ABSTRACT: This paper describes a test setup and methodology for centrifuge modeling of energy pile pullout from saturated soft clay, with the goal of understanding how pile heating improves the interface shear strength through thermal consolidation. A kaolinite clay layer was first consolidated outside the centrifuge within a cylindrical container having an inner diameter of 551 mm using a hydraulic piston to reach a thickness of 220-240 mm then permitted to equilibrate in the centrifuge under 50 g. An aluminum energy pile having a model-scale diameter of 25 mm and length of 255 mm was then installed at a constant displacement rate through the clay layer and embedded into an underlying sand layer. An electrical resistance heater within the pile was used to heat the soil-pile interface to a target temperature and thermocouples and pore water pressure transducers in the clay layer were used to track the coupled heat transfer and water flow processes. Detailed results are reported from a baseline test on an unheated pile and from a test on a pile where pullout was performed after heating the pile from 20 to 65 °C and cooling back to 20 °C with no head restraint. The pullout capacity of the heated energy pile was 1.43 times greater than that of the unheated energy pile. Insights into the increase in capacity were gained from undrained shear strength profiles in the clay layers measured using push-pull T-bar penetration tests performed after pullout.

KEYWORDS: Energy piles, soft clay, pullout, centrifuge modeling, thermal consolidation

24 INTRODUCTION

25 Because of their relatively low undrained shear strength and high compressibility, soft clay
26 deposits routinely pose challenges to geotechnical engineers interested in improving the axial load-
27 carrying capacity of deep foundations or piles. Beyond increasing the dimensions or mass of piles,
28 several techniques have been used to increase the pullout capacity of piles by enhancing the
29 mechanical behavior of the surrounding soft clay layer, including preconsolidation with a
30 surcharge or vacuum loading, installation of vertical drains, or electro-osmosis (Nicholson 2015).
31 While these soil improvement techniques have been shown to work well for soft clay deposits on
32 land, they may be difficult to implement in offshore clay deposits. Accordingly, increasing the
33 pullout capacity of offshore piles in soft clays used as anchors for floating structures is particularly
34 important to avoid having to install additional piles to meet the required anchorage support. A
35 promising soil improvement technique may be to convert deep foundation into an energy pile that
36 can be used to strategically heat the surrounding soil and improve its mechanical behavior via
37 thermal consolidation. Thermal consolidation has been used successfully to densify soft clays
38 using arrays of geothermal heat exchangers (Bergentahl et al. 1994) or thermal drains (Abuel-
39 Naga et al. 2006; Pothiraksanon et al. 2010; Artidteang et al. 2011; Salager et al. 2012), but has
40 not yet been investigated for energy piles in soft clays. While several studies have investigated the
41 behavior of energy piles in soft clays (Ng et al. 2014; Yazdani et al. 2019, 2020), they considered
42 temperature ranges representative of heat exchange applications (maximum temperatures of 34-
43 38 °C) that are lower than those necessary for thermal improvement (e.g., temperatures of 60-
44 80 °C were used by Bergentahl et al. 1994).

45 This study proposes a thermal soil improvement concept that builds upon but also deviates
46 from recent research on energy piles, where closed-loop fluid circulation pipes are embedded into

1
2
3 47 a reinforced concrete pile to convert it to a geothermal heat exchanger (Brandl 2006). Most studies
4
5 48 on energy piles have focused on the behavior of energy piles in relatively stiff soil deposits with
6
7 49 downward axial loading under temperatures ranging from 5 to 40 °C (e.g., Brandl 2006; Laloui et
8
9
10 50 al. 2006; Bourne-Webb et al. 2009; Murphy et al. 2015; Murphy and McCartney 2015; McCartney
11
12 51 and Murphy 2017). When simulating energy piles in stiff soil deposits it is often assumed that the
13
14 52 soil is thermo-elastic (e.g., Laloui et al. 2006). While nonlinear interface stress-displacement
15
16 53 curves have been considered in load-transfer analyses (e.g., Knellwolf et al. 2011; Chen and
17
18
19 54 McCartney 2016), these studies did not consider elasto-plastic changes in the stress-displacement
20
21 55 curve with temperature associated with thermal consolidation. Different from typical energy pile
22
23 56 heat exchange operations, the concept of soil improvement using energy piles proposed in this
24
25 57 study is to increase the temperature of the pile by a target increment and maintain this elevated
26
27 58 temperature for a certain time before cooling back to ambient temperature after thermal
28
29 59 consolidation is complete. An electrical or chemical heating element may be used in the pile in the
30
31 60 case that heat exchange tubing cannot be installed. The imposed change in temperature should be
32
33 61 significant enough to lead to appreciable thermal consolidation (i.e., 60 to 80 °C), but not so high
34
35 62 as to risk thermal failure where the change in pore water pressure approaches the mean total stress
36
37 63 (Houston et al. 1985). This change in temperature of the pile, which is assumed to be uniform with
38
39 64 depth based on observations from instrumented energy piles (e.g., Murphy et al. 2015), is expected
40
41 65 to result in thermal pressurization and generation of excess pore water pressure due to the
42
43 66 differential thermal expansion of the clay particles and water (Campanella and Mitchell 1968).
44
45 67 This change in pore water pressure may increase with depth (Uchaipichat and Khalili 2009;
46
47 68 Ghaaowd et al. 2017). Ghaaowd et al. (2017) reviewed several studies on undrained heating from
48
49 69 the literature and found that the magnitude of excess pore water pressure generation depends on
50
51
52
53
54
55
56
57
58
59
60

1
2
3 70 the plasticity index of the clay as well as the stress state and initial void ratio. As soon as thermally
4
5 71 induced excess pore water pressures are generated, water flow will occur away from the heat
6
7
8 72 source (the energy pile) and the excess pore water pressure will decrease with time until returning
9
10 73 to hydrostatic conditions. Accordingly, fully undrained heating is not expected and depending on
11
12 74 the permeability of the soil, the heating process may result in partial drainage where excess pore
13
14
15 75 water pressures dissipate as it is generated and do not reach the magnitudes predicted using
16
17 76 approaches like Campanella and Mitchell (1968) or Ghaaowd et al. (2017).

18
19 77 The generation and dissipation of excess pore water pressure in saturated soils is known to be
20
21 78 closely coupled with changes in volume, which are in turn coupled with changes in undrained
22
23
24 79 shear strength (e.g., Houston et al. 1995; Samarakoon et al. 2018). Undrained heating of soils leads
25
26 80 to elastic thermal expansion (e.g., Uchaipichat and Khalili 2009). Berghenstahl et al. (1994)
27
28 81 observed an initial thermal expansion of a normally consolidated clay layer immediately after
29
30
31 82 heating before drainage started to occur. As the thermally-induced excess pore water pressures
32
33 83 dissipate, permanent volume changes may occur depending on the stress history of the soil layer.
34
35 84 Of greatest interest to this study are normally consolidated soils, which will contract volumetrically
36
37
38 85 during drainage of thermally induced excess pore water pressures, or during drained heating
39
40 86 (where the rate of heating is so slow that excess pore water pressures dissipate as soon as they are
41
42 87 generated). Attaining this volumetric contraction is the main objective of the thermal soil
43
44
45 88 improvement process. Accordingly, it is important that the increased temperature be maintained
46
47 89 until thermo-hydraulic equilibrium is reached and thermal volume changes are stabilized, as
48
49 90 premature cooling will reduce the thermally induced excess pore water pressures that drive the
50
51 91 thermal improvement process.

1
2
3 92 A wealth of experience on the volume change of saturated clays during drained heating from
4
5 93 element-scale tests has been established in the literature (Baldi et al. 1988; Towhata et al. 1993;
6
7 94 Hueckel et al. 1998; Burghignoli et al. 2000; Sultan et al. 2003; Cekerevac et al. 2005; Abuel-
8
9 95 Naga et al. 2007a, 2007b; Takai et al. 2016; Samarakoon et al. 2018; Zeinali and Abdelaziz 2021).
10
11 96 The studies indicate that normally consolidated clays experience a plastic contractile volumetric
12
13 97 strain of approximately 1 to 2% during heating to temperatures up to 90 °C, depending on the clay
14
15 98 mineralogy and initial void ratio. While overconsolidated soils will experience excess pore water
16
17 99 pressure generation during undrained heating similar to normally consolidated soils, they show a
18
19 100 transitional response in volume change during drained heating (Baldi et al. 1988; Vega and
20
21 101 McCartney 2015). For example, lightly overconsolidated clays may contract by a smaller amount
22
23 102 than normally consolidated clays during drained heating, while heavily overconsolidated clays will
24
25 103 expand elastically during drained heating. Accordingly, this thermal improvement technique is
26
27 104 most appropriate for normally consolidated and lightly overconsolidated soils. The results from
28
29 105 the literature also indicate that after reaching thermo-hydraulic equilibrium, further volumetric
30
31 106 contraction may occur during cooling due to elastic contraction, depending on the rate of cooling.
32
33 107 In some cases, a partial recovery of thermal strains can occur for fast cooling (e.g., Samarakoon
34
35 108 and McCartney 2020). The cumulative decrease in void ratio of the clay following a heating-
36
37 109 cooling cycle will lead to an increase in the undrained shear strength of the clay (Houston et al.
38
39 110 1985; Samarakoon et al. 2018). This change in undrained shear strength of the soil surrounding an
40
41 111 energy pile will result in a change in ultimate bearing capacity, and for the case of offshore
42
43 112 foundations used as anchors it will result in an increase in pullout capacity.

