K by a helium cryostat. The carrier gas for this experiment is neon, which condenses into a solid matrix upon colliding with the 5 K window. A standard matrix is formed by flowing 200 Torr of sample mixture from a roughly 3 liter gas manifold, which leads to a deposition time of around 1 h. After dosing is complete, the reactor assembly is rotated 90° out of the way and the CsI window is lowered into the beampath of a commercial Fourier transform IR spectrometer (Nicolet 6700). The MCT-A detector has a spectral range of $4000\text{--}600\text{ cm}^{-1}$ and is operated with 0.25 cm^{-1} resolution, with typical spectra constructed by averaging 500 scans. Although the neon matrix is chemically inert, it does affect the vibrational spectra of entrained molecules. Average matrix shifts are on the order of $1\text{--}5\text{ cm}^{-1}$ from the unperturbed, gas-phase values.

D. Sample preparation

Pyrolysis of bitropyl (7,7'-bi(1,3,5-cycloheptatriene)) is a good source of the tropyli radical.¹⁹ Cleavage of the C—C bond produces two tropyli radicals,

The bond energy, $\text{DH}_{298}(\text{C}_7\text{H}_7\text{—C}_7\text{H}_7)$, was measured²⁹ to be $43 \pm 1\text{ kcal mol}^{-1}$. Bitropyl is solid at room temperature and was purchased from Sigma-Aldrich and used without further purification. Another tropyli precursor, cycloheptatriene (C_7H_8), was explored. The C—H bond strength³⁰ of cycloheptatriene is 74 kcal mol^{-1} and this implies that C_7H_8 could be an attractive thermal precursor for the tropyli radical; see Table I. Cycloheptatriene is a liquid at room temperature and was purchased from Sigma-Aldrich with a purity of 95% and used without further purification. A final potential precursor for tropyli radical to be considered is 2,5-norbornadiene. This hydrocarbon was purchased from Sigma-Aldrich with 98% purity and was used without further purification. All of the pyrolysis experiments use dilute gas samples with either helium or neon as the carrier gas. Previous work with SiC reactors^{7,31,32} has shown that bimolecular chemistry can obscure decomposition spectra so samples were made as dilute as possible while maintaining sufficient signal-to-noise. Typical dilutions are 0.1%–0.01%. For some experiments the dilution is difficult to control because the solid bitropyl precursor must be heated to $50\text{--}65^\circ\text{C}$ to achieve sufficient vapor pressure, depending on the gas flow rate and amount of sample surface area present. At the ALS, the sample was heated in a 1 cm I.D. glass test tube and He carrier gas was directed over the surface before traveling downstream to the reactor. The matrix IR experiments make use of a 1 mm I.D. glass vial that is inserted directly behind the pulse valve, where it is then heated. Pyrolysis appears to be unimolecular since no change in products was observed over a range of sample temperatures.

III. RESULTS AND DISCUSSION

Fig. 2 shows the 9.5 eV PIMS spectrum that results from a dilute sample of bitropyl being heated in a continuous flow micro-reactor to 600 K, where there should be no thermal decomposition of bitropyl. Earlier threshold photoelectron spectra of bitropyl reported¹⁹ ions at both m/z 91 and 182 with VUV photons of 8.7 eV. The 9.5 eV spectrum in Fig. 2 shows signals at m/z 91 and 104 only; there are no parent ions at m/z 182 indicating that the bitropyl sample is completely dissociatively ionized,

The m/z 91 ion is C_7H_7^+ while the smaller feature at m/z 104 remains unidentified but given its similar response to heating as other dissociative ionization products, we believe it is not a contaminant but rather that it stems from dissociative ionization of bitropyl. The results in Fig. 2 are consistent with earlier PIMS studies,²⁹ which revealed that the appearance energy for the C_7H_7^+ ion from bitropyl was $8.09 \pm 0.05\text{ eV}$. The extensive dissociative ionization in Fig. 2 results from the fragmentation of the $[\text{C}_7\text{H}_7\text{—C}_7\text{H}_7]^+$ cation into a pair of exceptionally stable products: $\tilde{X}^2\text{E}_2''\text{C}_7\text{H}_7$ and $\tilde{X}^+{}^1\text{A}_1'\text{C}_7\text{H}_7^+$, which is an aromatic cation.

Fig. 3 shows the PIMS spectra that result as bitropyl is heated in the micro-reactor up to 1500 K. As the sample is heated to 1100 K, the 11.8 eV PIMS reveals the appearance of a peak at m/z 26 (circled in red) that is shown to be HCCH^+ by PIE spectra. The signal at m/z 65 is assigned to C_5H_5^+ via PIE spectra at reactor temperatures of 1200 K and higher. At temperatures below 1100 K, signals at m/z

FIG. 2. The 9.5 eV PIMS spectra of bitropyl ($\text{C}_7\text{H}_7\text{—C}_7\text{H}_7$ m/z 182) pyrolyzed in a continuous flow micro-reactor heated to 600 K. The absence of a signal at m/z 182 indicates that the bitropyl sample is dissociatively ionized. The feature at 104 is the result of dissociative ionization of the precursor and is probably [styrene]⁺.

FIG. 3. PIMS spectra of bitropyl ($C_7H_7-C_7H_7$) recorded in a continuous flow micro-reactor at temperatures of 400 K, 1100 K, 1200 K, 1300 K, 1400 K, and 1500 K. Pyrolysis of tropyl ($C_7H_7 + M \rightarrow HCCH + C_5H_5$) commences at 1100 K as indicated by the small signal for $HCCH^+$ at m/z 26 (denoted with a red circle).

