$$N_2 + 10\ H^+ + 8\ e^- \rightleftharpoons H_2 + 2\ NH_4^+ \qquad (2\text{–}330)$$

*In the Birch reduction, sodium metal is used as the reductant.

occurs and dinitrogenase reductase, the iron protein, that provides each of the electrons

$$\text{reduced ferredoxin} + 2\,\text{MgATP}^{2-} + 2\,H_2O \rightleftharpoons 2\,H^+ + e^- + \text{oxidized ferredoxin} + 2\,\text{MgADP}^- + 2\,HOPO_3^{2-} \quad (2\text{–}331)$$

required for the reduction of N_2. Dinitrogenase reductase is the electron-transferring coenzyme specific to dinitrogenase that in turn uses reduced ferredoxin as the source of the electron. No external reductant, regardless of its standard reduction potential, is able to substitute for dinitrogenase reductase in providing electrons to dinitrogenase for the reduction of N_2 nor is any other reductase or small electron-transferring coenzyme. The expression of nitrogenase activity requires both enzymes simultaneously, but they associate with and dissociate from each other at particular steps during the complete catalytic cycle.[2233]

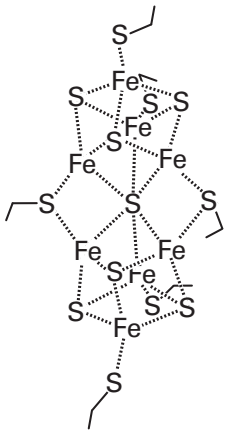
Dinitrogenase, the molybdenum–iron protein, from *A. vinelandii* **contains a prosthetic [Mo–7Fe–9S–C] molybdenum–iron–sulfur–carbon cluster** that is responsible for the reduction of the N_2 to NH_4^+. This cluster has three local twofold rotational axes of pseudosymmetry, normal to a local threefold rotational axis of symmetry, and is also bilaterally pseudosymmetric (Figure 2–62).[2234] In the center of the cluster there is a mononuclear carbide ion (C^{4-}) that is surrounded by six iron ions.[2235-2237] This mononuclear carbide is derived from *S*-adenosyl-L-methionine[2238] and is a permanent feature of the cluster.[2239]

The bond angles and bond lengths in the central [6Fe–C] iron–carbon subcluster[2234] are almost identical to those in the [6Fe–C] iron–carbon subclusters found in cementite, an iron carbide (Fe_3C) in which each mononuclear carbide is coordinated by six iron ions and each iron ion is coordinated by two mononuclear carbides.[2240,2241] Cementite is a hard, brittle solid, and this property suggests that the [6Fe–C] iron–carbon subcluster might form a rigid central scaffold stabilizing the [Mo–7Fe–9S–C] cluster.[2242] This rigid scaffold allows the cluster to be unsupported by any cysteines over its entire length, unlike a normal iron–sulfur cluster.

The 322 (D_3) rotational symmetry of this central [6Fe–C] iron–carbon subcluster produces the rotational pseudosymmetry of the complete [Mo–7Fe–9S–C] cluster. The iron ion at one end of the cluster is coordinated by a cysteine from the protein, and the pseudosymmetrically related molybdenum at the other end is coordinated by the imidazolyl group of a histidine. In addition to the imidazolyl group and three of the sulfide dianions in the cluster, the remaining two octahedral positions around the molybdenum ion are occupied by one of the carboxylate oxygens and the central hydroxy oxygen of a molecule of homocitrate.

The mononuclear carbide must decrease the reduction potential of the cluster because as the iron ions are oxidized, a portion of the excess negative charge should shift from the carbon to the iron ions to compensate for their increase in charge number.[2243] In the resting state of the cluster, however, three of the iron ions—the one at the vertex and the two above the carboxylato group of the homocitrate that is a ligand to the molybdenum ion—are Fe^{2+} and the other four are Fe^{3+} (Figure 2–62),[2244] a ratio similar to the ratio of Fe^{2+} and Fe^{3+} in a typical [4Fe–4S] iron–sulfur cluster in which there is no mononuclear carbide. The molybdenum ion, however, is Mo^{3+}, a more reduced molybdenum ion than is usually found in the active sites of enzymes.[2245]

There is also a prosthetic **[8Fe–7S] iron–sulfur cluster** in dinitrogenase that has the following structure in the native, reduced enzyme



2–152

This [8Fe–7S] iron–sulfur cluster participates in transfer of each of the eight electrons between dinitrogenase reductase, the protein providing the electrons to dinitrogenase, and the [Mo–7Fe–9S–C] cluster at which the reduction of N_2 occurs. The closest iron ion in this cluster is 1.4 nm from the [Mo–7Fe–9S–C] cluster,[2246] so transfer of an electron from the one to the other is outer sphere through the protein itself.

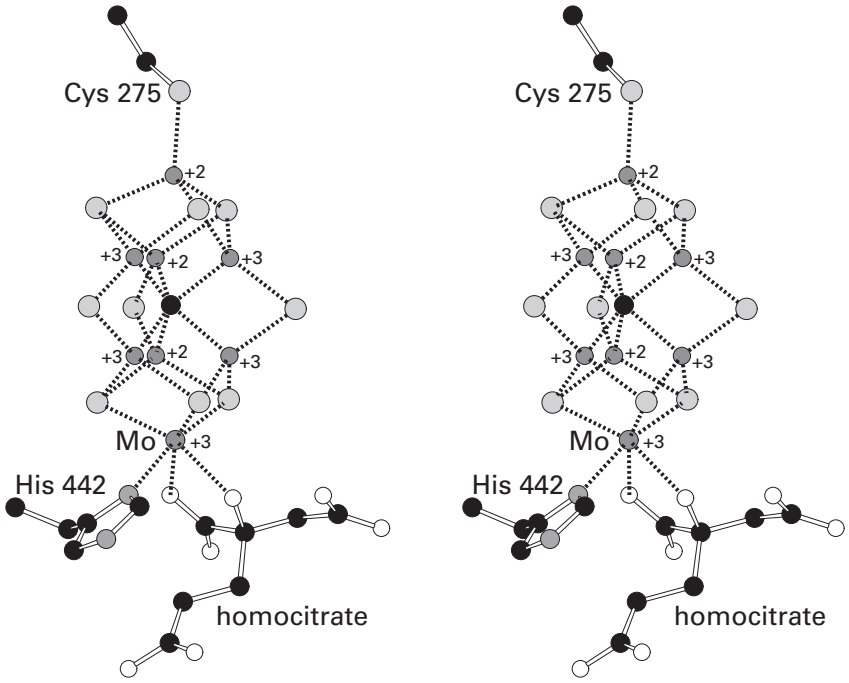


Figure 2–62: Stereodrawing[50] from the crystallographic molecular model of dinitrogenase, the molybdenum–iron protein of nitrogenase.[2234] Black atoms are carbons, white atoms are oxygens, and gray atoms are nitrogens. In the molybdenum–iron–sulfur–carbon cluster, large light gray spheres are sulfides, small dark gray spheres are iron ions, and the single molybdenum ion is labeled. The drawing includes the [Mo–7Fe–9S–C] molybdenum–iron–sulfur–carbon cluster in the active site as well as the sulfido group of Cysteine 275, coordinating one of the iron ions of the complex, and the imidazolyl group of Histidine 442, coordinating the molybdenum ion. A homocitrate completes the coordination of the molybdenum ion by providing one of its carboxylates and its central hydroxy group as ligands. The single carbon of the mononuclear carbide ion (C^{4-}) is the black sphere in the middle of the structure.

The resting, fully reduced [8Fe–7S] iron–sulfur cluster has the same disposition of iron ions as the [Mo–7Fe–9S–C] cluster with several exceptions. The molybdenum ion is replaced with an iron ion, and that iron is coordinated by a single cysteine rather than a histidine and a homocitrate. One of the central equatorial sulfide ions is missing, the other two are replaced by two sulfido groups from two cysteines, and the mononuclear carbide tetraion is replaced by a sulfide diion. The two iron ions that are not joined by the sulfido group of a cysteine (the two iron ions in the center rear of **2–152**), but are each coordinated by their own cysteines, move apart from each other, and as a result, one of the bonds from the central sulfide to one of these iron ions (the one in the lower rear) is abnormally long and, presumably, abnormally weak.

This [8Fe–7S] iron–sulfur cluster contains a standard [4Fe–4S] iron–sulfur subcluster (upper half of **2–152**). Depending on the oxidation state of the [8Fe–7S] iron–sulfur cluster, this standard [4Fe–4S] iron–sulfur subcluster is coupled through one of its sulfide dianions (the central sulfide in **2–152**) to three, two or one of the iron ions in a [4Fe–3S] iron–sulfur subcluster that forms the other half of the entire cluster (lower half of **2–152**).[647]

In the resting, reduced form of the [8Fe–7S] iron–sulfur cluster (**2–152**), the **sulfide dianion joins the two iron–sulfur subclusters** by acting as a ligand to six iron ions and as a result occupying simultaneously in two [4Fe–4S] iron–sulfur subclusters the respective positions normally occupied by one of their sulfides.[2247] The [8Fe–7S] iron–sulfur cluster **can be oxidized in two one-electron transfers** ($E^{\circ\prime}_1 = -310$ mV; $E^{\circ\prime}_2 = -270$ mV). In the cluster oxidized by the removal of one electron, the central sulfide has dissociated from the iron ion with which it was most loosely associated but remains associated with two of the iron ions in the [4Fe–3S] iron–sulfur subcluster, and in the cluster oxidized by the removal of two electrons, the sulfide is associated with only one of the iron ions in the [4Fe–3S] iron–sulfur subcluster.[647,2248] In the most oxidized, most dissociated state, in which the sulfide is associated with only one of the iron ions in the [4Fe–3S] iron–sulfur subcluster, the [4Fe–4S] iron–sulfur subcluster has the magnetic circular dichroic spectrum of a normal [4Fe–4S] iron–sulfur cluster.[2249] Neither of these oxidized forms of the [8Fe–7S] iron–sulfur cluster, however, participates in the reduction of N_2 to NH_4^+.

The reduced form of the cluster in the resting enzyme cannot be reduced further by any external reductant.[2250,2251] There is, however, no uncontroversial evidence that either of the observed oxidized states is involved in the normal transfer of the electron between dinitrogenase reductase and the [Mo–7Fe–9S–C] cluster that is mediated by this [8Fe–7S] iron–sulfur cluster. In fact, the biochemical standard reduction potentials associated with these two oxidations seem to be too positive to be involved in at least the first step in the reduction of N_2. It follows that there may be a further accessible reduced state, of significantly more negative reduction potential, that can only be accessed by dinitrogenase reductase, which is a most unusual reductant.

Dinitrogenase reductase, the iron protein, is a homodimeric protein that contains only one [4Fe–4S] iron–sulfur cluster.[2252,2253] This [4Fe–4S] iron–sulfur cluster is in the interface between the two subunits, bridges them, and is bisected by the twofold rotational axis of symmetry of the homodimer. Kinetic studies[2254,2255] and the results of site-directed mutation[2256] indicate that molecules of dinitrogenase reductase provide electrons from this [4Fe–4S] iron–sulfur cluster one at a time in the usual manner by associating with the dinitrogenase, transferring one electron, and then dissociating.[2233] The transfer of each electron from dinitrogenase reductase, however, is unusual because for every electron transferred, **two molecules of $MgATP^{2-}$ are hydrolyzed** by this electron-transferring coenzyme while it is associated with dinitrogenase.

Although no substitute for this coenzyme for the delivery of electrons to dinitrogenase during the reduction of N_2 has been discovered, Eu^{2+} coordinated by ethylenediaminetetraacetate ($E^{\circ\prime} = -1100$ mV) can provide the two electrons required for dinitrogenase from *A. vinelandii* to reduce hydrazine (**2–123**) to two NH_3 (**2–124**).[2257] It is also possible to deliver electrons photochemically to dinitrogenase from *A. vinelandii* in the absence of dinitrogenase reductase by attaching bis(2,2′-bipyridine)(phenanthroline)-ruthenium dication covalently to the enzyme. Upon illumination, with dithionite as the source of the electrons, this modified enzyme is able to photochemically reduce hydrogen cyanide to NH_4^+ and methane, a six-electron reduction.[2258] In both alternatives, all the complications of the reaction catalyzed by dinitrogenase reductase are avoided, but the most difficult step in the reduction of N_2, the addition of the first two electrons, can be accomplished at the moment only with electrons provided by dinitrogenase reductase.

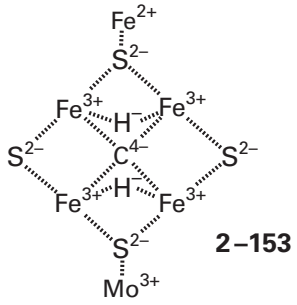
The reduced form of dinitrogenase reductase binds two molecules of $MgATP^{2-}$, one on each of its identical subunits. The binding of the two $MgATP^{2-}$ to dinitrogenase reductase from *A. vinelandii* decreases the biochemical standard reduction potential of its [4Fe–4S] iron–sulfur cluster[2259] from –300 to –400 mV and alters the conformation of dinitrogenase reductase to permit its association with dinitrogenase.[2233,2260] This conformational change ensures that only dinitrogen reductases associated with two $MgATP^{2-}$ can associate with dinitrogenase. Upon the association of $(MgATP^{2-})_2$·dinitrogenase reductase with dinitrogenase, an electron is transferred from the [4Fe–4S] iron–sulfur cluster on dinitrogenase reductase (140 s^{-1} at 25 °C).[2233,2261] The [4Fe–4S] iron–sulfur cluster is thrust up against the surface of the dinitrogenase, and the electron passes through the [8Fe–7S] iron–sulfur cluster to the [Mo–7Fe–9S–C] cluster.[2253,2262] This transfer of the electron is followed immediately by hydrolysis (70 s^{-1} at 25 °C) of the two $MgATP^{2-}$ molecules to two $MgADP^{-}$ molecules and two phosphates,[2263] which induces a conformational change in the dinitrogenase reductase. This conformational change and the reduction of the now-oxidized [4Fe–4S] iron–sulfur cluster of dinitrogenase reductase from *A. vinelandii* by the flavodoxin[2228,2229,2264] that is one of its physiological reductants promote the dissociation of the complex between dinitrogenase and dinitrogenase reductase.[2233] The reduction of the [4Fe–4S] iron–sulfur cluster in dinitrogenase reductase also decreases the free energy of dissociation for the two molecules of $MgADP^{-}$ by –20 kJ mol^{-1}, which promotes their release and returns the system to the initial state.[2259]

This complex sequence of events, by coupling steps in the hydrolysis of $MgATP^{2-}$ to steps in transfer of the electron, is **a way to ensure that every time an electron is transferred from dinitrogenase reductase to dinitrogenase, two molecules of $MgATP^{2-}$ are hydrolyzed** and every time two molecules of $MgATP^{2-}$ are hydrolyzed by dinitrogenase reductase, an electron is transferred.[2265] This coupling has the effect of decreasing the biochemical standard reduction potential (–425 and –619 mV) of each electron delivered by the indigenous ferredoxin in *A. vinelandii*[2266,2267] by an additional –1100 mV, an amount equal to the free energy of hydrolysis (–100 kJ mol^{-1}) for two $MgATP^{2-}$ (Equation 2–331) at physiological concentrations of $MgATP^{2-}$, $MgADP^{-}$, and phosphate.[2268] This estimate of the decrease in the biochemical standard reduction potential provided by the hydrolysis of $MgATP^{2-}$ assumes that the system is at equilibrium. In the normal reduction of N_2, the system is not at equilibrium during turnover and the decreases in actual biochemical standard reduction potential may be less than these estimates.

In the benzoyl-CoA reductases from *A. evansii* and *T. aromatica*, there is a similar reductant the reduction potential of which is decreased by the hydrolysis of $MgATP^{2-}$ so that it is a strong enough reductant to break the aromaticity of benzoyl-SCoA during its conversion to cyclohexa-1,5-diene-1-carbonyl-SCoA.[2269]

When reductions are initiated by mixing dinitrogenase reductase and dinitrogenase from *K. pneumoniae* with $MgATP^{2-}$ in the presence of reductant and N_2 and quenched in acid at various times,[2270] the only products observed[2271] are H_2, hydrazine (N_2H_4), and NH_3 (Figure 2–56). By following the production of these three products as a function of time and the concentration of the reactants, N_2, $MgATP^{2-}$, and reductant, a kinetic mechanism could be formulated[2270] that is consistent with later observations. Consistent with this scheme, dinitrogenase reductase from *A. vinelandii* reduces the resting dinitrogenase from *A. vinelandii* in three **one-electron steps**, each involving the association and then the dissociation of a dinitrogenase reductase, before N_2 can associate with the [Mo–7Fe–9S–C] cluster, but N_2 can also associate after four electrons have been transferred.[2272-2275] Electron paramagnetic resonance and electron–nuclear double resonance spectra of dinitrogenase from *A. vinelandii* has identified two μ-hydrido groups, each of them between two of the iron ions, in this reduced form of the cluster.[2276-2280] The identity of the iron ions that participate is not known, but it is assumed that they are four of the iron ions that coordinate the mononuclear carbide on one of the faces of the triangular prism that surrounds it, that each hydride is bound by two adjacent iron ions, and that the two hydrides are forced to be immediately adjacent to each other by the hybridization around the iron ions.*

*Recall that the mononuclear carbide is well below the two hydrides in this diagram (see Figure 2–62).



2–153

Calculations are consistent with this distribution of atoms.[2281] Because the four electrons have been added to two hydrons to produce the two μ-hydrido groups, the metals in the cluster remain at the oxidation state of the resting state,[2277] but they are not necessarily distributed as they are in the resting state. It is assumed,[2281] however, that the electrons are distributed so that the four iron ions to which the two hydrides are ligands are Fe^{3+}. In the absence of N_2, hydrons slowly associate with these μ-hydrido groups in a detrimental side reaction that continuously produces H_2, just as hydrons normally do in hydrogenase, and when the concentration of N_2 is not high enough, the ratio of H_2 to NH_3 in the products exceeds the stoichiometric equation (Equation 2–329) because of this side reaction.[2282-2285]

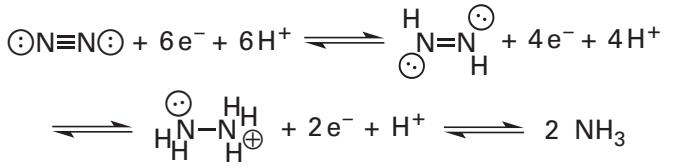
When N_2 binds to the [Mo–7Fe–9S–C] cluster, a molecule of H_2 is released from it, which is formed from the two μ-hydrido groups. The formation of a molecule of H_2 from two hydrides is a two-electron oxidation, so this reductive elimination has the effect of reducing the [Mo–7Fe–9S–C] cluster by two electrons, and this reduction is driven by formation of the bond between the two hydrides and dissociation of the H_2. This exchange of H_2 for N_2 is fully reversible,[2286] and the equilibrium constant is equal to 5 when the cluster has been reduced by three electrons and equal to 1 when the cluster has been reduced by four electrons.[2270] The rate constants for the steps in the overall reaction, however, are such that at high electron flux, the cluster reduced by four electrons is the predominant species with which N_2 associates.[2270,2285] At temperatures below 20 K it is possible to photolytically induce the dissociation of H_2 from the intermediate with the two μ-hydrido groups, and this hyperreduced cluster reassociates with the H_2 as the temperature is raised,[2287] a fact demonstrating that the dissociation of H_2 is also reversible in the absence of N_2.

The source of the two hydrons that become the two μ-hydrido groups, the hydrons that add to the two nitrogens in N_2 as it becomes N_2H_2, and the hydrons that eventually become the three hydrogens on the two NH_3 is unclear. There is a water channel from the solution into a location near the [Mo–7Fe–9S–C] cluster, but aside from the carboxy group on the homocitrate that is a ligand to the molybdenum ion, the acid–bases of the amino acid side chains in the vicinity of the [Mo–7Fe–9S–C] cluster are not conserved among the dinitrogenases from different species.[2288] In the different active sites, however, there is always a side chain in a location from which it could act as a donor in a hydrogen bond to N_2 after it associates with the cluster, an outcome that has been shown to weaken the triple bond in a molecule of N_2 that is a ligand to a metallic ion.[2289]

The [Mo–7Fe–9S–C] cluster that has been hyperreduced by the formation and dissociation of H_2 is a powerful enough reductant to reduce N_2 immediately by two electrons, which is the most difficult step in the reduction of N_2, without the need for any additional electrons. The product of the reduction of N_2 by two electrons and two hydrons is diazene, N_2H_2 (**2–122**). When the intermediate in the reaction with which the N_2H_2 is associated, however, is quenched with acid or base during the kinetic studies and the diazene is released into the solution, it rapidly disproportionates to N_2 (**2–121**) and hydrazine, N_2H_4 (**2–123**). This N_2H_4 is observed as one of the products in the kinetic studies, and it stands in for the diazene that is actually produced in the active site at this step.

Neither the hydronation state of the nitrogens at this level of reduction nor whether or not the nitrogen atoms are still covalently associated with each other, however, is known. There is a crystallographic molecular model of dinitrogenase from *A. vinelandii* in which molecules of either N_2 or N_2H_2, which cannot be distinguished crystallographically, are bound to the [Mo–7Fe–9S–C] cluster. In one asymmetric unit, however, each nitrogen atom in N_2 or N_2H_2 is a ligand to a different iron ion. In the other asymmetric unit, two molecules of N_2 or N_2H_2 are bound and in each case only one of the nitrogen atoms is a ligand to each of the two iron ions. Furthermore, the molecules are each bound to different iron ions in the respective active sites, so it is impossible to know which, if any, of these dispositions are relevant to the reduction of N_2. In each case, however, only one of the two nitrogen atoms is an acceptor in one or more hydrogen bonds from the protein surrounding the respective cluster.[2290]

Both **diazene, N_2H_2 (2–122)**,[2291] and **hydrazine, N_2H_4 (2–123)**,[2292] are substrates for the dinitrogenase, which, with the proper number of electrons, converts both into NH_4^+. Consequently, it is possible that the enzymatic reaction proceeds in three two-electron steps



(2–332)

with N_2H_2 and N_2H_4 remaining tightly bound as ligands to one or more[2293] of the metallic ions in the [Mo–7Fe–9S–C] cluster. The bond order of the nitrogens at these oxidation states, however, is unknown. The kinetic mechanism has identified intermediate steps in the overall reduction[2270] and is consistent with the two NH_3 dissociating from the active site in different steps separated by two one-electron reductions,[2294] but this conclusion says nothing about when the two NH_3 are created in the active site. Several intermediate forms of nitrogen on the [Mo–7Fe–9S–C] cluster have been identified.[2272,2295] Single nitrogen atoms, unbonded to another nitrogen atom and reduced by the addition of either two or three hydrogen atoms, respectively, comprise two of the latter intermediates.[2296,2297] The precise structures of none of these intermediates, however, is known.[2295]

When the structure of the [Mo–7Fe–9S–C] cluster became available from crystallographic molecular models, it was not known that the central atom was a mononuclear carbide. At the time it was thought that the most unusual feature of the cluster in the active site of dinitrogenase was the molybdenum ion rather than the iron ions.[2298] This assumption led to an examination of **synthetic complexes of molybdenum ions** that were able to reduce N_2 to NH_3.[2299-2302] The recent discovery of a more reduced molybdenum ion in the [Mo–7Fe–9S–C] cluster than in any other enzymatic prosthetic group has reinvigorated some of the enthusiasm for the molybdenum ion to be involved directly in the reduction.[2245]

When it became known that the central ion was a mononuclear carbide, it also became obvious that the completely unprecedented feature of the [Mo–7Fe–9S–C] cluster was the [6Fe–3S–C] iron–sulfur–carbon subcluster at its core. In addition, the fact that there are nitrogenases that have [8Fe–9S–C] iron–sulfur–carbon clusters[2303] and [V–7Fe–9S–C] clusters rather than a [Mo–7Fe–9S–C] cluster[2304] belied the conclusion that the molybdenum ion plays a direct role in the reduction. For example, a nitrogenase that has a vanadium ion in place of the molybdenum ion[2242] has been purified from *Azotobacter chroococcum*.[2305] This vanadium nitrogenase is closely related to the molybdenum nitrogenase from *A. vinelandii* (31% identity; 1.7 gap percent), and the [V–7Fe–9S–C] cluster has an identical structure with the exception of the substitution of a vanadium ion for a molybdenum ion.[2306] In cells of *A. vinelandii*, three related (31% identity; 1.4 gap percent; 32% identity; 1.9 gap percent; and 54% identity; 0 gap percent) but definitely different dinitrogenases are present,[2307] one with a [Mo–7Fe–9S–C] cluster, one with an [8Fe–9S–C] cluster, and one with a [V–7Fe–9S–C] cluster in the respective active sites,[2308] and as expected, the mechanism by which the [8Fe–9S–C] cluster and the [V–7Fe–9S–C] cluster convert N_2 to NH_4^+ is the same as that of the [Mo–7Fe–9S–C] cluster.[2309] In cells of *R. capsulatus*, there is both an iron version and a molybdenum version of dinitrogenase.[2310] Further evidence that the molybdenum ion is not involved in the reduction of N_2 is that upon dissociation of H_2 from the [Mo–7Fe–9S–C] cluster in the active site of dinitrogenase from *A. vinelandii* as a result of the reductive elimination that leaves behind two electrons, the oxidation state of the Mo^{3+} is unchanged.[2280]

When it became clear that the iron ions in the core of the [Mo–7Fe–9S–C] cluster were in a [6Fe–3S–C] subcluster, synthetic complexes of iron ions were examined for their ability to reduce N_2 to NH_3. A synthetic complex between tri(2-diisopropylphosphinophenyl)borane and a single Fe^+ is able to catalyze the reduction of N_2 to NH_4^+ (as many as 7 equivalents of NH_4^+ from every iron ion) in diethyl ether at –70 °C, using as a reducing agent atomic potassium dispersed on graphite ($E^{\circ\prime} \geq -2900$ mV).[2311,2312] A mononuclear ion coordinated by three diisopropylphenylphosphines as equatorial ligands and either a triphenylsilane[2313] or a triphenylborane[2314] as the axial ligand, in which the iron is formally Fe^0, forms a complex with N_2 at the open site on the trigonal bipyramid. Upon addition of acid to either of these complexes,[2315,2316] the distal nitrogen becomes dihydronated, and the complex is now between a formally Fe^{4+} and $N_2H_2^{2-}$, the dianionic conjugate base of N_2H_4. The triphenylborane complex is able to convert N_2 into NH_3 catalytically,[2314] in a reduction in which, presumably, hydrazidoiron(IV) is an intermediate. The hydrazidoiron(IV), if reduced to

hydrazidoiron(III), would be the nitrogen analogue of hydroperoxyiron(III), the precursor of oxoiron(V). This analogy suggests that an azoiron(V) could be produced by hydronation of the distal nitrogen in a hydrazidoiron(III) and dissociation of NH_3 and that an azoiron(V) could be another intermediate in this reduction of N_2 to NH_3. Stable complexes containing azoiron(V) have been synthesized.[2317,2318]

The catalysis in the industrial **Haber–Bosch process** for converting N_2 to NH_4^+ occurs on surfaces of metallic iron in the catalyst.[2319] In this instance, the catalyst is produced from a dust of magnetite (Fe_2O_3) that has been partially reduced to form a layer of ferrous oxide surrounded by a layer of porous metallic iron. The first step in this surface catalysis is the chemisorption of a molecule of N_2 on a surface of the elemental iron. Following its association, the second step in the Haber–Bosch catalysis is the dissociation of nitrogen gas into individual nitrogen atoms spread over the metallic surface that are then reduced by H_2. The activation energy for the dissociation of N_2 by the surface is small, so the most difficult step is the chemisorption, after which the dissociation proceeds rapidly. These observations suggest that one step in the enzymatic reaction could be the initial dissociation of N_2 into two nitrogen atoms.

The biochemical standard reduction potential for the reduction catalyzed by dinitrogenase (Equation 2–330) is –310 mV,[2320] which appears to explain the fact that, in the absence of N_2 or at low electron flux,[2272,2273] the enzyme produces H_2 from two hydrons ($E^{\circ\prime} = -410$ mV). These rather normal standard reduction potentials, however, are misleading. Nonenzymatic electrochemical reductions of N_2 to NH_4^+ always requires voltages that are equal to or less than –1000 mV,[2321,2322] an overpotential necessitated by the fact that the first transfer of an electron to N_2 is significantly endergonic. Nonenzymatic reductions of N_2 to NH_4^+ by synthetic mononuclear molybdenum complexes require reductants with standard reduction potentials of around –1000 mV;[2299,2300] the nonenzymatic, catalytic reduction of N_2 to NH_4^+ by the synthetic mononuclear iron complex requires strong reductants such as potassium dispersed on graphite; and the standard reduction potential for converting N_2 to N_2H_4 is –750 mV. These observations explain why a rather strong reductant is needed in the enzymatic reaction.

The Haber–Bosch process and the reduction of N_2, both electrochemically and under catalysis by a mononuclear molybdenum ion or a mononuclear iron ion, in turn illustrate two of the most vexing problems with converting N_2 into NH_4^+. The first is the **difficulty in promoting the association of N_2 with the catalyst**. In the case of the metallic surfaces in a Haber–Bosch catalyst, only one in 10^6 to one in 10^8 collisions of N_2 with the surface results in successful chemisorption.[2319] How the active site of the enzyme solves this problem, if it does, is unknown. The second problem is the **high voltages needed to reduce N_2** because of the overpotential. This second problem has been solved by dinitrogenase reductase, which uses a stratagem to decrease dramatically the standard reduction potential of the electrons it delivers.[2254,2255,2260,2263]

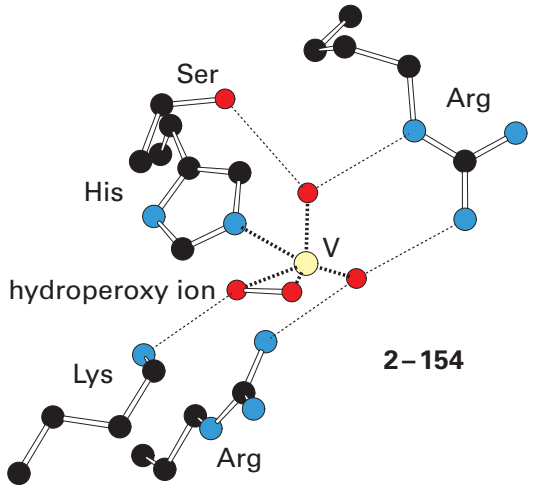
In addition to the vanadium nitrogenases, there are chloride peroxidases

$$H_2O_2 + Cl^- + H^+ + RH \rightleftharpoons RCl + 2\,H_2O \qquad (2\text{–}333)$$

and bromide peroxidases that use vanadium as a mononuclear metallic ion in their active sites. The difference between a bromide peroxidase and a chloride peroxidase is that the former can only catalyze halogenations with the more nucleophilic bromide while the latter can catalyze halogenations with the less nucleophilic chloride as well as bromide. This difference suggests that the halides are acting as nucleophiles. Bromide peroxidase from *Ascophyllum nodosum* and chloride peroxidase from *Curvularia inaequalis* have superposable tertiary structures[2323] and, therefore, share a common ancestor. The carbon–hydrogen bonds that are converted into carbon–chlorine bonds or carbon–bromine bonds by the halogenations are at a wide array of aliphatic, alkenyl, and aryl positions in natural products.[2324-2326] The halogenations performed by bromide peroxidase from *A. nodosum* display a regiospecificity that differs from brominations that occur in solution. This fact requires that the substrates associate with the enzyme before they are brominated[2325] and that the brominations occur in the active site of the enzyme.

The first step in the enzymatic reaction is the **association of hydrogen peroxide** with the halogenase. Kinetic studies as a function of pH of the reactions catalyzed by bromide peroxidase from *A. nodosum*[2327] and chloride peroxidase from *C. inaequalis*[2328] are consistent with the conclusion that the hydroperoxy ion associates with the vanadium in the respective active sites. In the crystallographic

molecular model of the active site in chloride peroxidase from *C. inaequalis* with which a hydroperoxy ion has associated, the **hydroperoxy ion has become a ligand to the vanadium ion**[2329]



The hydroperoxy ion occupies two sites on the vanadium that are occupied by hydroxy groups in the unoccupied active site. That these two ligands in the unoccupied enzyme[2330] are hydroxy groups follows from the lengths of their vanadium–oxygen bonds: 0.195 and 0.169 nm.[2331] The lengths of the respective bonds to the two oxygens of the hydroperoxy group remain the same: 0.188 and 0.167 nm. The shorter bond is for the oxygen that forms a hydrogen bond to the ammonio group of the lysine. The oxygen that forms hydrogen bonds to the two arginines (the oxygen to the right in **2–154**) is also a hydroxy group (0.168 nm), and the oxygen that forms trigonal hydrogen bonds to the serine and the δ-imino group of the arginine (vertical bond in **2–154**) is an oxo group (0.154 nm). There is a strong interaction between the imidazolyl group of a histidine and the vanadium ion (0.20 nm) to complete the pentacoordination. The vanadium ion in the active site of bromide peroxidase from *A. nodosum* is also pentacoordinated, with the imidazolyl group of a histidine as again the only ligand from the protein to the vanadium ion, but the side chains forming hydrogen bonds to the oxo group and the three hydroxy groups on the vanadium, although they are the same, differ somewhat in their orientations.[2323]

When a vanadium ion is coordinated by two amino nitrogens and two phenolato oxygens by the ligand ethylenebis[(*o*-hydroxyphenyl)glycine], it can exist in solution as dioxovanadium(V), oxohydroxyvanadium(V), oxovanadium(V), and oxovanadium(IV)\as well as in the oxidation state V^{+3}, and the various oxidation statess can be readily interconverted.[2332] These results suggest that vanadium has the capability to remove or provide electrons in the reactions catalyzed by haloperoxidases. From electron paramagnetic resonance spectra, however, it was concluded that the vanadium ion in bromide peroxidase from *A. nodosum* **remains in the oxidation state V^{+5}** throughout the enzymatic reaction and is not required to remove or add electrons to either the substrates or the intermediates in the reaction.[2327] In effect, the oxovanadium(V) is simply a metallic ion on which nucleophilic substitutions can proceed.

From the situation of the peroxy ion in the active site (**2–154**), it has been concluded that, in both chloride peroxidase and bromide peroxidase, **the halide, as a nucleophile, adds to the adjacent oxygen** of the peroxy ion. The other oxygen, which is engaged in a hydrogen bond to the ammonio group of the lysine, is hydronated by that ammonio group to become the leaving group in the nucleophilic substitution, and it eventually leaves the active site as either a hydroxide or a molecule of water. That the former **oxygen is electrophilic** and susceptible to nucleophilic substitution is illustrated by the fact that it is transferred from the peroxy ion in the active site of bromide peroxidase from *A. nodosum* to methyl phenyl sulfide to produce methyl phenyl sulfoxide.[2333] A synthetic model compound, in which an oxovanadium(V) is coordinated by three phenolato oxygens and a tertiary amine, is able to catalyze both the oxidation of methyl phenyl sulfide to a mixture of methyl phenyl sulfoxide and methyl phenyl sulfone by hydrogen peroxide (900 turnovers) and the bromination of 1,3,5-trimethoxybenzene using hydrogen peroxide as the oxidant (200 turnovers).[2334]

The immediate product of the normal nucleophilic substitution that occurs in the active site of bromide peroxidase or chloride peroxidase—in which a bromide or a chloride, respectively, is the nucleophile and the bound hydroperoxide is the electrophile—should be hypobromite or hypochlorite bound as a ligand to the vanadium ion. The species that performs halogenations of the natural substrates has not been definitively established.[2324] That bromide peroxidase from *A. nodosum*, in the absence of a substrate that can be brominated, produces hypobromous acid as a product[2335] and chloride peroxidase from *C. inaequalis*, in the absence of a substrate that can be chlorinated, produces hypochlorous acid as a product,[2328] however, suggests that the **intermediate responsible for the brominations and chlorinations** is either hypo-

bromite or hypochlorite, respectively. If so, the hypobromite or the hypochlorite must remain bound as a ligand to the vanadium ion because kinetic studies of bromide peroxidase have shown that once hypobromous acid has dissociated as the conjugate acid from the vanadium, even though it is still bound to the enzyme, it is not the species brominating substrates.[2335]

Bromide peroxidase from *A. nodosum* brominates 2,3-dimethoxytoluene within the phenyl ring rather than at the methyl group and produces the same product as the electrophilic aromatic substitution performed by bromonium ion.[2336,2337] This result demonstrates that the species halogenating this unnatural substrate in the active site of the enzyme must be a bromonium ion or its equivalent rather than a bromine radical. Consequently, the **brominations catalyzed by the enzyme are heterolytic**. It is likely that the ammonio group of the lysine can hydronate the oxygen of the hypobromite or hypochlorite bound as a ligand to the vanadium ion to make that oxygen a better leaving group and make the bromine more electrophilic and more like a bromonium ion if not, after the oxygen leaves in the first step of a dissociative nucleophilic substitution, an actual bromonium ion. The intermediate responsible for the brominations catalyzed by bromide peroxidase is also able to oxidize hydrogen peroxide, which is a singlet molecule, to singlet molecular oxygen[2336,2338] in yet another **heterolytic reaction**. This latter oxidation permits the enzyme to be a catalase in the absence of a substrate it would otherwise brominate.

The enzyme contains a nonheme iron ion coordinated by two histidines and a glutamate (see Figure 2–57D for a similar coordination).[2344] If $^{18}O_2$ were used as a substrate, where would the two atoms of oxygen-18 end up?

Problem 2–35: Draw a detailed mechanism for the oxidation of carbon monoxide catalyzed by the prosthetic group **2–143**.

1,2-Benzoquinones

There are several different 1,2-benzoquinones that act as electrophiles in enzymatic reactions. In this sense, they are one of the prosthetic groups that make up for the fact that there are no electrophiles among the side chains of the amino acids. These 1,2-benzoquinones are the prosthetic group pyrroloquinoline quinone (**2–155**),[2345-2347] which is synthesized from a glutamate and a tyrosine in a short peptide,[2348,2349] and the posttranslational modifications 2,4,5-trihydroxyphenylalanylquinone (**2–156**),[7]

lysine tyrosylquinone (**2–157**),[2350] tryptophan tryptophylquinone (**2–158**),[2351,2352] and cysteine tryptophylquinone (**2–159**)[2353,2354]

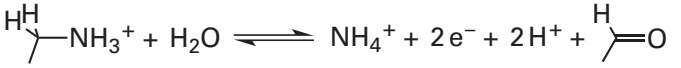
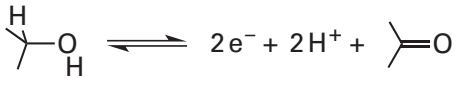
The 1,2-benzoquinones produced by the four post-translational modifications catalyze the oxidation of primary amines to aldehydes



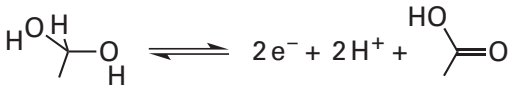
(2–334)

and pyrroloquinoline quinone (**2–155**) catalyzes the oxidation of primary and secondary alcohols to aldehydes and ketones



(2–335)

and *gem*-diols to carboxylic acids



(2–336)

The **oxidation of primary amines to aldehydes by 2,4,5-trihydroxyphenylalanylquinone** in the active site of primary-amine oxidase (Equation 2–334) is an introduction to the capabilities of 1,2-benzoquinones. The two electrons resulting from the oxidation are transferred to molecular oxygen, reducing it to hydrogen peroxide. The enzyme also contains a prosthetic copper ion coordinated by three imidazolyl groups from three histidines. Either one or two molecules of water or the oxygen at carbon 4 of 2,4,5-trihydroxyphenylalanylquinone (**2–156**), depending on the situation,[2355-2360] completes the coordination of the copper ion. In the crystallographic molecular models of the primary-amine oxidases in which it is not a direct ligand to the copper ion, 2,4,5-trihydroxyphenylalanylquinone is either immediately adjacent to or forming a hydrogen bond through one of its oxygens to one of the molecules of water that is a ligand to the copper ion. In the resting state of the enzyme, the copper ion is in the oxidized cupric state.

The mechanism of oxidation of primary amines to aldehydes (Figure 2–63)[2361,2362] is homologous to the one for conversion of secondary amines to ketones catalyzed by pyridoxal 5′-phosphate. The primary amine forms **proximal imine 2–160**[2363,2364] with the carbonyl carbon 5 of 2,4,5-trihydroxyphenylalanylquinone.[2361,2365] This imine has been trapped as the stable amine by reduction with sodium cyanoborohydride.[2366] As in deaminations catalyzed by pyridoxal phosphate (Equation 2–4), the next step in the reaction catalyzed by primary-amine oxidase is the dehydronation of the secondary carbon immediately adjacent to the imino nitrogen in proximal imine **2–160**. When a series of benzylamines with different substituents in the phenyl ring were used as substrates for bovine primary-amine oxidase, the rate at which a hydrogen was removed from the benzyl carbon increased as the ability of the substituents to withdraw electron density from the benzyl carbon increased,[2367] as expected if a hydrogen is removed from the benzylic carbon as a hydron.

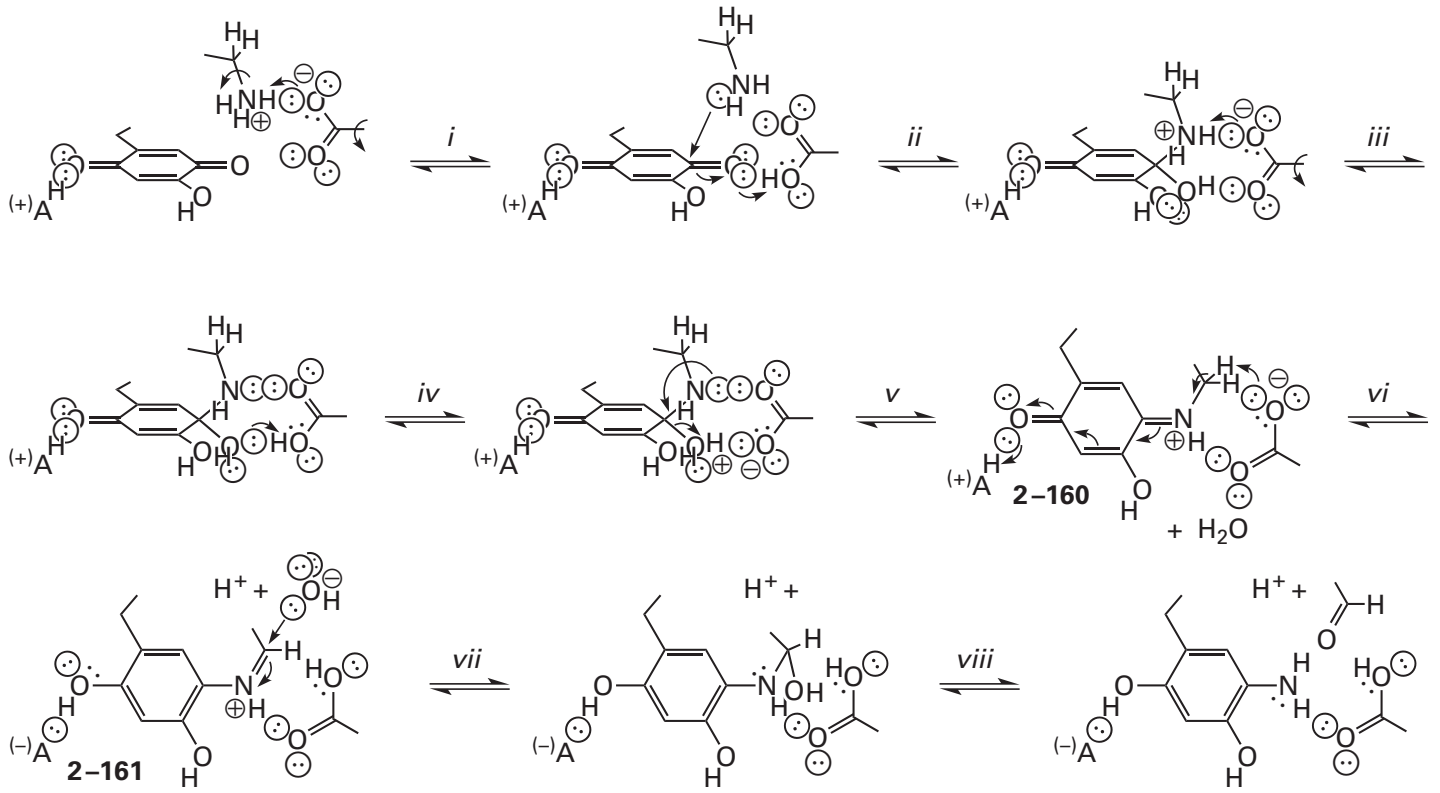


Figure 2–63: Mechanism for the conversion of a primary amine to an aldehyde by the 2,4,5-trihydroxyphenylalanylquinone in primary-amine oxidase.[2361,2362] The hydron of the primary amine is (*i*) removed by the carboxylate of an aspartate in the active site of the enzyme, and the resulting carboxy group (*ii*) hydronates the carbonyl oxygen at position 5 in the 2,4,5-trihydroxyphenylalanylquinone as the lone pair of electrons on the amine attacks the carbonyl carbon to form the conjugate acid of the internal hemiaminal. The carboxylate of the aspartate then (*iii*) transfers a hydron from the ammonium nitrogen to the hydroxy group of the hemiaminal, and the hydronated hydroxy group (*iv*) is pushed away as a leaving group by the lone pair of electrons on the adjacent amino group to produce the internal iminium ion. Both oxygens of the resulting 2,4-dihydroxy-5-amino-phenylalanylquinone (*v*) withdraw electrons through the π system of the quinone from the bond between the primary carbon of the former amine and one of its hydrogens when that bond is parallel to the π system. The carboxylate of the aspartate (*vi*) removes the hydron from the weakened bond, creating an *N*-(5-alkyl-2,4-dihydroxyphenyl)-imine. A hydroxide (*vii*) nucleophilically attacks the iminium carbon of this external *N*-hydronated imine to produce the external hemiaminal. The carboxy group of the aspartate is available (*viii*) to provide a hydron to the oxygen and remove a hydron from the nitrogen of the hemiaminal to promote the dissociation of 5-alkyl-2,4-dihydroxy-aniline and form the aldehyde. During all these transfers, a hydron is never required to enter or leave the active site, although hydrons probably do so.

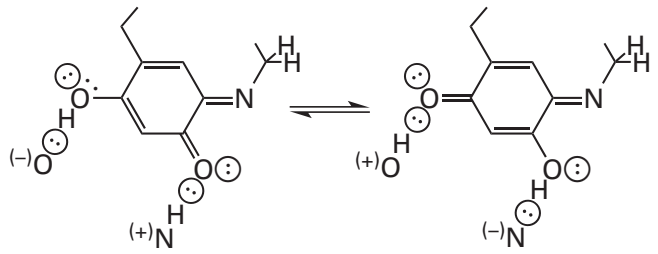
The atoms in proximal imine **2–160** that **withdraw electron density from the this primary carbon–hydrogen bond** are the two oxygens at positions 2 and 4 rather than the pyridyl nitrogen in an external pyridoximine (Equation 2–4). These two oxygens are involved in a tautomeric equilibrium



(2–337)

that interconverts each of them, respectively, between an oxo group and a hydroxy group. In primary-amine oxidase, acid–bases form hydrogen bonds to each of these two oxygens that give or take the respective hydrons as needed. For example, in primary-amine oxidase from several different species, the hydroxy group of a tyrosine ($pK_a \cong 9.8$)* forms a hydrogen bond to oxygen 4, and an acidic molecule of water ($pK_a \geq 7$) is coordinated to the prosthetic Cu^{2+} and forms a hydrogen bond to oxygen 2.[2356,2361,2365] In the primary-amine oxidase from *P. sativum*, the ammonio group of a lysine ($pK_a \cong 10.5$) forms a

*The values of pK_a are for an average tyrosine, lysinium ion, or aspartic acid in a protein.[2368] Acid–bases in active sites often have quite different acidities.

hydrogen bond at oxygen 4, and the carboxy group of an aspartic acid ($pK_a \cong 4.0$) forms a hydrogen bond at oxygen 2.[2355] Consequently, at any instant either oxygen 2 or oxygen 4 can be a carbonyl oxygen at the ortho or para position to the proximal imine, respectively, and can withdraw electron density from the carbon–hydrogen bond immediately adjacent to that imino nitrogen.

To permit this electron withdrawal by the oxo groups in the ring to occur, the acidic carbon–hydrogen bond in the proximal imine is held parallel to the π molecular orbital system (Equation 2–337) connecting the imino nitrogen to the carbonyl oxygens at positions 2 and 4[2361,2369] in proximal imine **2–160**. Removal of the hydron from the carbon produces **distal imine 2–161** and is coincident with the **aromatization** that produces a 2,4-dihydroxyphenyl group on the nitrogen of the distal imine (Figure 2–63). This aromatization provides significant favorable free energy of activation to the removal of the hydron from the carbon, usually a difficult reaction. After a **hydrolysis** that produces the aldehyde and its dissociation, the initial 1,2-benzoquinone has been reduced to the aminobenzoquinol 5-amino-2,4-dihydroxyphenylalanine.

In most of the primary-amine oxidases, the hydron is removed from the carbon adjacent to the imino nitrogen of proximal imine **2–160** by the **carboxylato group of an aspartate**.[2370] that is properly situated and aligned for the removal.[2361] This carboxylato group is also in the proper location to remove the hydron from the incoming amine, to add a hydron to the 5-oxido oxygen, to remove a second hydron from the amino group in the proximal hemiaminal, and to add a second hydron to the 5-hydroxy group of the hemiaminal to create the water that leaves (Figure 2–63), just as the oxygen of the phenoxylato group in the proximal pyridoximine catalyzes its transimination to the external pyridoximine (Figure 2–2). The conclusion that this is one of the roles played by this aspartate is supported by the fact that, in addition to the rate of the dehydronation of the secondary carbon in distal imine **2–161**, the rate for the formation of proximal imine **2–160** in the active site of primary-amine oxidase from *A. globiformis* is dramatically decreased (by a factor of 10^6) when this aspartate is mutated to alanine.[2361] In addition, this aspartic acid may act as an acid and then a base in the hydrolysis of the distal imine between 5-amino-2,4-dihydroxyphenylalanine and the aldehyde. It is also positioned so that it sterically pins the ring of 2,4,5-trihydroxyphenylalanylquinone in its proper orientation for catalysis. The plenipotency of this carboxy group is reminiscent of the plenipotency of the amino group of the lysine in enzymes using pyridoxal phosphate as a prosthetic group.

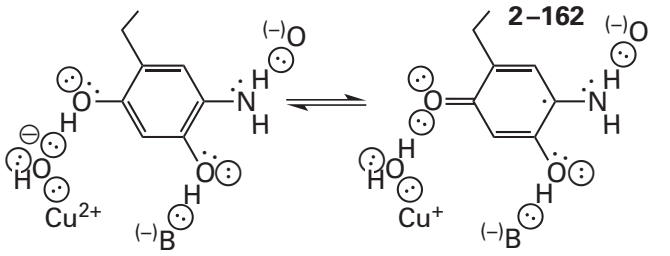
Several 2,4,5-trihydroxyphenylquinones that differ only in the substituents at carbon 1 have been synthesized. These **synthetic models** are able to catalyze, in solution nonenzymatically, the oxidation of primary amines to their aldehydes using molecular oxygen as the receptacle for the electrons,[2371,2372] just as a primary-amine oxidase is able to do. The proximal imine of the primary amine and the synthetic 2,4,5-trihydroxyphenylquinone, the distal imine of the product aldehyde and the synthetic aminodihydroxyphenylquinol, and the aminodihydroxyphenylquinol itself (see Figure 2–63) have all been identified under anaerobic conditions as intermediates in the deaminations that are accomplished by these synthetic models.[2371,2373,2374]

In the primary-amine oxidases as well as in bovine protein-lysine 6-oxidase, which uses lysine tyrosylquinone (**2–157**) as an electrophile,[2350,2375] 5-amino-2,4-dihydroxyphenylalanine and lysine tyrosylquinol, which are the reduced products of the respective prosthetic groups following the oxidations of amines to aldehydes, are reoxidized to 2,4,5-trihydroxyphenylalanylquinone (**2–156**) and lysine tyrosylquinone (**2–157**), respectively, by molecular oxygen, which is reduced by the two electrons to hydrogen peroxide. Although the precise **mechanism of the reoxidation by molecular oxygen** has not yet been established,[2376] there are several provocative observations.

Oxygen is only able to bind to a Cu^+, not a Cu^{2+}. In the reduced enzyme that must be reoxidized, however, the copper ion, because it does not participate as an oxidant in deamination of the substrate by the 2,4,5-trihydroxyphenylalanylquinone, remains the Cu^{2+} that it was in the resting enzyme. In fact, all the steps leading to the formation of 5-amino-2,4-dihydroxyphenylalanine and the release of the aldehyde are unaffected by the removal of the Cu^{2+} from the active site of primary-amine oxidase from *Lens culinaris*.[2377] Nevertheless, in the active site from which the Cu^{2+} has been removed, the enzymatic reaction cannot proceed beyond formation of the prosthetic 5-amino-2,4-dihydroxyphenylalanine in the presence of saturating concentrations of oxygen, so the **Cu^{2+} is required for the reoxidation**.

In several primary-amine oxidases that are in the reduced state after oxidizing an amine under anaerobic conditions, the 5-amino-2,4-dihydroxyphenylalanine in their active sites engages in an

electron transfer with the adjacent Cu^{2+} to produce a Cu^{+} and the semiquinone of 5-amino-2,4-dihydroxyphenylalanine (**2–162**)[2378,2379]



(2–338)

which was identified from the electron-spin resonance spectrum of its unpaired electron.[2380] In reduced primary-amine oxidase from *P. sativum*, in the absence of oxygen, this equilibrium is rapidly established.[2381] There is a crystallographic molecular model of the cuprous semiquinone in the active site of primary-amine oxidase from *Ogataea parapolymorpha* in which the anionic conjugate base of the 4-hydroxy group of the semiquinone has swung over to displace a molecule of water and become the fourth ligand to the copper ion.[2382] Such a ligation could represent an intermediate in this electron transfer, but it should not be necessary because the Cu^{2+} is coupled to the 5-amino-2,4-dihydroxyphenylalanine in the outer sphere through the molecule of water. Nevertheless, inner-sphere electron transfer is usually instantaneous.

The **biochemical standard reduction potential of 2,4,5-trihydroxyphenylalanylquinone**[2383] in free solution is +75 mV. This reduction is fully reversible but is a reduction by two electrons. No evidence for the presence of the semiquinone of 2,4,5-trihydroxyphenylalanine was seen in the voltammograms of this reduction in solution. Consequently, the biochemical standard reduction potential for the redox couple of the semiquinone and the fully reduced 2,4,5-trihydroxyphenylalanine should be significantly more positive than +75 mV, which is not surprising since the single ring is unable to delocalize the unpaired electron as well as it is delocalized, for example, in the semiquinone of a flavin or a pterin. The one-electron biochemical standard reduction potential of the semiquinone of 5-amino-2,4-dihydroxyphenylalanine (**2–162**), however, should be less positive than that for the semiquinone of 2,4,5-trihydroxyphenylalanine because the amino group is a stronger electron-releasing functional group. Dehydronation of the 2-hydroxy group by the cupric hydroxide should decrease the one-electron standard reduction potential even further. Cupric ions involved in electron transfer in proteins usually have biochemical standard reduction potentials greater than +80 mV (Figure 2–19), so a Cu^{2+} immediately adjacent to 5-amino-2,4-dihydroxyphenylalanine and connected to it in the inner sphere should be able to oxidize it by one electron, as is observed.

In a crystallographic molecular model of primary-amine oxidase from *E. coli*, **molecular oxygen is associated with cuprous semiquinone 2–162**,[2384] displacing the molecule of water that is a ligand to the copper ion and sitting between the copper ion and the 2-hydroxy group of the semiquinone of 5-amino-2,4-dihydroxyphenylalanine.[2385] This observation suggests that this complex between molecular oxygen and the cuprous semiquinone is an intermediate in reoxidation of the 5-amino-2,4-dihydroxyphenylalanine. The proposal can be divided into three steps. First, molecular oxygen associates with cuprous semiquinone **2–162** and is reduced by the Cu^{+} to superoxide radical anion. Second, the superoxide radical anion is then hydronated to form hydroperoxy radical that removes the electron from the semiquinone of 5-amino-2,4-dihydroxyphenylalanine. Third, the resulting hydroperoxy ion or, upon hydronation, the hydrogen peroxide then dissociates.[2386] The imine of the resulting 5-imino-2,4-dihydroxyphenylalanylquinone is then hydrolyzed to 2,4,5-trihydroxyphenylalanylquinone, returning the enzyme to the resting state.

In other primary-amine oxidases, however, the equilibrium between the cupric 5-amino-2,4-dihydroxyphenylalanine and the cuprous semiquinone (Equation 2–338) cannot be observed. This failure may simply indicate that the equilibrium constant is smaller in these instances, but when the Cu^{2+} in primary-amine oxidase from *S. cerevisiae*[2387] and the Cu^{2+} in primary-amine oxidase from *A. globiformis*[2388] were each **replaced with Co^{2+}**, with which this transfer of an electron does not occur, the respective enzyme nevertheless retained 100% or 2% of its activity at saturating concentrations of reactants. This result brings into question the importance of the rapid electron transfer and the role of the copper ion as a participant in the oxidation–reductions involved in the reoxidation of the 5-amino-2,4-dihydroxyphenylalanine.

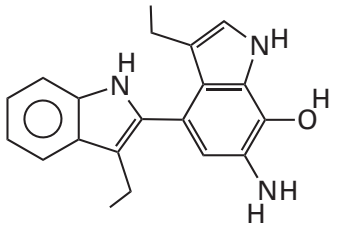
Direct transfer of an electron between 5-amino-2,4-dihydroxyphenylalanine and molecular oxygen to form superoxide radical anion and the semiquinone of 5-amino-2,4-dihydroxyphenylalanine has been proposed as the first step in its reoxidation.[2389] Such a transfer of an electron is reminiscent of the

direct transfer of an electron from reduced flavin to molecular oxygen (Equation 2–207). Transfer of an electron from 5-amino-2,4-dihydroxyphenylalanine to molecular oxygen ($E^{\circ\prime}$ = –160 mV for 1 M O_2 and 1 M $O_2^{\bullet-}$), however, should be significantly endergonic, even when electron donation of the amino nitrogen and dehydronation of the 2-hydroxy group are considered. If such an electron transfer is actually the first step in reoxidation of 5-amino-2,4-dihydroxyphenylalanine by molecular oxygen, the superoxide radical anion that is being formed or that has been formed would be able to associate with the Cu^{2+} during or after the transfer, respectively, but not before, and this association would definitely stabilize the superoxide radical anion and facilitate the transfer. By both this mechanism and the mechanism involving the cuprous semiquinone, hydroperoxy copper(II) 5-amino-2,4-dihydroxyphenylalanyl semiquinone is a common intermediate even though the details of its formation differ.

The enzymes that oxidize primary amines to aldehydes with **tryptophan tryptophylquinone (2–158)** and **cysteine tryptophylquinone (2–159)** use the same mechanism for the oxidation as that used by 2,4,5-trihydroxyphenylalaninylquinone (Figure 2–63). The amine adds as a nucleophile to the 6-oxo carbon[2352] to form the proximal imine.[2390] There is a crystallographic molecular model of the proximal imine formed between the prosthetic cysteine tryptophylquinone and L-lysine in the active site of L-lysine 6-oxidase from *Marinomonas mediterranea*,[2354] and a stable proximal imine forms between the prosthetic cysteine tryptophylquinone and glycine in the active site of glycine oxidase from *Pseudoalteromonas luteoviolacea*[2391] that has been defined by its resonance Raman spectra and that has been observed in a crystallographic molecular model.[2392] In the active site of glycine oxidase from *P. luteoviolacea*, Aspartate 678 is responsible for catalyzing the transimination that forms the proximal imine and for the transimination of the distal imine. This conclusion follows from the facts that when it is mutated to an asparagine, the proximal imine cannot form, and when it is mutated to a glutamate, the distal imine accumulates.[2393]

The hydron on the carbon immediately adjacent to the nitrogen of the proximal imine in the active sites of the enzymes that use prosthetic tryptophan tryptophylquinone and cysteine tryptophylquinone is then removed, again by the carboxylate of an aspartate.[2352,2354,2394] Electron withdrawal by substituents within benzylamines that have formed proximal imines with the prosthetic tryptophan tryptophylquinone in the active site of aralkylamine dehydrogenase (azurin) from *A. faecalis* causes the rate constant for the removal of this hydron from carbon to increase, as expected.[2395]

Following hydrolysis of the resulting distal imine and release of the aldehyde that is the product, the tryptophan tryptophylquinone in the active site of methylamine dehydrogenase (amicyanin) from *P. denitrificans* has become an **aminoquinol, 6-amino-7-hydroxy-4-(2-tryptophyl)tryptophan**[2396]



2–163

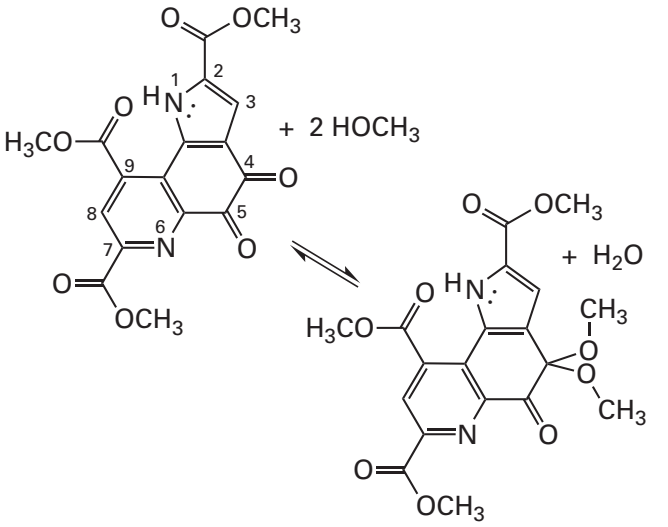
In a mutant in which Histidine 767 has been changed to alanine in glycine oxidase from *P. luteoviolacea*, the hemiaminal, which is an intermediate in hydrolysis of the distal imine that has formed between the glycine and the prosthetic cysteine tryptophylquinone, accumulates and can be observed in a crystallographic molecular model.[2397]

Unlike 5-amino-2,4-dihydroxyphenylalanine in the active site of a primary-amine oxidase, however, the aminoquinols of both tryptophan tryptophylquinone (**2–163**) and cysteine tryptophylquinone are usually **oxidized back to the respective quinones by two outer-sphere, one-electron transfers** to amicyanin, azurin, or a cytochrome, depending on the particular enzyme and the particular species.[2353,2398] 6-Amino-7-hydroxy-4-(2-tryptophyl)-tryptophan (**2–163**) in the active site of methylamine dehydrogenase (amicyanin) from *P. denitrificans* forms a stable, neutral radical upon transfer of the first electron and removal of a hydron. In this neutral radical the unpaired electron can be delocalized over four rings,[2399-2401] perhaps making this semiquinone even more stable relative to the quinol than the semiquinone of flavin is relative to reduced flavin. In the active site of glycine oxidase from *P. luteoviolacea*, however, in which the electron can delocalize only onto the sulfur of the cysteinyl group in the prosthetic cysteine tryptophylquinone, the biochemical standard reduction potential for the couple of the quinone and the semiquinone is +110 mV and that for the couple of the semiquinone and the quinol is +20 mV, so the semiquinone is again quite stable.[2402] In this latter instance, the ultimate receptacle for the two electrons is a molecule of oxygen, so the semiquinone is presumably

necessary to separate the unpaired electrons on the molecular oxygen in the first electron transfer, as in the case of flavin oxidases. The two-electron biochemical standard reduction potential of the cysteine tryptophylquinone in the active site of quinohemoprotein amine dehydrogenase from *P. denitrificans* is +40 mV, and the biochemical standard reduction potentials of the two hemes *c* within the enzyme, which pass in turn the two electrons to two cytochromes *c*-550, during the reoxidation of 6-amino-7-hydroxy-4-(*S*-cysteinyl)-tryptophan are +150 and +240 mV, respectively.[758] Even if the initial one-electron oxidation of 6-amino-7-hydroxy-4-(*S*-cysteinyl)tryptophan has a significantly higher biochemical standard reduction potential than +40 mV, it is clear that each transfer of an electron is probably exergonic.

The mechanisms for oxidations of alcohols catalyzed by enzymes that use pyrroloquinoline quinone (2–155) as a prosthetic group may or may not differ significantly from the mechanisms of the enzymes that use 2,4,5-trihydroxyphenylalanylquinone, lysine tyrosylquinone, tryptophan tryptophylquinone, and cysteine tryptophylquinone.

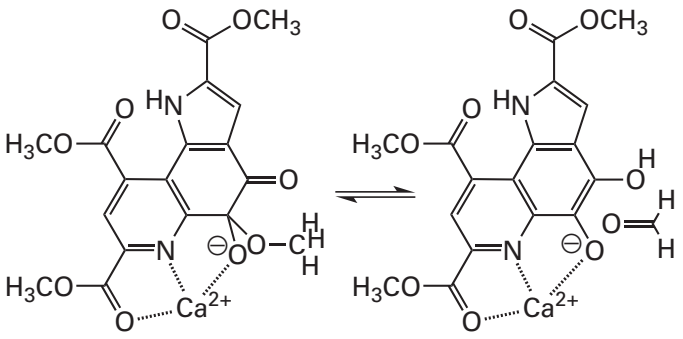
In methanolic solution under acidic conditions, the trimethyl ester of pyrroloquinoline quinone gives the dimethyl ketal at carbon 4[2403]



(2–339)

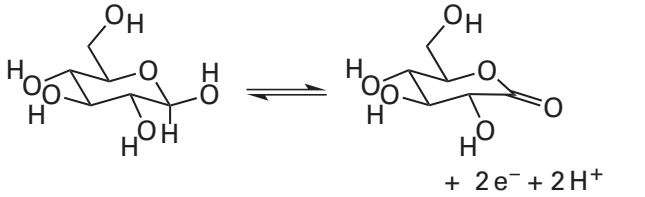
The required cationic intermediate in the formation of this ketal would be the vinylogous imidate at nitrogen 1, which delocalizes the positive formal elementary charge to nitrogen 1 from which the hydron can dissociate. The **more electrophilic carbonyl group** of the two in pyrroloquinoline quinone or its trimethyl ester, however, both in solution[2403,2404] and in an enzyme,[2405] is the carbonyl at **carbon 5**. In crystallographic molecular models, the structures for the active sites of enzymes using pyrroloquinoline quinone as a prosthetic group also suggest that the carbonyl at carbon 5 is the electrophile in the enzymatic reaction,[2347,2406] but an examination of the electronic structures of the hemiketals between the reactant alcohol and pyrroloquinoline quinone at oxocarbon 5[2347,2407] seem to afford no obvious way of directly improving the acidity of the primary carbon of the alcohol from which the hydrogen must be removed during the oxidation (Equations 2–335 and 2–336) because a saturated carbon sits between that hydron and the pyrroloquinolinyl group.

Nevertheless, in solution, the **methyl hemiacetal at carbon 5 of pyrroloquinoline quinone,** which was identified by its absorption spectrum,[2403] produces formaldehyde and pyrroloquinoline quinol upon treatment with strong base[2408]



(2–340)

as long as there is a Ca^{2+} bound to the pyrroloquinoline quinone, as there is in the crystallographic molecular models of glucose 1-dehydrogenase (PQQ, quinone) from *Acinetobacter calcoaceticus*[2406]



(2–341)

and the methanol dehydrogenases (cytochrome *c*) from *Methylophilus methylotrophus,*[2347] *Methylorubrum extorquens,*[2407,2409] and *M. capsulatus.*[2410]

These observations in solution suggest a mechanism for the observed oxidation of methanol under catalysis by pyrroloquinoline quinone, Ca^{2+},

and strong base (Figure 2–64)[2408] that proceeds through the hemiketal at carbon 5 of the pyrroloquinoline quinone and that is an analogue of the oxidation of amines by 1,2-benzoquinones (Figure 2–63). The methanol adds to carbon 5 to form the hemiacetal. The hydroxy group leaves as a hydroxide on Ca^{2+}, and the usual carbenium ion that is an intermediate in this dissociation of the leaving hydroxy group is delocalized to nitrogen 1 while the hydron on nitrogen 1 is removed by the adjacent carboxylato group to give the enol ether at carbon 5. Rehydronation of nitrogen 1 creates a widely delocalized proximal oxocarbenium ion on carbon 5. Removal of a hydron from the methyl group that creates the distal oxocarbenium ion aromatizes the entire pyrroloquinolinyl group. Aromatization provides the driving force for the dehydronation. The resulting distal oxocarbenium ion of formaldehyde hydrolyzes at the former methyl carbon of the methanol to produce pyrroloquinoline quinol and formaldehyde. Although not shown in the figure, the hydroxide on Ca^{2+} could be the nucleophile that hydrolyzes the distal oxocarbenium ion.

There are, however, problems with this mechanism. Oxygen is a more electronegative atom than nitrogen. Oxocarbenium ions have very short lifetimes. The dissociation of water from a hemiacetal has only been observed to occur under quite acidic conditions, never under basic conditions, but this is an unusual hemiketal. While the Ca^{2+} as a Lewis acid could satisfy this requirement for a hydron to add to the hydroxy group of the hemiketal, it seems unlikely since Ca^{2+} is a significantly weaker acid (10^{-14}) than a hydron.

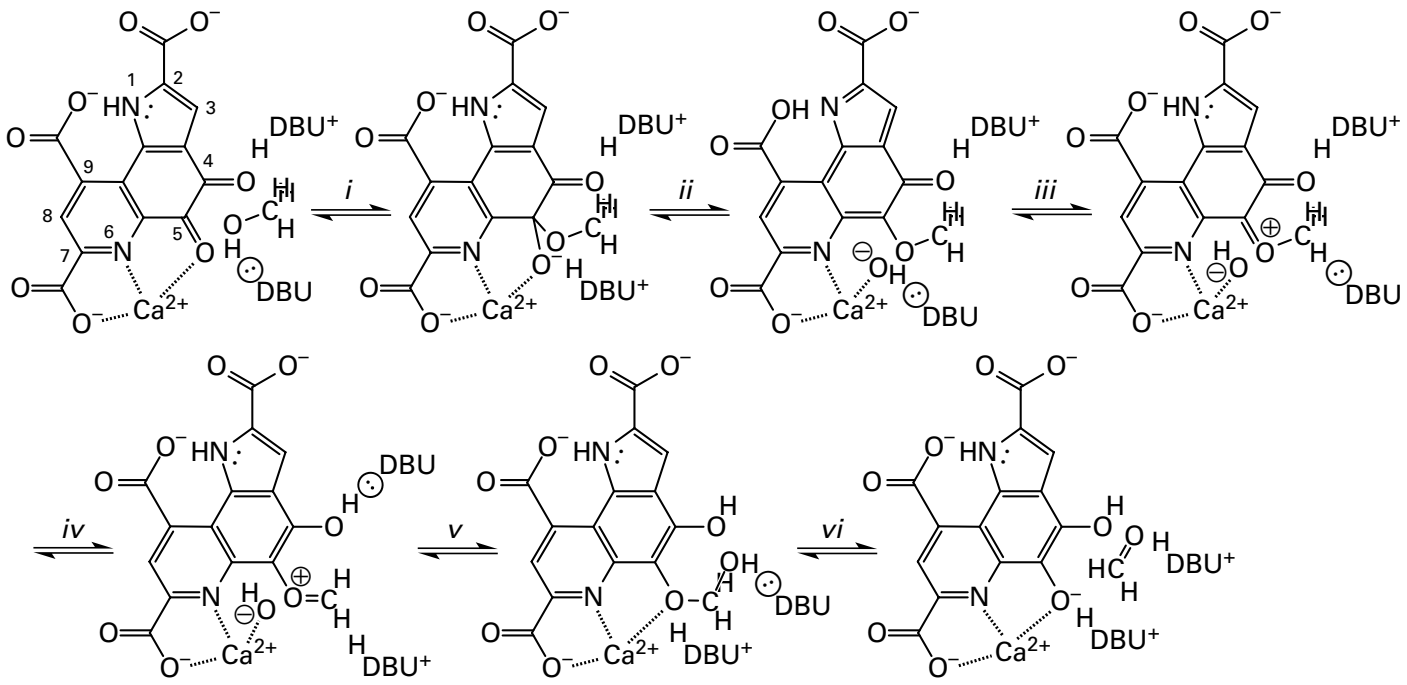


Figure 2–64: Mechanism for the nonenzymatic oxidation of methanol by pyrroloquinoline quinone that has been shown to proceed through the formation of a hemiketal at the carbonyl at carbon 5.[2408] The reaction is carried out in a solution of anhydrous acetonitrile to which has been added the nonnucleophilic base 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and methanol. Methoxide (*i*) adds to carbon 5 to form the hemiketal. The Ca^{2+} facilitates this nucleophilic addition of the hydroxy group of methanol as the DBU removes its hydron. The lone pair of nitrogen 1, upon its dehydronation, is (*ii*) delocalized to provide the push to eliminate the hydroxy group of the hemiketal and form a vinylogous imido ester. The hydroxy group remains as a ligand to the Ca^{2+}, which has enhanced its ability as a leaving group. Rehydronation of nitrogen 1 (*iii*) promotes the formation of a delocalized proximal oxocarbenium ion that (*iv*) tautomerizes to the distal oxocarbenium ion. The aromatization of the prosthetic group promotes the tautomerization. A hydroxide, either the one on the calcium or one that has been released into the solution from another calcium, (*v*) adds to the distal oxocarbenium ion to form the hemiacetal. The oxygen on carbon 5 of the pyrroloquinoline quinol (*vi*) leaves the hemiacetal to give formaldehyde. This oxygen of the pyrroloquinoline quinol ($pK_a \cong 9$), especially as a ligand to a Ca^{2+}, is a good leaving group.

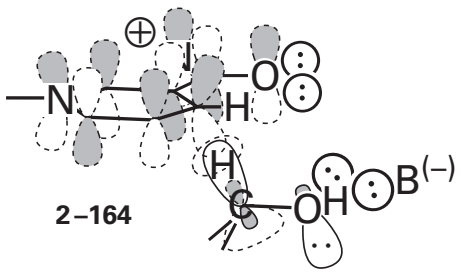
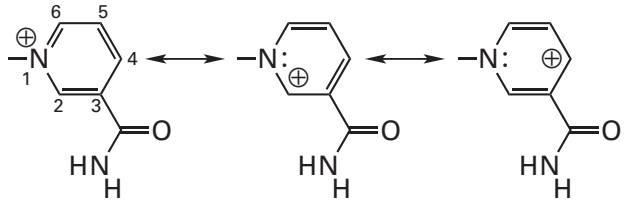
In the crystallographic molecular model of the complex between methanol and methanol dehydrogenase (cytochrome *c*) from *M. capsulatus*,[2410] the electron density for the molecule of methanol is situated immediately adjacent to carbon 5 of the pyrroloquinoline quinone and one of the atoms of methanol is only 0.21 nm from carbon 5, well within van der Waals contact.[2410] It is not possible, however, to distinguish whether this atom is the carbon or the hydroxy group of the methanol since they differ in electron density by only one electron. If, as the authors believe, it is the hydroxy group, this observation is consistent with formation of the hemiacetal at carbon 5 during the oxidation (Figure 2–64), but it is also possible that the atom intimately pushed up against carbon 5 is the methyl group of the methanol. This disposition would be consistent with the fact that the other atom in the electron density for the methanol is not far from the Ca^{2+} in the active site. If the methyl group is actually adjacent to carbon 5, then this regiochemistry would be consistent with a crystallographic molecular model of the complex between glucose 1-dehydrogenase (PQQ, quinone) (Equation 2–341) and D-glucopyranose.[2406] In the crystallographic molecular model of the complex, in which the pyrroloquinoline is the quinol rather than the quinone to prevent further reaction by pairing reduced substrate with reduced prosthetic group, the **carbon–hydrogen bond on carbon 1 of the D-glucopyranose is unmistakably pointed at carbon 5 of the pyrroloquinoline quinol.**

The **biochemical standard reduction potential of pyrroloquinoline quinone** in aqueous solution in a two-electron reduction, in which it takes up the equivalent of two hydrons and two electrons, is +70 mV,[2411] which is considerably more positive than that for NAD^+ (–310 mV), so it should be a better oxidant. In many dehydrogenases, the formal equivalent of a hydride is transferred from the carbon immediately adjacent to the hydroxy group of a simple, unadulterated alcohol (previously **1–76**)



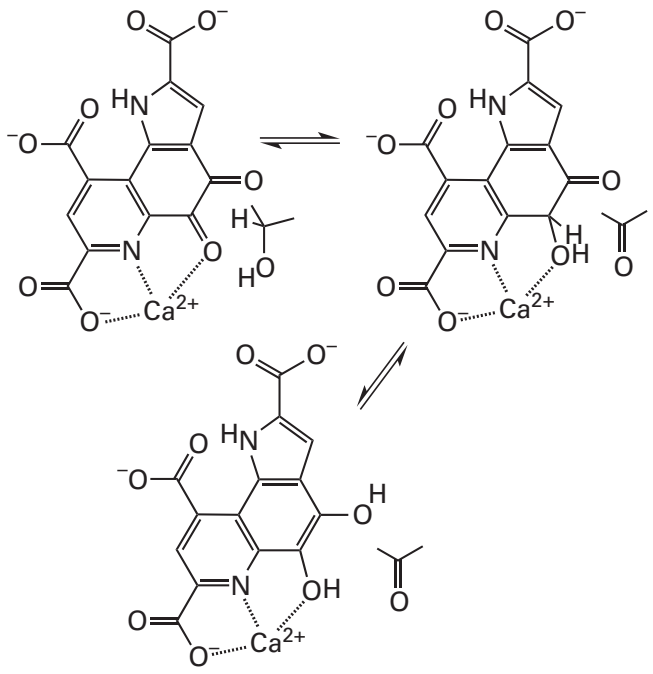
2–164

to NAD^+, which is a vinylogous iminium (previously **1–67**)



2–165

Consequently, it should also be possible for a hydride to be transferred from the carbon of an alcohol to carbon 5, a carbonyl rather than a vinylogous iminium, of pyrroloquinoline quinone



(2–342)

This **transfer of a hydride** should be facilitated by the Ca^{2+} that has the carbonyl oxygen on carbon 5 on the pyrroloquinoline quinone as one of its ligands in each of the crystallographic molecular models.[2347,2406,2407] This divalent cation would further increase both the electrophilicity and the standard reduction potential of carbon 5 of the pyrroloquinoline quinone, making it an even better acceptor of a hydride. Following transfer of the hydride, the hydrogen becomes a hydrogen on a carbon α to a carbonyl group, which would even nonenzymatically tautomerize to the fully aromatic pyrroloquinoline quinol.

The hydrogen on carbon 1 of D-glucopyranose, and perhaps one of the hydrogens on the methyl group

of methanol, would be removed by carbon 5 of the prosthetic pyrroloquinoline quinone (Equation 2–342) in the active sites of both glucose 1-dehydrogenase (PQQ, quinone) and methanol dehydrogenase (cytochrome *c*). In the crystallographic molecular model of glucose 1-dehydrogenase (PQQ, quinone), the distance between carbon 1 of D-glucopyranose and carbon 5 of pyrroloquinoline quinol (0.32 nm) is also well within van der Waals contact (0.40 nm),[2406] and in the complex between the quinone and the hemiketal, the distance should be even shorter because one fewer hydrogen would be in the gap. The oxygen of the hydroxy group on carbon 1 of D-glucopyranose, which would form the hemiacetal during an addition (Figure 2–64), is actually pointed in the other direction and is farther (0.36 nm) from carbon 5 of the pyrroloquinoline quinol than carbon 1. In the crystallographic molecular model, this hydroxy group at carbon 1 of D-glucopyranose, from which a hydron must be removed in either mechanism (Figure 2–64; Equation 2–342), forms a hydrogen bond to the imidazolyl group of a histidine, as occurs in alcohol dehydrogenase,[2412] which uses NAD^+ as the oxidant. All these structural features suggest that in the normal oxidation of D-glucopyranose catalyzed by pyrroloquinoline quinone, and if so in the oxidation of methanol, the formal transfer of a hydride occurs between carbon 1 of the D-glucopyranoside or the methyl group and carbon 5 of pyrroloquinoline quinone to produce the keto tautomer of pyrroloquinoline quinol (Equation 2–342) and the carbonyl group of the product. It appears that pyrroloquinoline quinone has a mechanism more similar to that of nicotinamideadenine dinucleotide than to that of the other 1,2-benzoquinones.

The pyrroloquinoline quinol formed in these enzymatic oxidations, regardless of mechanism, is reduced back to the quinol in two one-electron, outer-sphere transfers, which should be permitted because the semiquinone radical of pyrroloquinoline quinone is a stable species.[2413,2414] In the case of methanol dehydrogenase (cytochrome *c*) in *M. extorquens*, the outer-sphere transfers of single electrons are to successive cytochromes c_L, which have a biochemical standard reduction potential of +260 mV.[2415] The radical anion of a nearby cystine, identified both by its absorption spectrum and by electron paramagnetic resonance, in the active site of methanol dehydrogenase from *M. capsulatus*[2410] has been observed to exist in the active site in a steady-state concentration during the enzymatic reaction. This radical anion may be a relay station in the transfer of each electron to a cytochrome c_L.

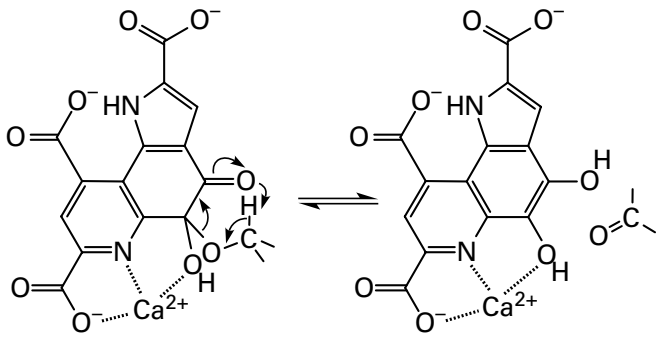
Problem 2–36: Write three different mechanisms for the reoxidation of 5-amino-2,4-dihydroxyphenylalanine in primary-amine oxidase: one by molecular oxygen in which there are two successive electron transfers from the 5-amino-2,4-dihydroxyphenyl group to molecular oxygen; one in which transfer of an electron from the 5-amino-2,4-dihydroxyphenyl group to the Cu^{2+} precedes the association of molecular oxygen;[2376] and one in which Cu^{2+} is coordinated by the 4-hydroxy group of 5-amino-2,4-dihydroxyphenylalanine, a radical is formed at carbon 4 by electron withdrawal, as in protocatechuate 3,4-dioxygenase (Equation 2–275) and quercetin 2,3-dioxygenase (Equation 2–303), and oxygen adds to the radical at carbon 4. What could be the role of Cu^{2+} in the first mechanism?

Problem 2–37: The following concerted mechanism has been proposed for oxidation of an alcohol in an active site with a prosthetic pyrroloquinoline quinone

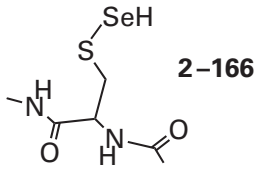


Build a ball-and-stick model of the reactant and rotate around the exocyclic bonds until the molecular orbitals participating in the concerted reaction as written are all aligned parallel to each other, as they must be, and criticize the proposal (see Chapter 1).

Selenocysteine

Selenium is found in several enzymes from diverse sources such as glycine reductase and some of the anaerobic carbon monoxide dehydrogenases, hydrogenases, and formate dehydrogenases from aerobic bacteria; the nicotinate dehydrogenases, 6-hydroxynicotinate dehydrogenases, hydrogenases, and formate dehydrogenases from some obligate and facultative anaerobic bacteria;[2416] and thioredoxin-disulfide reductase and glutathione peroxidase from mammals and birds.

The cysteines in certain prosthetic groups in particular enzymes are replaced with ***S*-selanylcysteines**



2–166

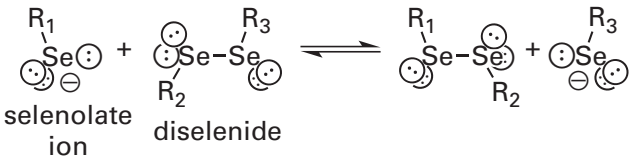
Anaerobic carbon monoxide dehydrogenase from *A. carboxidovorans* has an **oxomolybdenum(VI) molybdopterin** with two equatorial hydroxy groups, and the molybdenum ion is adjacent to but not coordinated to an *S*-selanylcysteine.[2417] Formate dehydrogenase (hydrogenase) from *E. coli* has a hydroxymolybdenum(VI) bismolybdopterin in its active site with the four sulfanyl groups of the molybdopterins as equatorial ligands and the selanyl group of a selenocysteine as the sixth ligand to the molybdenum ion adjacent to the hydroxy group.[2418,2419] In the active site of formate dehydrogenase from *D. gigas*, the central transition metal is a tungsten ion rather than a molybdenum ion,[2423] but all the other components, including the selanyl group of the selenocysteine, are the same as formate dehydrogenase (hydrogenase) from *E. coli*.[2424] Nicotinate dehydrogenase from *Eubacterium barkeri* has an oxomolybdenum(VI) molybdopterin in its active site that has a hydroxy group as a ligand at one of its equatorial positions and a **selenide** as a ligand at its other equatorial position instead of a sulfide (see Equation 2–327).[2420] In the active site of ferredoxin hydrogenase from *D. vulgaris*, one of the cysteines coordinating the nickel ion in the **nickel–iron dinuclear cluster 2–139** (the one on the lower right) has been replaced with a selenocysteine.[2421,2422]

Selenium is the element in group 16 below oxygen and sulfur on the periodic table, which themselves are abundant elements in living organisms. In most of the enzymes that have a selenium in their active sites, it is a selanyl group on a **selenocysteine**, as is the case with ferredoxin hydrogenase from *D. vulgaris* and the formate dehydrogenases. Selenocysteine is an amino acid homologous to serine and cysteine, in which a selenium replaces the oxygen or sulfur, respectively.[2425-2427] Rather than as a posttranslational modification, in those organisms that contain selenocysteine in one or more of their enzymes, the selenocysteine is inserted into their sequences of amino acids during the translation of their mRNA by redefining the UGA stop codon with a special transfer ribonucleic acid, $tRNA^{Sec}$.[2416] For this reason, selenocysteine is the "21st amino acid".

The selanyl group (–SeH) in a selenol such as selenocysteine offers several advantages over its closest relative, the sulfanyl group in a thiol such as cysteine, as well as a few disadvantages.[2428] Just as a thiolate is more nucleophilic but less basic [$pK_a(H_2S) = 7.0$; pK_a(L-cysteine) = 9.1] than an alcoholate [$pK_a(H_2O) = 15.7$; pK_a(L-serine) = 14], **a selenolate is more nucleophilic but less basic** [$pK_a(H_2Se) = 3.9$; pK_a(L-selenocysteine) = 5.4][2429] than a thiolate. Consequently, a selenol is fully ionized at pH 7 in addition to being more nucleophilic. When the two are surrounded by the same functional groups, a selenide is also **more electrophilic** than a sulfide. This electrophilicity has the disadvantage of making an organoselenium compound susceptible to **deselenation** proceeding through nucleophilic substitution at selenium, leading to the dissociation of the selenium–carbon bond with the carbanion as the leaving group. A selenolate is also a **better leaving group** than a thiolate. A disadvantage, however, of this enhanced ability of selenium as a leaving group is that selenols are more prone to elimination of

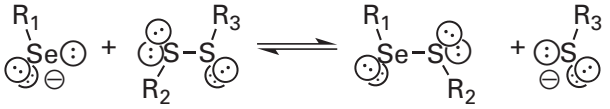
hydrogen selenide, to give the alkene, than are thiols to elimination of hydrogen sulfide. Because of its larger size and greater number of electrons, a selenium atom is easier to ionize than a sulfur atom, either by removing an electron or adding an electron.

Several of the advantages of selenium are illustrated by **selenol–diselenide exchange**



(2–343)

the homologue of thiol–disulfide exchange (see Equation 2–136). In solution, selenol–diselenide exchange is 10^7 times more rapid than thiol–disulfide exchange[2430] because the selenolate ion is a better nucleophile than a thiolate, a selenium is a better electrophile than a sulfur, and a selenolate is a better leaving group than a thiolate. The exchange that is more relevant for the active sites of selenoenzymes, however, is a selenol–disulfide exchange and thiol–sulfenoselenoate exchange



(2–344)

which is an equilibrium that is also more rapidly established than a thiol–disulfide exchange.