46
47
48
49
50

51 113 The process of soil improvement using in-situ heating in saturated, normally consolidated clays
52
53 114 is expected to be a complex, coupled thermo-hydro-mechanical process. Heat transfer in saturated
54
55
56
57
58
59
60

1
2
3 115 soils may be due to a combination of both conduction and convection, as changes in the pore water
4
5 116 density with temperature may lead to buoyancy-driven water flow. However, Savvidou (1988)
6
7 117 found that for clays with low hydraulic conductivity, heat transfer due to convection will be slower
8
9 118 than that due to conduction. Accordingly, this study only considers conductive heat transfer.
10
11 119 Generation of excess pore water pressures will lead to flow of water away from the heat source
12
13 120 (the pile), leading to time-dependent thermal consolidation (Booker and Savvidou 1985; Zeinali
14
15 121 and Abdelaziz 2021). Thermal volumetric contraction will lead to a decrease in hydraulic
16
17 122 conductivity, which may slow the improvement process. However, thermal volumetric contraction
18
19 123 will also lead to an increase in thermal conductivity, affecting the heat transfer process. The zone
20
21 124 of influence of the thermal consolidation process will depend on the applied temperature boundary
22
23 125 condition (magnitude and duration) as well as the characteristics of the surrounding soil. But for
24
25 126 normally consolidated soils an improvement is expected in the same zone of influence as a change
26
27 127 in temperature.
28

30
31
32

33 128 The centrifuge physical modeling methodology developed in this study builds upon previous
34
35 129 work on the consideration of temperature effects in soft clays. Maddocks and Savvidou (1984)
36
37 130 investigated the heat transfer from a hot cylinder installed in soft saturated clay in a centrifuge test,
38
39 131 and observed the generation and dissipation of excess pore water pressure and subsequent thermal
40
41 132 consolidation as a function of distance from the cylinder. Ng et al. (2014) used a centrifuge to
42
43 133 study the effects of cyclic heating of an aluminum energy pile in soft clay and observed permanent
44
45 134 settlement that accumulated with each cycle. Ng et al. (2019) found that heat transfer in clays due
46
47 135 to conduction was not affected by the g-level and confirmed the scaling factor for diffusive time
48
49 136 of N^2 derived by Savvidou (1988). Stewart and McCartney (2014) and Goode and McCartney
50
51 137 (2015) found that centrifuge modeling provides useful information on soil-structure interaction
52
53
54
55
56
57
58
59
60

1
2
3 138 phenomena and load testing to failure for energy piles that cannot be obtained easily from full-
4
5 139 scale testing, and centrifuge test results are useful for validation of numerical simulations. Physical
6
7 140 modeling of thermal improvement of soft clays using in-situ heating has not been fully explored
8
9
10 141 and could benefit from further experimental evaluations like those in this study.

11
12 142 This study presents the details of a centrifuge physical modeling methodology developed to
13
14 143 assess the impact of a heating-cooling cycle on the pullout capacity of energy piles embedded in
15
16 144 soft clay layers. The results from tests on heated and an unheated energy piles in separate soil
17
18 145 layers within the geotechnical centrifuge at the University of California San Diego are presented
19
20 146 in this study to demonstrate the methodology and typical results. After preparation of a soft clay
21
22 147 layer, the energy pile was installed using jacked-in procedures, heated to a constant temperature
23
24 148 with an unrestrained head boundary condition, cooled, then pulled out at a constant rate after
25
26 149 reaching equilibrium. Preliminary tests on this topic were presented by Ghaaowd and McCartney
27
28 150 (2018) and Ghaaowd et al. (2018), albeit with an energy pile having a fixed head boundary
29
30 151 condition during heating which may not be representative of offshore piles that act as anchors for
31
32 152 floating structures. The fixed head boundary condition in the energy piles considered in these
33
34 153 preliminary studies may prevent possible mobilization of side shear stresses along the length of
35
36 154 the end-bearing pile during the heating process, which may affect the pullout force-displacement
37
38 155 curve. In addition to the load-displacement curves from installation and pullout, data on variations
39
40 156 in temperature and pore water pressure generation in the clay layer and measurements of the
41
42 157 undrained shear strength profile using a T-bar test are presented to interpret the coupled thermo-
43
44 158 hydro-mechanical soil improvement process. The methodology presented in this study may be
45
46 159 used to assess the conditions leading to thermal improvement for anchors in normally consolidated

6

7 162 **EXPERIMENTAL SETUP**

8
9
10 163 The Actidyne C61-3 geotechnical centrifuge at the University of California San Diego shown
11
12 164 in Figure 1 was used in this study. This 50 g-ton geotechnical centrifuge was designed to carry
13
14 165 payloads a maximum mass of 500 kg up to 100 g. The specifications of the UCSD geotechnical
15
16 166 centrifuge are shown in Table 1. Centrifuge testing uses the concept of geometric similitude to
17
18 167 ensure that a model with reduced dimensions will have a similar stress state to a prototype in the
19
20 168 field (Kutter 1992). Centrifuge modeling permits careful control of soil layer preparation, dense
21
22 169 instrumentation arrays, and parametric evaluations of different key variables that may not be
23
24 170 possible in field prototype testing, while ensuring that stress-dependent soil properties and soil-
25
26 171 structure interaction mechanisms are captured under a representative stress state. In the case of the
27
28 172 centrifuge testing program detailed in this study, all tests were performed at a centrifugal
29
30 173 acceleration of 50 g (i.e., $N = 50$).
31
32
33
34

35 174 An aluminum cylindrical container with an integrated reaction frame was developed for this
36
37 175 testing program, with a cross-sectional schematic shown in Figures 2(a) and 2(b). The aluminum
38
39 176 container consists of a base plate, a cylindrical tank, and an upper reaction plate where loading
40
41 177 motors or a hydraulic piston can be mounted. The base and reaction plates of the container have
42
43 178 dimensions of 0.62 m \times 0.62 m \times 0.05 m, which corresponds to the internal dimensions of the
44
45 179 centrifuge basket. The cylindrical tank has an inside diameter of 0.55 m, a wall thickness of 16
46
47 180 mm, and a height of 0.47 m, and was connected to the base plate via four restraining brackets that
48
49 181 connect to threaded rods shown in Figure 2(c). The base plate has an “O”-ring groove to provide
50
51 182 a water-tight seal. The top reaction plate can be fixed at different locations above the cylindrical
52
53
54
55
56
57
58
59
60

1
2
3 183 tank using bolts. The reaction plate supports stepper motors for applying axial loads to the energy
4
5 184 pile and T-bar, as shown in Figure 2(d). Drainage from the base of the container is permitted using
6
7
8 185 a porous stone connected to a drainage port in the bottom of the base plate. A standpipe was
9
10 186 connected to the drainage port that can be connected to a selected port in the container side wall
11
12 187 corresponding to a layer of ponded water atop the clay layer to maintain double drainage
13
14
15 188 conditions.

16
17 189 The scale-model energy pile consists of a 25 mm-diameter, 255 mm-long, aluminum split-shell
18
19 190 cylinder having a wall thickness of 3.3 mm, as shown in Figure 3. At 50 g, the model pile
20
21 191 corresponds to a prototype pile having a diameter of 1.25 m and a length of 12.75 m. The insides
22
23 192 of the cylinder halves were instrumented with thermocouples which measure the temperature at
24
25 193 the pile wall. Internal strain gages were also installed but did not function well during heating to
26
27 194 high temperatures and were not used in this study. This study focused only on the pullout response
28
29 195 of the pile so soil-structure interaction mechanisms or the axial rigidity of the pile were not
30
31 196 considered. The pile was assumed to act like a rigid body for the pullout analyses, which is a
32
33 197 reasonable assumption for a short pile in soft soil. The halves of the split-shell cylinder are held
34
35 198 together by screw-on top and bottom caps. To control the pile temperature, a cylindrical 500W
36
37 199 Watlow Firerod heating element having a diameter of 12 mm and a length of 200 mm was
38
39 200 centralized within the pile. The space between the heating element and the split-shell cylinder was
40
41 201 filled with dense Ottawa sand to act as a thermal grout to promote uniform heat exchange. In
42
43 202 addition to a K-type thermocouple within the heating element, two additional K-type
44
45 203 thermocouples were installed on the inside of the aluminum pile surface. The heating element was
46
47 204 connected to a Watlow EZ Zone PM controller to control the temperature during centrifugation,
48
49 205 using the output from the thermocouple on the inside surface of the aluminum shell of the pile at
50
51
52
53
54
55
56
57
58
59
60

1
2
3 206 mid-height as the control objective when applying a target temperature. Accordingly, the effects
4
5 207 of the thermal grout on heat transfer from the heater to the outer shell of the pile were not
6
7
8 208 considered. The coefficient of thermal expansion of the pile was found to be $24 \mu\epsilon/^\circ\text{C}$, which is
9
10 209 close to that of aluminum despite the different components of the pile (steel heating element, sand
11
12 210 grout, aluminum shell). The controller was interfaced with LabVIEW on a computer located on
13
14
15 211 the arm of the centrifuge which was remotely accessed from a host computer in the centrifuge
16
17 212 control room. The heating element and heat controller had sufficient power to apply temperatures
18
19 213 measured at the inside surface of the pile shell as high as 80°C , although higher temperatures are
20
21 214 possible. To minimize heat transfer to the water ponded above the clay surface, the top cap was
22
23
24 215 fabricated from Delrin to provide an insulating effect while still being sufficiently stiff for applying
25
26 216 mechanical loads. This top cap design was found to not lead to significant heating of the water on
27
28
29 217 top of the clay surface. The top cap also contained several holes to provide access for the internal
30
31 218 instrumentation wires.