Bitropyl (C_7H_7)₂ Decomposition in CW He

FIG. 4. PIE (m/z 65) recorded during the thermal decomposition of bitropyl ($C_7H_7-C_7H_7$) in a continuous flow micro-reactor in He at 900 K, 1200 K, and 1500 K. The red trace is the PIE spectrum of the C_5H_5 radical recorded previously.³⁶ The ionization threshold³⁵ for $\tilde{X}^2E_1'$ C_5H_5 is indicated. There is no evidence for cyclopentadienyl radical being present at 900 K.

Bitropyl (C_7H_7)₂ Decomposition in Pulsed Neon

FIG. 5. Neon matrix absorption IR spectrum of the 1200 K pyrolysis of bitropyl ($C_7H_7-C_7H_7$) in a pulsed micro-reactor is shown in red. The presence of acetylene⁸³ is demonstrated by observation of the intense bands of $\nu_3(HCCH)$. The black trace is that of the bitropyl precursor, which is un-pyrolyzed at 400 K. The green trace is the background spectrum of pure Ne heated to 1100 K.

FIG. 6. PIMS spectra comparing the thermal decomposition of the benzyl radical and the tropyl radical. In both experiments the precursors (ethyl benzene and bitropyl) are decomposed in a continuous, 0.6 mm I.D. micro-reactor that is heated to 1500 K. No isomerization from the C_7H_7 radical to the more stable $C_6H_5CH_2$ is observed, as indicated by the paucity of benzyl decomposition products found in tropyl decomposition spectra.

65 arise from dissociative ionization. Since the ionization energy of acetylene is so large (11.4 eV, see Table I), the signal at m/z 26 will only arise from photoionization of thermally produced $\text{HC}\equiv\text{CH}$ and not from dissociative ionization. When molecules are ionized with excess photon energy, cations are formed with internal energy that can be used to fragment the cation to a daughter ion and a neutral fragment(s). Dissociative ionization pathways are generally governed by energetic considerations. A pathway that produces HCCH^+ and C_5H_5 will be energetically less favorable than one producing $\text{HCCH} + \text{C}_5\text{H}_5^+$ by 3 eV, given the difference in ionization energies ($\text{IE}(\text{HCCH}) = 11.4$ eV and $\text{IE}(\text{C}_5\text{H}_5) = 8.4$ eV). By recording PIMS at 11.8 eV, we conclude that the feature at m/z 65 results from dissociative ionization whenever the co-produced fragment, $\text{HC}\equiv\text{CH}$, is not detected. At 1100 K and hotter, the spectra imply thermal cracking of tropylium to acetylene and cyclopentadienyl,

As the reactor temperature is increased to 1500 K, the pyrolysis of tropylium radical is complete and m/z 91 is no longer present. At 1400 K, a 10.0 eV PIMS signal at m/z 39 is detected that is assigned to propargyl radical; the $\text{IE}(\text{HCCCH}_2)$ is 8.7 eV (see Table I). In earlier studies,^{7,33,34} it was observed that at

1300 K the cyclopentadienyl radical thermally dissociates to propargyl radical and acetylene,

The thermal decomposition of the tropylium radical from 1200 K up to 1500 K is remarkably simple. We observe features at m/z 65 and 26 that are predicted to be cyclopentadienyl and acetylene, consistent with Eq. (3) and Fig. 1. To confirm the identity of the feature at m/z 65, the PIE spectrum of m/z 65 was recorded between 8.0 and 10.5 eV; see Fig. 4. At 900 K and below there is no signal for PIE(m/z 65). At temperatures of 1200 K and above, the PIE for m/z 65 shows a threshold at 8.5 ± 0.1 eV, consistent with the observed³⁵ $\text{IE}(\text{C}_5\text{H}_5)$ of 8.4 eV (see Table I). The PIE(m/z 65) at 1200 K and 1500 K in Fig. 4 agrees with the PIE of an authentic sample³⁶ of C_5H_5 . The assignment of m/z 39 to the propargyl radical in Fig. 3 is also confirmed³⁷ by a measurement of the PIE(m/z 39). Both the threshold and the shape of the PIE(m/z 39) match the known³⁸ $\text{IE}(\text{HCCCH}_2)$ and photoionization cross section³⁹ of the propargyl radical.

Fig. 5 shows the neon matrix IR spectrum of the products of the thermal decomposition of bitropylium in a pulsed reactor at 1200 K. This vibrational spectrum confirms $\text{HC}\equiv\text{CH}$ as a pyrolysis product of tropylium radical. Both the PIE(m/z 65) spectrum in Fig. 4 and the IR spectrum in Fig. 5 confirm the products in Eq. (3).

Fig. 6 is a contrast between the pyrolysis products of ethylbenzene (top) and bitropylium (bottom). Both samples are thermally decomposed in a 0.6 mm I.D., continuous flow

Bitropylium (C_7H_7)₂ Decomposition in Pulsed Neon

FIG. 7. Neon matrix absorbance IR spectra of the pyrolysis of bitropylium (C_7H_7 — C_7H_7) in a pulsed micro-reactor at 400 K (thin black), 1000 K (thick black), 1100 K (thin red), and 1200 K (thick red). The feature at 3030 cm^{-1} is assigned as the bitropylium precursor. A new band at $3056 \pm 6\text{ cm}^{-1}$ is assigned to the C_7H_7 radical. This assignment is corroborated by the temperature dependence observed here and in the PIMS of Fig. 3. The green trace is a background spectrum of Ne heated to 1100 K.