In the same surroundings, **the biochemical standard reduction potential of a diselenide** in a protein is more negative than that of a disulfide.[2431] When the two sulfanyl groups in glutaredoxin from *E. coli* that form the cystine in the active site that participates in thiol–disulfide exchange were in turn substituted with selanyl groups and then when both were substituted with selanyl groups, the biochemical standard reduction potential of the disulfide decreased from −194 mV to −260 and −275 mV and then to −309 mV, respectively.[2432]

At pH 7, hydrogen selenide ion (HSe^-; $pK_a = 11$) is less prone thermodynamically to **oxidation** ($E^{\circ\prime} = -70$ mV) to hydrogen selenite ($HSeO_3^-$; $pK_a = 8.3$) than is the equilibrium mixture of hydrogen sulfide ($pK_a = 7.0$) and its conjugate base to oxidation ($E^{\circ\prime} = -120$ mV) to the equilibrium mixture of hydrogen sulfite (HSO_3^-; $pK_a = 7.0$) and sulfite. This feature would tend to cause selanyl groups to be more stable to oxidation than sulfanyl groups, but because of their increased nucleophilicity, selenols are kinetically more reactive with oxidants than thiols.[2428] Selenium, however, has the advantage that it is much more difficult both kinetically and thermodynamically to oxidize the **selenino group** ($-SeO_2H$) in a **seleninic acid**, which is easy to reduce back to a selenol, to the **selenono group** ($-SeO_3H$) in a **selenonic acid** ($RSeO_3H$), which is difficult to reduce back to a selenol, than it is to oxidize a sulfinate (RSO_2^-) to a sulfonate (RSO_3^-). Consequently, selenocysteine is less prone to adventitious complete oxidation, and the consequent inactivation of an enzyme in which it is a catalyst, than is cysteine. Murine thioredoxin-disulfide reductase has a selenocysteine in its active site involved in the enzymatic reaction. It is significantly more stable to added oxidants than is the enzyme from *D. melanogaster* (46% identity; 1.3 gap percent), in the active site of which there is a cysteine instead of a selenocysteine. When the cysteine in thioredoxin-disulfide reductase from *D. melanogaster* is changed to a selenocysteine, the enzyme becomes as resistant to oxidation as the murine enzyme.[2433] Murine thioredoxin-disulfide reductase is inactivated by various electrophiles but can be reactivated by oxidation with hydrogen peroxide. When its selenocysteine, however, was mutated to a cysteine, the cysteinyl enzyme inactivated with electrophiles could not be reactivated.[2434]

Natural selection may have capitalized on these advantages of selenium relative to sulfur. It has been argued,[2435] however, that the lower values of pK_a, the more negative values of biochemical standard reduction potential, and the nucleophilicity of the selanyl group, each on its own, is probably not so advantageous as it seems. Active sites are able to efficiently lower the pK_a of the sulfanyl group of a cysteine. They are also able to significantly adjust biochemical standard reduction potentials of cystines. For example, just within the family of thioredoxins,[2436] the biochemical standard reduction potentials for their cystines span the range from −130 to −270 mV. Finally, the nucleophilicities of selenocysteine and cysteine, which are reflected in the rates of selanol–disulfide exchange and thiol–disulfide exchange, can also be adjusted by an active site. For example, the single selenocysteine in human thioredoxin–disulfide reductase, which is required for enzymatic activity, is replaced by a cysteine in the closely related (49% identity; 1.9 gap per cent) thioredoxin-disulfide reductase from *D. melanogaster*.

These enzymes rely on four successive selenol–disulfide exchanges and thiol–sulfenoselenoate exchanges or four successive thiol–disulfide exchanges, respectively, during each turnover, and yet the enzyme from *D. melanogaster* has an enzymatic activity that is somewhat greater than that of the human enzyme,[2437] and replacement of its cysteine with a selenocysteine does not improve the rate of its enzymatic reaction,[2438] even though the nucleophilicity of the cysteine in its active site can be changed by altering side chains surrounding it in the active site.[2438,2439] Thioredoxin reductase from *Plasmodium falciparum* is also related to the human enzyme (39% identity; 1.9 gap per cent), but replacing the cysteine that is in the homologous position in its sequence of amino acids with the selenocysteine that is in the human enzyme decreases the rate of its reaction at saturating concentrations of thioredoxin[2440] by a factor of 4.

When one considers these observations, the selective advantage of selenocysteine relative to cysteine is not so obvious. It may, however, be that the combination of all these advantages is so beneficial that natural selection has gone to all the trouble of selecting a way of inserting selenocysteine in some enzymes. Or it may be that there is another reason for the presence of selenocysteine. It is also possible that the use of selenocysteine is adventitious, but both the fact that the natural abundance of selenium in the seawater in which life evolved is 10^{-7} that of sulfur and the fact that a complicated mechanism for its insertion into sequences of amino acids has evolved suggest that there is some compelling selective pressure.

There is a formate dehydrogenase (hydrogenase) from *E. coli* that catalyzes the oxidation of formate

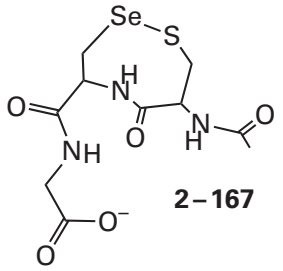
$$HCOO^- \rightleftharpoons CO_2 + H^+ + 2\,e^- \qquad (2\text{–}345)$$

In the hydroxymolybdenum(VI) bismolybdopterin in its active site,[2418,2419] a selenocysteine occupies the same position as the serine in the active site of respiratory dimethylsulfoxide reductase (Figure 2–60) and a hydroxide is the sixth ligand at the same position as the oxo group in respiratory dimethylsulfoxide reductase. Because the selenium in the selenocysteine is a direct ligand to the molybdenum in the oxidized, molybdenum(VI) form of the prosthetic group[2157,2419,2441] and because it is selenium rather than sulfur, it is electrophilic enough to remove a hydride from an immediately adjacent formate when one of the oxygens of the formate replaces the hydroxide and becomes the sixth ligand to the molybdenum.[2419] **Transfer of this hydride from the carbon of the formate to the selenium** turns the formate directly into carbon dioxide, with no incorporation of oxygen from the hydroxide that was coordinated to the molybdenum before it was displaced by the formate,[2442] which is the usual outcome with enzymes using molybdenum ions and molybdopterins. The hydride transferred to the electrophilic selenium of the molybdenum(VI) selenolate produces a molybdenum(IV) selenol, and the hydron is then removed from the resulting selenol by the adjacent imidazolyl group of a histidine[2419] to produce molybdenum(IV) bismolybdopterin selenolate,[2157] which is reoxidized to hydroxymolybdenum(VI) bismolybdopterin selenolate by two successive one-electron transfers in the outer sphere to a [4Fe–4S] iron–sulfur cluster.[2419,2443]

Human thioredoxin-disulfide reductase

$$NADP^+ + \text{thioredoxin dithiol} \rightleftharpoons NADPH + H^+ + \text{thioredoxin disulfide} \qquad (2\text{–}346)$$

contains a selenocysteine[2444] that is essential for its activity.[2445] It is the penultimate amino acid in the sequence of the protein. The amino acid on its carboxy-terminal side is the carboxy-terminal glycine of the protein, and the amino acid on its amino-terminal side is a cysteine. When the enzyme is oxidized, the **selenocysteine forms a vicinal sulfenoselenoate**



2–167

with that cysteine.[2446] The carboxy-terminal 12 amino acids, including this sulfenoselenoate, are only loosely incorporated in the structure and can be considered a **flexible arm**.[2447] The enzyme is a close relative of human glutathione-disulfide reductase (34% identity; 2 gap per cent), The structure of the active site is almost the same as that of glutathione-

disulfide reductase (Figure 2–11), and the mechanism of the enzyme is probably quite similar.

Consistent with the enhanced facility of selenol–disulfide exchange (Equation 2–344), a sulfenoselenoate such as **2–167** should be much more reactive than a disulfide. **Replacement of the selenocysteine with a cysteine** in human thioredoxin-disulfide reductase[2448] or thioredoxin-disulfide reductase from *R. norvegicus*[2445] decreases the enzymatic activity 10–100-fold, as would be expected if the enzyme is capitalizing on the more favorable electrophilicity and nucleophilicity of the selenium and the consequent increase in the rate of selenol–disulfide exchange. It has also been shown that, probably because of its larger size, the selenium atom makes the strained, vicinal sulfenoselenoate **2–167** more stable than the corresponding vicinal disulfide in the same location.[2446,2448] The following mechanism for thioredoxin-disulfide reductase involving **three successive sulfenoselenoates** and four consecutive selenol–disulfide and thiol–sulfenoselenoate exchanges[2449] is consistent with the observations that have been reported.

Starting with fully reduced human thioredoxin-disulfide reductase and oxidized thioredoxin, in which the disulfide is between Cysteine 32 and Cysteine 35, the selanyl group of the selenocysteine on the flexible arm in the reduced enzyme exchanges with the sulfanyl group of Cysteine 35 (Equation 2–344) and forms a sulfenoselenoate with Cysteine 32.[2450] This initial selenol–disulfide exchange takes advantage of the nucleophilicity of the selenido group. In the crystallographic molecular model of the complex between human thioredoxin and human thioredoxin-disulfide reductase in which the selenocysteine has been mutated to a cysteine, there is an intermolecular cystine between the mutant cysteine in the thioredoxin-disulfide reductase and Cysteine 32.[2451] This disulfide is the homologue of the normal sulfenoselenoate. The thiol of the cysteine adjacent in the sequence of amino acids to the selenocysteine in the native enzyme exchanges with the Cysteine 32 from thioredoxin in the native intermolecular sulfenoselenoate to form sulfenoselenoate **2–167** and release reduced thioredoxin. This thiol–sulfenoselenoate exchange takes advantage of the electrophilicity of the selenide.

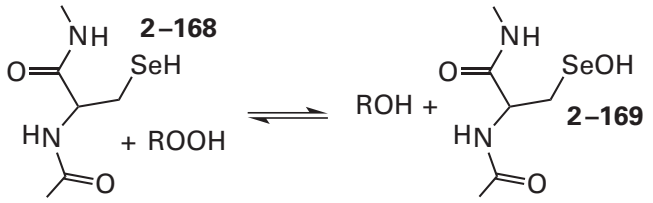
The arm with this sulfenoselenoate then swings into the active site of the enzyme. There is a crystallographic molecular model of this conformation of human thioredoxin-disulfide reductase in which the arm is within the active site.[2447] The cysteine within the active site distal to the flavin (Figure 2–11) nucleophilically attacks the selenium in the sulfenoselenoate **2–167** in exchange for its cysteine (see reverse of Equation 2–136).[2452] The proximal cysteine at the flavin then nucleophilically attacks the resulting acyclic, intramolecular sulfenoselenoate, releasing the selenolate ion and forming a cystine adjacent to the flavin. This step takes advantage of the ability of the selenido group as a leaving group. The resulting disulfide, adjacent to nitrogen 5 and carbon 4a, is reduced in the normal fashion by the flavin, which in turn is reduced by NADPH.

Glutathione peroxidase serves as a paradigm for the **interaction of selenocysteine with oxides of oxygen.** The enzyme catalyzes the reaction

$$\mathrm{ROOH + 2\,GSH \rightleftharpoons ROH + H_2O + GSSG} \qquad (2\text{–}347)$$

where GSH is glutathione, and its purpose is to eliminate adventitious peroxides from the cytoplasm. There is a selenocysteine in the active site of the enzyme that participates in its catalysis. Although one might think that the enzyme is taking advantage of the superior nucleophilicity of selenocysteinate, human thioredoxin-dependent peroxiredoxin,[2453] a peroxidase that is distantly related to glutathione peroxidase[2454,2455] and in which a cysteine serves the same purpose as the selenocysteine in glutathione peroxidase, catalyzes the reduction of hydrogen peroxide at a rate[2453] comparable to that of bovine glutathione peroxidase,[2456] again belying the advantages of selenocysteine.

When bovine glutathione peroxidase has been reduced by reduced glutathione, the selenocysteine is the selenol (**2–168**)



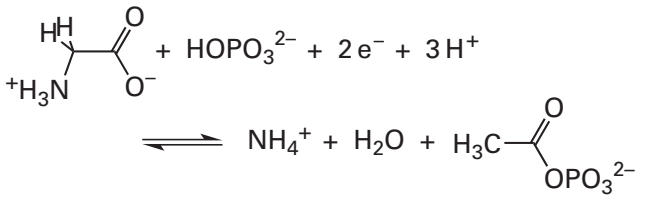
(2–348)

but when the enzyme is oxidized with a peroxide, the selenium is the **hydroxyselanyl group** (–SeOH) in a **selenenic acid** (**2–169**).[2457] From these observations, a plausible mechanism for the reduction of peroxides can be formulated (Figure 2–65),[2458] which is consistent with the kinetics of the enzymatic reaction.[2456,2459] The three exchanges—selenium for oxygen, sulfur for oxygen, and sulfur for selenium—

are all within group 16 and resemble the four exchanges that occur in the mechanism of thioredoxin-disulfide reductase.

The selenenic acid (RSeOH) has not been observed directly in glutathione peroxidase because in the crystals of the oxidized enzyme the selenol has become the seleninic acid ($RSeO_2H$).[2460] It is, however, possible to trap chemically a selenenic acid intermediate[2461] in the peroxidase reaction catalyzed by human selenoprotein S, and in a human peroxiredoxin, the sulfenic acid (RSOH) that is an intermediate in its peroxidase reaction has been observed in a crystallographic molecular model.[2454] A cysteinesulfenic acid has also been observed by nuclear magnetic resonance spectroscopy in yet another peroxidase in which it is an intermediate in the enzymatic reaction.[2462] Finally, there is a synthetic selenol that is able to catalyze the reduction of *tert*-butyl hydroperoxide by benzylsulfide in a mechanism equivalent to that drawn in Figure 2–65,[2463] and replacing the cysteine in the active site of the endopeptidase subtilisin with a selenocysteine converts it to a peroxidase.[2464,2465]

Glycine reductase from *Acetoanaerobium sticklandii* catalyzes the reaction



(2–349)

The enzyme catalyzes the reaction by a mechanism (Figure 2–66) that involves a selenocysteine and a posttranslation modification that has produced the modified amino-terminal amino acid, *N*-pyruvoylvaline (see Equation 2–45). There are three proteins participating in the catalysis.[2466] One contains the *N*-pyruvoyl group that catalyzes the **deamination**.[2467,2468] Another contains the selenocysteine[2425] as well as the cysteine that is the nucleophile accomplishing the deselenation and producing the sulfenoselenoate. The third protein contains the cysteine that forms the thioacyl intermediate in a **thioacylation** that is necessary for the stabilization of the enolate that leaves during the **deselenation**.[2467,2469] This last protein, by itself, then catalyzes the phosphorolysis of the resulting *S*-acetylcysteine that was formed at its active site to give acetyl phosphate.

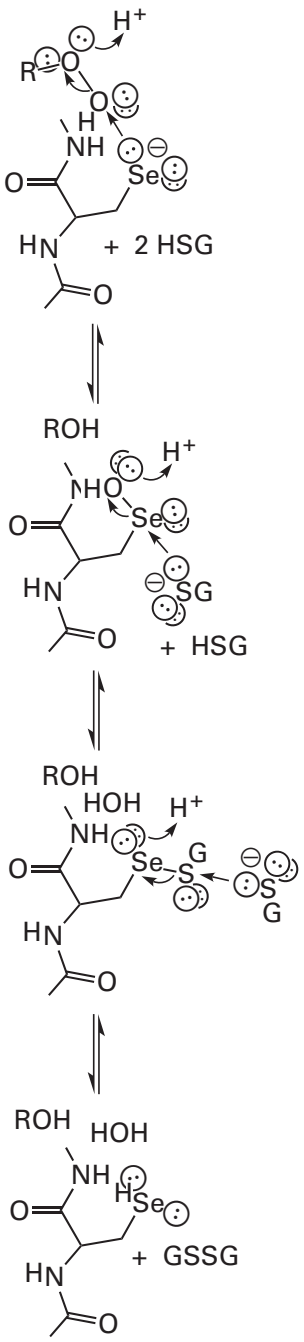


Figure 2–65: Mechanism for the reduction of peroxides catalyzed by glutathione peroxidase.[2458] The mechanism is a series of reactions, each analogous to selenol–diselenide exchange or thiol–disulfide exchange. The selenolate ion is used in the first step because it is a stronger nucleophile than sulfur and more able to cleave the oxygen–oxygen bond of the peroxide heterolytically. In the second step, the greater electrophilicity of selenium facilitates the nucleophilic attack of the sulfido group of glutathione upon the selenium, with water or hydroxide as the leaving group. In the last step, the sulfido group of glutathione performs a thiol–sulfenoselenoate exchange to regenerate the selenol and produce oxidized glutathione.

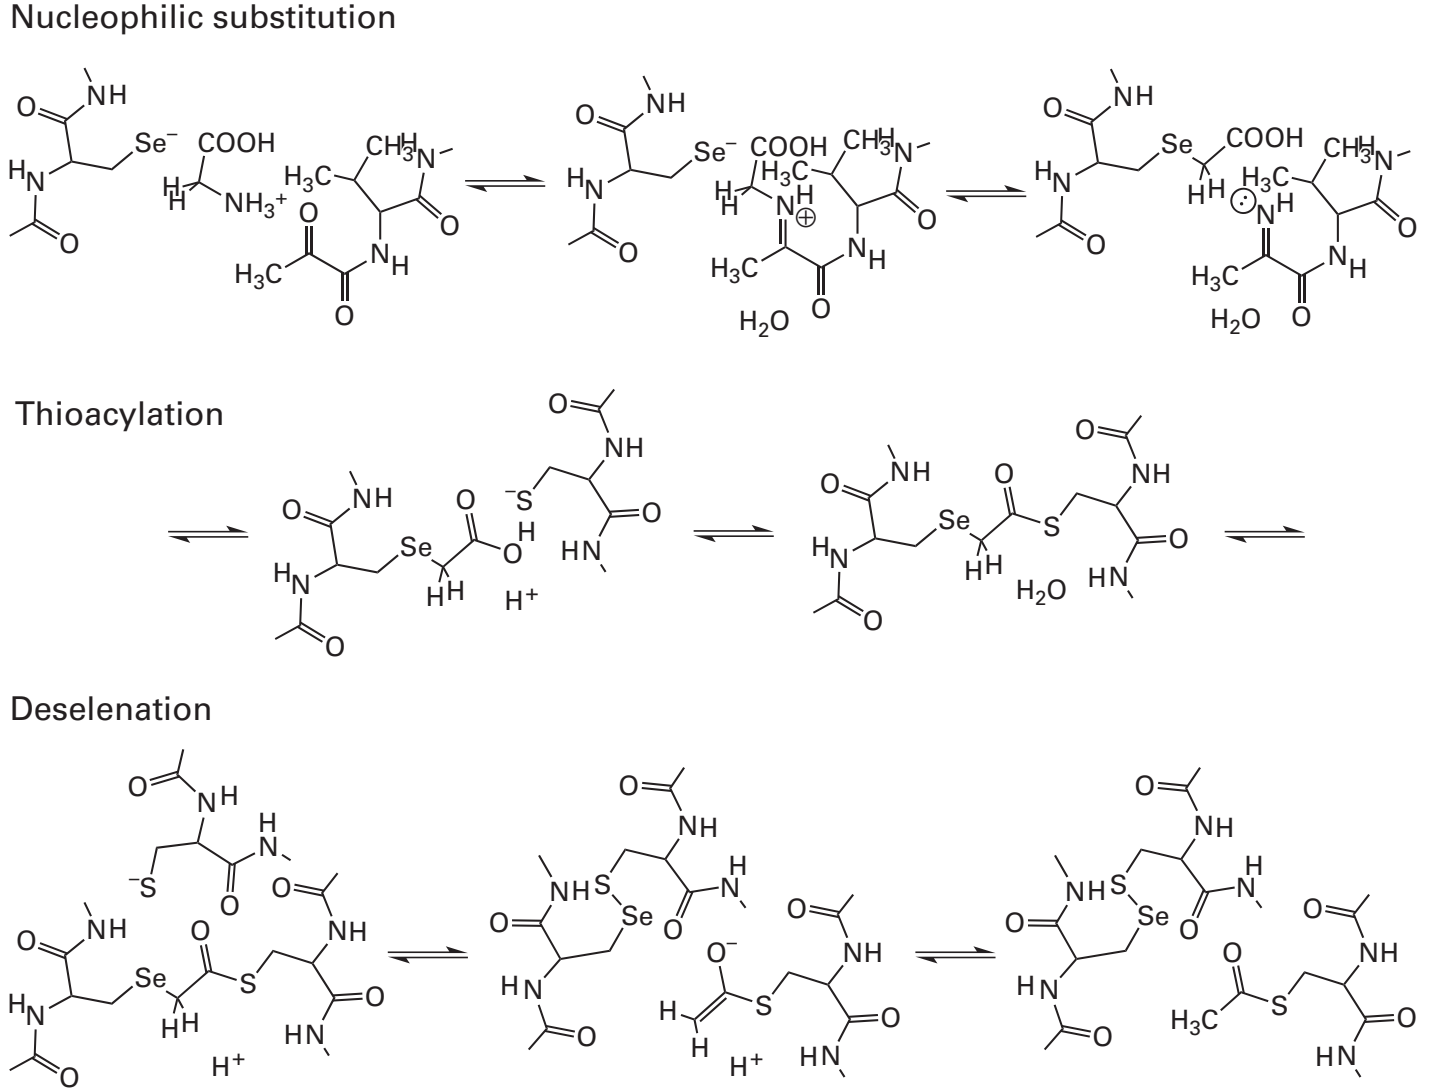

Figure 2–66: Mechanism for the reductive deamination of glycine catalyzed by glycine reductase.[2425,2466-2471] The overall mechanism can be divided into three transformations: nucleophilic substitution of a nitrogen with a selenium, thioacylation of a carboxy group, and deselenation of the α carbon of the thioester. During the nucleophilic substitution, glycine forms an imine with an *N*-pyruvoyl group at the amino terminus of one of the three proteins catalyzing the overall reaction. The imine ($pK_a \cong 8$) should be a better leaving group than ammonia ($pK_a = 9.2$), and the selenolate ion of a selenocysteine in the second protein catalyzing the reaction is the nucleophile. A selenoether is the product of the nucleophilic substitution of selenium for nitrogen at the primary carbon. The pyruvoyl imine hydrolyzes to produce ammonia, one of the products of the reaction, and to regenerate the *N*-pyruvoyl group (not shown). During thioacylation, a cysteine in the third protein catalyzing the overall reaction participates in a nucleophilic substitution at the unactivated carboxy group of *Se*-(carboxymethyl)selenol to produce the thioester, which activates the acyl group. During deselenation, the sulfido group of a cysteine from the second protein catalyzing the overall reaction, the same protein in which the selenocysteine is located, is the nucleophile in a nucleophilic substitution at selenium in which the enolate or enol of the thioacetyl group leaves and the intramolecular sulfenoselenoate is formed. The enolate is hydronated to form the thioacetyl group. The thioester is phosphorolyzed to produce acetyl phosphate (not shown), one of the products of the overall reaction, and to regenerate the unmodified cysteine. The sulfenoselenoate is reduced to regenerate the selenocysteine and the cysteine (not shown). Because four different amino acid side chains and three different proteins are involved in the overall reaction, only the side chains involved in the particular transformation are included in the respective drawing to avoid confusion. Only the hydrons needed are included in each transformation.

The *Se*-carboxymethylselenocysteine produced by the deamination[2470] in the active site of glycine reductase has been produced by direct alkylation of the selenocysteine by bromoacetate and shown to participate in the thioacetylation and the deselenation,[2471] and the intermediate sulfenoselenoate in the deselenation has been isolated.[2470] The third protein by itself catalyzes the exchange of [^{32}P]phosphate into acetyl phosphate, a reaction that relies on the protein establishing the equilibrium of the phosphorolysis of the *S*-acetylcysteine, and this third protein catalyzes the formation of *S*-acetyl-cysteine within itself upon the addition of acetyl phosphate.[2467]

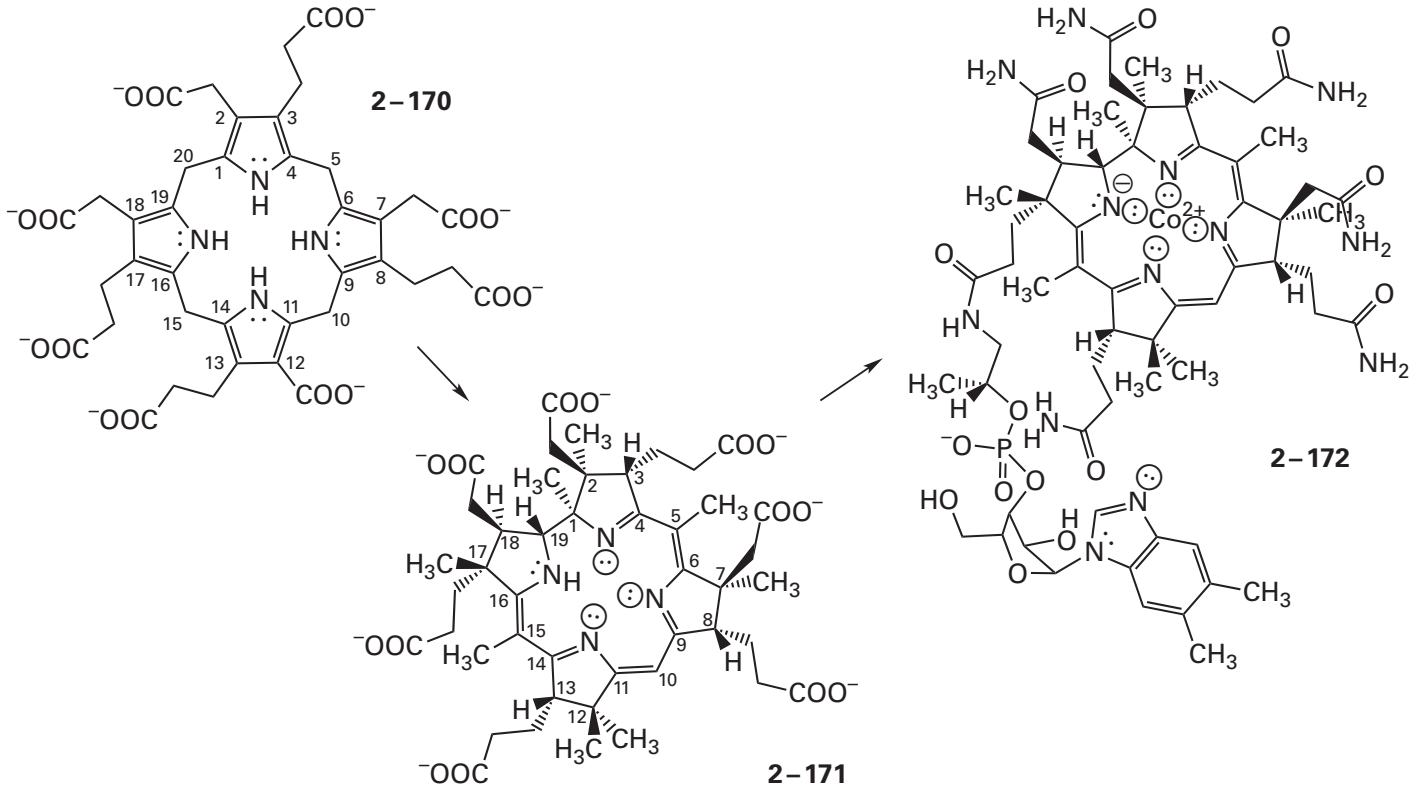
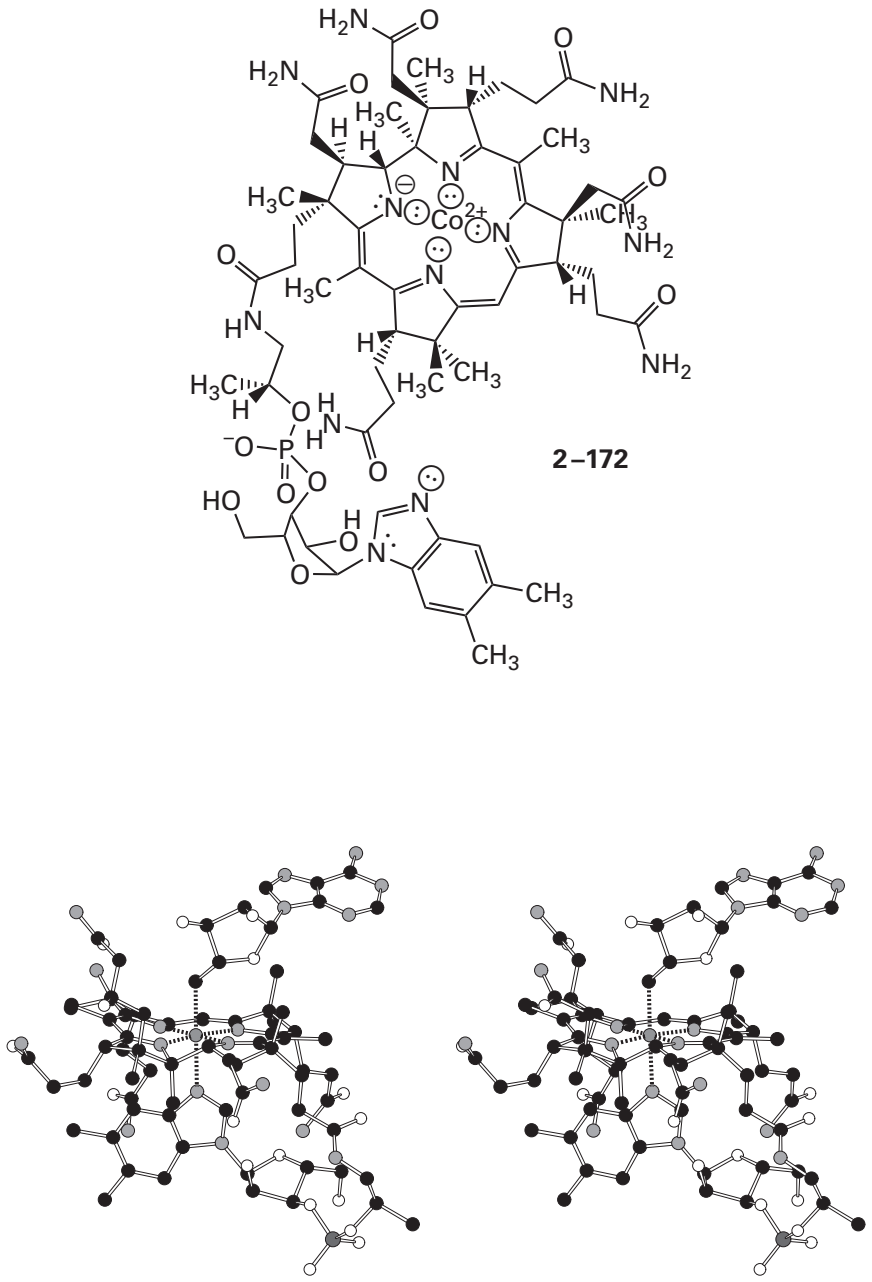
Cobalamins

Cobalamin (**2–172**) is a prosthetic group that contains a cobalt ion





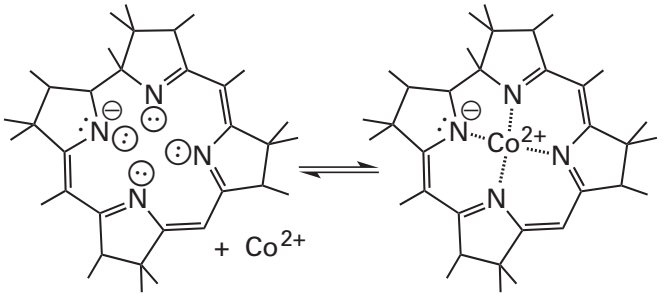
2–172

Figure 2–67: Crystallographic molecular model of adenosylcobalamin.[2472] Crystals were produced by slowly diffusing acetone into a concentrated solution of adenosylcobalamin in water. The drawing of the chemical structure of cobalamin (**2–172**), which is adenosylcobalamin without the adenosyl ligand, can be used as a guide to the stereodrawing[50] of the crystallographic molecular model built from maps of electron density derived from a crystallographic analysis. Black atoms are carbons, white atoms are oxygens, gray atoms are nitrogens, and the small gray sphere is the cobalt ion surrounded by its ligands.

Four of the ligands around the cobalt ion are lone pairs of electrons from the four central nitrogens in a **corrinoid**. The corrinoids are a group of compounds containing four reduced pyrrole rings joined into a macrocyclic ring by links between their α positions; three of these links are formed by one-carbon units and the other by a direct carbon–carbon bond. The tetrapyrrole that forms the core of a corrinoid, when it is completely unsubstituted and uncoordinated to a cobalt ion, is the heterocycle **corrin**.

As is the porphyrin in heme *b* or siroheme, the corrinoid that coordinates the cobalt ion in cobalamin is derived biosynthetically from the tetrapyrrole uroporphyrinogen III (**2–170**). One of the corrinoids along the aerobic biosynthetic pathway through which cobalamin is constructed is hydrogenobyrinic acid (**2–171**)

To form **cobyrinic acid,** a cobalt ion replaces the one acidic hydron of hydrogenobyrinic acid (**2–171**)



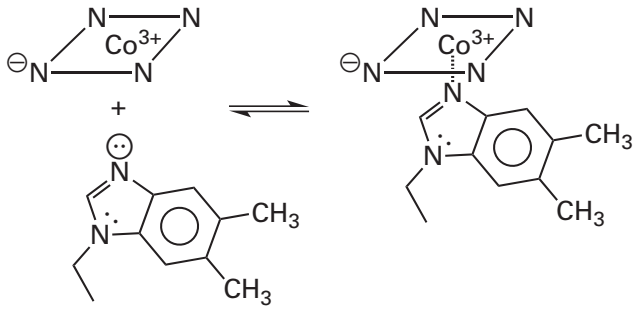
(2–350)

In the actual aerobic biosynthetic pathway, however, a Co^{2+} is not inserted into hydrogenobyrinic acid until it is modified by amidation of the carboxymethyl groups at positions 2 and 7. This insertion produces cob(II)byrinic acid *a*,*c*-diamide.

In cobalamin (**2–172** in Figure 2–67),[2472] six of the seven carboxylates of hydrogenobyrinic acid are **primary amides** and the seventh is an amide formed with (*R*)-1-amino-*O*-[1-(5,6-dimethylbenzimidazol-1-yl)-3-phospho-α-D-ribofuranosyl]propan-2-ol.* When the seventh amide is the one formed with only (*R*)-1-aminopropan-2-ol and there is no cobalt coordinated, the corrinoid is **cobinamide**.

A corrinoid, unlike a porphyrin, is **not aromatic** because saturation at several locations prevents it from having an unbroken ring of *p* orbitals. The tetrapyrrole ring is also one carbon smaller than a porphyrin because during its biosynthesis from uroporphyrinogen III (**2–170**), one of the methylene carbons connecting two of the pyrroles is removed, turning a porphyrin into a corrinoid. This ring contraction, however, would have no effect on the aromaticity. If the tetrapyrrole were still as unsaturated as it is in protoporphyrin, it would be aromatic.

The axial ligand in cobalamin (Figure 2–67)[2472] is a lone pair of electrons from nitrogen 3 of the intramolecular **5,6-dimethylbenzimidazolyl group**

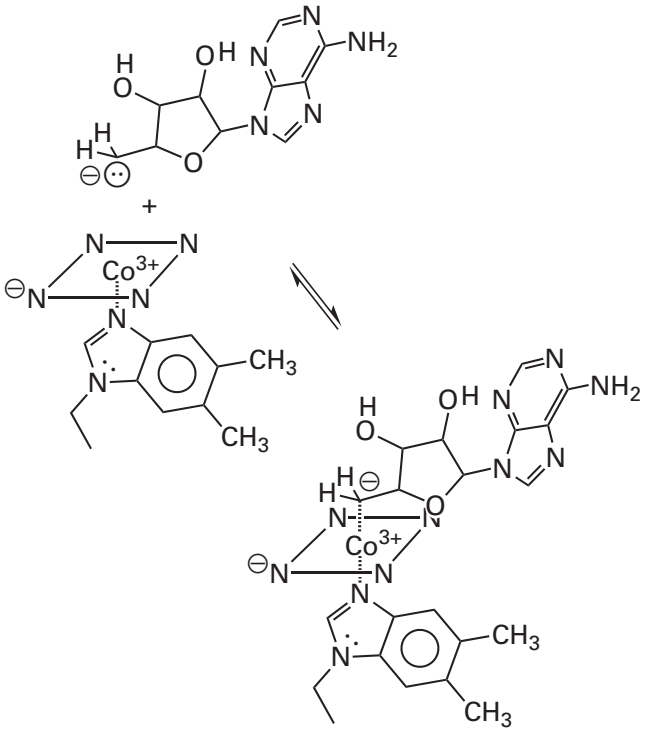


(2–351)

that is covalently attached to the cobinamido group in cobalamin in an α-N-glycosidic linkage to a ribose that is in turn attached through a phosphate diester to the hydroxy group of the (*R*)-1-aminopropan-2-ol.

When cobalamin is a prosthetic group in an enzyme, it is usually alkylated at the open axial position on its cobalt. An alkylcobalamin is an **organocobalt compound**, and the source of its reactivity is its carbon–cobalt bond. In **adenosylcobalamin** (Figure 2–67), the open axial position on the formal Co^{3+} is occupied by a formal 5′-deoxy-5′-adenosyl carbanion

*From here on, the corrinoid of cobalamin will be abbreviated, as was a porphyrin, by a square with four nitrogens at its vertices.



(2–352)

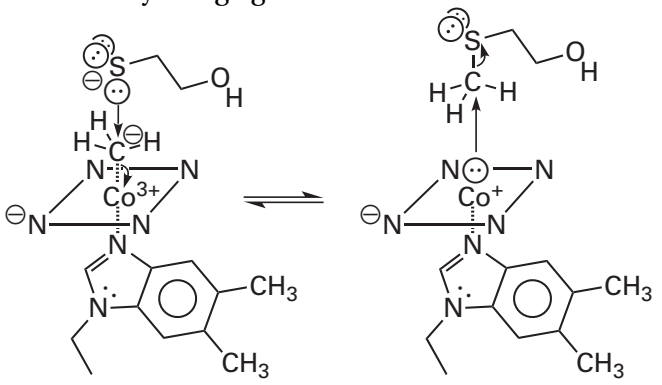
In **methylcobalamin**, a methyl group, formally a carbanion participating in a carbon–cobalt bond with the formal Co^{3+}, is the axial ligand to the cobalt in its cobalamin. Unlike the carbon in an organolithium compound or an organomagnesium compound, the carbon in an organocobalt compound such as adenosylcobalamin or methylcobalamin is much less carbanionic. When it is unalkylated, cobalamin coordinating a Co^{3+} can be **aquocobalamin** or **hydroxycobalamin**, in which the oxygen of a molecule of water or a hydroxide, respectively, is the axial ligand. Commercially, cobalamin is sold as the vitamin cyanocobalamin, in which cyanide is the axial ligand.

The cobalt in a cobalamin can be in the +3, +2, or +1 **oxidation state**, which is indicated as, for example, methylcob(III)alamin, cob(II)alamin, or cob(I)alamin, respectively. The standard reduction potential in solution for the reduction of aquocob(III)alamin to cob(II)alamin is +220 mV, and that for the reduction of cob(II)alamin to cob(I)alamin is –630 mV.[2473,2474] Upon the first reduction, the molecule of water dissociates, and upon the second reduction, which forms cob(I)alamin, the 5,6-dimethylbenzimidazolyl group dissociates from the cobalt, leaving both axial positions vacant. Cob(I)alamin is a strong reductant and may act as a one-electron donor in the microbial reduction of perchloroethylene to trichloroethylene,[2475] but usually cobalamins do not participate in productive oxidation–reduction reactions in biochemical situations. Cob(I)alamin, however, because of its susceptibility to oxidation, can be adventitiously oxidized to cob(II)alamin.

When adenosylcobalamin or methylcobalamin is incorporated as a tightly bound[2476] prosthetic group into the active site of an enzyme, the 5,6-dimethylbenzimidazolyl group usually, but not always,[2477,2478] swings well away from the cobalt as it does in solution upon reduction to cob(I)alamin, and is **replaced by the imidazolyl group of a histidine** in the protein (Figure 2–68).[2479-2486] In this way the enzyme is able to modulate the reactivity of the carbon–cobalt bond more effectively by controlling the environment around this histidine.[2487] When the cobalt is in the oxidation state of +1 (Co^{+}), the histidine can dissociate and swing away.[2488]

Many **organometallic compounds,** such as organolithium, organomagnesium, organocadmium, and organocopper compounds, react heterolytically. In these heterolytic reactions, the carbon participating in the carbon–metal bond acts as if it were a nucleophilic carbanion, and the dissociating metal ends up as its most stable cation. The reactivity of the carbanion in such situations is determined by the ionic character of the bond.[2489] In theory, a carbon–cobalt bond should have about the same ionic character as a carbon–copper bond. Were the carbon–cobalt in adenosylcobalamin to cleave heterolytically, the products would be 5′-deoxyadenosyl anion and cob(III)alamin.

In fact, alkylcobalamins such as methylcobalamin, unlike alkylmagnesium compounds such as methylmagnesium chloride, are electrophilic rather than nucleophilic at carbon. Methylcobalamin in solution reacts with 2-sulfanylethanol as an electrophilic methylating agent



(2–353)

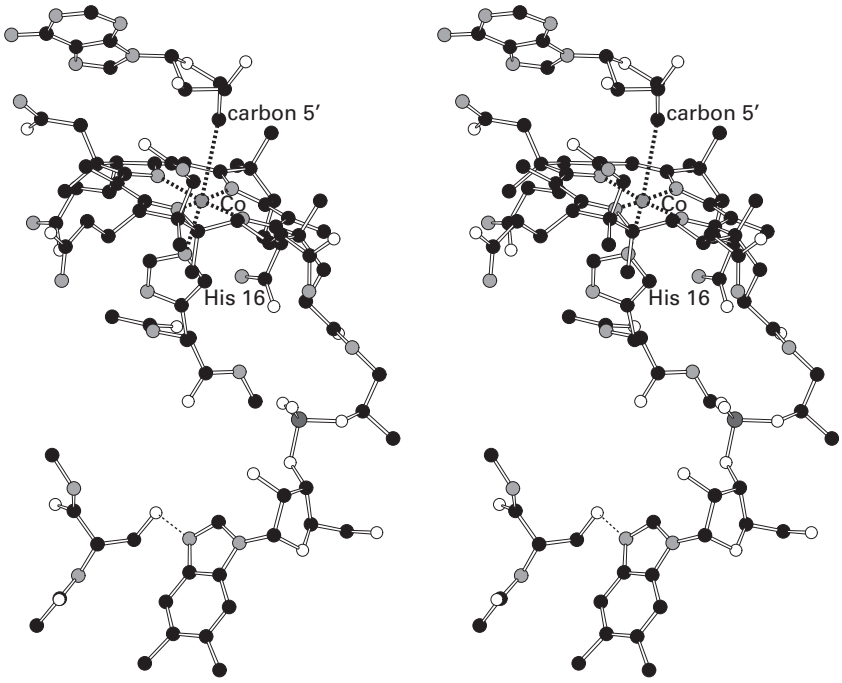


Figure 2–68: Stereodrawing[50] from the crystallographic molecular model of adenosylcobalamin in the active site of methylaspartate mutase from *C. cochlearium*.[2479,2483] Black atoms are carbons, white atoms are oxygens, gray atoms are nitrogens, and the small gray sphere is the cobalt ion surrounded by its ligands. The gene for the protein from *C. cochlearium* was expressed in *E. coli*, and the resulting enzyme was purified and crystallized. Data were gathered to Bragg spacing of 0.19 nm. The enzyme is an $\alpha_2\beta_2$ heterotetramer with two symmetrically positioned active sites in each tetramer. The crystallographic asymmetric unit is the heterotetramer. In the map of electron density, in each active site, two conformations of the adenosyl group can be discerned.[2479] The conformation in the drawing is the one in which carbon 5′ is closest to the cobalt ion (Co) and is an axial ligand. Upon association of adenosylcobalamin with the enzyme, the 5,6-dimethylbenzimidazolyl group swings out of coordination with the cobalt, and the imidazolyl group of Histidine 16 takes its place. Nitrogen 3 of the 5,6-dimethylbenzimidazolyl group forms a hydrogen bond with the hydroxy group of a serine (lower left) in the active site.

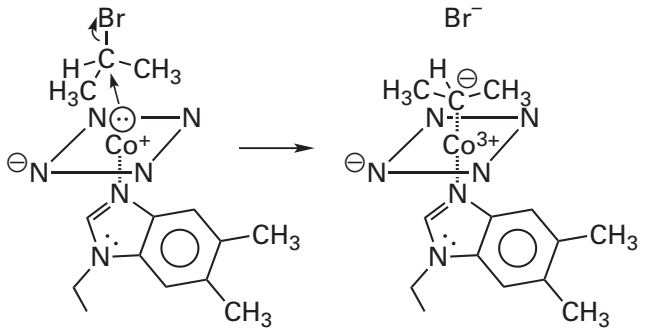
and the leaving group is cob(I)alamin.[2490] This nonenzymatic methylation is equivalent to the methylation of L-homocysteine performed enzymatically by the intermediate prosthetic methyl-cob(III)alamin in the active site of methionine synthase

5-methyltetrahydrofolate + L-homocysteine
⇌ tetrahydrofolate + L-methionine
(2–354)

In the active site of methionine synthase, the 5,6-dimethylbenzimidazolyl group of the prosthetic cobalamin has been replaced by the imidazolyl group of a histidine, and the sulfido group of the L-homocysteine upon its association with the active site is a ligand to a Zn^{2+}, which ensures that it remains unhydronated and nucleophilic.[2491] The enzymatic reaction is the simple direct, concerted nucleophilic substitution at the methyl group of the Co^{+} by the anionic conjugate base of the sulfanyl group of L-homocysteine (see Equation 2–353).

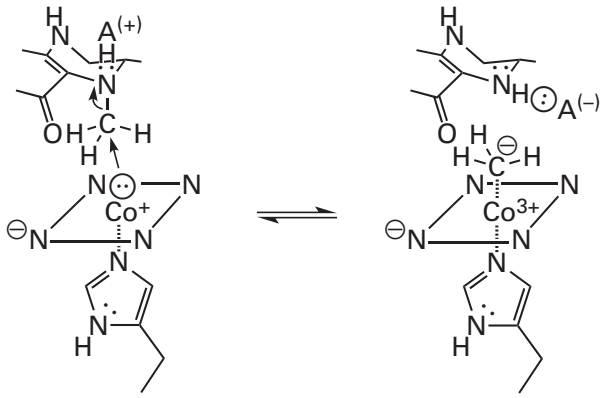
A dehalogenase from *Nitratireductor pacificus* reductively dehalogenates 2,2-dichloro- and 2,2-dibromophenols. The dehalogenation is a reduction because chloride or bromide, in each case the final product, is replaced at the ortho position by a hydron, a substitution that requires two electrons. The chlorine or bromine that is removed from the phenol ends up at first as a chlorocob(II)alamin or a bromocob(II)alamin, respectively. The chlorocob(II)alamin has been observed in a crystallographic molecular model of the enzyme.[2492] These observations suggest that in the formal electrophilic aromatic substitution of the halogen for a hydrogen that occurs ortho to the hydroxy group of the phenol, the actual leaving group is the **electrophilic chlorocob(III)alamin** or bromocob(III)alamin, which is then immediately reduced by one electron from an adjacent [4Fe–4S] iron–sulfur cluster to chlorocob(II)alamin or bromocob(II)alamin. The chlorocob(III)alamin or bromocob(III)alamin would dissociate from the intermediate 2,6-dichlorocyclo-hexa-2,4-dien-1-one or 2,6-dibromocyclohexa-2,4-di-en-1-one coordinated to the initial cob(I)alamin through the chlorine or bromine that is substituted. This intermediate 2,6-dihalo-2,4-cyclohexadien-1-one would be formed by hydronation of the reactant at the position from which the halogen is removed as in the usual electrophilic aromatic substitution. There is a second [4Fe–4S] iron–sulfur cluster in the enzyme, so the two electrons needed for reductive substitution of a chloride or bromide by a hydron can be supplied on site. The second electron reduces chlorocob(II)alamin or bromocob(II)alamin to the respective cob(I)alamin from which the halide dissociates.

Cob(I)alamin is a strong nucleophile. Cobalt(I) has an even number of electrons (8 valence electrons). In cob(I)alamin, there is a nucleophilic lone pair of electrons on the cobalt in the axial position. Cob(I)alamin reacts nucleophilically with primary alkyl halides[2493] and with secondary alkyl halides under acidic conditions[2494] to yield alkylcobalamins



(2–355)

The cob(I)alamin produced upon methylation of L-homocysteine by methionine synthase (see Equations 2–353 and 2–354), or upon methylations catalyzed by other methyltransferases that use cobalamin as a prosthetic group, is the nucleophile in transfer of the methyl group of 5-methyltetrahydrofolate to the cobalt in a direct, concerted nucleophilic substitution



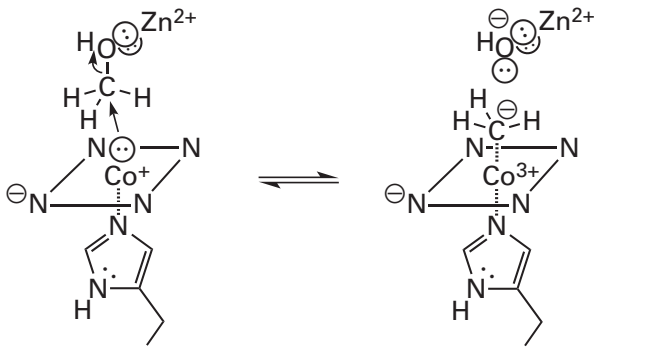
(2–356)

that regenerates the methylcobalamin.[2495,2496] The cob(I)alamin participating as the nucleophile in the direct, concerted nucleophilic substitutions performed by the enzymes is often adventitiously inactivated by oxidation to cob(II)alamin ($E^{\circ\prime} \cong -430$ mV on an enzyme), and there are strategies specific to each of

the enzymes for rereducing it[2497-2500] to retain enzymatic activity.

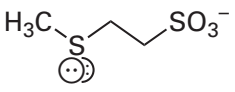
Adenosylcobalamin is synthesized biochemically by the direct, concerted nucleophilic attack of cob(I)alamin on carbon 5′ of $MgATP^{2-}$ in which magnesium triphosphate is the leaving group.[2501] In the active site of the enzyme that catalyzes this substitution, the side chains of a phenylalanine and a tryptophan at one of the axial positions of the cobalt ion exclude an axial ligand and raise its biochemical standard reduction potential so that it can be maintained in the nucleophilic Co^{+} oxidation state.[2502]

A cob(I)amide is the nucleophile that accepts the methyl group of methanol in one of the several steps in the **production of methane** in certain bacteria.[2503-2505] The cob(I)amide, with the imidazolyl group of a histidine replacing the benzimidazolyl group, nucleophilically attacks the carbon of methanol in a direct, concerted nucleophilic substitution



(2–357)

under Lewis acid catalysis by a Zn^{2+} in the active site that is coordinated by the hydroxy group of the methanol.[2485] The methyl group is then transferred in a second direct, concerted nucleophilic substitution (see Equation 2–353) to 2-sulfanylethanesulfonate, known as coenzyme M, abbreviated as HSCoM. The resulting 2-(methylsulfanyl)ethanesulfonate, methyl-SCoM



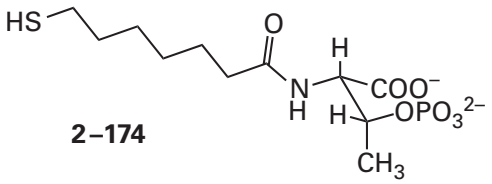
2–173

is the source of the methyl group converted to methane in all methanobacteria. Butyl-SCoM is converted by certain archaea into butane.[2506]

The enzyme catalyzing the actual production of methane is coenzyme-B sulfoethylthiotransferase

(2–358)

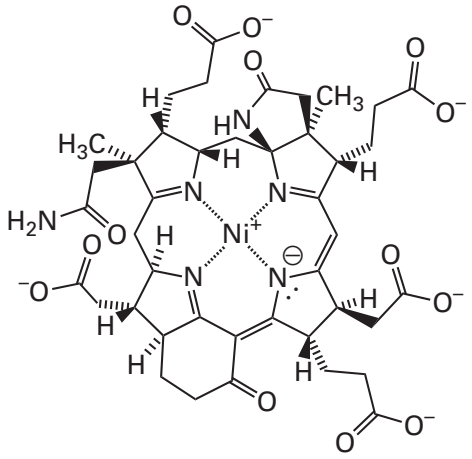
where coenzyme B, abbreviated as CoBSH, is *N*-(7-sulfanylheptanoyl)-L-threonine 3-*O*-phosphate



2–174

Kinetic isotopic effects indicate that the rate-limiting step in the production of methane by the enzyme is the breaking of the carbon–sulfur bond in methyl-SCoB for which the transition state involves a trigonal methyl group.[2511]

The nucleophilic prosthetic group in coenzyme-B sulfoethylthiotransferase is **coenzyme F_{430}**



2–175

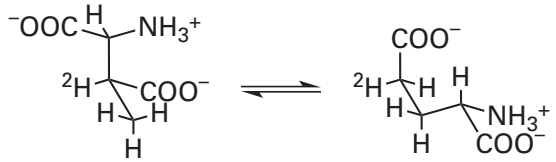
Coenzyme F_{430} is an extensively saturated, modified, nonaromatic porphyrin that contains **nickel(I) rather than cobalt(I)**. The porphyrin in coenzyme F_{430} is also derived from uroporphyrinogen III (**2–170**). As with cobalamin, the metallic ion replaces a single hydron from the conjugate acid of the porphyrin (see Equation 2–350).[2507,2508] The Ni^{+} in coenzyme F_{430} is poorly coordinated by water[2509] and is extremely nucleophilic,[2488] and when it is in the active site of coenzyme-B sulfoethylthiotransferase, it can react with methyl bromide to give a methylnickel(III).[2510,2511] Even though a methylnickel(III) can be formed in the active site when an analogue of coenzyme B, which is shorter by one methylene group, is used as a substrate for coenzyme-B sulfoethylthiotransferase

from *Methanothermobacter marburgensis*,[2513] this methylnickel(III) may not be an intermediate in the normal enzymatic reaction. This conclusion follows from the observation that an adduct between the nickel and a sulfur, rather than between nickel and a methyl group, has been identified by magnetic circular dichroism spectroscopy as an intermediate in the active site of the enzyme.[2512] Consequently, the reaction may involve a nucleophilic substitition at sulfur rather than carbon.

The majority of the enzymatic reactions in which adenosylcobalamin participates as a prosthetic group can be written as variations on a common enzymatic theme that is completely different from that of the direct, concerted nucleophilic substitutions in which methylcobalamin participates. Formally, a hydrogen atom in the reactant for the enzyme undergoes a **1,2 migration in concert with a reciprocal 2,1 migration** by one of the substituents on the carbon to which the hydrogen moves

(2–359)

where each pair of substituents, R_1 and R_2 or R_3 and R_4, can be two hydrogens, a hydrogen and an alkyl group, a hydrogen and a hydroxy group, or a hydrogen and a carboxy group. Consequently, the carbons between which the substituents migrate can be electron-donating or electron-withdrawing or neither. Either **inversion or retention of configuration** at each of the two carbon occurs, depending upon the particular enzyme,[2514] and this requires that the mechanism of the catalysis performed by adenosylcobalamin be consistent with either stereochemical outcome. One of the two participants migrating is always a hydrogen, but the other can be any one of a number of apparently unrelated functional groups (Table 2–3). An example of one of these reactions is that catalyzed by bovine methylaspartate mutase. This reaction proceeds with inversion of configuration at carbon 3[2514] when [3-^{2}H]-L-*threo*-3-methylaspartate is used as a reactant



(2–360)

Table 2–3: Substituents Migrating in Reactions Catalyzed by Adenosylcobalamin

enzyme	X in Equation 2–359
ethanolamine ammonia-lyase[2515]	$-NH_3^+$
propanediol dehydratase[2516]	$-OH$
lysine 5,6-aminomutase[2517,2518]	D-ornithine 4,5-aminomutase[2519]	
methylaspartate mutase[2520]	methylmalonyl-CoA mutase[2521]	ethylmalonyl-CoA mutase[2522]	
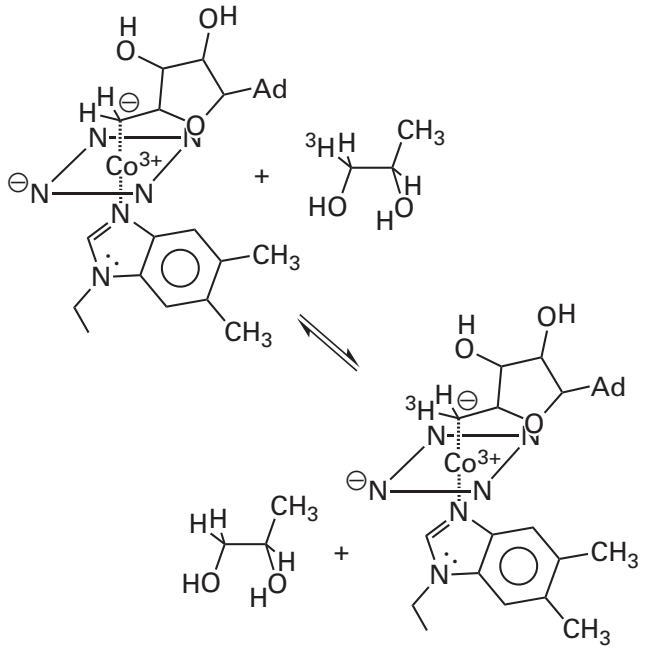
2-hydroxyisobutanoyl-CoA mutase[2523]	
isobutyryl-CoA mutase[2521,2524,2525]	
2-methyleneglutarate mutase[2526]	
In reactions catalyzed by adenosylcobalamin as a prosthetic group, the hydrogen that formally migrates across the reactant (Equation 2–359) does not exchange with hydrons in the solvent.[2527] If, however, reactant labeled at this hydrogen is mixed with the appropriate enzyme, the hydrogens at carbon 5′ of the 5′-deoxy-5′-adenosyl group of the adenosylcobalamin become labeled; or if the 5′-deoxy-5′-adenosyl group is labeled on carbon 5, the hydrogens on the reactant become labeled,[2528,2529] as in

the isotopic exchange catalyzed by propanediol dehydratase from *Klebsiella aerogenes*



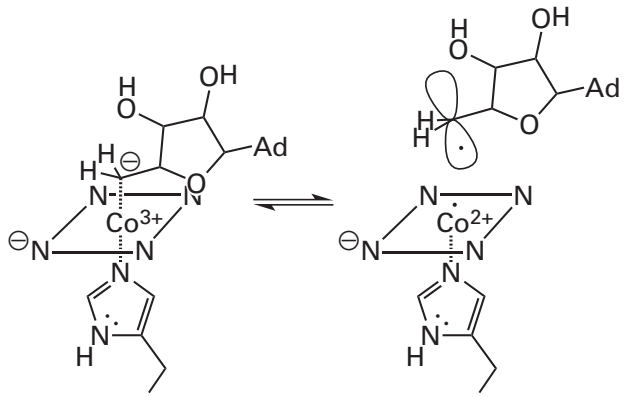
(2–361)

where Ad is an adenin-9-yl group. The **hydrogens equilibrating between substrates and carbon 5′ of the 5′-deoxy-5′-adenosyl group** of the prosthetic group do so in such a way that they occupy one of three equivalent locations when they enter carbon 5′ of the deoxyadenosine,[2527] so it must be the case that 5′-deoxyadenosine itself, which has a methyl group at the 5′ position, rather than adenosylcobalamin, is an intermediate.

All these observations are consistent with the existence of a step in the mechanism for the normal enzymatic reactions in which the carbon–cobalt bond of the adenosylcobalamin dissociates, **the hydrogen that is to migrate is transferred to the adenosyl group**, and the products of these two steps are 5′-deoxyadenosine and some form of the substrate lacking the hydrogen. When 2-aminopropanol, a slower (0.7%) substrate[2529] than the normal reactant 2-aminoethanol, is added to ethanolamine ammonia-lyase from *Clostridium*, the carbon–cobalt bond of adenosylcobalamin dissociates rapidly to produce 5′-deoxyadenosine and cob(II)alamin. This intermediate, containing the dissociated prosthetic group, is still fully active in the normal ethanolamine ammonia-lyase reaction,[2530] a fact consistent with the conclusion that this dissociated form of adenosylcobalamin is an intermediate in the normal enzymatic reaction. The 2-aminopropanol, because the isomerization that occurs in the next step of its enzymatic reaction is so slow that it becomes rate-limiting, causes the enzyme to accumulate in the intermediate state in which the carbon–cobalt bond has dissociated and the hydrogen on carbon 1 of 2-aminopropanol has been transferred to carbon 5′ of deoxyadenosine but the isomerization of the dehydro reactant has not yet occurred.

The form of the reactant in the intermediate state of an enzymatic reaction catalyzed by adenosylcobalamin, immediately after the carbon–cobalt bond has dissociated and the 5′-deoxyadenosine has been produced, could be the carbenium ion of the dehydro reactant and cob(I)alamin, the radical of the dehydro reactant and cob(II)alamin, or the carbanion of the dehydro reactant and cob(III)alamin. To produce one of these three outcomes, the initial step in the reaction would be dissociation of the carbon–cobalt bond of the adenosylcobalamin to produce a 5′-deoxy-5′-adenosyl carbenium ion, a 5′-deoxy-5′-adenosyl radical, or a 5′-deoxy-5′-adenosyl carbanion that then removes the appropriate hydride, hydrogen atom, or hydron, respectively, from the reactant for the enzyme. An intermediate 5′-deoxy-5′-adenosyl carbenium ion is unlikely, as it should rearrange immediately by an intramolecular 4′,5′-hydride migration to the more stable 5′-deoxy-4′-adenosyl carbenium ion. In fact, under basic conditions, 5′-deoxy-5′-adenosylcobaloxime dissociates heterolytically to give cob(I)aloxime and 4′,5′-dehydroadenosine, the conjugate base of the 5′-deoxy-4′-adenosyl carbenium ion.[2531] Both the 5′-deoxy-5′-adenosyl radical and the 5′-deoxy-5′-adenosyl carbanion, however, are so reactive that they should be able to remove a hydrogen atom or a hydron, respectively, from side chains of the amino acids surrounding them as readily as they would from the unactivated, often primary alkyl position of the reactant for the enzyme, a problem that has been solved by natural selection. In the intermediate state that accumulates when 2-aminopropanol is used as a reactant for ethanolamine ammonia-lyase,[2530] the cobalt is in oxidation state Co^{+2}. This observation is most consistent with an intermediate radical of the reactant, but it could also be consistent with a carbanionic intermediate if that carbanionic intermediate has at some point transferred an electron to the cob(III)alamin because of the wait resulting from using the slow reactant.

In the currently accepted mechanism, however, for the isomerizations catalyzed by adenosylcobalamin, the first step is homolytic cleavage of the carbon–cobalt bond of the adenosylcobalamin to yield 5′-deoxy-5′-adenosyl radical and cob(II)alamin*



(2–362)

When ethanolamine ammonia-lyase from *Clostridium*,[2532] methylmalonyl-CoA mutase from *Propionibacterium freudenreichii*,[2533] methylaspartate mutase from *Clostridium tetanomorphum*,[2534] or D-ornithine 4,5-aminomutase from *A. sticklandii*,[2535] each containing its full complement of adenosylcobalamin, is mixed with its reactant, there is a rapid decrease in its absorbance at 525 nm and increase in its absorbance at 475 nm, as expected if the adenosylcobalamin has been converted into cob(II)alamin. This **appearance of cob(II)alamin** is rapid enough to be a step in the overall enzymatic reaction and accounts for 20–30% of the adenosylcobalamin on the enzyme at equililbrium. 5′-Deoxyadenosine is also formed in the active site of methylaspartate mutase from *C. tetanomorphum* rapidly with the same rate constant as that for the formation of cob(II)alamin.[2536] In crystallographic molecular models of active sites that are occupied by their substrates or by substrate analogues, the carbon–cobalt bond often has broken,[2482,2537-2539] but crystallography cannot distinguish whether the products are those of heterolytic or homolytic dissociation or what the products were in the first instant after dissociation of the carbon–cobalt bond.

Upon mixing propanediol dehydratase from *K. aerogenes* with 1,2-propanediol,[2540] methylaspartate mutase from *Clostridium cochlearium* with L-glutamate,[2541-2543] ethanolamine ammonia-lyase from *S. typhimurium* with ethanolamine,[2544-2546] or methylmalonyl-CoA mutase from *P. freudenreichii* subsp. *shermanii* with (*R*)-methylmalonyl-SCoA,[2547] a **neutral radical of the respective reactant** or a neutral radical of the already rearranged reactant, in which the localized unpaired electron occupies the carbon from which or to which the hydrogen migrates (Equation 2–359), respectively, also forms rapidly in 20–50% yield. The cob(II)alamin and the radical of the reactant are in an equilibrium with the ternary complex of reactant or product and undissociated adenosylcobalamin.[2548] These observations are consistent with homolytic cleavage of the carbon–cobalt bond of adenosylcobalamin (Equation 2–362) followed immediately by the removal of a hydrogen atom from the appropriate carbon of the reactant by the 5′-deoxy-5′-adenosyl radical. No 5′-deoxy-5′-adenosyl radical is detected, presumably because it is unstable relative to the observed participants in the equilibrium.

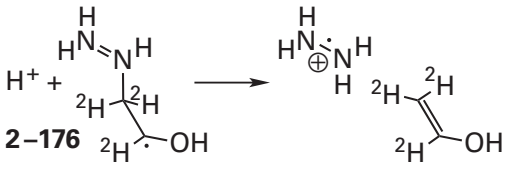
In the case of propanediol dehydratase, the neutral radical present at equilibrium has been identified by **electron paramagnetic resonance spectra** as the 1,2-dihydroxypropyl radical, produced by abstraction of a hydrogen from the hydoxymethyl carbon of the 1,2-propanediol.[2549] In the case of ethanolamine ammonia-lyase, the neutral radical present at equilibrium has also been identified by electron paramagnetic resonance spectra as the 1-hydroxy-2-aminoethyl radical, produced by the abstraction of a hydrogen from the hydoxymethyl carbon of the ethanolamine, because only when [1-^{13}C]ethanolamine is used as the reactant, and not [2-^{13}C]ethanolamine, is the absorbance of the radical split in two.[2550] No 1-amino-2-hydroxyethyl radical, the product of the normal isomerization leading to product, is observed during the enzymatic reaction because rearrangement of the 1-hydroxy-2-aminoethyl radical to the 1-amino-2-hydroxyethyl radical is the rate-limiting step in the overall reaction.[2551] As soon as the rearrangement produces 1-amino-2-hydroxyethyl radical, it immediately converts to the final product. The fact that the rearrangement is rate-limiting explains why the intermediate 1-hydroxy-2-aminoethyl radical can be observed in the first place. In the case of methylmalonyl-CoA mutase, however, the radical that accumulates during the enzymatic reaction has been identified by electron paramagnetic spectroscopy as that of the properly rearranged (*R*)-methylmalonyl-SCoA,[2547] so the rate-limiting step of this

*Cob(II)alamin has one unpaired electron and is a radical, as is the 5′-deoxy-5′-adenosyl radical.

reaction must be abstraction of the hydrogen from 5′-deoxyadenosine by this radical.

As was the case when 2-aminopropanol was used as an unnatural reactant for ethanolamine ammonia-lyase, the catalytic reaction of an enzyme using adenosylcobalamin as a prosthetic group can be stopped in its tracks by using an **appropriate unnatural analogue** of the reactant or an analogue of adenosylcobalamin, and in some of these instances **intermediates consistent with a homolytic mechanism accumulate**. In the case of 2-aminopropanol and ethanolamine ammonia-lyase, 2-amino-1-hydroxy-1-propyl radical accumulates in the active site, consistent with abstraction of the hydrogen from the carbon of the hydroxymethyl group of 2-aminopropanol, just as in the normal reaction the hydrogen would be abstracted from the carbon of the hydroxymethyl group of 2-aminoethanol.[2552,2553]

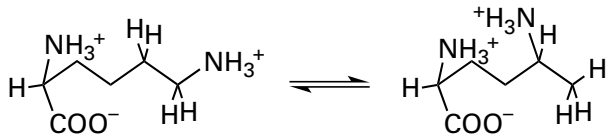
When ethanolamine ammonia-lyase from *S. typhimurium* is mixed with [1,1,2,2-$^2H_4$]-2-hydroxyethylhydrazine, another unnatural analogue of ethanolamine, cob(II)alamin, [5′-^{2}H]-5′-deoxyadenosine, [1,2,2-$^2H_3$]acetaldehyde, and the radical cation of hydrazine are formed rapidly on the enzyme.[2554,2555] [1,2,2-$^2H_3$]Acetaldehyde and the radical cation of hydrazine are the products expected from the decomposition of 1-hydroxy-2-hydrazino-1-ethyl radical **2–176**



(2–363)

that is formed by abstraction of a hydrogen from the carbon of the hydroxymethyl group of 2-hydroxyethylhydrazine.

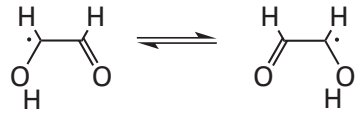
In the active site of D-ornithine 4,5-aminomutase from from *A. sticklandii*, it is actually the **pyridoximine** that forms between a prosthetic pyridoxal 5′-phosphate in the active site and the 5-amino group of the L-ornithine that migrates (Table 2–3). When D-ornithine 4,5-aminomutase is mixed with D-2,4-diaminobutyrate, an analogue one carbon shorter than D-ornithine, cob(II)alamin is formed rapidly on the enzyme.[2556] Electron paramagnetic resonance spectra identified a radical formed from the imine of D-2,4-diaminobutyrate and the prosthetic pyridoxal 5′-phosphate. In the enzymatic reaction catalyzed by lysine 5,6-aminomutase, the 6-amino group of L-lysine migrates to carbon 5



(2–364)

and again the pyridoximine forms between a prosthetic pyridoxal 5′-phosphate in the active site and the 6-amino group of the L-lysine that migrates (Table 2–3). When carbon 4 of L-lysine is replaced by a sulfur and the resulting unnatural analogue, 4-thia-L-lysine, is mixed with the enzyme from *Porphyromonas gingivalis*, one of the hydrogens on carbon 5 is abstracted by the adenosylcobalamin, and the resulting radical, which is the analogue of the radical that should be formed in the first step of the normal enzymatic reaction by abstraction of hydrogen from the pyridoximine, can be observed. The immediately adjacent sulfur at position 4 stabilizes the radical at carbon 5 by sharing the unpaired electron, and this stabilization prevents the migration of the 6-imino group.

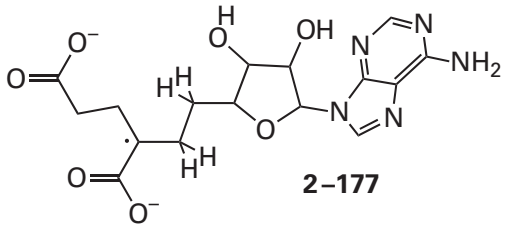
When the hydrate of glycolaldehyde is used as an unnatural reactant for propanediol dehydratase from *K. aerogenes* (Table 2–3), the immediate product of the reaction is the stable 1-oxo-2-hydroxy-2-ethyl radical[2557,2558]



(2–365)

as expected from the removal of a hydrogen atom from the carbon of the hydroxymethyl group of the glycolaldehyde.

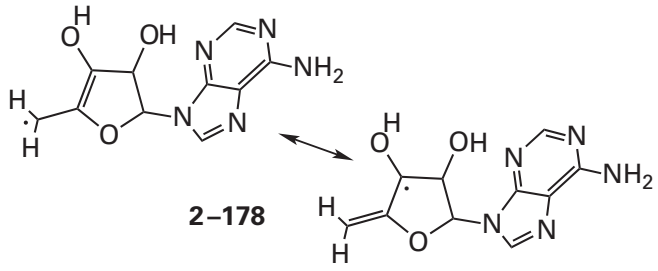
There are also **unnatural substrates that reveal the formation of a 5′-deoxy-5′-adenosyl radical**. When methylaspartate mutase from *C. tetanomorphum* (Table 2–3) is mixed with 2-methyleneglutarate, an analogue of the substrate L-glutamate, the carbon–cobalt bond of the adenosylcobalamin cleaves homolytically and the 5′-deoxy-5′-adenosyl radical adds to the double bond of the methylene group at the distal carbon to give a stable adduct in which the unpaired electron ends up on a tertiary carbon[2559]



2–177

The same observation was made later with methylmalonyl-CoA mutase from *M. tuberculosis*. When methylmalonyl-CoA mutase is mixed with 2-methylenesuccinyl-SCoA, an analogue of the substrate succinyl-SCoA, the 5′-deoxy-5′-adenosyl radical generated in the active site again adds to the methylene group to give a stable adduct analogous to **2–177** with a succinyl-SCoA group rather than a glutaryl group covalently attached to the 5′-deoxy-5′-adenosyl group. In this instance, the adduct was stable enough that it could be identified unambiguously by crystallography.[2560] The 5′-deoxy-5′-adenosyl radical, however, as a radical at a primary carbon, is so unstable that when it dissociates from the adenosylcobalamin, it either abstracts a hydrogen immediately upon its formation or recolligates with cob(II)alamin, so it has not yet been observed directly in any enzyme with a prosthetic adenosylcobalamin.

Rather than an unnatural analogue of the reactant, an **unnatural analogue of adenosylcobalamin** can be incorporated into an enzyme. When adenosin-3′,4′-enylcobalamin[2561] is used as a prosthetic group in the active site of propanediol dehydratase from *K. aerogenes*, its carbon–cobalt bond cleaves upon the addition of 1,2-propanediol to the enzyme to produce a 5′-deoxyadenosin-4′,5′-en-3′-yl radical.[2562] The unpaired electron in this radical



2–178

is delocalized over the immediately adjacent 4′,5′ double bond and stabilized captodatively by the 3′-hydroxy group, both effects that result in a stable intermediate insufficiently reactive to abstract a hydrogen from the 1,2-propanediol at anywhere near the rate at which the normal 5′-deoxy-5′-adenosyl radical does.[2563] Instead, the delocalized radical is reduced by the cob(II)alamin and hydrogenated to give the final product 3′,5′-dideoxyadenosin-4′,5′-ene, which registers the formation of radical **2–178**.

Several of these stable radicals that can be observed in the active site have been used to obtain estimates of the distances involved in the enzymatic reaction. These estimates are for the distances from the respective radical to either the cobalt ion in cob(II)alamin, from which the 5′-deoxy-5′-adenosyl radical dissociated, or to the methyl group of the 5′-deoxyadenosine produced during creation of the respective radical.

Analysis of the shapes of the lines in spectra from electron paramagnetic resonance,[2553,2564] spectra from X-band electron spin-echo electron paramagnetic resonance and spin-echo envelope modulation,[2565,2566] and spectra from pulsed electron–nuclear double resonance[2567] of either the radical of 2-aminopropanol or the radical of [$^2H_4$]-2-aminoethanol in the active site of ethanolamine ammonia-lyase from *S. typhimurium* all provide consistent estimates of the distance between the respective radicals and the cobalt ion in cob(II)alamin of 1.0 ± 0.1 nm. Spectra from X-band and Q-band electron paramagnetic resonance[2568] provide an estimate of distance between the radical on 4-thia-L-lysine and the cobalt ion in cob(II)alamin within the active site of lysine 5,6-aminomutase from *A. sticklandii* of 1.0 nm. In the crystallographic molecular model of the complex between (*S*)-1,2-propanediol and propanediol dehydratase from *Klebsiella oxytoca*,[2569] the distance from the cobalt of the prosthetic cobalamin to the carbons of the reactant between which the hydrogen migrates is 0.9 nm; in the crystallographic molecular model of the complex between methylaspartate mutase from *C. cochlearium* and an equilibrium mixture of L-glutamate and (2*S*,3*S*)-3-methylaspartate,[2479] the distance from the cobalt of the prosthetic cobalamin to the carbons of the substrates between which the hydrogen migrates is 0.7 nm; and in the crystallographic molecular model of the complex between methylmalonyl-CoA mutase from *P. freudenreichii* and the inhibitor *S*-2-carboxypropyl-SCoA,[2570] the distance from the cobalt of the prosthetic cobalamin to the carbons of the inhibitor between which the hydrogen would migrate in the substrates is 0.6 nm.

All these distances seem to require that, in each instance, the carbon–cobalt bond dissociates and the 5′-deoxy-5′-adenosyl radical swings over to the reactant from the cobalt ion it leaves behind before the hydrogen can be abstracted. While it is

swinging over to the reactant, it is a rather reactive 5′-deoxy-5′-adenosyl radical that can abstract a hydrogen from almost any carbon in the protein. There is, however, no such thing as empty space in a condensed solution, so the apparently empty space through which the 5′-deoxy-5′-adenosyl radical must swing between the cobalt and the reactant must be occupied by disordered molecules of water. In fact, in the crystallographic molecular model of the complex between methylmalonyl-CoA mutase from *P. freudenreichii* and *S*-2-carboxypropyl-SCoA, there are several fixed molecules of water between the cobalt ion of the cobalamin and the carbons in the inhibitor between which the hydrogen would migrate in the substrates. The reason for surrounding the 5′-deoxy-5′-adenosyl radical with molecules of water is that of all the hydrogens in the solution, the most difficult to abstract are the hydrogens on molecules of water (bond dissociation energy = 497 kJ mol^{-1}), none of which can be abstracted by a 5′-deoxy-5′-adenosyl radical (bond dissociation energy = 390 kJ mol^{-1}). In a sense, it is almost as if, during its lifetime in transit, the 5′-deoxy-5′-adenosyl radical were surrounded by vacuum as it swings over to the reactant.

The 5′-deoxyadenosine remains intimately associated with the radical of the reactant that it forms upon abstraction of the respective hydrogen. Spectra from electron spin-echo envelope modulation of the radical of [$^2H_4$]-2-aminoethanol,[2571] spectra from X-band electron spin-echo electron paramagnetic resonance and from electron spin-echo envelope modulation of the radical of 2-aminopropanol[2565] and the radical of [$^2H_4$]-2-aminoethanol,[2566] and spectra from pulsed electron–nuclear double resonance of the radical of 2-aminopropanol,[2572] each in the active site of ethanolamine ammonia-lyase from *S. typhimurium*, are consistent with all three hydrogens on the 5′-methyl group of the deoxyadenosine being located within 0.23–0.42 nm of the respective radical and the carbon of the 5′-methyl group being located 0.35 nm from the radical. If this is so, then the 5′-methyl carbon is within van der Waals contact with the carbon on which the unpaired electron resides.

When the hydrogen on the reactant that migrates during the reaction catalyzed by methyl-malonyl-CoA mutase from *P. freudenreichii* is converted to a deuterium, the rate constant for the appearance of cob(II)alamin decreases dramatically.[2533,2534] This observation suggests that **homolysis of the carbon–cobalt bond is concerted with abstraction of a hydrogen from the reactant**, which would require that the carbon of the reactant from which the hydrogen is abstracted be positioned by the enzyme immediately adjacent to carbon 5′ of the adenosyl group in the intact adenosylcobalamin. The distances observed by spectroscopy and crystallography rule out this possibility. It may simply be the case that the homolysis of the carbon–cobalt bond precedes abstraction of the hydrogen from the substrate[2573] and is not concerted with it but that the equilibrium constant for homolysis of the carbon–cobalt bond is significantly less than 1, as might be expected. Abstraction of the hydrogen from the reactant for the enzyme shifts the equilibrium by mass action, in favor of dissociation of the carbon–cobalt bond. This sequence of events would explain both the requirement that the hydrogen must be abstracted from the reactant as the cob(II)alamin is formed, as required by the kinetic isotope effect, and the fact that no 5′-deoxy-5′-adenosyl radical is ever observed as a transient intermediate in any of these enzymatic reactions.[2548] These considerations suggest that, **rather than being concerted, dissociation of the carbon–cobalt bond is coincident with abstraction of the hydrogen** simply because the equilibrium is shifted by subsequent abstraction of the hydrogen. In this way, the lifetime of the 5′-deoxy-5′-adenosyl radical is kept to a minimum.

Homolytic dissociation of the carbon–cobalt bond of adenosylcobalamin should be the most difficult step in the accepted mechanism, especially if it is not concerted with abstraction of the hydrogen from the reactant. The bond dissociation energy of a carbon–cobalt bond in an alkylcobalamin[2574] is around 100 kJ mol^{-1}, and that for the homolysis of adenosylcobalamin[2575] is 125 ± 10 kJ mol^{-1}. Even more remarkable is that the rate constant for uncatalyzed dissociation of the carbon–cobalt bond in adenosylcobalamin at 25 °C is 4×10^{-10} s^{-1}.

Nevertheless, the active site of an enzyme that uses adenosylcobalamin as a prosthetic group somehow **overcomes these formidable thermodynamic and kinetic barriers.** In the map of electron density within an active site of methylaspartate mutase from *C. cochlearium* unoccupied by substrates, two orientations of the 5′-deoxyadenosyl group can be discerned. The orientation in the drawing (Figure 2–68) is the one in which carbon 5′ is closest to the cobalt ion (Co). In the other orientation, which is not drawn, the carbon–cobalt coordination is broken; carbon 5′ is farther (0.45 nm) from the cobalt, well out of coordination; carbon 5′ is not in an axial position; and it is pointing instead toward the location in the active site in which substrates are

normally bound.[2479,2483] The conclusion that can be drawn in this instance is that there is an equilibrium established in the active site between the intact carbon–cobalt bond and the dissociated carbon–cobalt bond even in the absence of substrate. How the active site is able to change the equilibrium constant from the highly unfavorable value in solution to such an isoergonic one is puzzling but perhaps only because catalysis of homolytic reactions by the active sites of enzymes is not so well understood as is the catalysis of heterolytic reactions.

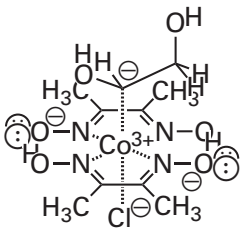
When the reactant binds to one of these enzymes with a prosthetic cobalamin in its active site, there is spectroscopic evidence that the carbon–cobalt bond of adenosylcobalamin, if it is not broken almost immediately,[2533] is distorted,[2576] and this distortion and other **steric effects**[2577,2578] may weaken the bond. These steric effects are probably not exerted on the corrin itself because it has virtually the same conformation in both adenosylcobalamin and cob(II)alamin.[2579] It is possible that the carbon–cobalt bond could be stretched by the active site. For example, the undissociated orientation of the carbon–cobalt bond of the adenosylcobalamin in the crystallographic molecular model of methylaspartate mutase from *C. cochlearium*, in which the carbon is closest to the cobalt ion (Figure 2–68), the distance between carbon and cobalt (0.32 nm) is significantly longer than the unstretched carbon–cobalt bond in free adenosylcobalamin (0.205 nm).[2472] When amino acids the side chains of which form hydrogen bonds to the ribosyl ring of the adenosyl group in the active site of methylaspartate mutase are mutated,[2580] the rate of dissociation of the carbon–cobalt bond upon addition of substrate decreased by a factor of 100–10,000. These hydrogen bonds could enforce a distortion or stretching of the carbon–cobalt bond. The carbon–cobalt bonds of adenosylcobalamins in the active sites of isobutyryl-CoA mutase from *Cupriavidus metallidurans*[2581] and human methyl-malonyl-CoA mutase,[2537] however, are of normal length (0.23 and 0.22 nm).

When adenosylcobalamin is bound to an enzyme and the benzimidazolyl group has been replaced by **the imidazolyl group of the histidine**, the carbon–cobalt bond loses only about 2% of its strength.[2582] Consistent with the small decrease in its strength observed upon its association with an enzyme and the exchange of its axial ligand, the exchange of the benzimidazolyl group in adenosylcobalamin with *N*-methylimidazole does increase the rate constant for homolytic dissociation of the carbon–cobalt bond in free solution but only by 8-fold. This exchange, however, also increases by 350-fold the heterolysis of the carbon–cobalt bond that produces the 5′-deoxy-5′-adenosyl carbanion and cob(III)alamin (Equation 2–352) to give this heterolytic dissociation the same rate constant as the homolytic dissociation.[2583] Another factor that may decrease the homolytic bond dissociation energy of the carbon–cobalt bond is that the unpaired electron in the 5′-deoxy-5′-adenosyl radical, during the majority of its short lifetime of around 1 ns,[2584] remains less than 0.5 nm from the cobalt in cob(II)alamin,[2577] presumably before it happens to move to its effective location.

If it is assumed that, following the required rearrangement (Equation 2–359), the radical of the dehydro product of the enzymatic reaction abstracts a hydrogen from the 5′-methyl group of deoxyadenosine to become the product and the 5′-deoxy-5′-adenosyl radical immediately recombines with cob(II)alamin to restore the adenosylcobalamin (reverse of Equation 2–362), then the only remaining question is **how the rearrangement of the radical of the reactant to the radical of the product occurs**. It has already been noted that in crystallographic molecular models of complexes between enzymes that use adenosylcobalamin as a prosthetic group and their substrates, the carbons from which the hydrogen is abstracted by the 5′-deoxy-5′-adenosyl radical are located 0.6–0.9 nm from the cobalt of cob(II)alamin.[2479,2569,2570] These observations seem to preclude a carbon–cobalt bond involving cob(II)alamin and either the dehydro radical of the reactant or the dehydro radical of the product, so model reactions that involve the rearrangements of organocobalt compounds that mimic those catalyzed by the enzyme but that require the rearrangement to occur on the metallic ion[2585] are probably irrelevant.

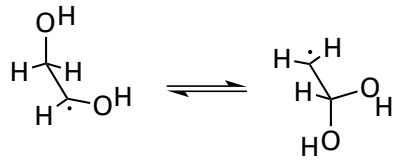
There are a number of nonenzymatic rearrangements that mimic the rearrangements that occur in the active sites containing prosthetic cobalamins.

There are nonenzymatic rearrangements that use **organocobalt compounds** as precursors to radicals, which then rearrange appropriately after their dissociation from the cobalt. For example, 1,2-dihydroxyethyl cobaloxime



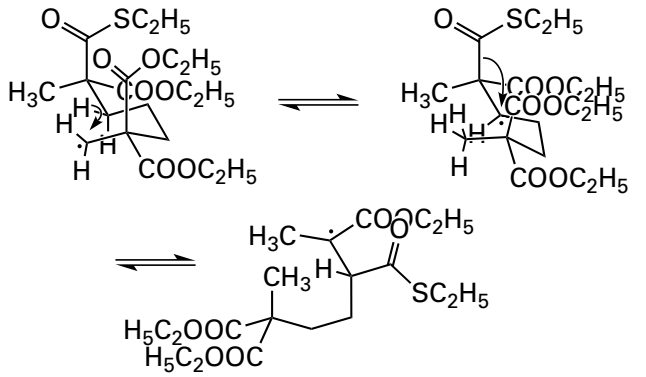
2–179

produces high yields of ethanal as a result of homolytic cleavage of its carbon–cobalt bond and subsequent rearrangement of the 1,2-dihydroxyethyl radical to the 2,2-hydroxyethyl radical



(2–366)

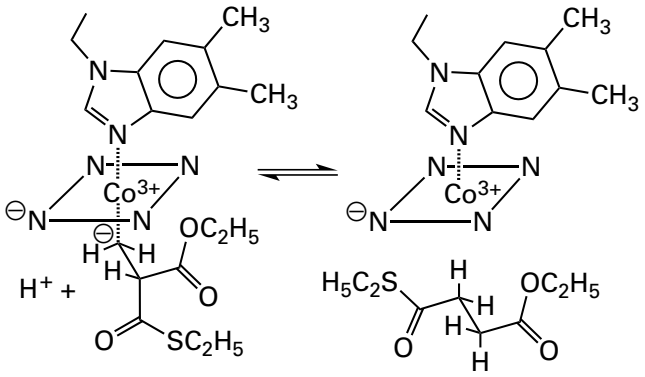
followed by abstraction of a hydrogen from the solvent.[2586] The other product of the reaction is cob(II)aloxime. This rearrangement mimics that performed by propanediol dehydratase (Table 2–3). Homolysis of 2,2,6-triethoxycarbonyl-6-(*S*-ethylthiocarboxy)-1-heptylcobalamin produces the 2,2,6-triethoxycarbonyl-6-(*S*-ethylthiocarboxy)heptyl radical that undergoes intramolecular transfer of a hydrogen and subsequent isomerization[2587]



(2–367)

by a migration that resembles those catalyzed by methylmalonyl-CoA mutase and isobutyryl-CoA mutase (Table 2–3).

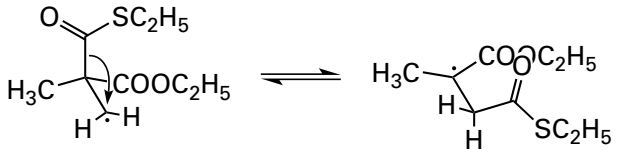
These reactions, however, that use the respective cobaloxime or cobalamin as the precursor for what is believed to be a neutral radical from a homolytic cleavage of the carbon–cobalt bond are **equivocal**. For example, in the rearrangement[2588]



(2–368)

which is a model for methylmalonyl-CoA mutase (Table 2–3), it has been demonstrated with **radical clocks** and traps for radicals that the 2-ethoxycarbonyl-2-(*S*-ethylthiocarboxy)-1-propyl radical is not formed by a homolytic cleavage of the carbon–cobalt bond[2589,2590] and therefore is not the species rearranging.

It is also possible, however, to unambiguously **generate either chemically or photolytically appropriate radicals** that subsequently rearrange. For example, 2-ethoxycarbonyl-2-(*S*-ethylthiocarboxy)-propyl bromide, when treated with tri-(*n*-butyl)tin hydride, yields the 2-ethoxycarbonyl-2-(*S*-ethylthiocarboxy)propyl radical, which then rearranges to the 1-ethoxycarbonyl-1-methyl-2-(*S*-ethylthiocarboxy)-ethyl radical[2591]



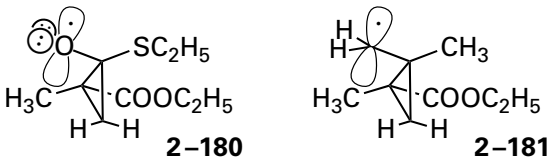
(2–369)

This isomerization is a model for the reaction catalyzed by methylmalonyl-CoA mutase. Phenylseleno groups (C_6H_6Se–) dissociate homolytically upon photolysis to yield the radical at the carbon to which they were attached, and these precursors have also been used to generate appropriate radicals for rearrangement.[2592,2593]

The **mechanisms by which the rearrangements of these various radicals proceed in solution,** which mimic the heterolytic rearrangements thought to occur in the active sites of enzymes, are either associative, dissociative, or concerted. As always, in an associative mechanism,[2591] a bond forms before another bond is broken; in a dissociative mechanism,[2594] a bond breaks before another bond is formed; and in a concerted mechanism, one bond is breaking as the other is forming. As in most cases

when there are associative, dissociative, and concerted alternatives for any reaction, the differences between them are not substantive; rather, they are differences in timing. In addition, it is probably the case that some rearrangements catalyzed by these enzymes are associative, others are dissociative, and others are concerted. Furthermore, the timing in solution may not be the same as that on an active site, even for the same rearrangement.