32
33 219 A T-bar penetrometer having dimensions shown in Figure 4 was used to perform penetration-
34
35 220 extraction tests to measure the undrained shear strength profile in the clay layer using the
36
37
38 221 correlations developed by Stewart and Randolph (1991). The T-bar can be used to measure the
39
40 222 intact undrained shear strength during downward penetration, and the disturbed undrained shear
41
42 223 strength during extraction, which permits evaluation of the sensitivity of the soil layer. The load
43
44
45 224 applied to the T-bar was only measured at the head of the T-bar so the effects of shaft friction on
46
47 225 the penetration of the T-bar could not be isolated. Nonetheless, the measured load was found to
48
49 226 correlate well with the undrained shear strength of the clay at the tip of the T-bar.

50
51 227 The loads applied to the head of the pile and the T-bar were measured using miniature in-line
52
53
54 228 compression-tension load cells from Futek having model-scale capacities of 1.1 kN, as shown in
55
56
57
58
59
60

1
2
3 229 Figure 5(a). The connection between the pile and the load cell incorporated a custom slip
4
5 230 connection to the loading system so that the pile could have a free-head boundary condition during
6
7 231 heating. Specifically, the slip connection allows the pile to be pushed downward into the soil layer
8
9 232 during installation. After this, the loading system can be raised upward by a small increment until
10
11 233 contact with the pile is lost, which permits the pile to be heated with no head restraint (i.e., the pile
12
13 234 is free to expand upward during heating). After the heating and cooling cycle, the loading system
14
15 235 is raised upward until the slip connection comes into contact with the internal bolt and initiates
16
17 236 pile pullout. Horizontal brackets were connected to the top of the pile and T-bar to connect to
18
19 237 digital linearly variable differential transformers (LVDTs) for monitoring displacements, as shown
20
21 238 in Figure 5(a). The pore water pressure at different locations within the soil layer were measured
22
23 239 using Druck PDCR81 miniature pore pressure transducers (PPTs) having a range of 0-1500 kPa.
24
25 240 The sensors were inserted through ports in the side walls of the container after placement of the
26
27 241 clay during the initial consolidation process that will be described below. To ease the sensor
28
29 242 insertion to the targeted radial location in the soil layer, the sensor wire was strengthened by a thin
30
31 243 steel rod connected to the transducer cable with heat shrink tubing as shown in Figure 5(b). A
32
33 244 Swagelok Ultra-Torr fitting was used to provide a seal between the sensor cable and the container
34
35 245 wall to prevent any leakage. Several thermocouples were used to measure the temperature in the
36
37 246 soil at different depths and radial locations. The thermocouples were also strengthened with a thin
38
39 247 steel rod in a similar manner to the PPTs as shown in Figure 5(c) so that they could be inserted
40
41 248 into the clay horizontally through ports through the tank wall. In addition, K-type thermocouples
42
43 249 were placed on the surface of the soil and on the outside of the container to measure the temperature
44
45 250 of the boundaries. The soil surface deformation was monitored using an LVDT connected to a
46
47 251 lightweight aluminum plate to provide a bearing platform.

3 252 Pictures of the data acquisition system components mounted on the centrifuge are shown in
4
5 253 Figure 6. The temperature control unit for the heating element within the pile is shown in
6
7
8 254 Figure 6(a), along with the computer used for temperature data acquisition. A National Instruments
9
10 255 (NI) CompactDAQ chassis was used to acquire the temperature data, while an NI CompactRio
11
12 256 chassis was used to acquire the force and displacement data and to control Haydon-Kerk stepper
13
14
15 257 motors used to apply axial loads to the pile and T-bar, as shown in Figure 6(b).

16 17 258 **MATERIALS**

18 19 259 **Kaolinite Clay**

20
21
22 260 The soil used in the experiments was kaolinite clay obtained from M&M Clays Inc. of
23
24 261 McIntyre, Georgia whose geotechnical properties are summarized in Table 2. The liquid limit of
25
26 262 the kaolinite clay is 47, and the plastic limit was 28, so the clay classifies as CL according to the
27
28 263 Unified Soil Classification Scheme (USCS). Results from an isotropic compression test indicates
29
30
31 264 that the slopes of the normal compression line (λ) and the recompression line (κ) for the clay are
32
33 265 0.080 and 0.016, respectively. The hydraulic conductivity of the clay inferred from consolidation
34
35 266 data ranges from 2.8×10^{-9} to 8.2×10^{-9} m/s for void ratios ranging from 1.05 to 1.45, respectively.
36
37
38 267 The thermal pressurization response of this clay was characterized by Ghaaowd, the effects of
39
40 268 temperature on the undrained shear strength of this clay were characterized by Samarakoon et al.
41
42 269 (2018), and the thermal volume change of the clay was characterized by Samarakoon and
43
44 270 McCartney (2020).

45 46 47 271 **Ottawa Sand Bearing Layer**

48
49 272 Ottawa F-65 sand was used as a drainage layer beneath the clay layer, and as a firm bearing
50
51 273 layer for the energy pile upon insertion. The sand has a relatively uniform grain size distribution
52
53
54 274 ranging from 0.1 to 0.5 mm. Its hydraulic conductivity varies from 0.0022 to 0.0012 m/s for the
55
56
57
58
59
60

1
2
3 275 loosest and densest states, respectively (Bastidas 2016), which is several orders of magnitude
4
5 276 greater than that of the clay. The sand was tamped in moist conditions to reach a relative density
6
7 277 of approximately 100% in both tests to form a stable bearing layer for the pile while still providing
8
9 278 drainage for the clay layer.

12 279 **MODEL CONSTRUCTION PROCEDURE**

14
15 280 Approximately 45 kg of kaolinite clay in powder form was mixed with deaired water to form
16
17 281 a slurry with a gravimetric water content of 135% within a vacuum mixer (a cement mixer with a
18
19 282 sealed plate that permits application of vacuum to the mixing chamber). The clay slurry was then
20
21 283 carefully poured into the container as shown in Figure 7(a). A layer of filter paper was placed at
22
23 284 the top of the clay layer as shown in Figure 7(b). A porous stone having the same diameter as the
24
25 285 inside of the container was lowered onto the surface of the slurry as shown in Figure 7(c) after
26
27 286 which 24 hours were permitted for self-weight consolidation. The porous stone was manufactured
28
29 287 of coarse sand mixed with 6% epoxy and reinforced with stainless steel mesh. A loading plate was
30
31 288 then placed atop the porous stone as shown in Figure 7(d) and several dead weights were added in
32
33 289 five 24-hour stages as shown in Figure 7(e), leading to a surcharge stress of 8 kPa. Changes in the
34
35 290 vertical position of the steel loading plate were tracked using a micrometer, which were used to
36
37 291 calculate changes in void ratio of the clay layer. A hydraulic piston connected to the top reaction
38
39 292 plate was then used to apply higher axial stresses to the top of the clay layer as shown in Figure
40
41 293 7(e) until reaching a maximum surcharge stress of 21.7 kPa. A schematic of the clay layer with
42
43 294 the hydraulic piston attached for 1 g consolidation is shown in Figure 8 (dead weights atop the
44
45 295 steel weight are not shown). In some tests, a thermal needle connected to a KD2Pro thermal
46
47 296 analyzer from Decagon Devices was included at the base of the clay layer at the location shown in
48
49 297 Figure 8 to track the evolution in thermal conductivity with void ratio.
50
51
52
53
54
55
56
57
58
59
60

1
2
3 298 The compression curve of the clay layer measured during 1 g consolidation is shown in Figure
4
5 299 9(a). This curve is not from either of the two tests presented in this paper but is shown here as an
6
7
8 300 example because the test corresponding to this curve was performed with a thermal needle. The
9
10 301 vertical stresses correspond to those applied to the top of the clay layer with dead weights and the
11
12 302 hydraulic piston and side friction may affect the vertical stress distribution within the specimen.
13
14 303 The slope of the compression curve defined between the highest two vertical stresses was
15
16 304 consistent with the compression index in Table 2. The void ratio achieved after this compression
17
18 305 process varied slightly from test to test depending on the initial water content of the slurry, which
19
20 306 was 130-135%. During the 1g compression process for the test in Figure 9(a), the variation in
21
22 307 thermal conductivity with void ratio is shown in Figure 9(b). This figure also includes the results
23
24 308 from thermal conductivity measurements made on kaolinite clay specimens in an isotropic triaxial
25
26 309 test setup developed by McCartney et al. (2013) shown in Figure 2(b). A relatively linear trend
27
28 310 between thermal conductivity and void ratio was obtained, and the results from two approaches
29
30 311 follow a consistent trend despite the different stress states.