Bitropylium (C_7H_7)₂ Decomposition in Pulsed Neon

FIG. 8. Neon matrix absorbance IR spectra of the pyrolysis of bitropylium at 400 K (thin black), 1000 K (thick black), 1100 K (thin red), and 1200 K (thick red). The absorption feature at $1451 \pm 1\text{ cm}^{-1}$ is assigned to the tropylium radical. The green scan is a background spectrum of Ne heated to 1100 K.

micro-reactor that is heated to 1500 K. The thermal cracking of $C_6H_5CH_2CH_3$ initially generates⁷ methyl radicals (m/z 15) and benzyl radicals (m/z 91). Subsequent fragmentation of the $C_6H_5CH_2$ radical leads to the complex set of products at m/z 26, 39, 50, 63, 65, 76, 78, 89, and 90 that are discussed in Ref. 7. Pyrolysis of bitropyl at the bottom of Fig. 6 produces C_7H_7 (m/z 91) and the fragmentation products from tropyli, C_5H_5 (m/z 65), and $HC\equiv CH$ (m/z 26). Propargyl radical, $HCCCH_2$ (m/z 39), results from the thermal cracking of the cyclopentadienyl radical, Eq. (4). The dramatic differences between these two PIMS spectra in Fig. 6 provide strong evidence that the tropyli radical does not isomerize to the benzyl radical.

A. Matrix isolation spectroscopy

Because of the extensive dissociative ionization of the tropyli radical precursor, $C_7H_7-C_7H_7$, the application of PIMS to study tropyli radical pyrolysis is somewhat limited. Photo-ions of the pyrolysis products will always be partially obscured by fragments of dissociative ionization. Consequently IR spectroscopy is a very useful complementary detection tool.

However, the matrix IR spectroscopy of tropyli radical has its own set of complications. There are no definitive vibrational spectra of the C_7H_7 radical in a matrix environment. The gas phase IR spectrum was recorded for the tropyli radical (formed in a discharge from cycloheptatriene) with an IR-UV double resonance technique¹⁵ that used the free electron laser “FELIX.” Several vibrational modes of tropyli were observed in the fingerprint region but none could be assigned. LIF spectroscopy¹² has been used to identify some of the modes of C_7H_7 , $\tilde{X}^2E_2''$. This study presented a vibrational analysis of the $\tilde{A}^2E_3'' \leftarrow \tilde{X}$ electronic spectrum and several gas phase modes of the ground $^2E_2''$ state were reported. Unfortunately, because of the nature of LIF spectroscopy, there is no information available regarding IR intensities for the ground state C_7H_7 , $\tilde{X}^2E_2''$ fundamentals. An important complication for studying tropyli radical in a neon matrix is the presence of the Jahn–Teller effect, which distorts the tropyli radical from the D_{7h} surface to the C_{2v} surface. The effect of inert gas matrices on Jahn–Teller distorted molecules is not easy to predict and is expected to cause greater perturbations from gas-phase frequencies.

In spite of these difficulties, matrix isolation IR spectroscopy is useful as a secondary confirmation for tropyli radical decomposition. The precursor used is bitropyl and the experiments were performed using neon as the carrier gas. Fig. 7 shows four scans taken at different reactor temperatures for bitropyl decomposition: 400 K, 1000 K, 1100 K, and 1200 K; as well as a scan of pure neon run at 1100 K as a control to rule out any systematic contaminants. The thin black trace shows an absorption feature from the precursor, which has not undergone decomposition at 400 K. This peak is significantly depleted upon heating to 1000 K (thick black line) and a strong, broad feature has developed centered at 3056 ± 6 cm^{-1} . Upon heating to 1100 K (thin red trace) and 1200 K (thick red trace), this new peak is depleted as tropyli radical thermally decomposes. The feature from the bitropyl precursor is completely absent by 1100 K. This temperature

dependence is in qualitative agreement with that observed in Fig. 3, although one could expect minor discrepancies due to differing carrier gas (Ne vs. He) and flow conditions (pulsed vs. continuous). None of the vibrational features for tropyli radical in the CH stretch region have been previously assigned. A recent helium nanodroplet²¹ study observed a pair of vibrational bands at 3052.9 cm^{-1} and 3057.4 cm^{-1} that are assigned to the tropyli radical. The helium nanodroplet spectra agree well with the matrix IR feature illustrated in Fig. 7. Fig. 8 shows an additional intense absorption feature appearing in the decomposition of bitropyl at 1451 cm^{-1} . This feature exhibits similar temperature dependence to that shown in Fig. 7; it is not observed at 400 K and is strongest at 1000 K and begins to decay at 1100 K and 1200 K.

Neither the 3056 cm^{-1} nor the 1451 cm^{-1} bands were observed in the spectra from benzyl decomposition⁷ nor were any vibrational assignments for benzyl radical observed in the tropyli radical decomposition spectra. This provides further confirmation that the benzyl and tropyli radicals do not interconvert, even at temperatures where both radicals thermally decompose.