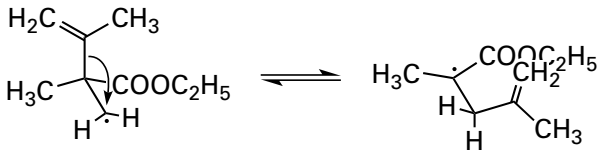
The rearrangement in solution of the 2-ethoxycarbonyl-2-(*S*-ethylthiocarboxy)propyl radical (Equation 2–369) has several kinetic properties consistent with **an associative mechanism** that has cyclopropyl radical **2–180** as an intermediate



2–180 **2–181**

This **cyclopropyl radical** is formed by intramolecular cyclization of the radical of the reactant or, in the reverse reaction, the radical of the product, and it cleaves to form either the radical of the reactant or the radical of the product.[2591] The homologous associative rearrangement with the homologous intermediate cyclopropyl radical has also been proposed to occur in the active site of methylmalonyl-CoA mutase (Table 2–3).[2595]

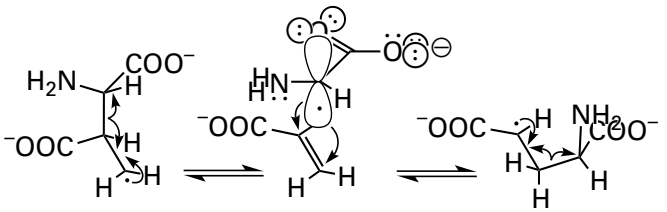
Rearrangement of 2-ethoxycarbonyl-2-(1-methylethenyl)propyl radical



(2–370)

which is a model for the reaction catalyzed by 2-methyleneglutarate mutase (Table 2–3) and in which a 1-methylethenyl group [–C(CH$_3$)=CH$_2$)] replaces the *S*-ethylthiocarbonyl group [–C(SC$_2$H$_5$)=O] in Equation 2–369, is even more facile. The intermediate in this latter nonenzymatic reaction, cyclopropyl radical **2–181**, has been trapped and identified.[2593] When 2-[*E*-^{2}H$_1$]methyleneglutarate is mixed with 2-methyleneglutarate mutase from *E. coli*, the 2-[*E*-^{2}H$_1$]methyleneglutarate at equilibrium with 2-methylene-3-methylsuccinate, the product of the enzymatic reaction, gradually isomerizes, in a reaction catalyzed by the enzyme, to an equimolar mixture of 2-[*E*-^{2}H$_1$]methyleneglutarate and 2-[*Z*-^{2}H$_1$]methyleneglutarate.[2596] This result is consistent with the unesterified carboxylic acid of cyclopropyl radical **2–181** being an intermediate in the enzymatic reaction because rotation about the exocyclic carbon–carbon bond in the radical should be allowed while such a rotation forbidden in either the reactant or the product.

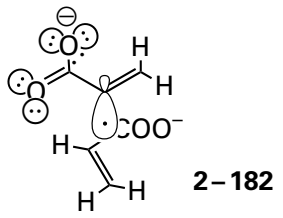
Rearrangement of the (2*S*,3*R*)-2-amino-3-carboxy-4-butanoate radical catalyzed by methylaspartate mutase (Table 2–3), however, cannot proceed by an associative mechanism because the carbon that is migrating is saturated. In the **dissociative isomerization** through which this rearrangement would have to proceed, a glycyl radical, stabilized by extensive delocalization, moves across the double bond in the conjugate base of acrylic acid[2597]



(2–371)

Both of these fragments, glycine and acrylate, have been shown to be formed during the rearrangement catalyzed by methylaspartate mutase from *C. cochlearium*,[2598] and spectroscopic evidence for the intermediacy of the glycyl radical in the enzymatic reaction has also been presented.[2543] When (2*S*,3*R*)-2-sulfanyl-3-carboxy-4-butanoate is used as a sulfanyl analogue of the usual amino reactant, (2*S*,3*R*)-2-amino-3-carboxy-4-butanoate, the even more stable 1-sulfanylcarboxymethyl radical forms in the active site rather than the glycyl radical (Equation 2–371). The thiyl radical was identified by its electron paramagnetic resonance spectrum, and zero-field splitting parameters suggested that the radical was the proper distance from the cobalt.[2599]

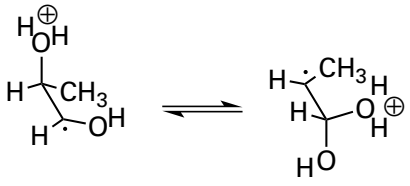
The reaction catalyzed by 2-methyleneglutarate mutase (Table 2–3) from *E. barkeri* is inhibited by two acrylate anions acting in concert but is not inhibited by 1-methylcyclopropane 1,2-dicarboxylate, an analogue of the cyclopropyl radical that would be the intermediate in an associative mechanism (see **2–180**).[2600] These observations suggest that a dissociative migration



2–182

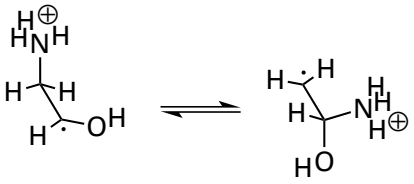
involving an acrylate anion and a 2-acrylate radical anion (**2–182**) occurs in this enzymatic reaction. The chemical evidence from nonenzymatic model reactions, however, suggest it should proceed by an associative mechanism.[2591] These contradictions throw the exact assignment of mechanism in doubt, but they could be resolved if the mechanism in the active site differs from that in solution.

For both the rearrangement of the 1,2-dihydroxypropyl radical to 1-methyl-2,2-dihydroxyethyl radical



(2–372)

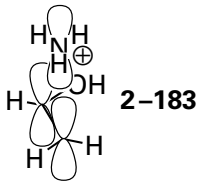
in the reaction catalyzed by propanediol dehydratase and the rearrangement of the homologous 1-hydroxy-2-aminoethyl radical to 2-hydroxy-2-aminoethyl radical



(2–373)

in the reaction catalyzed by ethanolamine ammonia-lyase, the hydroxy group that is migrating and the amino group that is migrating, respectively, are each **hydronated before the migration takes place**.[2601,2602] In the former rearrangement, the hydroxy group is hydronated by the conjugate acid of the imidazolyl group of a histidine in the active site,[2569] and in the latter rearrangement, the ammonio group that enters the active site is maintained in its hydronated state by a hydrogen bond to the carboxylato group of a glutamate.

In neither of these two reactions is either an associative mechanism or a dissociative mechanism realistic. An associative mechanism would require that either the migrating oxygen or the migrating nitrogen be pentavalent, which is impossible. A dissociative mechanism would require a hydronated hydroxyl radical cation or a hydronated amino radical cation, neither of which is realistic, to migrate across a double bond, or it would require a molecule of water or a molecule of ammonia to migrate across the radical cation of a double bond, which is also unrealistic. Consequently, it is believed that both reactions (Equations 2–372 and 2–373) are **concerted isomerizations** with the bond to the oxygen of the hydronated hydroxy group or the bond to the nitrogen of the ammonio group breaking as the other bond to the oxygen of the hydronated hydroxy group or the nitrogen of the ammonio group, respectively, is forming.[2601,2602] Each concerted isomerization would have a transition state with a π molecular orbital system that combines a p orbital from each of the two carbons and a p orbital from the planar sp^2 oxygen or the planar sp^2 nitrogen

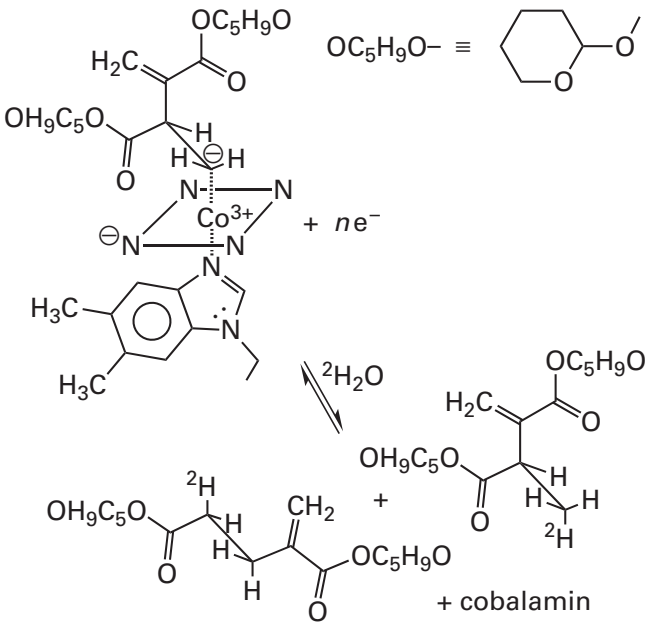


2–183

respectively. Each of these respective π molecular orbital systems, the one in which the oxygen is the third atom and the one in which nitrogen is the third atom (**2–183**), is occupied by three electrons.

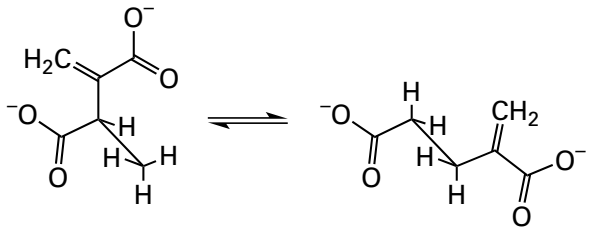
In this transition state in the active site of ethanolamine ammonia-lyase from *E. coli*, a hydrogen bond between one of the nitrogen–hydrogens on the ammonio group on the conjugate acid of ethanolamine and a σ lone pair on one of the carboxylato oxygens of the glutamate that maintains the hydronation of the amino group during the migration guides the nitrogen from one carbon to the other. This pivoting carboxylato group is planted on the hydroxy group of the ethanolamine by a hydrogen bond to its other oxygen.[2602]

The large majority of the evidence at the moment suggests that the radical of the dehydro reactant isomerizes to the radical of the dehydro product in the rearrangements catalyzed by enzymes using adenosylcobalamin as a prosthetic group. Several isomerizations of carbanions, however, that resemble the carbanions of the dehydro reactants in the enzymatic reactions also mimic the rearrangements performed by the respective enzymes. When the rearrangement of bis(tetrahydro-*H*-pyran-2-yl) 2-methylcobalaminylitaconate



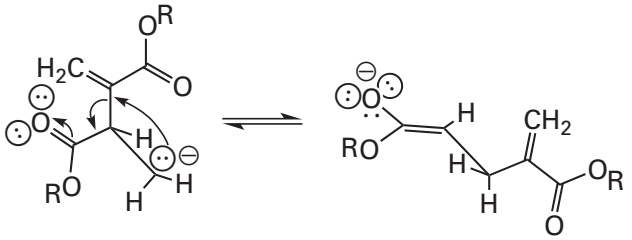
(2–374)

was performed in ^2H_2O in the absence of any enzyme, a deuterium atom was found in the products at the locations at which the hydrogen migrating during the reaction catalyzed by 2-methyleneglutarate mutase



(2–375)

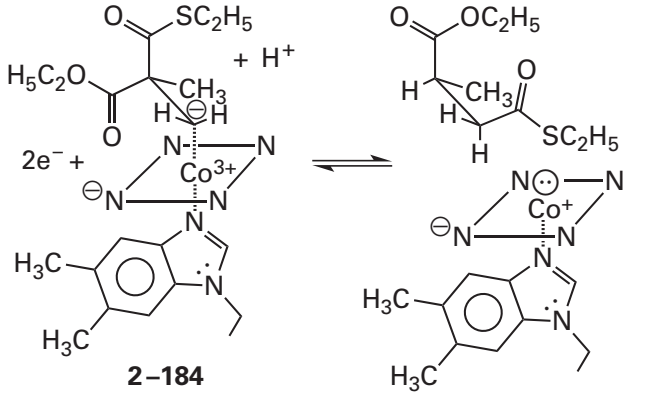
would have occupied.[2526,2603] Although water gives up a hydron readily, a hydrogen atom (bond dissociation energy = 497 kJ mol^{-1}) is abstracted from water only with great difficulty. This result and the requirement for coincident reduction of cobalt to yield rearranged products has led to the conclusion that these rearrangements occur within a carbanion released from the cobalt directly or upon reduction



(2–376)

The carbanions released during these reactions would readily pick up a hydron from the solvent prior to or following their rearrangement.

Under similar reductive conditions, alkylcobalamin **2–184**



(2–377)

rearranges to produce high yields of the product, thioethyl 3-ethoxycarbonylbutanoate.[2604] This reaction serves as a model for the rearrangement catalyzed by methylmalonyl-CoA mutase (Table 2–3).

A radical of the dehydro reactant and cob(II)alamin is only the transfer of an electron away from a carbanion of the dehydro reactant and cob(III)alamin. Perhaps, just as the distinction between a concerted nucleophilic substitution and a dissociative nucleophilic substitution is ambiguous, the distinction between a homolytic rearrangement and a heterolytic rearrangement, at least in this context, is ambiguous. In the case of lysine 5,6-aminomutase from *A. sticklandii* (Table 2–3), however, the appearance of cob(III)alamin resulting from transfer of an electron from cob(II)alamin to an intermediate in the enzymatic reaction, as would be required if the reaction were some hybrid of homolytic and heterolytic, produces the irreversible inactivation of the enzyme.[2605] It may be the case that the radicals of reactant and product are held so far away from the cobalt ion to prevent just such a detrimental electron transfer.

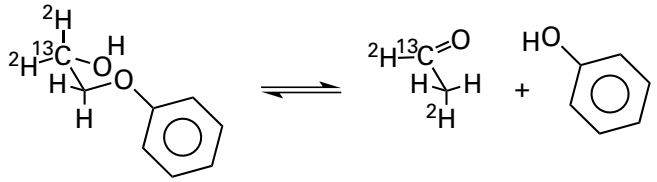
Problem 2–41: Write the mechanism for methionine synthase (Equation 2–354), which uses methylcobalamin as a prosthetic group.[2495]

Problem 2–42: Write a mechanism for the conversion



as it would be catalyzed by an enzyme using adenosylcobalamin as a prosthetic group and an intermediate radical.[2606]

Problem 2–43: Write associative and dissociative homolytic mechanisms for each of the reactions in Table 2-3.

(A) Write the overall equation for the reaction with the chemical structures of the reactant and the product, each drawn in the sawhorse projection with the orientation of the sawhorse in Equation 2–360. When necessary, make sure that the chirality of each of the two central carbons between which the hydrogen and the substituent are interchanged is correct.

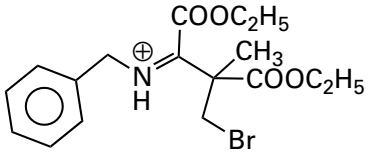
(B) To write the mechanism, remove the hydrogen atom and produce the radical of the reactant as would be done on the enzyme by a 5′-deoxy-5′-adenosyl radical.

(C) Write the cyclopropyl radical for the associative mechanism and the radical of the product resulting from the dissociation of the proper bond in the cyclopropyl radical.

(D) Write the two fragments, one a radical and one an alkene, of the dissociative mechanism.

(E) Decide in each case which alternative—the associative, the dissociative, or a concerted mechanism—is the more likely for that particular rearrangement.

Problem 2–44: When 1,4-diethyl 2-(bromomethyl)-2-methyl-3-[*N*-benzylimino]succinate



is treated with tri-(*n*-butyl)tin hydride, its neutral radical is formed. Draw the neutral radical and the product of its rearrangement that mimics the rearrangement catalyzed by methylaspartate mutase (Table 2–3).[2607]

Problem 2–45: Each of the following reactions is catalyzed by an enzyme that has a catalytic prosthetic group in its active site. What is the particular prosthetic group used in each of these reactions? Do not write mechanisms.

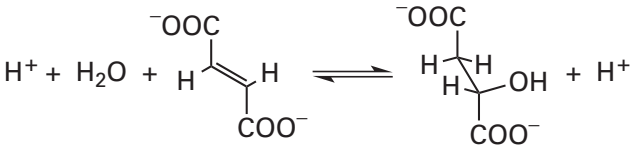
Chapter 3
Association of Substrates with the Active Site

The Reaction or Reactions Catalyzed

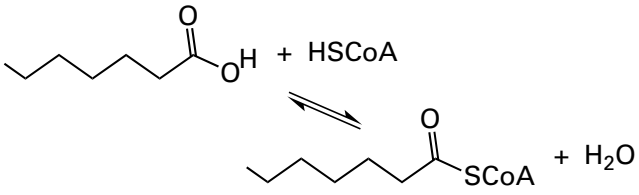
Before the mechanism of a particular enzyme can be studied kinetically, a stoichiometric and complete chemical equation must be established for the chemical reaction that it catalyzes. Although the stoichiometric equation seems clear in the cases of interconversions such as that between fumarate and malate catalyzed by fumarate hydratase (previously Equation 1–1)



(3–1)

there are many instances in which it is obscured.

In many enzymatically catalyzed reactions, there are **substrates that are not explicit in the reaction** as it was originally identified. For example, fatty acids can be converted into the thioesters of coenzyme A in an acyl exchange reaction



(3–2)

but the reaction as written is endergonic. Therefore, the actual reaction catalyzed by long-chain-fatty-acid–CoA ligase involves the coupled hydrolysis of a phosphodiester of $MgATP^{2-}$ as well[1]

$$MgATP^{2-} + \text{fatty acid} + HSCoA \rightleftharpoons \text{fatty acyl-SCoA} + 2\,H^+ + MgOPO_3PO_3^{2-} + AMP^{2-} \quad (3–3)$$

Procollagen-lysine 5-dioxygenase hydroxylates the carbons 5 of lysines in procollagen but only when stoichiometric amounts of 2-oxoglutarate are present to consume the other half of the molecular oxygen.[2]

$$\text{procollagen-lysine} + \text{2-oxoglutarate} + O_2 \rightleftharpoons \text{succinate} + CO_2 + \text{procollagen-5-hydroxylysine} \quad (3–4)$$

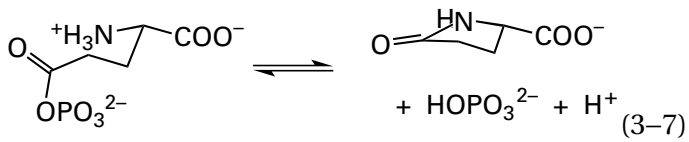
Unlike the examples just considered, sometimes the **additional substrates** are not part of the formal stoichiometric equation for the reaction catalyzed by the enzyme because they are **regenerated during the reaction**. Nevertheless, they must be present for the enzymatic reaction to occur. For example, the observed reaction[3] for glutamate-5-semialdehyde dehydrogenase from *Escherichia coli* is

$$NADP^+ + \text{L-glutamate 5-semialdehyde} \rightleftharpoons 2\,H^+ + \text{5-oxopyrrolidine-2-carboxylate} + NADPH \quad (3–5)$$

For enzymatic activity to be observed, however, phosphate must be present in the solution. There are several facts which lead to the conclusion that the reaction actually catalyzed by the enzyme is the production of L-glutamate 5-phosphate

$$NADP^+ + \text{L-glutamate 5-semialdehyde} + HOPO_3^{2-} \rightleftharpoons H^+ + \text{L-glutamate 5-phosphate} + NADPH \quad (3–6)$$

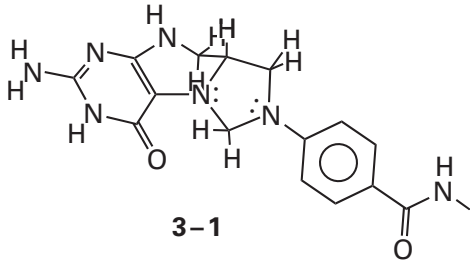
and the 5-oxopyrrolidine-2-carboxylate arises from a subsequent, nonenzymatic cyclization proceeding by nucleophilic substitution



(3–7)

and regenerating the phosphate. Pyrogallol hydroxytransferase from *Pelobacter acidigallici* catalyzes the migration of a hydroxy group from carbon 2 of 1,2,3-trihydroxybenzene to carbon 5, producing 1,3,5-trihydroxybenzene, but the enzyme requires, as a second reactant, 1,2,3,5-tetrahydroxybenzene, which is also a product of the reaction, so it is not a participant in the stoichiometric equation for the enzymatic reaction.[4] The enzyme that catalyzes the transport of D-glucose 6-phosphate across the plasma membrane of *E. coli*, a reaction that is of physiological interest, is required to transport a phosphate ion in the opposite direction for every molecule of D-glucose 6-phosphate it transports.[5]

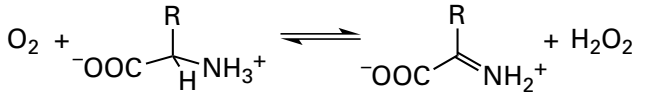
A related ambiguity arises when an enzyme, following its purification, is observed to catalyze a reaction that turns out to be an **incomplete version of its actual reaction in the cell** because a natural substrate has been overlooked. For example, purified sarcosine oxidase from *Corynebacterium* readily converts sarcosine and molecular oxygen to formaldehyde, glycine, and hydrogen peroxide. It was discovered, however, that tetrahydrofolate is a coenzyme for the enzyme under physiological conditions, and when it is present, the enzyme produces N^5,N^{10}-methylenetetrahydrofolate (previously **1–83**)



3–1

instead of formaldehyde, at the same rate.[6] An enzyme involved in oxidation–reduction is often purified by using an unnatural oxidant or reductant in the assay, and the natural oxidant or reductant may remain unknown for a considerable period.

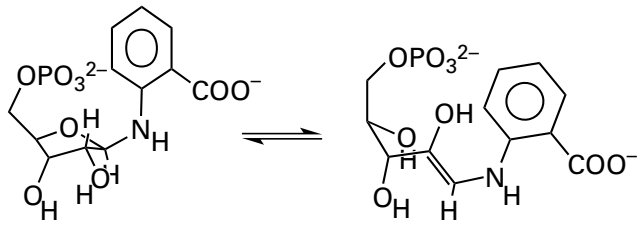
Glutamate-5-semialdehyde dehydrogenase from *E. coli* (Equation 3–5) is an example of an enzyme catalyzing a reaction for which the ultimate product that is used by the next enzyme in a metabolic sequence, in its case 5-oxopyrrolidine-2-carboxylate, is formed by the **rapid nonenzymatic transformation of the actual product** produced by the enzyme, in its case L-glutamyl 5-phosphate.[7] When the nonenzymatic transformation of the actual product of an enzymatically catalyzed reaction is rapid enough,[8,9] there is no selective pressure to catalyze that transformation enzymatically. Usually the actual product of such an enzymatic reaction is the result of a simpler, more obvious transformation of the reactant, and a more complicated mechanism for the enzyme or the need for another enzyme is avoided by permitting the transformation of the actual product to remain uncatalyzed. For example, porcine D-amino-acid oxidase and L-amino-acid oxidase from *Crotalus adamanteus* release, as their respective actual products, the **imines** that are the products of a direct dehydrogenation of the respective reactants



(3–8)

even though the α-oxo acids formed by the rapid nonenzymatic hydrolysis of the imines are the ultimate biochemical products,[10] and the equation written for the actual enzymatic reaction (Equation 3–8) must reflect this fact. Bovine monoamine oxidase also produces the imine of its reactant amine.[11]

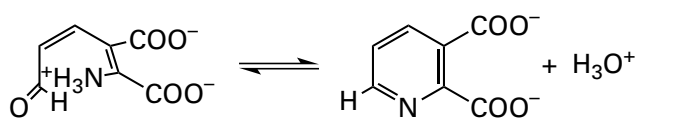
Phosphoribosylanthranilate isomerase from *E. coli* catalyzes a simple elimination



(3–9)

to produce an **enol** as its actual product. The enol then undergoes an enol–keto tautomerization, uncatalyzed by the enzyme, to produce 1-[(2-carboxyphenyl)amino]-1-deoxyribulose 5-phosphate, which has an oxo group at carbon 2 and is the ultimate biochemical product.[12] Other enzymes, however, catalyze final keto–enol tautomerizations before releasing the required tautomer for the next step in the metabolic sequence,[13] either because the uncatalyzed tautomerizations are too slow, because they are too nonspecific, or because they produce an undesired product.

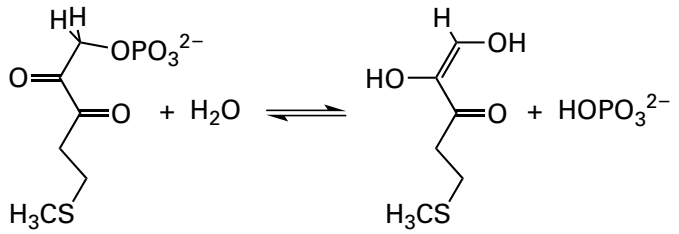
Another nonenzymatic **cyclization** of the actual product, like the one that produces 5-oxopyrrolidine-2-carboxylate (Equation 3–7), is the cyclization and subsequent aromatization of the 2-amino-3-carboxymuconate semialdehyde



(3–10)

that is the actual product of the reaction of 3-hydroxyanthranilate 3,4-dioxygenase from *Cupriavidus metallidurans*.[14] An almost identical postenzymatic cyclization, however, to form (2*S*,4*S*)-4-hydroxy-2,3,4,5-tetrahydrodipicolinate from the 2-amino-4-hydroxy-6-oxopimelic acid produced from pyruvate and L-aspartate-4-semialdehyde from *E. coli* is catalyzed by the enzyme, 4-hydroxy-tetrahydrodipicolinate synthase, perhaps because it lacks the cis double bond approximating the nucleophile and the electrophile.[15]

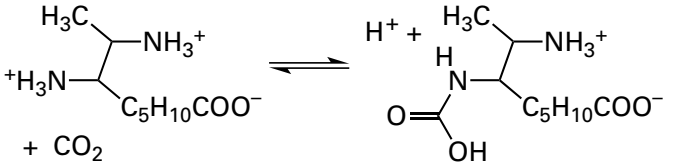
The nonenzymatic conversion of the actual product of an enzymatic reaction into the metabolically required product sometimes requires that **another reactant not involved in the enzymatic reaction** be present in the cytoplasm or the extracellular solution. Acireductone synthase catalyzes the conversion of 2,3-dioxo-5-methylsulfanyl-1-phosphopentane to phosphate, formate, and 2-oxo-4-methylsulfanylbutanoate, but only in the presence of molecular oxygen. The actual products of the enzymatic reaction are phosphate and 1,2-dihydroxy-5-methylsulfanyl-3-oxo-1-pentene



(3–11)

The latter is oxidized nonenzymatically by molecular oxygen to the ultimate products of the reaction, which is why the molecular oxygen appears to be a reactant.[16,17]

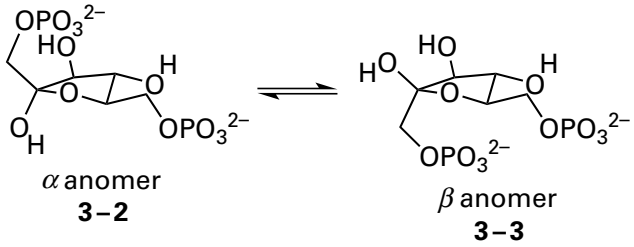
Just as the product of an enzymatic reaction may be nonenzymatically transformed after dissociating from the active site, the **actual reactant in an enzymatic reaction is often one formed nonenzymatically** from the compound originally thought to be the reactant. For example, dethiobiotin synthase from *E. coli* uses as its actual reactant the 7-carbamate formed nonenzymatically in solution from 7,8-diaminononanoic acid



(3–12)

and carbon dioxide rather than 7,8-diaminononanoic acid itself.[18]

In many instances, a substrate in an enzymatic reaction exists in solution in several different forms in rapid equilibrium with each other, but the enzyme will recognize **only one of these several equilibrating forms**. Although only 3% of the D-glyceraldehyde 3-phosphate in solution is the unhydrated aldehyde, that is the only form of this substrate recognized by glyceraldehyde-3-phosphate dehydrogenase from *Homarus gammarus*.[19] In a solution of fructose 1,6-diphosphate, there is an equilibrium mixture containing 20% α anomer (**3–2**) and 80% β anomer (**3–3**) of the furanose[20]



(3–13)

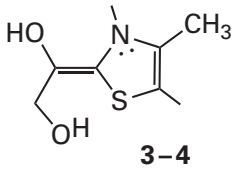
Although these are interconverted through the open ketone, less than 1% of either the open ketone or its hydrate is present in solution. The enzymes glucose-6-phosphate isomerase from *Saccharomyces cerevisiae*[21] and fructose-bisphosphatase from *Oryctolagus cuniculus*[22] act preferentially, but not exclusively, on the α anomer and catalyze the opening of the furanose ring to produce the ketone, which is required for the subsequent steps in the enzymatic reaction.[23] Human fructose-bisphosphate aldolase, however, acts preferentially on the β anomer[24] but also catalyzes the opening of the furanose ring.[25]

Carbon dioxide and carbonic acid are in equilibrium with each other, and it is difficult to distinguish which is the actual substrate in a given enzymatic reaction. By following the uptake of hydrons, it could demonstrated that the product of the reaction catalyzed by tartronate-semialdehyde synthase from *E. coli*, an enzyme containing thiamine diphosphate, is carbon dioxide[26]

$$H^+ + \text{2 glyoxylate} \rightleftharpoons \text{2-hydroxy-3-oxopropanoate} + CO_2 \quad (3\text{–}14)$$

Were carbonic acid the product, almost no hydrons would have been consumed. It could be shown, however, that β-ketoacyl-[acyl-carrier-protein] synthase I in the fatty-acid synthase system from *Rattus norvegicus* produces bicarbonate rather than CO_2 by following the production of bicarbonate in a continuous coupled assay.[27]

Many enzymes are able to **accept more than one reactant** and **produce more than one product**. For example, cytosine deaminase from *E. coli*, in addition to deaminating cytosine, also, and with even greater efficiency, deaminates isoguanine, a mutagenic purine that is produced during the repair of DNA and that would itself produce mutations if it were not eliminated effectively.[28] Transketolase can use either D-xylulose 5-phosphate or D-fructose 6-phosphate as the ketone in its reaction and, using thiamine diphosphate, transfers the same hydroxyacetyl group derived from either of these substrates, as the α-hydroxy enamine of thiamine diphosphate



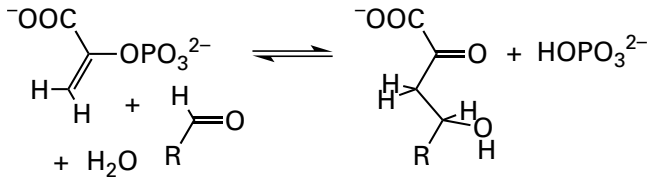
3–4

to ribose 5-phosphate[29]

D-xylulose 5-phosphate + D-ribose 5-phosphate $\rightleftharpoons$ sedoheptulose 7-phosphate + D-glyceraldehyde 3-phosphate (3–15)

D-fructose 6-phosphate + D-ribose 5-phosphate $\rightleftharpoons$ sedoheptulose 7-phosphate + D-erythrose 4-phosphate (3–16)

Likewise, 3-deoxy-7-phosphoheptulonate synthase from *Pyrococcus furiosus* is able to condense phospho*enol*pyruvate with any one of the aldehydes D-erythrose 4-phosphate, 2-deoxy-D-erythrose 4-phosphate, D-arabinose 5-phosphate, D-ribose 5-phosphate, or 2-deoxy-D-ribose 5-phosphate to produce the respective elongated product[30]



(3–17)

In these latter two examples, the respective enzyme either transfers the same fragment from two different ketones to the same aldehyde or condenses the same enolate with one of five different aldehydes, respectively, but in each case, the regiochemistry remains the same in the vicinity of the condensation. Ovine 3β,20α-hydroxysteroid oxidoreductase, however, catalyzes two reactions with **different regiochemistries**: the reduction of the 20-oxo group of progesterone to the 20-hydroxy group and the reduction of the 3-oxo group of 5α-dihydrotestosterone to the 3-hydroxy group.[31] These two different locations are on the opposite ends of the respective steroids.

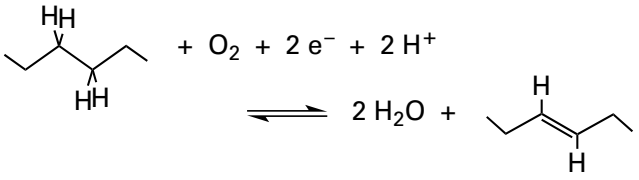
There are also enzymes that catalyze two different reactions with the same regiochemistries but **different stereochemistries**. For example, 3-hydroxybutyryl-CoA epimerase from *E. coli* is able to dehydrate both the *R* and the *S* stereoisomers of 3-hydroxy-4-*trans*-decenoyl-CoA.[32] Alginate lyase from *Pseudomonas aeruginosa* cleaves disaccharides and trisaccharides of D-mannuronate and L-guluronate from the nonreducing end of the polysaccharide alginate. The active site is able to remove the disaccharide or the trisaccharide from the nonreducing end regardless of whether it is removed from either a D-mannuronate or an L-guluronate in the alginate, even though D-mannuronate and L-guluronate have the opposite chiralities at the carbon from which the enzyme is required to remove a hydron during the elimination that accomplishes the cleavage.[33] Both D-mannuronate and L-guluronate, from which the disaccharide and trisaccharide are respectively cleaved, are turned into a 4-deoxy-α-L-*erythro*-hex-4-enuronosyl group at the nonreducing end of the shortened polymer as a result of the elimination.[34]

There are enzymes that produce **different products from the same reactant**. For example, the fatty-acid synthase system produces a mixture of saturated fatty acids of variable chain length from the same two reactants, acetyl-SCoA and malonyl-SCoA. The composition of the mixture of products depends on the tissue and the species, and it can be varied by the presence of distinct [acyl-carrier-protein] hydrolases in a particular tissue.[35]

In addition to aphidicolan-16β-ol, aphidicolan-16β-ol synthase from *Neocamarosporium betae* produces aphidicol-15-ene and aphidicol-16-ene, which are the products of dehydration of aphidicolan-16β-ol. To solve the problem of this lack of specificity, all three products are converted by other enzymes to aphidicolin, the ultimate product of the metabolic pathway.[36]

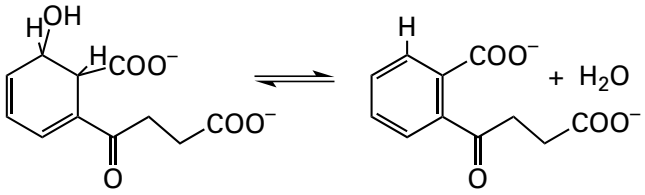
There are many enzymes that are designed to perform the **same reaction on many different substrates**. For example, certain of the enzymes containing a heme P450 are designed to hydroxylate a large array of xenobiotics; aldehyde reductase is designed to reduce a large array of aldehydes, some of which are dangerously reactive, and at least one ketone[37] to the respective alcohols;[38] and phosphotriesterase is able to hydrolyze a variety of phosphate triesters.[39]

There are a number of proteins that can catalyze more than one enzymatic reaction because they have more than one active site within their structure, one dedicated to each of the different reactions, but there are also enzymes with only one active site that **perform different reactions depending on the identity of the reactant** they encounter. Palmitoyl-[glycerolipid] 7-desaturase from *Arabidopsis thaliana* desaturates palmityl groups in phospholipids



(3–18)

but the desaturation occurs between carbons 7 and 8 or between carbons 9 and 10 depending on the head group of the phospholipid that is the substrate.[40] Tartrate dehydrogenase from *Pseudomonas putida*, however, catalyzes significantly different reactions, not the same reaction with different regiochemistry, depending on the substrate. (*R,S)*-Tartrate is dehydrogenated to (*R)*-oxaloglycolate; D-malate is dehydrogenated and then decarboxylated to pyruvate; and *meso*-tartrate is dehydrogenated, decarboxylated, and dehydrogenated again to D-glycerate.[41] There are enzymes that can catalyze two reactions with substrates significantly more different from each other than (*R,S)*-tartrate is from D-malate. For example, *o*-succinylbenzoate synthase



(3–19)

from *Amycolatopsis* can also catalyze the racemization of *N*-acylamino acids.[42,43] The fact, however, that an enzyme can catalyze the same reaction in both directions does not qualify as an example of the same active site catalyzing different reactions.[44]

When the same active site is able to catalyze different reactions or the same reaction with different substrates, this ability is often an important **clue as to its mechanism**. For example, the fact that glucose-6-phosphate isomerase from *O. cuniculus*, in addition to converting D-glucose 6-phosphate to D-fructose 6-phosphate, can convert D-glucose 6-phosphate to D-mannose 6-phosphate is evidence for an intermediate enediol in the enzymatic reaction.[45]

There is an enzyme in *Mycobacterium tuberculosis* that converts 7,8-dihydroneopterin into three products.[46] All three outcomes can be explained by a common intermediate enol. 6-(Hydroxymethyl)-7,8-dihydropterin is the product of a retroaldol cleavage of 7,8-dihydroneopterin followed by tautomerization of the intermediate enol, and glycolaldehyde is the other product. 7,8-Dihydromonapterin is the product of an epimerization of 7,8-dihydroneopterin that results from the same retroaldol cleavage followed by an aldol condensation of the intermediate enol with the glycolaldehyde. And 7,8-dihydroxanthopterin is the result of the same retroaldol cleavage followed by the oxidative cleavage of the intermediate enol.

There is an enzyme from mammalian erythrocytes that can catalyze three reactions:[47] phosphoglycerate mutase

2-phospho-D-glycerate $\rightleftharpoons$ 3-phospho-D-glycerate

(3–20)

bisphosphoglycerate mutase

H^+ + 2,3-bisphospho-D-glycerate $\rightleftharpoons$ 3-phospho-D-glyceroyl phosphate

(3–21)

and bisphosphoglycerate phosphatase

2,3-bisphospho-D-glycerate + H_2O ⇌
3-phospho-D-glycerate + $HOPO_3^{2-}$ (3–22)

The first two reactions are interrelated by the fact that the same **phosphorylated enzyme** is an intermediate in both. Equation 3–20 can be expanded to include the phosphorylated enzyme (E-OPO_3^{2-})

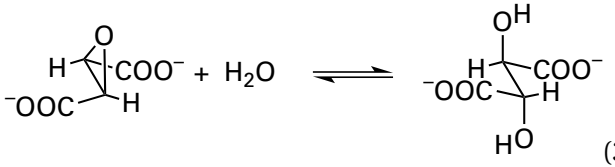
2-phospho-D-glycerate + E–OPO_3^{2-} ⇌
2,3-bisphospho-D-glycerate + EOH ⇌
3-phospho-D-glycerate + E–OPO_3^{2-} (3–23)

and Equation 3–21 can be expanded to include the phosphorylated enzyme

H^+ + 2,3-bisphospho-D-glycerate + EOH ⇌
H^+ + 3-phospho-D-glycerate + E–OPO_3^{2-} ⇌
3-phospho-D-glyceroyl phosphate + EOH (3–24)

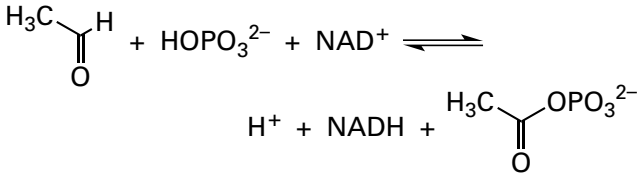
Equation 3–22 is simply a result of the spontaneous hydrolysis of the phosphorylated enzyme. These expansions imply that if the enzyme added to the solution were completely dephosphorylated, the conversion of 2-phospho-D-glycerate to 3-phospho-D-glycerate would not be catalyzed; and if the enzyme added to the solution were completely and stably phosphorylated, the conversion of 2,3-bisphospho-D-glycerate to 3-phospho-D-glyceroyl phosphate would not be catalyzed. In the cell, however, phosphoenzyme is always being slowly dephosphorylated (Equation 3–22) and dephosphoenzyme is always being phosphorylated by 3-phospho-D-glyceroyl phosphate (reverse of second step in Equation 3–24) produced by glyceraldehyde-3-phosphate dehydrogenase (phosphorylating).

Just as the different reactions among natural metabolites that can be catalyzed by an enzyme provide insight into the mechanism of that enzyme, so too do the **transformations of unnatural substrates** catalyzed by the enzyme. Porcine fumarate hydratase, in addition to its normal reaction (Equation 3–1), can also catalyze the stereospecific hydration of *trans*-2,3-epoxysuccinate[48]



(3–25)

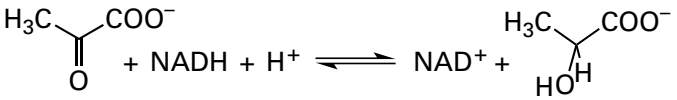
and any mechanism proposed for the natural reaction must explain this unnatural reaction. Because glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) from *O. cuniculus* can catalyze the production of acetyl phosphate from acetaldehyde[49]



(3–26)

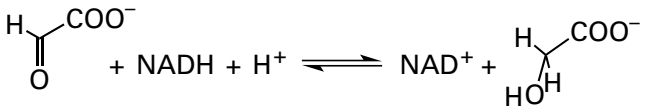
there is no portion of the normal substrate, D-glyceraldehyde 3-phosphate, other than the aldehyde, that is essential for the normal reaction.

Glyoxylate is not a natural substrate for L-lactate dehydrogenase, the enzyme that normally catalyzes the reaction



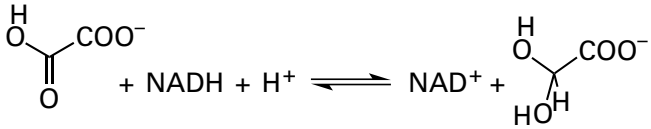
(3–27)

but the enzyme from *O. cuniculus* nevertheless reduces glyoxylate to glycolate[50]



(3–28)

and reduces oxalate to glyoxylate.[51]



(3–29)

These results suggest that either a hydrogen or a hydroxy group, respectively, can be mistaken by the enzyme for a methyl group. Both of these functional groups are smaller than a methyl group and

would not be sterically excluded from substituting for it, but the hydroxy group is polar while the methyl group, with its three hydrogen–carbon bonds,[52] is nonpolar.

Often, one of the natural substrates for an enzyme cannot be used for kinetic experiments for some reason. For example, the product of the *oatA* gene in *Streptococcus pneumoniae* acetylates 6-hydroxy groups in the insoluble peptidoglycan forming the cell wall of the bacterium. Kinetic studies of the enzyme take advantage of the ability of the enzyme to acetylate an unnatural substrate, the soluble trisaccharide chitotriose.[53]

In many enzymatic reactions, in addition to those that use small electron carriers, a molecule of **another protein serves as a substrate**. For example, the reaction catalyzed by acetyl-CoA carboxylase from avian liver is

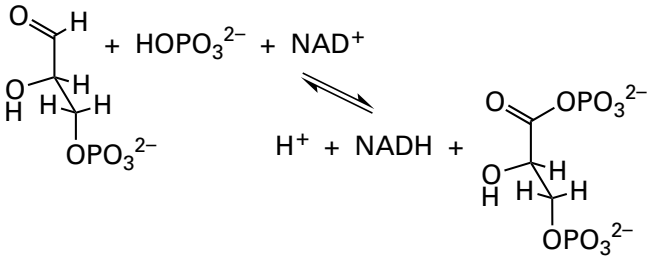
$$\text{acetyl-SCoA} + HCO_3^- + MgATP^{2-} \rightleftharpoons H^+ + HOPO_3^{2-} + MgADP^- + \text{malonyl-SCoA} \quad (3\text{–}30)$$

but the enzyme from *E. coli*[54] utilizes the carbamate of a biotin attached to a small protein (α_2; 2×210 aa), referred to as biotin carboxyl-carrier protein (BCCPNH)[55]

$$\text{acetyl-SCoA} + \text{BCCPN–}CO_2^- \rightleftharpoons \text{BCCPNH} + \text{malonyl-SCoA} \quad (3\text{–}31)$$

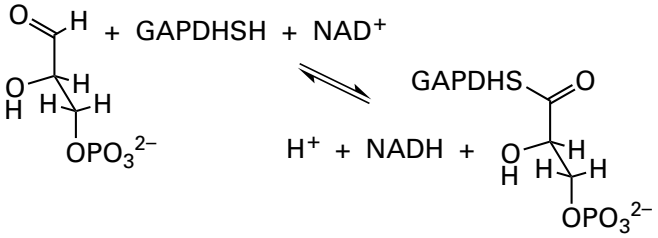
The biotin carboxyl-carrier protein is carboxylated in a separate reaction[56] that also requires the hydrolysis of $MgATP^{2-}$ (Figure 1–29). The enzyme from avian liver has a domain that is an intramolecular biotin carboxyl-carrier protein and another domain that is an intramolecular biotin carboxylase.[57]

In a few enzymatic reactions, the molar **concentration of active sites of the enzyme in the cytoplasm is equal to or greater than the concentrations of the substrates**. In such reactions, the enzyme must be considered as an explicit participant in the reaction. The enzyme glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) catalyzes the reaction

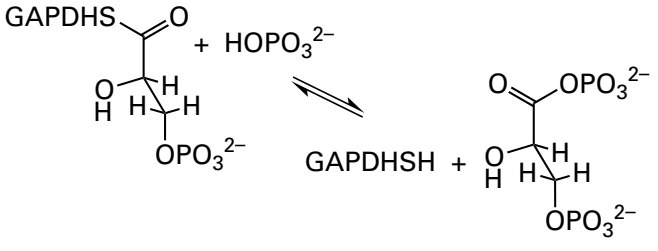


(3–32)

The substrate D-glyceraldehyde 3-phosphate is a reactive aldehyde that would be either bound as an imine to other proteins in the cell or present in solution as the hydrate,[19] and neither of these forms would be available to the enzyme, which can process only the unhydrated aldehyde.[19] The substrate 1,3-diphosphoglycerate is an acyl phosphate that is readily hydrolyzed. For both of these reasons, the strategy that seems to have evolved is to maintain the concentrations of these two substrates at low levels (<0.10 mM) in the cytoplasm but to have a high concentration of 3-phosphoglycerate bound at the active site of the enzyme as a thioester with a unique cysteine in the folded polypeptide.[58] For this reason, the molar concentration of the enzyme in the cytoplasm is abnormally high (1 mM). As a result, two of the reactions in glycolysis have glyceraldehyde-3-phosphate dehydrogenase (GAPDHSH) and its phosphorylated derivative, phosphoglyceryl glyceraldehyde-3-phosphate dehydrogenase, as reactants as well as catalysts



(3–33)



(3–34)

and the stoichiometric equations describing the enzymatic reactions that actually occur in the cyto-

plasm explicitly incorporate the concentrations of enzyme and phosphoglyceryl enzyme.

Lately, the publication of sequences of nucleic acids for genomes has provided sequences of amino acids for a large number of **proteins of unknown function** that can be shown to be evolutionarily related to known enzymes. These proteins often are able to catalyze the same types of reaction that are catalyzed by their relatives but with different substrates, often with several different substrates. For example, a protein encoded by the genome of *Salmonella typhimurium* that is related to glucarate dehydratase was shown to be able to dehydrate both L-talarate and galactarate,[59] and a protein encoded by the genome of *Dianthus caryophyllus* that is related to isocitrate lyase was shown to be able to cleave a number of 2-alkyl and 2,3-dialkyl-(2*R)*-malates as well as oxaloacetate at the carbon–carbon bonds between their respective carbons 2 and 3,[60] just as isocitrate lyase does to isocitrate. Once the ability of these enzymes to catalyze these reactions has been established, it is then necessary to discover which of these reactions are physiologically relevant.

Once the chemical reaction or reactions catalyzed by the enzyme have been unambiguously defined, the steps in the enzymatic reaction can be defined. The usual first step in this definition is to examine the steady-state kinetics of the reaction.

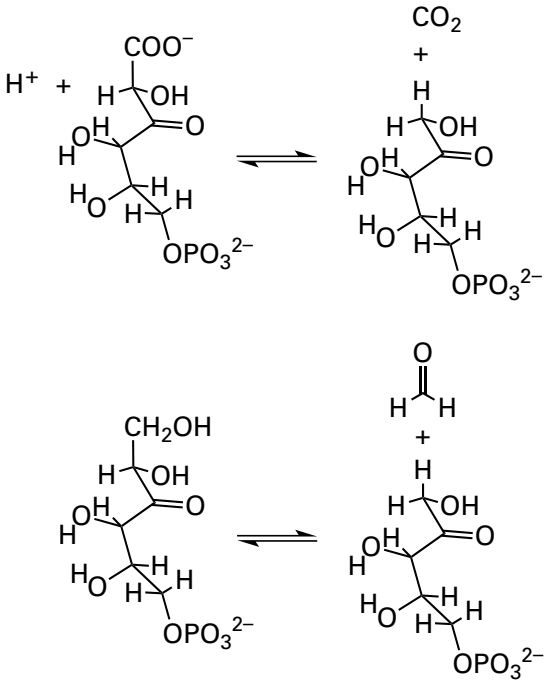
Problem 3–2: Write a mechanism for the production of (2*S*,4*S*)-4-hydroxy-2,3,4,5-tetrahydrodipicolinate from pyruvate and L-aspartate-4-semialdehyde catalyzed by 4-hydroxy-tetrahydrodipicolinate synthase[15] and its subsequent nonenzymatic conversion to (*S*)-2,3-dihydrodipicolinate.

Problem 3–3: Write reactants, intermediates, and products for the three reactions catalyzed by tartrate dehydrogenase: (*R,S*)-tartrate to oxaloglycolate, D-malate to pyruvate, and *meso*-tartrate to D-glycerate.[41]

Problem 3–4: The active site of 3-hexulose-6-phosphate synthase catalyzes the two reactions[61]



Write a mechanism for each reaction involving the same intermediate.

Steady-State Kinetics[62]

There are certain facts about the catalysis performed by an enzyme in an experimental situation and definitions of the parameters controlling the observations that are fundamental to a discussion of steady-state

kinetics. When an enzyme—for example, fumarate hydratase (Equation 3–1)—is added to a solution containing only the substrates appearing on one side of the stoichiometric chemical equation for the particular reaction for which it is responsible—for example, an aqueous solution of fumarate—all the substrates appearing on the other side of the equation—for example, malate—begin to appear in the solution. In this instance, the substrates present initially and decreasing in concentration as the reaction proceeds are necessarily the **reactants** in the chemical reaction being studied kinetically, and those appearing in the solution and increasing in concentration as the reaction proceeds are the **products**. Consequently, a **conscious decision** is made by the investigator as to the identity of the reactants and the identity of the products.

The **increase in the rate** of the designated reaction that is catalyzed by the enzyme is directly **proportional to its molar concentration** because the reaction is performed at an active site or several active sites present on each molecule of enzyme, and each molecule of enzyme is an independent actor. The reactants associate with an **active site** and are converted to products while they are there, and the products then dissociate from the active site.

Under normal circumstances, tens to thousands of substrate molecules are interconverted during each second by one molecule of enzyme. Therefore, only low molar concentrations of enzyme are almost always added to the solution to produce a measurable increase in the rate of the reaction. If too much enzyme is added, the reaction occurs so rapidly that rates at steady state cannot be measured leisurely. Because so many molecules of reactant are being processed in succession by the same molecule of enzyme, each molecule of enzyme, ready to process the next molecule of reactant, **must be regenerated** in exactly the same state at the end of each turnover. The enzyme, because it is usually present in the solution at a very small molar concentration and because it must be regenerated after each transformation, **cannot be a stoichiometric participant** in the chemical reaction, unlike the situation described for glyceraldehyde-3-phosphate dehydrogenase in the cytoplasm.

Because of **microscopic reversibility**, an enzymatically catalyzed reaction must pass through the same transition states but in opposite order in the forward and reverse directions. The enzyme accelerates the reaction by lowering the relative free energy of one or more of the transition states in this sequence. Therefore, it must **accelerate the reaction in both directions**. For this reason, enzymatically catalyzed reactions are approaches to equilibrium (as are all chemical reactions), and as the products begin to appear, the enzyme begins to catalyze the reaction in the reverse direction as it continues to catalyze it in the forward direction.

If a purified enzyme is added to a solution containing a mixture of all the substrates that appear on one side of the chemical equation for the reaction catalyzed by that enzyme

$$k\mathrm{A} + l\mathrm{B} + m\mathrm{C} + \ldots \rightleftharpoons \ldots + n\mathrm{X} + o\mathrm{Y} + p\mathrm{Z} \tag{3–35}$$

but missing one or more of the substrates that appear on the other side, the concentrations of the reactants will begin to decrease and the concentrations of the products will begin to increase. The **reactants** (A, B, C…) are the complete set of substrates from the one side of the chemical equation. The **products** (Z, Y, X…) are the incomplete or entirely absent set of substrates from the other side of the chemical equation. Again, in this artificial situation, what is a reactant and what is a product are defined by the investigator, who has purposely left out one or more of the products. The reaction will also proceed in one direction if all the products are present but purposely added at concentrations below their equilibrium levels. In this case, however, the initial rate of the reaction does not represent a unidirectional process. Unidirectional processes are easier to study.

The **progress of the reaction can be followed** by monitoring the concentration of one of the reactants or one of the products as a function of time because all changes in concentration are stoichiometrically related by the chemical equation for the reaction catalyzed

$$\frac{d[\mathrm{Z}]}{p\,dt} = \frac{d[\mathrm{Y}]}{o\,dt} = \frac{d[\mathrm{X}]}{n\,dt} = \ldots$$

$$\ldots = -\frac{d[\mathrm{C}]}{m\,dt} = -\frac{d[\mathrm{B}]}{l\,dt} = -\frac{d[\mathrm{A}]}{k\,dt} \tag{3–36}$$

where k, l, m, n, o, and p are integers that define the stoichiometry of the reaction.

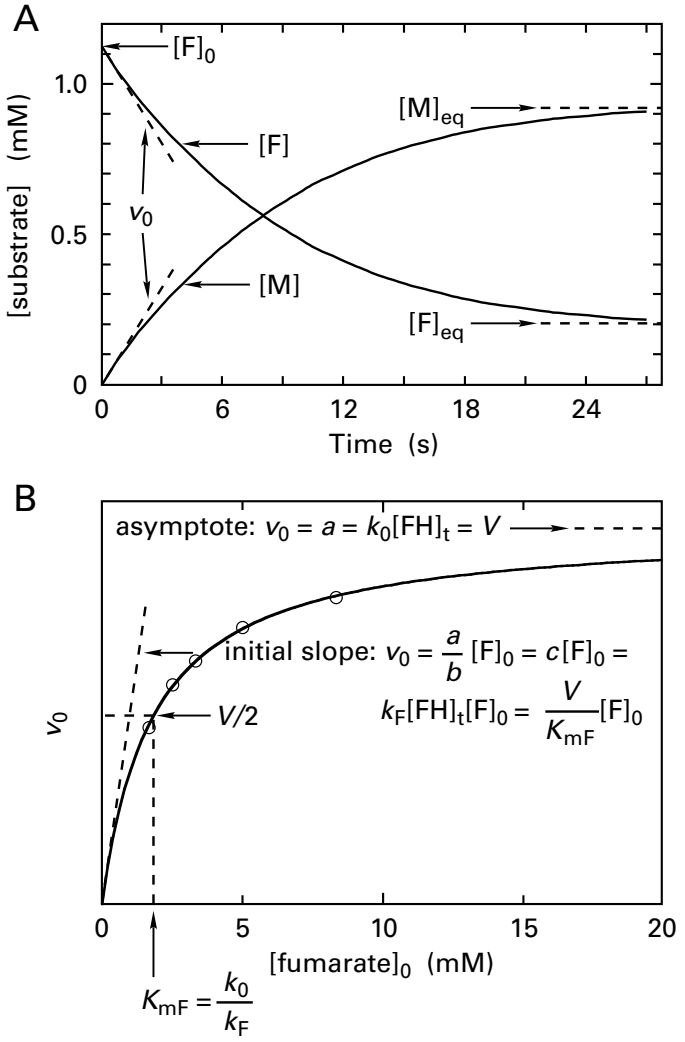


Figure 3–1: **(A)** Progress of the conversion of fumarate to (*S*)-malate catalyzed by the enzyme fumarate hydratase.[63] A solution of fumarate at pH 7 and 25 °C was added to the cuvette of a spectrophotometer. Each hydration was initiated by adding porcine fumarate hydratase (FH) to a final concentration of 15 μg mL^{-1}, and the initial concentration of fumarate was 1.13 mM. The decrease in the molar concentration of fumarate ([F]) was followed as a function of time by monitoring its absorbance at 270 nm. The increase in the concentration of (*S*)-malate ([M]) was estimated by difference. The concentrations of the two substrates (millimolar) are plotted as a function of time (seconds). At times greater than 1 min, the concentration of fumarate no longer decreased because it had reached its equilibrium level ($[F]_{eq}$). The initial slope of the decrease of fumarate as a function of time is the initial rate (v_0) in units of millimolar second^{-1}. **(B)** Behavior of the initial rates of the hydration catalyzed by fumarate hydratase as a function of the initial concentrations of fumarate.[1390] Equivalent amounts of fumarate hydratase were added to a series of mixtures at pH 6.4 and 23 °C that had various initial concentrations of fumarate. The decrease in absorbance at 295 nm was followed as a function of time for each mixture, and the initial slope of each progress curve was measured and converted to an initial rate. Initial rates (v_0 in unnoted units) are plotted as a function of the initial concentrations of fumarate (millimolar). The curve is the fit of the data to Equation 3–52, with x equal to $[\text{fumarate}]_0$ and y equal to v_0. Each of the two parameters, the catalytic constant $k_0[FH]_t$ and the limiting rate V, is the value for the initial rate at the horizontal asymptote (parameter a) of the rectangular hyperbola. The specificity constant for fumarate, $k_F[FH]_t$, is parameter c of the fit, and the Michaelis constant K_m is parameter b. The Michaelis constant is the value of $[F]_0$ when v_0 is $V/2$.

In the case of the reaction catalyzed by fumarate hydratase (Equation 3–1), if the purified porcine enzyme is added to a solution containing fumarate (F) from which malate (M) is absent, the concentration of fumarate will decrease as the concentration of malate increases until the equilibrium concentrations are reached. At this point, the reaction cannot proceed further (Figure 3–1).[63] Although no net change can occur at equilibrium, unidirectional changes are still taking place, albeit at rates somewhat less than the initial rates; it is just that the unidirectional rate of the reaction in the forward direction equals the unidirectional rate of the reaction in the reverse direction. At equilibrium, the enzyme is still catalyzing the reaction in both directions.

The curves describing the concentrations of fumarate and malate (Figure 3–1) describe the **complete kinetic course of the approach to equilibrium**. These curves can be simulated by using equations the form and parameters of which can be derived from simple kinetic mechanisms.[63-65] The strategy of fitting complete kinetic courses, however, is rarely applied because the form of the integrated rate equations is complicated: too many variables usually are changing at once, the enzyme may slowly inactivate with time, and the most characteristic changes occur late in the reaction, when the observations are most uncertain. In addition, in some instances the approach to equilibrium can pass beyond the point of equilibrium in an overshoot before returning to equilibrium,[66] behavior that further complicates a kinetic analysis. Instead, studies of initial rates of an enzymatic reaction are usually performed, and kinetic mechanisms consistent with these observations are formulated.

The **initial rate** (v_0 in Figure 3–1A) of an enzymatically catalyzed reaction is the rate of decrease in the concentration of reactant, A, or the rate of increase in the concentration of product, Z, observed immediately after initiating the reaction, either by adding the enzyme or by adding the final reactant necessary to complete the set of reac-

tants.[64] The initial rate is measured over a period of time so short that the rate remains constant rather than slowly decreasing with time. Over this short period of time, only small changes in the concentrations of substrates occur. If necessary, an extrapolation of the curve can be performed by numerical analysis to obtain the rate of the reaction at zero time. Consequently,

$$v_0 = \lim_{t \to 0} -\frac{d[\mathrm{A}]}{k\,dt} \tag{3–37}$$

or

$$v_0 = \lim_{t \to 0} \frac{d[\mathrm{Z}]}{p\,dt} \tag{3–38}$$

where the integers k and p are the molar stoichiometries of the overall reaction (Equation 3–35).

Because there are few enzymes that do not have unitary stoichiometries for all their reactants and products and because the decrease in the concentration of a reactant with unitary stoichiometry or the increase in a product with unitary stoichiometry is often followed in the few cases where there are substrates that do not have unitary stoichiometry, the **stoichiometry for the reactant or product** monitored (k in Equation 3–37 or p in Equation 3–38) in measuring an initial rate will be assumed to be one from here on.

If the initial rate of an enzymatic reaction measured by following the change in the concentration of a reactant or a product is, in fact, the desired limit, then the concentration of any reactant governing the initial rate must be the concentration initially present, or the initial concentration. For example, for reactant A, the initial concentration is designated as $[\mathrm{A}]_0$. The data collected in an experiment of this kind are the initial rates of the reaction at a systematic series of respective initial concentrations of reactants.

If there is only one reactant, for example, *N*-(5′-phosphoribosyl)anthranilate for the enzyme phosphoribosylanthranilate isomerase (Equation 3–9) from *S. cerevisiae* (Figure 3–2);[67] if the second reactant is water and hence always remains fixed in concentration, for example, during the hydrolysis of sucrose by β-fructofuranosidase*

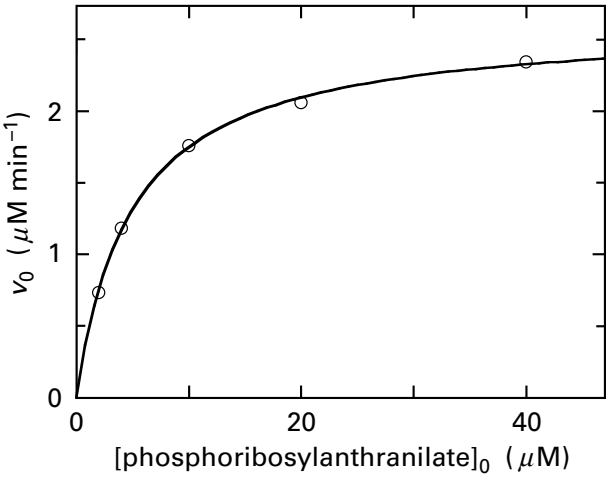

Figure 3–2: Kinetics for the isomerization of *N*-(5-phospho-β-D-ribosyl)anthranilate (Equation 3–9) by phosphoribosylanthranilate isomerase from *S. cerevisiae*.[67] Solutions were prepared that contained various concentrations of anthranilate and fixed concentrations of anthranilate phosphoribosyltransferase and magnesium 5-phospho-α-D-ribose 1-diphosphate sufficient to convert all the anthranilate to *N*-(5-phospho-β-D-ribosyl)anthranilate (phosphoribosylanthranilate) in less than 2 minutes. As soon as all the anthranilate in a solution had been converted to phosphoribosylanthranilate, which is unstable ($t_{½} \cong 10$ min), phosphoribosylanthranilate isomerase (PI) was added to initiate each isomerization, and the production of 1-(2-carboxyphenylamino)-1-deoxy-D-ribulose 5-phosphate was followed by monitoring the decrease in emission of fluorescence at 400 nm upon excitation at 310 nm. Each rate for the change in emission of fluorescence was converted to an initial rate for the production of 1-(2-carboxyphenylamino)-1-deoxy-D-ribulose 5-phosphate, v_0 (micromolar minute^{-1}). These initial rates are presented as a function of the initial concentrations of phosphoribosylanthranilate (micromolar). The curve is the fit of the data to Equation 3–52, with x equal to $[\text{phosphoribosylanthranilate}]_0$ and y equal to v_0. Parameter a for the fit is the catalytic constant, $k_0[\mathrm{PI}]_t$ (2.61 ± 0.03 μM min^{-1}), and parameter c is $k_{\mathrm{pRA}}[\mathrm{PI}]_t$, the specificity constant for phosphoribosylanthranilate [0.52 ± 0.02 μM min^{-1} (μM phosphoribosylanthranilate)$^{-1}$].

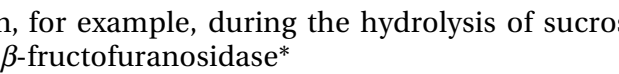

(3–39)

from *S. cerevisiae* (Figure 3–3A)[64,65] or the hydration

*For a discussion of kinetics, in either chemistry or enzymology, it is unnecessary to know either the structures of the reactants or products or the chemical mechanism of the reaction. All that one needs to know is the names of the reactants, intermediates, and products, and the only reason for knowing their names is to distinguish between them. Consequently, there is no need to try to figure out what is happening chemically when only kinetics are being examined.

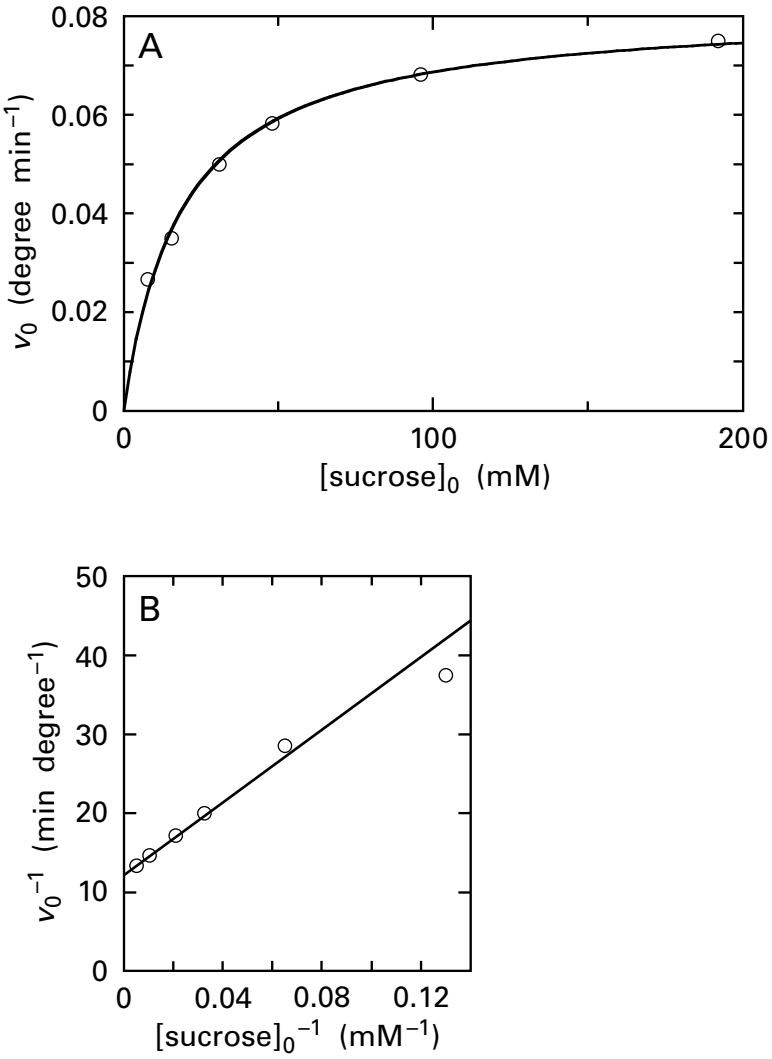

Figure 3–3: Kinetics for the hydrolysis of sucrose by β-fructofuranosidase.[64] Solutions were prepared with various concentrations of sucrose in 0.4 M sodium acetate at pH 4.7 and 25 °C. The hydrolysis of sucrose to D-glucose and D-fructose was monitored by the change in optical rotation of the solution at a wavelength of 589 nm. Each hydrolysis was initiated by adding an equal volume of an extract from cells of *S. cerevisiae* that contained β-fructofuranosidase (FF). The change in optical rotation of the solution (degrees) was followed as a function of time (minutes). **(A)** Initial rates of this change, v_0 (degrees minute^{-1}), are presented as a function of initial concentrations of sucrose (millimolar). The curve is the fit of the data to Equation 3–52, with x equal to $[\text{sucrose}]_0$ and y equal to v_0. Parameter a for the fit is the catalytic constant, $k_0[\text{FF}]_t$ (0.082 ± 0.002 degree min^{-1}), and parameter c is $k_{suc}[\text{FF}]_t$, the specificity constant for sucrose [4.3 ± 0.3 degrees min^{-1} (M sucrose)$^{-1}$]. **(B)** Reciprocals of the initial rates (minutes degree^{-1}) are presented as a function of reciprocals of the concentrations of sucrose (millimolar^{-1}). The line drawn in this panel is for the equation v_0^{-1} = 12.3 min degree^{-1} + 230 min degree^{-1} mM ($[\text{sucrose}]_0^{-1}$). The two parameters used in this equation are calculated from the numerical values for the two kinetic constants, $k_0[\text{FF}]_t$ and $k_{suc}[\text{FF}]_t$, obtained from the direct fit of the data to the equation for a hyperbola (Panel A).

of fumarate by porcine fumarate hydratase (Figure 3–1B);[68] or if the concentration of one of the reactants in a reaction with more than one reactant is varied while the concentrations of the other substrates are fixed (Figure 3–4A,E),[69] the **increase in the initial rate of the enzymatic reaction as a function of the initial concentration of the varied reactant** is described by the equation*

$$v_0 = \frac{[\text{E}]_t}{\dfrac{1}{k_A[\text{A}]_0} + \dfrac{1}{k_0}} = \frac{k_0 k_A [\text{E}]_t [\text{A}]_0}{k_0 + k_A[\text{A}]_0} \qquad (3\text{–}40)$$

where $[\text{E}]_t$* is the **total molar concentration of active sites** added to the solution, $[\text{A}]_0$ is the initial molar concentration of the varied reactant A, and k_0 and k_A are kinetic constants. The kinetic constant k_0 is the **catalytic constant**, and the kinetic constant k_A is the **specificity constant for reactant A**.[64,65]

The initial rate of an enzymatic reaction is almost always **directly proportional to the concentration of enzyme** in the solution at all values for the initial concentrations of substrates, as long as the enzyme is added at molar concentrations that are all at least an order of magnitude less than the change in the molar concentrations of reactants and products measured during the period of initial rate, and this fact is explicitly noted in Equation 3–40.

*As in the rest of this volume, the formalism chosen by the International Union of Biochemistry and Molecular Biology (http://www.chem.qmul.ac.uk/iubmb/kinetics/) will be used.

*The letter E has been used historically to designate the "enzyme concentration"[62,68] because the molar masses and oligomeric structures of enzymes were in doubt. Those doubts no longer exist in the age of sequences for genomes.

Figure 3–4: Kinetics for the phosphorylation of D-fructose catalyzed by hexokinase from the brain of *R. norvegicus*.[69] Solutions containing $MgATP^{2-}$ and D-fructose at various initial concentrations were prepared at pH 7.6 and 28 °C. The concentration of uncomplexed Mg^{2+} was fixed at 1.0 mM throughout by adding appropriate amounts of $MgCl_2$. Each phosphorylation was initiated by adding hexokinase (HK), and the production of D-fructose 6-phosphate was followed in a coupled assay with glucose-6-phosphate isomerase, glucose-6-phosphate dehydrogenase, and NAD^+ by monitoring the increase in A_{340} from the conversion of NAD^+ to NADH. Each initial rate of change in A_{340} was converted to an initial rate for the production of D-fructose 6-phosphate, v_0 (micromolar minute^{-1}). The initial concentrations of D-fructose chosen for the studies were 1.1, 1.43, 2.00, 3.33, and 10.00 mM, and the initial concentrations of $MgATP^{2-}$ were 0.28, 0.36, 0.50, 0.83, and 2.5 mM. The complete set of the 25 combinations of these initial concentrations was used to measure 25 separate initial rates. **(A)** Initial rates for production of D-fructose 6-phosphate are presented as a function of initial concentrations of $MgATP^{2-}$ (millimolar) at the five fixed initial concentrations of D-fructose. Each curve is for a higher fixed concentration of D-fructose than the one below it. The curves drawn are fits of Equation 3–52 to the data with x equal to $[MgATP^{2-}]_0$ and y equal to v_0. **(B)** Reciprocals of the initial rates (minutes micromolar^{-1}) are presented as a function of reciprocals of the initial concentrations of $MgATP^{2-}$ (millimolar^{-1}) at the five fixed initial concentrations of D-fructose. Each line fit to the data is for a higher fixed concentration of D-fructose than the one above it. **(C)** The five values for parameter a, the apparent catalytic constants for $MgATP^{2-}$, $k_{0,ATP,app}[HK]_t$ (micromolar minute^{-1}), for the five fits of Equation 3–52 to each of the five subsets of data in Panel A (the five curves on the graph), are presented as a function of the fixed initial concentrations of D-fructose corresponding to each value of $k_{0,ATP,app}[HK]_t$. The curve drawn is a fit of Equation 3–52 to the data with x equal to the respective fixed initial concentration of D-fructose and y equal to the respective $k_{0,ATP,app}[HK]_t$. Parameter a for this fit is the catalytic constant for the enzymatic reaction, $k_0[HK]_t$ (3.49 ± 0.05 μM D-fructose 6-phosphate min^{-1}), and parameter c is the specificity constant for D-fructose, $k_{fruc}[HK]_t$ [1.29 ± 0.03 μM D-fructose 6-phosphate min^{-1} (mM D-fructose)$^{-1}$]. **(D)** The five values for parameter c, the apparent specificity constants for $MgATP^{2-}$, $k_{ATP,app}[HK]_t$ (micromolar minute^{-1} millimolar^{-1}), for the five fits of Equation 3–52 to each of the five subsets of data in Panel A, are plotted as a function of the respective fixed initial concentrations of D-fructose. The curve drawn is a fit of Equation 3–52 to the data with x equal to the fixed initial concentration of D-fructose and y equal to $k_{ATP,app}[HK]_t$. Parameter a for this fit is the specificity constant for $MgATP^{2-}$, $k_{ATP}[HK]_t$ [5.9 ± 0.2 μM D-fructose 6-phosphate min^{-1} (mM $MgATP^{2-}$)$^{-1}$], and parameter c is $k_{ATP,fruc}[HK]_t$ [2.7 ± 0.2 μM D-fructose 6-phosphate min^{-1} (mM $MgATP^{2-}$)$^{-1}$ (mM fructose)$^{-1}$]. **(E)** Initial rates for production of D-fructose 6-phosphate are presented as a function of initial concentrations of D-fructose (millimolar) at the five fixed initial concentrations of $MgATP^{2-}$. Each curve is for a higher fixed concentration of $MgATP^{2-}$ than the one below it. The curves drawn are fits of Equation 3–52 to the data with x equal to $[D\text{-fructose}]_0$ and y equal to v_0. **(F)** Reciprocals of the initial rates (minutes micromolar^{-1}) are presented as a function of reciprocals of the initial concentrations of D-fructose (millimolar^{-1}) at the five fixed initial concentrations of $MgATP^{2-}$. Each line fit to the data is for a higher fixed concentration of $MgATP^{2-}$ than the one above it. **(G)** The five values for parameter a, the apparent catalytic constants for D-fructose, $k_{0,fruc,app}[HK]_t$ (micromolar minute^{-1}), for the five fits of Equation 3–52 to each of the five subsets of data in Panel E (the five curves on the graph), are presented as a function of the fixed initial concentrations of $MgATP^{2-}$ corresponding to each value of $k_{0,fruc,app}[HK]_t$. The curve drawn is a fit of Equation 3–52 to the data with x equal to the respective fixed initial concentration of $MgATP^{2-}$ and y equal to the respective $k_{0,fruc,app}[HK]_t$. Parameter a of this fit is the catalytic constant for the enzymatic reaction, $k_0[HK]_t$ (3.47 ± 0.06 μM D-fructose 6-phosphate min^{-1}), and parameter c is the specificity constant for $MgATP^{2-}$, $k_{ATP}[HK]_t$ [5.9 ± 0.2 μM fructose 6-P min^{-1} (mM $MgATP^{2-}$)$^{-1}$] **(H)** The five values for parameter c, the apparent specificity constants for D-fructose, $k_{fruc,app}[HK]_t$ (micromolar minute^{-1} millimolar^{-1}), for the five fits of Equation 3–52 to each of the five subsets of data in Panel A, are plotted as a function of the respective fixed initial concentrations of $MgATP^{2-}$. The curve drawn is a fit of Equation 3–52 to the data with x equal to the fixed initial concentration of $MgATP^{2-}$ and y equal to $k_{fruc,app}[HK]_t$. Parameter a of this fit is the specificity constant for D-fructose, $k_{fruc}[HK]_t$ [1.30 ± 0.02 μM fructose 6-P min^{-1} (mM fructose)$^{-1}$], and parameter c is $k_{ATP,fruc}[HK]_t$ [2.72 ± 0.07 μM fructose 6-P min^{-1} (mM fructose)$^{-1}$ (mM $MgATP^{2-}$)$^{-1}$]. Averages of these values for $k_0[HK]_t$, $k_{ATP}[HK]_t$, $k_{fruc}[HK]_t$, and $k_{ATP,fruc}[HK]_t$ were inserted into Equation 3–106 to obtain the lines in Panels B and F.

At the upper limit for Equation 3–40

$$\lim_{[A]_0 \to \infty} v_0 = k_0[E]_t \tag{3–41}$$

and at the lower limit

$$\lim_{[A]_0 \to 0} v_0 = k_A[E]_t[A]_0 \tag{3–42}$$

(Figure 3–1B). Consequently, in this formalism, the fundamental parameters defining the function, the rate constants $k_0[E]_t$ and $k_A[E]_t$, are its horizontal asymptote (Equation 3–41) and its initial slope (Equation 3–42). Recognizing these as the fundamental parameters allows Equation 3–40 to be rewritten as

$$v_0 = \frac{(k_0[E]_t)(k_A[E]_t)[A]_0}{k_0[E]_t + k_A[E]_t[A]_0} \tag{3–43}$$

Historically, however, the behavior of the initial rate of an enzymatic reaction as a function of the initial concentration of reactant has been defined by the equation[70]

$$v_0 = \frac{V[A]_0}{K_{mA} + [A]_0} \tag{3–44}$$

where the parameter V is referred to as the **limiting rate** and the parameter K_{mA} as the **Michaelis constant for reactant A**. With this formalism

$$\lim_{[A]_0 \to \infty} v_0 = V \tag{3–45}$$

but K_{mA} is not a limit. Instead, the Michaelis constant, K_{mA}, is equal to the initial concentration of the varied reactant, $[A]_0$, at which the initial rate of the reaction, v_0, has half its asymptotic value, V (Figure 3–1B). By comparing Equations 3–43 and 3–44, it can be seen that

$$k_0 [E]_t = V \tag{3–46}$$

$$\frac{k_0 [E]_t}{k_A [E]_t} = K_{mA} \tag{3–47}$$

from which it follows that

$$k_A [E]_t = \frac{V}{K_{mA}} \tag{3–48}$$

Equations 3–40 and 3–44 are equations defining a **rectangular hyperbola**. The equation

$$pq = -d^2 \tag{3–49}$$

is the accepted definition of a rectangular hyperbola within the fourth quadrant of the coordinate system (p,q). Because this rectangular hyperbola is entirely within the fourth quadrant, all the values of p are positive numbers and all the values of q are negative numbers. The original coordinate system for this rectangular hyperbola is translated to a new origin at a point on the curve (p_o, q_o) to create a new coordinate system (x, y). Since

$$p = x + p_o \tag{3–50}$$

$$q = y + q_o \tag{3–51}$$

and $q_o p_o$ is equal to $-d^2$, Equation 3–49, upon substitution and rearrangement, becomes

$$y = \frac{(-q_o)x}{\left[\frac{d^2}{(-q_o)}\right] + x} = \frac{ax}{b+x} = \frac{acx}{a+cx} \tag{3–52}$$

for the still rectangular hyperbola. Because the ordinate of the point (p_o, q_o) on the curve was in the fourth quadrant of the original coordinate system, the numerical value of q_o is negative (as are all numerical values of q), and a, b, and c are positive numbers. The horizontal asymptote of the translated rectangular hyperbola, which used to be the axis of the abscissa before the translation, is now $y = -q_o = a$. The slope of the rectangular hyperbola at the new origin is either $a\,b^{-1}$ or c, which are both equal to $q_o^2\ d^{-2}$. Consequently, the value for the horizontal asymptote is defined by the choice of the new origin, and the value for the initial slope is then defined by the parameter d^2. Equation 3–52 has the same form as Equations 3–43 and 3–44.

The most accurate values for the rate constants $k_A[E]_t$ and $k_0[E]_t$ in Equation 3–43 or the Michaelis constant K_{mA} and the limiting rate V in Equation 3–44 are obtained by **numerical analysis from experimental values for the initial rate v_0 as a function of the initial concentration of reactant A, $[A]_0$.** The data are a set of initial rates for the reaction, v_0, corresponding to a set of initial molar concentrations of reactant A. A sequence of initial concentrations of reactant A is chosen so that the values are evenly spaced over a range from a nearly saturating concentration to a concentration well below that equal to the Michaelis constant. Spacing the concentrations evenly ensures that values throughout the range of concentrations in which the initial rate is changing most rapidly with concentration, in particular the region around the Michaelis constant, are sampled. At the present time, the equation for a rectangular hyperbola (Equation 3–52) is fitted directly to the data (Figures 3–1B, 3–2, and 3–3A) by nonlinear least-squares analysis.[71] For the fit, y is the initial rate v_0, and x is the initial concentration $[A]_0$. Parameter a obtained from the fit is the rate constant $k_0[E]_t$ or the limiting rate V, parameter c obtained from the fit is the rate constant $k_A[E]_t$, and parameter b obtained from the fit is the Michaelis constant K_m. In the past, to determine values for the kinetic constants, the data were first converted to a linear form before the fitting was performed; but that practice, although it is still done occasionally, has been supplanted by the nonlinear numerical analysis made possible by digital computers, which

were not available when the habit of linearizing the data was universal.

Numerical values for the parameters $k_A[E]_t$ and $k_0[E]_t$ or the Michaelis constant K_{mA} and the limiting rate V and standard deviations of those numerical values are the numerical values obtained by the fitting procedure and are the **experimental observations**. Although K_{mA} and V are the parameters most often tabulated, the specificity constant k_A for reactant A and the catalytic constant k_0 are the two rate constants that have been found to vary independently of each other when pH, temperature, and concentrations of reactants, products, and inhibitors are varied. They also turn out to be the **most fundamental and informative numbers**.[72]

There is unequivocal evidence from crystallographic observations that enzymes have on their surfaces, or within their protein, active sites, at which reactants bind and are transformed into products. Most enzymes are rotationally symmetric oligomeric proteins. The **protomers of a rotationally symmetric oligomeric protein** are the identical, constituent complexes, between one or several folded polypeptides, each different from the others, that when combined in a fixed stoichiometry, form the oligomeric protein.[73] There is almost always one and only one active site that catalyzes a particular reaction for each protomer in an oligomeric protein that is an enzyme. These facts define the molar concentration of active sites in a given solution as being equal to the molar concentration of protomers.

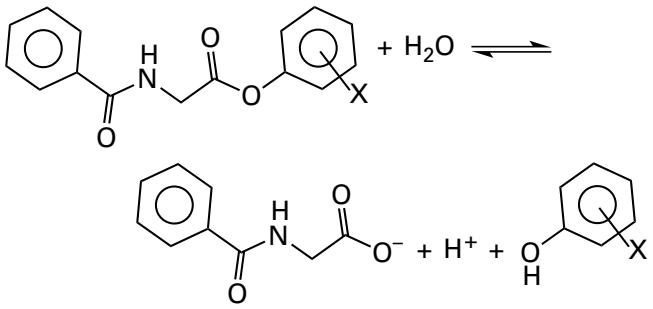
If the total molar concentration of enzymatic active sites in the solution, $[E]_t$, is known from both the mass concentration of protein and the molar mass of its protomers, then explicit values for the catalytic constant k_0 and the specificity constant k_A for reactant A can be obtained from the observed values for $k_0[E]_t$ and $k_A[E]_t$ by simple division. The units on the observed values for $k_0[E]_t$ are molar concentration of product minute^{-1}. When $k_0[E]_t$ is divided by the molar concentration of active sites and the units of liter and the Avogadro constants in numerator and denomitor are canceled, the units on k_0 become molecules of product second^{-1} (molecule of active site)$^{-1}$; in other words, the number of molecules that active site turns into product every second. These units are always simplified to second^{-1} by canceling molecules of product by molecules of enzyme, essentially dividing apples by oranges. The units on the observed values for $k_A[E]_t$ are molar concentration of product minute^{-1} (molar concentration of reactant A)$^{-1}$. When $k_A[E]_t$ is divided by the molar concentration of active sites, the units on k_A become molar concentration of product minute^{-1} (molar concentration of reactant A)$^{-1}$ (molar concentration of active sites)$^{-1}$. Again, apples and oranges are divided, and the value becomes (molar concentration of reactant A)$^{-1}$ second^{-1}. This second-order rate constant (molar^{-1} second^{-1}) can be thought of, in the simplest instance, as the rate constant for the association of reactant A with the active site, but it will become clear that this is a simplistic interpretation. An example of these two conversions would be those applied to the kinetic observations of phosphoribosyl-anthranilate isomerase from *S. cerevisiae* (Figure 3–2). From the known concentrations of active sites added to the solution, the values of the catalytic constant k_0 and the specificity constant k_{pra} for phosphoribosylanthranilate are 40 ± 0.4 s^{-1} and 8.0 ± 0.2 μM^{-1} s^{-1}, respectively.[67]

In the case of kinetic observations of β-fructofuranosidase (FF) from *S. cerevisiae* (Figure 3–3), however, a partially purified cellular extract was used, so the total molar concentration of enzymatic active sites was unknown, and the extinction coefficient for the optical rotation that was used to follow the rates of the reaction was not provided either. As a result, only the rate constants $k_0[FF]_t$, 0.032 ± 0.002 degree min^{-1}, and $k_{suc}[FF]_t$, 4.3 ± 0.4 M^{-1} degrees min^{-1}, where k_{suc} is the specificity constant for sucrose, could be determined. Values, however, for the limiting rate V, which is equal to $k_0[FF]_t$, and the Michaelis constant for sucrose $K_{m,suc}$, 0.74 mM sucrose, could be tabulated in this instance. The fact that the value for the limiting rate V exists in the absence of knowledge of the concentration of active sites and the fact that **the value for the Michaelis constant K_{mA} is determined only by the initial free molar concentrations of reactant** in the different samples, which are almost always known quantities, are superficial advantages to using these parameters. These facts also explain why Equation 3–44 was used so frequently in the past, when the concentrations of active sites were unknown or poorly known.

While the tabulated values for the parameters $k_A[E]_t$ and $k_0[E]_t$ or K_{mA} and V should always be obtained by direct numerical analysis, the data themselves are often presented graphically in a linear form. The most widely used linear form is that based on the inverse of Equation 3–43 or Equation 3–44

$$\frac{1}{v_0} = \frac{1}{k_A [E]_t [A]_0} + \frac{1}{k_0 [E]_t} = \frac{K_{mA}}{V [A]_0} + \frac{1}{V} \qquad (3\text{–}53)$$

If the values for v_0^{-1} are plotted against the corresponding values for $[A]_0^{-1}$, the points should define a straight line the intercept of which at the axis of the ordinate is $(k_0[E]_t)^{-1}$ or V^{-1} , the slope of which is $(k_A[E]_t)^{-1}$ or $K_{mA}\,V^{-1}$, and the intercept of which at the axis of the abscissa is $-k_A\,(k_0)^{-1}$ or $-K_{mA}^{-1}$ (Figure 3–3B). Because this linear form, referred to as the double-reciprocal plot,[74] separates all the important parameters, $k_A[E]_t$ and $k_0[E]_t$ or V, K_{mA}, and $V\,K_m^{-1}$, it is perhaps the most useful presentation for a rapid visual evaluation of the data. For example, if water is disregarded, chymotrypsin catalyzes the hydrolysis of a single reactant, namely, any one in a series of phenyl hippurates



(3–54)

In this equation, X stands for a series of different substituents on the phenyl group. The behavior of v_0^{-1} as a function of $[\text{hippurate}]_0^{-1}$ for the hydrolysis of phenyl hippurates by chymotrypsin is linear with positive slope for the whole series of phenyl hippurates that were studied (Figure 3–5).[75] It is immediately obvious from visual inspection that the identity of the functional group X has its major, if not exclusive, effect on the value of the specificity constant k_{phh} for phenyl hippurate. Such visual inspections are the reason that linear presentations are often used.