31
32
33
34
35 312 After 1 g consolidation of the clay layer, the applied load was removed and the top plate, porous
36
37 313 stone, and filter paper were carefully removed. Approximately 60 mm of water was left above the
38
39 314 clay layer to ensure the clay layer remained saturated. At the end of consolidation, the height of
40
41 315 the clay layer ranged from 220-240 mm. The stepper motors for the pile and T-bar were connected
42
43 316 to the top reaction plate, and the pile and T-bar were connected to the stepper motor loading rods.
44
45 317 The top reaction plate was then slowly lowered into place on top of the container and fastened into
46
47 318 place. Due the height limitation in the centrifuge basket above the top reaction plate, it was not
48
49 319 possible to suspend the pile and T-bar completely outside of the clay layer at the beginning of the
50
51 320 test. Accordingly, the pile had an initial penetration of approximately 124 mm in the clay layer,
52
53
54
55
56
57
58
59
60

1
2
3 321 and the T-bar was at an initial depth of 58 mm in the clay layer. It was still possible to install the
4
5 322 pile to its final penetration depth at a constant displacement rate during centrifugation to simulate
6
7 323 the jacked-in pile installation process, and the T-bar was able to characterize the undrained shear
8
9 324 strength in the lower 2/3 of the clay layer. After this point, the thermocouples and pore water
10
11 325 pressure sensors were inserted carefully through the ports in the container wall. After checking all
12
13 326 sensors and performing safety checks, the centrifuge was then spun to 50 g.
14
15

16 17 327 **TEST PROCEDURE**

18
19 328 The centrifuge modeling methodology involved five testing stages, which are summarized in
20
21 329 Table 3, and specific details of the tests performed according to his methodology will be discussed
22
23 330 later. After a period of in-flight consolidation (Stage I), the pile was pushed to its final location at
24
25 331 a constant displacement rate until the tip rested within the sand layer to result in end bearing
26
27 332 conditions (Stage II), the pile was heated until reaching thermo-hydro-mechanical equilibrium as
28
29 333 verified by the thermocouples and pore water pressure sensors embedded in the clay layer and in
30
31 334 which case the pile is expected to expand upward due to the end bearing condition in sand (Stage
32
33 335 III), was cooled until reaching thermo-hydraulic equilibrium and in which case the pile is expected
34
35 336 to contract downward (Stage IV), then vertical pullout testing was performed (Stage V). An
36
37 337 unheated pile was tested in the same manner as the heated pile except skipping Stages III and IV.
38
39 338 The pile was pulled out at a constant model-scale displacement rate of 0.1 mm/s, which is fast
40
41 339 enough in prototype scale to ensure undrained pullout conditions based on preliminary T-bar
42
43 340 penetration tests with different rates. After this point, a push-pull T-bar test was performed after
44
45 341 the unheated and heat pile tests. The T-bar test was performed at a model-scale radial distance of
46
47 342 75 mm from the pile (or $r_{T\text{-bar}}/r_{\text{pile}} = 6$), which was close enough to be affected by thermo-hydro-
48
49 343 mechanical changes in the clay layer due to pile heating. The T-bar is close enough to be affected
50
51
52
53
54
55
56
57
58
59
60

1
2
3 344 by pile pullout, but sufficient time was permitted after pile pullout and performing the T-bar test
4
5 345 to permit dissipation of excess pore water pressures (at least 5 hours). In the case of the unheated
6
7 346 pile, Stages III and IV were skipped. After the centrifuge was spun down, the specimen was
8
9
10 347 dissected to measure the gravimetric water content at different locations and to determine the final
11
12 348 sensor locations. The final locations of the thermocouples and pore water pressure transducers in
13
14 349 the heated pile test are shown in Table 4. A schematic of the assembled experimental setup
15
16 350 showing the approximate locations of the sensors and the installed pile is shown in Figure 10(a),
17
18 351 and a picture of the container on the basket is shown in Figure 10(b).

19
20
21 352 An example of the excess pore water pressure measured by a pore water pressure transducer
22
23 353 (PPT4) during in-flight consolidation in one of the tests is plotted against the square root of time
24
25 354 in Figure 11. This data permits definition of the value of t_{90} using the root time method (Taylor
26
27 355 1948) and permits evaluation of the end of primary consolidation. Due to the compression to
28
29 356 normally consolidated conditions at 1 g followed by unloading then in-flight consolidation, the
30
31 357 soil layer will be overconsolidated near the surface but normally consolidated below a model-scale
32
33 358 depth of 60 mm (prototype-scale depth of 3 m) within the clay layer. Early tests reported by
34
35 359 Ghaaowd et al. (2018) were performed with 7 PPTs, which were useful in confirming that the pore
36
37 360 water pressure profile had reached hydrostatic conditions at the end of consolidation. Several of
38
39 361 these PPTs were damaged in early tests, so the tests reported in this study only include two PPTs
40
41 362 at the same radial location but different depths.

42
43 363 A picture of the pile and T-bar prior to installation is shown in Figure 12(a), while a picture of
44
45 364 the installed pile and T-bar from the end of testing is shown in Figure 12(b). These figures
46
47 365 demonstrate why a ponded water height of only 60 mm was used in testing to avoid submerging
48
49 366 the load cells. The load penetration curves for the unheated and heated piles are shown in Figures
50
51
52
53
54
55
56
57
58
59
60

1
2
3 367 13(a) and 13(b), respectively. Although these curves were from two different clay layers, they have
4
5 368 similar shapes. The piles were installed to the same penetration depth corresponding to the top of
6
7 369 the sand layer, so the maximum axial force in both piles were slightly different and likely depend
8
9
10 370 more on the sand layer than on the clay layer. The pile stepper motor rod was moved 3 mm upward
11
12 371 to lose contact with the pile head, and the applied load was zeroed. After the pile was installed
13
14 372 through the clay layer so that its tip was resting on the sand drainage layer, time was allowed for
15
16 373 excess pore water pressures in the clay layer induced by pile installation to dissipate.
17
18

19 374 **RESULTS**

20
21 375 Time series of the main variables measured during testing on the unheated and heated piles are
22
23 376 shown in Figure 14. As the goal of this study is not to scale the transient heat transfer and water
24
25 377 flow processes, the time is shown in model scale. In the test on the unheated pile, the temperature
26
27 378 of the pile was observed to be 20 °C and stable throughout the test, but this channel was
28
29 379 unfortunately not recorded. The temperature at the surface of the clay layer shown in Figure 14(a)
30
31 380 indicated that the surface was slightly cooler and was approximately 18 °C at the time of pile
32
33 381 installation. In the test on the heated pile, the entire soil layer and pile were approximately 21 °C
34
35 382 until the pile was heated to a target temperature 65 °C. The elevated temperature was maintained
36
37 383 for approximately 30 hours, which was sufficient to reach thermo-hydraulic equilibrium in the clay
38
39 384 surrounding the energy pile (i.e., stable temperature and pore water pressures). This was followed
40
41 385 by ambient cooling for 6 hours, which was observed to be sufficient for the clay temperature and
42
43 386 pore water pressure to stabilize. During heating, it took approximately 5 hours to reach the target
44
45 387 temperature, and the temperatures in the soil at different radial locations were lower and took
46
47 388 longer to stabilize.
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 389 The pore water pressure time histories during the unheated pile test are shown in Figure 14(c).
4
5 390 After reaching the end of primary consolidation, the pore water pressures increased sharply during
6
7 391 pile installation in Stage II, which stabilized after approximately 10 hours. The pore water
8
9
10 392 pressures also increased sharply during pile pullout in Stage V. The pore water pressures sensors
11
12 393 in the heated pile tests were at different locations than in the unheated pile test, so the initial pore
13
14 394 water pressures measured by PPT3 and PPT4 were different. Nonetheless, similar behavior was
15
16
17 395 noted in the heated pile test in Figure 14(d) until the time of pile heating. At this point a smaller
18
19 396 increase in pore water pressure was observed than the magnitude of pore water pressure changes
20
21 397 during pile installation. During pile cooling, a decrease in pore water pressure below hydrostatic
22
23 398 conditions was observed. This negative pore water pressure may reflect that cooling was faster
24
25
26 399 than the rate of drainage. The pore water pressures stabilized before pullout, which also led to a
27
28 400 large increase in pore water pressure.

30
31 401 The pile head displacement in the unheated test is shown in Figure 14(e). Unfortunately, the
32
33 402 long stroke of the LVDT necessary to track the installation and pullout of the pile meant that the
34
35 403 small changes in pile head movement during heating were close to the resolution of the LVDT.
36
37 404 Nonetheless, a decrease in pile head position was observed after pile installation, which may be
38
39
40 405 due to time dependent dragdown on the pile. The pile head displacement in the heated pile test
41
42 406 shown in Figure 14(f) is interesting as it was expected that the pile would expand upward during
43
44 407 heating. However, less downward movement was observed in the heated pile than in the unheated
45
46
47 408 pile, which may imply that the upward movement of the pile due to thermal expansion was
48
49 409 compensating against the downward movement arising from time-dependent downdrag. During
50
51 410 the cooling stage, the pile head moved downward by approximately 0.28 mm due to the pile
52
53
54 411 thermal contraction. This downward movement corresponds to an axial strain of $1080 \mu\epsilon$ for the

1
2
3 412 decrease in temperature of 45 °C. The linear coefficient of thermal expansion for the pile is
4
5 413 approximately 24 $\mu\epsilon/^\circ\text{C}$, which is consistent with the linear coefficient of thermal expansion of
6
7
8 414 aluminum of 23 $\mu\epsilon/^\circ\text{C}$.
9

10 415 There was not a thermocouple at the same location as PPT3 and PPT4, so the time series of
11
12 416 temperature at a model-scale radius of 62 mm was linearly interpolated from the measurements of
13
14
15 417 TC3 and T4, as shown in Figure 15(a). For a change in temperature of approximately 13 °C an
16
17 418 increase in pore water pressure of approximately 4 kPa was observed at both depths. This is lower
18
19 419 than the change in pore water pressure expected for fully undrained conditions of 15.8 kPa at the
20
21 420 depth of PPT4 and 16.9 kPa at the depth of PPT3 predicted using the model of Ghaaowd et al.
22
23 421 (2017) for the effective stress and void ratio at the depth of these PPTs. The lower maximum pore
24
25 422 water pressures measured at these depths is attributed to partial drainage, as drainage will start to
26
27 423 occur as soon as pore water pressures are generated. Further, based on the model of Ghaaowd et
28
29 424 al. (2017) it was expected that the deeper PPT would have recorded a higher change in pore water
30
31 425 pressure associated with a higher effective stress and consolidation to a lower void ratio. This
32
33 426 inconsistent trend between the measurements of PPT3 with the predicted trend with depth from
34
35 427 the model of Ghaaowd et al. (2017) is mainly attributed to partial drainage as PPT3 was closer to
36
37 428 the sand drainage layer, although it possible that the actual temperature at the location of PPT4 is
38
39 429 higher than at the location of PPT3 (and different from the temperature at the same radial location
40
41 430 as the two PPTs obtained by the linear interpolation between the measurements of TC3 and TC4).
42
43
44
45
46