B. Cycloheptatriene or norbornadiene as tropyli precursors?

In addition to bitropyl, cycloheptatriene (C_7H_8) was considered as a pyrolytic source of C_7H_7 . Cycloheptatriene has been successfully used as a precursor to prepare gas-

FIG. 9. Isomerizations^{40–43} of norbornadiene, norcaradiene, cycloheptatriene, and toluene.

phase tropy radical in discharge sources.^{10,12,15} However, shock tube studies⁴⁰ of high-temperature pyrolysis of cycloheptatriene demonstrate complete conversion of C_7H_8 to $C_6H_5CH_3$. A gas-phase, stirred-flow reactor was used⁴¹ to explore the isomerizations of norbornadiene, cycloheptatriene, and toluene. No intermediate radicals could be detected in this early study because the reaction products were detected by gas chromatography with flame ionization detection. Fig. 9 is a summary⁴² of the interconversions of norbornadiene, cycloheptatriene, and toluene. Norcaradiene⁴³ has been predicted as an intermediate in the equilibration of norbornadiene and cycloheptatriene. The first decomposition pathway of norbornadiene is the retro-Diels-Alder fragmentation to cyclopentadiene and acetylene. At higher temperatures, norbornadiene, norcaradiene, cycloheptatriene, and toluene all interconvert, where toluene is the most stable isomer.⁴¹

Fig. 10 shows the IR spectra of a dilute mixture of 0.05% cycloheptatriene in neon that was thermally decomposed in a pulsed micro-reactor. As predicted,⁴⁰ C_7H_8 isomerizes to toluene rather than forming tropy radical. This finding was confirmed by assigning 11 absorption features to gas-phase⁴⁴ $C_6H_5CH_3$. At 300 K the only feature in this spectral window is due to the precursor, cycloheptatriene, but upon heating, three new bands emerge. The three peaks are assigned⁴⁴ as ν_{11} at 730 cm^{-1} , ν_4 at 695 cm^{-1} , and ν_{18b}

0.05% Cycloheptatriene (C_7H_8) in Pulsed Neon

FIG. 10. The neon matrix absorbance IR spectrum of cycloheptatriene (C_7H_8) pyrolysis in a pulsed micro-reactor at 1300 K is shown in thick black. The thin black line is the absorbance spectrum of cycloheptatriene at 300 K. The 300 K spectrum shows only one feature belonging to C_7H_8 . Upon heating to 1300 K, the precursor feature has diminished and new bands are observed. All three are assigned as vibrations of toluene⁴⁵

at 1083 cm^{-1} , which agree well with the gas-phase values: $\nu_{11} = 728\text{ cm}^{-1}$, $\nu_4 = 695\text{ cm}^{-1}$, and $\nu_{18b} = 1080\text{ cm}^{-1}$. At the highest temperature (1500 K), a few small features are observed that are assigned to $C_6H_5CH_2$ including ν_7 (762 cm^{-1}) and ν_{13} (1308 cm^{-1}), in agreement with the argon matrix spectrum of benzyl radical.⁴⁵

The isomerization of C_7H_8 to $C_6H_5CH_3$ is confirmed by the 118.2 nm PIMS, shown in Fig. 11. In this experiment, cycloheptatriene is subjected to pyrolysis in a pulsed micro-reactor heated to 300 K, 1400 K, and 1600 K. The products shown at 1600 K are nearly identical to those observed from benzyl radical precursors⁷ but with a higher temperature for decomposition onset; compare with top panel of Fig. 6.

We also studied the decomposition of 2,5-norbornadiene (Fig. 12). The IE(2,5-norbornadiene) is less than 8.35 eV (Table I) and the initial scan (400 K) reveals a small amount of dissociative ionization: norbornadiene + 118.2 nm $\rightarrow C_6H_5CH_2^+$ (m/z 91) + H atom. At 1300 K, it is observed that norbornadiene undergoes a retro-Diels-Alder reaction: norbornadiene (+ M) $\rightarrow C_5H_6$ (m/z 66) + $HC\equiv CH$ (see Fig. 9). As the reactor is heated to 1600 K, it appears that 2,5-norbornadiene isomerizes to $C_6H_5CH_3$, which thermally dissociates to H atom and benzyl radical. The fragmentation of $C_6H_5CH_2$ (top scan in Fig. 12) is very similar to the pyrolysis pattern observed for norbornadiene (bottom Fig. 12). At higher reactor temperatures, the retro-Diels-Alder pathway is still active but is obscured by fragmentation of the product cyclopentadiene: C_5H_6 (+ M) $\rightarrow C_5H_5$ (m/z 65) + H. See Fig. 5 of Ref. 46.

FIG. 11. PIMS spectra from the pyrolysis of cycloheptatriene in pulsed helium are shown at three reactor temperatures, 300 K, 1400 K, and 1600 K. At 1400 K the expected fragmentation of tropy radical (see Fig. 3) is not observed. At 1600 K a set of products appears that is very similar to those characteristic⁷ of benzyl radical decomposition (see Fig. 6).

FIG. 12. PIMS spectra from the pyrolysis of norbornadiene in pulsed helium are shown at three reactor temperatures, 400 K, 1300 K, and 1600 K. At 1300 K norbornadiene undergoes a retro-Diels-Alder fragmentation and produces HCCH and C_5H_6 (m/z 66); bottom scan. At 1600 K a set of products appears that is very similar to those characteristics⁷ of benzyl radical decomposition; top scan uses $C_6H_5CH_2CH_3$ as a source of benzyl radical.

IV. CONCLUSIONS

The results of Figs. 3–8 eliminate any participation of the C_7H_7 radical from the pyrolysis pathways of the $C_6H_5CH_2$ radical at temperatures up to 1600 K. Tropanyl radical only decomposes to acetylene and the cyclopentadienyl radical, Eq. (3). These findings are consistent with the failure⁷ of tunable PIMS to detect C_7H_7 radicals as benzyl undergoes pyrolysis. Very recently, time-resolved PIMS spectroscopy was used⁴⁷ to study soot formation. The addition of acetylene to propargyl radical in a slow flow quartz reactor at (10 Torr/1000 K) was found to induce molecular weight growth via the sequence: $HC\equiv CH + HCCCH_2 \rightarrow C_5H_5 \rightarrow C_7H_7$. This is exactly the reverse of the pyrolysis reactions (3) and (4) above. We conclude this paper with a reconsideration of the pathways for the thermal fragmentation of benzyl radical based on all experimental findings.^{7,8,13,48–53}