To provide an explanation of the observed kinetic behavior and to give meaning to the two parameters—the specificity constant k_A for reactant A and the catalytic constant k_0, or the Michaelis constant K_{mA} for reactant A and the limiting rate V—a **kinetic mechanism is proposed**, and it is demonstrated mathematically that the kinetic mechanism predicts that the enzymatic reaction will display the observed behavior. In this exercise, however, it is

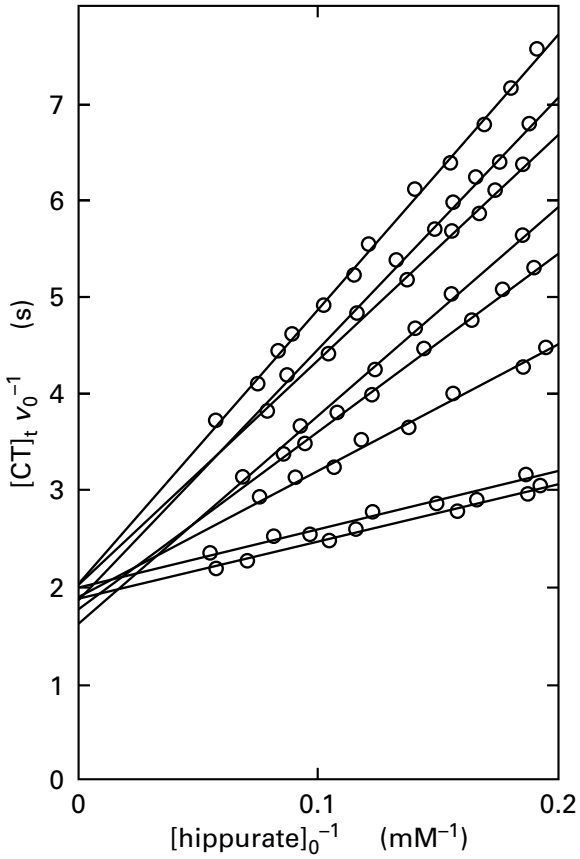


Figure 3–5: Kinetics for the hydrolysis of a series of phenyl hippurates by chymotrypsin.[75] Equivalent amounts of chymotrypsin (CT) were mixed with a series of solutions containing various concentrations of a particular phenyl hippurate at an ionic strength of 0.1 M, at pH 6.91 and 25 °C. The initial rate of release of the respective phenol was followed by its characteristic absorbance in the near-ultraviolet to provide a set of initial rates, v_0, corresponding to the set of concentrations of the respective phenyl hippurate. The reciprocal of each initial rate (seconds millimolar^{-1}) was multiplied by the total molar concentration for active sites of chymotrypsin ($[CT]_t$), and the resulting values ($[CT]_t\ v_0^{-1}$ in seconds) are plotted as a function of the reciprocals of the initial concentrations of the respective hippurate (millimolar) corresponding to those initial rates. The lines, in descending order, connect the data for the hydrolysis by chymotrypsin of the phenyl hippurates formed from phenol, 4-fluorophenol, 4-chlorophenol, 4-cresol, 4-methoxyphenol, 3-nitrophenol, 4-nitrophenol, and 4-acetophenol.

essential to maintain a separation between the observations and the kinetic mechanism proposed as an explanation for the observations. The reason for maintaining this separation is that the kinetic mechanism is **never an exclusive explanation** for the observations, only consistent with the observations.

Kinetic Mechanisms for One Reactant

Observation: In the case of an enzyme that has only one reactant and one product, such as phosphoribosylanthranilate isomerase from *S. cerevisiae* (Equation 3–9), the only observation to be explained is that the initial rate of an enzymatic reaction is usually a rectangularly hyperbolic function (Equation 3–40) of the initial concentration of the reactant (Figure 3–2).[67]

Explanation: A **kinetic mechanism**[76] that can explain the rectangularly hyperbolic behavior of the initial rate of the reaction as a function of the initial concentration of the lone reactant, $[A]_0$, is

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A \xrightarrow{k_2} E + Z \qquad (3\text{–}55)$$

A complex, E·A, is formed reversibly between reactant A and the active site of enzyme E but does not involve the chemical transformation of reactant A. In the next step, the bound reactant A is converted to product Z, and product Z then dissociates from the enzyme. The very last step, the dissociation of Z, is an irreversible process because there is no product Z in the solution under the initial conditions. It should be emphasized that this kinetic mechanism was written by intuition rather than by deduction and is only a proposal to explain the kinetic behavior.

A **rate equation is then derived from the proposed kinetic mechanism**. A rate equation is a mathematical equation, derived from the written kinetic mechanism, that relates the observed initial rate, v_0, of the reaction to the initial concentrations of reactants, in this case, $[A]_0$, and the total concentration of the enzyme, $[E]_t$, all of which are known quantities

$$v_0 = f([E]_t, [A]_0) \qquad (3\text{–}56)$$

In a rate equation, the only parameters are rate constants, in this instance, k_1, k_{-1}, and k_2.

Because the only way that a product can be formed is through the step governed by k_2, it follows that

$$v_0 = \frac{d[Z]}{dt} = k_2[E{\cdot}A] \qquad (3\text{–}57)$$

But [E·A] is not a known concentration as are $[E]_t$ and $[A]_0$. The concentration of the complex between the active site and reactant A, [E·A], and the concentration of unoccupied active site, [E], are unknowns, and an expression for [E·A] only in terms of known quantities and rate constants must be obtained. To eliminate the unknown variable [E] and solve for the unknown variable [E·A], a set of **independent simultaneous equations** must be formulated such that there are as many independent simultaneous equations as there are unknown variables, as in any algebraic solution for multiple unknowns.

The first simultaneous equation in all derivations of steady-state rate equations for enzymatic catalysis is the **conservation of enzyme**, in analogy to an equation for the conservation of mass in an acid–base calculation. The total molar concentration of active sites, which is usually a known quantity, but that always remains constant throughout the reaction, must be equal to the sum of the concentrations of all forms of the active site. In the simple case of the kinetic mechanism in Equation 3–55

$$[E]_t = [E] + [E{\cdot}A] \qquad (3\text{–}58)$$

The next group of simultaneous equations are the **steady-state relations**. The approximation that is always made in derivations of this kind is that because the concentration of reactant is so much greater than the concentration of enzyme, after the first few molecules of reactant have been turned into product by each molecule of enzyme, the concentration of each species involving the enzyme has reached a constant, steady state. This approximation follows in the simple case of the kinetic mechanism of Equation 3–55 from the consideration that if [E·A] were increasing, [E] would be decreasing, and the rate of formation of E·A would be decreasing while its rate of decay would be increasing. At some point, the rate of formation and the rate of decay of E·A would become equal, and its concentration would remain constant. A similar argument can be made for the situation in which [E·A] is decreasing. As long as $[A]_0$ remains unchanged, which is the definition of an initial rate (Equation 3–37), the individual concentrations of all forms of the enzyme will remain constant once the steady state has been reached.

Direct measurements of the **rate of attainment of steady state** have shown that it is usually achieved within less than 1 s with most enzymes, but some enzymes reach steady state more slowly, in at least one instance taking as long as an hour.[77] In such peculiar circumstances, the initial rate of the reac-

tion is seen to increase with time rather than remaining constant or decreasing with time.

For the kinetic mechanism of Equation 3–55, the **steady-state approximation** is

$$\frac{d[\mathrm{E}]}{dt} = -\frac{d[\mathrm{E{\cdot}A}]}{dt} = 0 \tag{3–59}$$

Although this relation seems to define two equations, they turn out to be the same equation. The number of simultaneous, independent steady-state equations is always one less than the number of kinetically unique forms of the enzyme, the concentrations of which are the unknowns, and the shortfall is made up by the equation stating the conservation of enzyme (Equation 3–58). The single steady-state equation for the kinetic mechanism of Equation 3–55 is

$$\frac{d[\mathrm{E{\cdot}A}]}{dt} = k_1[\mathrm{E}][\mathrm{A}]_0 - \left(k_{-1} + k_2\right)[\mathrm{E{\cdot}A}] = 0 \tag{3–60}$$

Equation 3–60 states that the difference between the rate at which E·A is formed and the rate at which E·A is lost must be zero at steady state.

When the two independent simultaneous equations, Equations 3–58 and 3–60, are used to **solve algebraically** for [E·A] in terms of the known quantities, it is found that

$$[\mathrm{E{\cdot}A}] = \frac{k_1[\mathrm{E}]_t[\mathrm{A}]_0}{\left(k_{-1} + k_2\right) + k_1[\mathrm{A}]_0} \tag{3–61}$$

and that

$$v_0 = \frac{k_2 k_1[\mathrm{E}]_t[\mathrm{A}]_0}{\left(k_{-1} + k_2\right) + k_1[\mathrm{A}]_0} = \frac{k_2[\mathrm{E}]_t\left(\dfrac{k_2 k_1}{k_{-1} + k_2}\right)[\mathrm{E}]_t[\mathrm{A}]_0}{k_2[\mathrm{E}]_t + \left(\dfrac{k_2 k_1}{k_{-1} + k_2}\right)[\mathrm{E}]_t[\mathrm{A}]_0} = \frac{k_2[\mathrm{E}]_t[\mathrm{A}]_0}{\left(\dfrac{k_{-1} + k_2}{k_1}\right) + [\mathrm{A}]_0} \tag{3–62}$$

Taking the limits of Equation 3–40 and Equation 3–62

$$\lim_{[\mathrm{A}]_0 \to \infty} v_0 = k_0[\mathrm{E}]_t = k_2[\mathrm{E}]_t \tag{3–63}$$

$$\lim_{[\mathrm{A}]_0 \to 0} v_0 = k_\mathrm{A}[\mathrm{E}]_t[\mathrm{A}]_0 = \frac{k_1 k_2}{k_{-1} + k_2}[\mathrm{E}]_t[\mathrm{A}]_0 \tag{3–64}$$

Equation 3–62 is of the form of Equation 3–43 and Equation 3–44 and, therefore, provides an explanation of the observed behavior. It states that the measured value of the catalytic constant, k_0, is k_2, the measured value of V is $k_2[\mathrm{E}]_t$, the measured value of the specificity constant k_A for reactant A is $k_1k_2(k_{-1} + k_2)^{-1}$, and the measured value of the Michaelis constant for reactant A, K_{mA}, is $(k_2 + k_{-1})(k_1)^{-1}$, if the kinetic mechanism of Equation 3–55 is the actual kinetic mechanism applicable to the enzyme in question.

The point of the exercise is that the kinetic mechanism of Equation 3–55, which was formulated only by intuition and which did not follow by deduction from the observations, is nevertheless consistent with the behavior of the reaction as it is experimentally observed.

All present explanations of the catalytic activity of enzymes assume that the molecules of reactant associate with a molecule of the enzyme and are converted to products while they are bound, as they are in the kinetic mechanism of Equation 3–55. This hypothesis and kinetic mechanisms of the type represented by Equation 3–55 were originally intended to[64] and do provide an explanation for the universally observed fact that **the initial rate of an enzymatic reaction approaches a horizontal asymptote** as the initial concentrations of the reactants are increased. This explanation is that at high concentrations of the reactants, the enzyme is saturated and this saturation limits the rate of the overall reaction to the rate at which reactants can be converted to products while they are bound to the enzyme and those products can dissociate. Nonenzymatic catalysis can also display saturation for the same reasons.[78]

To understand what the kinetic constants in a kinetic mechanism and a rate equation represent, the difference between an elementary reaction and a composite reaction and the difference between elementary rate constants and composite rate constants must be understood. These differences are easiest to understand in the simplest possible kinetic mechanism, that of an enzymatic

reaction with only one reactant and one product. In the kinetic mechanism of Equation 3–55, the rate constant k_2 can have one of two quite different meanings, depending on the intentions of the author of the kinetic mechanism. If k_2 was intended to be an elementary rate constant, then the step immediately following the formation of the complex E·A has been designated the rate-limiting step in the reaction. As the kinetic mechanism is written, however, there must be at least two steps between the complex E·A and the dissociated enzyme E and product Z. These steps are the transformation of reactant A to product Z on the active site of the enzyme and the dissociation of product Z from the active site. If the author intended the rate constant k_2 to include the rate constants for these steps, then k_2 is a composite rate constant.

An **elementary reaction** is a reaction for which no reaction intermediates have been detected or need to be postulated to describe the chemical reaction on a molecular scale. An elementary reaction occurs in a single step and passes through only one transition state. An **elementary rate constant** is the rate constant for an elementary reaction. If a step in a kinetic mechanism is an elementary reaction, the respective rate constants for its two directions are elementary rate constants. The ultimate ideal of a kinetic investigation is to define explicitly the complete sequence of elementary steps in a reaction and to assign a numerical value to each elementary rate constant. In simple nonenzymatic reactions, the chemical mechanism usually involves only a few steps, and the individual events, such as bond-making, bond-breaking, hydronation, electron transfer, or noncovalent association, can be written as explicit steps, each of which seems to have only one transition state. Rate constants are then assigned systematically to these steps to define the elementary kinetics. In such situations, the measured rate constants are assumed to be elementary rate constants associated with the explicit chemical events.

If the author of the kinetic mechanism of Equation 3–55 intended k_2 to be an elementary rate constant, then k_2 cannot include the rate constant for the release of product because the release of product must involve a different transition state from the transition state that immediately follows the formation of the complex between enzyme and reactant. If the rate constant k_2 is intended to be the elementary rate constant only for the step immediately following the formation of the complex between enzyme and reactant, then the author of the kinetic mechanism has implicitly designated the step governed by the rate constant k_2 as the **rate-limiting step** of the overall reaction.[79] This designation follows from the fact that the author ignored the elementary rate constants for all the later steps.

Most students have been exposed to simple chemical kinetics before they encounter enzymatic kinetics and are trained to treat an unadorned rate constant as an elementary rate constant. This habit is always a simplification because even straightforward chemical reactions often involve more transition states, and hence more elementary steps, than have been defined. Even if there are several elementary steps between two points in a kinetic mechanism, however, there is a rate at which the reaction proceeds between those two points and a rate constant that can be assigned to the flux between those two points.

A **composite reaction** is a chemical reaction or a step in the kinetic mechanism for a reaction for which the expression for the rate of disappearance of a reactant or the rate of appearance of a product involves elementary rate constants of more than one elementary reaction. A composite reaction proceeds through more than one transition state and involves more than one elementary step. A **composite rate constant** is a rate constant for a composite reaction or a step in a kinetic mechanism that is a composite reaction. A composite rate constant can be expressed as a combination of several elementary rate constants for the several elementary steps between the two points. In the literature in which steady-state enzymatic kinetics are presented, composite rate constants are often called net rate constants.[80]

Suppose that k_2 is not a rate-limiting elementary rate constant in the kinetic mechanism of Equation 3–55 and that it is a composite rate constant for two steps: the transformation of reactant to product and the dissociation of product

$$\mathrm{E{\cdot}A} \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} \mathrm{E{\cdot}Z} \xrightarrow{k_7} \mathrm{E} + \mathrm{Z} \qquad (3\text{–}65)$$

In this expansion of the second step in the kinetic mechanism of Equation 3–55, the dissociation of product, governed by the rate constant k_7, is written as an irreversible process, as was the second step in the kinetic mechanism of Equation 3–55, because there is no product in the solution under

the initial conditions. The rate at which product is produced

$$v_0 = \frac{d[Z]}{dt} = k_7[E{\cdot}Z] \tag{3–66}$$

If it is assumed that E·Z is in steady state, then

$$\frac{d[E{\cdot}Z]}{dt} = k_6[E{\cdot}A] - (k_{-6} + k_7)[E{\cdot}Z] = 0 \tag{3–67}$$

and

$$\frac{d[Z]}{dt} = \left(\frac{k_6 k_7}{k_{-6} + k_7}\right)[E{\cdot}A] \tag{3–68}$$

In the kinetic mechanism of Equation 3–55

$$\frac{d[Z]}{dt} = k_2[E{\cdot}A] \tag{3–69}$$

Therefore, if k_2 is a composite rate constant for the two steps in the expanded kinetic mechanism (Equation 3–65), then

$$k_2 = \frac{k_6 k_7}{k_{-6} + k_7} \tag{3–70}$$

If, however, k_6 is in fact the rate-limiting step of the reaction, then by definition[79] $k_7 >> k_{-6}$, k_2 equals k_6, and k_2 is the rate-limiting step.

Regardless of whether k_2 in the kinetic mechanism of Equation 3–55 is a rate-limiting elementary rate constant for the overall reaction or a composite rate constant including several steps, one of which is dissociation of the product, the transformation to which it refers, the conversion of reactant to product on the enzyme and the dissociation of the product from the enzyme, is kinetically irreversible. This property follows from the fact that the step governing the dissociation of the product must be irreversible because no product is present in the solution during the initial interval. The **creation of irreversibility by omitting one or more of the products** of a reaction is one purpose behind measuring its initial rates. In this way, the rate measured is a unidirectional rate and the equations are greatly simplified.

Formally, the rate constant k_1 in Equation 3–55 is the second-order rate constant for formation of the complex E·A, and the rate constant k_{-1} is the first-order rate constant for its dissociation. Although there is no necessity to assume it, the **rate constants k_1 and k_{-1} for formation of the complex preceeding the conversion of A to Z could also be composite rate constants**. In fact, they usually are. Suppose, for example, that there were three steps that preceded the conversion of reactant into product, one for association of the reactant with the enzyme and two involving isomerizations of the enzyme and reactant A, respectively

$$E + A \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E{\cdot}A \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} E'{\cdot}A \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} E'{\cdot}A' \tag{3–71}$$

The composite rate constant k_1 would then be the unidirectional rate constant for the conversion of E + A into E′·A′

$$E + A \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E{\cdot}A \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} E'{\cdot}A \xrightarrow{k_5} E'{\cdot}A' \tag{3–72}$$

If it is assumed that [E·A] and [E′·A] are at steady state, then

$$k_3[E][A]_0 + k_{-4}[E'{\cdot}A] = (k_{-3} + k_4)[E{\cdot}A] \tag{3–73}$$

and

$$k_4[E{\cdot}A] = (k_{-4} + k_5)[E'{\cdot}A] \tag{3–74}$$

respectively. Solving for [E′·A]

$$[E'{\cdot}A] = \frac{k_3 k_4[E][A]_0}{k_{-3}k_{-4} + k_{-3}k_5 + k_4 k_5} \tag{3–75}$$

Because

$$\frac{d[E'{\cdot}A']}{dt} = k_5[E'{\cdot}A] = k_1[E][A]_0 \tag{3–76}$$

$$k_1 = \frac{k_3 k_4 k_5}{k_{-3}k_{-4} + k_{-3}k_5 + k_4 k_5} \tag{3–77}$$

The composite rate constant k_{-1} is the unidirectional rate constant for the conversion of E′·A′ into E + A

$$\mathrm{E'{\cdot}A'} \underset{k_5}{\overset{k_{-5}}{\rightleftharpoons}} \mathrm{E'{\cdot}A} \underset{k_4}{\overset{k_{-4}}{\rightleftharpoons}} \mathrm{E{\cdot}A} \xrightarrow{k_{-3}} \mathrm{E + A} \tag{3–78}$$

If it is assumed that [E′·A] and [E·A] are at steady state, then

$$k_4[\mathrm{E{\cdot}A}] + k_{-5}[\mathrm{E'{\cdot}A'}] = \left(k_{-4} + k_5\right)[\mathrm{E'{\cdot}A}] \tag{3–79}$$

and

$$k_{-4}[\mathrm{E'{\cdot}A}] = \left(k_{-3} + k_4\right)[\mathrm{E{\cdot}A}] \tag{3–80}$$

respectively. Solving for [E·A]

$$[\mathrm{E{\cdot}A}] = \frac{k_{-4}k_{-5}[\mathrm{E'{\cdot}A'}]}{k_{-3}k_5 + k_4k_5 + k_{-3}k_{-4}} \tag{3–81}$$

Because

$$\frac{d[\mathrm{E}]}{dt} = k_{-3}[\mathrm{E{\cdot}A}] = k_{-1}[\mathrm{E'{\cdot}A'}] \tag{3–82}$$

$$k_{-1} = \frac{k_{-3}k_{-4}k_{-5}}{k_{-3}k_{-4} + k_{-3}k_5 + k_4k_5} \tag{3–83}$$

The expressions for k_1, k_{-1}, and k_2, when they are the composite rate constants for the steps in the now **expanded kinetic mechanism**

$$\mathrm{E + A} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \mathrm{E{\cdot}A} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \mathrm{E'{\cdot}A} \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} \mathrm{E'{\cdot}A'} \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} \mathrm{E{\cdot}Z} \xrightarrow{k_7} \mathrm{E + Z} \tag{3–84}$$

contain only rate constants, regardless of whether they themselves are elementary rate constants or composite rate constants. Consequently, the form of the rate equations for the kinetic mechanisms of Equations 3–55 and 3–84 must be the same, and both of these kinetic mechanisms must be consistent with the experimental observation that the initial rate of an enzymatic reaction as a function of the initial concentration of the reactant is defined by Equation 3–40. **Steady-state kinetics cannot decide which kinetic mechanism is the complete kinetic mechanism**, or if either of them is, because further expansion of the kinetic mechanism is possible by supplying additional steps, and each expanded kinetic mechanism will also be consistent with the observations. The only facts are the observed behavior, and kinetic mechanisms are simply attempts by the authors to explain the facts.

The rate equations for such expanded kinetic mechanisms, however, are not simply Equation 3–62 with k_1, k_{-1}, and k_2 replaced by the respective composite rate constants. Equations such as Equation 3–61 define the **fraction of the total enzyme that is in a particular form**, in this instance the fraction of the total enzyme that is E·A. In the kinetic mechanism defined by Equation 3–84, [E·A] at steady state is no longer the same fraction of the total enzyme as that defined by Equation 3–61. There are now new forms of the enzyme, E′·A, E′·A′, and E·Z, in addition to E·A and E. Consequently, the expression for $[\mathrm{E}]_t$ (Equation 3–58) must be expanded to include these new forms, a new equation for [E·A] as a new fraction of the total enzyme must be derived to replace Equation 3–61, and that equation will not be the same as Equation 3–61.

For example, consider the **most reasonable kinetic mechanism for an enzyme with one substrate**

$$\mathrm{E + A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}A} \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} \mathrm{E{\cdot}Z} \xrightarrow{k_7} \mathrm{E + Z} \tag{3–85}$$

If it is assumed that

$$v_0 = k_7[\mathrm{E{\cdot}Z}] \tag{3–86}$$

that

$$[\mathrm{E}]_t = [\mathrm{E}] + [\mathrm{E{\cdot}A}] + [\mathrm{E{\cdot}Z}] \tag{3–87}$$

that

$$\frac{d[\mathrm{E}]}{dt} = k_7[\mathrm{E{\cdot}Z}] + k_{-1}[\mathrm{E{\cdot}A}] - k_1[\mathrm{E}][\mathrm{A}] = 0 \tag{3–88}$$

and that Equation 3–67 supplies the required second steady-state relation, the rate equation that results from a standard derivation is

$$v_0 = \frac{\left(\frac{k_6 k_7 [\mathrm{E}]_t}{k_{-6} + k_6 + k_7}\right)\left(\frac{k_1 k_6 k_7 [\mathrm{E}]_t}{k_{-1}k_{-6} + k_{-1}k_7 + k_6 k_7}\right)[\mathrm{A}]_0}{\left(\frac{k_6 k_7 [\mathrm{E}]_t}{k_{-6} + k_6 + k_7}\right) + \left(\frac{k_1 k_6 k_7 [\mathrm{E}]_t}{k_{-1}k_{-6} + k_{-1}k_7 + k_6 k_7}\right)[\mathrm{A}]_0} \qquad (3\text{–}89)$$

Equations 3–67, 3–87, and 3–88 can be used to show that, for the kinetic mechanism proposed in Equation 3–85

$$[\mathrm{E{\cdot}A}] = \frac{(k_{-6} + k_7)k_1 [\mathrm{E}]_t [\mathrm{A}]_0}{(k_{-1}k_{-6} + k_{-1}k_7 + k_6 k_7) + (k_{-6} + k_6 + k_7)k_1 [\mathrm{A}]_0} \qquad (3\text{–}90)$$

If [E·A] defined by this equation is multiplied by the composite rate for formation of product from E·A (Equation 3–68), Equation 3–89 is again the result. Consequently, when a correct equation for the fraction of the total enzyme that is in a particular form is derived, this fraction and the appropriate composite rate constant can be combined to obtain the correct rate equation. This approach is a correct way of proceeding. If, however, k_2 in Equation 3–61 is simply replaced by the composite rate of Equation 3–68, Equation 3–90 is not the result, because Equation 3–61 does not give the correct value of [E·A] for the new kinetic mechanism. This approach is an incorrect way of proceeding. This exercise demonstrates that composite rate constants, which were used to show that expanded kinetic mechanisms give the same form of the rate equation and which will be used later for other purposes, can be misleading in deriving the rate equation from an explicit kinetic mechanism. It follows that the only infallible approach is to derive the rate equations for a proposed mechanism starting with the equation for conservation of enzyme and the steady-state equation.

An example of a kinetic mechanism for which it is known that there are **intermediates between the association of reactant and the production of product** bound in the active site, as in the first portion of Equation 3–84, would be that for the hydrolysis of phenyl hippurates by chymotrypsin (Equation 3–54). Chymotrypsin is an enzyme that hydrolyzes amides and esters by performing a nucleophilic substitution (Figure 1–10) that transfers the acyl group of the amide or ester to the hydroxy group of one of its serines, which acts as the nucleophile, to form an acyl intermediate (Figure 3–6).

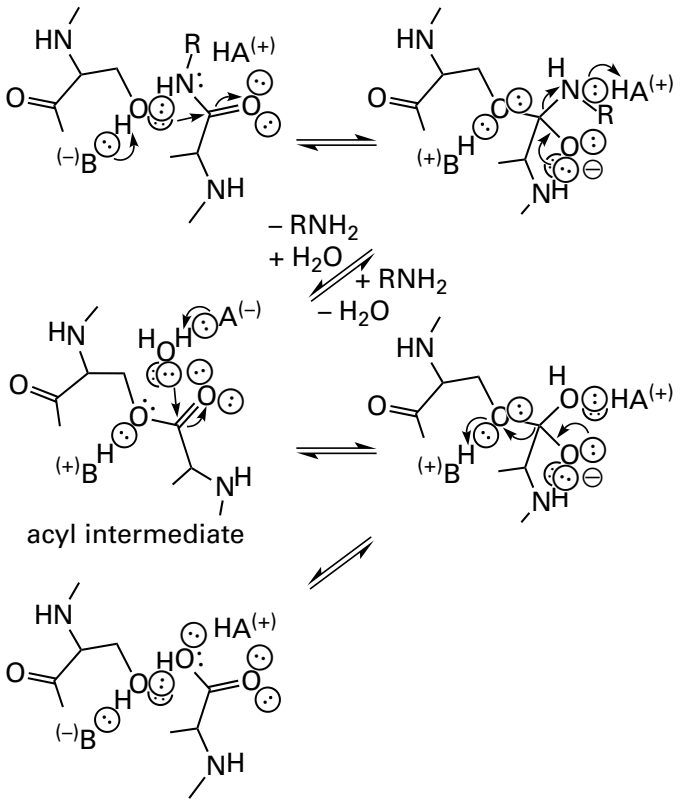

Figure 3–6: Mechanism by which serine endopeptidases catalyze the hydrolysis of a peptide bond. Attack of the hydroxy group of a serine in the active site, which is dehydronated as it adds to the acyl carbon of the amide of the peptide bond, produces the tetrahedral intermediate. The oxyanion of the tetrahedral intermediate pushes out the amine upon hydronation of its nitrogen to produce the acyl intermediate. A molecule of water replaces the amine in the active site. Attack of the molecule of water, which is dehydronated as it adds to the acyl carbon of the acyl intermediate, produces the second tetrahedral intermediate. The oxyanion pushes out the hydroxy group of the serine as it is being hydronated to produce the carboxylic acid. The hydrolysis requires a catalytic acid–base, $^{(-)}\mathrm{B}\odot$, at the hydroxy group of the serine and a catalytic acid–base, $\mathrm{HA}^{(+)}$, at the location occupied by the amino group and the molecule of water. These requirements are actually fulfilled by the same acid–base, usually a histidine, that pivots between the two positions.

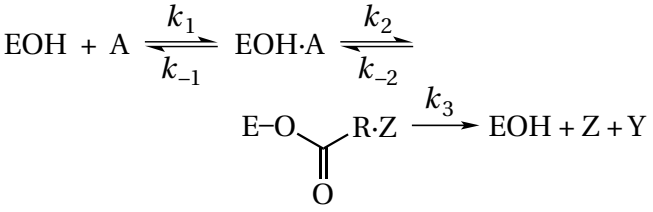
A kinetic mechanism for hydrolysis of phenyl hippurates catalyzed by chymotrypsin, which ignores the details of the hydrolysis of the ester of the serine and release of the two products, could be



(3–91)

where A is the ester that is the reactant (Equation 3–54), E–OC(O)R is the seryl ester that is the acyl intermediate, Z is the phenol that is one product, and Y is the carboxylic acid that is the other. The rate equation for the kinetic mechanism as written is Equation 3–43, which has a catalytic constant

$$k_0 = \frac{k_2 k_3}{k_2 + k_{-2} + k_3} \tag{3–92}$$

and a specificity constant for a particular phenyl hippurate

$$k_{\text{phh}} = \frac{k_1 k_2 k_3}{k_{-1} k_{-2} + k_{-1} k_3 + k_2 k_3} \tag{3–93}$$

Because the nucleophilic substitution in Equation 3–54 is an alcohol for a phenol, $k_2 >> k_{-2}$ (Table 1–3).

When the reciprocals of the initial rates for the hydrolysis of several phenyl hippurates by chymotrypsin are plotted as a function of the initial concentrations of several phenyl hippurates, it can be seen that the catalytic constant is the same for all of them (Figure 3–5). It is unlikely that k_2 is the same for all the substituted phenols, so only if $k_2 >> k_3$ and $k_0 = k_3$ would k_0 be invariant. The specificity constants for the phenyl hippurates, however, register the effects of changes in the functional groups on the elementary rate constants k_2 and k_{-2}, but only indirectly.

Parenthetically, the effects of functional groups on the rate of hydrolysis of phenyl hippurates is an example of a **structure–activity correlation**. In this case, a correlation between the ability of the phenol as a leaving group and the specificity constants for phenyl hippurates was sought, but no systematic relation was observed. In the case of hydrolysis of a series of aryl β-D-glucosides and aryl β-D-cellobiosides by cellulose 1,4-β-cellobiosidase from *Cellulomonas fimi*, however, there was a clear correlation between the pK_a of the phenol that was the leaving group and the specificity constant for that reactant.[81]

It is often stated that kinetics cannot prove a kinetic mechanism and that **a kinetic mechanism can only be consistent with kinetic observations**. There are two levels of meaning to this statement. The first level of meaning is that kinetics cannot prove a kinetic mechanism because the possibility always exists that there is a significantly different kinetic mechanism with a different sequence of steps that is, nevertheless, also consistent with all the experimental observations. In this meaning, the kinetic method, because it proceeds inductively, must always suffer from this problem, which is common to all inductive reasoning. It follows that the most powerful use of kinetics is to disprove a proposed kinetic mechanism. One should never make the mistake, however, of assuming that since all the kinetic mechanisms you could imagine but one have been disproven, the one that has not been disproven has been proven. The second level of meaning is that even if a particular kinetic mechanism can be shown by independent experiments to be the correct kinetic mechanism, it may, nevertheless, be incomplete. **The complete kinetic mechanism for a chemical reaction includes explicitly every elementary step in that reaction**. A kinetic mechanism in which one or more of the steps are composite reactions or one or more of the rate constants are composite rate constants is an incomplete kinetic mechanism for the reaction even if it is not an incorrect kinetic mechanism. Because any of the rate constants in a kinetic mechanism can be composite rate constants and because the number of steps covered by a composite rate constant can be large, no kinetic mechanism can be proven to be complete. The rate constants in the kinetic mechanisms proposed for most enzymatic reactions are usually composite rate constants, and those kinetic mechanisms are incomplete.

Kinetic Mechanisms for Two Reactants: Converging Double Reciprocals

Observation: Most enzymes, even chymotrypsin, have two reactants and two products. When an enzyme has two reactants that can be varied independently, the procedure followed is to choose several initial concentrations of one reactant and several initial concentrations of the other reactant evenly spaced over ranges between a nearly saturating concentration and a concentration well below the apparent values for the Michaelis constant. Spacing the concentrations evenly ensures that concentrations above, below, and close to the apparent

Michaelis constant are chosen and that values throughout the range of concentrations in which the initial rate of the enzymatic reaction is changing most rapidly with concentration, in particular the region around the Michaelis constant, are sampled. A couple of points are usually chosen at high concentrations to establish saturation and the value for the apparent rate constant at saturation of the varied reactant. The initial rate of the reaction is then measured at every combination of these two sets of initial concentrations. The initial rates of the enzymatic reaction are plotted as a function of the initial concentrations of reactant A, the **varied reactant**, at a constant concentration of reactant B, the **fixed reactant**. The behavior of the initial rate is usually that defined by Equation 3–43, but the values of the specificity constant k_A for reactant A and the catalytic constant for reactant A, $k_{0,A}$, in the equation change as the concentration of reactant B, the fixed reactant, is changed. Because the parameters $k_A[E]_t$ and $k_0[E]_t$ in Equation 3–43 have become functions of the concentration of reactant B and vary as the concentration of reactant B is varied and vice versa, they are actually not constants; they are only **apparent rate constants** ($k_{0,A,app}[E]_t$ and $k_{A,app}[E]_t$) for a fixed concentration of reactant B.

The kinetics of hexokinase (HK) from *R. norvegicus*

$$\text{D-hexose} + \text{MgATP}^{2-} \rightleftharpoons \text{H}^+ + \text{MgADP}^- + \text{D-hexose 6-phosphate} \tag{3–94}$$

serve as an example of such observations. Either $MgATP^{2-}$ was chosen to be the varied reactant at several fixed initial concentrations of the hexose, in this case D-fructose, (Figure 3–4A),[69] or D-fructose was chosen to be the varied reactant at several fixed concentrations of $MgATP^{2-}$ (Figure 3–4E).[69] At each initial concentration of the fixed reactant, the observed values for the initial rate of hexokinase as a function of the initial concentration of the varied reactant could be fit by Equation 3–52. From these fits, in which y is the initial rate v_0 and x is the initial concentration of either $MgATP^{2-}$ or D-fructose, values for the rate constants $k_{0,ATP,app}[HK]_t$ (parameter a) and $k_{ATP,app}[HK]_t$ (parameter c) or $k_{0,fruc,app}[HK]_t$ (parameter a) and $k_{fruc,app}[HK]_t$ (parameter c) were obtained for each initial concentration of the fixed reactants fructose and $MgATP^{2-}$, respectively. When parameters a and c for $MgATP^{2-}$ are plotted against the initial concentration of D-fructose (Figure 3–4C,D) and when parameters a and c for D-fructose are plotted against the initial concentration of $MgATP^{2-}$ (Figure 3–4G,H), the data can again be fitted by Equation 3–52 when y is the respective rate constant being plotted and x is the initial concentration of D-fructose or $MgATP^{2-}$, respectively.

The **general empirical equation** defining this observed behavior is

$$v_0 = \frac{[E]_t}{\frac{1}{k_{AB}[A]_0[B]_0} + \frac{1}{k_B[B]_0} + \frac{1}{k_A[A]_0} + \frac{1}{k_0}} = \frac{k_0 k_A k_B k_{AB}[E]_t[A]_0[B]_0}{k_0 k_A k_B + k_0 k_A k_{AB}[A]_0 + k_0 k_B k_{AB}[B]_0 + k_A k_B k_{AB}[A]_0[B]_0} \tag{3–95}$$

for which

$$\lim_{[A]_0 \to \infty} v_0 = k_{0,A,app}[E]_t = \frac{k_0[E]_t k_B[E]_t[B]_0}{k_0[E]_t + k_B[E]_t[B]_0} \tag{3–96}$$

$$\lim_{[A]_0 \to 0} v_0 = k_{A,app}[E]_t[A]_0 = \left(\frac{k_A[E]_t k_{AB}[E]_t[B]_0}{k_A[E]_t + k_{AB}[E]_t[B]_0}\right)[A]_0 \tag{3–97}$$

$$\lim_{[B]_0 \to \infty} v_0 = k_{0,B,app}[E]_t = \frac{k_0[E]_t k_A[E]_t[A]_0}{k_0[E]_t + k_A[E]_t[A]_0} \tag{3–98}$$

and

$$\lim_{[B]_0 \to 0} v_0 = k_{B,app}[E]_t[B]_0 = \left(\frac{k_B[E]_t k_{AB}[E]_t[A]_0}{k_B[E]_t + k_{AB}[E]_t[A]_0}\right)[B]_0 \tag{3–99}$$

The four rate constants that define Equation 3–95 are each isolated in turn from the other three in the **double limits**

$$\lim_{\substack{[A]_0 \to \infty \\ [B]_0 \to \infty}} v_0 = k_0[E]_t \tag{3–100}$$

$$\lim_{\substack{[A]_0 \to \infty \\ [B]_0 \to 0}} v_0 = k_B[E]_t[B]_0 \tag{3–101}$$

$$\lim_{\substack{[A]_0 \to 0 \\ [B]_0 \to \infty}} v_0 = k_A[E]_t[A]_0 \tag{3–102}$$

$$\lim_{\substack{[A]_0 \to 0 \\ [B]_0 \to 0}} v_0 = k_{AB}[E]_t[A]_0[B]_0 \tag{3–103}$$

A key feature of the general equation (Equation 3–95) is that $[A]_0$ and $[B]_0$ are interchangeable, which must be the case because the behavior of the initial rate of an enzymatic reaction when A is the varied reactant and B is the fixed reactant (Figure 3–4, panels A–D) is the same as its behavior when B is the varied reactant and A is the fixed reactant (Figure 3–4, panels E–H), albeit with different numerical values for the parameters governing the respective situations.

The products of the concentration of active sites with the apparent catalytic constant, $k_{0,A,app}[E]_t$, as a function of the initial concentration $[B]_0$ (Equation 3–96); with the apparent specificity constant for reactant A, $k_{A,app}[E]_t$, as a function of the initial concentration $[B]_0$ (Equation 3–97); with the apparent catalytic constant, $k_{0,B,app}[E]_t$, as a function of the initial concentration $[A]_0$ (Equation 3–98); and with the apparent specificity constant, $k_{B,app}[E]_t$, as a function of the initial concentration $[A]_0$ (Equation 3–99) are all rectangular hyperbolae (Equation 3–52). From fits of Equation 3–52 to the various plots of the apparent rate constants as functions of the initial concentrations of the fixed reactants (Figure 3–4C, D, G, and H) and extrapolation to determine the four respective double limits (Equations 3–100 through 3–103), values for the **four fundamental rate constants** $k_0[E]_t$, $k_A[E]_t$, $k_B[E]_t$, and $k_{AB}[E]_t$ are obtained. These four fundamental rate constants govern all the kinetics and can be used to generate all the curves describing the observations.

Historically, the general empirical equation that was used and is still sometimes used to define the observed behavior of the initial rate of an enzymatic reaction is

$$v_0 = \frac{V[A]_0[B]_0}{K_{iA}K_{mB} + K_{mB}[A]_0 + K_{mA}[B]_0 + [A]_0[B]_0} \tag{3–104}$$

The symmetry of the equation is not so obvious, but it is the same equation as Equation 3–95 with the parameters given different notation.

The **double reciprocal** of Equation 3–95 is

$$\frac{1}{v_0} = \frac{1}{k_{AB}[E]_t[A]_0[B]_0} + \frac{1}{k_B[E]_t[B]_0} + \frac{1}{k_A[E]_t[A]_0} + \frac{1}{k_0[E]_t} \tag{3–105}$$

Consequently, when the reciprocals of the initial rates for an enzymatic reaction are plotted as a function of the reciprocals of the initial concentrations of the varied reactant at any constant initial concentration of the fixed reactant, the data can be fitted with a straight line (Figure 3–4B,F). Equation 3–105 separates the four kinetic constants into four separated terms.

When A is the varied reactant and B is the fixed reactant

$$\frac{1}{v_0} = \left(\frac{k_A[E]_t + k_{AB}[E]_t[B]_0}{k_A[E]_t k_{AB}[E]_t[B]_0}\right)\frac{1}{[A]_0} + \left(\frac{k_0[E]_t + k_B[E]_t[B]_0}{k_0[E]_t k_B[E]_t[B]_0}\right) \tag{3–106}$$

and both the slope of the straight line and its intercept with the axis of the ordinate should be functions of $[B]_0$ (Figure 3–4B,F). Because the slopes of the lines defining each of the individual double reciprocals when A is the varied reactant is a function of $[B]_0$, the initial concentration of the fixed reactant, the lines for the variable $[A]_0^{-1}$ at two different fixed $[B]_0$ will necessarily intersect at some point, just as any two lines with different slopes must intersect. Furthermore, it can be shown, by solving for the coordinates of the point of intersection, that all the lines defined by Equation 3–106 **intersect at the same point** (Figure 3–4B,F) where

$$\frac{1}{[A]_{0,int}} = -\frac{k_{AB}}{k_B} \tag{3–107}$$

and

$$\frac{1}{v_{0,\text{int}}} = \frac{k_A [E]_t k_B [E]_t - k_0 [E]_t k_{AB} [E]_t}{k_0 [E]_t k_B [E]_t k_A [E]_t} \quad (3\text{–}108)$$

where $[A]_{0,\text{int}}^{-1}$ and $v_{0,\text{int}}^{-1}$ are the coordinates of the common point of intersection. The points of intersection can be in the third quadrant (Figure 3–4B,F) or the second quadrant.

Explanation: If one assumes that both reactant A and reactant B add to the enzyme before any products dissociate, that all steps preceding the realization of the resulting **ternary complex** (E·A·B) are reversible, that reactant A binds first to the enzyme followed by reactant B, and that products Y and Z dissociate from the active site in that order, then

$$\begin{aligned} E + A + B &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A + B \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} E{\cdot}A{\cdot}B \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \\ E{\cdot}Z{\cdot}Y &\xrightarrow{k_4} E{\cdot}Z + Y \xrightarrow{k_5} E + Y + Z \end{aligned} \quad (3\text{–}109)$$

The steps governed by rate constants k_4 and k_5 are formally irreversible because products Y and Z, respectively, dissociate during these steps and neither Y nor Z is present at initial times. The initial rate of the reaction is

$$v_0 = \frac{d[Z]}{dt} = \frac{d[Y]}{dt} = k_5 [E{\cdot}Z] \quad (3\text{–}110)$$

The principle of conservation of enzyme states that

$$[E]_t = [E] + [E{\cdot}A] + [E{\cdot}A{\cdot}B] + [E{\cdot}Z{\cdot}Y] + [E{\cdot}Z] \quad (3\text{–}111)$$

which is one of the simultaneous equations needed. As there are five unknowns, four other simultaneous equations are required. They are the four steady-state equations

$$k_1[E][A]_0 + k_{-2}[E{\cdot}A{\cdot}B] = (k_{-1} + k_2[B]_0)[E{\cdot}A] \quad (3\text{–}112)$$

$$k_2[E{\cdot}A][B]_0 + k_{-3}[E{\cdot}Z{\cdot}Y] = (k_{-2} + k_3)[E{\cdot}A{\cdot}B] \quad (3\text{–}113)$$

$$k_3[E{\cdot}A{\cdot}B] = (k_{-3} + k_4)[E{\cdot}Z{\cdot}Y] \quad (3\text{–}114)$$

and

$$k_4[E{\cdot}Z{\cdot}Y] = k_5[E{\cdot}Z] \quad (3\text{–}115)$$

Solving these five equations for [E·A·B] and entering that expression into Equation 3–110 gives a solution that has the form of Equation 3–95

$$v_0 = \frac{k_0 k_A k_B k_{AB} [E]_t [A]_0 [B]_0}{k_0 k_A k_B + k_0 k_A k_{AB} [A]_0 + k_0 k_B k_{AB} [B]_0 + k_A k_B k_{AB} [A]_0 [B]_0} \quad (3\text{–}116)$$

with*

$$k_0 = \frac{k_3 k_4 k_5}{k_3 k_4 + k_3 k_5 + k_{-3} k_5 + k_4 k_5} \quad (3\text{–}117)$$

$$k_B = \frac{k_2 k_3 k_4}{k_{-2} k_{-3} + k_{-2} k_4 + k_3 k_4} \quad (3\text{–}118)$$

$$k_A = k_1 \quad (3\text{–}119)$$

$$k_{AB} = \frac{k_1 k_2 k_3 k_4}{k_{-1}(k_{-2} k_{-3} + k_{-2} k_4 + k_3 k_4)} \quad (3\text{–}120)$$

Consequently, the kinetic mechanism in Equation 3–109 is consistent with the behavior that is observed.

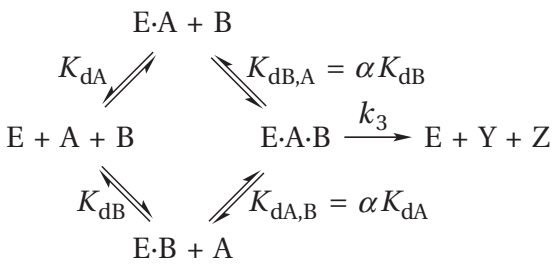
Again, there is an array of **expanded kinetic mechanisms**, each of which is also consistent with the observed behavior. As before, the introduction of steps after both A and B have been bound to the active site but before the competent ternary complex E·A·B has been formed produces expanded kinetic mechanisms consistent with the observations. The introduction of reversible steps between the association of A with the active site and the association of B with the active site—or the introduction of reversible steps between the conversion of E·A·B to E·Z·Y and release of products from the active site—also produces expanded kinetic mechanisms consistent with the observations for the same reason:

*The following four empirical rate constants, k_0, k_A, k_B, and k_{AB}, are extracted by taking, in turn, the four double limits (Equations 3–100 to 3–103) of the complete equation derived from the five independent simultaneous equations (Equations 3–111 to 3–115).

namely, that composite rate constants are usually indistinguishable from elementary rate constants by simple steady-state kinetics. Because of this fact that composite rate constants for a series of steps, none of which involves the entry or exit of a substrate to or from the active site of the enzyme, are indistinguishable from elementary rate constants, **steady-state kinetics alone based on initial rates can provide information only about entry of substrates from the solution into the active site or exit of substrates to the solution from the active site**. If a reactant must associate with the active site of the enzyme during the reaction, experimental variation of the concentration of that reactant will usually affect the observed initial rate for an enzymatic reaction by the relation of Equation 3–40.

There are, however, substantively different kinetic mechanisms that are also consistent with the observations. In particular, **the order in which A and B add to the active site of the enzyme cannot be distinguished** by observation of initial rates for the enzymatic reaction in which only $[A]_0$ and $[B]_0$ are varied. This ambiguity is due to the fact that $[A]_0$ and $[B]_0$ appear interchangeably in Equation 3–95. Because Equation 3–95 is the only relation defined by the experimental observations, the experimental observations cannot distinguish which reactant, A or B, associates first with the enzyme.

It also happens that the rate equation has the form of Equation 3–95 if the **association of reactants A and B is random** and each association of a reactant is at equilibrium in an **equilibrium-random mechanism**



(3–121)

where K_{dA} and K_{dB} are the dissociation constants for reactant A and reactant B from the unoccupied enzyme, $K_{dA,B}$ is the dissociation constant for reactant A from the enzyme occupied by reactant B, and $K_{dB,A}$ is the dissociation constant for reactant B from the enzyme occupied by reactant A. This equation defines an equilibrium-random kinetic mechanism. It states that the rates of the associations and the dissociations of the reactants with the active site are all significantly greater than the conversion of reactants to products on the active site.

The equilibrium constants for Equation 3–121 are related to each other by the **linkage equations**

$$K_{dA} K_{dB,A} = K_{dB} K_{dA,B} \tag{3–122}$$

$$K_{dB,A} = \frac{K_{dA,B}}{K_{dA}} K_{dB} = \alpha K_{dB} \tag{3–123}$$

and

$$K_{dA,B} = \frac{K_{dA,B}}{K_{dA}} K_{dA} = \alpha K_{dA} \tag{3–124}$$

Consequently

$$[E] = \left(\frac{\alpha K_{dB} K_{dA}}{[A]_0 [B]_0}\right)[E{\cdot}A{\cdot}B] \tag{3–125}$$

$$[E{\cdot}A] = \left(\frac{\alpha K_{dB}}{[B]_0}\right)[E{\cdot}A{\cdot}B] \tag{3–126}$$

$$[E{\cdot}B] = \left(\frac{\alpha K_{dA}}{[A]_0}\right)[E{\cdot}A{\cdot}B] \tag{3–127}$$

and, from the conservation of enzyme

$$[E]_t = [E] + [E{\cdot}A] + [E{\cdot}B] + [E{\cdot}A{\cdot}B] \tag{3–128}$$

These four equations together give

$$v_0 = \frac{k_3 [E]_t [A]_0 [B]_0}{\alpha K_{dA} K_{dB} + \alpha K_{dB} [A]_0 + \alpha K_{dA} [B]_0 + [A]_0 [B]_0} \tag{3–129}$$

Taking the double limits of both Equation 3–95 and Equation 3–129

$$\lim_{\substack{[A]_0 \to \infty \\ [B]_0 \to \infty}} v_0 = k_0 [E]_t = k_3 [E]_t \tag{3–130}$$

$$\lim_{\substack{[A]_0 \to \infty \\ [B]_0 \to 0}} v_0 = k_B [E]_t [B]_0 = \frac{k_3 [E]_t [B]_0}{\alpha K_{dB}} \tag{3–131}$$

$$\lim_{\substack{[A]_0 \to 0 \\ [B]_0 \to \infty}} v_0 = k_A [E]_t [A]_0 = \frac{k_3 [E]_t [A]_0}{\alpha K_{dA}} \tag{3–132}$$

$$\lim_{\substack{[A]_0 \to 0 \\ [B]_0 \to 0}} v_0 = k_{AB} [E]_t [A]_0 [B]_0 = \frac{k_3 [E]_t [A]_0 [B]_0}{\alpha K_{dA} K_{dB}} \tag{3–133}$$

Because over the period of time in which initial rates are measured, the initial concentrations of the reactants are constant, any kinetic mechanism used to derive a rate equation for an initial rate of an enzymatic reaction can be treated as a sequence of steps, the individual rate constants of the forward and reverse reactions of which are both simple first-order rate constants and pseudo-first-order rate constants. This is the case regardless of which steps involve association of substrates with the active site of the enzyme or dissociation of substrates from the active site of the enzyme. For example, if the kinetic mechanism in Equation 3–109 is modified by two steps to add an isomerization of the enzyme and to make the dissociation of the first product the rate-limiting step, rather than the dissociation of the second, then

$$\begin{aligned} E \underset{k_{-3}}{\overset{k_3[A]_0}{\rightleftharpoons}} E{\cdot}A \underset{k_{-4}}{\overset{k_4[B]_0}{\rightleftharpoons}} E{\cdot}A{\cdot}B \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} E'{\cdot}A{\cdot}B \\ \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} E{\cdot}Z{\cdot}Y \xrightarrow{k_7} E + Y + Z \end{aligned} \tag{3–134}$$

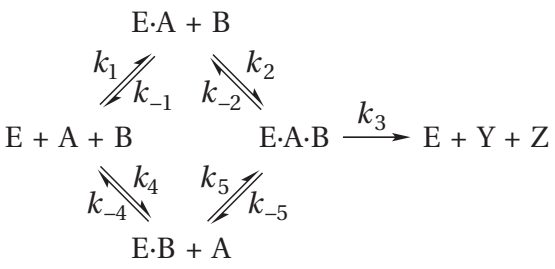
If Equation 3–84 is rewritten in the same way, then

$$\begin{aligned} E \underset{k_{-3}}{\overset{k_3[A]_0}{\rightleftharpoons}} E{\cdot}A \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} E'{\cdot}A \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} E'{\cdot}A' \\ \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} E{\cdot}Z \xrightarrow{k_7} E + Z \end{aligned} \tag{3–135}$$

Because the concentrations of reactants by definition remain constant at their initial values during the measurement of initial rates for an enzymatic reaction, the terms in these two kinetic mechanisms involving concentrations, such as $k_2[B]_0$ and $k_1[A]_0$, are pseudo-first-order rate constants that are formally equivalent to the normal first-order rate constants. In this sense, these two kinetic mechanisms are mathematically equivalent. Therefore, if reactant B is held at a fixed concentration, both should give equations for v_0 as a function of $[A]_0$ of the form of Equation 3–40.

This simplification that permits every kinetic mechanism for the initial rate of an enzymatic reaction to be written as a **series of first-order steps** has been exploited by King and Altman.[82,83] These investigators have formulated a series of rules by which an expression for v_0 can be obtained systematically from complicated kinetic mechanisms that have several reactants, several products, many steps, branching paths, coalescing paths, or several or all of these features. It is worth the time necessary to learn this system if one is required to derive rate equations for many long and complicated kinetic mechanisms. Most investigators, however, are only required to calculate initial rates for a few kinetic mechanisms, and these calculations can usually be performed without spending the time necessary to learn rather complicated general methods.

Because of Equations 3–121 and 3–129, one might imagine that the kinetic mechanism for the **steady-state random bimolecular association** of the two reactants



(3–136)

in which k_1 and k_5 are both first-order functions of $[A]_0$ and k_2 and k_4 are both first-order functions of $[B]_0$, would also give a kinetic rate equation consistent with Equation 3–95, but it does not. The rate equation for this kinetic mechanism, as derived by the method of King and Altman,[82] is

$$v_0 = \frac{a[\mathrm{A}]_0[\mathrm{B}]_0 + b[\mathrm{A}]_0[\mathrm{B}]_0^2 + c[\mathrm{A}]_0^2[\mathrm{B}]_0}{d + e[\mathrm{B}]_0 + f[\mathrm{B}]_0^2 + g[\mathrm{A}]_0 + h[\mathrm{A}]_0^2 + i[\mathrm{A}]_0[\mathrm{B}]_0 + j[\mathrm{A}]_0[\mathrm{B}]_0^2 + l[\mathrm{A}]_0^2[\mathrm{B}]_0} \quad (3\text{–}137)$$

where the parameters a through l are sums of the products of rate constants (Table 3–1).[84]

The reasons for the quadratic terms in Equation 3–137 are that the forms of the enzyme are not in rapid equilibrium with each other and that there are **two routes to the ternary complex** E·A·B. As the initial concentration of A is increased at a fixed initial concentration of B, the route in which A associates first with the enzyme becomes more dominant, and as the initial concentration of B is increased at a fixed initial concentration of A, the route in which B associates first with the enzyme becomes more dominant. At low initial concentrations of A and a fixed concentration of B, most of the flux goes on the path along which B binds first, and at high concentrations of A and the same fixed concentration of B, most of the flux goes on the path along which A associates first. The rate of flux on the two paths is almost always different, so increasing concentrations of A can cause the reaction to go either faster than the rate defined by Equation 3–95, leading to activation of the enzymatic rate by increasing concentrations of reactant A, or slower than the rate defined by Equation 3–95, leading to inhibition of the enzymatic rate by increasing concentrations of reactant A.[85]

Such **activation by a reactant or inhibition by a reactant** is observed frequently and may result from the consequences of this kinetic mechanism. It is probably often the case, however, that only one of the two routes in this kinetic mechanism dominates in the range of initial concentrations chosen, so the behavior observed is actually that of the kinetic mechanism of Equation 3–109. In fact, initial concentrations of reactants are often chosen to avoid activation or inhibition observed at higher concentrations of the reactants. The usual application of this habit suggests that the kinetic mechanism of Equation 3–136 may be more common than it seems to be. If it actually is fairly common, most of the conclusions drawn from inhibitors that are analogues of the reactants and from product inhibition that are about to be discussed may be misleading.

One should note that when k_{-3} is zero and k_4 and k_5 are both much larger than k_3 in the kinetic mechanism of Equation 3–109, it becomes a special case of the kinetic mechanism of Equation 3–136 in which the lower route actually is or has been assumed by the author to be kinetically nonexistent. When $k_4 = 0$ and $k_{-5} = 0$ in the kinetic mechanism of Equation 3–136 and when k_{-3} is zero and k_4 and k_5 are both much larger than k_3 in the kinetic mechanism of Equation 3–109, Equation 3–137 becomes Equation 3–95, as it must because, under these circumstances, the two kinetic mechanisms have become the same kinetic mechanism. This realization reinforces the point that it may be even more difficult to prove that all the flux in an enzymatic reaction proceeds through only one of the routes in the kinetic mechanism of Equation 3–136.

Table 3–1: Combinations of Rate Constants in Equation 3–136 that Define[82] the Parameters in Equation 3–137

$a = k_1k_2k_3k_{-4} + k_{-1}k_3k_4k_5$
$b = k_2k_3k_4k_5$
$c = k_1k_2k_3k_5$
$d = k_{-1}k_{-2}k_{-4} + k_{-1}k_{-4}k_{-5} + k_{-1}k_3k_{-4}$
$e = k_{-1}k_{-2}k_4 + k_{-1}k_4k_{-5} + k_{-1}k_3k_4 + k_2k_{-4}k_{-5} + k_2k_3k_{-4}$
$f = k_2k_4k_{-5} + k_2k_3k_4$
$g = k_1k_{-2}k_{-4} + k_1k_{-4}k_{-5} + k_1k_3k_{-4} + k_{-1}k_{-2}k_5 + k_{-1}k_3k_5$
$h = k_1k_{-2}k_5 + k_1k_3k_5$
$i = k_1k_2k_{-4} + k_{-1}k_4k_5 + k_1k_2k_{-5} + k_{-2}k_4k_5 + k_2k_3k_5$
$j = k_2k_4k_5$
$l = k_1k_2k_5$

Other than proving that the proposed kinetic mechanism is consistent with the observed behavior, the purpose of deriving a rate equation is to facilitate the **assignment of numerical values to the elementary rate constants and the composite rate constants** explicitly defined by that proposed kinetic mechanism. The complexity of the rate law (Equation 3–137 and Table 3–1) for Equation 3–136 indicates the difficulties of this endeavor for even as simple a kinetic mechanism as that for steady-state random bimolecular association. Theoretically, if each of the parameters a through l in Equation 3–137 could be obtained experimentally, one would have 11 equations (Table 3–1) with only 9 unknowns, the individual rate constants k_i, and numerical values for each of them could be calculated. This calculation, however, would require detailed measurements of the inhibition or activation that occurs at high concentrations of the reactants. Such systematic and detailed studies of the kinetics of any enzyme that proceeds by the kinetic mechanism of Equation 3–136 have probably not been performed. The difficulties of obtaining numerical values of the rate constants only increase for more complex steady-state kinetic mechanisms with more than two routes to the complex that produces products.

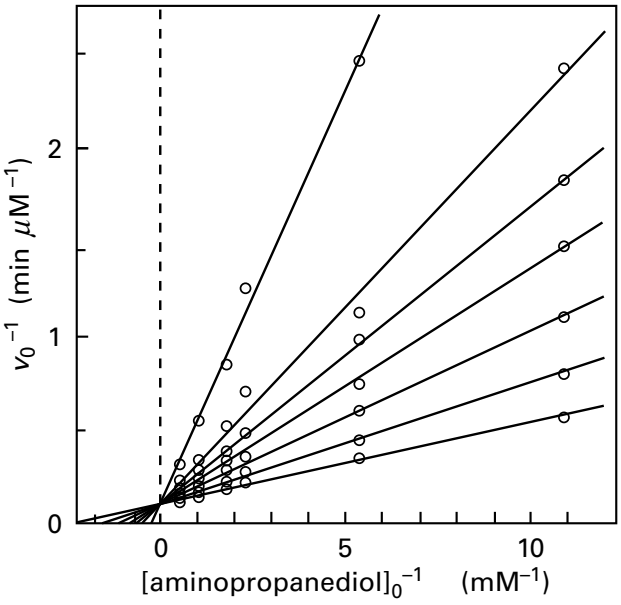


Figure 3–7: Kinetics for the phosphorylation of (*S*)-1-aminopropane-2,3-diol catalyzed by glycerol kinase from *C. mycoderma*.[86] Solutions were prepared that contained $MgATP^{2-}$ and (*S*)-1-aminopropane-2,3-diol at various concentrations at pH 9.4 and 25 °C. The concentration of uncomplexed Mg^{2+} was fixed at 7 mM throughout. Each phosphorylation was initiated by adding glycerol kinase, and the production of $MgADP^-$ was followed over the first few minutes in a coupled assay with phospho*enol*pyruvate, pyruvate kinase, dihydronicotinamide-adenine dinucleotide, and L-lactate dehydrogenase by monitoring the decrease in A_{340} from the conversion of NADH into NAD^+. Each initial rate of change in A_{340} was converted to an initial rate for the production of $MgADP^-$, v_0 (micromolar minute^{-1}). Reciprocals of the initial rates (minutes micromolar^{-1}) are presented as a function of reciprocals of the initial concentrations of (*S*)-1-aminopropane-2,3-diol (millimolar^{-1}) at fixed concentrations of $MgATP^{2-}$ (for the lines in descending order) of 0.13, 0.25, 0.37, 0.50, 0.76, 1.26, and 2.52 mM.

Kinetic Mechanisms for Two Reactants: Double Reciprocals Intersecting at the Axis of the Ordinate

Observation: An interesting and informative special case of Equation 3–95, which has been occasionally observed, is that in which the term $\boldsymbol{k_0 k_B k_{AB}[B]_0}$ **is missing from the denominator** and the empirical equation defining the behavior has become

$$v_0 = \frac{k_0 k_B k_{AB} [E]_t [A]_0 [B]_0}{k_0 k_B + k_0 k_{AB} [A]_0 + k_B k_{AB} [A]_0 [B]_0} \quad (3\text{–}138)$$

In this instance, unlike the more frequently encountered general case, the observations do distinguish between reactants A and B; the initial concentration of one of them does not have a term in the denominator. Because

$$\lim_{[B]_0 \to \infty} v_0 = k_0 [E]_t \quad (3\text{–}139)$$

has no terms in $[A]_0$, unlike the limit (Equation 3–98) for Equation 3–95, the curves for v_0 as a function of $[B]_0$ all converge to the same value for v_0 as $[B]_0$ is increased, regardless of the fixed concentration of reactant A. Consequently, the lines for the reciprocals of the initial rate as a function of the reciprocals of the initial concentrations of reactant B intersect at the axis of the ordinate because the term $(k_A[E]_t[A]_0)^{-1}$ is missing from Equation 3–105. This type of behavior is observed for the kinetics of glycerol kinase from *Candida norvegensis* (Figure 3–7)[86] when this enzyme phosphorylates (*S*)-1-aminopropane-2,3-diol

$$\begin{aligned}&(S)\text{-1-aminopropane-2,3-diol} + \\ &MgATP^{2-} \rightleftharpoons MgADP^- + \\ &\quad (S)\text{-}N\text{-phosphono-1-aminopropane-2,3-diol}\end{aligned} \quad (3\text{–}140)$$

Explanation: A simple kinetic mechanism consistent with this behavior is the **equilibrium-ordered mechanism with ordered association of reactants**

$$\begin{array}{l} \mathrm{E + A + B} \underset{K_{dA}}{\rightleftharpoons} \mathrm{E{\cdot}A + B} \underset{K_{dB,A}}{\rightleftharpoons} \mathrm{E{\cdot}A{\cdot}B} \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad \Big\downarrow k_3 \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad \mathrm{E + Y + Z} \end{array} \qquad (3\text{–}141)$$

where K_{dA} is the dissociation constant for reactant A from the unoccupied enzyme and $K_{dB,A}$ is the dissociation constant for reactant B from the enzyme occupied by reactant A. When the kinetic mechanism is written in this way, the author states that both the association of reactant A with the enzyme and the association of reactant B with the complex between enzyme and reactant A reach equilibrium so rapidly that the various complexes and free reactants are in equilibrium during the entire reaction. As before, in such an equilibrium kinetic mechanism, the steady-state approximations are unnecessary; the dissociation constants themselves provide the necessary relations

$$K_{dA} = \frac{[E][A]_0}{[E{\cdot}A]} \qquad (3\text{–}142)$$

$$K_{dB,A} = \frac{[E{\cdot}A][B]_0}{[E{\cdot}A{\cdot}B]} \qquad (3\text{–}143)$$

Upon rearrangement, these equilibria can be substituted into a shortened version of Equation 3–111 in which k_3 in the kinetic mechanism of Equation 3–109 is the rate-limiting step so that [E·Z·Y] and [E·Z] are zero. The resulting kinetic equation

$$v_0 = \frac{k_3[E]_t[A]_0[B]_0}{K_{dA}K_{dB,A} + K_{dB,A}[A]_0 + [A]_0[B]_0} \qquad (3\text{–}144)$$

has the same form as Equation 3–138. As before, taking the limits of Equation 3–138 and Equation 3–144

$$\lim_{\substack{[A]_0 \to \infty \\ [B]_0 \to \infty}} v_0 = k_0[E]_t = k_3[E]_t \qquad (3\text{–}145)$$

$$\lim_{\substack{[A]_0 \to \infty \\ [B]_0 \to 0}} v_0 = k_B[E]_t[B]_0 = \frac{k_3[E]_t[B]_0}{K_{dB,A}} \qquad (3\text{–}146)$$

$$\lim_{[A]_0 \to 0} v_0 = k_{AB}[E]_t[A]_0[B]_0 = \frac{k_3[E]_t[A]_0[B]_0}{K_{dA}K_{dB,A}} \qquad (3\text{–}147)$$

If glycerol kinase proceeds by the kinetic mechanism of Equation 3–141, $MgATP^{2-}$ must bind to the active site before (*S*)-1-aminopropane-2,3-diol.

Kinetic Mechanisms for Two Reactants: Double Reciprocals Parallel to Each Other

Observation: The observed kinetics of an enzyme with two reactants are defined by another special case of Equation 3–95, that in which the term $k_0k_Ak_B$ **is missing from the denominator** and the empirical equation has become

$$v_0 = \frac{k_0k_Ak_B[E]_t[A]_0[B]_0}{k_0k_A[A]_0 + k_0k_B[B]_0 + k_Ak_B[A]_0[B]_0} \qquad (3\text{–}148)$$

This relation is found, for example, with the kinetics of ovine 3-oxoacid CoA-transferase (Figure 3–8)[87-89]

$$\mathrm{acetoacetyl\text{-}SCoA + succinate} \rightleftharpoons \mathrm{acetoacetate + succinyl\text{-}SCoA} \qquad (3\text{–}149)$$

Two of the limits for Equation 3–148 are

$$\lim_{[A]_0 \to 0} v_0 = k_A[E]_t[A]_0 \qquad (3\text{–}150)$$

and

$$\lim_{[B]_0 \to 0} v_0 = k_B[E]_t[B]_0 \qquad (3\text{–}151)$$

Consequently, the **initial slopes** of the functions describing v_0 as a function of either $[A]_0$ or $[B]_0$ are no longer functions of $[B]_0$ or $[A]_0$, respectively, as they were before (Equations 3–97 and 3–99) and are now all the same for all concentrations of the fixed reactant, either $k_A[E]_t$ (Figure 3–8A) or $k_B[E]_t$ (Figure 3–8C).

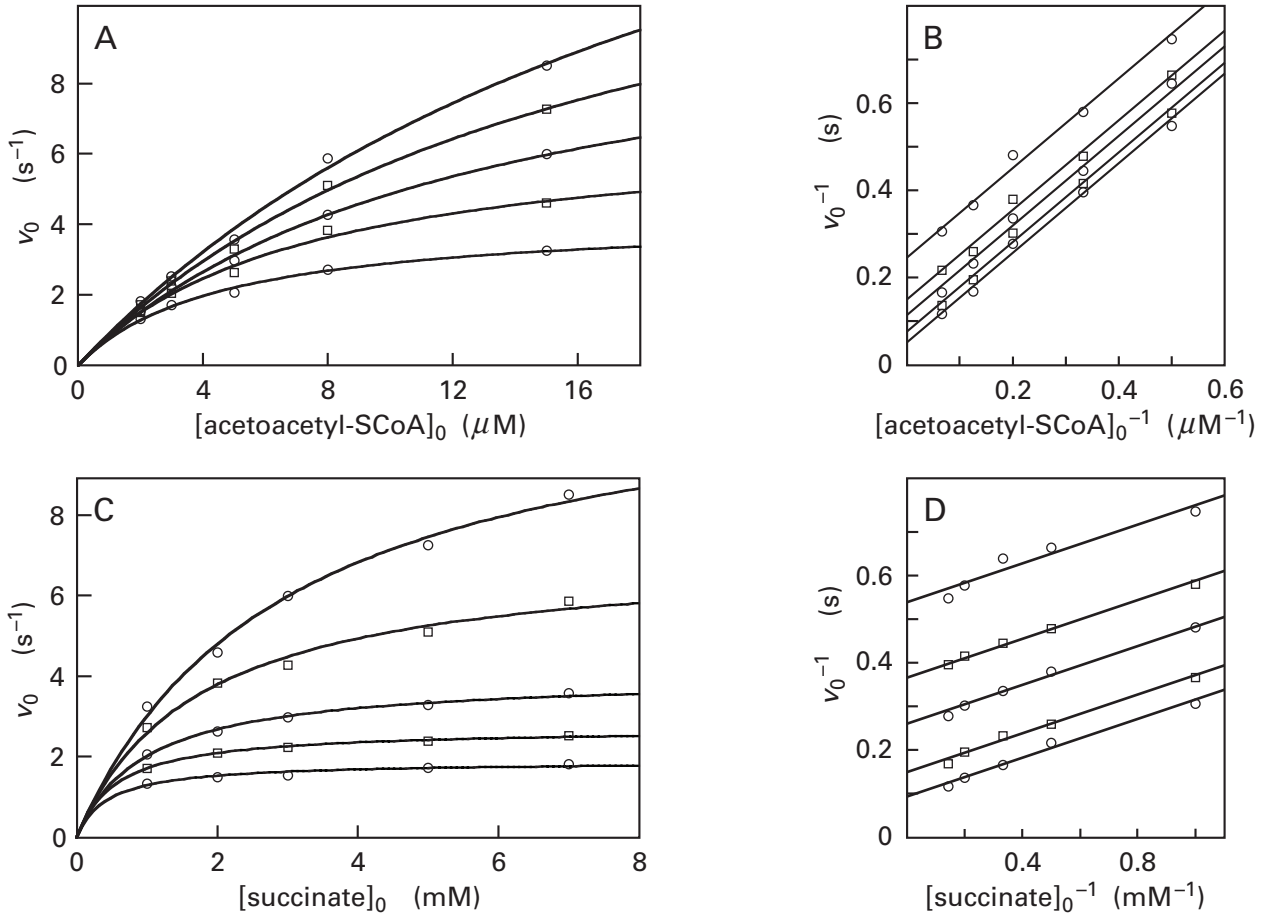

Figure 3–8: Kinetics for the transesterification catalyzed by 3-oxoacid CoA-transferase from ovine kidney.[87] Solutions containing 25 mM Mg^{2+} and various concentrations of acetoacetyl-SCoA and succinate were prepared at pH 8.1 and 30 °C. Each transesterification was initiated by adding purified 3-oxoacid CoA-transferase[88] to the mixture. The initial rate of each reaction was determined by monitoring the absorbance at 303 nm of the acetoacetyl-SCoA being lost as the transesterification proceeded. With the extinction coefficient for acetoacetyl-SCoA, the initial rate of each transesterification could be converted to micromoles of acetoacetyl-SCoA consumed $minute^{-1}$. With the molar mass of enzyme for each active site (51,000 g mol^{-1}),[89] the micromoles of acetoacetyl-SCoA $minute^{-1}$ (mg of enzyme)$^{-1}$ can be converted to the units of micromoles of acetoacetyl-SCoA $second^{-1}$ (micromole of 3-oxoacid CoA-transferase)$^{-1}$. The initial concentrations of acetoacetyl-SCoA chosen for the studies were 2, 3, 5, 8, and 15 μM, and the initial concentrations of succinate were 1, 2, 3, 5, and 7 mM. The complete set of the 25 combinations of these initial concentrations was used to measure 25 separate initial rates. **(A)** Initial rates ($second^{-1}$) are presented as a function of initial concentrations of acetoacetyl-SCoA at the five fixed concentrations of succinate, in order of ascent. The lines drawn are fits of Equation 3–52 to the data with x equal to [acetoacetyl-SCoA]$_0$ and y equal to v_0. The five values for parameter c of the fits (initial slopes of the five rectangular hyperbolae) deviated from each other at random, and the standard deviation of their mean was less than the standard deviations of each individual value. It was concluded that they all had the same value, 1.28 ± 0.05 s^{-1} (μM acetoacetyl-SCoA)$^{-1}$. **(B)** Reciprocals of the same initial rates (seconds) are plotted as a function of reciprocals of the initial concentrations of acetoacetyl-SCoA ($millimolar^{-1}$) at the five fixed initial concentrations of succinate. The slopes of the five lines fit separately to the data were the same within experimental error. Each line drawn in the figure has as its slope the mean of the five slopes of the individually fit lines. **(C)** Initial rates ($second^{-1}$) are presented as a function of initial concentrations of succinate at the five fixed concentrations of acetoacetyl-SCoA. The curves drawn are fits of Equation 3–52 to the data with x equal to [succinate]$_0$ and y equal to v_0. The initial slopes of the five rectangular hyperbolae (parameters c of the fits) were the same, 5.81 ± 0.37 s^{-1} (mM succinate)$^{-1}$, within experimental error. **(D)** Reciprocals of the same initial rates (seconds) are plotted as a function of reciprocals of the initial concentrations of succinate ($millimolar^{-1}$) at the five fixed initial concentrations of acetoacetyl-SCoA. The slopes of the five lines fit separately to the data were the same within experimental error. Each line drawn in the figure has as its slope the mean of the five slopes of the individually fit lines.

Because

$$\frac{1}{v_0} = \frac{1}{k_B[E]_t[B]_0} + \frac{1}{k_A[E]_t[A]_0} + \frac{1}{k_0[E]_t} \tag{3–152}$$

when A is the varied reactant and B is the fixed reactant

$$\frac{1}{v_0} = \left(\frac{1}{k_A[E]_t}\right)\frac{1}{[A]_0} + \left(\frac{k_0[E]_t + k_B[E]_t[B]_0}{k_0[E]_t k_B[E]_t[B]_0}\right) \tag{3–153}$$

and all the lines defining v_0^{-1} as a function of $[A]_0^{-1}$ have the same slope and are parallel (Figure 3–8B) Because of the symmetry of Equation 3–148, the same is true when B is the varied reactant and A is the fixed reactant (Figure 3–8D).

Explanation: A simple kinetic mechanism consistent with this behavior is

$$\begin{aligned} E + A + B &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A + B \xrightarrow{k_2} E'{\cdot}A + B \\ &\underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E'{\cdot}A{\cdot}B \xrightarrow{k_4} E + Y + Z \end{aligned} \tag{3–154}$$

in which the second step is kinetically irreversible. A **kinetically irreversible step** is a step in which the rate of the back reaction is so slow that it can have no effect on the kinetics of the overall reaction. Because, at steady state, the flux through the two kinetically irreversible steps must be equal

$$v_0 = \frac{d[Z]}{dt} = k_2[E{\cdot}A] = k_4[E'{\cdot}A{\cdot}B] \tag{3–155}$$

Using this equation, the equation for conservation of enzyme, and two steady-state equations, it can be shown that

$$v_0 = \frac{k_1 k_2 k_3 k_4 [E]_t [A]_0 [B]_0}{k_1 k_2 (k_{-3} + k_4)[A]_0 + k_3 k_4 (k_{-1} + k_2)[B]_0 + k_1 k_3 (k_2 + k_4)[A]_0[B]_0} \tag{3–156}$$

which has the form of Equation 3–148 and thus explains the observations. Consequently, if there is a kinetically irreversible step between the association of the first reactant with the enzyme and the association of the second reactant with the enzyme, the kinetics of the enzyme will display this behavior. As before, taking the limits of Equation 3–148 and Equation 3–156

$$\lim_{\substack{[A]_0 \to \infty \\ [B]_0 \to \infty}} v_0 = k_0[E]_t = \frac{k_2 k_4}{k_2 + k_4}[E]_t \tag{3–157}$$

$$\lim_{\substack{[A]_0 \to \infty \\ [B]_0 \to 0}} v_0 = k_B[E]_t[B]_0 = \frac{k_3 k_4}{k_{-3} + k_4}[E]_t[B]_0 \tag{3–158}$$

$$\lim_{\substack{[A]_0 \to 0 \\ [B]_0 \to \infty}} v_0 = k_A[E]_t[A]_0 = \frac{k_1 k_2}{k_{-1} + k_2}[E]_t[A]_0 \tag{3–159}$$

This kinetic mechanism is called a **ping-pong mechanism** because the enzyme oscillates between two forms, E and E′·A, each separated from the other by a respective irreversible step, and each form has the same pattern of rate constants relating it to the other form. This symmetry of the ping-pong mechanism is reflected in the symmetry of the pattern in which the rate constants appear in Equations 3–156 through 3–159.

One particular explanation for the existence of a kinetically irreversible step between the association of reactant A with the enzyme and the association of reactant B with the enzyme is that **before reactant B associates, product Z dissociates** from the enzyme, leaving the remainder of reactant A, A′, bound to the enzyme

$$\begin{aligned} E + A + B &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A + B \xrightarrow{k_2} E{\cdot}A' + B + Z \\ &\underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E{\cdot}A'{\cdot}B + Z \xrightarrow{k_4} E + Y + Z \end{aligned} \tag{3–160}$$

Because there is no product Z in the solution during the initial period, the step involving its release is necessarily kinetically irreversible.

It has been demonstrated by mass spectrometry that sulfate adenylyltransferase (ADP) from *Thiobacillus denitrificans*, which transfers an adenylyl group from sulfate to phosphate

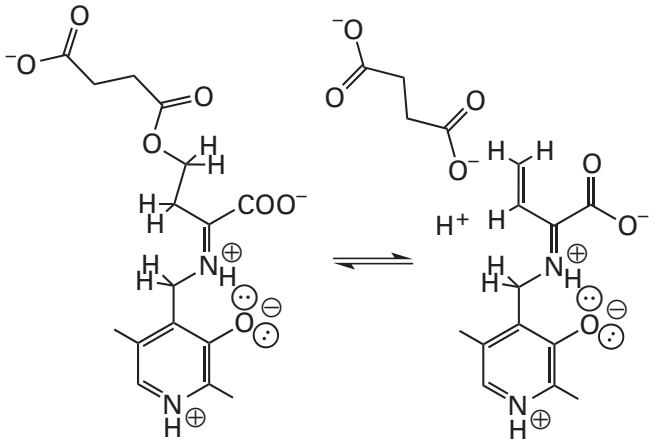
$$\text{magnesium adenosine 5′-phosphosulfate} + HOPO_3^{2-} \rightleftharpoons H^+ + SO_4^{2-} + MgADP^- \quad (3\text{–}161)$$

reacts with adenosine-5′-phosphosulfate to form an covalent adduct between the adenylyl group and the enzyme, from which sulfate, one of the products of the enzymatic reaction, must dissociate before phosphate, one of the reactants, can associate. Presumably the phosphate associates with the same location in the active site from which the sulfate has dissociated, and this sequence of events explains the parallel lines in plots of the double reciprocals of initial rate as a function of either the initial concentration of adenosine-5′-phosphosulfate or the initial concentration of phosphate at fixed initial concentrations of the other reactant, respectively.[90]

If the kinetically irreversible step is the release of the first product (Equation 3–160), **the release of that product must occur before the second reactant can associate** with the enzyme for the double reciprocals to be parallel. For example, L-cysteine can associate with cystathionine γ-synthase from *S. cerevisiae*

$$\textit{O}\text{-succinyl-L-homoserine} + \text{L-cysteine} \rightleftharpoons H^+ + \text{succinate} + \text{L-cystathionine} \quad (3\text{–}162)$$

before succinate dissociates from the adduct between *O*-succinyl-L-homoserine and pyridoxal phosphate (see Equations 2–32 and 2–34)



(3–163)

If the initial concentration of L-cysteine is low, however, the rate of its association is slower than the rate of dissociation of the succinate, and at low fixed initial concentrations of L-cysteine, the lines in a plot of the double reciprocals for the initial rates as a function of the initial concentrations of *O*-succinyl-L-homoserine are parallel. At higher concentrations of L-cysteine, its association becomes faster than the dissociation of succinate, and the double reciprocals at these higher concentrations intersect.[91] A similar switch from parallel double reciprocals to intersecting double reciprocals is observed in the kinetics of 1-deoxy-D-xylulose 5-phosphate synthase from *Rhodobacter capsulatus*.[92]

The dissociation of a product between the association of the first reactant and the association of the second reactant, however, is **not a necessary explanation for the existence of parallel double reciprocals**. Anything that causes the step between association of the first reactant and association of the second reactant to be kinetically irreversible will produce this behavior.

If there is a kinetically irreversible step between the association of reactant A and the association of reactant B, the lines in a plot of the double reciprocals are parallel to each other. If no products are present initially, the release of a product is, by definition of an initial rate, a kinetically irreversible step. Consequently, if the lines on a plot of the double reciprocals converge (Figure 3–4B,F), reactant A and reactant B must associate with the enzyme before any product dissociates. The complex between enzyme, unaltered reactant A, and unaltered reactant B (E·A·B) is a ternary complex, and **converging double reciprocals are considered to be evidence that a ternary complex is an intermediate** in the kinetic mechanism for the reaction.

There is another kinetic mechanism producing double reciprocals for the initial rates of an enzymatic reaction and the initial concentrations of a varied reactant that are parallel at various initial concentrations of a fixed reactant. This behavior is observed for the case in which reactant A is converted to product Z at one active site on the enzyme and the difference between A and Z—for example, an electron, a pair of electrons, or a carboxy group—is **transferred to another active site on the enzyme** to convert reactant B to product Y.[93] This mechanism is a fairly common one. For example, many enzymes engaged in electron transfer oxidize A to Z at one site, transfer the electron or electrons through a sequence of electron carriers, and then use those electrons to reduce B to Y. The enzyme methylmalonyl-CoA carboxytransferase removes a carboxy group from methylmalonyl-SCoA with biotin, transfers the carboxybiotin to another active site, and adds the carboxy group on that carboxybiotin to pyruvate. Both enzymes that transfer electrons between two active sites[94] and methylmalonyl-CoA carboxytransferase from *Propionibacterium freudenreichii* [93] have double reciprocals for which the lines, when one reactant is varied, are parallel at various fixed initial concentrations of the other reactant.

The kinetic constants governing the observed behavior of an enzymatic reaction in themselves have meaning. The catalytic constant k_0 is always a first-order rate constant (second^{-1}). The rate $k_0[E]_t$ is the product of a first-order rate constant and a concentration, and by definition it is the rate (molar second^{-1}) at which the enzymatic reaction proceeds at saturating concentrations of all the reactants at the particular concentration of enzyme. Depending on the kinetic mechanism thought to be consistent with the behavior of the enzymatic reaction, the catalytic constant k_0 can be a complex function of various rate constants for individual steps in that kinetic mechanism, but that complex function contains no terms in which any initial concentration appears. In all cases, the rate $k_0[E]_t$ is equal to the constant rate at which the enzymatic reaction proceeds as long as all reactants remain at saturation, and that rate is the fastest rate at which that particular concentration of enzyme can convert reactants to products. **The catalytic constant of the enzyme is the first-order rate constant for conversion of reactants free in solution to products free in solution** under conditions in which the enzymatic reaction is not limited by the rate of association of any of its reactants. It is not, however, necessarily the rate constant at which the assembled bound reactants are converted to assem-assembled bound products on the active site. There can be steps between the reactants free in solution and the unoccupied enzyme and this conversion, and there can be steps between this conversion and the complete dissociation of the products into the solution and the return of the enzyme to the unoccupied state prepared to associate with reactants.

When an enzyme converts a single reactant into one or more products, its observed initial rate is usually determined by only the catalytic constant k_0 and the specificity constant k_A for reactant A (Equation 3–40). The specificity constant k_A is a second-order rate constant with units of molar^{-1} second^{-1}. For the simplest kinetic mechanism (Equation 3–55), the specificity constant k_A is equal to $k_1[k_2(k_{-1} + k_2)^{-1}]$, which is the rate constant k_1 for the bimolecular association of E and A multiplied by a particular unitless fraction of rate constants, $k_2(k_2 + k_{-1})^{-1}$. This fraction is the fraction of the complex E·A that becomes product. Consequently, in this simple case, **the specificity constant is the rate constant for the formation of only those bimolecular associations between E and A that produce complexes that will be converted into product free in solution.** The specificity constant is the second-order "rate constant for the capture of…[reactant] into enzyme complexes that are destined to yield product…at some later time."[95]

It has been noted that the steps in the kinetic mechanism for an enzyme can be expanded indefinitely by adding steps that are not involved in the direct association of reactants and have no effect on the form of the rate law, only on the functions of the rate constants of the mechanism used to define the observed kinetic constants. For the expanded kinetic mechanism of Equation 3–84, the rate constants can be combined into the composite rate constants k_1 (Equation 3–77), k_{-1} (Equation 3–83), and k_2 (Equation 3–70). This combination reduces the expanded kinetic mechanism to that of Equation 3–55, for which the fraction of the complexes E′·A′ that becomes product is again $k_2(k_2 + k_{-1})^{-1}$, and

$$k_1\left(\frac{k_2}{k_{-1}+k_2}\right) = k_3\left(\frac{k_4k_5k_6k_7}{k_{-3}k_{-4}k_{-5}(k_{-6}+k_7)+k_5k_6k_7(k_{-3}+k_4)+k_{-3}k_{-4}k_6k_7}\right) \quad (3\text{–}164)$$

which is equal to the specificity constant k_A for reactant A in the rate equation for the kinetic mechanism of Equation 3–84. It follows that, regardless of the expansion performed to produce a kinetic mechanism, the specificity constant k_A will always be the product of the composite rate constant for the bimolecular association between enzyme and reactant A to produce the complex between enzyme and reactant A and the fraction of that complex destined to yield product.[72,95]

When an enzyme converts two reactants to one or more products, the initial rate of the reaction below saturation is determined by the catalytic constant k_0 and some combination of the specificity constants k_A, k_B,, and k_{AB} (Equation 3–95). For the ping-pong kinetic mechanism of Equation 3–154

$$k_A = k_1\left(\frac{k_2}{k_{-1}+k_2}\right) \quad (3\text{–}165)$$

which is again the rate constant for the bimolecular association of the unoccupied active site and reactant A multiplied by the fraction of the complex E·A that is destined to yield product. The same is true of k_B and reactant B. These simple expressions for the specificity constants k_A and k_B result from the fact that an irreversible step separates the association of reactant A and reactant B.

For the kinetic mechanism

$$\mathrm{E} + \mathrm{A} + \mathrm{B} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}A} + \mathrm{B} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{E{\cdot}A{\cdot}B} \xrightarrow{k_3} \mathrm{E} + \mathrm{Y} + \mathrm{Z} \quad (3\text{–}166)$$

with the rate equation

$$v_0 = \frac{k_1k_2k_3[\mathrm{E}]_t[\mathrm{A}]_0[\mathrm{B}]_0}{k_{-1}(k_{-2}+k_3)+k_1(k_{-2}+k_3)[\mathrm{A}]_0+k_2k_3[\mathrm{B}]_0+k_1k_2[\mathrm{A}]_0[\mathrm{B}]_0} \quad (3\text{–}167)$$

the apparent specificity constant for reactant A

$$k_{A,app} = \frac{k_1k_2[\mathrm{B}]_0k_3}{k_{-1}(k_{-2}+k_3)+k_2[\mathrm{B}]_0k_3} \quad (3\text{–}168)$$

which is equal to $k_1'[\mathrm{B}]_0k_3(k_3+k_{-1}')^{-1}$, where $k_1'[\mathrm{B}]_0$ is the composite second-order rate constant for formation of E·A·B from E and A at the fixed concentration of reactant B and k_{-1}' is the composite rate constant for dissociation of E·A·B to E and A. The apparent specificity constant for reactant B

$$k_{B,app} = k_2\left(\frac{k_1[\mathrm{A}]_0}{k_{-1}+k_1[\mathrm{A}]_0}\right)\left(\frac{k_3}{k_{-2}+k_3}\right) \quad (3\text{–}169)$$

where $k_3(k_{-2}+k_3)^{-1}$ is the fraction of ternary complexes E·A·B that proceed to free product, k_2 is the second-order rate constant for association of B and E·A, and $k_1[\mathrm{A}]_0(k_1[\mathrm{A}]_0+k_{-1})^{-1}$ is the fraction of complexes E and E·A that are E·A. In each of these instances, the observed value for $k_{A,app}$ or $k_{B,app}$ is the product of the second-order rate constant for formation of ternary complex E·A·B from the free version of the respective reactant and the unoccupied active site and the fraction of ternary complexes that produce product free in solution.

The initial rate of an enzymatic reaction is decreased by the addition of particular compounds to the solution that inhibit its activity, and an examination of the effect of such inhibitors on the initial rate of the enzymatic reaction can provide useful information about the kinetic mechanism.[96] An **inhibitor** is any chemical substance that, when added to the solution, decreases the initial rate of an enzymatically catalyzed reaction. **Reversible inhibitors** exert their effect by associating noncovalently and reversibly with the enzyme and, when associated, decrease or eliminate its ability to catalyze the reaction. When a reversible inhibitor is removed from the solution, its effect on the enzymatic reaction disappears or is reversed. Almost always, reversible inhibitors are used in steady-state kinetic studies of enzymatic reactions.

In the presence of only reactants, a kinetic mechanism for ordered addition of reactants (Equation 3–109) is indistinguishable from one for random addition of reactants (Equation 3–121) by steady-state kinetics. A kinetic mechanism in which an irreversible step is due to dissociation of a product (Equation 3–160) is indistinguishable from one in which an irreversible step is not due to dissociation of a product (Equation 3–154) by steady-state kinetics. These are two particular cases of the more general fact that studies of initial rates of an enzymatic reaction in the presence of only reactants cannot, in most cases, define **the order for either association of reactants with the enzyme or dissociation of products from the enzyme**. This information, however, can usually be obtained from studies of inhibition caused by analogues for the reactants and from studies of inhibition by products and analogues of products. To understand these strategies, the effects of inhibitors of enzymatic reactions on steady-state kinetics must first be explained.