47 431 The radial distribution in temperature at model scale after different times is shown in Figure 16.
48
49 432 Although the pile temperature reached 65 °C, which corresponded to an increase in temperature
50
51 433 of 45 °C, the soil temperature only increased by at most 22 °C for the locations monitored. It is
52
53 434 expected that larger changes in temperature, which correspond to greater changes in pore water
54
55
56
57
58
59
60

1
2
3 435 pressure and thermal consolidation, may have occurred close to the pile surface. Nonetheless, after
4
5 436 30 hours of heating the pile had a zone of influence of approximately 150 mm. The outer boundary
6
7
8 437 at a radial distance of 275 mm did not appear to influence the radial distribution in temperature.
9

10 438 The load-displacement curves for the heated and unheated piles during pullout are shown in
11
12 439 Figure 17, where a negative force is used to denote the tensile force measured by the load cell. The
13
14 440 maximum temperatures are shown in the legend of this figure to differentiate the unheated and
15
16 441 heated piles, but both pullout tests were performed at a room temperature of approximately 20 °C.
17
18 442 The force and pile displacement were zeroed at the point where the pile first started to move
19
20 443 upward. The pullout capacities for the unheated and heated piles are -1004 and -1434 kN
21
22 444 respectively, occurring at displacements of 0.09 and 0.16 m in prototype scale, respectively. The
23
24 445 pullout capacity of the heated pile was 1.43 times greater than that of the unheated pile. It should
25
26 446 be noted that the pile self-weight is 542 kN, so the self-weight makes up approximately half of the
27
28 447 pullout capacity of the unheated pile. It was interesting that the slope of the load-displacement
29
30 448 curve for the heated pile is only slightly greater than that of the unheated pile. This may be because
31
32 449 of the large coefficient of thermal expansion of the aluminum pile, which led to the mobilization
33
34 450 of side shear stresses before pullout occurred in the heated pile test. Although the pile likely
35
36 451 contracted after cooling, the heating-cooling cycle may have led to a softening response in the
37
38 452 load-displacement curve even though an increase in pullout capacity with increased temperature
39
40 453 is still observed. After reaching the pullout capacity, both piles show a softening response for the
41
42 454 displacement range shown. However, the heated pile shows a greater amount of softening. Similar
43
44 455 increases in pullout capacity were observed by Ghaaowd and McCartney (2018a, 2018b) for
45
46 456 energy piles with a fixed head boundary condition during heating.

1
2
3 457 The T-bar measurements in the clay layers with heated and not heated energy piles may help
4
5 458 understand the effects of heating and cooling on the behavior of normally consolidated clay layers.
6
7
8 459 To infer the profile of undrained shear strength in the clay layer, the T-bar was inserted into clay
9
10 460 layer at speed of 0.2 mm/s until reaching a maximum depth of 220 mm, which was close to the
11
12 461 bottom of the clay layer. As mentioned, due to the stroke limitation of the T-bar motor and the
13
14 462 space restriction within the centrifuge container, the initial position of the T-bar was at an initial
15
16 463 depth corresponding to 1/3 of the clay layer thickness. After reaching the maximum stroke, the T-
17
18 464 bar was extracted at the same speed from the clay layer until returning to its initial position. The
19
20
21 465 undrained shear strength was interpreted from the correlations of Stewart and Randolph (1991):

$$22 \quad 23 \quad 24 \quad 25 \quad 26 \quad 27 \quad 28 \quad 29 \quad 30 \quad 31 \quad 32 \quad 33 \quad 34 \quad 35 \quad 36 \quad 37 \quad 38 \quad 39 \quad 40 \quad 41 \quad 42 \quad 43 \quad 44 \quad 45 \quad 46 \quad 47 \quad 48 \quad 49 \quad 50 \quad 51 \quad 52 \quad 53 \quad 54 \quad 55 \quad 56 \quad 57 \quad 58 \quad 59 \quad 60$$

$$466 \quad c_u = \frac{F_v}{N_b D L} \quad (1)$$

467 where c_u is the undrained shear strength, D is the T-bar diameter of 14 mm, L is the T-bar length
468 of 57 mm, F_v is the measured T-bar force (positive for insertion and negative for extraction), and
469 N_b is the T-bar bearing factor. The T-bar bearing factor was calculated using the equation proposed
by Oliveira et al. (2010):

$$471 \quad N_b = 0.0053 \left(\frac{H}{D}\right)^6 - 0.1102 \left(\frac{H}{D}\right)^5 + 0.9079 \left(\frac{H}{D}\right)^4 - 3.7002 \left(\frac{H}{D}\right)^3 +$$

$$472 \quad 7.2509 \left(\frac{H}{D}\right)^2 - 3.9168 \left(\frac{H}{D}\right) + 5.3519 \quad (2)$$

473 where H is the height of soil above the T-bar. In their model the value of the T-bar bearing factor
474 N_b should be in the range of 5.14 to 10.50.

475 The profile of undrained shear strength from the T-bar test next to the unheated pile is shown
476 in Figure 18. The “positive” undrained shear strength values are for insertion into the intact lower
477 2/3 of the clay layer and the “negative” undrained shear strength values are for extraction from the
478 disturbed clay layer. The undrained shear strength is always positive, but it is conventional to show

1
2
3 479 hysteresis loops like those in Figure 18 for analysis of T-bar tests (Oliveira et al. 2010). To check
4
5 480 the undrained shear strengths from the T-bar tests, the undrained shear strengths were also
6
7 481 interpreted from the force-displacement data from pile insertion presented in Figure 13.
8
9
10 482 Specifically, the equations for side shear capacity Q_s and end bearing capacity Q_p of a pile in an
11
12 483 undrained clay layer were used to back-calculate the undrained shear strength at a given depth of
13
14
15 484 penetration $H_{\text{penetration}}$:

$$17 \quad 485 \quad Q = Q_s + Q_p \quad (3)$$

$$19 \quad 486 \quad Q_s = \alpha c_u A_s = c_u \pi D H_{\text{penetration}} \quad (4)$$

$$21 \quad 487 \quad Q_p = 9 c_u A_p = 2.25 \pi D^2 c_u \quad (5)$$

23
24 488 where α is the side shear factor (assumed to equal 1.0 for soft clays), A_s is the pile surface area,
25
26 489 and A_p is the point bearing area of the pile. Specifically, the undrained shear strength can be
27
28 490 estimated from the pile penetration as follows:

$$31 \quad 491 \quad c_u = Q / (\pi D H_{\text{penetration}} + 2.25 \pi D^2) \quad (6)$$

33 492 The interpreted undrained shear strength profiles interpreted from pile penetration data are also
34
35 493 shown in Figure 18(a). A good match is observed with the undrained shear strength profile from
36
37 494 the T-bar in the lower portion of the clay layer. The average measured undrained shear strength by
38
39 495 using the T-bar was 10 kPa (close to the value of 11 kPa obtained from pile insertion in Figure
40
41 496 18(a)) and Equation 3 was used to estimate the pullout capacity of 431 kN. When the pile weight
42
43 497 of 542 kN is added to this, the total pullout force is 973 kN, which is close to the measured pullout
44
45 498 capacity from the unheated pile test.

49 499 A comparison of the T-bar test results from the tests on the unheated and heated piles is shown
50
51 500 in Figure 18(b). Although the T-bar is located at a model-scale distance of approximately 100 mm
52
53 501 from the pile where the change in temperature was only about 8 °C, a slightly greater undrained
54
55
56
57
58
59
60

1
2
3 502 shear strength profile was observed during insertion. During extraction, the same undrained shear
4
5 503 strength was observed. The greatest change in undrained shear strength is expected at the soil-pile
6
7 504 interface, but the T-bar results in this figure indicate that improvement may occur in the
8
9 505 surrounding soil as well. Specifically, the spatial distribution of thermally induced changes in pore
10
11 506 water pressure and thermal consolidation will follow the change in temperature in the soil and the
12
13 507 excess pore water pressures will dissipate radially away from the energy pile.
14
15
16

17 508 After the pile pullout and T-bar tests, the centrifuge was spun down and the container was
18
19 509 removed. The final height of the clay layer was measured, and samples of clay were taken at
20
21 510 different locations within the clay layer. Also, the final locations of the sensors around the pile
22
23 511 were measured, with the final sensor locations for the heated pile test summarized in Table 4. The
24
25 512 post-test measurements of the gravimetric water content are shown in Figures 19(a) and 19(b) for
26
27 513 the tests on the unheated and heated piles, respectively. The initial void ratios achieved after 1g
28
29 514 consolidation in each of the tests are shown in these figures, with the unheated pile test having a
30
31 515 slightly lower initial void ratio of 1.35 than the heated pile test which had an initial void ratio of
32
33 516 1.45. In both clay layers, lower void ratios were observed near the center of the clay layer, and a
34
35 517 clear swelling is observed near the clay surface, reflected in the some of the final void ratios near
36
37 518 the clay surface being greater than the initial void ratios. The lower void ratios near the center of
38
39 519 the clay layer in both tests may have been due to the densification associated with dissipation of
40
41 520 excess pore water pressures generated by pile installation. Although the depths of the samples in
42
43 521 each test make it difficult to visualize trends, the changes in void ratio near the center of the clay
44
45 522 layer were greater for the heated pile test, ranging from 0.1 near the clay surface to 0.45 near the
46
47 523 pile toe. The changes in void ratio near the center of the clay layer for the unheated pile test ranged
48
49 524 from 0.1 near the clay surface to 0.36 near the pile toe. It is possible that the difference in the
50
51
52
53
54
55
56
57
58
59
60