The pyrolysis of the benzyl radical is a complex problem. None of the early experimental papers^{53–58} describing the pyrolysis of $C_6H_5CH_2$ were able to identify any of the thermal fragments except for the H atoms detected by ARAS.^{8,13} The only organic radicals resulting from pyrolysis of benzyl radical come from a few studies using heated micro-reactors outfitted with VUV PIMS.^{5–7}

The pyrolysis of toluene was studied⁵ in a quartz flow tube reactor at pressures of 8–15 Torr and temperatures of 1136–1507 K. A more recent study⁶ of toluene pyrolysis used a heated alumina (Al_2O_3) micro-reactor coupled to a VUV PIMS driven by tunable radiation from a synchrotron. The 248 nm photochemistry of benzyl radical has been studied⁵⁹ by photofragment translational spectroscopy. Dissociation

occurs following relaxation from the excited state⁶⁰ to the ground state, $C_6H_5CH_2$, $\tilde{X}^2B_1$, producing benzyl radicals ($C_6H_5CH_2$)* excited by 5 eV. The benzyl* radicals fragment to $H + C_7H_6$ and $CH_3 + C_6H_4$ radicals.

As mentioned in the Introduction, pyrolysis of either ethylbenzene or benzyl bromide in a heated SiC micro-reactor⁷ revealed an extended set of products that are summarized in Fig. 1. When $C_6H_5^{13}CH_2CH_3$ was heated⁷ to 1200 K, the labeled benzyl radical, $C_6H_5^{13}CH_2$, was produced. Decomposition of $C_6H_5^{13}CH_2$ at 1300 K produced a mixture of 12 cyclopentadienyl and 13 cyclopentadienyl radicals. One pathway to incorporate the ^{13}C label into the cyclopentadienyl radical would be isomerization of $C_6H_5^{13}CH_2$ to ^{13}C -labeled C_7H_7 (see Fig. 1). However, the use⁷ of 6.5 eV photons to search for the isomerization $C_6H_5CD_2 \rightarrow C_7H_5D_2$ detected no tropanyl radicals. This failure to observe C_7H_7 radicals did not conclusively prove that tropanyl is not present during the thermal cracking of benzyl radical. However, the current results in Figs. 3–8 demonstrate that clean samples of C_7H_7 radicals can be generated and that they fragment by a pathway independent of benzyl.

A. Pyrolysis of benzyl radical without tropanyl

In all the pyrolysis experiments performed on benzyl radicals⁷ or tropanyl radicals (this paper), care was taken to study dilute samples (0.1%–0.02% hydrocarbons in He or Ne). In the analysis of these results, we assume all fragmentation products result from unimolecular chemistry; there is no bimolecular chemistry to be analyzed. Pathways for the unimolecular, thermal decomposition of the benzyl radical are shown in Figs. 13 and 14. These schemes are based on the experimental findings from shock tubes with ARAS detection^{8,13} and heated micro-reactors monitored by PIMS and IR spectroscopy.⁷ Heating the $C_6H_5CH_2$ radical to 1300 K triggers an “extended” Benson fragmentation. The original suggestion⁸ only offered pathways for H atom loss and formation of the fulvenallenyl radical, $C_5H_4-C\equiv CH$. This mechanism⁸ also implies formation of the cyclopentadienyl radical and acetylene. The bicyclic radicals and vinylidene^{61,62} ($:C=CH_2$) in Fig. 13 will not be stable in the hot micro-reactor and are enclosed in brackets. The production of H atoms is known from both^{8,13} ARAS and PIMS spectra.⁷

The Benson fragmentation in Fig. 13 leads to formation of the cyclopentadienyl and the fulvenallenyl radicals (one could view $C_5H_4-C\equiv CH$ as a substituted cyclopentadienyl radical). As shown in Eq. (4), C_5H_5 decomposes to acetylene and propargyl radicals at 1300 K. Likewise the fulvenallenyl radical has been observed^{63,64} to decompose to propargyl radical and diacetylene. This can be summarized,³⁷

The presence of the cyclopentadienyl radical and $\text{HC}\equiv\text{CH}$ is confirmed by PIMS, PIE, and IR spectroscopy.⁷ PIMS and PIE spectroscopy also detect both $\text{C}_5\text{H}_4=\text{C}=\text{CH}_2$ and $\text{C}_5\text{H}_4-\text{C}\equiv\text{CH}$. The presence of fulvenallene is additionally confirmed by IR spectroscopy. PIMS and IR spectroscopy clearly identify the propargyl radical, HCCCH_2 . PIMS signals at m/z 50 and 63 are consistent with the presence of $\text{HC}\equiv\text{C}-\text{C}\equiv\text{CH}$ and the two radicals, $\text{CH}_2-\text{C}\equiv\text{C}-\text{C}\equiv\text{CH}$ and $\text{HC}\equiv\text{C}-\text{CH}-\text{C}\equiv\text{CH}$. However, neither the PIE nor IR spectra could distinguish between the $(\text{CH}_2-\text{C}\equiv\text{C}-\text{C}\equiv\text{CH}, \text{HC}\equiv\text{C}-\text{CH}-\text{C}\equiv\text{CH})$ pair.