Inhibition of Enzymatic Reactions: Definition of Types

Observation: A **competitive reversible inhibitor with respect to reactant A** is any reversible inhibitor the addition of which to the solution decreases the observed values of the specificity constant for reactant A, k_A, or the apparent specificity constant for reactant A, $k_{A,app}$, while having no effect on the value of the catalytic constant, k_0, or the apparent catalytic constant for reactant A, $k_{0,A,app}$, respectively (Figure 3–9A). The competitive inhibition is **linear** if the factor by which k_A, $k_A[E]_t$, $k_{A,app}$, or $k_{A,app}[E]_t$ is decreased is $K_{icI}([I] + K_{icI})^{-1}$, where [I] is the molar concentration of inhibitor I (Figure 3–9G). The constant K_{icI} is the **inhibition constant for competitive inhibition** by inhibitor I. An inhibitor I that is competitive with respect to reactant A is not necessarily competitive with respect to the other reactants in the enzymatic reaction.

In the general case, where only the initial concentration of reactant A and the concentration of inhibitor I are varied and the initial concentrations of all other reactants are fixed, the **observed initial rate for an enzymatic reaction upon addition of a linear competitive inhibitor** with respect to reactant A is

$$v_0 = \frac{k_{0,A,app}[E]_t k_{A,app}[E]_t \left(\frac{K_{icI}}{[I] + K_{icI}}\right)[A]_0}{k_{0,A,app}[E]_t + k_{A,app}[E]_t \left(\frac{K_{icI}}{[I] + K_{icI}}\right)[A]_0}$$

$$= \frac{k_{0,A,app}[E]_t[A]_0}{K_{mA,app}\left(\frac{[I] + K_{icI}}{K_{icI}}\right) + [A]_0} \qquad (3–170)$$

As the concentration of inhibitor I is increased, the apparent value of $k_{A,app}[E]_t$ decreases by the factor $K_{icI}([I] + K_{icI})^{-1}$. Consequently, the initial slopes of the curves of v_0 as a function of $[A]_0$ decrease by the same factor. Regardless of the concentration of inhibitor I, however, the asymptotes of all the curves at saturating $[A]_0$ are the same, and $v_0 = k_{0,A,app}$.

The values for v_0 (y) as a function of $[A]_0$ (x) at a fixed concentration of I are plotted and fit with Equation 3–52. This fit is repeated for all values of I. When the values for $k_{A,I,app}[E]_t$ (parameter c of the fit) obtained from these fits are plotted as a function of the concentration of inhibitor I, [I], the data can be fit by the equation

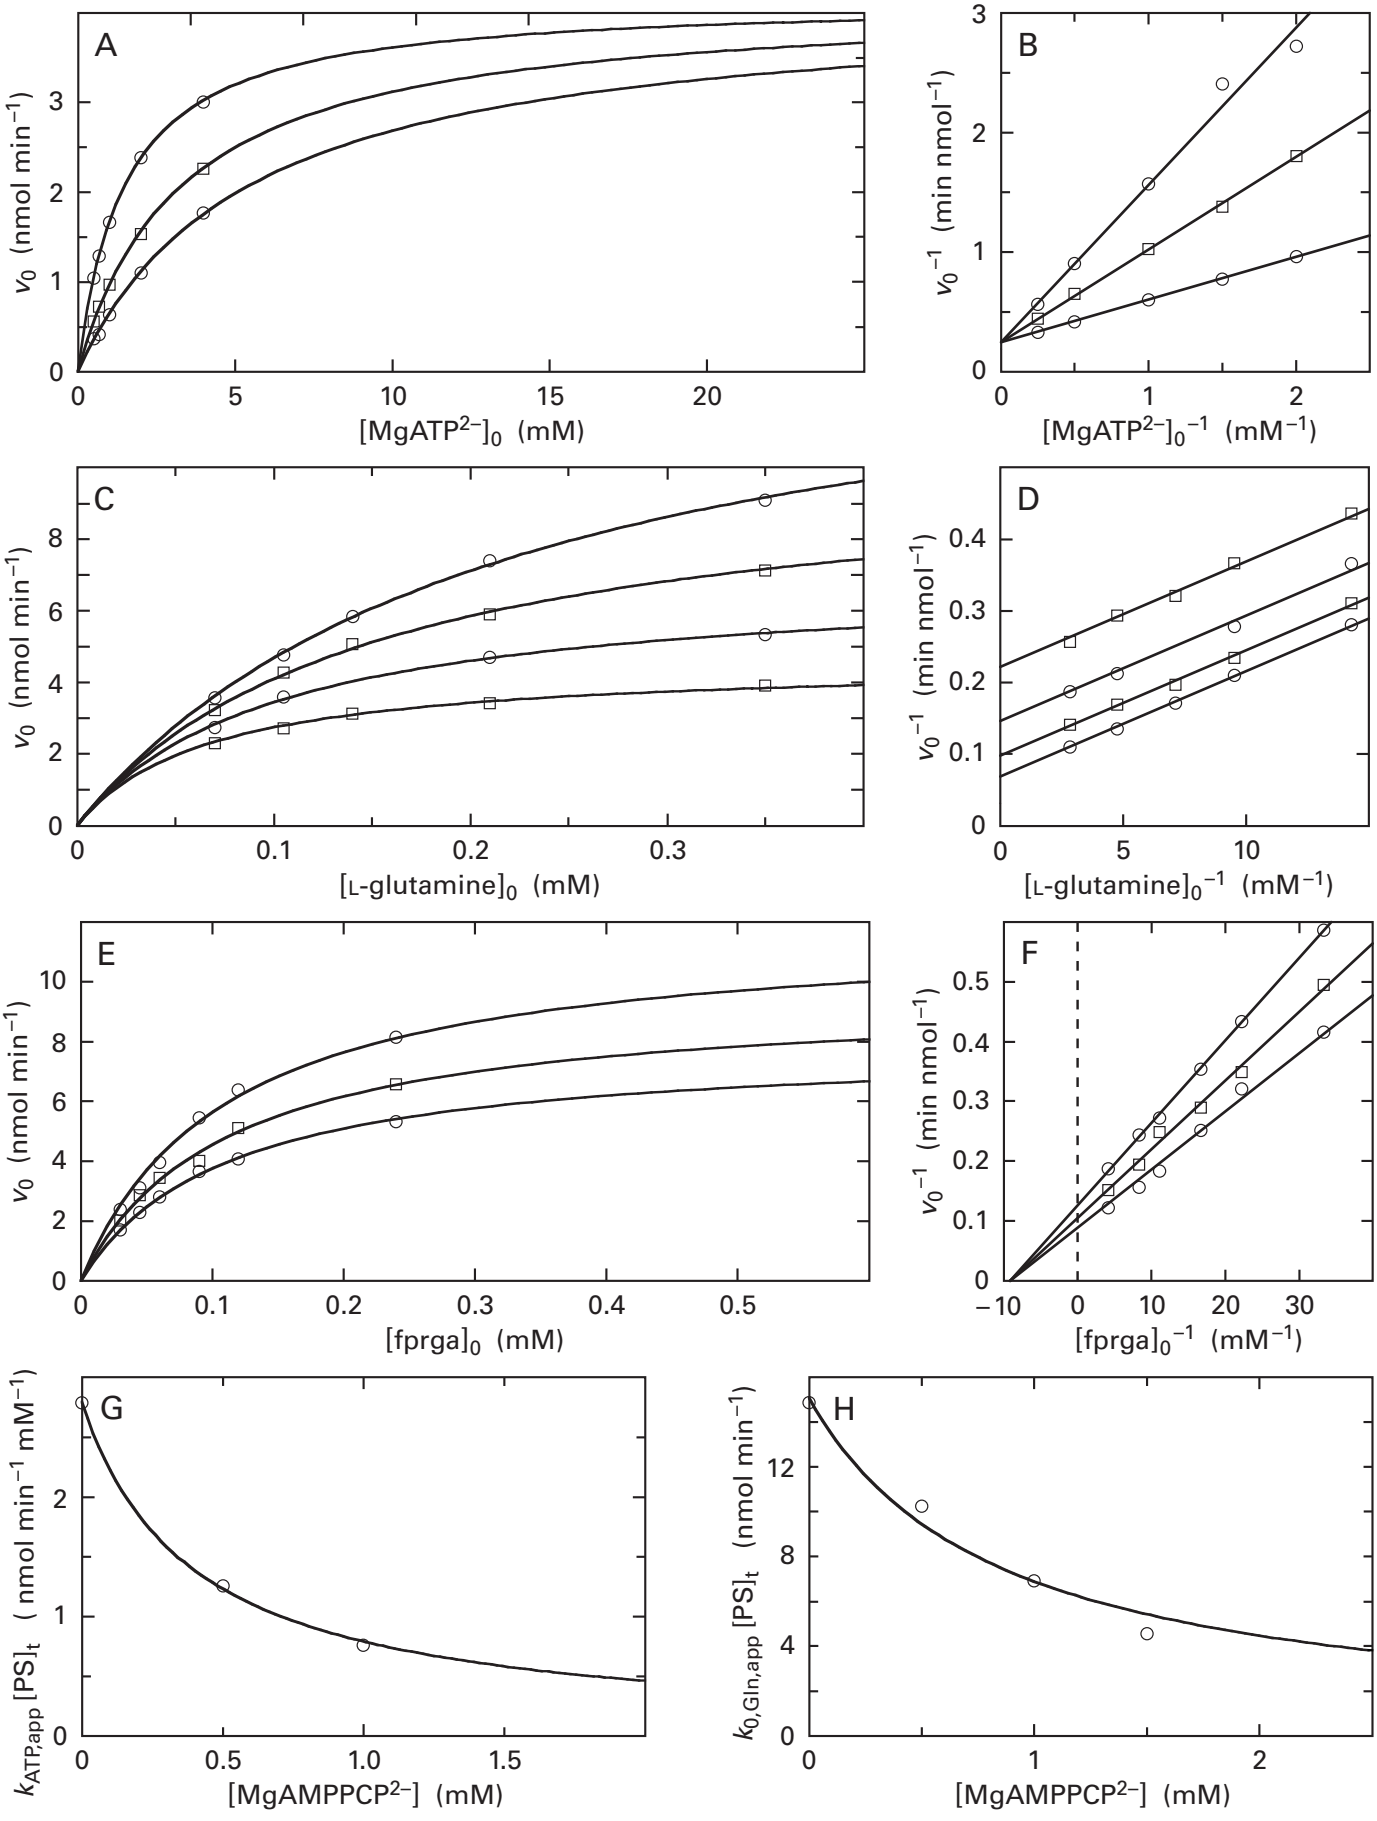
$$u = u_0\left(\frac{h}{z + h}\right) \qquad (3–171)$$

where u is the value for $k_{A,I,app}[E]_t$ at a given concentration of inhibitor, z is [I], u_0 is the value of the apparent rate constant $k_{A,app}[E]_t$ in the absence of inhibitor, and h is K_{icI}.

In double-reciprocal form

$$\frac{1}{v_0} = \frac{1}{k_{A,app}[E]_t\left(\frac{K_{icI}}{[I] + K_{icI}}\right)[A]_0} + \frac{1}{k_{0,A,app}[E]_t} \qquad (3–172)$$

Upon taking the limit, it can be seen that, for competitive inhibition, the lines in a plot of v_0^{-1} as a function of $[A]_0^{-1}$ at different fixed concentrations of inhibitor I all intersect at the axis of the ordinate where $[A]_0^{-1}$ is zero (Figure 3–9B). **This intersection of the double reciprocals at the axis of the ordinate is the most obvious characteristic of competitive inhibition** and is usually used to identify competitive inhibition.



A
v_0 (nmol min^{-1})

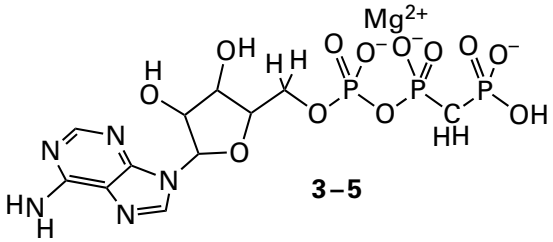
Figure 3–9: Kinetics for reversible inhibition of the transamidination catalyzed by phosphoribosylformylglycinamidine synthase from liver of *G. gallus*.[97] Solutions containing $MgATP^{2-}$, N^2-formyl-N^1-(5-phospho-D-ribosyl)glycinamide, and L-glutamine were prepared at pH 8.0 and 37 °C. The concentration of uncomplexed Mg^{2+} was fixed at 1 mM throughout. Each transamidination was initiated by adding phosphoribosylformylglycinamidine synthase (PS), and the production of L-glutamate was followed in a coupled assay with the 3-acetylpyridine analogue for NAD^+ and glutamate dehydrogenase by the increase in A_{363} upon reduction of the analogue. Each initial rate of the increase in A_{363} was converted to an initial rate for the production of L-glutamate, v_0 (micromolar minute^{-1}). **(A)** Initial rates (nanomoles minute^{-1}) and **(B)** reciprocals of the initial rates (minutes nanomole^{-1}) at 0.35 mM L-glutamine and 0.25 mM N^2-formyl-N^1-(5-phospho-D-ribosyl)glycinamide for different initial concentrations of $MgATP^{2-}$ (millimolar) and reciprocals of the different initial concentrations of $MgATP^{2-}$ (millimolar^{-1}), respectively, at 0, 0.5, and 1.0 mM $MgAMPPCP^{2-}$. The concentrations of inhibitor increase as the curves become lower in Panel A and as the lines become higher in Panel B. Equation 3–52, with x equal to $[MgATP^{2-}]_0$ and y equal to v_0, was fit to each set of data in Panel A. The three values for parameter a were equal to each other within their standard deviations. Consequently, they were set at the same value, 4.15 nmol of L-glutamate min^{-1}, and the data were refit to give the curves shown in the figure. The lines that were fit to the data in Panel B were forced to pass through 0.241 min (nmol of L-glutamate)$^{-1}$ at the axis of the ordinate. **(C)** Initial rates (nanomoles minute^{-1}) and **(D)** reciprocals of the initial rates (minutes nanomole^{-1}) at 2.0 mM $MgATP^{2-}$ and 0.25 mM N^2-formyl-N^1-(5-phospho-D-ribosyl)glycinamide for different initial concentrations of L-glutamine (millimolar) and reciprocals of the different initial concentrations of L-glutamine (millimolar^{-1}), respectively, at 0, 0.5, 1.0, and 1.5 mM $MgAMPPCP^{2-}$. The concentrations of inhibitor increase as the curves become lower in Panel C and as the lines become higher in Panel D. Equation 3–52, with x equal to $[\text{L-glutamine}]_0$ and y equal to v_0, was fit to each set of data in Panel C. The four values for parameter c, the initial slopes of the four curves, were equal to each other within their standard deviations. Consequently, they were set at the same value, 68 nmol of L-glutamate min^{-1} (mM L-glutamine)$^{-1}$, and the data were refit. These are the curves shown in the figure. The lines that were fit to the data in Panel D were forced to all have the slope of 0.0147 min (nmol of L-glutamate)$^{-1}$ mM L-glutamine. **(E)** Initial rates (nanomoles minute^{-1}) and **(F)** reciprocals of the initial rates (minutes nanomole^{-1}) at 0.35 mM L-glutamine and 2.0 mM $MgATP^{2-}$ for different initial concentrations of N^2-formyl-N^1-(5-phospho-D-ribosyl)glycinamide ($[\text{fprga}]_0$ in millimolar) and reciprocals of the different initial concentrations of N^2-formyl-N^1-(5-phospho-D-ribosyl)glycinamide ($[\text{fprga}]_0^{-1}$ in millimolar^{-1}), respectively, at 0, 0.5, and 1.0 mM $MgAMPPCP^{2-}$. The concentrations of inhibitor increase as the curves become lower in Panel E and as the lines become higher in Panel F. Equation 3–52, with x equal to $[\text{fprga}]_0$ and y equal to v_0, was fit to each set of data in Panel E. The three values for parameter b, the Michaelis constants K_m, from the fits for the three curves were equal to each other within their standard deviations. Consequently, they were set at the same value, 0.11 mM fprga, and the data were refit with this single parameter. These are the curves shown in the figure. The lines that were fit to the data in Panel F were forced to pass through –9.09 (mM fprga)$^{-1}$ at the axis of the abscissa. **(G)** The three values for parameter c for the curves in Panel A, the apparent specificity constants for $MgATP^{2-}$, $k_{ATP,app}[PS]_t$ (nanomoles minute^{-1} millimolar^{-1}), are plotted as a function of the concentrations of $MgAMPPCP^{2-}$ (millimolar). The data were fit by Equation 3–171 with u equal to these observed values and z equal to $[MgAMPPCP^{2-}]$. The value for $K_{icAMPPCP}$ (parameter h) obtained from the fit is 0.39 ± 0.01 mM. **(H)** The four values for parameter a from the fits in Panel C, the apparent catalytic constants for L-glutamine, $k_{0,Gln,app}[PS]_t$ (nanomoles minute^{-1}), are plotted as a function of the concentrations of $MgAMPPCP^{2-}$ (millimolar). The data were fit by Equation 3–171 with u equal to $k_{0,Gln,app}[PS]_t$ and z equal to $[MgAMPPCP^{2-}]$. The value for $K_{iuAMPPCP}$ obtained from the fit is 0.84 ± 0.14 mM $MgAMPPCP^{2-}$.

Phosphoribosylformylglycinamidine synthase (PS) from *Gallus gallus* catalyzes a reaction

$$N^2\text{-formyl-}N^1\text{-(5-phospho-D-ribosyl)glycinamide} + \text{L-glutamine} + MgATP^{2-} + H_2O \rightleftharpoons MgADP^- + HOPO_3^{2-} + \text{L-glutamate} + 2\,H^+ + 2\text{-(formamido)-}N^1\text{-(5-phospho-D-ribosyl)acetamidine} \quad (3\text{–}173)$$

that for kinetic purposes involves three reactants and four products. This enzymatic reaction is inhibited by magnesium 5′-adenylic methylenediphosphonic anhydride ($MgAMPPCP^{2-}$)



3–5

an inert analogue of $MgATP^{2-}$. When the initial concentrations of *N*-2-formyl-*N*-1-(5-phospho-D-ribosyl)-glycinamide and L-glutamine were fixed and $MgATP^{2-}$ was the varied reactant at several fixed concentrations of $MgAMPPCP^{2-}$, each curve describing a set of values for v_0 and $[MgATP]_0$ had the same value for the asymptote $k_{0,ATP,app}[PS]_t$, but the values for $k_{ATP,app}[PS]_t$, and

hence the initial slopes of the curves, decreased as the concentration of the inhibitor was increased (Figure 3–9A).[97] When the values for v_0^{-1} were plotted as a function of the respective values for $[MgATP]_0^{-1}$, the lines for the different fixed concentrations of the inhibitor all intersected at the axis of the ordinate (Figure 3–9B). Consequently, $MgAMPPCP^{2-}$ is a competitive inhibitor with respect to $MgATP^{2-}$ in the reaction catalyzed by phosphoribosylformylglycinamidine synthase.

When the various observed values for $k_{ATP,app}[PS]_t$ are plotted as a function of the respective concentrations of the inhibitor $MgAMPPCP^{2-}$ (Figure 3–9G), the plot is that for the function

$$k_{ATP,app,obs}[PS]_t = k_{ATP,app}[PS]_t\left(\frac{K_{icAMPPCP}}{[MgAMPPCP^{2-}] + K_{icAMPPCP}}\right) \quad (3–174)$$

with $K_{icAMPPCP} = 0.39 \pm 0.01$ mM, so the inhibition is linear. Magnesium 5′-adenylic methylenediphosphonic anhydride is also a linear competitive inhibitor with respect to $MgATP^{2-}$ in the reaction catalyzed by human Rho protein kinase (Figure 3–10A)[98] with an inhibition constant $K_{icAMPPCP}$ of 124 ± 1 μM (Figure 3–10B). *N*-Acetyl-D-glucosamine is a linear competitive inhibitor of hexokinase from *R. norvegicus* (Equation 3–94) with respect to hexose D-glucose (Figure 3–11A,B) with an inhibition constant K_{icNAG} of 70 ± 6 μM (Figure 3–11B).[99]

An **uncompetitive reversible inhibitor with respect to reactant A** is any reversible inhibitor the addition of which to the solution decreases the catalytic constant, k_0, or the apparent catalytic constant for reactant A, $k_{0,A,app}$, while having no effect on the value of the specificity constant for reactant A, k_A, or the apparent specificity constant for reactant A, $k_{A,app}$. Again, the uncompetitive inhibition is linear if the factor affecting k_0, $k_0[E]_t$, $k_{0,A,app}$ or $k_{0,A,app}[E]_t$ is $K_{iuI}([I] + K_{iuI})^{-1}$, where K_{iuI} is the **inhibition constant for the uncompetitive inhibition** produced by inhibitor I.

In the general case, where only the initial concentration of reactant A and the concentration of inhibitor I are varied and the initial concentrations of all other substrates are fixed, the **observed initial rate for an enzymatic reaction upon addition of a linear uncompetitive inhibitor** with respect to reactant A is

$$v_0 = \frac{k_{0,A,app}[E]_t\left(\frac{K_{iuI}}{[I] + K_{iuI}}\right)k_{A,app}[E]_t[A]_0}{k_{0,A,app}[E]_t\left(\frac{K_{iuI}}{[I] + K_{iuI}}\right) + k_{A,app}[E]_t[A]_0} \quad (3–175)$$

As the concentration of inhibitor I is increased, the apparent value for $k_0[E]_t$ in Equation 3–43, which is the kinetic constant observed in an experimental measurement, decreases by the factor $K_{iuI}([I] + K_{iuI})^{-1}$. Consequently, the asymptotes of the curves of v_0 as a function of $[A]_0$ at saturating $[A]_0$ decrease by the same factor. Regardless of the concentration of inhibitor I, however, the initial slopes of all the curves are the same because the apparent rate constant $k_{A,app}[E]_t$ is unaffected by the inhibitor.

In double-reciprocal form

$$\frac{1}{v_0} = \frac{1}{k_{A,app}[E]_t[A]_0} + \frac{1}{k_{0,A,app}[E]_t\left(\frac{K_{iuI}}{[I] + K_{iuI}}\right)} \quad (3–176)$$

For uncompetitive inhibition, the lines in a plot of v_0^{-1} as a function of $[A]_0^{-1}$ at several fixed concentrations of inhibitor I all have the same slope and are parallel to each other. **These parallel lines in the plots of the double reciprocals are the most obvious characteristic of uncompetitive inhibition.**

Magnesium 5′-adenylic methylenediphosphonic anhydride (**3–5**) is a linear uncompetitive inhibitor with respect to L-glutamine in the reaction (Equation 3–173) catalyzed by phosphoribosylformylglycinamidine synthase from *G. gallus* (Figure 3–9C,D) with an inhibition constant $K_{iuAMPPCP}$ of 0.84 ± 0.14 mM (Figure 3–9H). The chromium complex of ATP^{4-} ($CrATP^-$) is an uncompetitive inhibitor of glycerol kinase (Equation 3–140 with glycerol in place of (*S*)-1-aminopropane-2,3-diol) from *C. norvegensis* (Figure 3–12A)[100] with an inhibition constant $K_{iuCrATP}$ of 1.73 ± 0.02 μM (Figure 3–12B).

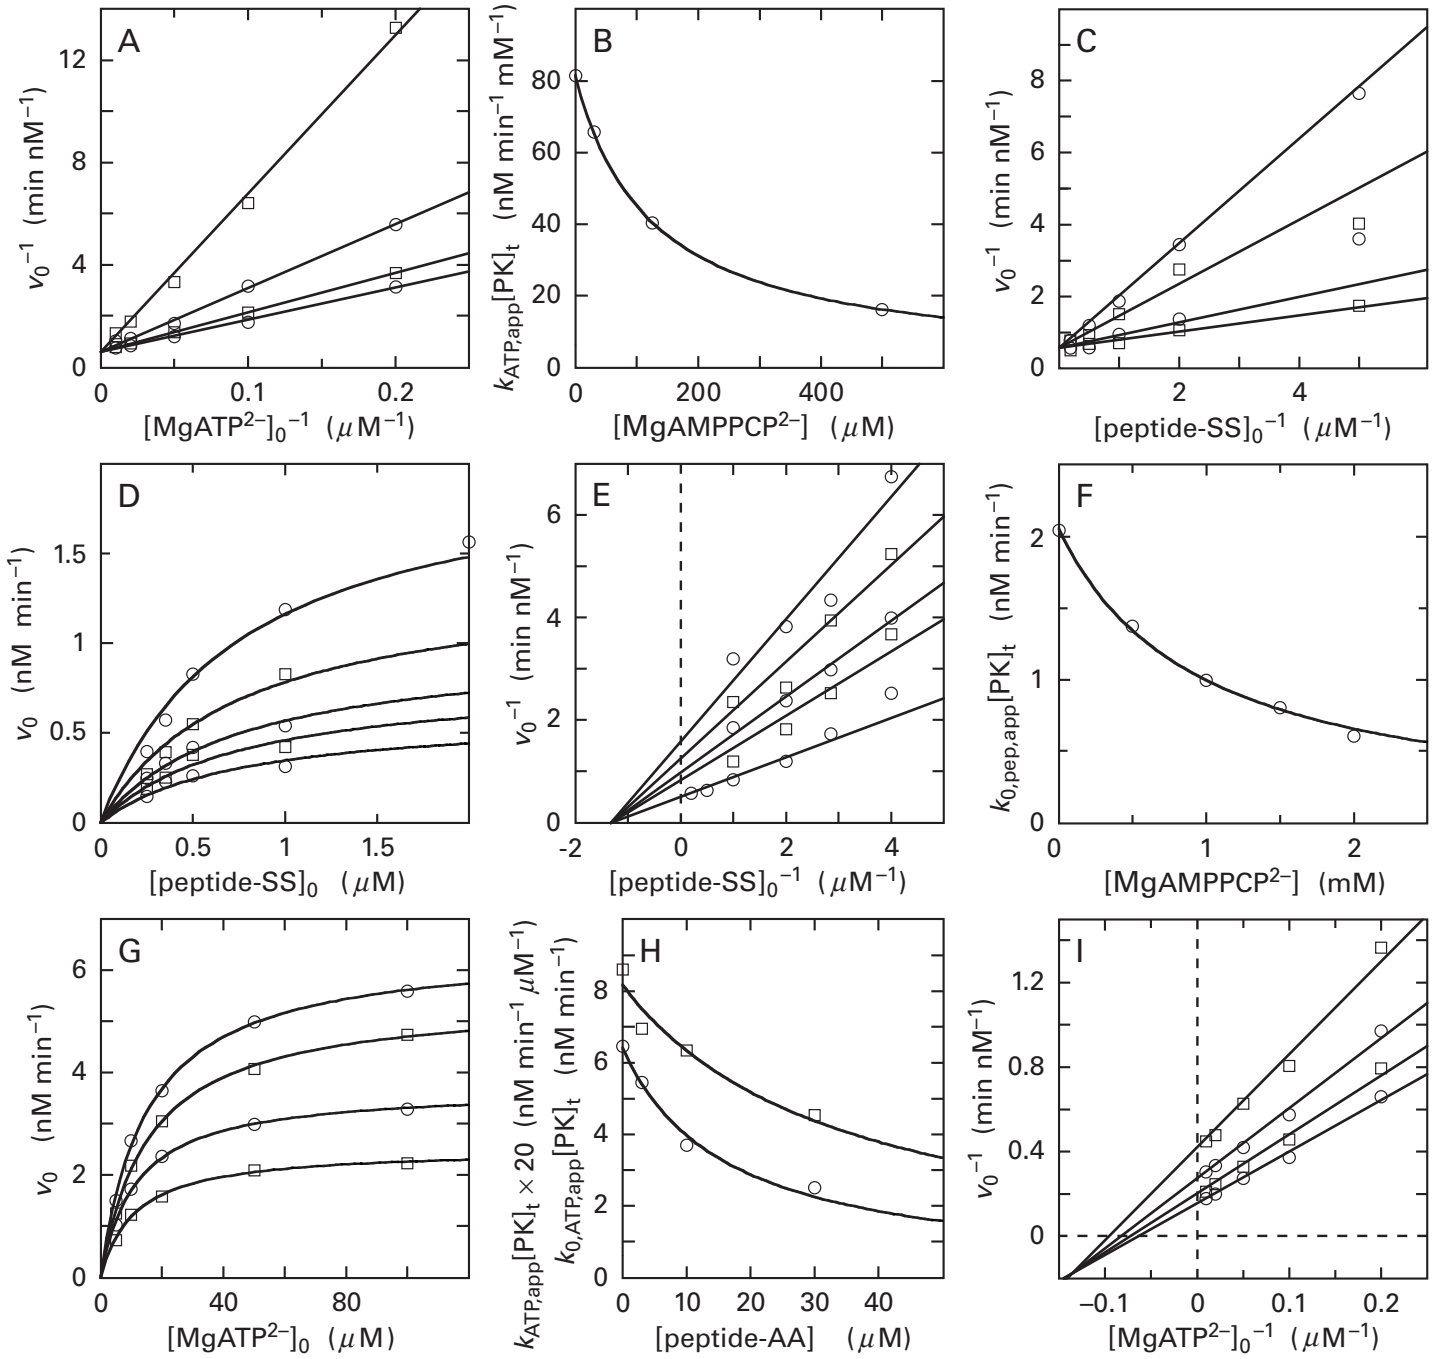


Figure 3–10: Kinetics for reversible inhibition of the phosphorylation catalyzed by the kinase domain (amino acids 1–543) of human Rho protein kinase.[98] The reactant used in place of one of the proteins that are physiological substrates for Rho protein kinase was the biotinylated peptide biotin-AKRRRLSSLRA-NH_2. This peptide contains a sequence of amino acids recognized by the enzyme that includes the two serines it phosphorylates. Solutions containing kinase domain (amino acids 1–543) of human Rho protein kinase (PK) and $MgATP^{2-}$ and [γ-^{32}P]$MgATP^{2-}$ or enzyme and biotin-AKRRRLSSLRA-NH_2 were prepared at pH 7.4 and 30 °C. The concentration of uncomplexed Mg^{2+} was fixed at 5 mM throughout. Each phosphorylation was initiated by adding biotin-AKRRRLSSLRA-NH_2 or $MgATP^{2-}$ and [γ-^{32}P]$MgATP^{2}$, Equation 3–52, with x equal to [peptide-SS]$_0$ and y equal to v_0, was fit to each set of data in Panel D. The five values for parameter b, the Michaelis constants, for the fits of the five curves varied unsystematically and were assumed to be equal to each other. Consequently, they were set at their average value, 0.75 μM biotin-AKRRRLSSLRA-NH_2, and the data were refit with this quotient. These are the curves shown in Panel D. The lines that were fit to the data in Panel E were forced to pass through –1.32 (μM biotin-AKRRRLSSLRA-NH_2)$^{-1}$ at the axis of the abscissa. (**F**) The five values for parameter a of the fits in Panel D, the observed values of the apparent catalytic constant for the peptide, biotin-AKRRRLSSLRA-NH_2, $k_{0,pep,app}$[PK]$_t$ (nanomolar minute^{-1}), are plotted as a function of the concentrations

respectively, and the rate of production of radioactively phosphorylated peptide was followed for 60 minutes by capturing the phosphopeptide through its covalently attached biotin with a membrane to which streptavidin had been covalently attached. Each initial rate of capture of phosphorus-32 was converted to an initial rate for the production of phosphorylated peptide, v_0 (micromolar minute^{-1}). **(A)** Reciprocals of the initial rates (minutes nanomolar^{-1}) at 2.5 μM biotin-AKRRRLSSLRA-NH_2 for reciprocals of different initial concentrations of $MgATP^{2-}$ (micromolar^{-1}) at 0, 30, 125, and 500 μM concentrations of the inhibitor $MgAMPPCP^{2-}$. The concentrations of inhibitor increase as the lines become higher. **(B)** Behavior of observed values for the apparent specificity constant for $MgATP^{2-}$, $k_{ATP,app}[PK]_t$ (nanomolar minute^{-1} millimolar^{-1}), which are reciprocals of the slopes of the lines fit to the data in Panel A, as a function of the concentrations of $MgAMPPCP^{2-}$ (micromolar). The data were fit by Equation 3–171 with u equal to the observed values for the apparent specificity constant and z equal to $[MgAMPPCP^{2-}]$, and the value for $K_{icAMPPCP}$ (parameter h of the fit) is 124 ± 0.4 μM. **(C)** Reciprocals of the initial rates (minutes nanomolar^{-1}) at 40 μM $MgATP^{2-}$ for reciprocals of different initial concentrations of biotin-AKRRRLSSLRA-NH_2 ($[peptide\text{-}SS]_0$; micromolar^{-1}) at 0, 2, 10, and 20 μM concentrations of the inhibitor acetyl-AKRRRLAALRA-NH_2, a peptide that lacks the serines phosphorylated by the enzyme. The concentrations of inhibitor increase as the lines become higher. **(D)** Initial rates (nanomolar minute^{-1}) and **(E)** reciprocals of the initial rates (minutes nanomolar^{-1}) at 40 μM $MgATP^{2-}$ for different initial concentrations of biotin-AKRRRLSSLRA-NH_2 (micromolar) and reciprocals of different initial concentrations of biotin-AKRRRLSSLRA-NH_2 (micromolar^{-1}), respectively, at 0, 0.5, 1.0, 1.5, and 2.0 mM concentrations of $MgAMPPCP^{2-}$. The concentrations of inhibitor increase as the curves become lower in Panel D and as the lines become higher in Panel E. **(F)** Reciprocals of the initial rates (minutes nanomolar^{-1}) at 2.5 μM biotin-AKRRRLSSLRA-NH_2 for reciprocals of different initial concentrations of $MgATP^{2-}$ (micromolar^{-1}) at 0, 3, 10, and 30 μM concentrations of the inhibitor $MgAMPPCP^{2-}$ (millimolar). The data were fit by Equation 3–171 with u equal to the observed values for the apparent catalytic constant and z equal to $[MgAMPPCP^{2-}]$. The value for $K_{inAMPPCP}$ (parameter h of the fit) is 0.94 ± 0.05 mM. **(G)** Initial rates (nanomolar minute^{-1}) at 2.5 μM biotin-AKRRRLSSLRA-NH_2 for different initial concentrations of $MgATP^{2-}$ (micromolar) at 0, 3, 10, and 30 μM concentrations of the inhibitor acetyl-AKRRRLAALRA-NH_2. The concentrations of inhibitor increase as the curves become lower. Equation 3–52, with x equal to $[MgATP^{2-}]_0$ and y equal to v_0, was fit to each set of data. **(H)** The four values for parameter c, the initial slopes of the four curves in Panel G, which are the observed values of the apparent specificity constant for $MgATP^{2-}$, $k_{ATP,app}[PK]_t$ (nanomolar minute^{-1} micromolar^{-1}; □) multiplied by 20, and the four values for parameter a, the asymptotes of the four curves, which are the observed values for the apparent catalytic constant for $MgATP^{2-}$, $k_{0,ATP,app}[PK]_t$ (nanomolar minute^{-1}; ○), are plotted against the concentrations of acetyl-AKRRRLAALRA-NH_2 ([peptide-AA] in micromolar). Equation 3–171, with z equal to [peptide-AA] and u equal to the respective observed rate constants, was fit to each set of data. The values for K_{icPAA} and K_{iuPAA} (parameters h from the respective fits) were 35 ± 9 μM and 16 ± 3 μM. **(I)** Reciprocals of the initial rates (minutes nanomolar^{-1}) at 2.5 μM biotin-AKRRRLSSLRA-NH_2 for reciprocals of the different initial concentrations of $MgATP^{2-}$ (micromolar^{-1}) at 0, 3, 10, and 30 μM concentrations of the inhibitor acetyl-AKRRRLAALRA-NH_2. The concentrations of inhibitor increase as the lines become higher. The values for K_{icPAA} and K_{iuPAA} and the values for $k_{0,ATP,app}$ and $k_{ATP,app}$ in the absence of inhibitor from the fits to the data in Panel H were used to calculate the theoretical point of intersection for the lines describing the double reciprocals for the observed mixed inhibition, and the four lines fit to the data in Panel I were forced to pass through that theoretical point of intersection.

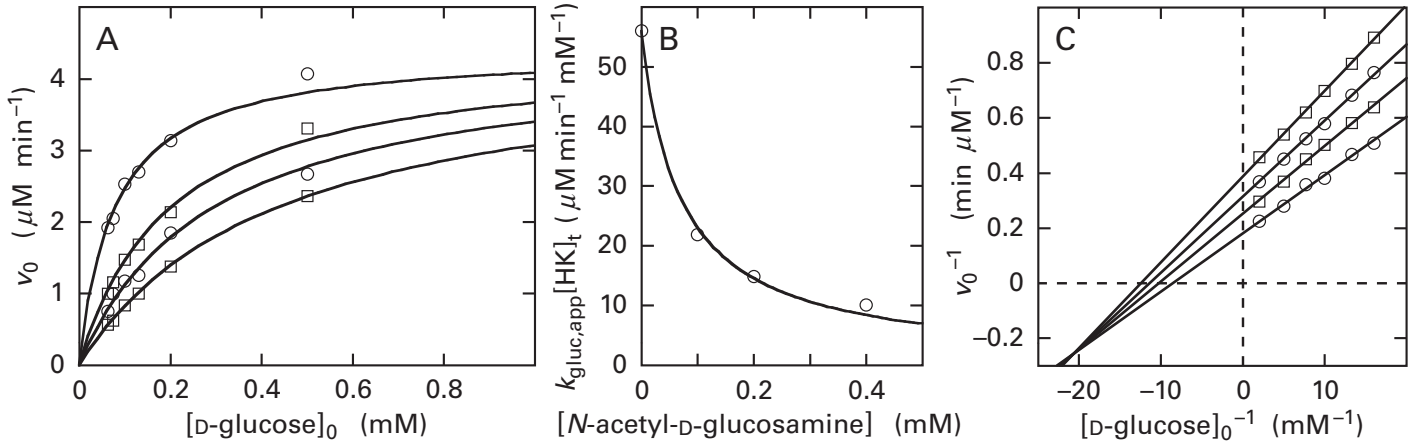

Figure 3–11: Kinetics for reversible inhibition of the phosphorylation catalyzed by partially purified hexokinase from skeletal muscle of *R. norvegicus*.[99] Solutions containing $MgATP^{2-}$ and D-glucose were prepared at pH 7.7 and 28 °C. Each phosphorylation was initiated by adding hexokinase (HK), and the production of D-glucose 6-phosphate was followed in a coupled assay with glucose-6-phosphate dehydrogenase and $NADP^+$ by monitoring the increase in A_{340} from the conversion of $NADP^+$ to constants for D-glucose, $k_{gluc,app}[HK]_t$, are plotted as a function of the concentrations of *N*-acetyl-D-glucosamine (millimolar). The data were fit by Equation 3–171 with u equal to the observed values for the apparent specificity constant and z equal to [*N*-acetyl-D-glucosamine]. The value for K_{icNAG} (parameter h of the fit) is 70 ± 6 μM. **(C)** Reciprocals of the initial rates (minutes micromolar^{-1}) at 0.25 mM $MgATP^{2-}$ for reciprocals of different initial concentrations of D-glucose (millimolar^{-1}) at 0, 0.5, 1.0,

NADPH (as in Figure 3–4). Each initial rate of change in A_{340} was converted to an initial rate for the production of D-glucose 6-phosphate, v_0 (micromolar D-glucose 6-phosphate minute^{-1}). **(A)** Initial rates (micromolar minute^{-1}) of hexokinase at 0.25 mM $MgATP^{2-}$ for different initial concentrations of D-glucose (millimolar) at 0, 0.1, 0.2, and 0.4 mM concentrations of the inhibitor *N*-acetyl-D-glucosamine. The concentrations of inhibitor increase as the curves become lower. Equation 3–52, with x equal to $[\text{D-glucose}]_0$ and y equal to v_0, was fit to each set of data. The four values for parameter a of the four fits, which are the observed values for $k_{0,\text{app,gluc}}[\text{HK}]_t$, were almost identical to each other within their standard deviations and did not vary systematically, a fact that defined the inhibition as competitive. Consequently, the four asymptotes were set at the same value, 4.4 μM D-glucose 6-phosphate min^{-1}, and the data were refit. These refits are the curves shown in the figure. **(B)** The four values for parameter c of the fits in Panel A, the apparent specificity constants for D-glucose, $k_{\text{gluc,app}}[\text{HK}]_t$, and the four values for parameter a, the apparent catalytic constants for D-glucose, $k_{0,\text{gluc,app}}[\text{HK}]_t$, were plotted against the concentrations of ATP^{4-}. The values for K_{icATP} and K_{iuATP} from the fits of these data to Equation 3–171 were 3.3 ± 0.5 mM and 1.4 ± 0.1 mM, respectively. The values for K_{icATP} and K_{iuATP} and the values for $k_{0,\text{app,gluc}}$ and $k_{\text{gluc,app}}$ in the absence of inhibitor from these fits to the data were used to calculate the theoretical point of intersection for the lines describing the double reciprocals for the observed mixed inhibition, and the four lines fit to the data in the figure were forced to pass through that calculated point of intersection.

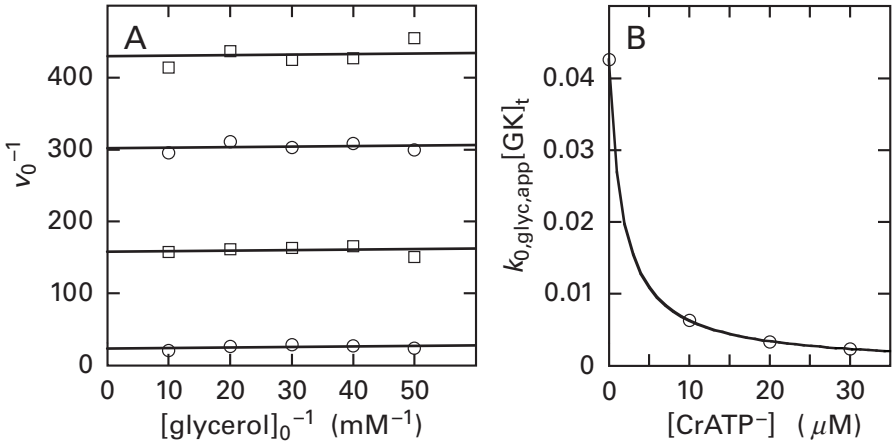

Figure 3–12: Kinetics for inhibition of glycerol kinase[100] from *C. norvegensis* by the chromium complex of ATP^{4-}. Solutions containing glycerol and $MgATP^{2-}$ were prepared at pH 7.0 and 25 °C. The concentration of uncomplexed Mg^{2+} was fixed at 3 mM throughout. Glycerol kinase (GK) was added to initiate the phosphorylation, and the production of $MgADP^-$ was monitored by coupling the production of $MgADP^-$ to the oxidation of NADH as in Figure 3–7. **(A)** Reciprocals of the initial rates for the production of $MgADP^-$ (in unreported units) at 20 μM $MgATP^{2-}$ for reciprocals of different initial concentrations of glycerol (millimolar^{-1}) at 0, 10, 20, and 30 μM $CrATP^-$. The concentrations of inhibitor increase as the lines become higher. The lines that were fit to the data were forced to be parallel to each other, as were the lines drawn by the authors, and to have the same slope as the lines drawn by the authors. **(B)** Reciprocals of the observed intersections of the lines fit to the data in Panel A with the axis of the abscissa, which are the observed values of the apparent catalytic constant for glycerol, $k_{0,\text{glyc,app}}[\text{GK}]_t$ (in unreported units), are plotted as a function of the concentration of $CrATP^-$ (micromolar). The data in this panel were fit by Equation 3–171 with u equal to the observed values for the apparent catalytic constant and z equal to $[CrATP^-]$, and the value for K_{iuCrATP} (parameter h of the fit) is 1.73 ± 0.02 μM.

A **noncompetitive reversible inhibitor with respect to reactant A** is any reversible inhibitor the addition of which to the solution decreases the specificity constant for reactant A, k_A , or the apparent specificity constant for reactant A, $k_{A,app}$, and the catalytic constant, k_0, or the apparent catalytic constant for reactant A, $k_{0,A,app}$ by the same factor. In this case, the inhibition is considered **linear** if the factor affecting each observed value of k_A, $k_A[E]_t$, $k_{A,app}$, or $k_{A,app}[E]_t$ and k_0, $k_0[E]_t$, $k_{0,A,app}$, or $k_{0,A,app}[E]_t$, is $K_{inI}([I] + K_{inI})^{-1}$, where K_{inI} is the inhibition constant for the noncompetitive inhibition produced by inhibitor I.

In the general case, where only the initial concentration of reactant A and the concentration of inhibitor I are varied and the initial concentrations of all other reactants are fixed, the **observed initial rate for an enzymatic reaction upon addition of a linear noncompetitive inhibitor** with respect to reactant A is

$$v_0 = \frac{k_{0,A,app}[E]_t\left(\frac{K_{inI}}{[I]+K_{inI}}\right)k_{A,app}[E]_t\left(\frac{K_{inI}}{[I]+K_{inI}}\right)[A]_0}{k_{0,A,app}[E]_t\left(\frac{K_{inI}}{[I]+K_{inI}}\right)+k_{A,app}[E]_t\left(\frac{K_{inI}}{[I]+K_{inI}}\right)[A]_0} = \left(\frac{k_{0,A,app}[E]_t k_{A,app}[E]_t[A]_0}{k_{0,A,app}[E]_t+k_{A,app}[E]_t[A]_0}\right)\left(\frac{K_{inI}}{[I]+K_{inI}}\right) \quad (3–177)$$

As indicated in the latter form of this equation, as the concentration of inhibitor I is increased, the value of v_0 at every $[A]_0$ for a fixed concentration of inhibitor I decreases by the same factor. Consequently, each successive curve shrinks in the vertical direction uniformly along its length. By combining Equations 3–43, 3–44, 3–46, and 3–177, it can be seen that

$$v_0 = \frac{k_{0,A,app}\left(\frac{K_{inI}}{[I]+K_{inI}}\right)[E]_t[A]_0}{K_{mA,app}+[A]_0} \quad (3–178)$$

From this equation, it can be concluded that two of the criteria for noncompetitive inhibition are that the apparent Michaelis constant is unaffected by the inhibitor, which also follows from the fact that every initial rate decreases by the same factor, and that the apparent catalytic constants decrease in proportion to the factor $K_{inI}([I]+K_{inI})^{-1}$.

In double-reciprocal form,

$$\frac{1}{v_0} = \frac{1}{k_{A,app}[E]_t\left(\frac{K_{inI}}{[I]+K_{inI}}\right)[A]_0} + \frac{1}{k_{0,A,app}[E]_t\left(\frac{K_{inI}}{[I]+K_{inI}}\right)} \quad (3–179)$$

By solving Equation 3–179 for the case in which v_0^{-1} is equal to zero, it can be seen that for noncompetitive inhibition, the lines in a plot of v_0^{-1} as a function of $[A]_0^{-1}$ at different fixed concentrations of I all intersect on the axis of the abscissa at the point $-k_{A,app}(k_{0,A,app})^{-1}$, as does the line for v_0^{-1} as a function of $[A]_0^{-1}$ in the absence of the inhibitor. **The intersection of the double reciprocals at the axis of the abscissa is the most obvious characteristic of noncompetitive inhibition.**

Magnesium 5′-adenylic methylenediphosphonic anhydride (**3–5**) is a noncompetitive inhibitor with respect to N^2-formyl-N^1-(5-phospho-D-ribosyl)-glycinamide in the reaction (Equation 3–173) catalyzed by phosphoribosylformylglycinamidine synthase from *G. gallus* (Figure 3–9E,F) with an inhibition constant of 1.1 mM. Rho protein kinase phosphorylates the two serines in the sequence –KRRRLSSLRA– in a protein that is a substrate using $MgATP^{2-}$ as the source of the phospho group. Magnesium 5′-adenylic methylenediphosphonic anhydride is a linear noncompetitive inhibitor of Rho protein kinase with respect to the synthetic peptide biotin-AKRRRLSSLRA-NH_2, when it is used as a reactant for the enzyme (Figure 3–10D,E),[98] with an inhibition constant $K_{inAMPPCP}$ of 0.94 ± 0.05 mM (Figure 3–10F).

A **mixed inhibitor with respect to reactant A** is any reversible inhibitor for which the inhibition constant K_{icI} that affects the specificity constant for reactant A, k_A, or the apparent specificity constant for reactant A, $k_{A,app}$, is different from the inhibition constant K_{iuI} that affects the catalytic constant, k_0, or the apparent catalytic constant for reactant A, $k_{0,A,app}$, and both inhibition constants are finite. As before, the mixed inhibition is **linear** if the factor affecting k_A, $k_A[E]_t$, $k_{A,app}$, or $k_{A,app}[E]_t$ is $K_{icI}([I]+K_{icI})^{-1}$ and the factor affecting k_0, $k_0[E]_t$, $k_{0,A,app}$, or $k_{0,A,app}[E]_t$ is $K_{iuI}([I]+K_{iuI})^{-1}$.

In the general case where only the initial concentration of reactant A and the concentration of inhibitor I are varied and the concentrations of all other reactants are fixed, **the observed initial rate for an enzymatic reaction upon addition of a linear mixed inhibitor** with respect to reactant A is

$$v_0 = \frac{k_{0,A,app}[E]_t\left(\frac{K_{iuI}}{[I]+K_{iuI}}\right)k_{A,app}[E]_t\left(\frac{K_{icI}}{[I]+K_{icI}}\right)[A]_0}{k_{0,A,app}[E]_t\left(\frac{K_{iuI}}{[I]+K_{iuI}}\right)+k_{A,app}[E]_t\left(\frac{K_{icI}}{[I]+K_{icI}}\right)[A]_0} \quad (3–180)$$

In double-reciprocal form

$$\frac{1}{v_0} = \frac{1}{k_{A,app}[E]_t\left(\frac{K_{icI}}{[I] + K_{icI}}\right)[A]_0} + \frac{1}{k_{0,A,app}[E]_t\left(\frac{K_{iuI}}{[I] + K_{iuI}}\right)} \quad (3\text{–}181)$$

Consequently, for **mixed inhibition**, the lines defined by a double-reciprocal plot of v_0^{-1} as a function of $[A]_0^{-1}$ at several fixed concentrations of the inhibitor do not intersect at the axis of the ordinate because K_{iuI} is not infinite, they do not intersect at the axis of the abscissa because $K_{uiI} \neq K_{icI}$, and they are not parallel to each other because K_{icI} is not infinite. Instead, **the double reciprocals intersect in the second or third quadrant**. If $K_{icI} < K_{iuI}$, they intersect in the second quadrant and the inhibition is **predominantly competitive**, and if $K_{icI} > K_{iuI}$, they intersect in the third quadrant and the inhibition is **predominantly uncompetitive**. Note that noncompetitive inhibition is a special case of mixed inhibition where $K_{icI} = K_{iuI} = K_{inI}$.

12-(Imidazolyl)dodecanoic acid (IDD) is a linear, predominantly competitive, mixed inhibitor with respect to laurate (Figure 3–13A,C)[101] in the reaction catalyzed by unspecific monooxygenase from *Bacillus megaterium*

$$\text{laurate} + O_2 + 2\,H^+ + 2\,e^- \rightleftharpoons H_2O + \text{12-hydroxylaurate} \quad (3\text{–}182)$$

which is an enzyme containing a heme P450. The inhibition constants are 1.6 ± 0.2 μM for K_{icIDD} and 7.0 ± 0.3 μM for K_{iuIDD} (Figure 3–13B) The synthetic peptide acetyl-AKRRRLAALRA-NH_2 (peptide-AA), in which the two serines phosphorylated by Rho protein kinase are replaced by alanines, is an inhibitor of the enzyme when it is phosphorylating the reactant biotin-AKRRRLSSLRA-NH_2 (peptide-SS).

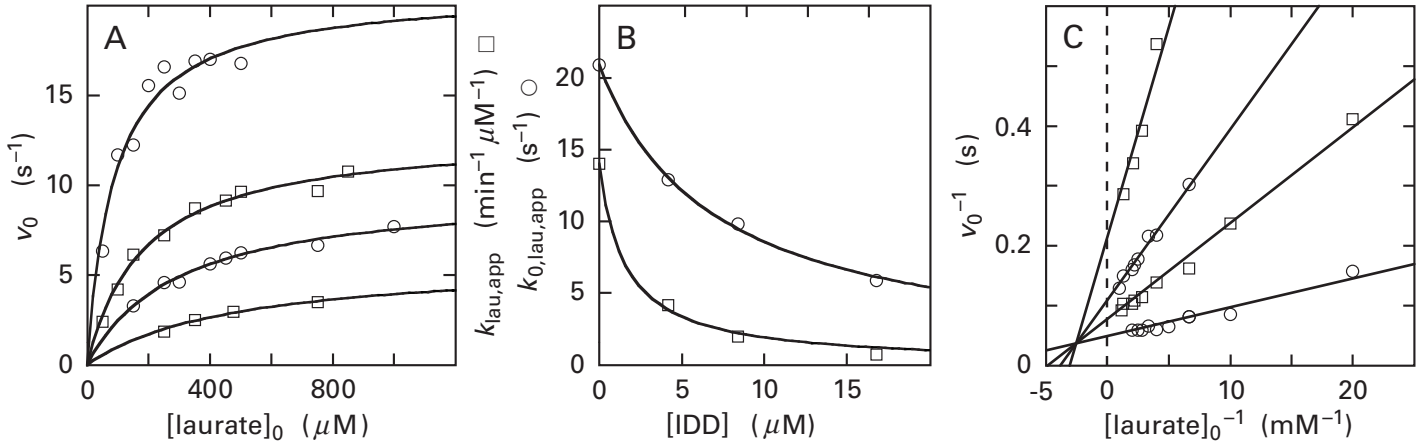

Figure 3–13: Kinetics for reversible inhibition of the oxidation of laurate catalyzed by unspecific monooxygenase (a cytochrome P450) from *B. megaterium*.[101] Buffered solutions containing ambient concentrations of molecular oxygen, various concentrations of laurate, and 0.2 mM NADPH were prepared at 30 °C. Unspecific monooxygenase was added to initiate each oxidation, and the production of $NADP^+$ was monitored by following the change in absorbance at 340 nm as NADPH was oxidized. Each initial rate of change in A_{340} was converted to an initial rate for the production of $NADP^+$ (micromoles minute^{-1}). The observed initial rates were divided by the molar concentration of active sites in the solution to give initial rates, v_0 (second^{-1}). **(A)** Initial rates for different initial concentrations of laurate (micromolar) at 0, 4.2, 8.4, and 16.8 μM concentrations of the inhibitor 12-(imidazolyl)dodecanoate. The concentrations of inhibitor increase as the curves become lower. Equation 3–52, with x equal to $[laurate]_0$ and y equal to v_0, was fit to each set of data. **(B)** The four values for parameter c of the four curves in Panel A, the specificity constants for laurate, $k_{lau,app}$ (minute^{-1} micromolar^{-1} ; □), and the four values for parameter a, the apparent catalytic constants for laurate, $k_{0,lau,app}$ (second^{-1}; ○), are plotted against the concentrations of the inhibitor 12-(imidazolyl)-dodecanoate ([IDD] in micromolar). Equation 3–171, with z equal to [IDD] and u equal to the observed values for $k_{lau,app}$ and $k_{0,lau,app}$, respectively, was fit to each set of data. The values for K_{icIDD} and K_{iuIDD}, respectively, were 1.6 ± 0.2 μM and 7.0 ± 0.3 μM. **(C)** Reciprocals of the initial rates (seconds) for reciprocals of the different initial concentrations of laurate (millimolar^{-1}) at 0, 4.2, 8.4, and 16.8 μM concentrations of the inhibitor 12-(imidazolyl)dodecanoate. The concentrations of inhibitor increase as the lines become higher. The values for K_{icIDD} and K_{iuIDD} and the values for $k_{lau,app}$ and $k_{0,lau,app}$ in the absence of inhibitor from the fits to the data in Panel B were used to calculate the theoretical point of intersection for the lines describing the double reciprocals for the observed mixed inhibition, and the four lines fit to the data in Panel C were forced to pass through that point of intersection.

Acetyl-AKRRRLAALRA-NH_2 is a linear, predominantly uncompetitive, mixed inhibitor of Rho protein kinase with respect to $MgATP^{2-}$ (Figure 3–10G,I)[98] with inhibition constants K_{icPAA} of $35 \pm 9\ \mu M$ and K_{iuPAA} of $16 \pm 3\ \mu M$ (Figure 3–10H).

The **decision as to what type of inhibition** is displayed by a particular inhibitor, I, with respect to a particular reactant, A, is usually made by examining graphical presentations of the experimental results gathered when all other substrates are at fixed concentrations. When the initial concentration of reactant A, $[A]_0$, is varied at a fixed concentration of inhibitor I and the experimentally determined values for the reciprocals of the initial rate, v_0^{-1}, are plotted against the respective values for $[A]_0^{-1}$, a linear relation between the two variables is usually observed. That relation is governed by Equation 3–53. If another fixed concentration of inhibitor I is then chosen and the experiment is repeated, a second line fitting the behavior of v_0^{-1} as a function of $[A]_0^{-1}$ will be generated and so forth. All the lines, each generated by a different fixed concentration of inhibitor I, will usually pass through the same point or be parallel to each other. If they intersect at the axis of the ordinate within the errors of the measurements, the inhibition is deemed competitive with respect to reactant A; if they intersect at the axis of the abscissa within the errors of the measurements, the inhibition is deemed noncompetitive with respect to reactant A; if they are parallel to each other within the errors of the measurements, the inhibition is deemed uncompetitive with respect to reactant A; and if they intersect in the second or third quadrant, the inhibition is mixed relative to reactant A.

A note of caution should be sounded, however. In two instances, uncompetitive inhibition and a ping-pong bisubstrate kinetic mechanism, sets of **parallel lines on such reciprocal plots** are considered to be diagnostic. If, however, concentrations of inhibitors and reactants are high enough, only a region of the field in which lines that are actually converging appear to be parallel may be being sampled. For example, in the case of 3-deoxy-7-phosphoheptulonate synthase from *S. typhimurium*, a set of apparently parallel lines generated by data at high concentrations of reactants became a set of clearly converging lines when much lower initial concentrations were employed to spread the data over a wider range.[102]

It should be emphasized that the definitions of competitive, uncompetitive, noncompetitive, and mixed inhibition and the designations of these types of inhibition are based entirely on observed behavior and do not involve any explanation of the observed behavior. There are, however, explanations.

Explanation: Suppose for the moment that the enzyme has only one reactant (Equation 3–55) and that inhibitor I can associate with both E and E·A

$$\begin{array}{ccccc} E + A & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & E{\cdot}A & \xrightarrow{k_2} & E + Z \\ + & & + & & \\ I & & I & & \\ k_{i,1}\Big\downarrow\Big\uparrow k_{i,-1} & & k_{i,2}\Big\downarrow\Big\uparrow k_{i,-2} & & \\ E{\cdot}I & & E{\cdot}A{\cdot}I & & \end{array} \qquad (3\text{–}183)$$

In this kinetic mechanism, reversible inhibitor I associates with the enzyme whether or not reactant A is bound, and the inhibition is **dead-end inhibition** because the complex with the inhibitor is unable to engage in any further reaction while the inhibitor is bound. If the steady-state approximation is applied to the form [E·I]

$$k_{i,1}[E][I] = k_{i,-1}[E{\cdot}I] \qquad (3\text{–}184)$$

and the form [E·A·I]

$$k_{i,2}[E{\cdot}A][I] = k_{i,-2}[E{\cdot}A{\cdot}I] \qquad (3\text{–}185)$$

Because the concentration of I does not change during the reaction

$$\frac{[E][I]}{[E{\cdot}I]} = \frac{k_{i,-1}}{k_{i,1}} \qquad (3\text{–}186)$$

and

$$\frac{[E{\cdot}A][I]}{[E{\cdot}A{\cdot}I]} = \frac{k_{i,-2}}{k_{i,2}} \qquad (3\text{–}187)$$

The ratio $k_{i,-1}(k_{i,1})^{-1}$ is equal to the **dissociation constant**, K_{dI}, for the complex between the inhibitor and the unoccupied enzyme

$$K_{dI} = \frac{[E][I]}{[E{\cdot}I]} \qquad (3\text{–}188)$$

and the ratio $k_{i,-2}(k_{i,2})^{-1}$ is equal to the dissociation constant $K_{dI,A}$ for the inhibitor from the complex between enzyme, inhibitor I, and reactant A

$$K_{dI,A} = \frac{[E{\cdot}A][I]}{[E{\cdot}A{\cdot}I]} \tag{3–189}$$

Consequently

$$\begin{array}{ccccc} E + A & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & E{\cdot}A & \xrightarrow{k_2} & E + Z \\ + & & + & & \\ I & & I & & \\ \Big\downarrow\uparrow K_{dI} & & \Big\downarrow\uparrow K_{dI,A} & & \\ E{\cdot}I & & E{\cdot}A{\cdot}I & & \end{array} \tag{3–190}$$

The existence of these complexes between enzyme and inhibitor expands the equation stating the **conservation of enzyme** (Equation 3–58)

$$[E]_t = [E] + [E{\cdot}I] + [E{\cdot}A] + [E{\cdot}A{\cdot}I] \tag{3–191}$$

and the number of unknowns, but it also provides two additional simultaneous equations, those for the two dissociation constants (Equation 3–188 and 3–189). It turns out that this is a trivial expansion because the unknowns [E·I] and [E·A·I] are eliminated immediately

$$\begin{aligned} [E]_t &= \left(1 + \frac{[I]}{K_{dI}}\right)[E] + \left(1 + \frac{[I]}{K_{dI,A}}\right)[E{\cdot}A] \\ &= \left(\frac{K_{dI} + [I]}{K_{dI}}\right)[E] + \left(\frac{K_{dI,A} + [I]}{K_{dI,A}}\right)[E{\cdot}A] \end{aligned} \tag{3–192}$$

Immediate eliminations of this type account for the appearance in expressions for v_0 of terms such as $(K_{dI} + [I])K_{dI}^{-1}$, $(K_a + [H^+])K_a^{-1}$, and $(K_{dL} + [L])K_{dL}^{-1}$, where K_a is an acid dissociation constant for the enzyme and K_{dL} is the dissociation constant for the complex of a ligand, L, and the enzyme. Because there are now only two unknowns in the equation for the conservation of enzyme (Equation 3–192), the only steady-state approximation needed is Equation 3–60, and

$$\begin{aligned} v_0 = & \\ & \frac{k_2[E]_t\left(\frac{K_{dI,A}}{[I] + K_{dI,A}}\right)\left(\frac{k_2k_1}{k_{-1} + k_2}\right)[E]_t\left(\frac{K_{dI}}{[I] + K_{dI}}\right)[A]_0}{k_2[E]_t\left(\frac{K_{dI,A}}{[I] + K_{dI,A}}\right) + \left(\frac{k_2k_1}{k_{-1} + k_2}\right)[E]_t\left(\frac{K_{dI}}{[I] + K_{dI}}\right)[A]_0} \\ & = \frac{k_0\left(\frac{K_{dI,A}}{[I] + K_{dI,A}}\right)[E]_t\, k_A\left(\frac{K_{dI}}{[I] + K_{dI}}\right)[E]_t\,[A]_0}{k_0\left(\frac{K_{dI,A}}{[I] + K_{dI,A}}\right)[E]_t + k_A\left(\frac{K_{dI}}{[I] + K_{dI}}\right)[E]_t\,[A]_0} \end{aligned} \tag{3–193}$$

Notice in this general case, the inhibition is linear because both the catalytic constant and the specificity constant are decreased by a term $K_I([I] + K_I)^{-1}$. **If the inhibition is in fact dead-end, kinetic measurements can be used to determine numerical values for the actual dissociation constants of the inhibitor.**

If $K_{dI,A} = \infty$ and I cannot associate with E·A, then Equation 3–193 has the form of Equation 3–170, and inhibitor I is competitive with respect to reactant A. Consequently, one explanation for the observation of reversible competitive inhibition is that, for whatever reason, a molecule of inhibitor I and a molecule of reactant A cannot associate simultaneously with the enzyme.

This explanation is often extended by the assumption that this exclusion results from the competition between the inhibitor and the reactant for the same location in an active site of the enzyme because the site with which inhibitor I associates includes a portion or all of the site with which reactant A associates so that the association of one precludes the association of the other. For example, it seems reasonable to assume that, since $MgAMPPCP^{2-}$ (**3–5**) is competitive with respect to $MgATP^{2-}$ in the reactions catalyzed by phosphoribosylformylglycinamidine synthase (Figure 3–9B) and Rho protein kinase (Figure 3–10A), $MgAMPPCP^{2-}$ and $MgATP^{2-}$, which differ from each other at only one atom in their structures, compete for association with the same location in the respective active site.

There is in general, however, no necessity to make this assumption of competition for the same site. For example, if reversible isomerizations of the enzyme occur between the dissociation of I and the

association of A, their existence will usually have no effect on the algebraic form of the final rate equation for v_0. There is one type of reversible isomerization, however, that can explain the ability of some enzymes to be inhibited competitively by inhibitors that do not resemble any of the reactants for the enzyme and do not compete with any of the reactants for the same location in the active site. If one isomer of the enzyme binds only inhibitor I and not reactant A and the other isomer of the enzyme binds only reactant A and not inhibitor I, inhibitor I will be competitive with respect to reactant A regardless of where it associates with the enzyme. Such competitive inhibition at a distance has been observed and will be discussed later.

The experimental observation that an inhibitor I is competitive with respect to reactant A (Figures 3–9A,B, 3–10A, and 3–11A,C) means that, regardless of the concentration of inhibitor I, increasing the concentration of reactant A can completely reverse the effect of inhibitor I on the initial rate for an enzymatic reaction.

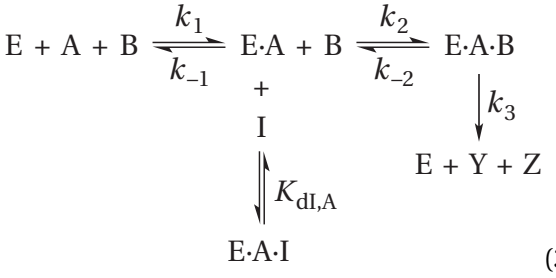
In Equation 3–193, if $K_{dI} = \infty$ and I cannot associate with E, then the equation has the form of Equation 3–175, and inhibitor I is uncompetitive with respect to reactant A. Consequently, one explanation for uncompetitive inhibition with respect to reactant A is that the inhibitor for whatever reason is able to associate only with the complex between the enzyme and reactant A. Uncompetitive inhibition can result from the fact that the association of reactant A with the enzyme creates the site with which inhibitor I associates. Reactant A can accomplish this feat by participating structurally in the site with which inhibitor I associates or by stabilizing the isomer of the enzyme containing the site with which inhibitor I associates. For example, the fact that $MgAMPPCP^{2-}$ (**3–5**) is uncompetitive with respect to L-glutamine (Figure 3–9C,D) is consistent with the proposal that the association of L-glutamine with phosphoribosylformylglycinamidine synthase creates the site with which $MgATP^{2-}$ associates. At the least, L-glutamine must associate with the enzyme before $MgAMPPCP^{2-}$ can associate with it.

In Equation 3–193, if $K_{dI} = K_{dI,A}$, then the equation has the form of Equation 3–177, and inhibitor I is noncompetitive with respect to reactant A. Consequently, one explanation for the observation of reversible noncompetitive inhibition is that the inhibitor has the same dissociation constant for the enzyme whether or not reactant A has associated with it. This explanation is usually invoked when the inhibitor resembles neither reactant and is noncompetitive with respect to both reactants.

In Equation 3–193, if $\infty > K_{dI} \neq K_{dI,A} < \infty$, then the equation has the form expected for mixed inhibition (Equation 3–180). Consequently, one explanation for mixed inhibition is that the inhibitor is able to associate with the complex between enzyme and reactant A and with the unoccupied enzyme, but for some reason the dissociation constant for its complex with enzyme when it is occupied by reactant A is different from the dissociation constant for its complex with the enzyme when it is unoccupied. If K_{dI} is less than $K_{dI,A}$ and the inhibitor has a greater affinity for the enzyme when it is unoccupied than when it is occupied by reactant A, the lines will intersect in the second quadrant. Because the effect of the inhibitor is greater on $k_A[E]_t$ in Equation 3–40 than it is on $k_0[E]_t$, this type of mixed inhibition is predominantly competitive. If $K_{dI,A}$ is less than K_{dI} and the inhibitor has a greater affinity for the enzyme when it is occupied by reactant A than when it is unoccupied, the lines will intersect in the third quadrant. Because the effect of the inhibitor is greater on $k_0[E]_t$ in Equation 3–40 than it is on $k_A[E]_t$, this type of mixed inhibition is predominantly uncompetitive.

The patterns of inhibition of an enzymatic reaction that has two or more reactants can provide evidence for the order in which the reactants associate with the active site.

Consider the case of a kinetic mechanism for two reactants that proceeds by the ordered association of its reactants (Equation 3–109) and in which inhibitor I can associate only after reactant A associates and inhibitor I excludes the association of reactant B



(3–194)

The rate equation for this kinetic mechanism is

$$v_0 = \frac{\left(\frac{k_1k_2k_3}{k_{-2}+k_3}\right)[\mathrm{E}]_t[\mathrm{A}]_0[\mathrm{B}]_0}{k_{-1}+k_1\left(\frac{[\mathrm{I}]+K_{\mathrm{dI,A}}}{K_{\mathrm{dI,A}}}\right)[\mathrm{A}]_0+\left(\frac{k_2k_3}{k_{-2}+k_3}\right)[\mathrm{B}]_0+\left(\frac{k_1k_2}{k_{-2}+k_3}\right)[\mathrm{A}]_0[\mathrm{B}]_0} \quad (3\text{–}195)$$

When $[A]_0$ is varied at several fixed concentrations of inhibitor I and at the same fixed concentration of $[B]_0$,

$$\lim_{[\mathrm{A}]_0\to\infty} v_0 = k_{0,\mathrm{A,app}}[\mathrm{E}]_t = \frac{\left(\frac{k_2k_3}{k_{-2}+k_3}\right)\left(\frac{K_{\mathrm{dI,A}}}{[\mathrm{I}]+K_{\mathrm{dI,A}}}\right)[\mathrm{E}]_t[\mathrm{B}]_0}{1+\left(\frac{k_2}{k_{-2}+k_3}\right)\left(\frac{K_{\mathrm{dI,A}}}{[\mathrm{I}]+K_{\mathrm{dI,A}}}\right)[\mathrm{B}]_0} = \left(\frac{K_{\mathrm{iuI,app}}}{[\mathrm{I}]+K_{\mathrm{iuI,app}}}\right)\frac{k_2k_3[\mathrm{E}]_t[\mathrm{B}]_0}{k_{-2}+k_3+k_2[\mathrm{B}]_0} \quad (3\text{–}196)$$

and

$$\lim_{[\mathrm{A}]_0\to 0} v_0 = k_{\mathrm{A,app}}[\mathrm{E}]_t[\mathrm{A}]_0 = \frac{\left(\frac{k_1k_2k_3}{k_{-2}+k_3}\right)[\mathrm{B}]_0[\mathrm{E}]_t[\mathrm{A}]_0}{k_{-1}+\left(\frac{k_2k_3}{k_{-2}+k_3}\right)[\mathrm{B}]_0} \quad (3\text{–}197)$$

Because [I] affects $k_{0,\mathrm{A,app}}[\mathrm{E}]_t$ but not $k_{\mathrm{A,app}}[\mathrm{E}]_t$, inhibitor I is uncompetitive with respect to reactant A at all $[B]_0$. The uncompetitive inhibition is linear with an apparent inhibition constant

$$K_{\mathrm{iuI,app}} = \left(\frac{k_{-2}+k_3+k_2[\mathrm{B}]_0}{k_{-2}+k_3}\right)K_{\mathrm{dI,A}} \quad (3\text{–}198)$$

The ratio $(k_{-2}+k_3)k_2^{-1}$ is the Michaelis constant, K_{mB}, for reactant B in the absence of inhibitor (Equation 3–104 and Equation 3–167). Only when the concentration of B is significantly less than its Michaelis constant is the apparent inhibition constant equal to the dissociation constant for the inhibitor.

If the inhibition is governed by Equation 3–195, when $[B]_0$ is varied at several fixed concentrations of inhibitor I, always at the same fixed concentration of $[A]_0$

$$\lim_{[\mathrm{B}]_0\to\infty} v_0 = k_{0,\mathrm{B,app}}[\mathrm{E}]_t = \frac{k_1k_3[\mathrm{E}]_t[\mathrm{A}]_0}{k_3 + k_1[\mathrm{A}]_0} \quad (3\text{–}199)$$

and

$$\lim_{[\mathrm{B}]_0\to 0} v_0 = k_{\mathrm{B,app}}[\mathrm{E}]_t[\mathrm{B}]_0 = \frac{\left(\frac{K_{\mathrm{dI,A}}}{[\mathrm{I}]+K_{\mathrm{dI,A}}}\right)\left(\frac{k_2k_3}{k_{-2}+k_3}\right)[\mathrm{A}]_0[\mathrm{E}]_t[\mathrm{B}]_0}{\left(\frac{K_{\mathrm{dI,A}}}{[\mathrm{I}]+K_{\mathrm{dI,A}}}\right)\left(\frac{k_{-1}}{k_1}\right)+[\mathrm{A}]_0} = \left(\frac{K_{\mathrm{icI,app}}}{[\mathrm{I}]+K_{\mathrm{icI,app}}}\right)\frac{k_1k_2k_3[\mathrm{A}]_0[\mathrm{E}]_t[\mathrm{B}]_0}{(k_{-2}+k_3)(k_{-1}+k_1[\mathrm{A}]_0)} \quad (3\text{–}200)$$

Because [I] affects $k_{\mathrm{B,app}}[\mathrm{E}]_t$ but not $k_{0,\mathrm{B,app}}[\mathrm{E}]_t$, inhibitor I is competitive with respect to reactant B at all $[A]_0$. The competitive inhibition is linear with an apparent inhibition constant

$$K_{\mathrm{icI,app}} = \left(\frac{k_{-1}+k_1[\mathrm{A}]_0}{k_1[\mathrm{A}]_0}\right)K_{\mathrm{dI,A}} \quad (3\text{–}201)$$

The ratio $k_{-1}\ k_1^{-1}$ is the dissociation constant, K_{dA}, for reactant A from the unoccupied active site. Only when the fixed concentration of reactant A is significantly greater than this dissociation constant will the apparent inhibition constant be equal to the dissociation constant for the inhibitor for the active site that is occupied by reactant A. This conclusion makes sense because the site for association of the inhibitor exists only when the active site is occupied by reactant A.

Consequently, **the facts that inhibitor I is uncompetitive with respect to reactant A and competitive with respect to reactant B are consistent with the conclusion that reactant A must associate with the enzyme before reactant B**. For example, the facts that N^2-(carboxymethyl)-L-arginine is competitive with respect to N^2-(carboxyethyl)-L-argi-

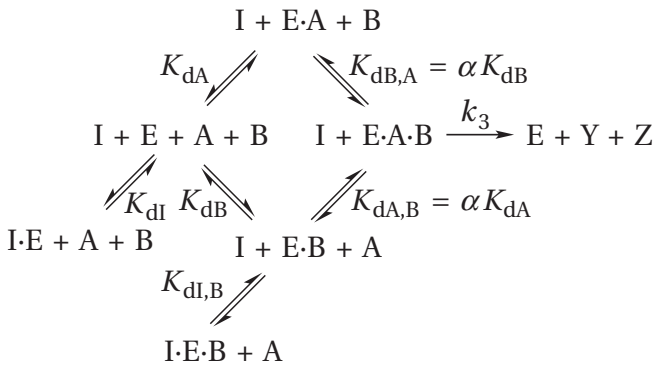
nine and uncompetitive with respect to $MgATP^{2-}$ are consistent with the conclusion that $MgATP^{2-}$ must associate with (carboxyethyl)arginine β-lactam-synthase from *Streptomyces clavuligerus*

$$\text{L-}N^2\text{-(2-carboxyethyl)arginine} + MgATP^{2-} \rightleftharpoons AMP^- + MgOPO_3PO_3^{2-} + \text{deoxyamidinoproclaviminate} \tag{3–202}$$

before N^2-(carboxyethyl)-L-arginine can associate with the enzyme.[103]

Regardless of the kinetic mechanism being tested, for any given enzymatic reaction, in the absence of any pertinent information, **either of the actual reactants can be reactant A or reactant B.** If there are more than two reactants, any one of them could be reactant A, reactant B, reactant C, and so forth. In the particular instance of (carboxyethyl)-arginine β-lactam-synthase, the fact that N^2-(carboxymethyl)-L-arginine is competitive with respect to N^2-(carboxyethyl)-L-arginine and uncompetitive with respect to $MgATP^{2-}$ is consistent with the conclusions that $MgATP^{2-}$ is actually reactant A and N^2-(carboxymethyl)-L-arginine is reactant B and that the addition of the two reactants to the active site is ordered.

Consider the case of a kinetic mechanism for two reactants that proceeds by the **random equilibrium association** of its reactants (Equation 3–121) and in which inhibitor I can associate with the active site only when reactant A is not bound



(3–203)

In this instance, the equation for conservation of enzyme becomes

$$[E]_t = [E] + [E{\cdot}I] + [E{\cdot}B] + [I{\cdot}E{\cdot}B] + [E{\cdot}A] + [E{\cdot}A{\cdot}B]$$
$$= \left(1 + \frac{[I]}{K_{dI}}\right)[E] + \left(1 + \frac{[I]}{K_{dI,B}}\right)[E{\cdot}B] + [E{\cdot}A] + [E{\cdot}A{\cdot}B] \tag{3–204}$$

Solving for the rate equation and taking the limits (see Equations 3–121 through 3–133)

$$\lim_{[A]_0 \to \infty} v_0 = k_{0,A,app}[E]_t = \frac{k_3[E]_t[B]_0}{\alpha K_{dB} + [B]_0} \tag{3–205}$$

$$\lim_{[A]_0 \to 0} v_0 = k_{A,app}[E]_t = \frac{k_3[E]_t[B]_0}{\left(\frac{[I] + K_{dI}}{K_{dI}}\right)\alpha K_{dA}K_{dB} + \left(\frac{[I] + K_{dI,B}}{K_{dI,B}}\right)\alpha K_{dA}[B]_0} \tag{3–206}$$

$$\lim_{[B]_0 \to \infty} v_0 = k_{0,B,app}[E]_t = \frac{k_3[E]_t[A]_0}{\left(\frac{[I] + K_{dI,B}}{K_{dI,B}}\right)\alpha K_{dA} + [A]_0} \tag{3–207}$$

$$\lim_{[B]_0 \to 0} v_0 = k_{B,app}[E]_t = \frac{k_3[E]_t[A]_0[B]_0}{\alpha K_{dB}\left\{\left(\frac{[I] + K_{dI}}{K_{dI}}\right)K_{dA} + [A]_0\right\}} \tag{3–208}$$

As expected, since the inhibitor cannot associate with the enzyme when the active site is occupied by A, the inhibitor is competitive with respect to reactant A at all concentrations of reactant B because there are no terms in Equation 3–205 involving the concentration of inhibitor I. If α is other than 1 and K_{dI} is not equal to $K_{dI,B}$, the inhibition is mixed with respect to reactant B, but if α is equal to 1 and K_{dI} is equal to $K_{dI,B}$, then the same factor involving the inhibitor decreases both $k_{0,B,app}$ and $k_{B,app}$, and the inhibition will be noncompetitive with respect to reactant B.

Consequently, **the facts that inhibitor I is competitive with respect to reactant A and noncompetitive with respect to reactant B are consistent**

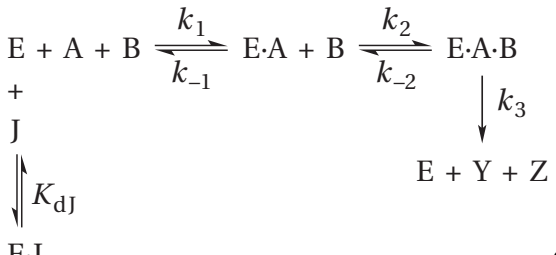
with the conclusion that reactant A and reactant B associate with the enzyme at random. For example, the fact that MgAMPPCP^{2-} (**3–5**) is competitive with respect to MgATP^{2-} (Figure 3–9B) and noncompetitive with respect to N^2-formyl-N^1-(5-phospho-D-ribosyl)glycinamide (Figure 3–9E,F) is consistent with the conclusions that the association of N^2-formyl-N^1-(5-phospho-D-ribosyl)glycinamide with phosphoribosylformylglycinamidine synthase (Equation 3–173) from *G. gallus* does not affect the association of MgATP^{2-} with the enzyme and that N^2-formyl-N^1-(5-phospho-D-ribosyl)glycinamide and MgATP^{2-} add at random to the enzyme. The uncompetitive inhibition by MgAMPPCP^{2-} with respect to L-glutamine (Figure 3–9D) is consistent with the conclusion that neither MgATP^{2-} nor N^2-formyl-N^1-(5-phospho-D-ribosyl)-glycinamide can associate with the enzyme until L-glutamine has. A similar pattern of competitive, noncompetitive, and uncompetitive inhibition by L-phenyllactate with respect to phenylpyruvate, NH_4^+, and NADH, respectively, has been observed with phenylalanine dehydrogenase from *Rhodococcus*[104]

$$H^+ + \text{NADH} + \text{phenylpyruvate} + NH_4^+ \rightleftharpoons \text{L-phenylalanine} + H_2O + NAD^+ \quad (3\text{–}209)$$

In studies that use inhibitors resembling reactants to provide evidence that reactants add at random to the enzyme, **it is desirable to have inhibitors that exclude each of the reactants in turn**. The ability of each inhibitor to exclude one of the reactants is validated by showing that each inhibitor is competitive with respect to its respective congeneric reactant. Suppose that two inhibitors are available, inhibitors I and J, that closely resemble reactants A and B. The association of inhibitor I with the enzyme excludes reactant A but does not affect the association of reactant B, and the association of inhibitor J with the enzyme excludes reactant B but does not affect the association of reactant A. If reactants A and B bind at random to the active site, then inhibitor I will be competitive with respect to reactant A but noncompetitive with respect to reactant B, and inhibitor J will be competitive with respect to reactant B but noncompetitive with respect to reactant A.

For example, the synthetic peptide biotin-AKRRRLSSLRA-NH_2, which contains the two serines to be phosphorylated by the enzyme, can serve as a reactant for human Rho protein kinase, and acetyl-AKRRRLAALRA-NH_2, in which those two serines have been replaced with alanines, can serve as an inhibitor homologous to biotin-AKRRRLSSLRA-NH_2. Magnesium 5′-adenylic methylenediphosphonic anhydride (**3–5**) can serve as an inhibitor homologous to the other reactant, MgATP^{2-}. Magnesium 5′-adenylic methylenediphosphonic anhydride is competitive with respect to MgATP^{2-} (Figure 3–10A) and noncompetitive with respect to biotin-AKRRRLSSLRA-NH_2 (Figure 3–10E), and acetyl-AKRRRLAALRA-NH_2 is competitive with respect to biotin-AKRRRLSSLRA-NH_2 (Figure 3–10C) and almost noncompetitive with respect to MgATP^{2-} (Figure 3–10I).[98] This symmetric behavior of the two inhibitors is more convincing evidence for the conclusion that the two reactants, MgATP^{2-} and biotin-AKRRRLSSLRA-NH_2, can associate at random with the enzyme than if only one of these inhibitors was used because, in this case, each inhibitor, the structure of which is based closely on the respective chemical structure of one of the reactants, has the same or almost the same dissociation constant from the enzyme whether or not the other reactant is associated with it.

In the case of an ordered mechanism, however, inhibitors that exclude reactant A, the first reactant to associate with the active site, rather than reactant B, the second, can produce ambiguous results. Suppose that reactant A must associate with the enzyme before reactant B. As has already been demonstrated for the kinetic mechanism of Equation 3–194, inhibitor I, which may or may not be structurally related to reactant B but the association of which excludes the association of reactant B, should be competitive with respect to reactant B and uncompetitive with respect to reactant A (Equation 3–195). This behavior was observed with MgAMPPCP^{2-} in its inhibition of phosphoribosylformylglycinamidine synthase (Figure 3–9D) and with N^2-(carboxymethyl)-L-arginine in its inhibition of (carboxyethyl)arginine β-lactamsynthase (Equation 3–202). Suppose, for the same active site, one also has an **inhibitor J that may or may not be structurally related to reactant A but the association of which excludes reactant A from associating with the active site** and that forms a dead-end complex with the unoccupied active site



(3–210)

The rate equation for this kinetic mechanism is

$$v_0 = \frac{\left(\frac{k_1 k_2 k_3}{k_{-2} + k_3}\right)[\mathrm{E}]_t[\mathrm{A}]_0[\mathrm{B}]_0}{k_{-1}\left(\frac{[\mathrm{J}] + K_{\mathrm{dJ}}}{K_{\mathrm{dJ}}}\right) + k_1[\mathrm{A}]_0 + \left(\frac{k_2 k_3}{k_{-2} + k_3}\right)\left(\frac{[\mathrm{J}] + K_{\mathrm{dJ}}}{K_{\mathrm{dJ}}}\right)[\mathrm{B}]_0 + \left(\frac{k_1 k_2}{k_{-2} + k_3}\right)[\mathrm{A}]_0[\mathrm{B}]_0} \tag{3–211}$$

and

$$\lim_{[\mathrm{A}]_0 \to \infty} v_0 = k_{0,\mathrm{A,app}}[\mathrm{E}]_t = \frac{\left(\frac{k_2 k_3}{k_{-2} + k_3}\right)[\mathrm{B}]_0[\mathrm{E}]_t}{1 + \left(\frac{k_2}{k_{-2} + k_3}\right)[\mathrm{B}]_0} \tag{3–212}$$

$$\lim_{[\mathrm{A}]_0 \to 0} v_0 = k_{\mathrm{A,app}}[\mathrm{E}]_t[\mathrm{A}]_0 = \frac{\left(\frac{K_{\mathrm{dJ}}}{[\mathrm{J}] + K_{\mathrm{dJ}}}\right)\left(\frac{k_1 k_2 k_3}{k_{-2} + k_3}\right)[\mathrm{B}]_0[\mathrm{E}]_t[\mathrm{A}]_0}{k_{-1} + \left(\frac{k_2 k_3}{k_{-2} + k_3}\right)[\mathrm{B}]_0} \tag{3–213}$$

so inhibitor J is a linear competitive inhibitor with respect to reactant A at all values of $[\mathrm{B}]_0$.

The limits for the inhibition of inhibitor J with respect to reactant B are

$$\lim_{[\mathrm{B}]_0 \to \infty} v_0 = k_{0,\mathrm{B,app}}[\mathrm{E}]_t = \frac{\left(\frac{K_{\mathrm{dJ}}}{[\mathrm{J}] + K_{\mathrm{dJ}}}\right)k_3[\mathrm{A}]_0[\mathrm{E}]_t}{\left(\frac{k_3}{k_1}\right) + \left(\frac{K_{\mathrm{dJ}}}{[\mathrm{J}] + K_{\mathrm{dJ}}}\right)[\mathrm{A}]_0} = \left(\frac{K_{\mathrm{iuJ,app}}}{[\mathrm{J}] + K_{\mathrm{iuJ,app}}}\right)\frac{k_1 k_3[\mathrm{A}]_0[\mathrm{E}]_t}{k_3 + k_1[\mathrm{A}]_0} \tag{3–214}$$

where

$$K_{\mathrm{iuJ,app}} = \left(\frac{k_3 + k_1[\mathrm{A}]_0}{k_3}\right)K_{\mathrm{dJ}} \tag{3–215}$$

and

$$\lim_{[\mathrm{B}]_0 \to 0} v_0 = k_{\mathrm{B,app}}[\mathrm{E}]_t[\mathrm{B}]_0 = \frac{\left(\frac{K_{\mathrm{dJ}}}{[\mathrm{J}] + K_{\mathrm{dJ}}}\right)\left(\frac{k_2 k_3}{k_{-2} + k_3}\right)[\mathrm{A}]_0[\mathrm{E}]_t[\mathrm{B}]_0}{\left(\frac{k_{-1}}{k_1}\right) + \left(\frac{K_{\mathrm{dJ}}}{[\mathrm{J}] + K_{\mathrm{dJ}}}\right)[\mathrm{A}]_0} = \left(\frac{K_{\mathrm{icJ,app}}}{[\mathrm{J}] + K_{\mathrm{icJ,app}}}\right)\frac{k_1 k_2 k_3[\mathrm{A}]_0[\mathrm{E}]_t[\mathrm{B}]_0}{(k_{-2} + k_3)(k_{-1} + k_1[\mathrm{A}]_0)} \tag{3–216}$$

where

$$K_{\mathrm{icJ,app}} = \left(\frac{k_{-1} + k_1[\mathrm{A}]_0}{k_{-1}}\right)K_{\mathrm{dJ}} \tag{3–217}$$

It turns out that the value of the kinetic constants for this particular kinetic mechanism and the concentration of reactant A determine the type of inhibition displayed by inhibitor J with respect to reactant B. If both k_{-1} and k_3 are greater than $k_1[A]_0$, then both the apparent catalytic constant, $k_{0,B,app}$, and the apparent specificity constant, $k_{B,app}$ will be decreased by the same factor, and inhibitor J will be noncompetitive with respect to reactant B. The fact that the initial concentration of reactant A, however, appears in the expressions for the apparent inhibition constants means that there can be situations in which such noncompetitive inhibition will not be observed. Situations in which the inhibition with respect to reactant B are mixed are uninformative. If, however, $k_{-1} << k_3$, so that reactant A is a sticky reactant, then at high enough concentrations of reactant A, $K_{iuJ,app} << K_{icJ,app}$. When the concentrations of inhibitor J are all significantly less than $K_{icJ,app}$ but in the range of $K_{iuJ,app}$, the apparent specificity constant $k_{B,app}$ will be unaffected by the inhibitor while the apparent catalytic constant $k_{0,B,app}$ is decreasing significantly. In these circumstances, the inhibition observed will be uncompetitive with respect to reactant A rather than noncompetitive. An example of such behavior may be that for the inhibition of 4-hydroxy-tetrahydrodipicolinate synthase

$$\text{pyruvate} + \text{L-aspartate-4-semialdehyde} \rightleftharpoons (2S,4S)\text{-4-hydroxy-2,3,4,5-tetrahydrodipicolinate} + H^+ + H_2O \quad (3\text{–}218)$$

from *E. coli*. Both fluoropyruvate and 2-oxobutyrate are competitive inhibitors of the enzyme with respect to pyruvate at pH 8, but fluoropyruvate is noncompetitive with respect to L-aspartate-4-semialdehyde while 2-oxobutyrate is uncompetitive with respect to L-aspartate-4-semialdehyde.[105]

An **ambiguity** is raised by these considerations. It has already been stated that, because the letter designations can be interchanged, the facts that inhibitor I is uncompetitive with respect to reactant B and competitive with respect to reactant A are consistent with the conclusion that reactant B must associate with the enzyme before reactant A. It has just been demonstrated, however, that if an inhibitor I is competitive with respect to reactant A and uncompetitive with respect to reactant B, these observations are consistent with the conclusion that reactant A associates with the enzyme before reactant B. This contradiction is disconcerting. Dethiocoenzyme A, in which the sulfanyl group is replaced by a hydrogen,[106] is competitive with respect to acetyl-SCoA and uncompetitive with respect to glyoxylate in the reaction catalyzed by malate synthase

$$\text{glyoxylate} + \text{acetyl-SCoA} + H_2O \rightleftharpoons H^+ + \text{HSCoA} + (S)\text{-malate} \quad (3\text{–}219)$$

from *M. tuberculosis*. These facts are consistent with a kinetic mechanism in which glyoxylate must associate with the active site before acetyl-SCoA (Equations 3–194, 3–196, and 3–197), but they are also consistent with a kinetic mechanism in which acetyl-SCoA must associate with the active site before glyoxylate (Equations 3–210, 3–214, and 3–216). The fact, however, that the product malate is competitive with respect to glyoxylate and noncompetitive with respect to acetyl-SCoA is consistent only with the former kinetic mechanism[107] and resolves the ambiguity.