1
2
3 525 change in void ratios of the clay layers in the heated and unheated pile tests could be partly
4
5 526 attributed to the rapid rate of cooling in the heated pile test, which may result in some partial
6
7
8 527 recovery of thermal contractions as observed by Samarakoon and McCartney (2020) in thermal
9
10 528 triaxial tests on this clay. It is possible that lower void ratios may have been measured at the pile
11
12 529 interface in the heated pile test, but unfortunately this data was not collected. The greater change
13
14 530 in void ratios near the center of the clay layer in the heated pile test support the improvement due
15
16
17 531 to thermal consolidation with the pullout results in Figure 17 and the T-bar tests in Figure 18. In
18
19 532 addition, similar observations in pullout results and T-bar tests were made in other tests on heated
20
21 533 pile restrained head conditions reported by Ghaaowd and McCartney (2018) and Ghaaowd et al.
22
23
24 534 (2018).

535 **CONCLUSION**

536 This paper described the development of a new centrifuge modeling methodology that can be
537 used to understand the impacts of using an energy pile to improve the mechanical properties of
538 saturated clays, leading to an increase in pullout capacity. Time series of temperature, pore water
539 pressure, and deformation were interpreted to understand the transient process of soil improvement.
540 Despite small changes in pore water pressure during heating and small changes in void ratio at the
541 end of testing, the pullout capacity of pile heated from 20 to 65 °C before being cooled to 20 °C
542 was significantly greater than the pullout capacity of a pile at 20 °C. Interpretation of the unheated
543 pile pullout capacity using undrained shear strengths from T-bar tests shows good agreement with
544 measured values. Undrained shear strength values after the heating-cooling cycle from T-bar tests
545 showed improvement even at distances away from the pile.

546 Overall, the centrifuge testing methodology provides useful insight into the transient thermal
547 consolidation process under realistic boundary conditions and stress states and provides useful data

1
2
3 548 for validation of numerical simulations. The main implication of the typical results from the testing
4
5 549 methodology presented in this study is that heating can be used to improve the undrained shear
6
7
8 550 strength of normally consolidated soil surrounding offshore foundations. This provides a practical
9
10 551 advantage as the pile can be installed into the ground with ease, then improved using heat generated
11
12 552 within the pile without the need to apply mechanical stresses to the clay layer. The testing approach
13
14
15 553 presented in this study can help provide guidance on the appropriate temperature range to apply to
16
17 554 energy piles to reach a desired level of improvement in pullout capacity and can help provide
18
19 555 guidance on the time required to apply a temperature boundary condition in the field.

669 **TABLE 1.** Details of the UCSD Actidyne C61-3 geotechnical centrifuge

Quantity	Value
Rated capacity (g-tons)	50
Radius to basket (m)	2.0
Basket width (m)	0.6
Basket length (m)	1.0
Basket depth (m)	0.6
Maximum centripetal acceleration (g)	130
Maximum capacity under maximum acceleration (kg)	230
Maximum capacity (kg)	500
Maximum acceleration under maximum capacity (g)	100

670
671 **TABLE 2.** Properties of the kaolinite clay used in this study.

Property	Value
Liquid limit	47
Plastic limit	28
Plasticity index	19
Specific gravity	2.6
C_c	0.230
C_r	0.037

672
673 **TABLE 3.** Summary of testing stages

Testing Stage	Stage Description
I	In-flight consolidation
II	Pile installation
III	Pile heating
IV	Pile cooling
V	Pile pullout

674
675 **TABLE 4.** Sensor locations in heated pile test determined after testing

Sensor	r (mm)	z (mm)
TC1	36	142
TC2	94	162
TC3	46	102
TC4	81	112
TC5	101	122
TC6	146	122
PPT3	62	150
PPT4	62	140

FIG. 1. UCSD geotechnical centrifuge.

88x49mm (600 x 600 DPI)

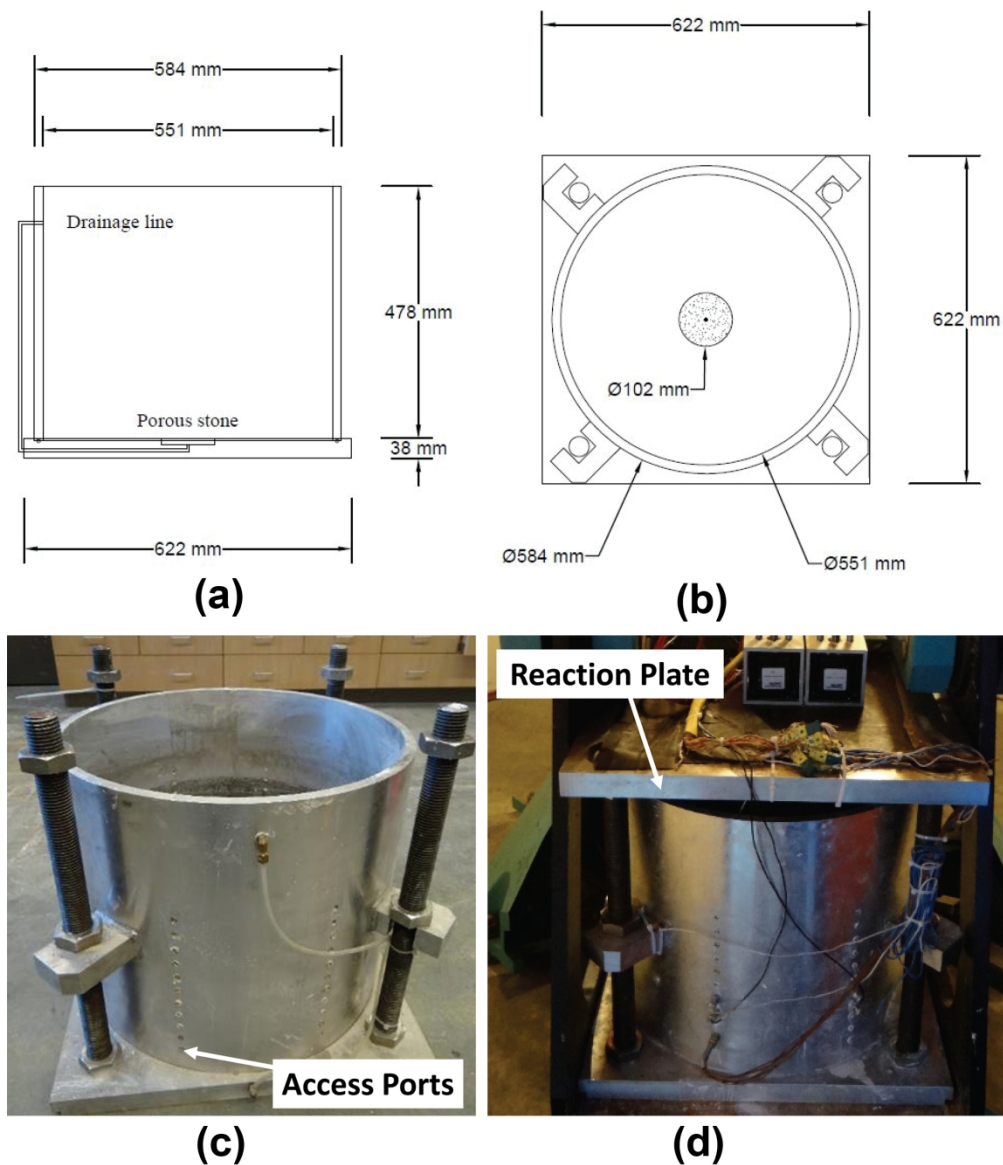

FIG. 2. Cylindrical centrifuge container with reaction plate for load application: (a) Cross section schematic, (b) Plan view schematic, (c) Container without reaction plate showing access ports at different heights from base; (d) Container with reaction plate inside the centrifuge.

101x120mm (600 x 600 DPI)

FIG. 3. Details of the centrifuge-scale energy pile with internal heating element: (a) Assembled pile, (b) Pile cross section with model-scale dimensions, (c) Disassembled pile showing heating rod and internal instrumentation.

88x145mm (600 x 600 DPI)

FIG. 4. T-bar for soil characterization before and after pile heating: (a) Photo; (b) Schematics.

88x90mm (600 x 600 DPI)

FIG. 6. Centrifuge data acquisition system components: (a) Pile heat controller components; (b) Data acquisition chasses with signal conditioning units and motor controller modules along with motor control hardware.

88x112mm (600 x 600 DPI)

45 FIG. 7. Soil preparation procedures: (a) Placing the mixed slurry in the container; (b) Filter paper
46 placement; (b) Filter paper placement on the top of clay layer; (c) Porous stone on top of clay slurry mix;
47 (d) Placement of loading plate on top of porous stone; (e) Slurry pre-consolidated under dead weights at 1
48 g.