The Benson fragmentation predicts loss of H atom from $\text{C}_6\text{H}_5\text{CH}_2$ to produce a pair of isomers, $\text{C}_5\text{H}_4=\text{C}=\text{CH}_2$ and $\text{C}_5\text{H}_5-\text{C}\equiv\text{CH}$, both at m/z 90. Recently pyrolysis of $\text{C}_6\text{H}_5\text{CD}_2$ in a shock tube with ARAS detection¹³ revealed the formation of both H and D atoms in agreement with this prediction. Pyrolysis of $\text{C}_6\text{H}_5\text{CD}_2\text{CD}_3$ in a micro-reactor⁷ provided further support with the detection of both $\text{C}_5\text{H}_4=\text{C}=\text{CD}_2$ (m/z 92) and $\text{C}_5\text{H}_5-\text{C}\equiv\text{CD}$ (m/z 91).

The Benson fragmentation shown in Fig. 13 cannot be the complete story for the thermal cracking of the benzyl radical. PIMS and PIE spectra confirm⁷ that heating $\text{C}_6\text{H}_5^{13}\text{CH}_2$ radicals to 1300 K produces $^{13}\text{CH}_3$, ^{13}C -labeled C_5H_5 , and $o\text{-C}_6\text{H}_4$; these products cannot be explained by Benson's mechanism.⁸ Fig. 14 shows two additional pathways

FIG. 13. The “extended” Benson fragmentation of the benzyl radical, $\text{C}_6\text{H}_5\text{CH}_2$, $\tilde{X}^2\text{B}_1$. The original mechanism⁸ provided pathways for H atom loss and formation of the fulvenallenyl radical, $\text{C}_5\text{H}_4-\text{C}\equiv\text{CH}$. This suggestion also implies formation of the cyclopentadienyl radical and acetylene. The bicyclic radicals and vinylidene ($:\text{C}=\text{CH}_2$) will not be stable in the hot micro-reactor and are enclosed in brackets. The tropyli radical, C_7H_7 , $\tilde{X}^2\text{E}_2''$, does not participate.

FIG. 14. Fragmentation pathways of the benzyl radical, $\text{C}_6\text{H}_5\text{CH}_2$, $\tilde{X}^2\text{B}_1$, are shown. The internal H-atom abstraction from the ring that leads to the formation of the α methyl-phenyl radical will be endothermic⁷² by roughly 1 eV. This process also requires a curve-crossing from the $^2\text{B}_1$ benzyl (π radical) to the $^2\text{A}'$ methyl-phenyl (σ radical). Decomposition of the α methyl-phenyl radical produces CH_3 and $o\text{-C}_6\text{H}_4$. A second pathway is the isomerization of benzyl to the bridgehead norbornadienyl radical. The α methyl-phenyl radicals, bridgehead norbornadienyl radicals, and $^2\text{A}'$ cyclopentadienyl radicals will not be stable in the hot micro-reactor and are enclosed in brackets. The tropyli radical, C_7H_7 , $\tilde{X}^2\text{E}_2''$, does not participate.

for thermal cracking of benzyl radicals that address these products.

The pyrolysis of $\text{C}_6\text{H}_5^{13}\text{CH}_2$ produces⁷ both $^{13}\text{CH}_3$ (m/z 16) and $o\text{-C}_6\text{H}_4$ (m/z 76). These products could be the result of an isomerization of the 13 [benzyl] radicals to the $[\alpha\text{-}^{13}\text{methyl-phenyl}]$ radicals in Fig. 14. The isomerization would be initiated by H-abstraction from the aromatic ring by the $-\text{CH}_2$ side chain. Such an abstraction would be difficult because of a required ($\pi \rightarrow \sigma$) curve-crossing ($\text{C}_6\text{H}_5\text{CH}_2$, $^2\text{B}_1 \rightarrow \text{C}_6\text{H}_4\text{CH}_3$, $^2\text{A}'$). In addition the internal abstraction will be endothermic by about 1 eV because of the difference in the $\text{C}_6\text{H}_5\text{CH}_2-\text{H}$ and $\text{C}_6\text{H}_5-\text{H}$ bond energies (see Table I). Formation of the $\text{C}_6\text{H}_4\text{CH}_3$, $^2\text{A}'$ radical in Fig. 14 will be followed by rapid fragmentation to the methyl and o -benzyne radicals and both are confirmed to be present.⁶⁵ Heating $o\text{-C}_6\text{H}_4$ to high temperatures is known⁶⁶ to trigger fragmentation to $\text{HC}\equiv\text{CH}$ and $\text{HC}\equiv\text{C}-\text{C}\equiv\text{CH}$. The pyrolysis reactions of both the $\text{C}_6\text{H}_5\text{CD}_2$ and $\text{C}_6\text{D}_5\text{CH}_2$ radicals are consistent with this pathway.⁷ Decomposition of $\text{C}_6\text{H}_5\text{CD}_2$ radicals at 1500 K forms small quantities of the CD_2H (m/z 17) radicals while heating $\text{C}_6\text{D}_5\text{CH}_2$ radicals to 1400 K leads to appearance of CH_2D (m/z 16) radicals.

A second pathway for fragmentation of the benzyl radical shown in Fig. 14 is isomerization of $\text{C}_6\text{H}_5\text{CH}_2$ to the bridgehead, norbornadienyl radical. Such a bridgehead radical would suffer a retro-Diels-Alder fragmentation producing $\text{HC}\equiv\text{CH}$ and the $^2\text{A}'$ C_5H_5 radical. The planar (σ) $^2\text{A}'$ C_5H_5

radical is certainly the initial adduct in the reaction^{67,68} of propargyl with acetylene and it rapidly isomerizes to the ground state, cyclopentadienyl radical, C_5H_5 , $\bar{X}^2E_1''$. The ^{13}C [norbornadienyl] radical will automatically incorporate the ^{13}C label into the cyclopentadienyl radical, as observed in Fig. 13 of Ref. 7.