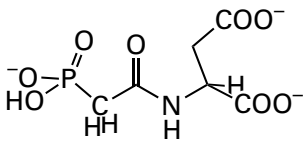
The situation can be summarized. Consider the two reactants, A and B. There are three possibilities: reactant A must associate with the active site before reactant B; reactant B must associate with the active site before reactant A; or reactant A and reactant B can associate with the active site at random.

If reactant A and reactant B add to the active site at random, an inhibitor that excludes the association of only reactant A will be competitive with respect to reactant A and noncompetitive with respect to reactant B, and an inhibitor that excludes only the association of reactant B will be competitive with respect to reactant B and noncompetitive with respect to reactant A. These four observations are unique and distinguish random addition from ordered addition of the reactants, but it is necessary to use both inhibitors to make the distinction.

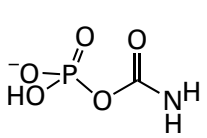
If reactant A is required to associate with the active site before reactant B in an ordered kinetic mechanism, if inhibitor I can associate only after reactant A associates, and if inhibitor I excludes the association of reactant B (Equation 3–194), inhibitor I will be competitive with respect to reactant B and uncompetitive with respect to reactant A. If reactant A is required to associate with the active site before reactant B in an ordered kinetic mechanism, if inhibitor I can associate only with the empty active site, and if inhibitor I excludes the association of

reactant A (Equation 3–210), inhibitor I will be competitive with respect to reactant A and noncompetitive, mixed, or uncompetitive with respect to reactant B. Consequently, if one of the inhibitors is uncompetitive with respect to the reactant that is not its congener and the other is noncompetitive with respect to the reactant that is not its congener, then both results are consistent with an ordered addition of the former reactant before the latter. **If, however, the two inhibitors are competitive with respect to their respective congeners but both are uncompetitive with respect to the other reactant, these observations are consistent with an ordered addition of reactants but cannot distinguish which reactant associates first**.

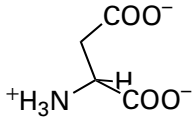
An inhibitor that specifically excludes both reactants from associating with the enzyme can provide evidence that the two reactants must associate with an enzyme in a particular order. The inhibitor *N*-phosphonacetyl-L-aspartate (**3–6**)[108]



3–6



3–7



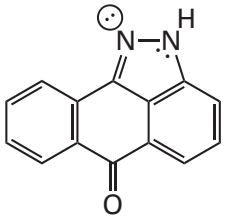
3–8

associates with aspartate carbamoyltransferase

$$\text{carbamoyl phosphate} + \text{L-aspartate} \rightleftharpoons \text{H}^+ + \textit{N}\text{-carbamoyl-L-aspartate} + \text{HOPO}_3^{2-} \quad (3\text{–}220)$$

from *E. coli* only when its active site is unoccupied. This exclusivity is due to the fact that *N*-phosphonacetyl-L-aspartate is a **bisubstrate analogue** composed of portions from both reactants for the enzyme, carbamoyl phosphate (**3–7**) and L-aspartate (**3–8**). If carbamoyl phosphate must associate with aspartate carbamoyltransferase before L-aspartate can associate, this behavior would be consistent with the observation that *N*-phosphonacetyl-L-aspartate is a competitive inhibitor with respect to carbamoyl phosphate but a noncompetitive inhibitor with respect to L-aspartate (Figure 3–14).[109,110] Had *N*-phosphonacetyl-L-aspartate, however, been competitive with respect to both reactants, then either reactant could have been bound by the unoccupied active site and the order of their addition in the enzymatic reaction would have been random. If inhibitor I can bind only to the completely unoccupied enzyme, every reactant with respect with which it is competitive should also be able to bind to the unoccupied active site, and the order of addition to the active site among that subset of reactants should be random.

In studies of the effect of inhibitors on steady-state kinetics, **the inhibitors do not have to resemble the reactants** so closely as the two used for Rho protein kinase or *N*-phosphonacetyl-L-aspartate; they need only associate with the enzyme in such a way as to exclude the association of one or the other reactant. For example, the inhibitor



3–9

happens to associate with human c-Jun amino-terminal protein kinase so as to prevent $MgATP^{2-}$ from associating with the enzyme, and the peptide RPKRPTTLNLF, which does not even contain the sequence of the region of the protein c-Jun that is phosphorylated by the enzyme and is not itself phosphorylated, nevertheless associates with the enzyme so as to prevent the association of the protein c-Jun. Inhibitor **3–9** is competitive with respect to $MgATP^{2-}$ and noncompetitive with respect to a peptide that can be phosphorylated by the enzyme, and the peptide RPKRPTTLNLF is competitive with respect to the peptide that can be phosphorylated but noncompetitive with respect to $MgATP^{2-}$.[111] A conclusion consistent with these observations is that $MgATP^{2-}$ and the protein or peptide to be phosphorylated associate at random with the active site of the enzyme.

The observation of mixed inhibition is usually uninformative about the order of addition of reactants, but not always. In the case of the inhibition of Rho protein kinase, acetyl-AKRRRLAALRA-NH_2 is not quite noncompetitive with respect to $MgATP^{2-}$ (Figure 3–10G–I) because its apparent dissociation constant for the unoccupied enzyme (Equation 3–193; $K_{dPAA} = 35\ \mu M$) is somewhat greater than its

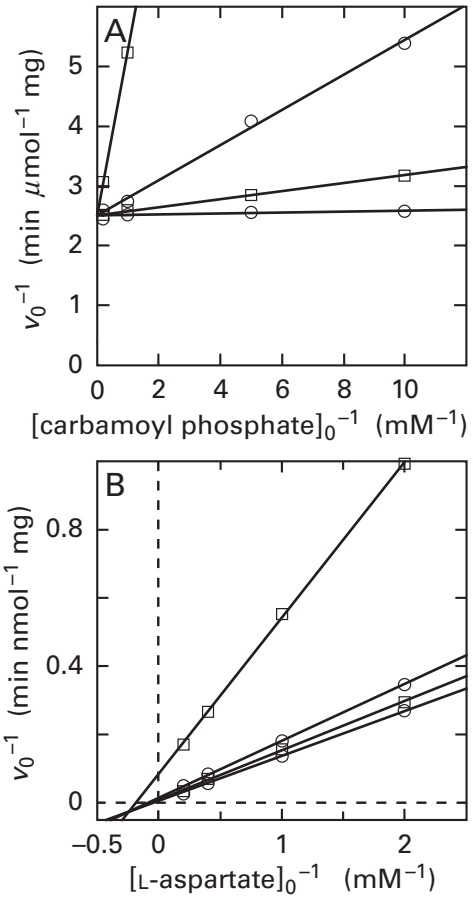


Figure 3–14: Kinetics for reversible inhibition of the carbamoyl transfer catalyzed by partially purified aspartate carbamoyltransferase from murine spleen by *N*-phosphonacetyl-L-aspartate.[110] Solutions containing L-aspartate and carbamoyl phosphate were prepared at pH 7.4 and 37 °C. Each carbamoyl transfer was initiated by adding enzyme. **(A)** The rate of production of *N*-carbamoyl-L-[^{14}C]aspartate (cAsp) was followed over several minutes to obtain each initial rate. For this assay, a small amount of L-[^{14}C]aspartate was added to a mixture, samples were withdrawn at appropriate intervals after addition of enzyme and quenched with acetic acid, and the *N*-carbamoyl-L-[^{14}C]aspartate was purified from each sample by cation-exchange chromatography. Reciprocals of initial rates for the production of *N*-carbamoyl-L-aspartate, v_0^{-1} [minutes micromole^{-1} (milligram of protein)] at 10 mM L-aspartate are presented as a function of the reciprocals of the initial concentrations of carbamoyl phosphate (millimolar^{-1}) at 0, 0.1, 1, and 10 μM *N*-phosphonacetyl-L-aspartate. The concentrations of inhibitor increase as the lines become steeper in slope. The initial rates were plotted directly as a function of the initial concentrations of carbamoyl phosphate (not shown), and the data were fit to Equation 3–52. The four values for parameter *a* of these fits were identical within their standard deviations, and a value of 0.40 μmol of *N*-carbamoyl-L-aspartate min^{-1} (mg of protein)$^{-1}$ was assigned to each of them. The lines in the drawing were forced to intersect at the axis of the ordinate at a value of 2.51 min (μmol of *N*-carbamoyl-L-aspartate)$^{-1}$ mg of protein. **(B)** The rate of production of *N*-[^{14}C]carbamoyl-L-aspartate was followed over several minutes to obtain each initial rate. For this assay, a small amount of [^{14}C]carbamoyl phosphate was added to a mixture, and samples were withdrawn at appropriate intervals after addition of enzyme and quenched with 10% perchloric acid. The strong acid hydrolyzed the [^{14}C]carbamoyl phosphate, but not the *N*-[^{14}C]carbamoyl-L-aspartate, to $^{14}CO_2$, and this radioactive CO_2 was flushed from each sample with unradioactive $^{12}CO_2$ to leave the enzymatically synthesized [^{14}C]carbamoyl-L-aspartate. Reciprocals of initial rates for the production of *N*-carbamoyl-L-aspartate, v_0^{-1} [minutes micromole^{-1} (milligram of protein)] at 20 mM carbamoyl phosphate are presented as a function of the reciprocals of the initial concentrations of L-aspartate (millimolar^{-1}) at 0.01, 0.05, 0.1, and 1 μM *N*-phosphonacetyl-L-aspartate. Lines were fit to the data, and average values for the ordinates and abscissas of the intersections of the line for 1 μM *N*-phosphonacetyl-L-aspartate and the other three lines were calculated. Lines forced to pass through this average point of intersection were then refit to the data, and these are the lines drawn in the figure.

apparent dissociation constant for the enzyme occupied by MgATP^{2-} (Equation 3–193; $K_{dPAA,ATP} = 16\,\mu M$). It comes as no surprise, however, that since the two reactants, MgATP^{2-} and biotin-AKRRRLSSLRA-NH_2, are to combine with each other while they are on the active site to produce products and hence must occupy adjacent subsites in the active site, the **association of one reactant can affect the affinity of the enzyme for an inhibitor mimicking the other**. In this case, the association of MgATP^{2-} increases the apparent affinity of the enzyme for the peptide inhibitor about 2-fold. If the association of MgATP^{2-} slightly improves the site on the enzyme with which the sequence –KRRRLAALRA– associates, then the observation that acetyl-AKRRRLAALRA-NH_2 is a competitive inhibitor relative to biotin and almost a noncompetitive inhibitor relative to MgATP^{2-} (Figure 3–10I) is still consistent with random association of reactants with the active site.

It is often difficult to distinguish uncompetitive inhibition, for which the double-reciprocal lines are parallel (Figure 3–9D) from mixed, predominantly uncompetitive inhibition, for which the double-reciprocal lines are almost parallel. This problem can be illustrated with a comparison of the inhibition of glycerol kinase from *C. norvegensis* by CrATP^{-} and the inhibition of hexokinase from *R. norvegicus* by unchelated ATP^{4-}.

If reactant A must associate with the enzyme before reactant B can associate, inhibitor I that excludes the association of reactant B will be competitive with respect to reactant B and uncompetitive with respect to reactant A. This proposal is an explanation for the behavior observed with glycerol kinase when the chromium complex of ATP^{4-}, CrATP^{-}, which closely resembles MgATP^{2-} but cannot engage in the enzymatic reaction, is used as an inhibitor (Figure 3–12).[100] The conclusion that MgATP^{2-} binds

to the enzyme only after glycerol binds to the enzyme would be consistent with these observations. It has already been noted, however, that when glycerol kinase phosphorylates (*S*)-1-aminopropane-2,3-diol, the observed kinetic behavior (Figure 3–7) is consistent with a kinetic mechanism in which $MgATP^{2-}$ binds to the enzyme before (*S*)-1-aminopropanol, an analogue for glycerol. Furthermore, glycerol kinase has a slow, but measurable, MgATPase activity in the absence of any cosubstrate, and this activity is another indication that $MgATP^{2-}$ can bind to the active site in the absence of glycerol.[86] Weak binding of $MgATP^{2-}$ to the unoccupied active site would allow it to precede (*S*)-1-aminopropanol onto the active site of glycerol kinase from *C. norvegensis*, even though it usually follows glycerol. Both of these observations seem to contradict the fact that $CrATP^{-}$ is an uncompetitive inhibitor with respect to glycerol. It could be the case, however, that either reactant can associate with the unoccupied active site but that the association of glycerol, rather than being required to precede the association of $MgATP^{2-}$ with the active site, simply decreases the dissociation constant for $MgATP^{2-}$ from the active site. This alteration does not have to involve a dramatic decrease in dissociation constant before the **converging double reciprocals for mixed, predominantly uncompetitive inhibition become indistinguishable from the parallel double reciprocals of uncompetitive inhibition**.

When unchelated ATP^{4-} is used as an inhibitor of hexokinase from *R. norvegicus*,[112] it is a mixed, predominantly uncompetitive inhibitor with respect to the reactant D-glucose (Figure 3–11C).[99] This observation and the fact that *N*-acetyl-D-glucosamine is a mixed, predominantly competitive inhibitor with respect to $MgATP^{2-}$ are consistent with the conclusion that D-glucose and $MgATP^{2-}$ associate with the enzyme at random. The lines in the double-reciprocal plot, however, are almost parallel when ATP^{4-} is the inhibitor with respect to D-glucose (Figure 3–11C). If they had been parallel, this pattern of inhibition would have indicated that the reactants must enter the active site of hexokinase in order, D-glucose before $MgATP^{2-}$.[113] If the association of D-glucose with hexokinase simply increases the affinity of the respective enzyme for $MgATP^{2-}$ by a significant factor, rather than being obligatory for the binding of $MgATP^{2-}$, then almost uncompetitive inhibition would be observed. If it is assumed, for the sake of argument, that K_{icATP} (3.3 mM) is the dissociation constant for unchelated ATP^{4-} from the unoccupied active site and K_{iuATP} (1.4 mM) is the dissociation constant for unchelated ATP^{4-} from the active site occupied by D-glucose, it would follow that a decrease in the dissociation constant of only a factor of 2.5 is sufficient to turn noncompetitive inhibition into almost uncompetitive inhibition. A significantly larger, but not dramatic, decrease in dissociation constant should accomplish this transformation. If this description is the explanation, $MgATP^{2-}$ should bind to the empty active site, albeit weakly.[86]

These considerations suggest that **all kinetic mechanisms in which the reactants are required to associate with an enzyme in a particular sequence are probably oversimplifications**. Reactants appear to associate in a particular order because the association of one reactant significantly, but not infinitely, decreases the dissociation constant of the other reactant from the enzyme.[86] In other words, the factor α in the kinetic mechanism of Equation 3–121 does not have to be that much smaller than 1 for random addition to become indistinguishable from ordered addition. An extreme example of this ambiguity is the fact that the apparent requirement for (4-hydroxyphenyl)-pyruvate to associate with human 4-hydroxyphenylpyruvate dioxygenase before molecular oxygen associates[114] is the result of a finite, albeit 3600-fold, increase in the rate at which oxygen associates with the enzyme caused by the association of (4-hydroxyphenyl)pyruvate.[115]

The association of a reactant frequently increases or decreases the affinity of the active site for an inhibitor, so mixed inhibition is often observed. In fact, the distinction between noncompetitive inhibition and mixed inhibition although formally justified, is in practice misleading.* It is usually assumed that the inhibition constants K_{icI} and K_{ucI} are the dissociation constants K_{dI} and $K_{dI,A}$ for inhibitor I from the active site unoccupied or occupied by reactant A, respectively (Equations 3–180 and 3–193). It is informative when the association of reactant A does not alter the dissociation constant of an inhibitor but not surprising when it does not. It is reasonable that the association of a reactant would change the affinity of the active site for

*The International Union of Biochemistry and Molecular Biology formally distinguishes noncompetitive inhibition from mixed inhibition. It seems that this distinction has been justified by the dramatic difference in form between Equations 3–177 and 3–180. In effect, the distinction is made at the level of observation. When, however, explanations for the various behaviors are considered, the distinction becomes ambiguous and is counterproductive.

the inhibitor because the complex between enzyme and reactant A is necessarily different from the enzyme when it is unoccupied by reactant A.

As a result of these considerations, it should never be assumed that inhibition by inhibitor I is formally noncompetitive and that K_{icI} and K_{ucI} are the same. The Michaelis constant for reactant A for the general case of mixed inhibition

$$K_{mA} = \frac{k_{0,A,app}\left(\frac{K_{iuI}}{[I] + K_{iuI}}\right)}{k_{A,app}\left(\frac{K_{icI}}{[I] + K_{icI}}\right)} \qquad (3\text{–}221)$$

Only when each curve is fit with Equation 3–52 to the values for the initial rate as a function of the initial concentration of reactant A at several concentrations of inhibitor I and the Michaelis constant, parameter *b* of the fits, remains the same within the standard deviations of the fits can it be concluded that K_{icI} and K_{ucI} are statistically the same and that the inhibition is formally noncompetitive.

In any case, it is reasonable to conclude that noncompetitive inhibition is actually a special case of mixed inhibition in which K_{iuI} and K_{icI} are the same. Traditionally, however, when a distinction between noncompetitive inhibition and mixed inhibition has purposely been avoided, the term noncompetitive inhibition has been used interchangeably for both situations.[96] This practice is both widely accepted and defensible. Semantically, noncompetitive inhibition encompasses any inhibition that is neither competitive nor uncompetitive, two special cases that do define mechanistically significant differences. Most publications describing enzymatic kinetics treat mixed inhibition and noncompetitive inhibition as the same thing and use the term noncompetitive inhibition for both of them. Consequently, when the actual data are not shown and it is simply stated that "noncompetitive inhibition was observed", there is no way to tell whether the inhibition was noncompetitive by the definition of the International Union of Biochemistry and Molecular Biology or just mixed inhibition. It follows that from here on it will be necessary to make no distinction between noncompetitive inhibition and mixed inhibition. In some cases, however, when the inhibition observed is mixed, that fact will be noted because it is usually informative to know whether the mixed inhibition is predominantly competitive or predominantly uncompetitive.

So far, the patterns of inhibition discussed have been for kinetic mechanisms in which reversible steps separate the associations of the reactants with the enzyme. Dead-end inhibition by reversible inhibitors homologous to reactants can also **provide information about kinetic mechanisms in which a kinetically irreversible step separates the association of the two reactants** for an enzymatic reaction. For example, in a ping-pong kinetic mechanism, the enzyme alternates symmetrically between two forms, each separated from the other by a respective irreversible step (Equation 3–154). An inhibitor I that excludes reactant A from the active site will be competitive with respect to reactant A and uncompetitive with respect to reactant B, and an inhibitor J that excludes reactant B from the active site will be competitive with respect to reactant B and uncompetitive with respect to reactant A.[116] Although they are consistent with the existence of an irreversible step between the association of reactant A and the association of reactant B and the existence of an irreversible step between the association of reactant B and the association of reactant A, such observations cannot determine whether the two irreversible steps are both due to the release of products of the reaction, only one is due to the dissociation of a product, or neither of them is due to the dissociation of a product. Product inhibition is used to make this determination.

The use of products of an enzymatic reaction as inhibitors can clarify the order in which reactants associate with an enzyme and are required to determine the order in which products dissociate from an enzyme. Because the products are directly derived from the reactants and relationships between reactants and products are more readily established, the inhibition displayed by a product is less equivocal than the inhibition displayed by an inhibitor that only resembles the reactant. By microscopic reversibility, **a product must be able to associate with the same location in the active site from which it dissociates** during the enzymatic reaction. This location is usually the same one with which one or more of the reactants associate. Consequently, **the association of a product with the enzyme necessarily prevents the association of a reactant that shares a portion of its structure with that product**. In the instance of product inhibition there is usually, but not always, little doubt that the

Table 3–2: Some Patterns of Product Inhibition[a]

mechanism		variable reactant			
		A		B	
	product inhibitor	unsaturated with B	saturated with B	unsaturated with A	saturated with A
A and B associate at random, Y and Z associate at random, and both complexes E·A·Y and E·Z·B can form[b]	Y	NC[c]	NI[d]	C[c]	C
	Z	C	C	NC	NI
A and B associate at random, Y and Z associate at random, B and Z share no common atoms, and B and Z can bind simultaneously to form E·Z·B, but the complex E·A·Y cannot form[b]	Y	C	NI	C	NI
	Z	C	C	NC	NI
A must associate before B, and Y and Z dissociate at random	Y	C	C	NC	
	Z	C	C	NC	
A must associate before B, and Y must dissociate before Z	Y	NC	UC[c]	NC	NC
	Z	C	C	NC	NI
A must associate before B, and X must dissociate before Y, which must dissociate before Z	X	NC	UC	NC	NC

	Z	C	C	NC	
Z dissociates after A associates but before B associates, and Y dissociates after B associates but before A associates[e]	Y	C	C	NC	NI
	Z	NC	NI	C	C
A and Z associate with one active site, B and Y associate with another active site, and the difference between A and Z is transferred from the first active site to the second[93]	Y	NC	NI	C	C
	Z	C	C	NC	NI

[a]These are patterns expected for product inhibition for an enzymatic reaction with formally two reactants and two or three products. For a more complete list see references 62 and 119, which are the sources for this table. [b]Reactants and products must associate and dissociate so rapidly that they are always at equilibrium with the active site. [c]Abbreviations: NC, noncompetitive (term includes mixed inhibition); C, competitive; UC, uncompetitive; [d]NI indicates that no inhibition occurs. In all these situations, in theory, the saturation of the active site with the indicated reactant would block access to the active site for the product that shares the same atoms and prevent it from being an inhibitor. In practice, the reactant, because its concentration cannot be infinite, simply increases the apparent dissociation constant for the inhibitory product by a finite factor. [e]Refers only to a mechanism confined to one active site, not cases where intermediates are moved between two or more different active sites as in the next mechanism.

association of the product as an inhibitor is with the active site of the enzyme and that its effect as an inhibitor is to sterically exclude one or more of the reactants. For example, when (*S*)-malate as a product associates with the active site of fumarate hydratase (Equation 3–1), fumarate as a reactant cannot also associate because (*S*)-malate and fumarate share the same carbon skeleton and associate at the same location in the active site.

Moreover, the hydroxy group of (*S*)-malate shares the same subsite in the active site as the other reactant, water, and when (*S*)-malate is bound to the active site, it should also prevent the association of that molecule of water. This latter consideration illustrates the fact that **at least one of the products of an enzymatic reaction that has two or more reactants usually contains atoms derived from two or more of the reactants** and will often exclude both or all of those reactants from the active site when it is bound there, depending upon how tightly the shared structures are bound. Therefore, the structures of the products and reactants and the structure of the active site will dictate which products exclude which reactants. In the following discussion, it will be assumed that product Z comes mainly from reactant A and product Y comes mainly from reactant B. This convention can be expanded to product X coming mainly from reactant C, product W coming mainly from reactant D, and so forth.

Because an active site must catalyze its reaction in both directions and because most of the reactions catalyzed by enzymes have fairly small changes in standard free energy associated with them, the products of an enzymatic reaction associate with the active site often as well as, if not more avidly than, the reactants do. In the occasional instance in which the change in standard free energy of an enzymatic reaction has a large negative value, it is possible, but not necessarily so, for the dissociation constant of a product to be so large that it does not associate with the active site at any achievable level of its concentration, and thus it cannot inhibit the enzymatic reaction. Usually, however, the dissociation constant of a product is within an achievable range of concentration, and in that range, the product will associate with the active site. **If it associates with the active site within an achievable range of concentration, a product will inhibit the conversion of reactants into products by enzymatic reaction.**

Inhibition of Enzymatic Reactions: Product Inhibition

Observation: An **example of the inhibition of an enzymatic reaction by its products** is the inhibition of pyruvate kinase from *O. cuniculus*

$$\text{phospho}\textit{enol}\text{pyruvate} + H^+ + \text{MgADP}^- \rightleftharpoons \text{MgATP}^{2-} + \text{pyruvate} \quad (3\text{–}222)$$

by the products pyruvate and $MgATP^{2-}$ when the reactants are chosen to be phospho*enol*pyruvate and $MgADP^-$ (Figure 3–15).[117,118] Pyruvate is a linear (Figure 3–15F) competitive (Figure 3–15A) inhibitor with respect to phospho*enol*pyruvate and a linear (Figure 3–15F) noncompetitive (Figure 3–15D) inhibitor with respect to $MgADP^-$, and $MgATP^{2-}$ is a linear (Figure 3–15E) competitive inhibitor with respect to both $MgADP^-$ (Figure 3–15B) and phospho*enol*pyruvate (Figure 3–15C).

Explanation: Rate equations for enzymatic reactions with two reactants and two products have been derived for kinetic mechanisms that differ one from the other in the order in which reactants and products enter and leave the active site.[62] These derivations include all steps involving association of the reactants with the active site and dissociation of each product that is chosen to act as the inhibitor in turn from the active site. From each of these rate equations, **the pattern in which each of the products should inhibit the reaction for a given kinetic mechanism could be established** (Table 3–2).[62,119]

Consider an **enzymatic reaction in which reactants A and B associate with the active site at random and products Y and Z dissociate at random**, and all complexes between substrates and enzyme are in rapid equilibrium relative to the rate of the conversion between E·A·B and E·Z·Y. Suppose that product Y excludes only reactant B and product Z excludes only reactant A, so complexes E·A·Y and E·Z·B can form. If product Y is present, so

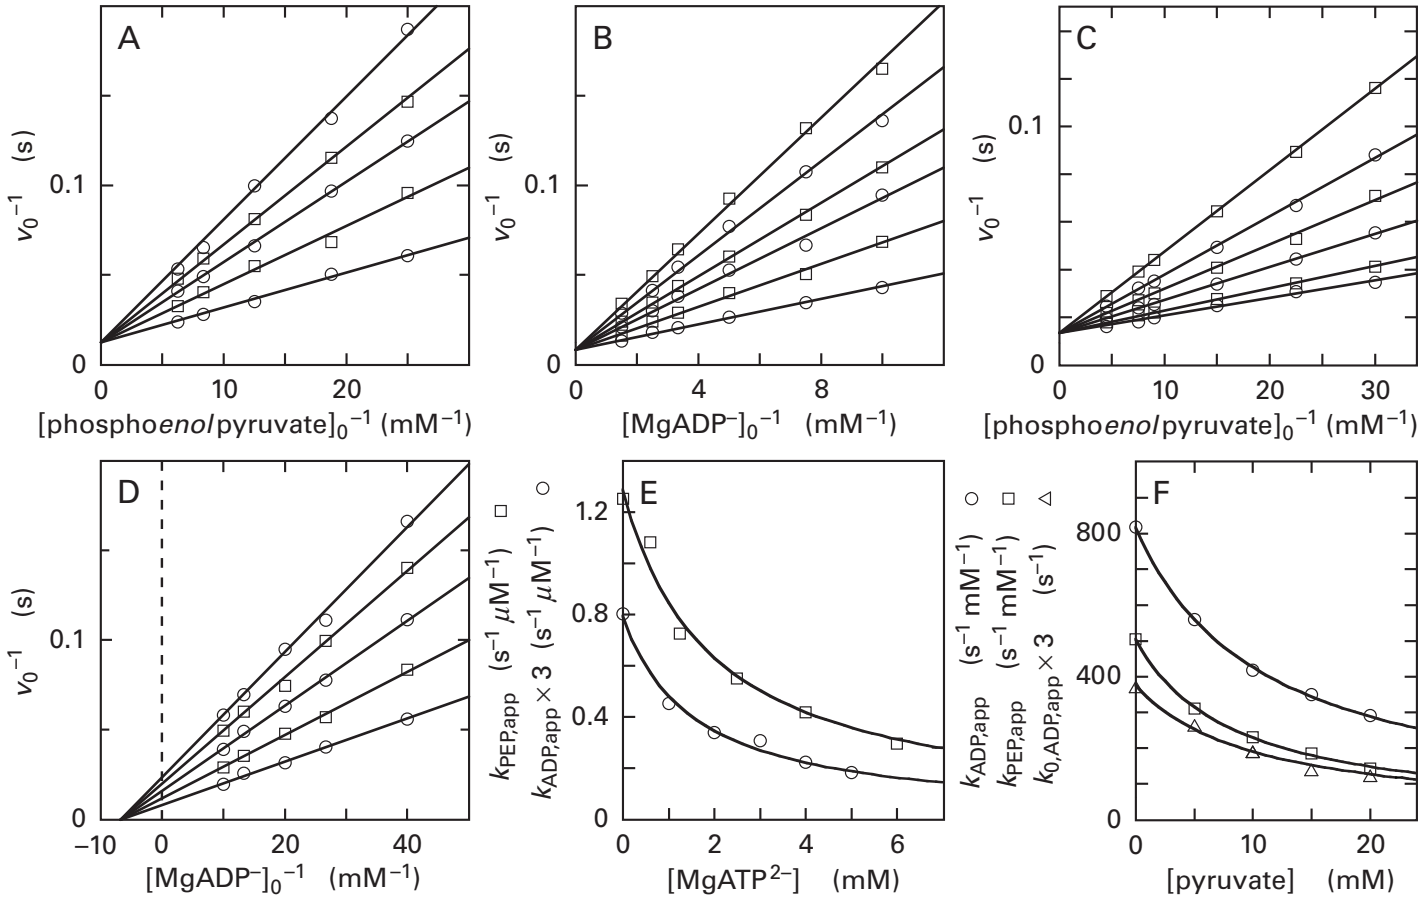

Figure 3–15: Kinetics for reversible inhibition by the products pyruvate and $MgATP^{2-}$ of the conversion of phospho*enol*pyruvate and $MgADP^-$ catalyzed by pyruvate kinase from *O. cuniculus*.[117] Solutions containing $MgADP^-$, phospho*enol*pyruvate , and $MgATP^{2-}$ or pyruvate, acting as product inhibitors, were prepared at pH 6.2. The concentration of uncomplexed Mg^{2+} was fixed at 10.0 mM and that of KCl at 0.10 M. Pyruvate kinase was added to initiate each phosphotransfer. When pyruvate was the inhibitor, production of $MgATP^{2-}$ was monitored by coupling it to the phosphorylation of 3-phospho-D-glycerate by phosphoglycerate kinase and the reduction of the resulting 3-phospho-D-glyceroyl phosphate by glyceraldehyde-3-phosphate dehydrogenase (phosphorylating). When $MgATP^{2-}$ was the inhibitor, production of pyruvate was followed by monitoring the oxidation of NADH by pyruvate catalyzed by L-lactate dehydrogenase. In each instance, the initial rate of decrease in A_{340} was used to calculate initial rates for the production of $MgATP^{2-}$ or pyruvate [micromoles minute^{-1} (microgram of enzyme)$^{-1}$]. The molar mass of a subunit of the enzyme (58,000 g mol^{-1}), which contains one independent active site,[118] was used to convert initial rates into units of second^{-1}. The concentrations of pyruvate or $MgATP^{2-}$ when one or the other is used as an inhibitor do not change significantly during the measurements of intial rates. **(A)** Reciprocals of the initial rates for the production of $MgATP^{2-}$, v_0^{-1} (seconds), as a function of reciprocals of the initial concentrations of phospho*enol*pyruvate (millimolar^{-1}). The concentrations of the product pyruvate were 0.0, 5.0, 10.0, 15.0, and 20.0 mM for the lines in ascending order. When the data were plotted directly (not shown) and fitted to Equation 3–52 with y equal to v_0 and x equal to the initial concentration of phospho*enol*pyruvate, the five values for parameter a of the fits, the apparent catalytic constants for phospho*enol*pyruvate, $k_{0,PEP,app}$, fluctuated unsystematically around a mean of 80 s^{-1}. Consequently, the five lines in this panel were forced to intersect the axis of the ordinate at 0.0125 s. **(B)** Reciprocals of the initial rates for the production of $MgATP^{2-}$, v_0^{-1} (second), as a function of reciprocals of the initial concentrations of phospho*enol*pyruvate (millimolar^{-1}). The concentrations of the product $MgATP^{2-}$ were 0.0, 0.6, 1.25, 2.5, 4.0, and 6.0 mM for the respective lines in ascending order. When the data were plotted directly and fit to Equation 3–52 (not shown) with y equal to v_0 and x equal to the initial concentration of phospho*enol*pyruvate, the values for parameter a of the fits, the apparent catalytic constants for phospho*enol*pyruvate, $k_{0,PEP,app}$, fluctuated unsystematically and were within a standard deviation of a mean of 73 s^{-1}. Consequently, the six lines in this panel were forced to intersect the axis of the ordinate at 0.0137 s. **(D)** Reciprocals of the initial rates for the production of $MgATP^{2-}$, v_0^{-1} (second), as a function of reciprocals of the initial concentrations of $MgADP^-$(millimolar^{-1}). The concentrations of pyruvate were 0.0, 5.0, 10.0, 15.0, and 20.0 mM for the respective lines in ascending order. When the data were plotted directly and fit to Equation 3–52 (not shown) with y equal to v_0 and x equal to the initial concentration of $MgADP^-$, the values for parameter b of the fits, the apparent Michaelis constants K_m, fluctuated unsystematically and were within a standard deviation of a mean of 0.148 mM. Consequently, the five lines in this panel were forced to intersect the axis of the abscissa at –6.8 mM^{-1}. **(E)** The observed values of the apparent specificity constant for phospho*enol*pyruvate, $k_{PEP,app}$ (second^{-1} micromolar^{-1}; □), from the direct plot and fit of the data in Panel C and the observed values of the apparent specificity constant for $MgADP^-$ $k_{ADP,app} \times 3$ (second^{-1} micromolar^{-1}; ○) from the direct plot and fit of the data in Panel B are plotted against the concentrations of $MgATP^{2-}$. The two values for parameter h, K_{ic}, in the fits of Equation 3–171 to the data, with y equal to $k_{PEP,app}$ or $k_{ADP,app}$ and x equal to [$MgATP^{2-}$], are 1.9 ± 0.3 mM and 1.55 ± 0.13 mM, respectively, which are identical within the errors of the measurements. **(F)** The observed values of the apparent specificity

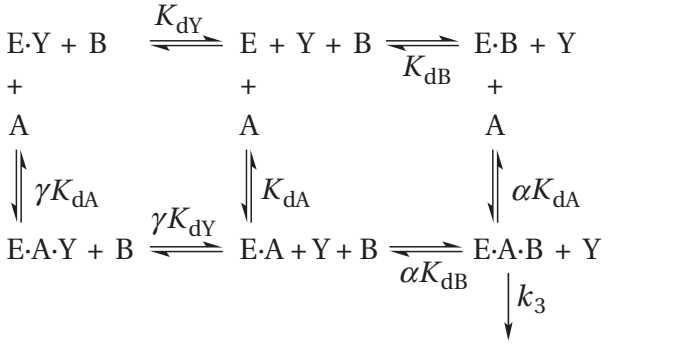
rocals of the initial rates for the production of pyruvate, v_0^{-1} (second), as a function of reciprocals of the initial concentrations of $MgADP^-$ (millimolar^{-1}). The initial concentrations of product $MgATP^{2-}$ were 0.0, 1.0, 2.0, 3.0, 4.0, and 5.0 mM for the lines in ascending order. When the data were plotted directly and fit to Equation 3–52 (not shown) with y equal to v_0 and x equal to the initial concentration of $MgADP^-$, the six values for parameter a of the fits, the apparent catalytic constants for $MgADP^-$, $k_{0,ADP,app}$, fluctuated unsystematically around a mean of 120 s^{-1}. Consequently, the six lines in this panel were forced to intersect the axis of the ordinate at 0.0083 s. **(C)** Reciprocals of the initial rates for the production of pyruvate, v_0^{-1} constant for $MgADP^-$, $k_{ADP,app}$ (second^{-1} millimolar^{-1}; ○), from the direct plot and fit of the data in Panel D; the observed values of the apparent specificity constant for phospho*enol*pyruvate, $k_{PEP,app}$ (second^{-1} millimolar^{-1}; □) from the direct plot and fit of the data in Panel A; and the observed values of the apparent catalytic constant for $MgADP^-$, $k_{0,ADP,app} \times 3$ (second^{-1}; △) from the direct plot and fit of the data in Panel D are plotted against the concentrations of pyruvate (millimolar). The three values for K_i, parameters h in the fits of Equation 3–171 with $k_{ADP,app}$, $k_{PEP,app}$, and $k_{0,ADP,app}$ equal to u and [pyruvate] equal to z, are 10.9 ± 0.2 mM, 8.4 ± 0.3 mM, and 10.2 ± 0.8 mM, respectively, which are identical within the errors of the measurements.

that product inhibition can be observed, but product Z[120] is absent to prevent the reaction from running in reverse



(3–223)

(see Equations 3–121 through 3–124), and

$$v_0 = \frac{k_3[E]_t[A]_0[B]_0}{\alpha K_{dA}K_{dB}\left(\frac{K_{dY} + [Y]}{K_{dY}}\right) + \alpha K_{dB}\left(\frac{\gamma K_{dY} + [Y]}{\gamma K_{dY}}\right)[A]_0 + \alpha K_{dA}[B]_0 + [A]_0[B]_0} \quad (3–224)$$

If $[B]_0$ is saturating, product Y cannot be an inhibitor with respect to reactant A. If $[B]_0$ is not saturating, product Y is noncompetitive with respect to reactant A. Product Y is competitive with respect to reactant B at all concentrations of reactant A. When product Z is used as an inhibitor, B and A are interchanged in Equations 3–223 and 3–224, as are Y and Z. Consequently, the pattern of the inhibitions by product Z is symmetrical to the pattern of the inhibitions by product Y (Table 3–2).

Human phosphoinositide-dependent protein kinase uses $MgATP^{2-}$ to phosphorylate serines and threonines in particular proteins

$$MgATP^{2-} + \text{protein} \rightleftharpoons H^+ + \text{phosphoprotein} + MgADP^- \quad (3–225)$$

The product $MgADP^-$ is a competitive inhibitor with respect to $MgATP^{2-}$ as a reactant and a noncompetitive inhibitor with respect to a peptide 39 amino acids long used as a reactant in place of a protein. The apparent dissociation constants for $MgADP^-$, K_{icADP} and K_{iuADP}, are the same. The phosphorylated peptide is a competitive inhibitor with respect to the unphosphorylated peptide as a reactant but a noncompetitive inhibitor relative to $MgATP^{2-}$ as a reactant. The apparent dissociation constants for the phosphorylated peptide (pp), K_{icpp} and K_{iupp}, are the same. These facts are consistent with the proposals that reactants and products associate with and dissociate from the enzyme at random (Table 3–2), association of the phosphorylated peptide has little or no effect on the association of $MgATP^{2-}$, and association of $MgADP^-$ has little or no effect on the association of the unphosphorylated peptide.[121]

This example illustrates the way in which patterns of product inhibition are collected and used to reach a conclusion concerning the order in which reactants associate with an enzyme and products dissociate from an enzyme. It should be empha-

sized that, as with all kinetic observations, **a given pattern of product inhibition is only consistent with a particular kinetic mechanism** in which a particular order of association and dissociation of substrates is postulated and cannot prove that this is the actual order.

If, as in the foregoing example, the reactants and products associate with and dissociate from the active site so rapidly that they are always in rapid equilibrium with it, and if they associate at random with the active site, then **the patterns of product inhibition usually incorporate a specific pair of competitive inhibitions**. If the substrates associate with the active site at random, any one of them—reactant A, reactant B, product Y, or product Z—can associate with the empty active site. If this is the case, the reactants and the products that share most of their structure with each other usually compete with each other for the same location in the empty active site, and a product that shares most of its structure with a given reactant will be a competitive inhibitor of the enzymatic reaction with respect to that reactant.

In this situation, two dead-end complexes often can form, one between reactant A and product Y that share only a few atoms with each other, such as $MgATP^{2-}$ and the phosphorylated peptide, and one between reactant B and product Z that share no atoms with each other, such as the unphosphorylated peptide and $MgADP^{-}$. If, however, a significant portion of one reactant is transferred to the other reactant during the reaction, **the product that has gained the portion transferred may be large enough to exclude the reactant that loses the portion transferred as well as the reactant that shares all its atoms with that product**.

In the case of pyruvate kinase (Figure 3–15),[117] the product pyruvate is a linear competitive inhibitor with respect to the reactant, phospho*enol*pyruvate (Figure 3–15A,F), and the product $MgATP^{2-}$ is a linear competitive inhibitor with respect to the reactant $MgADP^{-}$ (Figure 3–15B,E). These results are consistent with a kinetic mechanism in which $MgADP^{-}$ and phospho*enol*pyruvate associate with the active site of the enzyme at random and $MgATP^{2-}$ and pyruvate dissociate from the active site at random (Table 3–2). The other two product inhibitions that are observed are peculiar, but they make sense. Magnesium adenosine triphosphate as a product is a linear competitive inhibitor relative to phospho*enol*pyruvate as a reactant (Figure 3–15C,E) because $MgATP^{2-}$ carries the phospho group that is transferred between phospho*enol*pyruvate and $MgADP^{-}$, and phospho*enol*pyruvate, a small molecule, cannot occupy its location in the active site when $MgATP^{2-}$ is bound. Pyruvate, however, is a linear noncompetitive inhibitor with respect to $MgADP^{-}$ (Figure 3–15D,F), and the dissociation constants for pyruvate from the unoccupied enzyme and from the enzyme occupied by $MgADP^{-}$ appear to be the same. Because neither $MgADP^{-}$ nor pyruvate has the phospho group that is transferred, the association of pyruvate with the active site cannot sterically interfere with the association of $MgADP^{-}$. This lack of overlap would be consistent with the fact that only one dissociation constant is needed to explain the inhibition. A phospho group, even in situations in which it is not transferred but certainly in situations in which it is transferred, is usually surrounded extensively by an oriented array of donors of hydrogen bonds when it is bound to an active site, and as a result it is tightly associated. Consequently, it comes as no surprise that the association of $MgATP^{2-}$ appears to prevent the association of phospho*enol*pyruvate.

As was the case with phosphoinositide-dependent protein kinase (Equation 3–225), however, even though a portion of one reactant is transferred to the other reactant during an enzymatic reaction, **the product and the reactant that overlap may not exclude each other from the active site**. Even if the portion that overlaps is large, exclusion may not occur if both reactant and product are large molecules. For example, citrate (*Si*)-synthase from *R. norvegicus* catalyzes the reaction

$$H^+ + \text{HSCoA} + \text{citrate} \rightleftharpoons H_2O + \text{oxaloacetate} + \text{acetyl-SCoA} \qquad (3\text{–}226)$$

The reactants enter the active site at random, and the products leave the active site at random,[112] yet the product acetyl-SCoA is a mixed inhibitor with respect to the reactant citrate,[112] even though both of these substrates share the acetyl group that is transferred. Presumably, acetyl-SCoA is so large that it can associate with the enzyme even when its acetyl group is prevented from occupying its usual position in the active site by citrate, and this ability allows citrate and acetyl-SCoA to bind simultaneously to the enzyme. In fact, since the mixed inhibition is predominantly uncompetitive, acetyl-SCoA seems to increase the affinity of the active site for citrate rather than decreasing it by steric interference.

An assignment of a random order for the association and dissociation of substrates from the active site can often be made by **examining patterns of product inhibition in both directions** of the enzymatic reaction. For example, orotate phosphoribosyltransferase from *S. typhimurium* catalyzes the reaction

$$\begin{aligned}\text{magnesium 5-phospho-}\alpha\text{-D-ribose 1-diphosphate} \\ + \text{ orotate} \rightleftharpoons MgOPO_3PO_3^{2-} \\ + H^+ + \text{ orotidine 5}'\text{-phosphate}\end{aligned} \quad (3\text{–}227)$$

In the forward direction, the product orotidine 5′-phosphate is competitive with respect to both reactants, orotate and magnesium 5-phospho-α-D-ribose 1-diphosphate, and the product magnesium diphosphate is competitive with respect to the reactant magnesium 5-phospho-α-D-ribose 1-diphosphate and noncompetitive with respect to the reactant orotate. In the reverse direction, the product magnesium 5-phospho-α-D-ribose 1-diphosphate is competitive with respect to both reactants, magnesium diphosphate and orotidine 5′-phosphate, and the product orotate is competitive with respect to the reactant orotidine 5′-phosphate and noncompetitive with respect to the reactant magnesium diphosphate. The observations in each direction are consistent (Table 3–2) with the conclusion that all substrates associate with and dissociate from the enzyme at random.[122] The observations in each direction by themselves are consistent with this conclusion; that they are both consistent with the same conclusion is reassuring. It also makes sense that these results are consistent with the conclusion that the complex containing both orotidine 5′-phosphate and magnesium 5-phospho-α-D-ribose 1-diphosphate cannot form. In this case, the phosphoribosyl group transferred from magnesium diphosphate to orotate is so large and the groups between which the transfer takes place are so small that the two substrates containing the group that is transferred exclude each other from the active site.

In a few instances, the binding of either product to the active site seems to be sufficient to exclude either reactant. Glycine dehydrogenase (decarboxylating) from *G. gallus* is an enzyme containing pyridoxal phosphate and N^6-(lipoyl)lysine that catalyzes the reaction

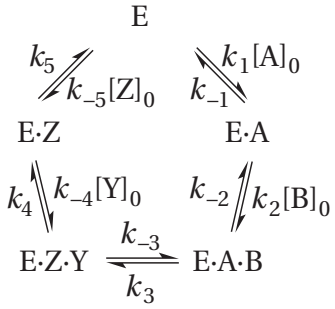
$$\begin{aligned}H^+ + \text{glycine} + \text{H-protein-lipoyllysine} \rightleftharpoons CO_2 \\ + \text{H-protein-}S\text{-aminomethyldihydrolipoyllysine}\end{aligned} \quad (3\text{–}228)$$

Either product, CO_2 or *S*-aminomethyldihydrolipoyllysine, is competitive with respect to either reactant, glycine or oxidized H-protein-lipoyllysine.[123] This observation suggests that neither product can associate with the active site to form a dead-end complex when either reactant is bound, and this conclusion is supported by isotope exchange studies. An explanation consistent with the observation of these exclusions, which cannot be entirely steric, is that the enzyme itself undergoes a reversible isomerization between dissociation of products and association of reactants. In one conformation, the active site can bind only products, and in the other conformation, it can bind only reactants.

To this point, only mechanisms that involve the random addition of reactants and the random dissociation of products have been discussed. In such situations, the inhibitions by products can be treated as if they resulted from the formation of dead-end complexes. **Another property of a product, however, that affects its inhibition of an enzymatic reaction is its ability to reverse the reaction, rather than forming a simple dead-end complex.** This property of a product is not consequential with enzymatic reactions that proceed by the random dissociation of products, but it is consequential when enzymatic reactions proceed by the ordered dissociation of products.

Consider an **enzymatic reaction in which the reactants, A and B, associate with the active site of the enzyme in a particular order and the products, Y and Z, dissociate in a particular order**.* If all these substrates are present initially in the solution at subsaturating concentrations, none of the steps in the kinetic mechanism of the reaction

*Usually, for steric reasons, if there is an obligate order in the addition of the two reactants, the product that incorporates most of the atoms in the second reactant to add to the active site will be the product that dissociates first from the active site, and the product that incorporates most of the atoms in the first reactant will be the product that dissociates second from the active site.



(3–229)

is formally irreversible because none of the substrates is missing. The **direction of net flux around the circle will be determined only by the standard free energy change of the reaction** and the concentration of the four substrates. If, however, one or both of the products are missing, the flux around the circle will always be clockwise because that **absence of a product converts a reversible step into an irreversible step**.

If the **substrate Y is not present initially**, the net flux must be in a clockwise direction because step 4 is forced by this choice to be formally irreversible in the other direction, and the kinetic mechanism becomes

$$\begin{aligned} \mathrm{E{\cdot}Z + A + B} &\underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} \mathrm{Z + E + A + B} \\ &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{Z + E{\cdot}A + B} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{Z + E{\cdot}A{\cdot}B} \\ &\underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \mathrm{Z + E{\cdot}Z{\cdot}Y} \xrightarrow{k_4} \mathrm{Z + E{\cdot}Z + Y} \end{aligned} \tag{3–230}$$

Because k_3, k_{-3}, and k_4 do not involve entry of substrates into the active site, they can be combined as a composite rate constant, k_{34},* by considering the two steps

$$\mathrm{E{\cdot}A{\cdot}B} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \mathrm{E{\cdot}Z{\cdot}Y} \xrightarrow{k_4} \mathrm{E{\cdot}Z + Y} \tag{3–231}$$

as one step

$$\mathrm{E{\cdot}A{\cdot}B} \xrightarrow{k_{34}} \mathrm{E{\cdot}Z + Y} \tag{3–232}$$

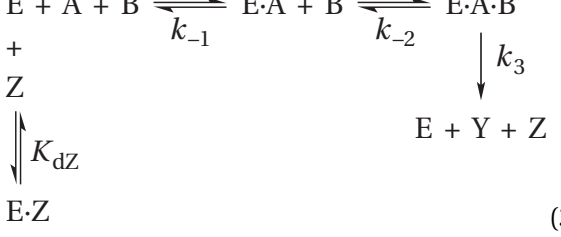
In analogy with Equation 3–70

$$k_{34} = \frac{k_3 k_4}{k_{-3} + k_4} \tag{3–233}$$

and the kinetic mechanism of Equation 3–230 becomes

$$\begin{aligned} &\mathrm{E{\cdot}Z + A + B} \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} \mathrm{Z + E + A + B} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \\ &\mathrm{Z + E{\cdot}A + B} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{Z + E{\cdot}A{\cdot}B} \xrightarrow{k_{34}} \mathrm{Z + E{\cdot}Z + Y} \end{aligned} \tag{3–234}$$

which is formally equivalent to the kinetic mechanism of Equation 3–210



(3–235)

because, in the absence of product Y, **product Z does actually form a dead-end complex** with the enzyme, and the equation for its inhibition has the same form as Equation 3–211

*From here on, when the rate constants of two or more steps are purposely combined into a composite rate constant, the subscript on the composite rate constant will be the integer of the first forward rate constant and the integer of the last.

$$v_0 = \frac{k_0 k_A k_B k_{AB} [E]_t [A]_0 [B]_0}{k_0 k_A k_B \left(\frac{[Z] + K_{dZ}}{K_{dZ}}\right) + k_0 k_A k_{AB} [A]_0 + k_0 k_B k_{AB} \left(\frac{[Z] + K_{dZ}}{K_{dZ}}\right) [B]_0 + k_A k_B k_{AB} [A]_0 [B]_0} \quad (3–236)$$

and the dissociation constant of product Z from the active site ($K_{dZ} = k_{-5}\ k_5^{-1}$) is an explicit term in the equation.

From the conclusions drawn earlier from the kinetic mechanism of Equation 3–210, it follows that when product Z is added to the reaction, it will behave as a competitive inhibitor with respect to reactant A (Equation 3–170) and a noncompetitive or uncompetitive inhibitor with respect to reactant B. Therefore, if product Z is competitive with respect to reactant A and noncompetitive with respect to reactant B, then the conclusion that reactant A must bind to the enzyme before reactant B and product Y must be released by the enzyme before product Z is consistent with these observations (Table 3–2). If, however, it is not noncompetitive with respect to reactant B, the situation, as before, is indeterminate.

If, however, **product Z is not present initially** and product Y is present, product Y can convert the complex from which it dissociates back to a complex between the active site and both reactants, E·A·B, as well as the complex between the active site and both products, E·Z·Y. Consequently, **product Y does not form a dead-end complex** with the active site because it is able to reverse the enzymatic reaction if it associates with the active site before product Z dissociates. The general kinetic mechanism of Equation 3–229 becomes

$$\begin{aligned} E + A + B &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A + B \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} E{\cdot}A{\cdot}B \\ &\underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E{\cdot}Z{\cdot}Y \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} E{\cdot}Z + Y \xrightarrow{k_5} E + Y + Z \end{aligned} \quad (3–237)$$

The rate equation for this kinetic mechanism has the form of Equation 3–116

$$v_0 = \frac{k_0 k_A k_B k_{AB} [E]_t [A]_0 [B]_0}{k_0 k_A k_B + k_0 k_A k_{AB} [A]_0 + k_0 k_B k_{AB} [B]_0 + k_A k_B k_{AB} [A]_0 [B]_0} \quad (3–238)$$

except that the catalytic constant k_0, the specificity constant k_B for reactant B, and the specificity constant k_{AB} are apparent rate constants, $k_{0,Y,app}$, $k_{B,Y,app}$, and $k_{AB,Y,app}$, respectively, because they contain terms that include the concentration of product Y

$$k_{0,Y,app} = \frac{k_3 k_4 k_5}{(k_3 k_4 + k_3 k_5 + k_{-3} k_5 + k_4 k_5) + k_{-4}(k_3 + k_{-3})[Y]} = \left(\frac{K_{iuY}}{[Y] + K_{iuY}}\right) \frac{k_3 k_4 k_5}{(k_3 k_4 + k_3 k_5 + k_{-3} k_5 + k_4 k_5)} \quad (3–239)$$

$$k_A = k_1 \quad (3–240)$$

$$k_{B,Y,app} = \frac{k_2 k_3 k_4 k_5}{k_5(k_{-2} k_{-3} + k_{-2} k_4 + k_3 k_4) + k_{-2} k_{-3} k_{-4}[Y]} = \left(\frac{K_{icY}}{[Y] + K_{icY}}\right) \frac{k_2 k_3 k_4}{k_{-2} k_{-3} + k_{-2} k_4 + k_3 k_4} \quad (3–241)$$

$$k_{AB,Y,app} = \frac{k_1 k_2 k_3 k_4 k_5}{k_{-1} k_5 (k_{-2} k_{-3} + k_{-2} k_4 + k_3 k_4) + k_{-1} k_{-2} k_{-3} k_{-4}[Y]} = \left(\frac{K_{icY}}{[Y] + K_{icY}}\right) \frac{k_1 k_2 k_3 k_4}{k_{-1}(k_{-2} k_{-3} + k_{-2} k_4 + k_3 k_4)} \quad (3–242)$$

where

$$K_{iuY} = \frac{(k_3 k_4 + k_3 k_5 + k_{-3} k_5 + k_4 k_5)}{k_{-4}(k_3 + k_{-3})} \quad (3–243)$$

$$K_{icY} = \frac{k_5(k_{-2}k_{-3} + k_{-2}k_4 + k_3k_4)}{k_{-2}k_{-3}k_{-4}} \quad (3\text{–}244)$$

Neither of the inhibition constants in this instance of product inhibition are dissociation constants. Notice that when [Y] is zero, Equations 3–239 through 3–242, which are no longer for apparent rate constants, become Equations 3–117 through 3–120, as they must.

Because, in the absence of product Y

$$k_{0,A,app} = \frac{k_{0,Y,app}\,k_{B,Y,app}[B]_0}{k_{0,Y,app} + k_{B,Y,app}[B]_0} \quad (3\text{–}245)$$

$$k_{A,app} = \frac{k_A k_{AB,Y,app}[B]_0}{k_A + k_{AB,Y,app}[B]_0} \quad (3\text{–}246)$$

$$k_{0,B,app} = \frac{k_{0,Y,app}\,k_A[A]_0}{k_{0,Y,app} + k_A[A]_0} \quad (3\text{–}247)$$

$$k_{B,app} = \frac{k_{B,Y,app}\,k_{AB,Y,app}[A]_0}{k_{B,Y,app} + k_{AB,Y,app}[A]_0} \quad (3\text{–}248)$$

(see Equations 3–96 through 3–99), product Y will be noncompetitive with respect to reactant B, uncompetitive with respect to reactant A when saturating initial concentrations of reactant B are present, and noncompetitive with respect to reactant A when reactant B is not at saturating concentrations (Table 3–2).[62]

D-Lactate dehydrogenase from *Streptomyces toyocaensis* catalyzes the reaction

$$\text{NADH} + \text{H}^+ + \text{pyruvate} \rightleftharpoons (R)\text{-lactate} + \text{NAD}^+ \quad (3\text{–}249)$$

As a product, NAD^+ is competitive with respect to NADH as a reactant and noncompetitive with respect to pyruvate as a reactant. (*R*)-Lactate as a product is noncompetitive with respect to pyruvate as a reactant, noncompetitive with respect to NADH as a reactant at concentrations of pyruvate below saturation, and uncompetitive with respect to NADH as a reactant at saturating concentrations of pyruvate.[124] These facts are consistent with an ordered kinetic mechanism in which NADH must associate with the enzyme before pyruvate can associate and D-lactate must dissociate before NAD^+ dissociates (Table 3–2). It follows that NADH and NAD^+, which are large, complex substrates, can associate with the enzyme in the absence of the other substrates. Historically, this fact has led to the distinction between an "apoenzyme" to which these two coenzymes are not bound in the active site and a "holoenzyme" to which one of these dinucleotides is bound, a distinction that has little practical use.

Coenzyme A as a product is a competitive inhibitor of histone acetyltransferase from *S. cerevisiae*

$$\text{acetyl-SCoA} + \text{histone} \rightleftharpoons \text{acetylhistone} + \text{HSCoA} \quad (3\text{–}250)$$

with respect to acetyl-SCoA as a reactant but does not inhibit the enzyme at saturating concentrations of acetyl-SCoA. Acetylhistone as a product is noncompetitive with respect to acetyl-SCoA as a reactant and noncompetitive with respect to histone as a reactant at concentrations of histone below saturation.[125] These facts are consistent with a kinetic mechanism in which acetyl-SCoA must associate with the active site of the enzyme before histone can associate and acetylhistone must dissociate before coenzyme A dissociates (Table 3–2).

Again, **if the reaction catalyzed by the enzyme can be assayed in both directions**, the patterns of inhibition by products in each direction reinforce a conclusion about kinetic mechanism. 5-Phospho-α-D-ribose 1-diphosphate as a product is competitive with respect to inosine 5′-phosphate as a reactant, and inosine 5′-phosphate as a product is competitive with respect to 5-phospho-α-D-ribose 1-diphosphate as a reactant in the reaction catalyzed by hypoxanthine phosphoribosyltransferase from *Tritrichomonas foetus*

$$\text{magnesium 5-phospho-}\alpha\text{-D-ribose 1-diphosphate} + \text{hypoxanthine} \rightleftharpoons \text{MgOPO}_3\text{PO}_3^{2-} + \text{inosine 5′-phosphate} + \text{H}^+ \quad (3\text{–}251)$$

Magnesium diphosphate as a product is noncompetitive with respect to both of the reactants hypoxanthine and magnesium 5-phospho-α-D-ribose 1-diphosphate in one direction, and magnesium 5-phospho-α-D-ribose 1-diphosphate as a product is noncompetitive with respect to magnesium diphosphate as a reactant in the other direction.[126]

These facts are consistent with a kinetic mechanism in which magnesium 5-phospho-α-D-ribose 1-diphosphate must associate with the enzyme before hypoxanthine and magnesium diphosphate must dissociate before inosine 5′-phosphate (Table 3–2).

Reactants also can associate in an obligate order and products can dissociate at random. Both magnesium uridine 5′-diphosphate and deoxycytidine 5′-phosphate as products are competitive with respect to magnesium uridine 5′-triphosphate as a reactant in the reaction catalyzed by human deoxycytidine kinase

$$\mathrm{MgUTP^{2-}} + \text{deoxycytidine} \rightleftharpoons \mathrm{H^+} + \text{deoxycytidine 5′-phosphate} + \mathrm{MgUDP^-} \quad (3\text{–}252)$$

while magnesium uridine 5′-diphosphate as a product is uncompetitive and deoxycytidine 5′-phosphate as a product is noncompetitive with respect to deoxycytidine at saturating magnesium uridine 5′-triphosphate.[127] These facts are consistent with a kinetic mechanism in which magnesium uridine 5′-triphosphate must associate with the enzyme before deoxycytidine can associate but deoxycytidine 5′-phosphate and magnesium uridine 5′-diphosphate dissociate at random (Table 3–2).

In the case of an enzyme displaying double reciprocals for the initial concentrations of each varied reactant that are parallel to each other at fixed concentrations of the other reactant (Figure 3–8), inhibition by products determines **whether the two irreversible steps in this ping-pong kinetic mechanism are each the result of the dissociation of a product or one or both of them is due to some other irreversible process**. For example, in the reaction catalyzed by ovine 3-oxoacid CoA-transferase (Equation 3–149)

$$\text{acetoacetate} + \text{succinyl-SCoA} \rightleftharpoons \text{acetoacetyl-SCoA} + \text{succinate} \quad (3\text{–}253)$$

the double reciprocals for the reactants succinyl-SCoA and acetoacetate when one is fixed and the other is varied are both sets of parallel lines.[87] Succinate (succ) as a product is competitive with respect to acetoacetate (acac) as a reactant, and acetoacetyl-SCoA (acac-SCoA) as a product is competitive with respect to succinyl-SCoA as a reactant. Succinate as a product is noncompetitive with respect to succinyl-SCoA (succ-SCoA) as a reactant, and acetoacetyl-SCoA as a product is noncompetitive with respect to acetoacetate as a reactant.[87] These facts are consistent with a kinetic mechanism

$$\begin{aligned} &\mathrm{E} + \text{succ-SCoA} + \text{acac} \rightleftharpoons \mathrm{E{\cdot}succ\text{-}SCoA} + \text{acac} \\ &\rightleftharpoons \mathrm{E(SCoA)} + \text{succ} + \text{acac} \rightleftharpoons \\ &\mathrm{E(SCoA){\cdot}acac} + \text{succ} \rightleftharpoons \mathrm{E{\cdot}acac\text{-}SCoA} + \text{succ} \\ &\rightleftharpoons \mathrm{E} + \text{acac-SCoA} + \text{succ} \end{aligned} \quad (3\text{–}254)$$

in which succinate dissociates from the enzyme in a step preceding the association of acetoacetate (acac) and acetoacetyl-SCoA dissociates from the enzyme in a step preceding the association of succinyl-SCoA (Table 3–2).

In this kinetic mechanism, the irreversible steps separating the associations of each of the two reactants, succinyl-SCoA and acetoacetate, both result from the dissociation of a product, acetoacetyl-SCoA and succinate, respectively. Succinate in the reverse direction and acetoacetate in the forward direction associate with the same form of the enzyme, E(SCoA), and compete with each other for that form (Equation 3–254). Acetoacetyl-SCoA and succinyl-SCoA associate with the same form of the enzyme, E, and compete with each other for that form (Equation 3–254). These two competitions are consistent with the conclusion that succinate and acetoacetate, in turn, occupy the same locations in the active site and that succinyl-SCoA and acetoacetyl-SCoA, in turn, occupy the same locations in the active site. The fact that, in this kinetic mechanism, succinate must dissociate from the enzyme before acetoacetate can associate requires that the coenzyme A portion of succinyl-SCoA remain associated with the active site in the undefined form E(SCoA) because, if it did not, the reaction would become a simple acyl-CoA hydrolase, and the free energy of hydrolysis of the thioester would be lost.

Patterns of product inhibition such as the one just described are not alone sufficient to define a ping-pong kinetic mechanism in which the dissociations of products provide the irreversible steps (compare the first entry and sixth entry in Table 3–2), but the behavior of the initial rates of the enzymatic reaction as a function of the reactants (Figure 3–8) and the product inhibitions (Table 3–2) together are sufficient.

There are enzymes that convert reactant A to product Z at one active site, transfer to another active

site the functional group that was subtracted from reactant A to make product Z, and add that functional group to reactant B at that other active site to convert reactant B into product Y. In such instances, the pattern of product inhibition is opposite[93] from that for the kinetic mechanism in which product A is released before reactant B can bind and product Y is released before product A can bind (Table 3–2) because the product and the reactant for each of the independent active sites compete with each other. This latter kinetic mechanism, however, also produces double reciprocals for the initial concentrations of each varied reactant that are parallel to each other at fixed concentrations of the other reactant, but it is distinguished from the former by the pattern of product inhibition.

In the foregoing discussion, rate equations for the effects of product inhibition on the various kinetic mechanisms—random addition and dissociation, ordered association and dissociation, and ping-pong association—were derived as an academic exercise. In general, if the behavior of the observed product inhibition is that described by one and only one of the entries in Table 3–2, there is no necessity to derive a rate equation because it has already been done for that situation. First, a full set of kinetic data is obtained by varying both the concentration of each reactant and the concentration of each product, in both the forward and the reverse direction, if possible. Second, the types of product inhibition are assigned by examining double-reciprocal presentations of the data. Third, each set of data is fit directly by the appropriate equations for the type of product inhibition observed to obtain numerical values for the observed rate constants. With all this information in hand, simple consultation of the table is usually sufficient to discover a particular kinetic mechanism consistent with the observations.[128]

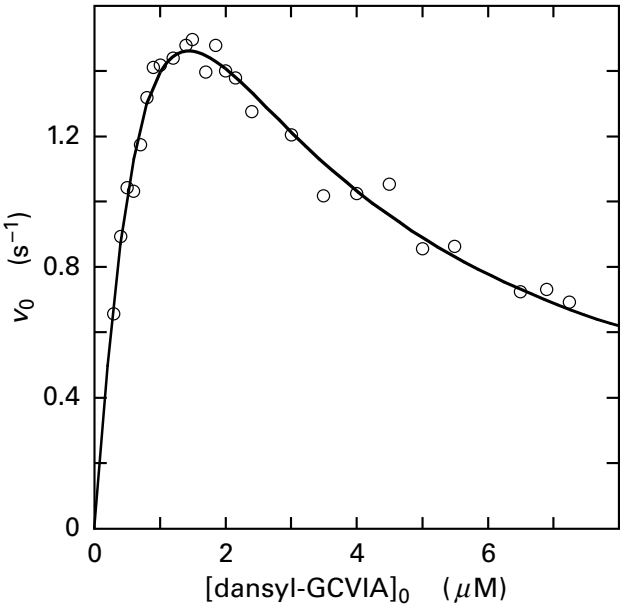


Figure 3–16: Behavior of the initial rates of the farnesylations catalyzed by protein farnesyltransferase as a function of the initial concentrations of the synthetic peptide GCVIA that has been modified at its amino terminus with 5-(dimethylamino)-naphthalene-1-sulfonyl chloride (dansyl chloride).[129] Equivalent amounts of protein farnesyltransferase were added to a series of reaction mixtures at pH 7.0 and 30 °C in which the concentration of magnesium (2*E*,6*E*)-farnesyl diphosphate was fixed at 5 μM and the concentrations of dansyl-GCVIA was varied between 0.3 and 7.25 μM. The increase in fluorescence of the dansyl group upon alkylation of the cysteine in the dansylated peptide was monitored continuously to obtain initial rates that were converted to the units of second^{-1} using an emission coefficient for dansyl-GC(farnesyl)VIA and the molar mass of protein for each mole of active sites. The initial rates (second^{-1}) are plotted as a function of the initial concentrations of dansyl-GCVIA (micromolar). The data were fit with Equation 3–257, and the values for the parameters of the fit were $k_0 = 5.5 \pm 0.9$ s^{-1}, $k_{pep} = 2.77 \pm 0.15$ s^{-1} μM^{-1}, and $K_{i,pep} = 1.05 \pm 0.21$ μM, where pep refers to the reactant dansyl-GCVIA and k_{pep} is the specificity constant for dansyl-GCVIA.

Inhibition of Enzymatic Reactions: Reactant Inhibition

Observation: When the initial concentration of a reactant in a reaction catalyzed by an enzyme is increased from zero, the initial rate of the reaction increases, passes through a maximum, and then begins to decrease. The synthetic peptide dansyl-GCVIA is a reactant in the farnesyl transfer catalyzed by protein farnesyltransferase from *S. cerevisiae*

$$\text{magnesium (2}E\text{,6}E\text{)-farnesyl diphosphate} + \text{–GCVIA–} \rightleftharpoons \text{–GC(}S\text{-farnesyl)VIA–} + H^+ + MgOPO_3PO_3^{2-} \quad (3\text{–}255)$$

where –GCVIA– is the segment of a protein containing a cysteine that is farnesylated by the enzyme. The fact that the synthetic peptide is a competent reactant suggests that the active site recognizes only this short sequence in the much larger proteins that are its natural substrates. When the initial concentration of dansyl-GCVIA is varied, the initial rate of the reaction increases and then decreases (Figure 3–16).[129]

The **decrease in the initial rate as the initial concentration of the reactant is increased beyond the maximum** is an inhibition of the enzymatic reaction by that reactant. In fact, in the seminal examination of enzymatic kinetics, that of the reaction catalyzed by β-fructofuranosidase (Figure 3–3),[64] the reaction was inhibited at 770 mM sucrose.

When reactant inhibition is observed, the initial rates for the enzymatic reaction at the various initial concentrations of reactant A, the reactant producing the inhibition, can usually be described by the equation

$$v_0 = \frac{k_0[\mathrm{E}]_t k_\mathrm{A}[\mathrm{E}]_t[\mathrm{A}]_0}{k_0[\mathrm{E}]_t + k_\mathrm{A}[\mathrm{E}]_t[\mathrm{A}]_0 + \left(\frac{k_\mathrm{A}[\mathrm{E}]_t}{K_\mathrm{iA}}\right)[\mathrm{A}]_0^2}$$

$$= \frac{k_0[\mathrm{E}]_t k_\mathrm{A}[\mathrm{E}]_t[\mathrm{A}]_0}{k_0[\mathrm{E}]_t + k_\mathrm{A}[\mathrm{E}]_t[\mathrm{A}]_0\left(\frac{K_\mathrm{iA} + [\mathrm{A}]_0}{K_\mathrm{iA}}\right)} \quad (3\text{–}256)$$

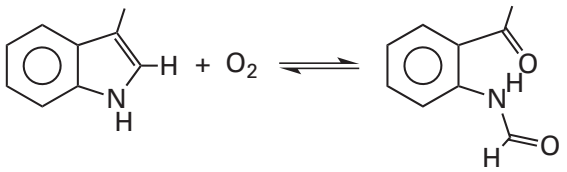
where K_iA is the **inhibition constant** for reactant A. In a reaction with two reactants, for which the catalytic constant for reactant A and the specificity constant for reactant A are apparent rate constants, the same equation will describe reactant inhibition by reactant A as reactant A is varied at fixed concentrations of reactant B. In cases of reactant inhibition, the data are fit with the equation

$$y = \frac{acx}{a + cx + \left(\frac{c}{d}\right)x^2} \quad (3\text{–}257)$$

where y is v_0, x is $[\mathrm{A}]_0$, a is $k_0[\mathrm{E}]_t$, c is $k_\mathrm{A}[\mathrm{E}]_t$, and d is K_iA. This equation is the one fit to the curve in Figure 3–16, for which $K_\mathrm{iGCVIA} = 1.05 \pm 0.21$ μM and the Michaelis constant = 2.0 ± 0.21 μM. Notice that when $K_\mathrm{iA} = \infty$, Equation 3–256 reduces to Equation 3–43 as it must.

Equation 3–256 states that the reactant A is uncompetitive with respect to itself because, if the respective limits are taken, it can be seen that the inhibitor only affects the catalytic constant but not the specificity constant for reactant A. This feature of the equation makes sense because reactant A cannot compete with itself.

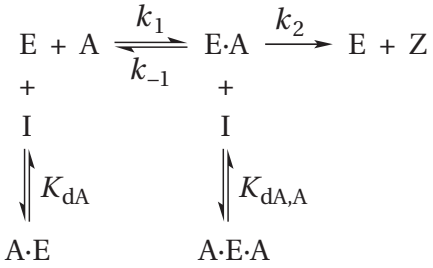
The dissociation constant for a reactant acting as an inhibitor does not have to be in the range of the Michaelis constant, as it is when synthetic peptide GCVIA is a reactant for protein farnesyltransferase. L-Tryptophan is a reactant which is also an inhibitor of the reaction catalyzed by human indoleamine 2,3-dioxygenase (previously Equation 2–248)



(3–258)

Its Michaelis constant is 15 μM and its inhibition constant is 170 μM.[130]

Explanation: Consider the kinetic mechanism of Equation 3–190 for an enzymatic reaction with only one reactant but with **reactant A as the inhibitor instead of inhibitor I**



(3–259)

If K_dI is replaced by K_dA, $K_\mathrm{dI,A}$ is replaced by $K_\mathrm{dA,A}$, and [I] is replaced by $[\mathrm{A}]_0$, Equation 3–193 can be rearranged to

$$v_0 = \frac{\left\{\dfrac{k_1k_2K_{dA}[E]_t}{(k_{-1}+k_2)+k_1K_{dA}}\right\}\left\{\dfrac{k_1k_2[E]_t}{k_{-1}+k_2}\right\}[A]_0}{\dfrac{k_1k_2K_{dA}[E]_t}{(k_{-1}+k_2)+k_1K_{dA}} + \left(\dfrac{k_1k_2[E]_t}{k_{-1}+k_2}\right)[A]_0 + \dfrac{\left(\dfrac{k_1k_2[E]_t}{k_{-1}+k_2}\right)}{\left(\dfrac{k_{-1}+k_2}{k_1}\right)\left(\dfrac{K_{dA,A}}{K_{dA}}\right)+K_{dA,A}}[A]_0^2} \quad (3\text{–}260)$$

which has the form of Equation 3–256. For the kinetic mechanism of Equation 3–55, which is that for Equation 3–259 in the absence of any reactant inhibition, K_m is $(k_2 + k_{-1})\,k_1^{-1}$, so in Equation 3–256

$$K_{iA} = \frac{K_mK_{dA,A}}{K_{dA}} + K_{dA,A} \quad (3\text{–}261)$$

Therefore, in the abstract, if reactant A can associate with a site that is distinct from the active site with which it associates productively, and if that association produces a dead-end complex,[131] Equation 3–256 should describe that inhibition. It has been concluded that, in the case of human indoleamine 2,3-dioxygenase, the L-tryptophan associates with a site other than the active site when it is acting as an inhibitor.[130] If $K_{dA} = K_{dA,A} > K_m$, the measured value of K_{iA} is K_{dA}, the dissociation constant for reactant A from the site at which it inhibits the enzyme.

One site with which reactant A can associate to produce a fully inhibited, dead-end complex is **the site with which reactant B associates** in an enzyme that has two reactants. For example, the inhibition by the reactant phospho*enol*pyruvate of the reaction catalyzed by 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli*

$$\text{phospho}\textit{enol}\text{pyruvate} + \text{3-phosphoshikimate} \rightleftharpoons \text{phosphate} + \text{5-}O\text{-(1-carboxyvinyl)-3-phosphoshikimate} \quad (3\text{–}262)$$

is thought to result from the dead-end association of phospho*enol*pyruvate with the site with which 3-phosphoshikimate associates because increasing the initial concentration of 3-phosphoshikimate increases the inhibition constant K_{iPEP} for phospho*enol*pyruvate as an inhibitor.[132] Likewise, the inhibition by the reactant L-homocysteine of the reaction catalyzed by cystathionine β-synthase from *S. cerevisiae*

$$\text{L-homocysteine} + \text{L-serine} \rightleftharpoons H_2O + \text{L-cystathionine} \quad (3\text{–}263)$$

is thought to result from its dead-end association with the site with which L-serine must associate during the enzymatic reaction.[133] This conclusion makes sense because both of the reactants are L-amino acids.

Suppose that, in an enzymatic reaction with two reactants, the **two reactants must associate with the enzyme in a particular order** for a productive ternary complex between the enzyme and the reactants to be produced (Equation 3–109). If the reactant required to be second (reactant B) associates before the reactant required to be first (reactant A), a dead-end complex that cannot participate in the enzymatic reaction could form. For example, in the reaction catalyzed by protein farnesyltransferase from *S. cerevisiae* (Equation 3–255), there is kinetic evidence consistent with the conclusion that (2*E*,6*E*)-farnesyl diphosphate (reactant A) must associate with the active site before the protein to be farnesylated (reactant B) associates to produce a productive ternary complex. Consequently, the reactant inhibition observed with dansyl-GCVIA (Figure 3–16) is thought to result from the formation of a binary, unproductive, dead-end complex between the enzyme and the peptide (E·B) associating in its usual location in the active site and that this complex is unproductive because it prevents association of (2*E*,6*E*)-farnesyl diphosphate.[129] In the case of the reactant inhibition of human tryptophan 5-monooxygenase by L-tryptophan, it was concluded that the reactant inhibition was due to the association of L-tryptophan in its usual location in the active site but in the wrong order so that the association of the reactant 5,6,7,8-tetrahydropteridine is prevented. To form a productive ternary

complex, the reactant 5,6,7,8-tetrahydropteridine must associate before L-tryptophan. This conclusion that the inhibition is the result of L-tryptophan associating with the active site in its usual location was based on examinations of crystallographic molecular models of the occupied enzyme as well the fact that 5,6,7,8-tetrahydropteridine competes with L-tryptophan for the form of the enzyme with which L-tryptophan associates as an reactant inhibitor.[134]

A kinetic mechanism in which reactants are required to associate in a particular order (Equation 3–109) is a special case of the kinetic mechanism of Equation 3–136 in which only one of the two paths is productive. Suppose that only the upper path in the kinetic mechanism of Equation 3–136 is productive. If, however, only the first step in the lower path can occur—namely, the association of reactant B in the wrong order—this association would result in a dead-end complex and inhibition by that reactant, but the lower path can also produce a productive ternary complex E·A·B, albeit at a significantly slower rate than the upper.[135] In this case, reactant B, by shunting the reaction onto the lower path, would be an inhibitor of the reaction at high concentration, but it would not be a dead-end inhibitor. In this situation, there will still be a finite rate to the catalytic reaction at an infinite concentration of reactant B, which is possible for Equation 3–137, rather than a zero rate as required by Equation 3–256. Consequently, reactant inhibition that shows the behavior of Equation 3–137, with a finite rate at saturating initial concentrations of the reactant, is consistent with the steady-state kinetic mechanism of Equation 3–136. Again, however, perhaps because the kinetic equations are so complex (Table 3–1), few if any kinetic studies have concluded that the kinetic mechanism of an enzyme is that of Equation 3–136.

In addition to dead-end inhibition, product inhibition, and reactant inhibition, the trapping of a radioisotopically labeled reactant provides another observation in a determination of the order in which reactants associate with an enzyme.

When orotate phosphoribosyltransferase from *S. typhimurium* (Equation 3–227) at a high concentration (40 μM) was equilibrated with a saturating concentration (40 μM) of magnesium 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate in 10 μL of solution and then rapidly diluted into a large volume (800 μL) of a second solution containing 10 mM nonradioactive magnesium 5-phospho-α-D-ribose 1-diphosphate and 2.5 mM orotate, an amount of magnesium [^{32}P]diphosphate equivalent to 88% of the active sites present in the first solution was produced in the first few seconds of the enzymatic reaction that commenced in the second solution.[136] This observation demonstrates that magnesium 5-phospho-α-D-ribose 1-diphosphate must be able to associate with the enzyme in the absence of orotate. If it had to wait for orotate, no radiolabeled magnesium 5-phospho-α-D-ribose 1-diphosphate could have associated with the enzyme before the dilution, only insignificantly radiolabeled magnesium 5-phospho-α-D-ribose 1-diphosphate could have associated after the dilution, and no radiolabeled diphosphate would have been produced. It also demonstrates that this magnesium 5-phospho-α-D-ribose 1-diphosphate that associates with the unoccupied active site is capable of participating in the reaction. When enzyme (150 μM) and [2-^{14}C]orotate (180 μM) in 10 μL of solution were diluted into 800 μL of a solution containing 1.9 mM nonradioactive orotate and 2 mM magnesium 5-phospho-α-D-ribose 1-diphosphate, an amount of [2-^{14}C]orotidine 5′-phosphate equal to 55% of the active sites present was produced in the first few seconds.[136] Consequently, both magnesium 5-phospho-α-D-ribose 1-diphosphate and orotidine must be able associate productively with the unoccupied active site, and consequently they must be able to associate at random during the normal enzymatic reaction.

Squalene synthase from *S. cerevisiae* is unusual in that it converts two molecules of the same reactant, (2*E*,6*E*)-farnesyl diphosphate, into an intermediate in the active site that is then reduced by NADPH to give the product squalene. If the enzyme is mixed first with a saturating concentration of [^{14}C]-(2*E*,6*E*)-farnesyl diphosphate and then mixed with solution containing a saturating concentration of [4-^{3}H]NADPH and unlabeled (2*E*,6*E*)-farnesyl diphosphate in significant excess over the initial [^{14}C]-(2*E*,6*E*)-farnesyl diphosphate, the ratio between carbon-14 and tritium in the product after the first turnover of the reaction could be estimated by extrapolation of the ratio observed over time. The results clearly demonstrated that two molecules of [^{14}C]-(2*E*,6*E*)-farnesyl diphosphate were trapped on the active site by the association of the [4-^{3}H]NADPH. It could be concluded that two molecules of (2*E*,6*E*)-farnesyl diphosphate can associate with the unoccupied active site in the absence of NADPH and presumably form the intermediate that is then reduced after the dilution when the NADPH was present.[137]

Unfortunately, the results expected from trapping of isotopically labeled reactants in the case of their ordered addition to the enzyme are often ambiguous. For example, in the case of 2-*C*-methyl-D-erythritol 4-phosphate cytidylyltransferase

$$\mathrm{MgCTP^{2-}} + \text{2-}C\text{-methyl-D-erythritol 4-phosphate} \rightleftharpoons \mathrm{MgOPO_3PO_3^{2-}} + \text{4-(cytidine 5′-diphospho)-2-}C\text{-methyl-D-erythritol} \quad (3\text{–}264)$$

from *E. coli*, Mg[2-^{14}C]CTP^{2-} associated with the unoccupied active site is trapped in the product upon addition of 2-*C*-methyl-D-erythritol 4-phosphate, but [2-^{14}C]2-*C*-methyl-D-erythritol 4-phosphate is not trapped in the product[138] upon addition of MgCTP^{2-}. This result is consistent with a kinetic mechanism in which MgCTP^{2-} must associate with the enzyme before 2-*C*-methyl-D-erythritol 4-phosphate, but it is also consistent with a kinetic mechanism in which reactants can associate at random but the dissociation of 2-*C*-methyl-D-erythritol 4-phosphate from the enzyme is much more rapid than the conversion of the two reactants to the products once they are in the active site. In other words, for such observations to be consistent with an ordered addition of reactants, both reactants, MgCTP^{2-} and 2-*C*-methyl-D-erythritol 4-phosphate, once they are in the active site, must dissociate from the active site more slowly than they are converted to the products free in solution.[139] Likewise, the failure to trap $^{18}O_2$ preequilibrated with unoccupied active site in the product 5-hydroxyisourate can mean, in the absence of other observations, either that urate must associate with urate oxidase from *Glycine max* before O_2 can associate or that O_2 equilibrates with the enzyme much more rapidly than urate can be turned into 5-hydroxyisourate on the active site,[140] which seems reasonable when the structures of the two reactants are considered. Such measurements, however, can be used to provide further evidence consistent with the existence of an ordered addition, along with other kinetic measurements.

In the case of the reaction catalyzed by bovine cAMP-dependent protein kinase

$$\mathrm{H^+ + MgADP^- + LRRAS(PO_3^{2-})LG} \rightleftharpoons \mathrm{LRRASLG + MgATP^{2-}} \quad (3\text{–}265)$$

where LRRASLG is the peptide of this sequence, the failure of the peptide to trap Mg[2-^{3}H]ADP$^-$ preequilibrated with the unoccupied active site in the product MgATP^{2-} was attributed to the rapid equilibration of MgADP$^-$ with the enzyme relative to the conversion of reactants to products on the active site rather than a requirement that LRRAS(PO$_3^{2-}$)LG must associate before MgADP$^-$ does.[141]

The kinetics of any enzymatic reaction in which there are more than two reactants can be simplified to the kinetics of a reaction with two reactants by adding saturating concentrations of the other reactants to the solution. This stratagem, however, has consequences that depend on the order in which reactants associate with the enzyme.

If the reactants must associate with the enzyme in a particular order, A, B, C, …, then the **place in that sequence of each reactant that is set in turn at saturation** determines the patterns of bireactant kinetics observed. When any one of the reactants is held at saturation, this choice of conditions has the effect of converting the step in which this reactant associates with the enzyme into a **kinetically irreversible step**.

Consider an enzyme with three reactants, A, B, and C, that must add in the order reactant A before reactant B before reactant C. When reactant C is held at saturation, its association with the enzyme becomes a formally and kinetically irreversible step and is **incorporated into the kinetically silent processes** of the conversion of reactants to products on the active site and the release of products. The bireactant kinetics for variation in the initial concentrations of reactant A and reactant B, the effects of dead-end inhibitors, and the inhibitions by products are those for two reactants that must associate with the enzyme in the order reactant A before reactant B.

When reactant A is held at saturation, the unoccupied active site is converted entirely to the complex E·A, and a kinetically irreversible step has been formally created between the dissociation of products and the association of reactant B. The bireactant kinetics for variations in the initial concentrations of reactant B and reactant C and the effects of dead-end inhibitors are those for two reactants that must associate with the enzyme in the order reactant B before reactant C, and the patterns of product inhibition are those for a kinetic mechanism in which a kinetically irreversible step exists between the dissociation of products and the association of the first reactant, reactant B.

When reactant B is held at saturation, however, the association of reactant B with the complex E·A to form the complex E·A·B becomes formally and kinetically irreversible. This situation places a kinetically irreversible step between the association of reactant A and the association of reactant C. When one of these two reactants, A or C, is varied at several fixed concentrations of the other, **the bireactant kinetics are those in which the double reciprocals are parallel lines**. For example, when the initial concentration of carbon dioxide was varied at several fixed concentrations of NADH, the double reciprocals of the initial rates for the reaction catalyzed by homoisocitrate dehydrogenase from *S. cerevisiae*

$$\text{NADH} + \text{2-oxoadipate} + \text{CO}_2 \rightleftharpoons \text{NAD}^+ + (1R,2S)\text{-1-hydroxybutane-1,2,4-tricarboxylate} \quad (3\text{–}266)$$

were parallel lines if a saturating concentration of 2-oxoadipate was present. This observation is consistent with a kinetic mechanism in which NADH must associate with the enzyme before 2-oxoadipate, which must associate with the enzyme before CO_2.[142]

The observation of parallel double reciprocals when one reactant is varied at several fixed concentrations of the other while a third reactant is held at saturation, however, is not alone indicative of a fully ordered kinetic mechanism. For example, when the initial concentration of tetrahydrobiopterin was varied at several fixed initial concentrations of molecular oxygen, the double reciprocals of the initial rates for the reaction catalyzed by phenylalanine 4-monooxygenase from *Chromobacterium violaceum*

$$\text{O}_2 + \text{L-phenylalanine} + \text{tetrahydrobiopterin} \rightleftharpoons \text{L-tyrosine} + \text{4a-hydroxytetrahydrobiopterin} \quad (3\text{–}267)$$

at saturating concentrations of L-phenylalanine were parallel.[143] In this case, however, other observations indicated that the kinetic mechanism for the enzyme is one in which molecular oxygen must associate first and then L-phenylalanine and tetrahydrobiopterin associate at random. When the concentration of L-phenylalanine is at saturation, it associates immediately and irreversibly with the active site after molecular oxygen has associated, and its kinetically irreversible association separates the association of oxygen and the association of tetrahydrobiopterin, resulting in the parallel double reciprocals. In this case, the reason for the parallel double reciprocals is the same; namely, that the saturation with one reactant creates a kinetically irreversible step between the association of the other two, but the kinetic mechanism of the reaction is not fully ordered.

The kinetics of phosphopantothenate—cysteine ligase (CTP)

$$\text{Mg CTP}^{2-} + (R)\text{-4′-phosphopantothenate} + \text{L-cysteine} \rightleftharpoons 2\,\text{H}^+ + \text{MgOPO}_3\text{PO}_3^{2-} + \text{CMP}^{2-} + N\text{-[(}R\text{)-4′-phosphopantothenoyl]-L-cysteine} \quad (3\text{–}268)$$

from *Enterococcus faecalis* illustrate the complexity that can be encountered when an enzyme has three reactants and three products.