49 88x153mm (600 x 600 DPI)

FIG. 8. Schematic of the container with the reaction plate during 1-g consolidation showing the thermal needle (TR-1 Sensor).

178x90mm (599 x 599 DPI)

FIG. 9. Typical data obtained from 1 g consolidation of the clay layer: (a) Compression curve; (b) Thermal conductivity as a function of void ratio for the clay along with a comparison from thermal needle tests on isotropically consolidated clay specimens in a triaxial cell.

88x128mm (600 x 600 DPI)

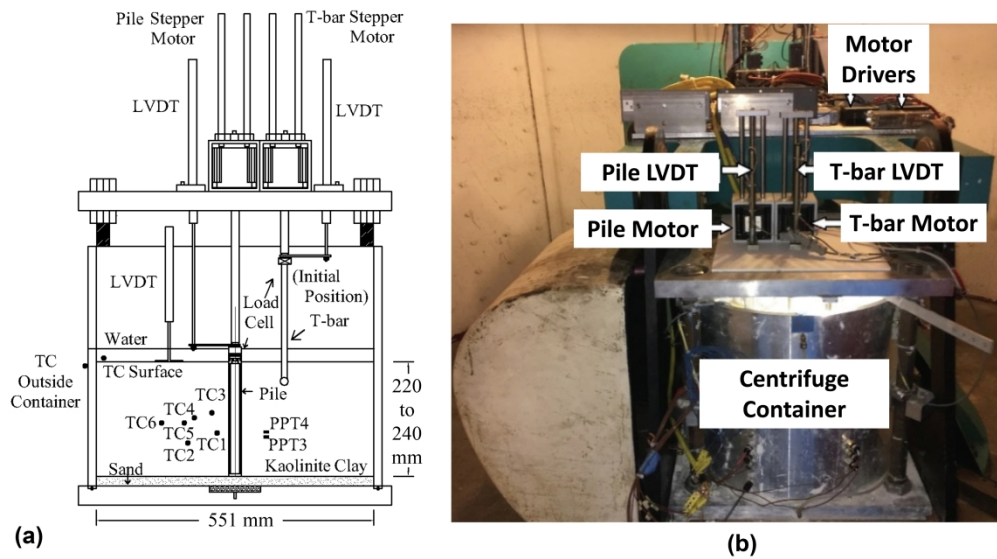

FIG. 10. System configuration for testing of energy piles in soft clay: (a) Cross-section schematic with approximate locations of sensors; (b) Picture of stepper motors mounted to the reaction plate prior to testing.

177x98mm (600 x 600 DPI)

FIG. 11. Example of in-flight consolidation results in the centrifuge

88x63mm (600 x 600 DPI)

FIG. 12. In-flight pictures of the energy pile and T-bar: (a) At the initial partially-installed positions; (b) After installation.

177x87mm (600 x 600 DPI)

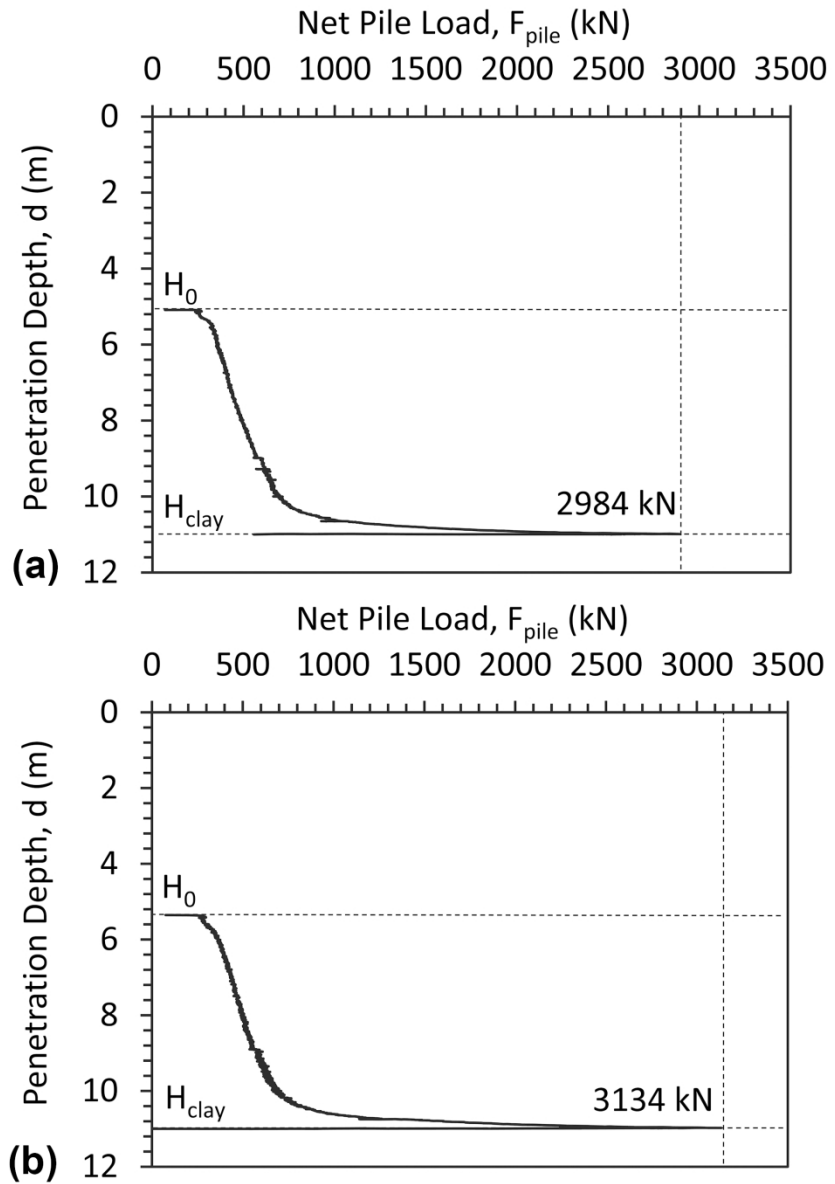

FIG. 13. Load-penetration curves of the piles during room-temperature installation to the target depth (with maximum load shown as a vertical line): (a) Unheated pile; (b) Heated pile

88x128mm (600 x 600 DPI)

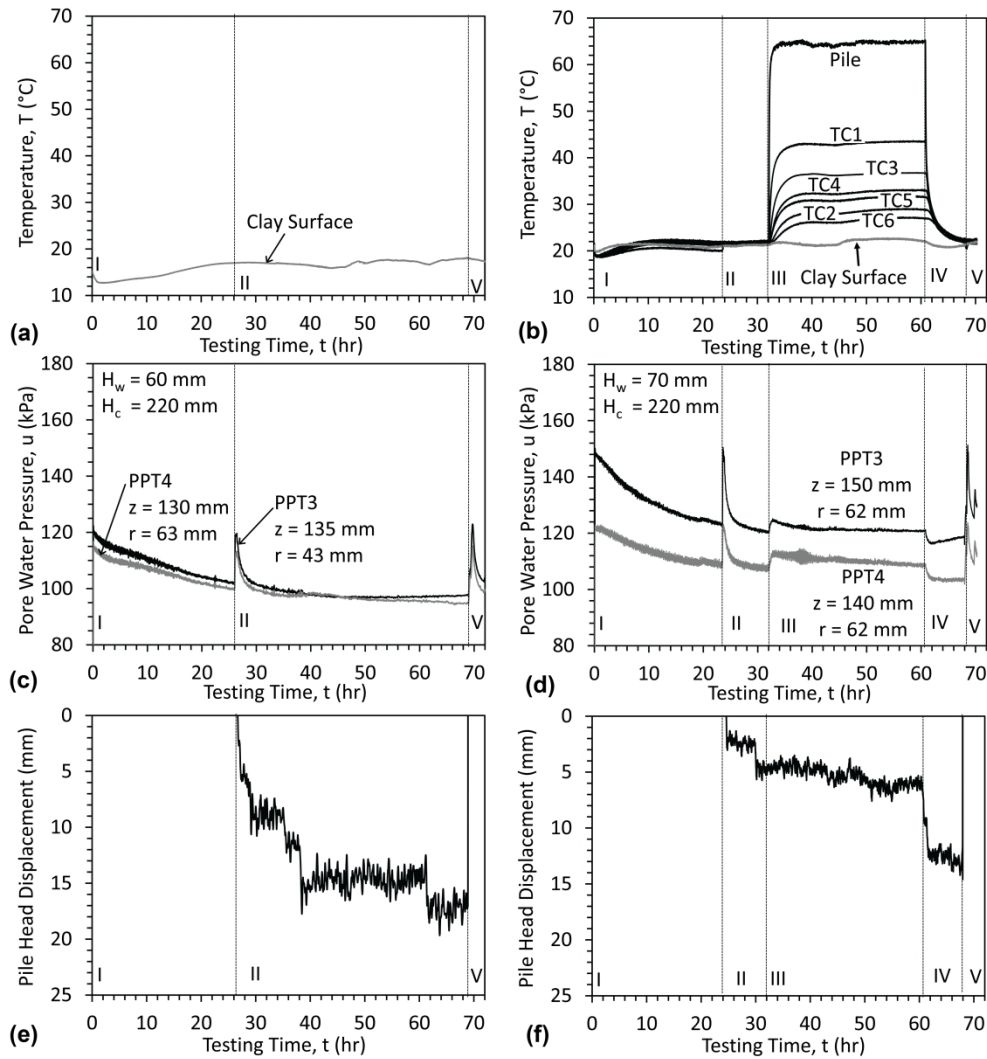

FIG. 14. Testing time series results for centrifuge tests, with time in model scale and other variables in prototype scale: (a) Temperature at clay surface (unheated pile); (b) Temperature of soil at different radii (heated pile); (c) Pore water pressure at different radii (unheated pile); (d) Pore water pressure at different radii (heated pile); (e) Pile head displacement (unheated pile); (f) Pile head displacement (heated pile).