The pyrolysis pathways for $C_6H_5CH_2$ shown in Figs. 13 and 14 are consistent with all of the major peaks of the PIMS in Fig. 2 of Ref. 7. The corresponding pathways for the isotopically substituted benzyl radicals, $C_6H_5CD_2$, $C_6D_5CH_2$, and $C_6H_5^{13}CH_2$ are contained in Figs. S1–S6 in the supplementary material.⁶⁹ As in the case of the parent benzyl radical, these predicted $C_6H_5CD_2$, $C_6D_5CH_2$, and $C_6H_5^{13}CH_2$ pathways⁶⁹ can be used to assign the major peaks of the experimental PIMS spectra in Figs. 8, 10, and 11 of Ref. 7.

A recent paper¹⁸ applied *metadynamics* to the pyrolysis of benzyl. These calculations suggested that both C_5H_5 and its isomer, $(CH_2)_2C\equiv C$, are intermediates in the high temperature pyrolysis of benzyl. The $IE(C_5H_5)$ is measured to be 8.4 eV (see Table I) and the measured⁷ $PIE(m/z\ 65)$ has its threshold at 8.4 ± 0.1 eV. The $IE(HC\equiv C-C(CH_2)_2)$ is not measured but it is likely less than that of the allyl radical, 8.1 eV (see Table I). The $PIE(m/z\ 65)$ resulting from the thermal cracking of the $C_6H_5CH_2$ radical indicates that there is little (or no) $(CH_2)_2C\equiv C$ present in the pyrolysis of benzyl. It was also predicted by the *metadynamics* calculations¹⁸ that the initial $C_6H_5CH_2$ radicals could isomerize to a pair of isomeric, dimethylene-cyclopentenyl radicals. The spectroscopic probes of Ref. 7 could not confirm the presence of these two isomers.

There are small features at $m/z\ 41, 51, 64, 77$, and 78 present in the PIMS of $C_6H_5CH_2$ (Fig. 2 of Ref. 7) that cannot be rationalized by either pathways of Figs. 13 and 14. The peaks at $m/z\ 77$ and 78 are likely the phenyl radical (C_6H_5) and benzene. There is a theoretical calculation that predicts⁶⁴ a small channel for pyrolysis of fulvenallene to $(C_5H_4 + HC\equiv CH)$. The singlet carbene (C_5H_4) is consistent with the peak at $m/z\ 64$.

There are small bands in the 118.2 nm PIMS spectra of $C_6H_5CD_2$ and $C_6D_5CH_2$ (Figs. 8 and 10 of Ref. 7) that suggest an interesting subtlety to the α methyl-phenyl radical in Fig. 14. Perhaps there is some equilibration of benzyl radicals with the α methyl-phenyl radicals? If so, then the $C_6H_5CD_2$ and $C_6D_5CH_2$ radicals will scramble: $C_6H_5CD_2 \rightleftharpoons [C_6H_4-CHD_2] \rightleftharpoons C_6H_4D-CHD$. Application of the [Benson fragmentation, methyl-phenyl, norbornadienyl] pathways to the o - C_6H_4D-CHD radical leads to the formation of complex set of labeled (fulvenallenes, ethynyl cyclopentadienes, and fulvenallenyl) radicals.³⁷ Fragmentation of these radicals predicts formation of $C_5H_4-C\equiv CH$ ($m/z\ 89$), C_5H_4D (cyclopentadienyl radical- d_1 , $m/z\ 66$), o - C_6H_3D (o -benzyne, $m/z\ 77$), $HC\equiv C-CH-C\equiv CH$ ($m/z\ 63$), and $DC\equiv C-C\equiv CD$ ($m/z\ 52$). There are signals in Fig. 8 of Ref. 7 that are compatible with these radicals. A similar scrambling of benzyl radical- d_5 ($C_6D_5CH_2 \rightleftharpoons [C_6D_4-CDH_2] \rightleftharpoons C_6D_4H-CHD$) leads to production of $C_5H_3D-C\equiv CH$ ($m/z\ 92$), C_5D_4H ($m/z\ 69$), o - C_6D_3H ($m/z\ 79$), and $(DC\equiv C-C\equiv C-CD_2$ or $DC\equiv C-CD-C\equiv CD)$ m/z

66. Weak features for all of these radicals are present in Fig. 10 of Ref. 7.

Examination of the isotopic spectra for pyrolysis of benzyl radical permits a rough estimation of the energetics of the three decomposition pathways for benzyl radical. It appears that two channels (Benson fragmentation and the bridgehead norbornadienyl radical) open at roughly the same reactor temperature. The methyl-phenyl radical channel becomes active at slightly higher temperatures. The PIMS spectrum of $C_6H_5^{13}CH_2$ (Fig. 11 in Ref. 7) demonstrates that benzyl radical decomposition begins at 1300 K. The Benson fragmentation products 13 (fulvenallene, $m/z\ 91$) and 13 (fulvenallenyl, $m/z\ 90$) are both observed. The norbornadienyl pathway produces 13 (cyclopentadienyl, $m/z\ 66$) while the methyl-phenyl radical channel generates $^{13}(CH_3, m/z\ 16)$ and both species are also present. For the case of the $C_6H_5CD_2$ radical, Fig. 8 of Ref. 7, radical decomposition is underway at 1300 K and products of the Benson fragmentation ($m/z\ 91, 92$, and 90) are present as well as cyclopentadienyl- d_2 ($m/z\ 67$) resulting from the norbornadienyl channel. Products from the methyl-phenyl radical channel, CHD_2 ($m/z\ 17$) and o - C_6H_4 ($m/z\ 76$), appear at 1500 K. Decomposition of the $C_6D_5CH_2$ radical (Fig. 10 of Ref. 7) yields a similar result; radicals from the methyl-phenyl radical channel, CDH_2 ($m/z\ 16$) and o - C_6D_4 ($m/z\ 80$), are detected at 1500 K. At 1300 K evidence of the Benson fragmentation ($m/z\ 94, 95, 93$) and the norbornadienyl route (cyclopentadienyl radical- d_3 , $m/z\ 68$) is evident. Qualitatively it appears that the Benson fragmentation and the norbornadienyl channels become activated at 1300 K while the methyl-phenyl radical pathway is present at 1500 K.