When the initial concentration of $MgCTP^{2-}$ is varied at saturating concentrations of L-cysteine and several fixed concentrations of (*R*)-4′-phosphopantothenate, the double reciprocals are a set of lines that intersect in the second quadrant. When, however, the initial concentration of L-cysteine is varied at several fixed concentrations of either $MgCTP^{2-}$ or (*R*)-4′-phospho-pantothenate while the other reactant is held at saturating concentrations, the double reciprocals in each case are a set of parallel lines. These observations are consistent with a kinetic mechanism in which a kinetically irreversible step exists between the association of $MgCTP^{2-}$ and (*R*)-4′-phospho-pantothenate and the association of L-cysteine with the active site.

The product CMP^- is competitive with respect to the reactant $MgCTP^{2-}$ and noncompetitive with respect to the reactant (*R*)-4′-phosphopantothenate when both L-cysteine and the third reactant, (*R*)-4′-phosphopantothenate or $MgCTP^{2-}$, are held at saturating concentrations. These observations are consistent with a requirement that $MgCTP^{2-}$ must to add to the unoccupied active site before (*R*)-4′-phosphopantothenate, and CMP^- can be the last product to dissociate from the active site.

The product CMP^- is uncompetitive with respect to the reactant L-cysteine when both $MgCTP^{2-}$ and (*R*)-4′-phosphopantothenate (PPA) are held at saturating concentrations. This observation can be shown to be consistent with the following kinetic mechanism

$$\begin{aligned}
\text{E}{\cdot}\text{CMP} + \text{CTP} + \text{PPA} + \text{Cys} &\xrightleftharpoons{K_{\text{d,CMP}}} \\
\text{CMP} + \text{E} + \text{CTP} + \text{PPA} + \text{Cys} &\xrightarrow{k_1} \\
\text{CMP} + \text{E}' + \text{Cys} + \text{PP}_\text{i} &\underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \\
\text{CMP} + \text{E}'{\cdot}\text{Cys} + \text{PP}_\text{i} &\xrightarrow{k_3} \\
\text{CMP} + \text{E} + \text{PPCys} + \text{CMP} + \text{PP}_\text{i}
\end{aligned} \tag{3–269}$$

The irreversible step between the unoccupied enzyme, E, and a form of the enzyme with an altered active site, E′, which is governed by the rate constant k_1, includes the association of $MgCTP^{2-}$ and the association of (*R*)-4′-phosphopantothenate, which are both at saturating concentrations, and the dissociation of diphosphate (PP_i), one of the products of the enzymatic reaction, which is absent from the solution. The irreversible step between the complex E′·Cys and the unoccupied enzyme E, which is governed by the rate constant k_3, includes the dissociation of *N*-[(*R*)-4′-phosphopantothenoyl]-L-cysteine (PPCys), one of the products of the enzymatic reaction, which is absent from the solution. The dissociation of the product CMP^- cannot be an irreversible step because it is present in the solution as a product inhibitor. The rate equation for the kinetic mechanism of Equation 3–269

$$v_0 = \frac{k_1 k_2 k_3 [\text{E}]_t [\text{Cys}]_0}{\left\{k_1 k_2 + k_2 k_3 \left(\frac{[\text{CMP}] + K_{\text{d,CMP}}}{K_{\text{d,CMP}}}\right)\right\}[\text{Cys}]_0 + k_1(k_{-2} + k_3)} \tag{3–270}$$

requires that CMP^- be an uncompetitive inhibitor, which it is. Because both $MgCTP^{2-}$ and (*R*)-4′-phosphopantothenate are held at saturating concentrations, this fact alone makes the step governed by the rate constant k_1 irreversible, so there is no requirement that the dissociation of a product occur during that step governed. It may be the case that diphosphate dissociates after L-cysteine has associated rather than before.

All these kinetic observations are consistent with a kinetic mechanism in which $MgCTP^{2-}$ associates first with the unoccupied active site, followed by (*R*)-4′-phosphopantothenate. These two bound reactants undergo a kinetically irreversible transformation after which L-cysteine associates. Following a further chemical transformation, *N*-[(*R*)-4′-phosphopantothenoyl]-L-cysteine dissociates from the active site before CMP^-, or the two dissociate from the active site at random.[144] If the kinetically irreversible step governed by rate constant k_1 is the dissociation of diphosphate, then diphosphate should be competitive with respect to L-cysteine, an experiment that was not performed.

The same kinetic mechanism has been proposed for the reaction catalyzed by EntE, the protein encoded by the *entE* gene

$$\begin{aligned}
\text{2,3-dihydroxybenzoate} + \text{MgATP}^{2-} + \text{HSEntB} &\rightleftharpoons \text{MgOPO}_3\text{PO}_3^{2-} + \text{H}^+ + \text{AMP}^{2-} \\
&\quad + \text{2,3-dihydroxybenzoyl-SEntB}
\end{aligned} \tag{3–271}$$

in *E. coli*, where HSEntB is the protein encoded by the *entB* gene and 2,3-dihydroxybenzoyl-SEntB is HSEntB that has had a 2,3-dihydroxybenzoyl group esterified onto the sulfanyl group of its covalently attached phosphopantetheinyl group to produce a thioester. In this instance, the kinetic mechanism that is consistent with the results is one in which 2,3-dihydroxybenzoate associates first with the unoccupied active site, followed by $MgATP^{2-}$. These two bound reactants undergo a transformation after which magnesium diphosphate dissociates from the active site and then HSEntB associates. Following a further chemical transformation, 2,3-dihydroxybenzoyl-SEntB dissociates from the active site before AMP^-. This order is consistent with the facts that when the initial concentration of 2,3-dihydroxybenzoate is varied at saturating concentrations of a truncated form of HSEntB that acts as a reactant and several fixed concentrations of $MgATP^{2-}$, the double reciprocals are a set of lines that intersect in the second quadrant. When, however, the initial concentration of either 2,3-dihydroxybenzoate or the initial concentration $MgATP^{2-}$ is varied at several fixed concentrations of the truncated form of HSEntB, when the other reactant is held at saturating concentrations the double reciprocals in each case are a set of parallel lines. That the dissociation of magnesium diphosphate is the only irreversible step separating the association of 2,3-dihydroxybenzoate and $MgATP^{2-}$ and the association of the truncated form of HSEntB, and is therefore responsible for these parallel double reciprocals, was demonstrated by showing that when magnesium diphosphate is

included in the solution, the double reciprocals become a set of intersecting lines.[145]

In both the reaction catalyzed by phosphopantothenate—cysteine ligase (CTP) and the reaction catalyzed by the product of the *entE* gene, a nucleoside triphosphate and a reactant with a carboxy group associate with the active site, and diphosphate dissociates before the third reactant associates. These kinetic observations in each case suggest that a covalent intermediate, an anhydride between the carboxy group and either a cytidylate or an adenylate, is formed on the active site by a nucleophilic substitution at the α phosphorus of the respective nucleoside triphosphate with the respective carboxylato group as the nucleophile and diphosphate as the leaving group. This intermediate anhydride, which is electrophilic and susceptible to nonenzymatic hydrolysis because the cytidylate or the adenylate is a good leaving group, is tightly held in the active site awaiting the association of the respective thiol to which the carboxy group is to be transferred in a second nucleophilic substitution.

If the reactants associate at random with the enzyme, then the patterns of the bireactant kinetics observed when any two are varied and the others are held at saturation will all be the same because all the reactants are equivalent as far as their association with the active site is concerned. For example, if there are four reactants (A, B, C, and D) and reactant C and reactant D are held at saturation, the unoccupied active site is converted completely into the complex E·C·D. A kinetically irreversible step is placed between the release of products and the association of reactant A and reactant B, but since at least one of the products must be absent, the dissociation of that product is already an irreversible step. The bireactant kinetics for variation in the initial concentrations of reactant A and reactant B and the effects of dead-end inhibitors will be those for the random addition of A and B to the enzyme. The same kinetic patterns will be observed when reactant A and reactant B are held at saturation and reactant C and reactant D are varied and so forth.

For example, for the reaction catalyzed by phosphoribosylaminoimidazolesuccinocarboxamide synthase from *E. coli*

$$\begin{aligned}&\text{5-amino-1-(5-phospho-D-ribosyl)imidazole-4-carboxylate} + \text{MgATP}^{2-} + \text{L-aspartate} \rightleftharpoons \\ &\text{MgADP}^{-} + \text{H}_2\text{OPO}_3^{-} + \\ &\text{(}S\text{)-2-[5-amino-1-(5-phospho-D-ribosyl)imidazole-4-carboxamido]succinate}\end{aligned} \tag{3–272}$$

when each of the reactants in turn was held at saturation, the initial rates as a function of the initial concentrations of the other two all showed intersecting patterns for the double reciprocals. The patterns of dead-end inhibition for each bireactant combination at saturation with the third were those expected for a kinetic mechanism in which the two reactants associate at random with the active site on the enzyme.[146] Consequently, all the observations together were consistent with a kinetic mechanism in which all three of the reactants combined with the enzyme at random.

When there are three or more products for an enzymatic reaction, **patterns of product inhibition** will suggest the order in which they dissociate (Table 3–2). For example, *S*-adenosylmethionine:tRNA ribosyltransferase-isomerase from *E. coli* catalyzes a reaction with two reactants and three products. It modifies 7-(aminomethyl)-7-deazaguanosine in a transfer RNA (preQ_1-tRNA) to produce epoxyqueuosine at that site in the transfer RNA (oQ-tRNA) in the reaction

$$\begin{aligned}&\text{preQ}_1\text{-tRNA} + \textit{S}\text{-adenosyl-L-methionine} \\ &\rightleftharpoons \text{adenine} + \text{L-methionine} + \text{oQ-tRNA}\end{aligned} \tag{3–273}$$

The patterns of product inhibition (Table 3–3) are consistent with a kinetic mechanism in which preQ_1-tRNA must associate with the enzyme before *S*-adenosyl-L-methionine, and adenine must dissociate before L-methionine, which must dissociate before oQ-tRNA. Were the association of reactants at random and the dissociation of products at random, each product the structure of which overlapped significantly the structure of one of the reactants would be competitive with respect to that reactant, which is not observed to be the case.

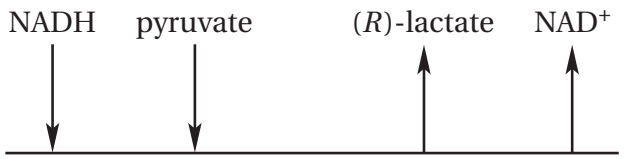
Table 3–3: Pattern of Product Inhibitions of *S*-Adenosylmethionine:tRNA Ribosyltransferase Isomerase from *E. coli*[147]

product inhibitor	varied reactant	status of fixed reactant	pattern of inhibition
adenine	preQ$_1$-tRNA	unsaturating	noncompetitive
	preQ$_1$-tRNA	saturating	uncompetitive
	S-adenosylmethionine	unsaturating	noncompetitive
methionine	preQ$_1$-tRNA	unsaturating	uncompetitive
	S-adenosylmethionine	unsaturating	noncompetitive
	S-adenosylmethionine	saturating	uncompetitive
oQ-tRNA	preQ$_1$-tRNA	unsaturating	competitive
	S-adenosylmethionine	unsaturating	noncompetitive

The foregoing discussion has substantiated two features of steady-state kinetics. First, any step in the kinetic mechanism of the enzymatic reaction that involves the association of a substrate with the enzyme, or the dissociation of a substrate from the enzyme, is ultimately responsible for the variations in initial rate that are observed when the initial concentration of that substrate is varied. Because of this fact, **steady-state kinetics elucidate details of only the association and dissociation of substrates**. Second, any step following the assembly of all the reactants on the active site and preceding the release of the first product from the active site cannot be studied in isolation by steady-state kinetics because the rate constants for these steps are accumulated into composite rate constants and do not affect the form of the rate equation for the initial rate or the patterns of any inhibitions.

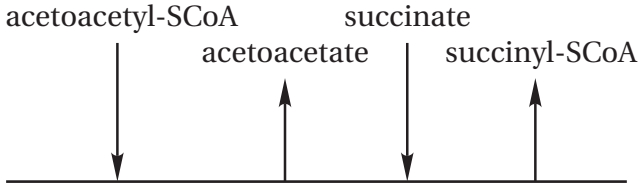
For such kinetically silent steps, steady-state kinetics provide only a value for a composite rate constant. The catalytic constant k_0 is usually such a composite rate constant and registers the overall rate of transformation of reactants into products, usually through several elementary steps, and the rates of dissociation of the products because the reaction is not limited by the rates at which the reactants associate with the active site. This property of the catalytic constant results from the fact that, at saturation, the initial concentrations of reactants are so high that their association with the active site is more rapid than those steps that do not involve their association.

Once these two aspects of steady-state kinetics have been understood, a **notation that is used to represent the only conclusion of a kinetic study** can be appreciated. A horizontal line is drawn that represents the progress of the enzymatic reaction. Vertical arrows above the horizontal line and joined to it connect each substrate to the horizontal line. An arrow entering the line indicates a reactant associating with the active site; an arrow exiting the line indicates a product dissociating from the active site. The order in which the arrows are drawn indicates the order in which substrates associate with or dissociate from the enzyme. For example, for the D-lactate dehydrogenase from *S. toyocaensis* (Equation 3–249), the notation would be



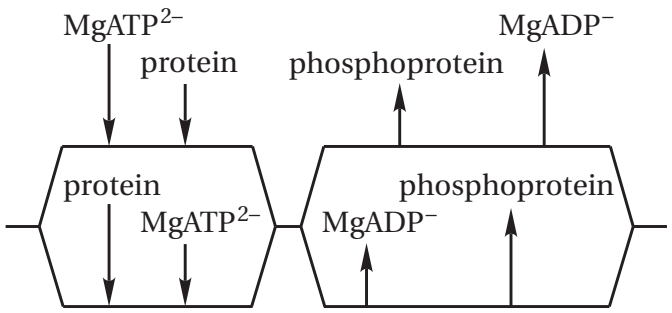
(3–274)

and for ovine 3-oxoacid CoA-transferase (Equation 3–149) the notation would be



(3–275)

If the order is random, the horizontal line is bifurcated. For example, for human phosphoinositide-dependent protein kinase (Equation 3–225) the notation would be



(3–276)

By microscopic reversibility, it must be the case that, in the reverse direction, the arrows are simply reversed, and the relative order of events must be the exact opposite of that in the forward direction.

In addition, however, to determining the order in which reactants associate with the active site and products dissociate from the active site, steady-state kinetics also **provide numerical values for the catalytic constant, the various specificity constants, and hence the various Michaelis constants**. These kinetic constants are **fundamental constants** describing a particular enzymatic reaction, and they are relied upon for, among others, comparisons of various reactants, comparisons of various site-directed mutants, and comparisons of the same enzyme from different species. For example, the fact that the catalytic constant and the specificity constant for a mismatched pair of nucleotide bases between the template and the 2′-deoxynucleoside triphosphate that is adding to the elongating strand of DNA are 0.02 s^{-1} mM^{-1} and 0.14 s^{-1}, respectively, while the catalytic constant and specificity constant for a matched pair are 15,000 s^{-1} mM^{-1} and 300 s^{-1}, respectively, dramatically demonstrates the fidelity of the active site of DNA-directed DNA polymerase from Escherichia phage T7 while it is replicating DNA.[148]

Problem 3–5: Porcine fumarate hydratase (FH) catalyzes the hydration of fumarate to L-malate (Equation 3–1). The following data were obtained when fumarate was used as the reactant and the initial rate of the hydration reaction was measured at pH 6.2 and 25 °C, and a concentration of active sites of 8 μM.

fumarate (mM)	rate of formation of malate (mmol L^{-1} min^{-1})
2.0	2.5
3.3	3.1
5.0	3.6
10.0	4.2

When the same reaction was studied in a buffer containing 0.06 M phosphate, at the same pH and concentration of enzyme, the following data were obtained.

fumarate (mM)	rate of formation of malate (mmol L^{-1} min^{-1})
2.0	4.0
3.3	5.0
5.0	5.8
10.0	6.6

(A) Determine the value of the observed catalytic constant, $k_{0,F}$, and the observed specificity constant for fumarate, k_F, for the two conditions listed. Analyze and discuss briefly any significant differences.

The Haldane equation for an enzymatically catalyzed reaction with a single reactant A and a single product Z relates the specificity constant k_A and the specificity constant k_Z for the forward and the reverse reaction, respectively, to the equilibrium constant for the reaction K_{eq}

$$K_{eq} = \frac{k_A}{k_Z}$$

The initial rates of the hydration reaction catalyzed by fumarate hydratase at 25 °C were measured as a function of pH and for various initial concentrations of fumarate and an enzyme concentration of 2×10^{-6} M. The values obtained, expressed as millimoles of malate $liter^{-1}$ $minute^{-1}$, were as follows.

	concentration of fumarate (mM)			
pH	10	5	2.5	1.25
5	0.92	0.81	0.66	0.48
6	4.00	3.28	2.42	1.60
7	5.40	4.30	3.08	1.96
8	2.67	2.40	1.99	1.53
9	0.21	0.17	0.16	0.12

The values of the limiting rate for the dehydration of L-malate ($k_{0,M}[FH]_t$), catalyzed by fumarate hydratase under the same conditions, had the following dependence on pH.

pH	$k_{0,M}[FH]_t$ for malate (mmol L^{-1} min^{-1})
5	0.068
6	0.044
7	3.00
8	5.88
9	2.00

The overall equilibrium constant for the reaction, K_{eq}, is independent of pH over the range from pH 5 to 9 and has a value of 4.7.

(B) Determine values for the observed catalytic constant, $k_{0,F}$, and the observed specificity constant for fumarate, k_F, for the hydration reaction at each value of pH.

(C) Calculate the values of the observed specificity constant for malate, k_M, for the dehydration reaction at each value of pH.

The decrease in the concentration of fumarate due to its hydration to D,L-malate was measured at pH 5.7 and 25 °C in the absence of enzyme.

fumarate (mM)	time (h)
20.0	0
19.1	20
18.3	40
17.5	60
16.7	80

(D) Compare the initial rate constant for this reaction with the catalytic constant for the catalyzed reaction and calculate the factor by which the rate of the hydration reaction is increased when the reactants are bound to the active site of the enzyme.

Problem 3–6: Derive the rate equations for the kinetic mechanisms in Equations 3–55, 3–84, 3–85, 3–91, 3–109, 3–121, 3–134, 3–141, 3–154, 3–183, 3–194, 3–210, 3–223, and 3–237.

Problem 3–7: Derive the rate equation for the kinetic mechanism

$$\mathrm{E + A + B} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}A + B} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{E{\cdot}A{\cdot}B} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \mathrm{E{\cdot}Z{\cdot}Y} \xrightarrow{k_4} \mathrm{E + Y + Z}$$

Problem 3–8: Hexokinase (HK) catalyzes the reaction in Equation 3–94. Magnesium ion, Mg^{2+}, is required for the enzymatic reaction. Magnesium dication forms complexes with the various conjugate bases of ATP

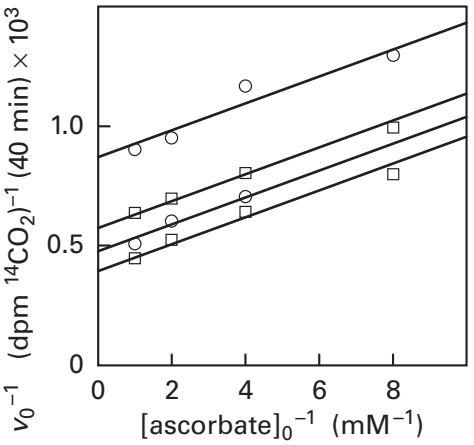
$$\mathrm{Mg^{2+} + H}_n\mathrm{ATP}^{(4-n)-} \rightleftharpoons \mathrm{MgH}_m\mathrm{ATP}^{(2-m)-} + (n-m)\mathrm{H^+}$$

where H_n and H_m are the numbers of hydrons on the free phosphotriester of ATP and the chelated phosphotriester, respectively. The values for these numbers depend on the pH. The values for the dissociation constants of these various complexes have been measured as a function of pH. At a particular pH, at any total concentration of Mg^{2+} in all its complexes, and at any total concentration of ATP in all its complexes, the following concentrations can be calculated: the total molar concentration of MgATP, $[MgATP]_t$, which is the total concentration of ATP in all hydronation states that is complexed with Mg^{2+}, and the total molar concentration of ATP, $[ATP]_t$, which is the total concentration of ATP in all hydronation states that is not complexed with Mg^{2+}. In this way the molar concentrations of MgATP and ATP can be varied independently. When $[ATP]_t$ was fixed and $[MgATP]_t$ was varied systematically, v_0^{-1} was a linear function of $[MgATP]_t^{-1}$. When $[ATP]_t$ was changed to a higher fixed level, the initial rate v_0 of hexokinase from *R. norvegicus* decreased at every $[MgATP]_t$, but the limiting rate, $k_0[HK]_t$, for $[MgATP]_t$ was unchanged (Figure 3–11A). How do these results define what is the actual reactant and what is an inhibitor of the enzymatic reaction? What type of inhibitor is it?

Problem 3–9: Procollagen-lysine 5-dioxygenase catalyzes the reaction

$$\text{lysyl peptide} + \text{2-oxoglutarate} + \mathrm{O_2} \rightleftharpoons (2S,5R)\text{-5-hydroxylysyl peptide} + \text{succinate} + \mathrm{CO_2}$$

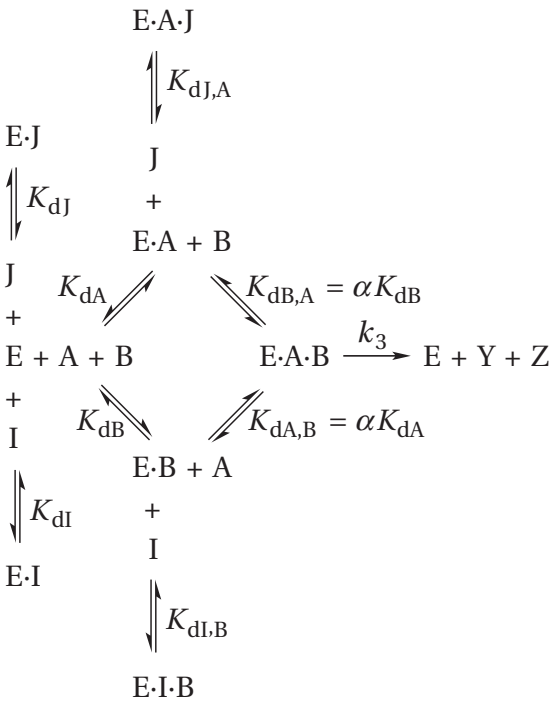
Although it is not a participant in the stoichiometric reaction, ascorbate (Equation 2–163) and Fe^{2+} are required to maintain the iron in the enzyme in the ferrous form. When the concentration of ascorbate is varied at a fixed concentration of any one of the three stoichiometric reactants and saturating concentrations of the other two, the reciprocal of the initial rate, v_0^{-1}, for the enzyme from *G. gallus* is a linear function of $[\text{ascorbate}]_0^{-1}$. If the fixed substrate is set at other concentrations, the lines defined by the data are all parallel.[149] For example, if lysyl peptide is the fixed substrate and oxygen and 2-oxoglutarate are always saturating



Behavior of the initial rate of the reaction catalyzed by procollagen-lysine 5-dioxygenase from *G. gallus* as a function of the initial concentrations of ascorbate and a peptide oxidized by the enzyme. The enzymatic reaction was assayed by using 2-oxo-[1-^{14}C]glutarate as a reactant and following the production of $^{14}CO_2$. The initial rates are the disintegrations per minute of $^{14}CO_2$ produced over 40 min at 37 °C. The reciprocals of the initial rates of the reaction, v_0^{-1}, are plotted as a function of the reciprocals of the initial concentrations of ascorbate (millimolar^{-1}) at different fixed concentrations of the peptide substrate.[149] The concentrations of the lysyl peptide were 0.1, 0.15, 0.2, and 0.75 mg mL^{-1} for the lines in descending order. The concentration of Fe^{2+} was 0.05 mM, and that of 2-oxo-[1-^{14}C]glutarate was 0.1 mM.

(A) What do these kinetic observations say about the relation between the lysyl peptide and ascorbate?
(B) Because the same type of behavior is observed between each of the other two stoichiometric reactants and ascorbate, what do these kinetic observations say about the relation between each of these other reactants and ascorbate?
(C) Explain this kinetic behavior on the basis of the role of ascorbate in the enzymatic reaction.
(D) Write a kinetic mechanism based on this explanation.

Problem 3–10: Derive the rate equation for the following kinetic mechanism.



Note that all the reactions preceding the reaction governed by k_3 are at equilibrium. Inhibitor I prevents reactant A from binding to the enzyme, and inhibitor J prevents reactant B from binding to the enzyme.

(A) What type of inhibition does inhibitor I display with respect to reactant A, and what type does it display with respect to reactant B?
(B) What type of inhibition does inhibitor J display with respect to reactant A, and what type does it display with respect to reactant B?

Problem 3–11: Suppose there is an enzyme that catalyzes the reaction A + B $\rightleftharpoons$ Y + Z. Suppose reactant A has to bind to the active site before reactant B can bind, and reactant B has to bind before products are formed. Suppose there were an inhibitor I that, like reactant B, could bind to the active site only after reactant A was bound.

(A) Write a kinetic mechanism describing both the enzymatic reaction and its inhibition by the inhibitor I.
(B) Show that the rate equation for the initial rate for this kinetic mechanism is

$$v_0 = \frac{k_0 k_A k_B k_{AB} [E]_t [A]_0 [B]_0}{k_0 k_A k_B + k_0 k_A k_{AB} \left(\frac{[I] + K_i}{K_i} \right) [A]_0 + k_0 k_B k_{AB} [B]_0 + k_A k_B k_{AB} [A]_0 [B]_0}$$

where K_i is an inhibition constant.

(C) If this were the kinetic mechanism, what would k_0, k_A, k_B, and k_{AB} be equal to in terms of the rate constants in your kinetic mechanism in (A)?
(D) If this mechanism were the actual kinetic mechanism, what dissociation constant would K_i be equal to in terms of your kinetic mechanism in (A)?
(E) What would plots of v_0^{-1} against $[A]_0^{-1}$ at constant $[B]_0$ and several fixed [I] look like?
(F) What would plots of v_0^{-1} against $[B]_0^{-1}$ at constant $[A]_0$ and several fixed [I] look like?

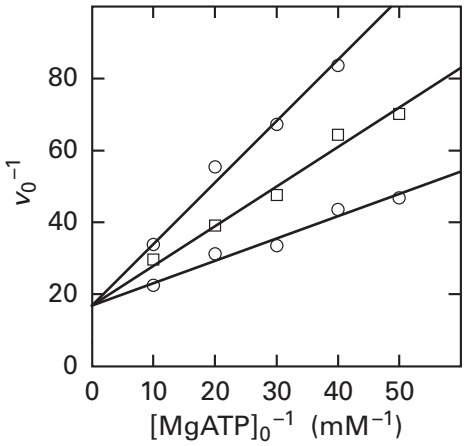
Glycerol kinase catalyzes the reaction

$$\text{glycerol} + \text{MgATP}^{2-} \rightleftharpoons \text{MgADP}^{-} + \textit{sn}\text{-glycerol 3-phosphate}$$

(G) Write a chemical mechanism for this reaction.

The chromium complex of ATP, $CrATP^{-}$, cannot be used by the enzyme as a reactant in the glycerol kinase reaction because the chromium–oxygen bonds are too strong, but it is a potent inhibitor of the enzyme.

Examine Figure 3–12 and the following figure.



Inhibition of the reciprocal of the initial rate v_0^{-1} for glycerol kinase from *C. norvegensis* by $CrATP^{-}$ as a function of the initial concentration of $MgATP^{2-}$. The concentration of glycerol was held constant at 5 mM throughout.[100] The concentrations of $CrATP^{-}$ were 0, 5, and 10 μM for the lines in ascending order.

(H) On the basis of these results, which of the reactants for glycerol kinase binds first to the active site?

Problem 3–12: 1-Deoxy-D-xylulose-5-phosphate synthase catalyzes the thiamine diphosphate-dependent reaction

$$H^+ + \text{pyruvate} + \text{D-glyceraldehyde 3-phosphate} \rightleftharpoons \text{1-deoxy-D-xylulose 5-phosphate} + CO_2$$

3-Fluoropyruvate is a competitive inhibitor of the enzyme from *R. capsulatus* with respect to pyruvate and an uncompetitive inhibitor with respect to D-glyceraldehyde 3-phosphate.[92] What do these results suggest about the order in which the reactants associate with the enzyme?

Problem 3–13: Pyruvate, phosphate dikinase catalyzes the reaction

$$\text{phospho}\textit{enol}\text{pyruvate} + MgOPO_3PO_3^{2-} + H^+ + AMP^{2-} \rightleftharpoons MgATP^{2-} + HOPO_3^{2-} + \text{pyruvate}$$

The following results were observed for inhibition of the enzyme from *Clostridium symbiosum* by the dead-end inhibitors adenosine 5′-monophosphorothioate ($AMPS^{2-}$) and magnesium imidodiphosphate ($MgOPO_2NHPO_3H^-$; MgPNP) when each of the respective unnamed reactants were held at saturation.

inhibitor	varied reactant	type of inhibition
AMPS	MgAMP	competitive
AMPS	$MgOPO_3PO_3^{2-}$	mixed
AMPS	phospho*enol*pyruvate	uncompetitive
PNP	$MgOPO_3PO_3^{2-}$	competitive
PNP	phospho*enol*pyruvate	uncompetitive
PNP	MgAMP	uncompetitive

(A) With what order of association for the three reactants is this pattern of dead-end inhibition consistent?

When initial rates for the reaction were measured at saturating concentrations of phospho*enol*pyruvate, the initial concentration of AMP^{2-} was varied at several fixed initial concentrations of $MgOPO_3PO_3^{2-}$, and the initial concentration of $MgOPO_3PO_3^{2-}$ was varied at several fixed initial concentrations of AMP^{2-}; in both cases, the double reciprocals were intersecting. When the initial rates were measured at saturating concentrations of AMP^{2-}, the initial concentration of $MgOPO_3PO_3^{2-}$ was varied at several fixed initial concentrations of phospho*enol*pyruvate, and the initial concentration of phospho*enol*pyruvate was varied at several fixed initial concentrations of $MgOPO_3PO_3^{2-}$; in both cases, the double reciprocals were parallel. When the initial rates were measured at a fixed subsaturating concentration of $MgOPO_3PO_3^{2-}$, the initial concentration of phospho*enol*pyruvate was varied at several fixed concentrations of AMP^{2-}, and the initial concentration of AMP^{2-} was varied at several fixed concentrations of phospho-*enol*-pyruvate; in both cases, the lines fitting the double reciprocals were parallel.[150]

(B) What do these results say about the steps between the associations of the three reactants?

(C) What observation, which would resolve an ambiguity about one of the steps between the associations of two of the reactants, is missing?

Problem 3–14: The flavoenzyme thymidylate synthase (FAD) from *Chlamydia trachomatis* catalyzes the reaction

$$\begin{aligned}&\text{5,10-methylenetetrahydrofolate} + \\ &\quad \text{NADPH} + \text{H}^+ + \text{dUMP}^{2-} \rightleftharpoons \\ &\qquad \text{dTMP}^{2-} + \text{tetrahydrofolate} + \text{NADP}^+\end{aligned}$$

When NADPH is held at saturating concentration and deoxyuridine 5′-phosphate is varied at several fixed concentrations of 5,10-methylenetetrahydrofolate, the double reciprocals of the initial rates are parallel lines. When NADPH is saturating, deoxythymidine 5′-phosphate is noncompetitive with respect to deoxyuridine 5′-phosphate and competitive with respect to 5,10-methylenetetrahydrofolate, and tetrahydrofolate is noncompetitive with respect to 5,10-methylenetetrahydrofolate and competitive with respect to deoxyuridine 5′-phosphate.[151] Write a kinetic mechanism for the enzyme that is consistent with these observations.

Problem 3–15: The enzyme adenine phosphoribosyltransferase catalyzes the reaction

$$\begin{aligned}&\text{magnesium 5-phospho-}\alpha\text{-D-ribose 1-diphosphate} \\ &\quad + \text{adenine} \rightleftharpoons \text{AMP}^{2-} + \\ &\quad \text{H}^+ + \text{magnesium diphosphate}\end{aligned}$$

The double-reciprocal plots of v_0^{-1} as a function of either $[\text{adenine}]_0^{-1}$ or $[\text{5-phospho-}\alpha\text{-D-ribose 1-diphosphate}]_0^{-1}$ at several fixed initial concentrations of either magnesium 5-phospho-α-D-ribose 1-diphosphate or adenine were sets of parallel lines as in Figure 3–8.

(A) Show that these data can be fit by the function

$$v_0 = \frac{k_0 k_{\text{Ad}} k_{\text{PRPP}} [\text{E}]_t [\text{Ad}]_0 [\text{PRPP}]_0}{k_0 k_{\text{PRPP}} [\text{PRPP}]_0 + k_0 k_{\text{Ad}} [\text{Ad}]_0 + k_{\text{Ad}} k_{\text{PRPP}} [\text{Ad}]_0 [\text{PRPP}]_0}$$

where $[\text{Ad}]_0$ is the initial molar concentration of adenine and $[\text{PRPP}]_0$ is the initial molar concentration of magnesium 5-phospho-α-D-ribose 1-diphosphate.

(B) Write the kinetic mechanism usually associated with this rate equation.

(C) For this kinetic mechanism to be correct, what type of inhibition must adenosine 5′-phosphate display toward magnesium 5-phospho-α-D-ribose 1-diphosphate?

(D) For this kinetic mechanism to be correct, what type of inhibition must magnesium diphosphate display toward adenine?

(E) Adenosine 5′-phosphate is a competitive inhibitor relative to magnesium 5-phospho-α-D-ribose 1-diphosphate, and magnesium diphosphate is a noncompetitive inhibitor relative to adenine.[152] Do these observations match your expectations?

(F) Derive the initial rate equation for the following kinetic mechanism

$$\begin{aligned}&\text{E} + \text{PRPP} + \text{Ad} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{E·PRPP} + \text{Ad} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \\ &\qquad \text{E·PRPP·Ad} \xrightarrow{k_3} \text{E} + \text{AMP} + \text{PP}\end{aligned}$$

where PP is magnesium diphosphate.

(G) Show how this equation can assume the form of the rate equation in part A if two reasonable inequalities hold.

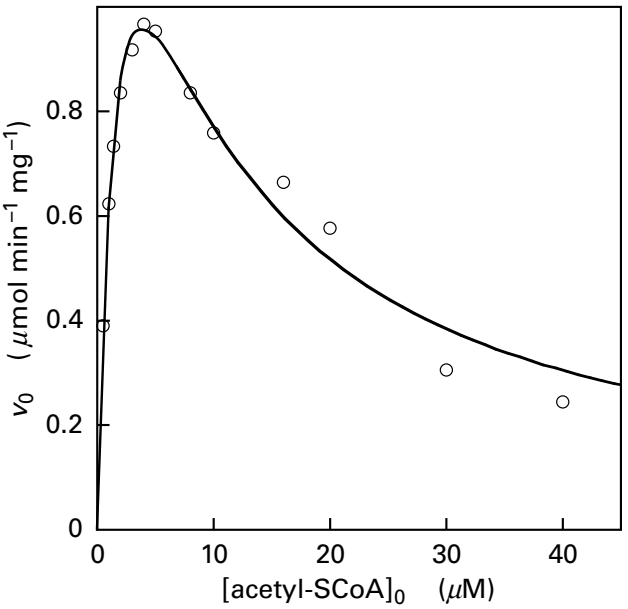
Problem 3–16: When methylmalonyl-CoA mutase (Table 2–3), which contains [5′-^{3}H]adenosylcobalamin as a prosthetic group, is mixed with methylmalonyl-SCoA and the reaction is allowed to proceed for 5 s, all the tritium is washed out of adenosylcobalamin and is transferred to methylmalonyl-SCoA and succinyl-SCoA in a ratio of 1 to 3. When methylmalonyl-CoA mutase that contains [5′-^{3}H]adenosylcobalamine is mixed with succinyl-SCoA and the reaction allowed to proceed for 5 s, all the tritium is again washed out of the adenosylcobalamin and is transferred to methylmalonyl-SCoA and succinyl-SCoA in the same ratio of 1:3.[153] Explain these results in terms of the simplest kinetic mechanism consistent with them and the rate-limiting steps and an intermediate equilibrium common to both of these reactions.

Problem 3–17: The fatty-acid synthase system, a multienzymatic complex, catalyzes the reaction

$$\begin{aligned}&\text{acetyl-SCoA} + n\text{-malonyl-SCoA} + 2n\,\text{NADPH} \\ &\quad + (3n-1)\,\text{H}^+ \rightleftharpoons 2n\,\text{NADP}^+ + n\,\text{CO}_2 + \\ &\quad (n+1)\,\text{HSCoA} + \text{CH}_3(\text{CH}_2\text{CH}_2)_n\text{COO}^-\end{aligned}$$

When the initial rate of the reaction at fixed concentrations of malonyl-SCoA and NADPH was fol-

lowed as a function of the concentration of acetyl-SCoA for the enzyme from *Columba livia*, the following behavior was observed.[154]



Initial rate of fatty acid synthesis v_0, in units of micromoles of NADPH oxidized minute^{-1} (milligram of protein)$^{-1}$, as a function of the initial concentration of acetyl-SCoA (micromolar). The reactions were run in 0.2 M phosphate buffer at pH 7.0. The concentrations of the other reactants were 10 μM malonyl-SCoA and 30 μM NADPH. Rates were followed spectrophotometrically with a 5 cm cell.

The inhibition observed at high concentrations of acetyl-SCoA decreases as the concentration of malonyl-SCoA is raised. Explain both the observed behavior of the initial rate as a function of the initial concentration of acetyl-SCoA and the decrease in inhibition as the concentration of malonyl-SCoA is raised. Why is this explanation reasonable?

Binding

Historically, it was the analysis of steady-state kinetics that led to the conclusion that reactants are assembled at an active site on an enzyme before they are transformed into products. It is now abundantly clear that reactants associate with the enzyme within an active site on the surface or in the interior of a protomer of the enzyme prior to the chemical interconversion between reactants and products within that active site and the subsequent dissociation of the products. If the association or dissociation of each substrate can be treated as a discrete step in an enzymatic reaction, then each of these steps involving only association and dissociation should be no different from the **association and dissociation that accomplishes reversible binding** of any small molecule, or ligand, to a particular site on a molecule of protein. Only what follows the association or precedes the dissociation makes the difference between the complex of a ligand with a site that is not an active site and the complex of a substrate with an active site.

A **ligand** is any molecule that binds to but is not chemically transformed by a protein. The lack of chemical transformation distinguishes a ligand from a substrate. An **agonist** is a ligand, either one that is endogenous to the organism in which the protein is found or a synthetic compound, that binds to a protein and, upon binding, produces a measurable change in the characteristic physiological function of that protein and accomplishes the normal response of that protein to the endogenous agonist. An **antagonist** is a ligand that binds to a protein, does not elicit this characteristic change in its function that is normally produced by an agonist, but blocks the ability of an agonist to effect that change. An **inhibitor** or an **activator** is a ligand that binds to an enzyme and forms a dead-end complex with a rate of catalysis that is smaller or larger, respectively. An inhibitor or an activator can form a complex either within the active site of an enzyme or at sites other than its active site. Inorganic anions, inorganic cations, and hydrophobic molecules that bind adventitiously to a protein are also examples of ligands.

Usually, one molecule of a ligand will associate specifically with a particular constellation of amino acids on the surface or in the interior of a protein, and because of symmetry, the number of those sites for binding that ligand on the protein will be equal to the number of protomers it contains. Usually, each of the symmetrically arrayed sites in a homooligomer will bind the ligand independently. In this situation, **the molar concentration of sites in a particular solution is equal to the molar concentration of native, properly folded protomers**. If, however, the site for the ligand is on an axis of symmetry and involves side chains of amino acids from two protomers, there will be half as many sites as protomers because there will be only one site for every dimer of protomers.

The binding of a ligand, L, to a site, ST, on a protein to form a specific complex, ST·L, is quantitatively described by a **dissociation constant**

$$K_{dL} = \frac{a_{ST}\, a_L}{a_{ST\cdot L}} \qquad (3\text{–}277)$$

where a_i is the activity of component i at equilibrium. In terms of molar concentrations

$$K_{dL} = \left(\frac{\gamma_{ST}\, \gamma_L}{\gamma_{ST\cdot L}}\right)\left(\frac{[ST]_{eq}\,[L]_{eq}}{[ST\cdot L]_{eq}}\right) \qquad (3\text{–}278)$$

where γ_i is the activity coefficient of component i, the subscript eq refers to molar concentrations at equilibrium, and $[L]_{eq}$ is the concentration of free, unbound ligand at equilibrium. If the actual molar concentrations of the various participants are low when the measurement is made, which is usually the case with biochemical measurements, and if the solution has an ionic strength of 0.1 M or greater, which is usually the case with experimental measurements, then the ratio of the activity coefficients is usually close enough to unity to be ignored. The dissociation constant, because it is an equilibrium constant, is **directly related to the standard free energy change for the dissociation** of the ligand from the protein. As an equilibrium constant, it must be distinguished from a kinetic parameter such as the Michaelis constant, K_m, which is rarely related directly to a thermodynamic variable.

The dissociation constant for the binding between a ligand and a site on a molecule of protein can be **determined directly from experimental observations**. In any solution in which the population of sites for the ligand is homogeneous, the dissociation is governed by the simple equation

$$K_{dL} = \frac{[ST]_{eq}\,[L]_{eq}}{[ST\cdot L]_{eq}} \qquad (3\text{–}279)$$

If all the sites are functional, the concentration of bound ligand at equilibrium is equal to

$$[ST\cdot L]_{eq} = \frac{[ST]_t\,[L]_{eq}}{K_{dL} + [L]_{eq}} \qquad (3\text{–}280)$$

where $[ST]_t$ is the total molar concentration of sites, both occupied and unoccupied. This equation has the form of the function defining a rectangular hyperbola with a horizontal asymptote (Equation 3–52) if the **concentration of protein**, and hence $[ST]_t$, **is fixed** at a constant value during the experimental measurements.

It is often not possible, however, to fix the concentration of sites at a constant value because unavoidable changes in volume occur during the experimental procedure[155] or because the experimental protocol itself requires the concentration of sites to be varied. It can be assumed, however, that for a given set of sites

$$C_{prot} = \frac{[ST]_t}{\kappa} \qquad (3\text{–}281)$$

where C_{prot} **is the concentration of protein expressed in any known units and** κ **is a constant of proportionality**. If the concentration of protein in each sample is known in grams liter^{-1}, the units of the constant of proportionality κ are moles of sites (gram of protein)$^{-1}$. To learn this number is often one of the goals of the experiment. If the concentration of protein in each sample is known in moles of protomer liter^{-1}, the constant of proportionality κ is unitless and equal to the fraction of the protomers in the solution that are competent to bind the ligand, which is also informative.

If the **concentration of protein is varied** as the measurements are made, then Equation 3–280 can be rewritten

$$\frac{[ST\cdot L]_{eq}}{C_{prot}} = \frac{\kappa\,[L]_{eq}}{K_{dL} + [L]_{eq}} \qquad (3\text{–}282)$$

This equation defines a rectangular hyperbola (Equation 3–52) in the free concentration of ligand, $[L]_{eq}$, regardless of the variations in the concentration of protein, C_{prot}. The parameters of that rectangular hyperbola are the constant of proportionality, κ, and K_{dL}. Regardless of the total concentration of sites and the total concentration of ligand, if values for $[L]_{eq}$ and $[ST\cdot L]_{eq}\,(C_{prot})^{-1}$ are known, they define the same rectangular hyperbola. For example, the binding of 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate to orotate phosphoribosyltransferase (Equation 3–227) from *S. typhimurium* can be followed by adding increasing amounts of phosphoribosyl [β-^{32}P]diphosphate to a series of samples each containing the same concentration of orotate phosphoribosyltransferase. Following equilibration, the free concentration of 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate in each sample, $[PRPP]_{eq}$, can be assessed

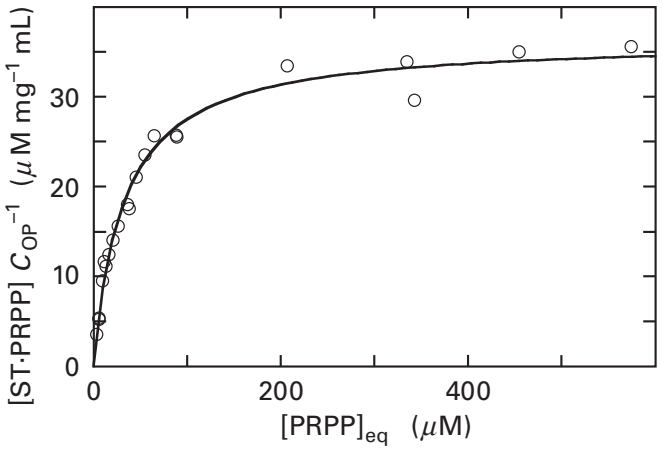


Figure 3–17: Binding of 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate to orotate phosphoribosyltransferase from *S. typhimurium*.[136] Various amounts of 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate (PRPP) were added to solutions of orotate phosphoribosyltransferase (OP) in 5 mM $MgCl_2$ and 80 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol chloride at pH 8.0. After 10 min, the samples were added to Centricon centrifugation tubes. The tubes were submitted to centrifugation until 50–100 μL of fluid had emerged from each of them. The protein remained entirely in the tube, so the fluid that emerged contained only free 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate at the same concentration as the free concentration in the tube at equilibrium. Its concentration was determined by scintillation counting. The amount of bound 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate ([ST·PRPP]) was calculated by subtracting the free concentration from the total concentration of 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate in the tube. The nominal molar concentration of the dimeric enzyme was varied in the range from 3 to 150 μM to ensure that the free concentration of substrate and the bound concentration of substrate would always be of the same order of magnitude so that a statistically significant difference between the two measurements could be obtained. The concentration of bound phosphoribose diphosphate (micromolar) divided by the concentration of enzyme (milligrams of protein milliliter^{-1}) is presented as a function of the concentration of 5-phospho-α-D-ribose 1-diphosphate (micromolar). The curves drawn are fits of Equation 3–52 to the data with x equal to [PRPP]$_{eq}$ and y equal to [ST·PRPP] C_{OP}^{-1}. The dissociation constant for 5-phospho-α-D-ribose diphosphate (parameter b in Equation 3–52) is 32 ± 2 μM, and the micromoles of sites (gram of protein)$^{-1}$ (parameter a in Equation 3–52) is 36.4 ± 0.8 μM mg^{-1} mL, which is equivalent to 28 g of protein (mmol of sites)$^{-1}$. The molar mass of a subunit of the dimeric protein is 23.45 g mmol^{-1}.

by ultrafiltration, and the concentration of 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate bound by the sites on the protein in each sample, [ST·PRPP]$_{eq}$, can be assessed by the difference between the total concentration and the free concentration of the ligand

$$[ST{\cdot}L]_{eq} = [L]_t - [L]_{eq} \qquad (3–283)$$

The molar concentration of bound 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate divided by the concentration of enzyme as function of the molar concentration of free 5-phospho-α-D-ribose 1-[β-^{32}P]diphosphate at equilibrium in the solution before ultrafiltration (Figure 3–17)[136] satisfies Equation 3–282.

To perform a direct determination of the binding of a ligand to a protein, simultaneous measurements at equilibrium must be made of the molar concentration of bound ligand, [ST·L]$_{eq}$, and the molar concentration of free ligand, [L]$_{eq}$, in several samples of known protein concentration, C_{prot}, at a number of different concentrations of free ligand (Figure 3–17). There are several ways to accomplish this feat.

Semipermeable membranes are polymer films that have pores large enough to permit small ligands to pass through them but too small to permit the passage of macromolecules such as proteins, polysaccharides, or nucleic acids. There are a number of ways to use these membranes to measure the binding of a ligand to a protein.

In one approach, the protein is placed on one side of a semipermeable membrane separating two compartments, ligand is added to both compartments, and the system is allowed to reach equilibrium. At equilibrium, in the absence of ionic imbalances because the ionic strength of the solutions is appropriate, the molar concentration of the ligand in the compartment without the protein will be equal to [L]$_{eq}$, and the total molar concentration, [L]$_t$, of the ligand in the compartment containing the protein will be [L]$_{eq}$ + [ST·L]$_{eq}$ (Figure 3–18).[156] The final concentration of protein in its compartment at equilibrium is measured independently.[155] This technique is referred to as **equilibrium dialysis**.[157,158]

In the next approach, a known concentration of protein, C_{prot}, and a known concentration of ligand, [L]$_t$, are placed in a compartment on one side of a semipermeable membrane, and the compartment on the other side is flushed continuously with a solution that does not contain the protein or the ligand. The unidirectional rate at which the ligand passes through the semipermeable membrane is directly proportional to its free concentration, [L]$_{eq}$, on the side from which it is leaving.[159] This **rate of dialysis** is measured by monitoring the amount of ligand appearing in the flushing solution as a function of time. If the chamber and the dialysis membrane are calibrated with known concentrations of

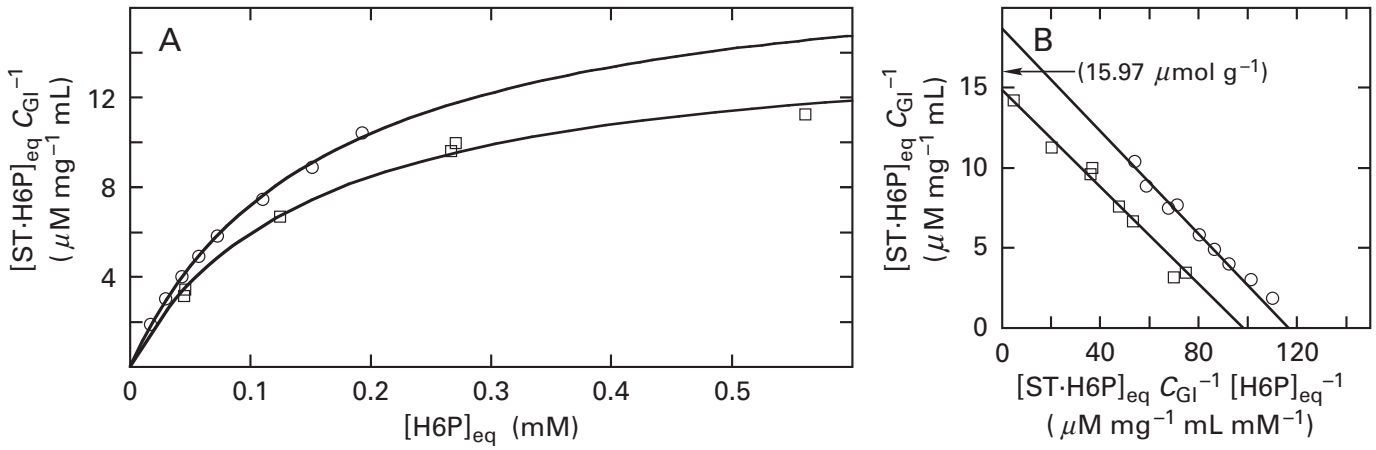

Figure 3–18: Measurement of the binding of an equilibrium mixture of [U-^{14}C]-D-glucose 6-phosphate and [U-^{14}C]-D-fructose 6-phosphate to glucose-6-phosphate isomerase from rabbit muscle by equilibrium dialysis and rate of dialysis.[156] For the measurements by equilibrium dialysis, a series of apparatuses separating two chambers by a dialysis membrane was used. In one chamber of each apparatus, D-glucose-6-phosphate isomerase (10.0 mg mL^{-1}) was present; in the other, buffer alone. [U-^{14}C]-D-Glucose 6-phosphate was added to both sides and allowed to reach equilibrium with fructose 6-phosphate as well as reach equilibrium across the membrane. The concentration of hexose 6-phosphate in the side lacking enzyme is the free concentration of the substrates in both chambers; the concentration of hexose 6-phosphate in the side containing the protein is the sum of free and bound concentrations of the substrates. For the measurements by rate dialysis, an apparatus separating two chambers by a dialysis membrane was used. The enzyme (6.6 mg mL^{-1}) in a buffer at pH 8.0 and 22 °C was in the upper chamber (1 mL). The lower chamber was a spiral groove, in contact with the membrane, through which solution was pumped at a steady rate (4 mL min^{-1}). [U-^{14}C]-D-Glucose 6-phosphate was added at a low concentration to the upper chamber, and the rate at which carbon-14 appeared in the lower chamber was determined by submitting the constantly flowing solution to scintillation counting. When equilibrium had been reached, the concentration of [U-^{14}C]-D-glucose 6-phosphate in the upper chamber was increased, and so forth. By calibrating the apparatus in the absence of protein, the rate of appearance of counts per minute (cpm) of carbon-14 in the lower fluid could be converted to the free concentration of [U-^{14}C]hexose 6-phosphate in the upper solution. From the known total concentration of hexose 6-phosphate in the upper solution, the concentration of bound substrates could be calculated by difference. **(A)** Direct presentation of the measurements. The variable $[ST{\cdot}H6P]_{eq}\ C_{GI}^{-1}$ (micromolar milligram^{-1} milliliter)—where ST is an active site of glucose-6-phosphate isomerase (GI), H6P is hexose 6-phosphate, and C_{GI} is the concentration of glucose-6-phosphate isomerase (milligrams milliliter^{-1})—is plotted as a function of the concentration of hexose 6-phosphate (millimolar). Data from measurements by equilibrium dialysis (□) and measurements by rate dialysis (○) are plotted. Equation 3–52 was fit to each set of data with y equal to $[ST{\cdot}H6P]_{eq}\ C_{GI}^{-1}$ and x equal to [H6P]. The apparent dissociation constants for the substrates (values for parameter b in Equation 3–52) are 0.15 ± 0.01 and 0.16 ± 0.01 mM, respectively, and the micromoles of sites (gram of protein)$^{-1}$ (values for parameter a in Equation 3–52) are 18.7 ± 0.7 and 14.8 ± 0.3 μM mg^{-1} mL, respectively, for the two different measurements. Because the molar mass of a protomer of glucose-6-phosphate isomerase is 62,630 g mol^{-1}, there are, in theory, 15.97 μmol of active sites on glucose-6-phosphate isomerase for every gram of protein. **(B)** Linear presentation of the measurements. The data from measurements by equilibrium dialysis (□) and by rate dialysis (○) are plotted in the linear form of $[ST{\cdot}H6P]_{eq}\ C_{GI}^{-1}$ (micromolar milligram^{-1} milliliter) as a function of $[ST{\cdot}H6P]_{eq}\ C_{GI}^{-1}\ [H6P]_{eq}^{-1}$ (micromolar milligram^{-1} milliliter millimolar^{-1}), where $[H6P]_{eq}$ is the concentration (millimolar) of hexose 6-phosphate at equilibrium. The lines are those calculated for the dissociation constants and the micromoles of sites (gram of protein)$^{-1}$ from the fits of the data in Panel A. The theoretical intercept of 15.97 micromoles of sites (gram of protein)$^{-1}$ is noted.

ligand, the rate of dialysis can be converted directly into a value for the free concentration of ligand, $[L]_{eq}$, in the compartment, and the concentration of bound ligand, $[ST{\cdot}L]_{eq}$, can be calculated by difference (Figure 3–18) from the known total concentration of ligand in the compartment with the protein, $[L]_t$, and the concentration of free ligand.

In yet another approach, the protein and the ligand are allowed to equilibrate in a solution, and then a portion of the solution is forced under pressure through a semipermeable membrane.[160] This process is referred to as **ultrafiltration**. The concentration of ligand in the ultrafiltrate will be the free concentration, $[L]_{eq}$, in the original solution, and the known total concentration of ligand in the original solution, $[L]_t$, will be the sum of that free concentration and the bound concentration, $[ST{\cdot}L]_{eq}$ (Figure 3–17).[136]

Chromatography by size exclusion takes place on a column of beaded, tightly crosslinked dextran that excludes the protein from the interior of the beads, that includes the free ligand in the interior of the beads, and that can been equilibrated with a solution containing a fixed concentration of ligand. If a sample of protein is run on such a size-exclusion column, the protein, which exits the column in the

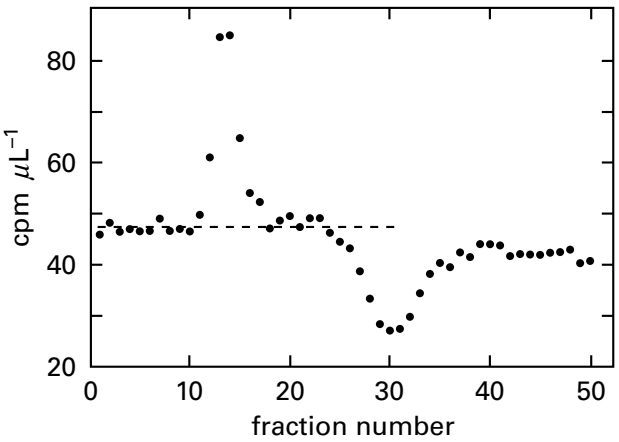

Figure 3–19: Determination of the concentration of histidinol bound to histidinol dehydrogenase by molecular exclusion.[161] A column (0.5 cm × 7.5 cm) of beaded, crosslinked dextran (Sephadex G-50) was equilibrated with buffer containing 0.5 mM $MnCl_2$, 1 mM potassium phosphate, 1.0×10^5 counts per minute mL^{-1} [^{32}P]phosphate, 10 μM [^{3}H]histidinol (4.7×10^6 counts per minute μmol^{-1}) and 50 mM sodium glycinate at pH 9.05. A sample of histidinol dehydrogenase dissolved in 100 μL of the buffer used to equilibrate the column was applied, and the column was eluted with 2.8 mL of the buffer. Each fraction from the column was one drop of effluent (48–53 μL). To determine the counts per minute (cpm) of [^{3}H]histidinol for every microliter of solution in each fraction, the exact volume of each drop was determined from the counts per minute of [^{32}P]phosphate, and the counts per minute of [^{3}H]histidinol in each fraction was divided by that volume. The counts per minute of [^{3}H]histidinol in each microliter of effluent (cpm μL^{-1}) is presented as a function of the fraction number. The free concentration of histidinol is represented by the counts per minute $microliter^{-1}$ in the effluent before and after the excluded volume of the column (fractions 11–17), as indicated by the dashed line. The counts per minute in excess of those representing the free concentration of [^{3}H]histidinol in each fraction were summed over the excluded volume and converted to nanomoles of bound histidinol.

excluded volume, will bind ligand as it passes through the beaded dextran until the binding reaches equilibrium. The concentration of the excess ligand eluting with the protein should be ligand that is bound to the protein. If the protein has moved far enough to leave behind the deficit it created by binding the ligand, and the deficit is separated completely from the fractions containing the protein, which is ascertained by locating the deficit in the included volume (Figure 3–19),[161] the concentration of free ligand, $[L]_{eq}$, in fractions from the excluded volume, at which the protein elutes, should be the molar concentration of ligand with which the column was initially equilibrated.[162,163] It is usually assumed that the amount of protein eluting in the excluded volume is equal to the amount added to the column, but that should be verified independently. A similar procedure uses electrophoresis on a gel of poly(acrylamide) cast in a solution containing ligand at a particular concentration to ascertain the concentration of ligand bound to sites, $[ST{\cdot}L]_{eq}$, at that free concentration of ligand, $[L]_{eq}$.[164]

In each of the five methods just described for direct determination of the concentration of sites and the dissociation constant for the ligand, the concentration of bound ligand, $[ST{\cdot}L]_{eq}$, is determined by assessing the difference between the total concentration of the ligand in the solution, $[L]_t$, and the free concentration of the ligand, $[L]_{eq}$

$$[ST{\cdot}L]_{eq} = [L]_t - [L]_{eq} \qquad (3\text{–}284)$$

Consequently, **the concentration of bound ligand must always be a significant fraction of the total concentration of ligand**. Since the binding is a hyperbolic function of the free concentration of ligand, the concentration of protein must usually be increased as the concentration of ligand is increased. This requirement, however, is an advantage. If the measured values for $[L]_{eq}$ satisfy Equation 3–282 as $[L]_t$ and C_{prot} are varied independently, there is increased confidence that an uncomplicated dissociation constant is being measured (Figure 3–17).

In all of the many different procedures that have been developed to follow directly the binding of a ligand to a protein, **three variables are simultaneously measured**: the free concentration of the ligand, $[L]_{eq}$; the total concentration of protein, C_p; and the concentration of the complex between protein and ligand, $[ST{\cdot}L]_{eq}$. Each one of a set of solutions whose molar concentrations of protein and ligand are systematically varied is allowed to reach equilibrium, and these three concentrations are then measured by techniques that can assess what their values were in the solution when it was at equilibrium. As in the case of an analysis of results from studies of enzymatic kinetics, the data from a study of the binding of a ligand are submitted to numerical analysis. In this case, the data are a set of measured values for $[ST{\cdot}L]_{eq}\ C_{prot}^{-1}$ corresponding to a set of equilibrium molar concentrations for the free ligand $[L]_{eq}$. Again, as in the case of enzymatic kinetics, it is now customary to fit a rectangular hyperbola (Equation 3–52), where y is $[ST{\cdot}L]_{eq}\ C_{prot}^{-1}$ and x is $[L]_{eq}$, to the data by nonlinear least-squares analysis.[136,165] The two parameters, a and b, and their standard deviations, provided by the fitting procedure, are κ and K_{dL} (Equation 3–282). Such nonlinear numerical analysis can be extended to situa-

tions where several different sites, at different relative concentrations, are binding the same ligand, and each site has its own unique dissociation constant.[166] In either case, the experimental results obtained from such analyses are the individual values for the dissociation constant, K_{dL}, and the individual values for κ, which can be the inverse of the grams of protein (mole of sites)$^{-1}$. If the protein is pure and the molar mass of a protomer is known, the fraction of the protomers capable of binding the ligand can be determined.

The techniques for measuring the equilibrium concentrations in two compartments separated by a semipermeable membrane, for measuring the rate at which ligand passes through a semipermeable membrane, and for measuring the total concentration of ligand in the excluded volume of a column of crosslinked dextran, respectively, were applied separately to the binding at pH 8.0 and 22 °C of the competitive inhibitor 6-phosphogluconate (PGN) to glucose-6-phosphate isomerase from *O. cuniculus*. Values for $K_{d,PGN}$ were 0.08, 0.04, and 0.03 mM, respectively, and values for the inverse of the constant of proportionality κ were 66,000, 66,000, and 63,000 g (mol of sites)$^{-1}$, respectively.[156] These latter values are only slightly larger than the molar mass of one protomer of this enzyme, 62,747 g mol^{-1}. Larger values are expected if the preparation of enzyme was not absolutely pure or if some of the enzyme in the preparation was defunct. At pH 8 and 30 °C, the dissociation constant, determined kinetically for 6-phosphogluconate as a competitive inhibitor of glucose-6-phosphate isomerase, is 0.03 mM,[167] which agrees satisfactorily with the values obtained for its dissociation constant when measured directly.

In kinetic equations derived as explanations of the dead-end inhibition of initial rates for an enzymatic reaction, the **inhibition constants**, K_i, are dissociation constants for the inhibitor. It is gratifying to find that one of them actually is a dissociation constant. In the absence of proof that it is,[168] an inhibition constant, K_i, is, nevertheless, usually assumed to be the dissociation constant of the inhibitor from the enzyme.[169,170]

In the past, the data for the binding of a ligand to a protein were first **converted to a linear form**[157] before the fitting was performed, but this mode of analysis is rarely done anymore because digital computers permit nonlinear numerical analysis to be performed readily. Mainly for historical reasons, however, when the data are presented graphically for the reader's evaluation, they are often presented in a linear form. Equation 3–282 can be cast in a linear form either by inversion[157]

$$\frac{C_{prot}}{[ST{\cdot}L]_{eq}} = \frac{1}{\kappa} + \frac{K_{dL}}{\kappa}\left(\frac{1}{[L]_{eq}}\right) \tag{3–285}$$

or by the rearrangement[171]

$$\frac{[ST{\cdot}L]_{eq}}{C_{prot}} = \kappa - K_{dL}\left(\frac{[ST{\cdot}L]_{eq}}{C_{prot}\,[L]_{eq}}\right) \tag{3–286}$$

Because it was pointed out by Professor Scatchard that the use of Equation 3–285 "gives undue weight to that portion of … [the] data which is poorest in experimental precision,"[157] Equation 3–286, that for a **Scatchard plot**, is usually used as the linear form of the function. This method of analysis is in contradistinction to the common use of Equation 3–53 as the linear form of the function for initial rate of an enzymatic reaction.

The **Donnan effect** is one potential drawback of all the techniques described so far. In each instance, a solution containing the protein and the ligand is physically separated from a solution containing only the ligand but remains in equilibrium with it. The protein is almost always charged at the pH at which the measurements are made. Even during chromatography by size exclusion, the dimensions of the two compartments, that containing the protein surrounding the beads and that lacking the protein in the interior of the beads, are greater than the thickness of the ionic double layer around the protein.[172] If the ligand is also charged, it will act as any other electrolyte in the diffuse layer of dissolved counterions around the protein. It will either be depleted in the layer if it is of the same charge as the protein or enriched in the layer if it is of opposite charge. This depletion has the effect of decreasing or increasing, respectively, the measured concentration of bound ligand in the compartment containing the protein. This source of error can be minimized by performing the binding experiments at a **concentration of supporting electrolyte high enough** to eliminate the contribution of the ligand itself to the layer of mobile counterions. This elimination can be seen in the following way.

Suppose that the solution of protein contains impermeant macromolecules, including the molecules of protein themselves, that have a net charge at the pH chosen for the measurements. In the sys-

tem there are two compartments: the compartment α containing the charged macromolecules and the compartment β lacking them. Assume that the only permeant electrolytes are the ligand, potassium, and chloride, and also assume that the solution of protein contains no binding sites for ligand L. By electroneutrality

$$[\text{charge}]_\alpha = [K^+]_\beta - [K^+]_\alpha + [Cl^-]_\alpha - [Cl^-]_\beta + z_L\left([L]_\beta - [L]_\alpha\right) \quad (3\text{–}287)$$

where $[\text{charge}]_\alpha$ is the net molar concentration of all impermeant elementary charge in compartment α (in equivalents liter^{-1}) which can have either a positive or a negative value), z_L is the charge number on ligand L, and the subscripts on the concentrations indicate the respective compartment. This equation defines the contribution of each ion to the maintenance of electroneutrality. A quantity $f_{\text{charge,L}}$ can be defined, which is the fraction of the charge compensation contributed by the ligand L

$$f_{\text{charge,L}} = \frac{z_L\left([L]_\beta - [L]_\alpha\right)}{[K^+]_\beta - [K^+]_\alpha + [Cl^-]_\alpha - [Cl^-]_\beta + z_L\left([L]_\beta - [L]_\alpha\right)} \quad (3\text{–}288)$$

If $|z_L| = 1$ and $[\text{charge}]_\alpha$ is much less than the sum of the concentrations of the permeant electrolytes, it can be shown[173] that

$$z_L\left([L]_\beta - [L]_\alpha\right) \cong \frac{[\text{charge}]_\alpha\,[L]}{\left([K^+] + [Cl^-]\right) + [L]} \quad (3\text{–}289)$$

This relation states that even if the solution of protein contains no sites for ligand L, it will **appear to contain binding sites for ligand L** if the charge of ligand L is opposite that of the nondiffusible charge on the macromolecules. The apparent dissociation constant measured for ligand L will be $[K^+] + [Cl^-]$.

If the Donnan effect is the only reason for the excess ligand in the compartment containing the protein, the apparent dissociation constant should be directly proportional to the concentration of supporting electrolyte. If, however, **a molar concentration of supporting electrolyte is purposely chosen so that it is always much greater than the molar concentration of ligand and the net concentration of impermeant elementary charge**, the amount of ligand retained or excluded from compartment β due to the Donnan effect, $[L]_\beta - [L]_\alpha$, as opposed to that due to legitimate binding, will be negligible (Equation 3–289). The Donnan effect, however, is difficult to eliminate if the macromolecule to which binding is being measured is nucleic acid instead of protein because nucleic acid is so negatively charged.

If the net charge of ligand L is the same as that of the nondiffusible macromolecules, the concentration of ligand L will be decreased in the compartment containing the protein, and if the net charge of ligand L is opposite that of the nondiffusible macromolecules, the concentration of ligand L will be increased in the compartment containing the protein. If there are legitimate sites for ligand L on the protein, the apparent binding to those sites will be less than the actual binding in the former case and greater in the latter case. The magnitude of these effects, however, decreases as the concentration of the supporting electrolyte is increased. Consequently, **dependence on ionic strength of any apparent binding** should be discounted until it is demonstrated that this dependence does not result simply from the Donnan effect.

There are also methods to **determine $[L]_{eq}$ and $[ST{\cdot}L]_{eq}$ by indirection**. In such an approach, the fraction of the population of molecules of ligand that is occupied by sites on the molecules of protein is still measured; and from the known total concentration of ligand in solution, $[L]_t$, the desired concentration of $[ST{\cdot}L]_{eq}$ and $[L]_{eq}$ can be calculated. For example, solutions each containing the same known concentration of an end-labeled fragment of DNA can be mixed with various concentrations, C_{prot}, of a protein that binds to a particular site on that fragment. After equilibrium is achieved, a small volume of deoxyribonuclease is added to the solution while the protein is still in equilibrium with the site on the DNA with which it associates. The amount of deoxyribonuclease added is small enough that it digests the DNA partially and at random. After a period of digestion, the DNA is submitted to electrophoresis, and the end-labeled fragments produced by deoxyribonuclease are quantified. When the protein is bound at its specific site, that site is protected from digestion by the deoxyribonuclease. As the digestion proceeds, the protein is associating and dissociating from its specific sites, but because of the equilibrium, the fraction of the sites protected ($[ST{\cdot}L]_{eq}\,[ST]_t^{-1}$) at any given instant remains constant during the digestion. As a result, fragments resulting from that particular cleavage decrease in amount in direct proportion to the frac-

tion of the sites occupied by the protein at equilibrium.[174,175] From the fraction of the sites occupied and the known molar concentration of the fragment of DNA in the initial solution, the concentrations $[ST{\cdot}L]_{eq}$ and $[L]_{eq}$ can be calculated. This method has the advantage that it can independently assess the binding of the protein to two or more sites on the same fragment of DNA.[176] This procedure is not immune from the Donnan effect because immediately adjacent to the DNA, which is a densely charged polyelectrolyte, the free concentration of protein can be significantly increased or decreased, depending upon its net charge and the ionic strength of the solution, and its occupation of the sites can be artifactually increased or decreased, respectively.[177]

Any physical or chemical property of the protein or of the ligand that changes upon the formation of a complex between a site and a ligand can be used to determine a value for the dissociation constant of the ligand. Examples of these properties would be the absorbance of the protein itself;[178] the absorbance of a prosthetic group in the protein, such as flavin,[179] heme,[101] or pyridoxal phosphate;[180] the absorbance of the ligand;[181] the fluorescence of the protein itself;[182-184] the fluorescence of a fluorophore that has been covalently attached to the protein;[185] the fluorescence of the natural ligand itself;[186] the fluorescence of a fluorescent derivative of the natural ligand;[187,188] the anisotropy of the fluorescence of a ligand;[189-191] the lifetime of the fluorescence of the protein[183] or the ligand; the chemical shift of a nuclear magnetic absorption of the ligand;[192] the absorption or emission of heat measured by a microcalorimeter;[193,194] or the rate of the covalent reaction of a particular amino acid in the protein with a particular chemical reagent.

For example, *N*-methylnicotinamide binds to lysozyme from *G. gallus* to form a complex that absorbs light at 350 nm, a wavelength at which both the ligand and the protein are transparent.[195] The **absorbance observed at a certain wavelength**, A_λ, of a particular complex between the ligand and the protein—in this instance the absorbance at 350 nm of the complex between *N*-methylnicotinamide and lysozyme—should be directly proportional to the molar concentration of the complex between the ligand, *N*-methylnicotinamide, and the protein, lysozyme, on which the site (ST) for binding is located

$$A_\lambda = \varepsilon_\lambda [ST{\cdot}L]_{eq} \qquad (3\text{–}290)$$

where ε_λ is the extinction coefficient of the complex at the wavelength chosen to monitor its formation, which in the case of *N*-methylnicotinamide binding to lysozyme was 350 nm. When Equation 3–290 is combined with Equation 3–282

$$\frac{A_\lambda}{C_{prot}} = \frac{\varepsilon_\lambda \kappa [L]_{eq}}{K_{dL} + [L]_{eq}} \qquad (3\text{–}291)$$

which defines a rectangular hyperbola. In the case of *N*-methylnicotinamide (NMN) binding to lysozyme, when C_{prot} is expressed in molarity, $[lysozyme]_t$

$$\frac{A_{350}}{[lysozyme]_t} = \frac{\varepsilon_{350}\, \kappa\, [NMN]_{eq}}{K_{dNMN} + [NMN]_{eq}} \qquad (3\text{–}292)$$

A plot (Figure 3–20)[195] of $A_{350}\,[lysozyme]_t^{-1}$ (y) as a function of $[NMN]_{eq}$ (x) is a rectangular hyperbola (Equation 3–52) with a equal to $\varepsilon_{350}\kappa$ and b equal to K_{dNMN}. If it is assumed that there is one site on each molecule of lysozyme, then κ is 1 and the horizontal asymptote a is the extinction coefficient, ε_{350}, for the complex, which in the case of the complex between *N*-methylnicotinamide and lysozyme is $1040 \pm 12\ M^{-1}$, and the dissociation constant for *N*-methylnicotinamide from lysozyme is 304 ± 9 mM.

The example just described, in which neither the protein nor the ligand itself absorbs nor fluoresces at the wavelength at which the complex absorbs or fluoresces, is rarely encountered. Usually, either the protein or the ligand, or both, absorbs or fluoresces over the entire range of wavelengths in which significant changes in absorption or fluorescence occur, and a **difference in absorption or fluorescence upon formation of the complex** is monitored. For example, when a series of solutions of various concentrations of the inhibitor D-malate between 1 and 50 mM was prepared, each with the same concentration (75 μM) of protomers of aspartate carbamoyltransferase (Equation 3–220), the absorbance of the solution at 290 nm increased as the concentration of D-malate increased.[178] Since D-malate is transparent at 290 nm, the absorbance of one or more tryptophans in the protomer of aspartate carbamoyltransferase is increasing. From this increase in the absorbance of the solution, the dissociation constant for D-malate can be determined.

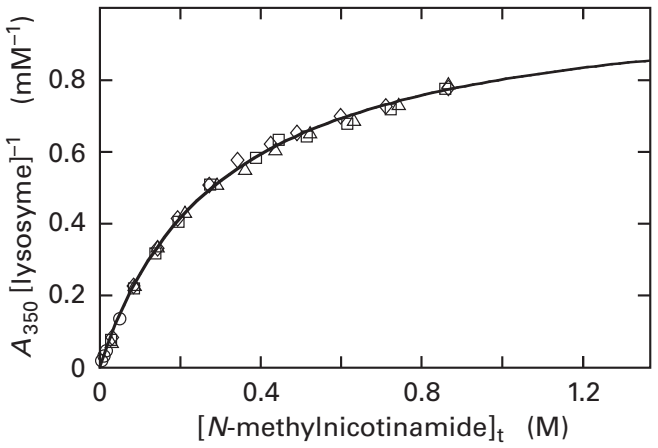

Figure 3–20: Binding of *N*-methylnicotinamide to lysozyme,[195] followed by the increase in absorbance of the solution at 350 nm. Crystalline lysozyme was dissolved at pH 5 and 22 °C to a final concentration of 10.0 mg mL^{-1} in a volume of 2.00 mL, which was assumed to be a concentration of 0.35 mM. Successive additions of solid *N*-methylnicotinamide (final concentrations between 5 and 890 mM) were made. After each addition, the absorbance of the solution at 350 nm was measured in a spectrophotometer, and the new concentration of protein resulting from the dilution caused by adding the solid was calculated. Because the concentration of *N*-methylnicotinamide was always in significant excess over the molar concentration of protein (8-fold to 1500-fold), it can be assumed that the total concentration of *N*-methylnicotinamide (molar) was equal to its free concentration. The quotient A_{350} [lysozyme]$_t^{-1}$ (millimolar^{-1}) is presented as a function of the concentration of *N*-methylnicotinamide. The different symbols refer to statistically independent measurements. The curve is the fit of Equation 3–52 to all the points with y equal to A_{350} [lysozyme]$_t^{-1}$ and x equal to [*N*-methylnicotinamide]$_t$. The dissociation constant for *N*-methylnicotinamide from lysozyme (parameter b) is 304 ± 9 mM, and the molar extinction coefficient (parameter a) is 1044 ± 12 M^{-1}.

For the dissociation of a ligand from a site on the protomer of a protein, Equation 3–280 usually applies and a **quantity *Y*, the fraction of the sites in the solution that are occupied by ligand**, can be defined

$$Y \equiv \frac{[\mathrm{ST{\cdot}L}]_{eq}}{[\mathrm{ST}]_t} = \frac{[\mathrm{L}]_{eq}}{K_{dL} + [\mathrm{L}]_{eq}} \qquad (3\text{–}293)$$

If the absorbance of the protein changes as a ligand that is transparent at the wavelength monitored associates with it, then

$$A_{obs} = \varepsilon_{uo}[\mathrm{ST}]_t(1 - Y) + \varepsilon_{occ}[\mathrm{ST}]_t Y \qquad (3\text{–}294)$$

where A_{obs} is the observed absorbance of a solution of the protein at a particular free concentration of ligand, ε_{uo} is the extinction coefficient of the protomers unoccupied by ligand, and ε_{occ} is the extinction coefficient of protomers occupied by ligand. The absorbance of a solution of the same concentration of protein in the absence of ligand

$$A_{uo} = \varepsilon_{uo}[\mathrm{ST}]_t \qquad (3\text{–}295)$$

and the absorbance of a solution of the same concentration of protein at saturating concentrations of ligand

$$A_{sat} = \varepsilon_{occ}[\mathrm{ST}]_t \qquad (3\text{–}296)$$

From Equations 3–293 through 3–296 it follows that

$$Y = \frac{A_{obs} - A_{uo}}{A_{sat} - A_{uo}} = \frac{\Delta A}{\Delta A_t} = \frac{[\mathrm{L}]_{eq}}{K_{dL} + [\mathrm{L}]_{eq}} \qquad (3\text{–}297)$$

and

$$\Delta A = \frac{\Delta A_t [\mathrm{L}]_{eq}}{K_{dL} + [\mathrm{L}]_{eq}} \qquad (3\text{–}298)$$

Consequently if the quantity ΔA (y) is plotted as a function of $[\mathrm{L}]_{eq}$ (x), the data should describe a rectangular hyperbola (Equation 3–52) with $a = \Delta A_t$ and $b = K_{dL}$. For the binding of D-malate to aspartate carbamoyltransferase, such hyperbolic behavior was observed for the increase in absorbance with a dissociation constant of 4.9 ± 0.2 mM.[178]

If the protein contains a **prosthetic group**, which will usually be within its active site, and that prosthetic group absorbs light of a particular wavelength, that absorption will often change upon the association of a ligand. For example, the absorbance of the heme in a mutant of unspecific monooxygenase BM3 from *B. megaterium* in which Phenylalanine 87 has been replaced with tyrosine shifts from a maximum at 419 nm to a maximum at 424 nm when the inhibitor 10-(imidazolyl)decanoate associates with the enzyme. This shift produces a characteristic difference spectrum (Figure 3–21A).[101] The greatest difference in absorbance between the active site occupied by 10-(imidazolyl)decanoate and the unoccupied active site is the difference in absorbance between that at 433 nm and that at 410 nm.

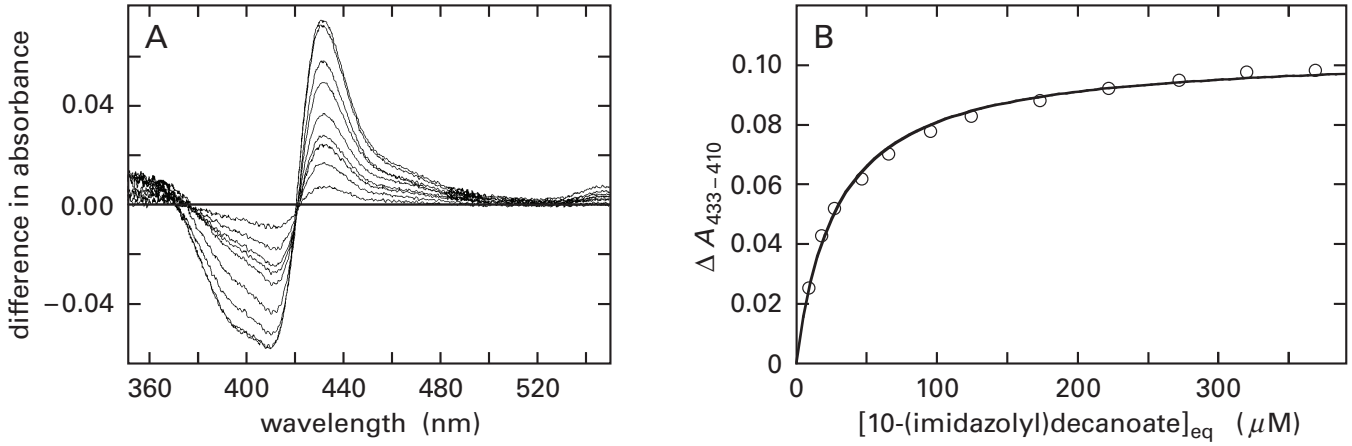

Figure 3–21: Binding of 10-(imidazolyl)decanoate to unspecific monooxygenase BM3 from *B. megaterium*, followed by the difference between absorbance of its heme at 433 nm and at 410 nm.[101] **(A)** Difference spectra resulting from addition of the ligand to the enzyme. A solution of the purified enzyme (5 μM) was prepared in 100 mM KCl and 20 mM 3-(*N*-morpholino)-propanesulfonic acid at pH 7.4. The absorption spectrum of this solution served as the reference spectrum for all difference spectra. Small amounts of a concentrated solution of 10-(imidazolyl)decanoic acid in dimethyl sulfoxide/methanol (1:1 v/v) were added to the solution of enzyme, and the reference spectrum was subtracted from the spectrum observed after the addition of the ligand. The final total concentrations of 10-(imidazolyl)decanoate for the difference spectra were 9.1, 18.3, 27.4, 36.5, 45.6, 63.8, 82.0, 119, and 228 μM, in order of increasing magnitude of difference. Notice that as the absorbance at 433 nm increases, the absorbance at 410 nm decreases, reflecting the shift in wavelength of maximum absorption from 419 to 424 nm. **(B)** Binding of 10-(imidazolyl)decanoate to a mutant of unspecific monooxygenase BM3 from *B. megaterium* in which Phenylalanine 87 has been replaced by a tyrosine. A solution of the mutant enzyme at a concentration of 3.1 μM in 100 mM KCl and 20 mM 3-(*N*-morpholino)propanesulfonic acid at pH 7.4 was titrated with increasing concentrations of 10-(imidazolyl)decanoate. The difference in absorbance between that at 433 nm and that at 410 nm ($\Delta A_{433-410}$) is plotted as a function of the equilibrium concentration of 10-(imidazolyl)-decanoate (micromolar). The differences in absorbance have been corrected for the effects of dilution on the spectra, and the total concentrations of 10-(imidazolyl)decanoate have been corrected for the amount of 10-(imidazolyl)decanoate bound to the enzyme. For this correction, it was assumed that one mole of enzyme binds one mole of ligand at saturation and that the observed difference in absorbance divided by the difference in absorbance at saturation is equal to the fraction of the sites that are occupied (Equation 3–297). The data were fitted with Equation 3–52 with y equal to $\Delta A_{433-410}$ and x equal to $[10\text{-(imidazolyl)decanoate}]_{eq}$. Parameter b is the dissociation constant for 10-(imidazolyl)decanoate from the enzyme, 29.2 ± 1.5 μM, and parameter a is the difference in absorbance at saturation, 0.104 ± 0.001. Adapted with permission from reference 101. Copyright 1998 American Chemical Society. https://doi.org/10.1021/bi980462d

Because the absorbance A_λ at every wavelength conforms to Equations 3–295 and 3–296, the **difference in absorbance between two wavelengths** $\Delta A_{\lambda_1-\lambda_2}$ must also conform to Equations 3–295 and 3–296, and consequently to Equations 3–297 and 3–298

$$\Delta A_{\lambda_1-\lambda_2} = \frac{\Delta A_{\lambda_1-\lambda_2,t}[L]_{eq}}{K_{dL} + [L]_{eq}} \qquad (3\text{–}299)$$

where $\Delta A_{\lambda_1-\lambda_2,t}$ is the difference in absorbance between the two wavelengths at saturating concentrations of ligand. In the case of the binding of 10-(imidazolyl)decanoate to the mutant of unspecific monooxygenase, the difference in absorbance between that at 433 nm and that at 410 nm, $\Delta A_{433-410}$, describes a rectangular hyperbola with parameter b (Equation 3–52) equal to the dissociation constant for 10-(imidazolyl)decanoate, $K_{d10D} = 29.2 \pm 1.5$ μM (Figure 3–21B).

In this instance, unlike the observations with aspartate carbamoyltransferase, the total concentrations of 10-(imidazolyl)decanoate used in the titration are only about 10-fold greater than the concentrations of occupied sites at the lower concentrations of ligand, and each total concentration of 10-(imidazolyl)decanoate had to be **corrected for the concentration of bound ligand** (Equation 3–283), on the assumption that there is only one site for ligand on each protomer, to give the equilibrium concentration of free ligand at each total concentration of ligand.

The same type of analysis can be performed upon a **change in the fluorescence of a protein**. For example, when 6-phosphofructokinase

$$\text{D-fructose 6-phosphate} + \text{MgATP}^{2-} \rightleftharpoons \text{H}^+ + \text{MgADP}^- + \text{D-fructose 1,6-bisphosphate} \quad (3\text{–}300)$$

from *E. coli* binds its substrate D-fructose 6-phosphate, the intrinsic fluorescence of its tryptophans decreases; and when it binds its substrate $MgATP^{2-}$, the intrinsic fluorescence of its tryptophans increases. Both the decrease in fluorescence and the increase in fluorescence are rectangularly hyperbolic functions of the free concentrations of the respective ligands with dissociation constants of 7 μM and 25 nM, respectively.[183] It is also possible to modify a protein with a fluorescent reagent to increase its fluorescence and use changes in the fluorescence of the inserted fluorophore to determine a dissociation constant.[185]

In Equation 3–279, the molar concentration of sites and the molar concentration of ligand are formally equivalent. Consequently, in the analogous arrangement to that producing Equation 3–280, the concentration of the complex between ligand and site at equilibrium

$$[\text{ST}\cdot\text{L}]_{eq} = \frac{[\text{L}]_t[\text{ST}]_{eq}}{K_{dL} + [\text{ST}]_{eq}} \quad (3\text{–}301)$$

A quantity Y_{lig}, the **fraction of the molecules of ligand in the solution that are occupied by sites**, can be defined

$$Y_{lig} \equiv \frac{[\text{ST}\cdot\text{L}]_{eq}}{[\text{L}]_t} = \frac{[\text{ST}]_{eq}}{K_{dL} + [\text{ST}]_{eq}} \quad (3\text{–}302)$$

Assume that the fluorescence of a protein is not elicited by a wavelength used to produce the fluorescence of a ligand. If the fluorescence of the ligand changes when a site on the protein associates with it, then in a derivation analogous to that for Equation 3–297

$$Y_{lig} = \frac{F_{obs} - F_{uo}}{F_{sat} - F_{uo}} = \frac{\Delta F}{\Delta F_t} = \frac{[\text{ST}]_{eq}}{K_{dL} + [\text{ST}]_{eq}} \quad (3\text{–}303)$$

where F_{obs} is the observed fluorescence of a solution of the ligand at a particular free concentration of sites, F_{uo} is the fluorescence of a solution of the same concentration of ligand in the absence of sites, ΔF is the difference between the two, F_{sat} is the fluorescence of a solution of the same concentration of ligand at a saturating concentration of sites, and ΔF_t is the total change in fluorescence observed when the concentration of ligand is at saturation. It follows that

$$\Delta F = \frac{\Delta F_t[\text{ST}]_{eq}}{K_{dL} + [\text{ST}]_{eq}} \quad (3\text{–}304)$$

and that when ΔF is plotted as a function of the free concentration of empty sites at equilibrium, the data should define a rectangular hyperbola. For example, a series of solutions, each with the same concentration (0.5 μM) of the peptide SIESDV, the amino terminus of which had been modified by a fluorescent 5-(dimethylamino)naphthalene-1-sulfonyl group, was prepared containing increasing concentrations of the PDZ domain from murine α-1-syntrophin (1–40 μM). As the concentration of the PDZ domain increased, the increase in the fluorescence of the solution was a hyperbolic function of the free concentration of PDZ domain, $[\text{ST}]_{eq}$, from which a dissociation constant of 1.93 ± 0.04 μM could be calculated (Figure 3–22).[188] Again, the concentration of sites has been corrected for the small concentration of sites that are occupied at each concentration of ligand to obtain the much larger values for the concentration of sites unoccupied by ligand.

In practice, however, these two formally equivalent participants, **site and ligand, are not actually equivalent**. It is often difficult if not impossible to ascertain the molar concentration of active, functional protomers but relatively easy to determine the concentration of ligand. It is often difficult or expensive to prepare solutions of protomers at molar concentrations in the range of the dissociation constant, an ability that is required to produce the hyperbolic curves necessary to assess the dissociation constant. Consequently, **the concentration of sites is usually held constant** at a level below the dissociation constant and the concentration of ligand that is varied in the range of the dissociation constant. This common practice is only for economy, not because the ligand and the site are not formally equivalent participants in the association.