177x187mm (600 x 600 DPI)

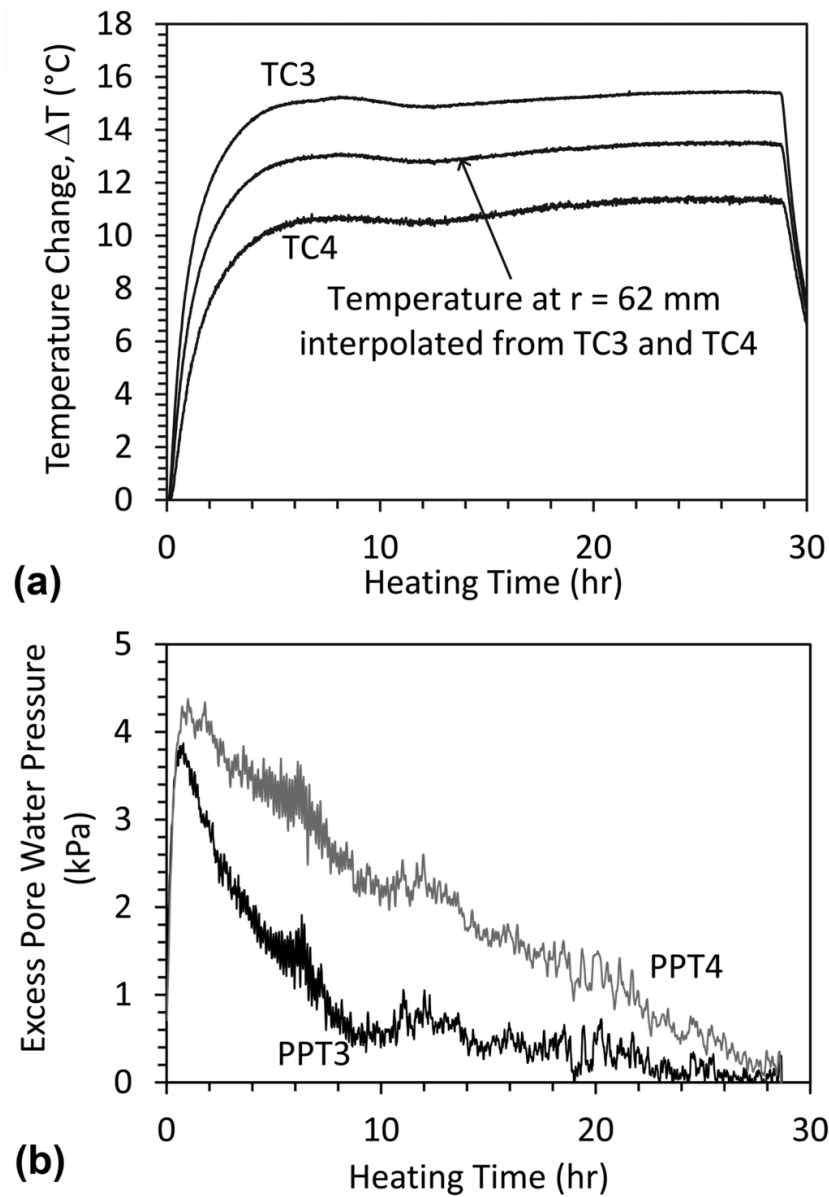

FIG. 15. Further interpretation of time series from heated pile test, with time in model scale: (a) Temperature change vs. heating time estimated at a radius representative of both pore water pressure transducer locations; (b) Thermally induced excess pore water pressure vs. heating time.

88x124mm (300 x 300 DPI)

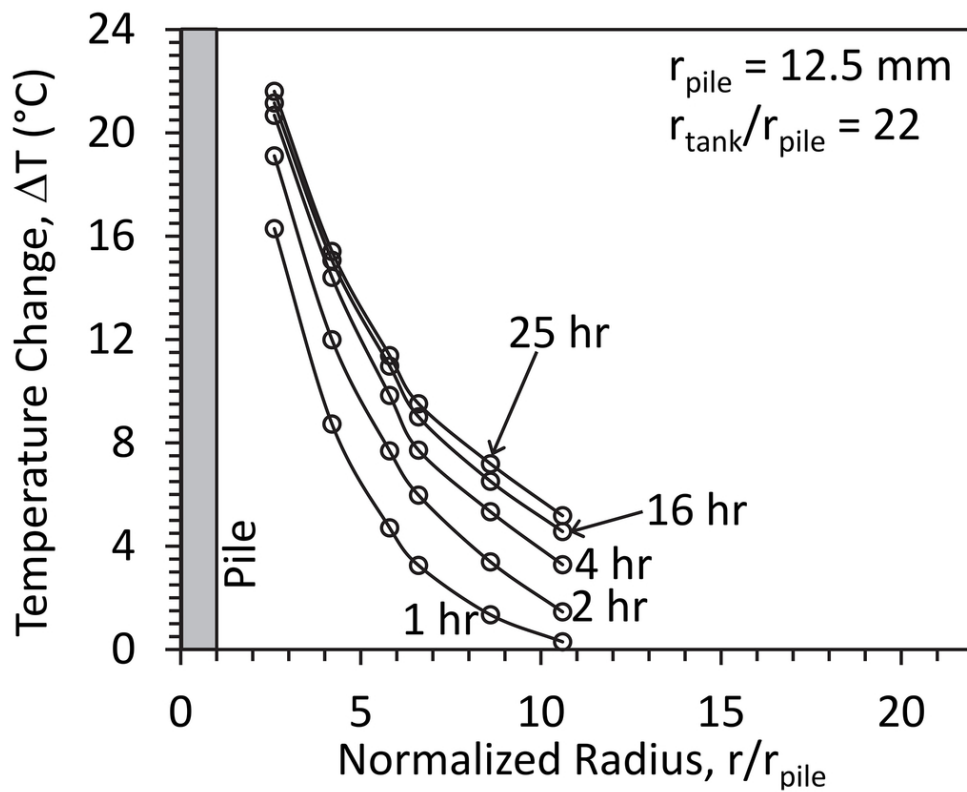

FIG. 16. Radial distribution in soil temperature change after different heating times.

88x72mm (300 x 300 DPI)

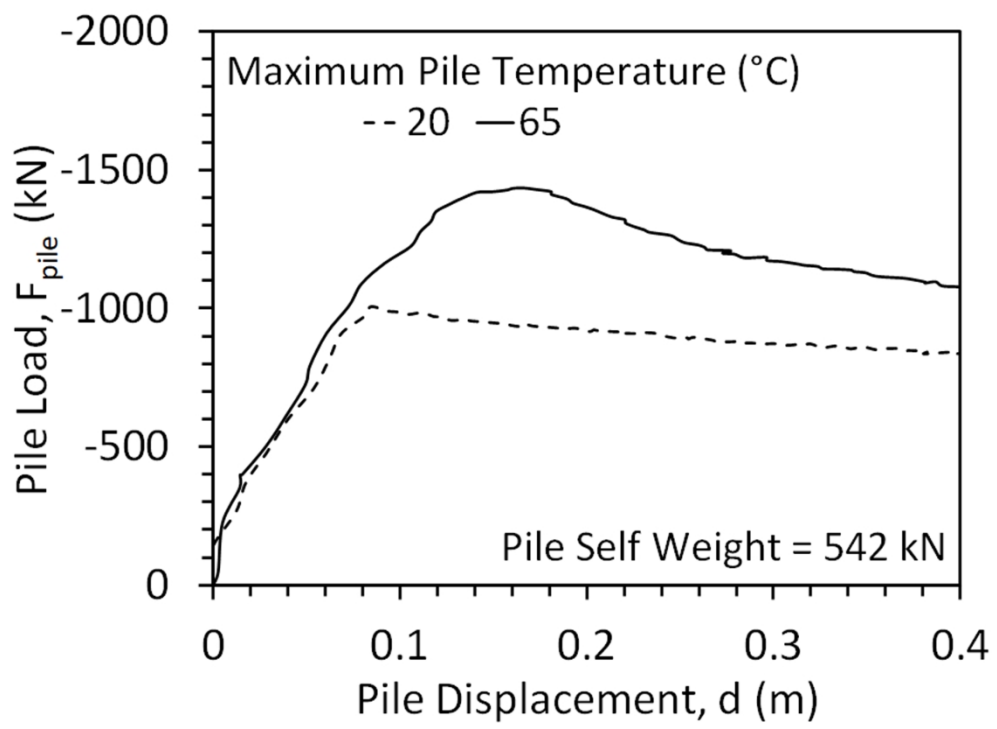

FIG. 17. Pullout load displacement curves for unheated and heated piles.

88x64mm (600 x 600 DPI)

FIG. 18. Undrained shear strength profiles (positive values used to denote the undrained shear strength during insertion and negative values denote the undrained shear strength during extraction): (a) T-bar measurements for tests on unheated and heated piles; (b) Comparison of T-bar measurements at room temperature with those inferred from pile installation with temperatures to differentiate the two piles.

88x123mm (300 x 300 DPI)

FIG. 19. Post-test measurements of void ratio as a function of depth and radial distance from the center of the pile (model-scale dimensions); (a) Unheated pile; (b) Heated pile.

88x132mm (300 x 300 DPI)