In principle it is possible to use the experimental results of the micro-reactor from this paper and Ref. 7 to put some bounds on the pyrolysis kinetics of the benzyl radical. As summarized in Figs. 13 and 14, there are at least three thermal decomposition pathways for the $C_6H_5CH_2$ radical. These are represented by Eqs. (6)–(8),

If the residence time in the micro-reactor is roughly 0.1 ms, then reactions with a rate of less than $10^3\ s^{-1}$ will not be observed while reactions with rates greater than $10^5\ s^{-1}$ will appear to be complete. The *effective* transit time (i.e., residence in the “sweet spot”) is even shorter, which puts a lower limit on the rate coefficients of the processes that can be observed. If kinetic modeling can provide a set of pre-exponential factors for Eqs. (6)–(8) or other reactions, then the residence time and the reactor temperature will put a bound on the heights of the barriers that this experiment can detect. Such estimates will require detailed computational fluid dynamics modeling of the SiC micro-reactor to find realistic residence times as well as the gas pressures and temperatures. This is an intriguing notion but is beyond the scope of this paper.

The decomposition of benzyl radical with its three distinct pyrolysis pathways (shown in Figs. 13 and 14) is

complicated. Nevertheless, the proposed mechanisms offer a set of predictions for the thermal cracking of more complex aromatic compounds that are included in surrogate fuel mixtures. Aviation fuels are composed of mixtures of a very large number of chemical components.⁷⁰ The detailed numerical simulation of real combustion fuels is currently too difficult to apply to any fuel that is not a pure component or a mixture of only a few species. One way to circumvent this problem is to study surrogate fuels. Such surrogate fuels should be comprised of a handful of components but be capable of emulating the gas phase combustion characteristics of the real fuel of interest. The advantage, of course, is that the resulting reaction mechanism will be a much more manageable size. A surrogate fuel for aviation diesels has been proposed⁷⁰ that is a mixture of ten compounds. This mixture includes 6 alkanes (*n*-decane, *n*-dodecane, iso-octane, iso-cetane, methyl cyclohexane, and *n*-butyl cyclohexane) and 4 aromatic species (toluene, *n*-propyl benzene, 1,3,5-trimethyl benzene, and 1-methyl naphthalene). Three of these species ($C_6H_5-CH_3$, $C_6H_3(CH_3)_3$, and $C_6H_5-CH_2CH_2H_3$) would be predicted to pyrolyze to benzyl radicals. The decomposition pathways for $C_6H_5CH_2$ in Figs. 13 and 14 will be relevant to these surrogates.

ACKNOWLEDGMENTS

We congratulate Professor Dr. Jürgen Troe on his appointment as the Benson Lecturer at the 24th *International Symposium on Gas Kinetics and Related Phenomena*, July 2016. The authors gratefully acknowledge the extensive helpful discussions with Nicole Labbe, Raghu Sivaramakrishnan, Hans-Heinrich Carstensen, John D. Savee, Veronica M. Bierbaum, and John F. Stanton. We are also in the debt of an anonymous referee for several useful suggestions. We acknowledge support from the National Science Foundation (Grant Nos. CHE-1112466 and CBET-1403979) to J.P.P., G.T.B., J.W.D., and G.B.E. G.T.B. was also funded by the Marion L. Sharrah Memorial Fund at the University of Colorado. M.A., O.K., and T.P.T. and the Advanced Light Source are supported by the Director, Office of Energy Research, Office of Basic Energy Sciences, and Chemical Sciences Division of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. D.J.R. and M.R.N. are supported by United States Department of Energy's Bioenergy Technology Office, under Contract No. DE-AC36-99GO10337 with the Sciences Division of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

- ⁸³T. Shimanouchi, *Tables of Vibrational Frequencies, Consolidated Vol. I*, NSRDS-NBS Vol. 39, p. 1972. The IR active modes of acetylene in an Ar matrix are slightly shifted from their gas-phase values. For the case of $\text{HC}\equiv\text{CH}$ the Ar matrix frequencies are $\sigma_u \nu_3 = 3302 \text{ cm}^{-1}$ and 3288 cm^{-1} (splitting by the Darling-Dennison resonance is 14 cm^{-1} in the cryogenic matrix) and the $\pi_u \nu_5$ is 736.8 cm^{-1} . For $\text{DC}\equiv\text{CD}$ the matrix frequencies are $\sigma_u \nu_3 = 2442 \text{ cm}^{-1}$ and $\pi_u \nu_5$ is 736.8 cm^{-1} . The symmetry is broken in acetylene- d_1 , $\text{HC}\equiv\text{CD}$. The matrix frequencies are $\sigma^+ \nu_1 = 3340 \text{ cm}^{-1}$, $\sigma^+ \nu_2 = 1854 \text{ cm}^{-1}$, $\sigma^+ \nu_3 = 2586 \text{ cm}^{-1}$, $\pi \nu_4 = 518 \text{ cm}^{-1}$, and $\pi \nu_5 = 683 \text{ cm}^{-1}$.