As has been already mentioned, there are several **physical properties other than absorbance and fluorescence** that can monitor the formation of a complex between a ligand and a site on a protein.

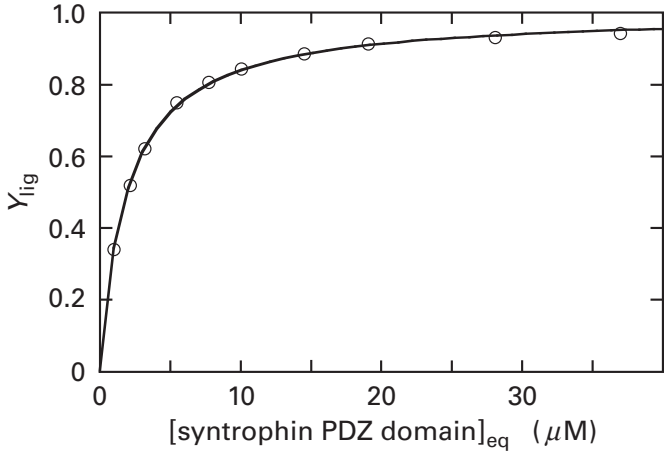

Figure 3–22: Binding of the PDZ domain (amino acids 77 through 171) of murine α-1-syntrophin to the fluorescently labeled hexapeptide *N*-[5-(dimethylamino)naphthalene-1-sulfonyl]serylisoleucylglutamylserylaspartylvaline (dansyl-SIESDV), followed by the change in fluorescence upon the association.[188] To a solution containing 0.5 μM dansyl-SIESDV (1.25 mL) in a continuously stirred cuvette in a fluorometer, small samples (2–5 μL) of a concentrated solution of the PDZ domain were added. After each addition, the fluorescence (excitation at 330 nm; emission at 540 nm) was monitored. The measured values of the fluorescence were corrected for any dilution that occurred upon addition of the concentrated solution, and the total concentrations of PDZ domain in the final solution were corrected by subtracting the concentration of bound PDZ domain to obtain the free concentration at equilibrium, [syntrophin PDZ domain]$_{eq}$. The concentration of bound PDZ domain was assumed to be equal to the fraction of dansyl-SIESDV bound, Y_{lig}, at each total concentration (Equation 3–303) times the concentration of dansyl-SIESDV (0.5 μM). The data were fitted with Equation 3–52 with y equal to $F_{obs} - F_{uo}$ and x equal to [syntrophin PDZ domain]$_{eq}$ (a rearranged form of Equation 3–303). Parameter a is $F_{sat} - F_{uo}$, and parameter b is K_{dPDZ} (1.93 ± 0.04 μM). By using the value of F_{sat} obtained from this fit, the fractional saturation, Y_{lig}, could be calculated (Equation 3–303). The fractional saturation (unitless) is presented as a function of the free concentration of PDZ domain at equilibrium ([syntrophin PDZ domain]$_{eq}$ in micromolar).

The increase or decrease in the fluorescence of a ligand or a protein observed when a complex forms is often accompanied by a change in the lifetime of the fluorescence, and the fraction of the fluorophore displaying the free lifetime and the fraction of the fluorophore displaying the bound lifetime can often be resolved so that Y or Y_{lig} can be measured directly.[183] When a large rotationally immobile molecule of protein, such as bovine pancreatic ribonuclease, associates with a small rotationally mobile ligand, such as the tetranucleotide dAdUdAdA that has been modified with fluorescein, the rotational mobility of the ligand bound to the active site decreases dramatically and the anisotropy of its fluorescence increases.[191] The chemical shift of a nucleus in a ligand in a nuclear magnetic resonance spectrum, such as the phosphorus-31 in [4-^{31}P]phosphatidylinositol 4,5-bisphosphate, can change upon association with a protein, such as a pleckstrin homology domain.[192] When a protein, such as gentamicin 2″-nucleotidyltransferase from *P. aeruginosa*, associates with a ligand, such as tobramycin, heat is either emitted or absorbed, and that heat can be measured in a microcalorimeter.[193]

Each of these latter changes—the increase in anisotropy, the change in chemical shift, or the emission or absorption of heat—is **directly proportional to the concentration of the complex** that is formed, and the same strategies and equations (Equations 3–297 and 3–303) can be used to evaluate the data, with the respective physical property, be it anisotropy, chemical shift, or heat emitted or absorbed, in place of absorbance or fluorescence. When the dissociation constant for binding of the inhibitor *N*-(phosphonomethyl)glycine to the complex ren shikimate 3-phosphate and 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli* was determined by following the heat emitted upon formation of the ternary complex, its value (0.15 ± 0.03 μM) agreed closely with its dissociation constant obtained by following changes in fluorescence (0.16 ± 0.02 μM) and its inhibition constant (0.16 μM) for the enzymatic reaction.[168]

In the measurements described so far, the concentration of the component that displays the physical property that changes during formation of the complex was held constant—for example, the concentration of aspartate carbamoyltransferase—and the concentration of the component that does not display that behavior was varied—for example, the concentration of D-malate. The latter concentration, however, can also be held constant and the former varied. For the moment, the physical property used in the following discussion will be fluorescence, but the equations and the conclusions are the same for any physical property.

The coenzyme NADPH displays fluorescence at 450 nm when it is excited by light at a wavelength of 290 nm. Its fluorescence is enhanced about 25-fold when it is bound at the active site of homoserine dehydrogenase from *E. coli*. The effect of an enhancement or diminution in fluorescence when a ligand associates with a protein—for example, in the case of homoserine dehydrogenase, the enhancement of the fluorescence of NADPH—can

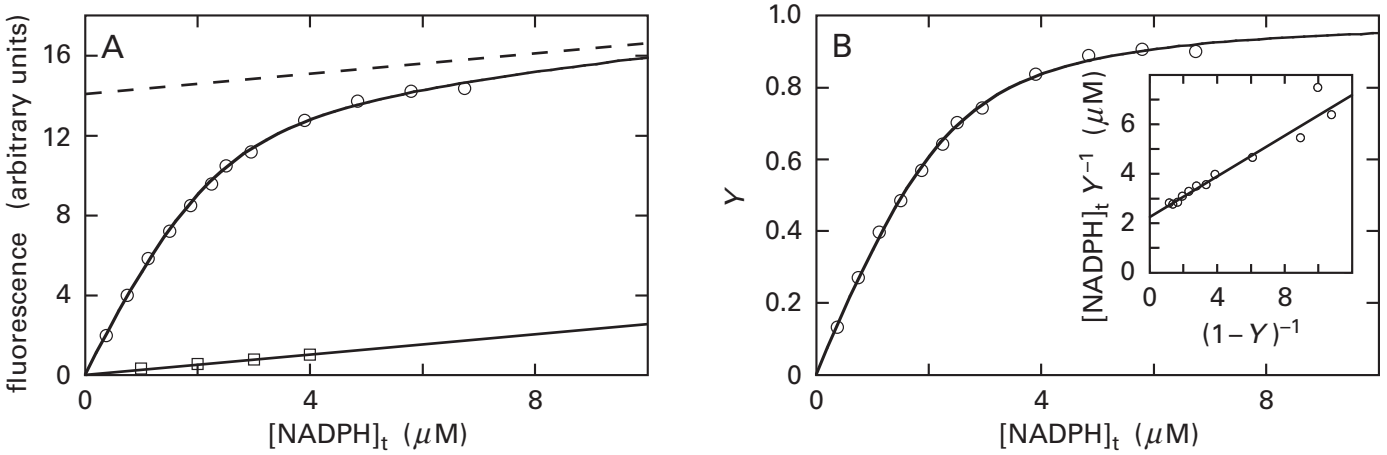

Figure 3–23: Binding of NADPH to homoserine dehydrogenase from *E. coli*, followed by the enhancement of the fluorescence of NADPH.[186] To a cuvette containing either a solution of 0.25 mg mL^{-1} homoserine dehydrogenase (HS) or buffer alone, successive additions of concentrated solutions of NADPH were made to produce the noted final, total concentrations of ligand. Between each addition, the fluorescence of the solution was determined ($\lambda_{excitation}$ = 285 nm; $\lambda_{emission}$ = 350 nm). **(A)** Fluorescence (in arbitrary units) as a function of the total concentration of NADPH (micromolar). Data for the fluorescence in the absence of enzyme (□) as a function of [NADPH]$_t$ were fitted with a line of direct proportionality to obtain a value for the constant of proportionality α (0.262 ± 0.006 μM^{-1}). Data for the fluorescence in the presence of enzyme (○) were then fitted with Equation 3–322, in which y is F_{obs}, x is [L]$_t$, parameter a is K_{dNADPH} (0.41 ± 0.08 μM), parameter b is [HS]$_t$ (2.2 ± 0.1 μM), and parameter c is the constant of proportionality, β (6.5 ± 0.4 μM^{-1}). The fit of Equation 3–322 to the data was then used to calculate the horizontal asymptote for the function (dashed line). **(B)** Fractional saturation of sites for NADPH on homoserine dehydrogenase, Y, as a function of the total concentration of NADPH (micromolar). Values for the constants of proportionality, α (0.262 μM^{-1}) and β (6.5 μM^{-1}), and the total molar concentration of sites, [HS]$_t$ (2.2 μM), were used in Equation 3–309 to convert each value for F_{obs} to the respective fractional saturation (Y, which is dimensionless). The curve drawn is that defined by Equation 3–322 into which were inserted the values for K_{dNADPH} (0.41 μM) and [HS]$_t$ (2.2 μM) obtained in the fit to the data in Panel A. (Inset to Panel B) The variable [NADPH]$_t$ Y^{-1}, where [NADPH]$_t$ is the total concentration of the ligand (in micromolar), is presented as a function of the dimensionless quantity $(1 - Y)^{-1}$. The line drawn is that for Equation 3–323 with the value of the dissociation constant K_{dNADPH} (0.41 μM) obtained from the fit in Panel A for its slope and the molar concentration of sites, [HS]$_t$ (2.2 μM), obtained from the fit in Panel A for its intercept with the axis of the ordinate.

be monitored. The values for the fluorescence are measured for a series of solutions in which **the total concentration of the participant in the complex that is responsible for the fluorescence is increased in increments**—for example, in the case of homoserine dehydrogenase when the total concentration of NADPH is increased incrementally at a fixed concentration of sites (Figure 3–23A).[186]

In the absence of sites, the fluorescence of the solution increases in direct proportion to the concentration of the fluorescent ligand, as in the case of NADPH (lower line in Figure 3–23A) as well as most fluorophores at low concentration, and the fluorescence observed, F_{free}, is due entirely to free ligand, unbound to any sites because there are no sites present in the solution. In this situation,

$$F_{free} = \xi_f [L]_t \qquad (3–305)$$

where ξ_f is a constant of proportionality for the free ligand. If, however, a fixed concentration of sites—for example, active sites on homoserine dehydrogenase that associate with NADPH—is present in the solution, then the fluorescence increases either less steeply or more steeply when increments of the ligand are added—as when NADPH is added to the solution containing homoserine dehydrogenase. The change in the incremental increase occurs because the fluorescence, F_{bound}, of the complex between ligand and protein, ST·L, is either less than or greater than, respectively, that of free ligand. The fluorescence of the bound fluorophore

$$F_{bound} = \xi_b [ST·L]_{eq} \qquad (3–306)$$

where ξ_b is also a constant of proportionality. The association of the ligand with the site either **enhances** its fluorescence ($\xi_b > \xi_f$) or **quenches** its fluorescence ($\xi_b < \xi_f$).

If [L]$_t$ is the total concentration of ligand, both bound and free, for each experimental point, and Y is, as before, defined as the fraction of the sites

occupied (Equation 3–293), then the fluorescence observed, F_{obs}, at any total concentration of ligand, $[L]_t$, will be

$$F_{obs} = F_{free} + F_{bound} \tag{3–307}$$

and

$$F_{obs} = \xi_f([L]_t - [ST]_t Y) + \xi_b [ST]_t Y \tag{3–308}$$

After rearrangement

$$Y = \frac{F_{obs} - \xi_f [L]_t}{(\xi_b - \xi_f)[ST]_t} \tag{3–309}$$

At saturation ($Y = 1$)

$$F_{obs} = \xi_f [L]_t + (\xi_b - \xi_f)[ST]_t \tag{3–310}$$

This equation defines the asymptote (dashed line in Figure 3–23A) of the curve observed in the presence of sites. This **asymptote** will be a line the slope of which is the same as the slope of the line in the absence of protein (ξ_f) and the intercept of which at the axis of the ordinate will be $(\xi_b - \xi_f)[ST]_t$. In the case of association of NADPH with homoserine dehydrogenase (HD), the intercept of the asymptote with the axis of the ordinate has a positive value. If association of the ligand with the protein quenches the fluorescence of the ligand, the intercept of the asymptote with the axis of the ordinate is at a negative value. By using the value for $(\xi_b - \xi_f)[HD]_t$ determined from this intercept and the value for ξ_f obtained from the slopes of both the asymptote and the linear increase in fluorescence in the absence of sites, values of Y can be obtained for each value of $[NADPH]_t$ (Equation 3–309) and can be plotted as a function of $[NADPH]_t$ (Figure 3–23B).

This approach is a general one for any physical property the magnitude of which is directly proportional to the concentration of ligand free in solution and also directly proportional to the concentration of ligand bound to sites and has significantly different constants of proportionality for free ligand (ξ_f) and bound ligand (ξ_b), respectively. The value for ξ_b can be greater than the value for ξ_f or it can be smaller; these two constants of proportionality just must differ enough to observe statistically significant differences between measurements in the presence of protein and measurements in its absence.

The values of Y obtained in the particular measurements just described for homoserine dehydrogenase and NADPH do not describe a rectangular hyperbola, although they seem to do so (Figure 3–23B). To understand why they do not, one must examine the behavior of Y as a function of the total concentration of sites

$$[ST]_t = [ST]_{eq} + [ST{\cdot}L]_{eq} \tag{3–311}$$

and the total concentration of ligand

$$[L]_t = [L]_{eq} + [ST{\cdot}L]_{eq} \tag{3–312}$$

There are three regimes in which the binding of a ligand can be quantified by monitoring a physical property. These three regimes can be understood by examining three quadratic equations.

To understand the **first regime**, Equations 3–279, 3–311, and 3–312 can be combined and rearranged to give the quadratic equation*

$$K_{dL}[L]_t - (K_{dL} + [ST]_t - [L]_t)[L]_{eq} - [L]_{eq}^2 = 0 \tag{3–313}$$

When measurements are made in the first regime, **either the fixed concentration of sites or the fixed concentration of ligand in the samples is purposely set at a value that is much lower than the dissociation constant**. If, for example, $[ST]_t << K_{dL}$ and the concentration of ligand is in the range of the dissociation constant, then because $[ST]_t << [L]_t$, Equation 3–313 can be factored

$$(K_{dL} + [L]_{eq})([L]_t - [L]_{eq}) \cong 0 \tag{3–314}$$

and

$$[L]_{eq} \cong [L]_t \tag{3–315}$$

This approach is the one that was chosen for measurements of the dissociation constant for *N*-methylnicotinamide from lysozyme (Figure 3–20; $[ST]_t$ = 0.35 mM, K_d = 300 mM) and for the dissociation constant for D-malate from aspartate carbamoyltrans-

*It should be noted in passing that this quadratic equation, because it can be solved for the free concentration of ligand, as opposed to the total concentration, if K_{dL} is known, is useful in its own right.[155]

ferase ($[ST]_t = 75\ \mu M$, $K_{d,mal} = 4900\ \mu M$). In the first regime, only the dissociation constant for the ligand can be ascertained.

If the concentration of sites is too close to the dissociation constant, then the concentration of free ligand $[L]_{eq}$ will not be approximately equal to the total molar concentration of ligand $[L]_t$, and the molar concentration of sites in which ligand is bound, $[ST{\cdot}L]_{eq}$, if at all possible, must be deducted from the total concentration of ligand originally added to the solution, $[L]_t$, to obtain the free concentration of ligand. In the case of the dissociation constant for 10-(imidazolyl)decanoate from unspecific monooxygenase (Figure 3–21B; $[ST]_t = 3\ \mu M$, $K_{dL} = 29\ \mu M$), which approaches the upper boundary of the first regime, the total concentrations of ligand could be **corrected for the amounts bound** to obtain the free concentration of ligand plotted in the graph. It should always be remembered that the concentration of ligand, $[L]_{eq}$, and the concentration of sites, $[ST]_{eq}$, in all the equations are the free concentrations, respectively, which are often unknown, not the total concentrations, which are usually known.

Because $[ST]_{eq}$ and $[L]_{eq}$ are mathematically equivalent in Equation 3–279, **the quadratic equation equivalent to Equation 3–313 can be derived for $[ST]_{eq}$**, and when the concentration of ligand is held constant at levels well below the dissociation constant ($[L]_t < K_{dL}$) and the concentration of sites is varied in the range of the dissociation constant, the concentration of total sites will be close to the concentration of free sites ($[ST]_t \cong [ST]_{eq}$) because $[L]_t < [ST]_t$. For titration of the fluorescently modified peptide SIESDV with the PDZ domain from murine α-1-syntrophin (Figure 3–22),[188] the concentration of ligand chosen, $0.5\ \mu M$, was significantly less than the dissociation constant, $1.9\ \mu M$. Nevertheless, the fixed concentration of the ligand was close enough to the dissociation constant that the free concentrations of the PDZ domain from murine α-1-syntrophin unoccupied by the peptide were ascertained by subtracting from the total concentration of sites the concentration of PDZ domain from murine α-1-syntrophin that was occupied by the fluorescent peptide. In this instance, the correction was easily done because the total concentration of ligand was known.

In this first regime, when a dissociation constant is measured by following a change in a physical property, **no independent estimate of the total concentration of sites** can be made from the results.

To understand the **second regime**, Equations 3–279, 3–311, and 3–312 can be combined and rearranged to give the quadratic equation

$$[ST]_t[L]_t - \left(K_{dL} + [ST]_t + [L]_t\right)[ST{\cdot}L]_{eq} + [ST{\cdot}L]_{eq}^{\,2} = 0 \qquad (3\text{–}316)$$

When measurements are made in the second regime, **the total concentration of sites and the total concentration of ligand are purposely set at values that are much higher than the dissociation constant**. Under these circumstances, because K_{dL} is much less than either concentration, Equation 3–316 can be factored

$$\left([ST]_t - [ST{\cdot}L]_{eq}\right)\left([L]_t - [ST{\cdot}L]_{eq}\right) \cong 0 \qquad (3\text{–}317)$$

Either the total concentration of ligand or the total concentration of sites is varied while the total concentration of the other is held constant. If the total concentration of ligand is varied, when $[ST{\cdot}L]_{eq} < [ST]_t$

$$[ST{\cdot}L]_{eq} \cong [L]_t \qquad (3\text{–}318)$$

Each mole of ligand added to the solution will be bound stoichiometrically by a site until all the sites are occupied. Beyond saturation, where $[ST{\cdot}L]_{eq} = [ST]_t$, further addition of ligand will simply be equivalent to the addition of ligand to a solution lacking the protein. In the second regime, a plot of the physical property responding to the binding of the ligand as a function of the total concentration of ligand provides an **estimate of the total concentration of sites** in the solution.

When either NADH or NADPH binds to bovine glutamate dehydrogenase [NAD(P)$^+$]

$$\text{L-glutamate} + H_2O + NAD(P)^+ \rightleftharpoons H^+ + \text{2-oxoglutarate} + NH_4^+ + NAD(P)H \qquad (3\text{–}319)$$

in the absence of 2-oxoglutarate and NH_4^+, the absorbance of the respective nucleotide at 320 nm decreases by about 25%. If the concentration of enzyme is fixed at $5.3\ mg\ mL^{-1}$ and increasing concentrations of either NADH or NADPH are added, the rate of increase in the absorbance of the solution is significantly lower than the rate of increase when

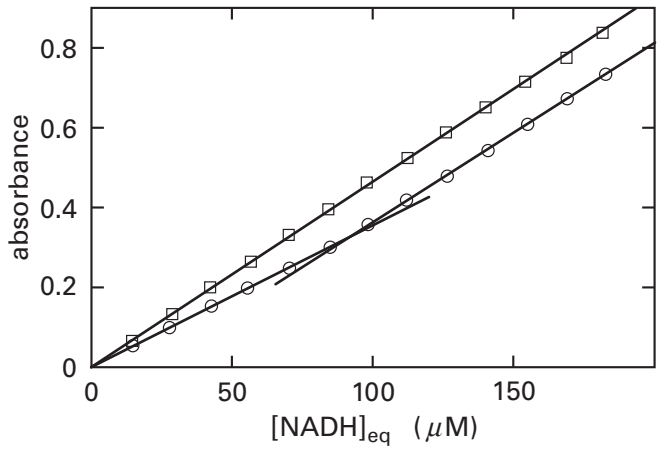

Figure 3–24: Spectrophotometric titration[181] of the sites on bovine glutamate dehydrogenase [NAD(P)+] for the binding of NADH. Crystalline glutamate dehydrogenase [NAD(P)+] was dissolved in a solution (3.00 mL) of 0.17 M glutamate at pH 7.0. The final concentration of enzyme in each solution was 5.30 mg of protein mL^{-1} based on an extinction coefficient determined by dry weight analysis. Successive additions (5 μL) of a standard solution of NADH were made to the solution to establish the noted final concentrations. An otherwise identical 3.00 mL solution of 0.17 M L-glutamate at pH 7.0, to which no enzyme had been added, served as the control. The same successive additions (5 μL) of NADH were made to the control. After each successive addition, the absorbance of each solution was measured. The absorbances of the several solutions (dimensionless) are presented as a function of the final equilibrium concentrations of NADH (micromolar). The intersection of the two lines is at 92 μM NADH, which gives a value of 57.5 mg of protein (μmol of sites)$^{-1}$. There are 55.726 mg of bovine glutamate dehydrogenase [NAD(P)+] for every micromole of active sites.

the enzyme is not present; but, beyond a concentration of ligand equal to that of the concentration of sites, the rate of increase in absorbance discontinuously assumes the value observed in the absence of enzyme (Figure 3–24).[181] At the point of inflection, the total concentration of ligand must equal the total concentration of sites. The concentration of sites in the 5.3 mg mL^{-1} solutions of glutamate dehydrogenase [NAD(P)+] was estimated in this way to be 93 μM; and consequently, there is one mole of sites for binding NADH or NADPH for every 57,000 g of protein. The molar mass of a protomer of bovine glutamate dehydrogenase [NAD(P)+] is 55,726 g. This exact molar mass was not known at the time the measurements were made, but if it had been, these results would have demonstrated that the number of active sites was equal to the number of protomers and that the preparation of the enzyme was 98% pure and active.

An experiment of this type is a **spectrophotometric titration** of the concentration of sites for binding of the ligand.[184] Properly, such a determination should be made at several different concentrations of protein because, as the concentration of protein is increased, the point of inflection must shift proportionally to the right if the total concentration of sites is actually greater than the dissociation constant. This shift should be demonstrated directly. Again, the same type of measurement can be performed by fixing the concentration of ligand at a level much greater than the dissociation constant and varying the concentration of protein.

The concentration of sites in a solution can also be determined by a kinetic titration performed in this second regime. A **kinetic titration** is a titration of the sites for an activator, substrate, or inhibitor of an enzyme that is followed by its effect on the kinetics of the enzymatic reaction. For example, when in the second regime, an inhibitor of the enzymatic activity that has a small enough dissociation constant is stoichiometrically bound by the enzyme if both the concentration of sites and the concentration of inhibitor are in excess of the dissociation constant for the inhibitor from the site. In this situation, the decreases in initial rate of the enzymatic reaction observed at several different concentrations of the inhibitor are directly proportional to the concentration of bound inhibitor, which is equal to the known total concentration of the inhibitor.[196] The molar concentration of inhibitor required to inhibit the enzyme completely is equal to the molar concentration of sites for the inhibitor. When the concentration of enzyme needed to exceed the dissociation constant of a ligand is so high that it is greater than that at which initial rates can be measured, a single turnover of the enzyme can often be followed. For example, the ligand can be a tightly bound substrate for the enzyme. A kinetic titration performed by increasing the concentration of the enzyme and following the increase in the initial rate of single turnovers can be used to estimate the molar concentration of sites for the substrate in a solution of the enzyme.[197] When the unknown concentration of active sites equals the known concentration of substrate, the rate of single turnovers no longer increases but discontinuously levels out.

In this second regime, when the concentration of sites is measured by following a change in a physical property or the kinetics of the enzymatic reaction, **no estimate of the dissociation constant can be made**.

To understand the **third regime**, Equations 3–279, 3–293, 3–311, and 3–312 can be combined and rearranged to give the quadratic equation

$$[ST]_t Y^2 - \left(K_{dL} + [ST]_t + [L]_t\right)Y + [L]_t = 0 \quad (3\text{–}320)$$

The relevant of the two roots of this quadratic equation is the one in which

$$Y = \frac{K_{dL} + [ST]_t + [L]_t - \sqrt{\left(K_{dL} + [ST]_t + [L]_t\right)^2 - 4[ST]_t[L]_t}}{2[ST]_t} \quad (3\text{–}321)$$

When measurements are made in the third regime, **the concentration of sites is purposely set at a value that is in the same range as the dissociation constant**, $[ST]_t \cong K_{dL}$. Under these circumstances, Y, the fraction of sites occupied by ligand L, is a function of the total concentration of ligand $[L]_t$, the dissociation constant K_{dL}, and the total concentration of sites $[ST]_t$ (Equation 3–321). As a result, in this range, both the total concentration of sites and the dissociation constant become parameters of the measurement.

For example, if fluorescence is being monitored, Equations 3–309 and 3–321 can be combined and

$$y = \left\{\frac{a + b + x - \sqrt{(a + b + x)^2 - 4bx}}{2}\right\}(c - \xi_f) + \xi_f x \quad (3\text{–}322)$$

where y is F_{obs} and x is $[L]_t$ and the parameters of the fit are a, b, and c. The value for ξ_f is known from the behavior of fluorescence in the absence of protein (lower line in Figure 3–23A). Parameter a from the fit is K_{dL}, parameter b is $[ST]_t$, and parameter c is ξ_b. Equation 3–322 can be fit by nonlinear least-squares analysis to the behavior of the observed fluorescence as a function of the total concentration of ligand L. In the example of homoserine dehydrogenase, the constant of proportionality from the slope of the line in the absence of the enzyme, ξ_f, is $0.262 \pm 0.006\ \mu M^{-1}$, and when Equation 3–322 is fit to the data directly (Figure 3–23A), the dissociation constant K_{dNADPH} is $0.41 \pm 0.08\ \mu M$, the molar concentration of sites is $2.26 \pm 0.11\ \mu M$, and the constant of proportionality ξ_b is $6.5 \pm 0.4\ \mu M^{-1}$. In an experiment of this type, once the values for K_{dL} and $[ST]_t$ have been estimated in preliminary experiments, $[ST]_t$ can be purposely chosen to be of the same magnitude as K_{dL}, as in the experiments with homoserine dehydrogenase. Because K_{dL} and $[ST]_t$ are of approximately equivalent weight in Equation 3–321, the most ideal situation is one in which they are approximately equal in magnitude.*

Equations 3–309, 3–321, and 3–322 **can be applied to any physical property** that, like fluorescence, is proportional to the concentration of free ligand and to the concentration of bound ligand and for which the two constants of proportionality, ξ_f and ξ_b, differ significantly simply by replacing F_{obs} by the symbol for the physical property being measured.[184,187,198] The fit of Equation 3–322 to the data provides the most accurate asymptote for the curve (dashed line in Figure 3–23A), and this asymptote can be used to convert the observed values for the physical property being measured (Equations 3–309 and 3–310) into values for the fractional saturation Y as a function of the total concentration of ligand so that they can be plotted (Figure 3–23B).

Equation 3–320 can be **rearranged to the linear form**

$$\frac{[L]_t}{Y} = \frac{K_{dL}}{1 - Y} + [ST]_t \quad (3\text{–}323)$$

When $[L]_t\ Y^{-1}$ is plotted as a function of $(1-Y)^{-1}$, a straight line[180] with a slope of K_{dL} and an intercept with the axis of the ordinate of $[ST]_t$ is observed (inset to Figure 3–23B). Equation 3–323 and its graphical representation define the information available in the three regimes. Because $0 < 1 - Y < 1$, when $[ST]_t << K_{dL}$, the intercept of the line will be indistinguishable from zero and only the dissociation constant can be measured, which is still the slope of the line. When $[ST]_t >> K_{dL}$, the slope of the line will be indistinguishable from zero and only $[ST]_t$ can be measured, which is still the intercept with the axis of the ordinate. It is only when the total concentration of sites is in the range of the dissociation constant that the line has both a slope other than zero and an intercept other than zero, and both of the terms can be measured.

A kinetic titration can also be carried out in the third regime. For example, a small protein, calmodulin, activates Ca^{2+}-transporting ATPase from human erythrocyte membranes.[199,200] If the initial rate of this enzymatic reaction is followed as a function of the concentration of calmodulin at saturation with Ca^{2+} and $MgATP^{2-}$, a monotonic increase in the initial rate, Δv_0, is observed that reaches a maximum, ΔV, at high concentrations of calmodulin. It can be

*This conclusion is supported by the almost equivalent standard deviations on these two parameters from the fit in Figure 3-23B.

shown[155] that $[CM]_{t,0.5}$, the total concentration of calmodulin producing an increase in the initial rate, Δv_0, equal to half the maximum increase, ΔV, is related to the total molar concentration of sites with which calmodulin associates by the equation

$$[CM]_{t,0.5} = K_{dCM,app} + \frac{[CM]_t}{2} \tag{3–324}$$

where $K_{dCM,app}$ is the apparent dissociation constant for the binding of calmodulin to Ca^{2+}-transporting ATPase. When Equation 3–324 is combined with Equation 3–281

$$[CM]_{t,0.5} = K_{dCM,app} + \frac{\kappa C_{CM}}{2} \tag{3–325}$$

If the concentration of protein (grams liter^{-1}) can be adjusted so that the concentration of sites has a value in the range of the value for the apparent dissociation constant and Equation 3–325 has a discernable slope, and if initial rates for the enzymatic reaction can be measured at these concentrations, a plot of $[CM]_{t,0.5}$ as a function of the concentration of the protein (in grams liter^{-1}) will have a slope of $(\kappa/2)$. In this instance, the parameter κ is the moles of sites (gram of protein)$^{-1}$. A simple way to understand Equation 3–324 is to consider that the free concentration of calmodulin is less than the total concentration by the amount bound to the enzyme. To effect the same fractional activation as the concentration of enzyme is increased, the total concentration of calmodulin must be increased to adjust for the increase in the bound calmodulin, and the additional calmodulin needed is directly proportional to half the concentration of sites.

When experimental studies of binding are performed, **a clear distinction among these three regimes must be made** from the start. If $[ST]_t$ is actually much less than K_{dL}, changing the concentration of protein will have no effect on the apparent dissociation constant measured with the assumption that $[L]_t = [L]_{eq}$. If $[ST]_t$ is actually in the range of K_{dL}, changing the concentration of protein will change the apparent dissociation constant measured with the assumption that $[L]_t = [L]_{eq}$. If $[ST]_t$ is actually much greater than K_{dL}, a titration with an inflection will be observed, and the point of inflection will shift proportionally as the concentration of protein is varied.

The dissociation constant for ligand L, the physical properties of which are unaffected by its association with a site ST, can be still be determined if it competes for site ST with ligand M, the physical properties of which are affected by its association with site ST. If the two ligands compete with each other for the same site on a protomer of a molecule of protein, then ligand M and ligand L cannot both bind to the site simultaneously, and the complex M·ST·L cannot form. It follows that

$$M{\cdot}ST + L \underset{}{\overset{K_{dM}}{\rightleftharpoons}} M + ST + L \underset{K_{dL}}{\rightleftharpoons} M + ST{\cdot}L \tag{3–326}$$

where

$$K_{dM} = \frac{[ST]_{eq}[M]_{eq}}{[M{\cdot}ST]_{eq}} \tag{3–327}$$

and

$$K_{dL} = \frac{[ST]_{eq}[L]_{eq}}{[ST{\cdot}L]_{eq}} \tag{3–328}$$

If, because of the competition

$$[ST]_t = [ST]_{eq} + [M{\cdot}ST]_{eq} + [ST{\cdot}L]_{eq} \tag{3–329}$$

and

$$[M]_t = [M]_{eq} + [M{\cdot}ST]_{eq} \tag{3–330}$$

and

$$[L]_t = [L]_{eq} + [ST{\cdot}L]_{eq} \tag{3–331}$$

it follows that

$$\left(K_{dL} - K_{dM}\right)[M{\cdot}ST]_{eq}^{3} + \left(K_{dM}^{2} - K_{dM}K_{dL} + K_{dM}[M]_t - 2K_{dL}[M]_t - K_{dM}[L]_t - K_{dL}[ST]_t + K_{dM}[ST]_t\right)[M{\cdot}ST]_{eq}^{2}$$
$$+ \left(K_{dL}K_{dM}[M]_t + K_{dL}[M]_t^{2} + K_{dM}[L]_t[M]_t - K_{dM}[ST]_t[M]_t + 2K_{dL}[ST]_t[M]_t\right)[M{\cdot}ST]_{eq} - K_{dL}[ST]_t[M]_t^{2} = 0 \quad (3\text{–}332)$$

which is a cubic equation in the molar concentration of the complex between ligand M and site ST on the protein.

In the absence of any information about the equilibrium constants, the appropriate **cubic root** of Equation 3–332 provides an equation for the value of the observed physical property for ligand M as a function of the total concentration of ligand L. When the total concentrations of ligand M and sites are in the proper range, this equation can be fit to the data to obtain values for K_{dM}, K_{dL}, and $[ST]_t$. If the experiment is designed properly so that certain terms in Equation 3–332 become negligible, the cubic equation can be simplified to a quadratic equation. From the appropriate root of this **quadratic equation**, an equation can be derived for the value of the observed physical property of ligand M as a function of the total concentration of ligand L when the concentrations of protein and ligand M are held constant, and this equation can be fit to the data to obtain values of K_{dM}, K_{dL}, and $[ST]_t$.[188,201]

If, however, the moles of sites (gram of protein)$^{-1}$ is known, so that the total concentration of sites in a particular solution is known, and if the dissociation constant for ligand M, K_{dM}, is also known, then a value of K_{dL}, the only missing parameter, can be obtained from the data without having to fit a cubic root or a quadratic root. Titrations can be performed in the usual manner, in the absence of ligand L, by following the physical property to obtain values for the dissociation constant of ligand M and the constant of proportionality κ, the moles of sites (gram of protein)$^{-1}$, so that the molar concentration of sites can be known for a given concentration of protein.

If a physical property Q of ligand M is affected by its association with site ST, then from Equations 3–293 and 3–297

$$Y_M = \frac{[M{\cdot}ST]_{eq}}{[ST]_t} = \frac{Q_{obs} - Q_M}{Q_{M{\cdot}ST} - Q_M} \quad (3\text{–}333)$$

where Q_{obs} is the observed value for the physical property at particular fixed concentrations of ligand M and site ST, Q_M is the value of that physical property at the same fixed concentration of ligand M in the absence of sites ST, and $Q_{M{\cdot}P}$ is the value of that physical property at the same fixed concentration of ligand M when ligand M is fully saturated with sites ST. If a series of solutions, each with the same fixed molar concentrations of ligand M and site ST, so that $Y_M > 0.5$, are titrated with different concentrations of ligand L, the bound concentration of ligand M, $[M{\cdot}ST]_{eq}$, will decrease as a result of the competition of ligand L for site ST, and Y_M will also decrease. The total concentration of ligand L, $[L]_{t,0.5}$, that brings Y_M to 0.5, which is where

$$Q_{obs} = 0.5\left(Q_{M{\cdot}ST} + Q_M\right) \quad (3\text{–}334)$$

can be measured in this titration. When $Y_M = 0.5$, regardless of the presence of ligand L, $[M]_{eq} = K_{dM}$ (Equation 3–293), and

$$K_{dL} = \frac{2K_{dM}^{2} + 2K_{dM}[L]_{t,0.5} + K_{dM}[M]_t - 2K_{dM}[ST]_t}{2[ST]_t - [M]_t - 2K_{dM}} \quad (3\text{–}335)$$

All the terms in the quotient on the right are known quantities. The measurements can be repeated with several different molar concentrations of sites, $[ST]_t$, and ligand M, $[M]_t$, each measurement beginning at levels where $Y_M > 0.5$, to show that K_{dL} is always the same.

There are many situations in which the concentration of sites for binding a ligand present in a biological preparation is too low for the methods described so far to be applied. Most of the experimental results and procedures examined so far require that the **molar concentration of binding sites** be fairly high. For example, in all the procedures where the bound concentration of the ligand is determined by the difference between the free concentration and the sum of bound and free concentrations, the bound concentration of the ligand must be of the same order of magnitude as the free concentra-

tion.[202] In experiments in which either the absorbance of the protein (Figure 3–21) or the absorbance of the protein in a complex between the ligand and the protein (Figure 3–20) is monitored, the concentration of the protein must be high enough and the protein must be pure enough to produce measurable changes in absorbance. Where differences in the fluorescence of a ligand are being followed (Figure 3–23), unless the increase in quantum yield is quite large, the concentrations of bound and free ligand must also be within the same range; and, since

$$\frac{[\mathrm{ST{\cdot}L}]_{eq}}{[\mathrm{L}]_{eq}} = \frac{[\mathrm{ST}]_{eq}}{K_{dL}} \qquad (3\text{–}336)$$

it follows that the concentration of sites must be of the same order of magnitude as the dissociation constant. Likewise, when the concentration of protein is varied to determine the dissociation constant (Figure 3–22), the concentration of sites must cover a range including the dissociation constant. In the titration of glutamate dehydrogenase by NADH (Figure 3–24), the concentration of sites had to be in excess of the dissociation constant. None of these requirements are prohibitive when the protein in question is abundant, soluble, and pure because molar concentrations as high as 1–10 mM in sites can be achieved under these circumstances. In other instances, however—particularly in situations where the protein on which the sites reside is only a small fraction of the protein present—it may not be possible to produce high enough concentrations of sites.

Many examples of this problem are encountered in the large group of proteins known as receptors. As the name implies, in many cases these proteins are identified only on the basis of their ability to bind a ligand. For example, the insulin receptor is defined as a protein in the plasma membrane of cells that binds insulin. Although one of the first receptors to be identified was identified by equilibrium dialysis,[202] often, for technical reasons, receptors are too impure, insoluble, and available only in small quantities. In such instances, the procedures described so far do not work.

When such problems arise, usually the binding is followed by **using radiolabeled ligands and rapidly separating the large quantities of unbound ligand from the small amount of bound ligand**. For example, the binding of insulin to the insulin receptor from *R. norvegicus*[203] that had been dissolved and purified in solutions of detergent was followed through the purification by using ^{125}I-labeled insulin of high specific radioactivity (1.7×10^{18} cpm mol^{-1}) and separating the small amount of bound insulin from the unbound insulin by precipitating the protein at 0 °C with poly(ethylene glycol) and rapidly capturing and washing the precipitate with buffer at 0 °C to complete the removal of free ligand.[204] The binding of epidermal growth factor to the human epidermal growth factor receptor in purified plasma membranes has been followed by using ^{125}I-labeled epidermal growth factor of high specific radioactivity (1.8×10^{17} cpm mol^{-1}) and separating the small amount of bound ^{125}I-labeled epidermal growth factor (usually <5% of the total) from the large amount of unbound ^{125}I-labeled epidermal growth factor by filtering the membranes directly.[205]

With the exception of these last examples, in all the methods for measuring binding discussed so far, the sites at which the ligand is bound remain in a solution in which the free concentration of ligand is unaltered by the procedure, and the ligand and the site remain at equilibrium. The measurements of the binding of ^{125}I-labeled insulin to insulin receptor or ^{125}I-labeled epidermal growth factor to epidermal growth factor receptor, however, are examples of procedures in which sites with their **bound ligands have to be separated completely from free ligand** to monitor the bound ligand.[204] Free ligand can also be completely separated from bound ligand by electrophoresis.[206-208] If the sites are attached to fragments of membrane or cells, the free ligand can be rapidly removed by centrifugation or filtration without the need to precipitate the protein.[204,209]

In all these instances, the concentration of **bound ligand begins to decrease from its level at equilibrium as soon as the free concentration of ligand begins to decrease**. In the extreme, no ligand will be left with the protein because it has all dissociated and then been washed away. If free ligand is removed abruptly and completely in some way, then an accurate estimate of the dissociation at equilibrium can still be made even if significant dissociation has occurred during the separation because the dissociation of ligand is a first-order reaction. Consequently, the same percentage of the initially bound ligand will be present in each washed sample, and the hyperbola defining the concentration of bound ligand as a function of the concentration of the ligand will decrease by the same fraction at each point. The concentration of bound ligand at saturation, however, will be less, often by a significant fraction, than its concentration at equilibrium before free ligand was removed, so the concentration of sites cannot be accurately

assessed by these procedures unless the binding is so tight that little if any dissociation occurs during the separation. If the removal of free ligand is gradual rather than abrupt, the dissociation constant determined will also be inaccurate.

In all these experiments examining the binding of ligands to receptors, two **controls** are usually run. First, it must be shown that the method used to separate physically the bound ligand and the unbound ligand is rapid enough that only manageable amounts of the ligand dissociate from the site during the procedure. Second, a control for nonspecific binding is also usually performed. In most cases, this control involves addition of a high concentration of nonradioactive ligand to see if this eliminates binding of the radioactive ligand. A better control, however, is to add a different ligand, known from independent experiments to block completely the binding of the ligand being tested. For example, specific binding of α-cobratoxin from *Naja siamensis* to murine acetylcholine receptor could be defined as the binding that was blocked by a high concentration of carbamoyl choline,[210] a structurally different ligand for acetylcholine receptor that competes with α-cobratoxin for binding.

There is a direct connection between a dissociation constant K_{dL} and the rate constants governing the kinetics of association of the ligand, k_1, and dissociation of the complex, k_{-1}. At equilibrium, Equation 3–279 applies as well as

$$k_1[ST]_{eq}[L]_{eq} = k_{-1}[ST{\cdot}L]_{eq} \qquad (3–337)$$

from which it follows that

$$K_{dL} = \frac{k_{-1}}{k_1} \qquad (3–338)$$

Equation 3–338, because it contains no concentrations, must be true under any set of circumstances. In particular, even in a situation in which an enzyme and its substrates exist in a steady state, which is not to be confused with existing at equilibrium, Equation 3–338 is valid. If a set of kinetic measurements, made in any situation, provides an unambiguous numerical value for the ratio of the two individual rate constants, k_{-1} $(k_1)^{-1}$, then the numerical value for this ratio is the numerical value of K_{dL}.

Under certain circumstances, the easiest way to measure a dissociation constant is to measure these **rate constants for the association and dissociation of the ligand.**[211] One of these circumstances is that in which the dissociation constant is so small that it cannot be measured directly. For example, at 25 °C the rate constant for the association of cyanocobalamin with haptocorrin from *G. gallus* is 0.24 nM^{-1} s^{-1} and the rate constant for its dissociation is 4×10^{-9} s^{-1}, from which an immeasurably small dissociation constant of 2×10^{-8} nM can be calculated.[212] Another circumstance is one in which equilibrium is established so slowly that it is easier to measure the rates at which the ligand associates and dissociates than it is to ensure that equilibrium has been established before a direct measurement is made.[213] In another instance, a measurement of the dissociation constant for tetrodotoxin from sodium channels from canine heart at –50 mV was made by assessing its rate constants of association and dissociation because a vanishingly small amount of protein was present in the membrane on which the difference in electric potential was imposed.[214] The dissociation constant (14 ± 2 μM) calculated from the rate constants for association (0.167 ± 0.003 μM^{-1} s^{-1}) of chorismate with the active site and dissociation (2.3 ± 0.1 s^{-1}) of chorismate from the active site in an inactive mutant of isochorismatase from *P. aeruginosa* was in good agreement with the dissociation constant (19 ± 2 μM) measured directly from changes in fluorescence.[198]

Up to this point, the binding between a site on a molecule of protein and a ligand has been discussed with the **assumption that the complex formed, ST·L, is a dead-end complex**. Because a dead-end complex is one in which the ligand is not transformed but dissociates from the complex in its original form, dead-end complexes are defined by a simple dissociation constant. Before they are interconverted, **reactants and products associate with and dissociate from the active sites** of enzymes as if they were ligands, but their transformation on the active site complicates the picture. Measurement of the dissociation constant for a dead-end complex is a thermodynamic measurement; that for a complex between an enzyme and its substrate is usually a kinetic measurement. One way to avoid the kinetic complication of turnover of the reactant by an enzyme is to examine the binding of that reactant to a mutant form of the enzyme that still binds the reactant but cannot convert it to product.[198] This strategy, however, is not so unambiguous as a measurement of the dissociation constant for the complex between the reactant and the unaltered enzyme.

There is significant confusion between the Michaelis constant for reactant A in an enzymatic reaction, K_{mA}, and the dissociation constant for the binding of reactant A to the active site, K_{dA}. This confusion arises from the provocative appeal of Equation 3–55, the simplest possible kinetic mechanism for an enzymatically catalyzed reaction. In the rate equation (Equation 3–62) for v_0 derived from the kinetic mechanism of Equation 3–55

$$K_{mA} = \frac{k_{-1} + k_2}{k_1} > \frac{k_{-1}}{k_1} = K_{dA} \qquad (3–339)$$

The assumption is that the step governed by the rate constant k_2, in which covalent bonds are made and broken, should be much slower than the step governed by the rate constant k_{-1}, in which only noncovalent bonds are broken and made, as would be the case in most uncatalyzed chemical reactions in which an encounter complex forms between two reactants many times before there is the proper orientation and kinetic energy of collision to achieve reaction. If $k_2 << k_{-1}$, then

$$K_{mA} \cong K_{dA} \qquad (3–340)$$

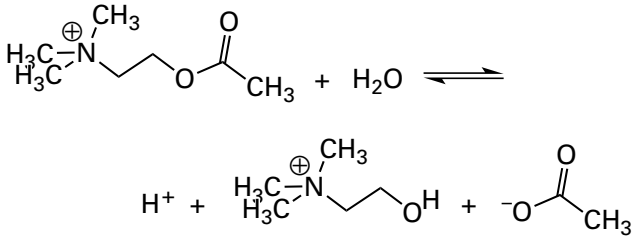
If all enzymatic reactions had kinetic mechanisms as simple as that of Equation 3–55, and if, in all cases, the chemical transformations of the reactants were slower than the rate constants for their dissociation from the active site, this approximation would be valid.

Unfortunately, **most enzymatic reactions have much more complicated kinetic mechanisms** involving multiple steps, and the expression for K_m is more complicated and more distant from the simple expression for a dissociation constant.* Even if the kinetic mechanism were as simple as the one in Equation 3–55, many enzymes have become so efficient that they are able to perform the transformations of the covalent bonds more rapidly than the bound reactants are able to dissociate from the active site. For both of these reasons, Equation 3–340 is seldom valid. An example of this ambiguity is that when two amino acids, Lysine 116 and Glutamate 135, which form hydrogen bonds with the α-phospho group of the reactant $MgATP^{2-}$ in the active site of cAMP-dependent protein kinase from *S. cerevisiae*,[215,216] are mutated in turn to alanines, the Michaelis constant for the peptide that is the other reactant for the enzyme increases by factors of 25 and 50, respectively, while the Michaelis constant for $MgATP^{2-}$ increases by factors of only 6 and 3.[217]

If it is desired that the observed Michaelis constant be approximately equal to the actual dissociation constant of the reactant from the active site, **that desire in that particular instance must be established experimentally**.

The common desire to treat a Michaelis constant as if it were a dissociation constant[218-223] arises from the fact that it is often difficult to measure the binding of a substrate to an enzyme because the enzyme transforms the substrate while the measurements are being attempted. Often, therefore, kinetic measurements are the only measurements available for determining the dissociation constants between an enzyme and its substrates.

In some instances, **the steady-state kinetics can be dissected** to isolate a dissociation constant. Acetylcholinesterase (AE) catalyzes the reaction

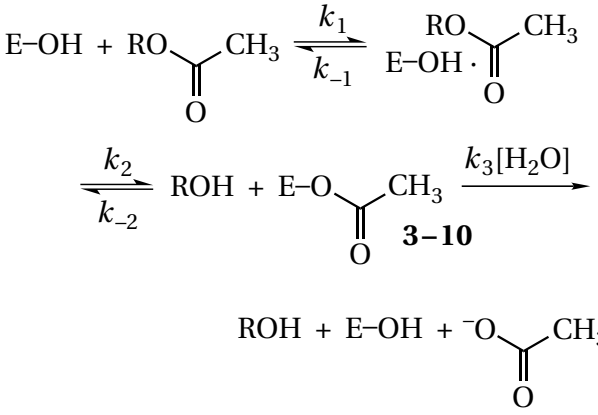


(3–341)

The enzyme also catalyzes the hydrolysis of a number of related acetyl esters. The binding of acetyl esters to acetylcholinesterase cannot be assessed in the absence of water, the other reactant in the reaction catalyzed by the enzyme, so a series of acetyl esters has been used to study the properties of the active site in the enzyme from *Electrophorus electricus* involved in binding these reactants by following the steady-state kinetics of the enzyme.[224]

It had been shown in earlier studies that the kinetic mechanism

*It was the realization that, during most enzymatic reactions, the association of a reactant with the active site is not at equilibrium that led Briggs and Haldane[76] to propose that the steps in an enzymatic reaction, including the associations of reactants, should be treated as being in a steady state rather than at equilibrium, as had been proposed by Michaelis and Menten.[64]



(3–342)

where E–OH is a serine in the active site, was consistent with all the kinetic observations that had been made with acetylcholinesterase. In this mechanism, the term $k_3[H_2O]$ had the same value for all the reactants used in the study because the reactants were all acetyl esters producing the same acetyl enzyme (**3–10**), and the value for the term $k_3[H_2O]$ had already been determined accurately. The catalytic constant, k_0, for the kinetic mechanism (Equation 3–342), when the initial concentration of the product alcohol, $[ROH]_0$, is zero is

$$k_0 = \frac{k_2 k_3 [H_2O]}{k_2 + k_3 [H_2O]} \qquad (3–343)$$

Consequently, from the observed values of the rate constant k_0 for each reactant and the known values for $k_3[H_2O]$ and $[AE]_t$, values of the rate constant k_2 could be calculated for each reactant.

For the kinetic mechanism (Equation 3–342)

$$k_A = \frac{k_2}{\left(\frac{k_{-1} + k_2}{k_1}\right)} \qquad (3–344)$$

With this equation, the observed values of the specificity constant k_A for reactant A, and the calculated values of k_2, values of $(k_{-1} + k_2)\ k_1^{-1}$ could be calculated for each reactant. From comparing measured values of k_2 to estimated values of k_{-1}, it was concluded that, for every reactant except acetylcholine, $k_{-1} >> k_2$ and $(k_{-1} + k_2)\ k_1^{-1}$ was an accurate estimate of the dissociation constant (Equation 3–339) for the binding of each reactant to the active site.[224]

Numerical values of the dissociation constants measured for complexes between enzymes and substrates, between enzymes and competitive inhibitors, or between proteins and ligands have a number of uses. Because they are directly related to changes in standard free energy, they are often related to the types of noncovalent interactions between the site and the ligand. In this way, these dissociation constants are often used to probe the structure of the binding site or the active site.

In the case of acetylcholinesterase, the dissociation constants for a series of *N*-methylated 2-aminoethyl acetates [$H_3N^+C_2H_4$–, $(CH_3)H_2N^+C_2H_4$–, $(CH_3)_2HN^+C_2H_4$–, and $(CH_3)_3N^+C_2H_4$–] were compared, respectively, with a series of corresponding alkyl acetates in which nitrogen has been replaced by carbon [$H_3CC_2H_4$–, $(CH_3)H_2CC_2H_4$–, $(CH_3)_2HCC_2H_4$–, and $(CH_3)_3CC_2H_4$–]. All these acetate esters, both the cations and the alkanes, were reactants in hydrolyses catalyzed by the enzyme (Table 3–4). The fact that little if any difference was observed between the estimated dissociation constants for pairs of substrates having or lacking the cationic elementary charge demonstrates that this feature of the structure of the physiologically relevant substrate, acetylcholine, does not contribute significantly to the favorable change in standard free energy accompanying its association with the active site. The fact that substrates with the same number of hydrogen–carbon bonds, regardless of their net charge, had about the same dissociation constants and the fact that the dissociation constants decrease as the number of hydrogen–carbon bonds increase suggest that it is mainly a hydrophobic effect that drives this association.

In the crystallographic molecular models of complexes between acetylcholinesterase from *Tetronarce californica*[225] and several inhibitors, each containing a trimethylammonium group, that group is found to be pushed up against the side chain of a tryptophan with two of its methyl groups in direct contact with the aromatic π system of the indolyl group, which isolates the hydrogen–carbon bonds from contact with the water of the solution. One of these methyl groups was also in direct contact with the aromatic π system of the phenyl group of a phenylalanine, and three molecules of water form a partial shell of hydration around the third otherwise unoccupied methyl group.[226,227] The fact that this third methyl group has no direct interaction with the active site may explain why the dissociation

Table 3–4: Dissociation Constants[224] for the Binding of Reactants to Acetylcholinesterase[a]

[a]Dissociation constants were estimated from steady-state kinetics at pH 7.8, 25 °C, and ionic strength of 0.18 M.

constants for the trimethyl reactants are essentially same as those for the dimethyl reactants (Table 3–4). In one of the complexes, a glutamate is 0.35 nm from one of the two methyl groups pushed up against theindolyl group. Site-directed mutations of the tryptophan,[228,229] the phenylalanine,[230] and the glutamate,[170] however, suggest that the π system of the indolyl group of the tryptophan provides the majority of the standard free energy stabilizing the complex between the enzyme and the quaternary ammonium ion. The quadrupole moment of the aromatic π sys-tems surrounding the cation permits the trimethyl-ammonium group to be tolerated in a nonpolar pocket and to bind with the same affinity as a *tert*-butyl group.[231]

In the instance of acetylcholinesterase, a cationic functional group interacts mainly with nonpolar, aromatic π molecular orbital systems, while in a crystallographic molecular model of exo-α-sialidase from influenza virus, the nonpolar methyl group contributing significantly to the potency of an inhibitor is surrounded by three carboxy groups from the side chains of two glutamates and an aspartate.[232] These examples indicate that the structures of the **binding sites for ligands on proteins are often counterintuitive**.

Hexokinase from *S. cerevisiae* associates with its reactants[233,234] with a preference for D-glucose to associate before $MgATP^{2-}$. Because the reactants associate and dissociate rapidly relative to their turnover and because D-glucose is usually the first substrate to bind in this rapid-equilibrium random kinetic mechanism, the Michaelis constant $K_{m,gluc}$ for D-glucose has been shown to be approximately equal to the dissociation constant for its binding to the open active site. Kinetic values for K_m were used as estimates of the dissociation constants for the binding of various analogues for D-glucose to the active site (Table 3–5).[235,236] As is D-glucose, most of these derivatives of D-glucose are phosphorylated at the 6-hydroxy group in a reaction

It is possible **to get a feeling for the structure of the active site** of hexokinase from the changes in K_m caused by various replacements. The active site of the enzyme seems to be open and unrestrictive at carbon 2 of D-glucose because epimerization or replacement of the OH with smaller (hydrogen or fluorine) or larger (chloro or acetamido) groups has little effect on the Michaelis constant. At both carbons 3 and 4, however, epimerization eliminates the ability of the monosaccharide to participate in the reaction. This result suggests that there are either amino acids or polypeptide on the side of the ring opposite the 3-hydroxy group and on the side of the ring opposite the 4-hydroxy group, and anything larger than a hydrogen is sterically excluded. This steric effect must also apply adjacent to the hydroxy group on carbon 3 because methylation at this oxygen produces a substrate that cannot participate in the reaction. A more subtle effect is seen when either the 3-hydroxy group or the 4-hydroxy group is replaced by a fluorine. The 550-fold increase in the Michaelis constant ($\Delta\Delta G^\circ = +15$ kJ mol^{-1}) suggests that in each case a noncovalent interaction, such as a hydrogen bond, directed toward the hydroxy group

Table 3-5: Michaelis Constants[235,236] for Derivatives of D-Glucose[a] as Reactants for Hexokinase[b]

derivative of glucose	Michaelis constant (mM)
D-glucose	0.14
2*S* epimer (D-mannose)	0.05
2-deoxy	0.30
2-deoxy-(2*R*)-acetamido	1.0
2-deoxy-(2*R*)-fluoro	0.19
2-deoxy-(2*S*)-fluoro	0.14
2-deoxy-(2*R*)-chloro	2.1
3*R* epimer (D-allose)	>100
3-deoxy-(3*S*)-fluoro	70
3-*O*-methyl	>100
4*S* epimer (D-galactose)	>50
4-deoxy-(4*R*)-fluoro	84
5-dehydroxymethyl (D-xylose)	10[c]
6-deoxy-6-fluoro	8[c]

[a](2*R*,3*S*,4*R*,5R)-2,3,4,5-Tetrahydroxy-5-(hydroxymethyl)-pentanal. [b]30 °C, pH 7–8.5. [c]Competitive inhibitor, K_i listed.

in particular has been prevented from occurring. A similar although 10-fold less dramatic change is seen when either the 6-hydroxy group is replaced by a fluorine or carbon 6 is eliminated entirely (xylose). All these intuitions about the active site that were derived from the values for these dissociation constants are consistent with the structure of the complex between D-glucose and the active site of the enzyme in a crystallographic molecular model that was constructed much later.[237]

The substitution of a hydrogen on a ligand with a halogen, as was just described in the case of hexokinase, can be used to probe the structure of the site for that ligand on a protein in the vicinity of that hydrogen. If the dissociation constant for the ligand decreases in the sequence –F,–H,–Cl,–Br,–I, this observation indicates that the vicinity is nonpolar.[238] If it decreases and then increases over the same sequence, this observation indicates that the vicinity is sterically hindered because the larger halogens are not tolerated.[239]

The **disposition of subsites** within a particular binding site can be probed systematically. For example, when the distance between a guanidinio group and a phosphate in a series of inhibitors for human purine-nucleoside phosphorylase was varied synthetically, a minimum in the values for the inhibition constant was observed at a distance of 1.1 nm,[240] which suggests that the subsites for these functional groups on the nucleotides that are the normal substrates for the enzyme are located at this distance from each other, as they should be.

In the studies just described, changes are made synthetically in the ligand to probe the structure of the site on the protein or its subsites, but often they are made in pharmaceutical research for the purpose of **improving systematically the affinity of the ligand** for the protein. The specificity of a site on a protein for a ligand can also be changed by directed evolution.[241-243] The protein is randomly mutated, the mutants are screened to discover those with altered affinity in the desired direction, and the best candidates are mutated again and rescreened.

Measurements of the binding of a substrate to an enzyme in the absence of its cosubstrates are often used to confirm or to reject kinetic mechanisms that propose a particular order in which the reactants bind to that active site during enzymatic catalysis.

Most enzymes operate on two or more reactants, and if only one of the two or more reactants is present, it will usually not be transformed by the enzyme. If the enzyme associates with its reactants at random or if the reactant of interest is the first one to associate with the active site, then in the absence of any coreactants, **a reactant will form a meaningful, dead-end complex** with the enzyme, the dissociation constant of which can be measured. For example, NADPH, in the absence of L-homoserine, forms a dead-end complex ($K_{dNADPH} = 0.41 \pm 0.08\ \mu M$) with homoserine dehydrogenase (Figure 3–23); NADH, in the absence of 2-oxoglutarate and ammonia, forms a dead-end complex with glutamate dehydrogenase (Figure 3–24); orotidine 5′-phosphate, in the absence of diphosphate, forms a dead-end complex ($K_{dOMP} = 3.1 \pm 0.3\ \mu M$) with orotate phosphoribosyltransferase; and 2′-deoxyuridine 5′-phosphate, in the absence of (6*R*)-5,10-methylenetetrahydrofolate, forms a dead-end complex ($K_{d,dUMP} = 5\ \mu M$) with thymidylate synthase from *E. coli*.[184]

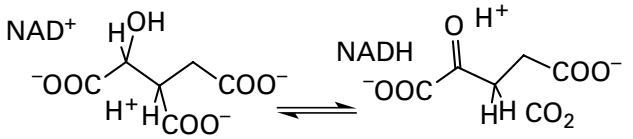
There are sometimes **ambiguities** in measurements of this kind. For example, the kinetic behavior of the inhibition of aspartate carbamoyltransferase (Equation 3–220) from *E. coli* by *N*-(phosphonacetyl)-L-aspartate (Figure 3–14) and studies of product inhibition of the enzyme,[244] as well as the fact that

addition of carbamoyl phosphate to a solution of aspartate carbamoyltransferase produces a major change in the conformation of the protein while addition of L-aspartate does not,[108,245] are all consistent with the conclusion that carbamoyl phosphate must associate with the active site before L-aspartate can associate with the active site in the reaction leading to products. Aspartate, however, can bind to the unoccupied enzyme, presumably at a site unrelated to the active site, with a dissociation constant even smaller than its dissociation constant when it is productively associating with the active site occupied by carbamoyl phosphate.[178] The substrate fructose 6-phosphate can bind to six sites on each protomer of ovine 6-phosphofructokinase (Equation 3–300), but the addition of phosphate, which eliminates the nonspecific binding attributable to the phospho group on fructose 6-phosphate, decreases the number of sites to one for each subunit.[246] Presumably, this one remaining site is the active site. Analogues for ATP bind to three sites on every protomer of 6-phosphofructokinase from *O. cuniculus*. One of these is a site at which fructose 1,6-bisphosphate also binds,[247] which cannot be the site for productive association of $MgATP^{2-}$.

When reactants enter the active site at random, either reactant must be able to bind to the enzyme in the absence of the other. For example, the observation that both $MgATP^{2-}$ and fructose 6-phosphate by themselves can associate with 6-phosphofructokinase from *E. coli* to form the respective dead-end complexes was presented as further evidence that these two reactants normally associate at random with the active site of the enzyme.[183]

If **the kinetic mechanism is rapid-equilibrium random** (Equation 3–121) so that $K_{mA} = \alpha K_{dA}$ and $K_{mB} = \alpha K_{dB}$ (Equations 3–104 and 3–129) and if those two reactants associate with the enzyme independently of each other ($\alpha = 1$), then the two Michaelis constants, K_{mA} and K_{mB}, should equal the dissociation constants for the respective reactants. Both quinolate alone ($K_{dQA} = 20\ \mu M$) and 5-phospho-α-D-ribose 1-phosphate alone ($K_{dPRPP} = 50\ \mu M$) bind to nicotinate-nucleotide diphosphorylase (carboxylating) from *S. typhimurium* and, in the absence of the other reactant, form dead-end complexes with the enzyme. The similarity between these two dissociation constants and the respective Michaelis constants ($K_{mQA} = 25\ \mu M$ and $K_{mPRPP} = 30\ \mu M$) was presented as evidence that the enzyme has a rapid-equilibrium, random kinetic mechanism.[163] The dissociation constants for either NAD^+ (300 μM) or UDP-glucose (40 μM) when either binds to bovine UDP-glucose dehydrogenase in the absence of the other[248] are of the same order of magnitude as the values for their Michaelis constants (500 μM and 10 μM, respectively),[249,250] which were measured under significantly different conditions, and these observations were presented as evidence for a kinetic mechanism in which the two reactants bind at random and at equilibrium in the first steps of the reaction catalyzed by this enzyme. The directly measured dissociation constants for either L-isoleucine (25 μM) or $MgATP^{2-}$ (150 μM) when either binds in the absence of the other[251] to isoleucine-tRNA ligase from *E. coli* are close to the values estimated for their dissociation constants calculated from kinetic measurements (4 μM and 150 μM, respectively).[252]

When **reactants must associate with the active site in a particular order**, only the first should be able to bind to the unoccupied enzyme. The fact that thymidine kinase from herpes simplex virus forms a dead-end complex with thymidine in the absence of $MgATP^{2-}$ but associates with H_2ATP^{2-}, an unreactive analogue of $MgATP^{2-}$, only in the presence of thymidine suggests[253] that, in the normal enzymatic reaction, thymidine must associate with the enzyme before $MgATP^{2-}$. Likewise, the facts that isocitrate forms a dead-end complex with isocitrate dehydrogenase (NAD^+)



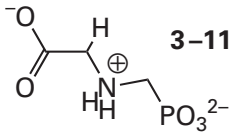
(3–345)

from *S. cerevisiae* in the absence of NAD^+, with a dissociation constant equal to its Michaelis constant, but that NAD^+ does not bind to the enzyme in the absence of isocitrate[254] are consistent with a kinetic mechanism in which isocitrate is required to enter the active site before NAD^+.* The facts that D-glucose binds to hexokinase from *S. cerevisiae*, in the absence of $MgATP^{2-}$, with a dissociation constant equal to its Michaelis constant but that $MgATP^{2-}$ binds much less strongly to the enzyme in the absence of a monosaccharide[234] confirms a kinetic mechanism in which D-glucose usually binds first to the active site.

*This behavior is an example of an active site that does not form a "holoenzyme" with a nicotinamide coenzyme in the absence of its nominal substrate.

In theory, in the situation when one reactant is required to associate with the enzyme before another, the association of the first reactant must decrease the dissociation constant for the second reactant from infinity to a finite value. This shift would be an extreme example of an increase in the affinity of a protein for one ligand caused by the binding of another. Usually, as one might expect, **one ligand increases the affinity of a protein for another** by less than an infinite factor. For example, the association of $MgGDP^-$ increases the affinity of amidophosphoribosyltransferase from *Bacillus subtilis* for $MgADP^-$ by only a factor of 200.[255] In the case of the binding of nitrate, creatine, and $MgADP^-$ to creatine kinase from *O. cuniculus*, any two of the ligands bind independently of each other, but for all possible combinations, the association of two of the ligands decreases the dissociation constant of the third by a factor of 10.[256] In reality, the conclusion that one reactant must associate with an active site before the other is actually a conclusion that the association of the first reactant simply increases the affinity of the active site for the second.

As already noted, the increase in the affinity of a protein for one ligand in the presence of another is best described by a linkage relation (Equation 3–122). For example, the inhibitor *N*-(phosphonomethyl)-glycine (PMG)



has a dissociation constant for 3-phosphoshikimate 1-carboxyvinyltransferase (Equation 3–262) from *S. pneumoniae* that is 1700 times smaller when the enzyme is occupied its substrate shikimate 3-phosphate ($K_{dPMG,S3P} = 0.25\ \mu M$) than when its active site is vacant ($K_{dPMG} = 420\ \mu M$).[257,258] The linkage relation defining this increase in affinity is

$$\begin{array}{ccc} E + S3P + PMG & \underset{K_{dS3P}}{\rightleftharpoons} & E{\cdot}S3P + PMG \\ \Big\Updownarrow K_{dPMG} & & \Big\Updownarrow K_{dPMG,S3P} \\ E{\cdot}PMG + S3P & \underset{K_{dS3P,PMG}}{\rightleftharpoons} & E{\cdot}S3P{\cdot}PMG \end{array} \qquad (3\text{–}346)$$

where E is the enzyme and S3P is shikimate 3-phosphate. In a clockwise direction around the cycle, $K_{dS3P}^{-1}\, K_{dPMG,S3P}^{-1}\, K_{dS3P,PMG}\, K_{dPMG} = 1$. If this linkage relation describes the situation, the observed dissociation constant for shikimate 3-phosphate from enzyme occupied by *N*-phosphonomethyl-glycine ($K_{dS3P,PMG} = 0.50\ \mu M$) should also be 1700 times smaller than that for the unoccupied enzyme ($K_{dS3P} = 770\ \mu M$), which it is. The independent measurement of the four dissociation constants in this particular cycle establishes the linkage relation.[257]

(A) Plot these data directly.
(B) Use a fitting program to fit these data to a rectangular hyperbola, or plot the data on a Scatchard plot.
(C) Determine the apparent dissociation constant for hexose 6-phosphate and the grams of protein (mole of sites)$^{-1}$ at saturation.
(D) The molar mass of glucose-6-phosphate isomerase from *O. cuniculus* calculated from the sequences of amino acids for its subunits is 125,230 g mol^{-1}. How many protomers does each oligomer contain?

Each measurement is made at equilibrium. At equilibrium, each step in the kinetic mechanism of the enzyme has come to equilibrium, as well as the concentrations of D-glucose 6-phosphate and D-fructose 6-phosphate.

(E) Write an equilibrium mechanism for the enzymatic reaction that takes into account the binding of substrates to the active site and the interconversion of the substrates on the active site. Your expression should be a set of four linked equilibria.
(F) What is the expression for the apparent dissociation constant

$$K_{dGP,app} = \frac{[E]_{eq}\left([F6P]_{eq} + [G6P]_{eq}\right)}{\left([E{\cdot}F6P]_{eq} + [E{\cdot}G6P]_{eq}\right)}$$

of the equilibrium mixture of substrates from the active site in terms of only equilibrium constants from your linked equilibria.

Problem 3–20: Using Equations 3–326 through 3–331, derive the cubic equation in $[M{\cdot}ST]_{eq}$ (Equation 3–332) and then the cubic equations in Y_M (Equation 3–333) and in Q_{obs} (Equation 3–334).

Problem 3–21: A group of proteins, the selectins, which are found on the surfaces of particular cells, are mammalian lectins that are distinguishable by their ability to recognize and bind unique oligosaccharides. When the specific selectins on the surface of one cell bind to the oligosaccharides on the surface of another cell, the first cell adheres to the second cell. The extracellular portion of E-selectin is a fragment of the intact molecule of E-selectin that lacks the membrane-spanning portions of the protein, is freely soluble, and contains one binding site for its particular ligands, one of which is the sialyl Lewis *x* oligosaccharide *N*AcNeu*p*-(β2,3)-D-Gal*p*-(β1,4)-[L-Fuc*p*-(α1,3)]-D-Glc, where *N*AcNeu is the pyranose of *N*-acetylneuraminic acid, β-D-Gal*p* is β-D-galactopyranose linked at the 4-hydroxy group of D-glucopyranose, α-L-Fuc*p* is α-L-fucopyranose linked at the 4-hydroxy group of the same D-glucopyranose, and D-Glc is D-glucose.[259] A fluoresceinyl group was attached synthetically to the hydroxy group of the hemiacetal of the D-glucose in this oligosaccharide, and the product is designated sLe^x[Glc]-Fl. When sLe^x[Glc]-Fl is bound by the extracellular portion of human E-selectin (E1), the anisotropy of the fluorescence from its fluoresceinyl group increases because it becomes less mobile. When samples containing 1.0 μM or 0.2 μM sLe^x[Glc]-Fl were mixed with various concentrations of E1, the following values for anisotropy of fluorescence were observed.[190]

	anisotropy of fluorescence (r)	
[E1] (μM)	1.0 μM sLe^x[Glc]-Fl	0.2 μM sLe^x[Glc]-Fl
173	0.172	0.184
140	0.159	0.164
53	0.130	0.133
41	0.121	0.120
34	0.115	0.115
25	0.108	0.110
23	0.105	
15	0.095	0.095
0	0.075	0.075

where the concentrations of E1 and sLe^x[Glc]-Fl are all total concentrations.

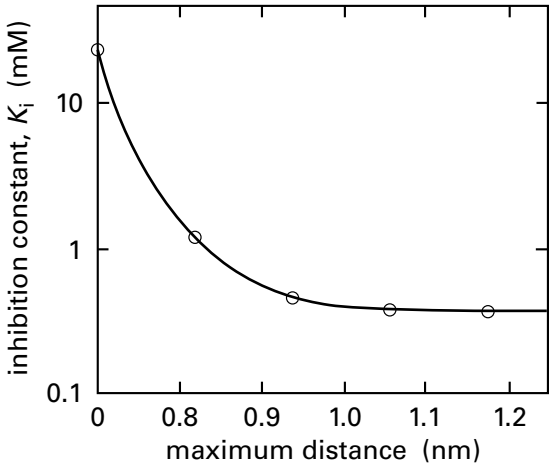
(A) Plot Δr against $[E1]_{eq}$ (Equation 3–303).
(B) Use a fitting program to fit these data to a rectangular hyperbola, or plot the data on a Scatchard plot.
(C) Determine the dissociation constant for sLe^x[Glc]-Fl from E1 and r_{sat}, the anisotropy of the fluorescence at saturation.
(D) Why were two different concentrations of sLe^x[Glc]-Fl used in the measurements?

Problem 3–22: Adenine phosphoribosyltransferase catalyzes the reaction

magnesium 5-phospho-α-D-ribose 1-diphosphate + adenine $\rightleftharpoons$ AMP^{2-} + magnesium diphosphate

Various phosphates have been found to be inhibitors of adenine phosphoribosyltransferase.[260] Values for the dissociation constants (determined as inhibition constants, K_i) between various inhibitors and the enzyme are shown in the table, and some are plotted in the figure on a common logarithmic scale.

compound	K_d (mM)
Mg 5-phospho-α-D-ribose 1-diphosphate	0.0002
D-ribose	>50
α-D-ribose 1-phosphate	>50
D-ribose 5-phosphate	3.3
D-fructose 6-phosphate	5.1
D-glucose 6-phosphate	5.1
α-D-ribose 1,5-bisphosphate	0.12
D-ribulose 1,5-bisphosphate	0.41
D-fructose 1,6-bisphosphate	0.20
α-D-glucose 1,6-bisphosphate	0.42
ethylene glycol bisphosphate	24
propane-1,3-diol bisphosphate	1.2
butane-1,4-diol bisphosphate	0.45
pentane-1,5-diol bisphosphate	0.39
hexane-1,6-diol bisphosphate	0.38



(A) Explain the dissociation constants listed in the table. Why were the other monosaccharide phosphates and bisphosphates included?
(B) Explain the dissociation constants plotted in the figure.
(C) What is the difference in free energy of binding between a diol bisphosphate that fits the active site well and α-D-ribose 1,5-bisphosphate?
(D) Assume that the main difference between a diol bisphosphate and D-ribose 1,5-bisphosphate is the hydroxy groups of the ribose, and discuss this difference of free energy in terms of the enthalpies of formation of the hydrogen bonds. Recall that the active site is constructed for a ribose.

Molecularity and Approximation

During an elementary chemical reaction or during one of the elementary steps of a composite reaction, **the nuclei of the atoms involved in the reaction change their mean positions relative to each other**. The relative positions of the atomic nuclei in the reactants are different from their relative positions in the products. If there are n nuclei in the reactants, and therefore n nuclei in the products, $3n-6$ coordinates are required to define the relative positions of these nuclei in space when they are close enough together to participate in the reaction. Assigning a numerical value to each of these $3n-6$ coordinates defines a relative distribution of the nuclei in space. It can be assumed that the electrons redistribute in response to the motion of the nuclei so rapidly that the positions of the nuclei are all that is needed to define the system.[261] This particular distribution of nuclei and electrons has a specific potential energy, E_p, associated with it. The atomic coordinates and the associated potential

energies together create a surface of potential energy in $(3n-5)$-dimensional space.

The initial state for an **intramolecular, unimolecular reaction** in which a bond will be formed between two atoms in the reactant is any conformation of a molecule of the reactant in which the two atoms to be joined are separated sufficiently that the behavior of each is not significantly affected by the motion of the other but are approaching each other on a trajectory that will lead to intramolecular collision and formation of the bond. The final state for such a reaction is the product containing the new bond in its ground state. The initial state for an intramolecular, unimolecular reaction in which a bond will be broken is the ground state of the molecule containing the susceptible bond. The final state for such a reaction is the molecules of product in which the two atoms previously bonded have separated from each other sufficiently that the behavior of each is not significantly affected by the motion of the other. The initial state for an **intermolecular, bimolecular reaction** is the separated molecules of the reactants, too distant from each other to affect their individual free energies but on trajectories that will lead to a productive collision. The final state is the separated molecules of product departing from the productive collision. In any given reaction, the initial state and the final state can be assigned to broad minima on the surface of potential energy describing that reaction.

Any reaction that converts reactants into products must **follow a path on the surface of potential energy** between the region occupied by the reactants and the region occupied by the products. Each path must pass through a point that has the highest potential energy for that particular path. Within the set of the infinite number of paths between reactant and product, there will be a col. The **col** is the highest point on a subset of these paths that has a lower potential energy than the highest points on all the other paths. This col is analogous to the pass of lowest altitude through a range of mountains separating two geographical points. Because this col represents the lowest barrier of potential energy between reactants and products, a chemical reaction connecting reactants and products usually will proceed on a path through or near this col. For a given reaction, if a local minimum of potential energy is encountered along the paths leading through a col so that all the paths have two cols, or two maxima of potential energy, then the reaction is a composite reaction that proceeds through

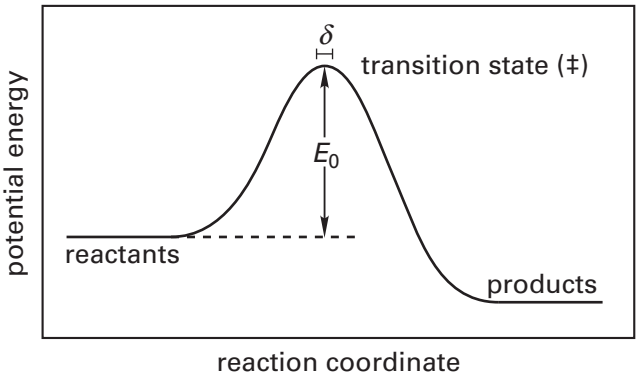


Figure 3–25: Variation in potential energy, E_p, as function of the distance along a reaction coordinate.[262] The plateaus on the two sides are the potential energies of separated reactants and separated products, far enough apart that they have no interaction with each other. The potential energy at the peak is the potential energy of the transition state (‡). The width, δ, is the portion of the reaction coordinate occupied by the transition state. The height, E_0, is the difference in potential energy between reactants and transition state.

an intermediate. In this instance, the reaction is divided into two steps, and each step is an elementary reaction. Consequently, a path between reactants and products, between reactants and an intermediate, between one intermediate and another intermediate, or between an intermediate and products on the surface of potential energy through the col for that particular step has only one maximum of potential energy, which is the col itself. **A reaction coordinate is a path through a col**.

A reaction coordinate is presented figuratively (Figure 3–25)[262] as a curve beginning on a plateau the potential energy of which is that of the separated reactants and ending on a plateau the potential energy of which is that of the separated products for a particular step in a reaction. The abscissa is the distance along the reaction coordinate over the surface of potential energy, and the ordinate is the potential energy associated with a given distance along the reaction coordinate. Each point on the reaction coordinate defines a distribution of atomic nuclei in space. As the reaction progresses along the reaction coordinate, the nuclei participating in the reaction are changing their relative positions as reactants are transformed into products.

The relative positions of the nuclei in space at the col, the point of highest potential energy, comprise the transition state. The transition state, as for any stable molecule, is a collection of nuclei distributed in space in association with a particular number of electrons, which are confined to the atomic and

molecular orbitals dictated by that distribution of nuclei. The only difference between a transition state for an elementary reaction and the reactants or products for that elementary reaction is that the transition state is directly unstable with respect to both. If the transition state were at rest at the highest point of the col, it would be immediately transformed with equal probability into either reactants or products.

For reactants to be transformed into products in an elementary reaction, **sufficient energy must be available** for the reactants to reach the potential energy of the transition state. This energy is usually provided by the kinetic energy of the collision in a multimolecular reaction or by fluctuations in internal energy in a unimolecular reaction, but any other source of energy is also acceptable.

According to **transition state theory**,[262,263] the rate constant of a chemical reaction, k_r, is

$$k_r = \kappa_T \frac{k_B T}{h} {}^{\ddagger}K' \tag{3–347}$$

where κ_T is the transmission coefficient, k_B is the Boltzmann constant, and h is the Planck constant. The transmission coefficient is the fraction of the transition states that have been successfully reached by the reactants and then decompose into products, and it is thought to be close to unity under normal circumstances because the motion along the reaction coordinate is usually in the direction of products.[263] The constant ${}^{\ddagger}K'$ is defined as

$${}^{\ddagger}K' = \frac{{}^{\ddagger}Q^{0\prime}}{Q^0_A Q^0_B \cdots} e^{-E_0/RT} \tag{3–348}$$

where ${}^{\ddagger}Q^{0\prime}$ is the **partition function of the transition state** calculated from all degrees of freedom available to the transition state except motion along the reaction coordinate, $Q^0{}_i$ is the partition function of reactant i, and E_0 is the difference in potential energy between the reactants and the transition state (Figure 3–25). The zeroes as superscripts denote partition functions for the same standard volume.

Although ${}^{\ddagger}K'$ is formally determined only by partition functions and potential energies, it is mathematically indistinguishable from the statistical mechanical expression for an equilibrium constant, and it is possible to define a **standard free energy of activation $\Delta^{\ddagger}G^{\circ\prime}$** for an elementary reaction by the equation

$$\Delta^{\ddagger}G^{\circ\prime} \equiv -RT \ln {}^{\ddagger}K' = -RT \ln\left(\frac{h k_r}{\kappa_T k_B T}\right) \tag{3–349}$$

It should be noted that this equation is a definition of $\Delta^{\ddagger}G^{\circ\prime}$ only in terms of the observed rate constant for the elementary reaction, k_r. While values for $\Delta^{\ddagger}G^{\circ\prime}$ can be estimated by calculation, at the moment, tabulated experimental values for $\Delta^{\ddagger}G^{\circ\prime}$ are nothing more than tabulations of values obtained with Equation 3–349 from particular observed rate constants, usually with the unacknowledged assumption that $\kappa_T = 1.0$.

In transition state theory, ${}^{\ddagger}Q^{0\prime}$ is the quotient of the actual partition function for the transition state, ${}^{\ddagger}Q^0$, and the factor $[\delta(2\pi {}^{\ddagger}m k_B T)^{1/2}]\ h^{-1}$, where ${}^{\ddagger}m$ is the mass of the transition state and δ is the distance along the reaction coordinate occupied by the transition state (Figure 3–25). This factor is **the partition function for translation of the transition state along the reaction coordinate**. Therefore

$$k_r = \frac{\kappa_T}{\delta}\left(\frac{k_B T}{2\pi {}^{\ddagger}m}\right)^{1/2}\left(\frac{{}^{\ddagger}Q^0}{Q^0_A Q^0_B \cdots}\right) e^{-E_0/RT} \tag{3–350}$$

The same reaction can be performed at the same temperature but under two separate situations. For example, it could be performed in solution and on the active site of an enzyme, or on the respective active sites of the same enzymes from two different species, or on the wild type and a mutant form of the same enzyme. If it is assumed that κ_T, δ, and ${}^{\ddagger}m$ are about the same in the two situations, then, because

$$\mu^{\circ}{}_i = -RT \ln Q^0{}_i \tag{3–351}$$

where $\mu^{\circ}{}_i$ is the standard chemical potential of species i

$$-RT \ln\left(\frac{k_1}{k_2}\right) = \Delta E_0 + \left({}^{\ddagger}\mu^{\circ}{}_1 - {}^{\ddagger}\mu^{\circ}{}_2\right) - \left(\mu^{\circ}{}_{A1} - \mu^{\circ}{}_{A2}\right) - \left(\mu^{\circ}{}_{B1} - \mu^{\circ}{}_{B2}\right) - \cdots \tag{3–352}$$

and

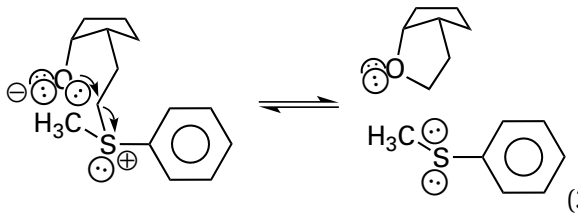
$$-RT \ln\left(\frac{k_1}{k_2}\right) = \Delta\Delta^{\ddagger}G^{\circ} \tag{3–353}$$

In Equation 3–353 the **difference in standard free energies of activation, $\Delta\Delta^{\ddagger}G^{\circ}$**, is the difference in the actual standard free energies of activation for the reactions under the two circumstances. The actual standard free energies of activation themselves, $\Delta^{\ddagger}G^{\circ}_{i}$, are the differences between the standard chemical potentials of the reactants and the standard chemical potentials of the respective transition states. Therefore, any difference between the two situations that increases the standard chemical potential of the reactants or decreases the standard chemical potential of the transition state in the second situation, or does both, will cause the reaction to have a greater rate in the second situation than in the first. The observed difference in rate between the two situations can be used to calculate the numerical value for the change in standard chemical potential of the transition state relative to that of the reactants. The three assumptions made in deriving Equation 3–353, however, should not be forgotten.

One of the more remarkable advantages of enzymatically catalyzed reactions is the increase in rate accomplished by the enzyme. Comparisons of enzymatically catalyzed rates of reaction and uncatalyzed rates of reaction are usually made with the catalytic constant of the enzyme, k_0, and the rate constant for the same reaction in aqueous solution at neutral pH, at the same temperature, and in the absence of catalysis. It has already been noted that increases of as much as 10^{20} and 10^{23} M in rate have been observed.[264,265] In discussions of enzymatic catalysis, these dramatic accelerations are usually emphasized.

The catalytic constant of an enzymatic reaction is the rate constant for that reaction as it occurs on the active site after all reactants have been assembled by their association with the active site. Rates of association of the reactants with the active site have been eliminated from consideration by adding saturating concentrations of all reactants to achieve the conditions producing a rate governed only by k_0. Therefore, **a catalytic constant is always the rate constant for an intramolecular reaction**.

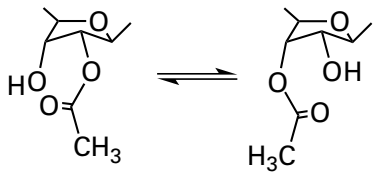
Intramolecular, nonenzymatic chemical reactions often occur at rates much greater than those of equivalent intermolecular reactions. In almost all cases, the intramolecular reactions involved in the comparisons are for a molecule containing two reactive centers that combine in a transition state. In the following discussion, bimolecular reactions between two separate reactants will be compared with intramolecular reactions between the same reactive centers. An example of such a comparison is that between the intramolecular attack of the hydroxy group in the intramolecular nucleophilic substitution[266]



(3–354)

for which the rate constant at 25 °C is 5×10^{-6} s^{-1} while the rate constant for the attack of water on 4-nitrophenyldimethylsulfonium at 25 °C is approximately 10^{-11} M^{-1} s^{-1}.

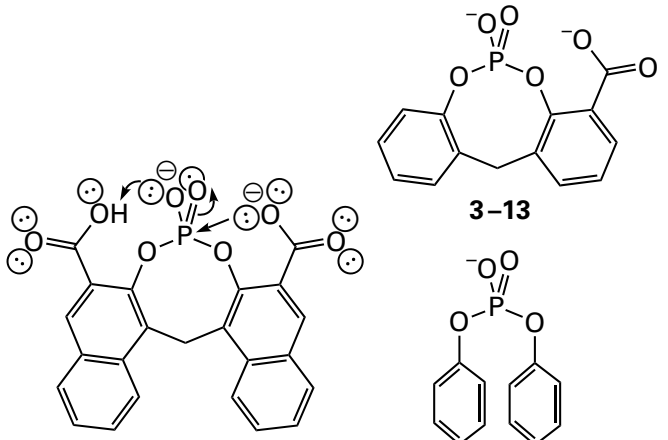
The rate constant for transfer of the acetyl group between the adjacent 2′- and 3′-hydroxy groups of the ribose in *O*-acetyluridine



(3–355)

is 0.01 s, and the rate constant for hydrolysis of *O*-acetyluridine by the water that surrounds it is 3×10^{-7} M^{-1} s^{-1}, in each case at neutral pH and 20 °C.[267,268]

At neutral pH and 50 °C, the rate constant (2×10^{-3} s^{-1}) for hydrolysis of the dianion of bis(salicylyl) phosphodiester **3–12**



3–13 **3–12** **3–14**

is 7×10^{4} times faster than the rate constant (3×10^{-8} s^{-1}) for hydrolysis of the phosphomonoanion

of *o*-carboxylatobisphenyl phosphodiester **3–13**, and the rate constant estimated for hydrolysis of the monoanion of diphenyl phosphate **3–14** is $1 \times 10^{-13}\ M^{-1}\ s^{-1}$. Hydrolysis of the bis(salicylyl) phosphodiester **3–12** results from rate-limiting intramolecular nucleophilic attack on phosphorus of one of the *o*-carboxy groups under intramolecular general acid catalysis by the other *o*-carboxy group.[269] Many other examples of intramolecular accelerations of rates have been reported.[270,271]

At one time it was fashionable to refer to these accelerations in rate as due to an increase in the **effective molarity** of one of the reactants brought about by attaching it covalently to the other. As more exaggerated examples of this phenomenon were reported, however, the unreality of discussing concentrations such as 5×10^5 M, as in the case of the intramolecular nucleophilic substitution of Equation 3–354, became apparent,[272] and a more sophisticated view of the situation was required.

In all instances in which the rate constant for an intramolecular reaction is compared to the rate constant for an intermolecular reaction, the difference observed in the two rate constants, k_{intra} and k_{inter}, is due in large part to the fact that the standard entropy of molecularity is missing from the standard free energy of activation for the intramolecular reaction. In the case of an intermolecular reaction, the **standard entropy of molecularity**, $\Delta^{\ddagger}S^{\circ}_{molec}$, is the change in standard entropy due solely to bringing two separate reactants together into the same solvent cage in an encounter complex. The formation within a solvent shell of a complex between the two molecules requires that two or more independent molecules become the equivalent of one molecule, and this combination of the two molecules involves a considerable decrease in standard entropy. The standard entropy of molecularity is a negative number because the intrinsic entropy of two separate reactants diffusing independently through solution is greater than that of a complex within a solvent cage into which the two reactants have entered that is also diffusing through the same solution. This decrease in standard entropy is a major, unavoidable, unfavorable term in the standard free energy of activation in any bimolecular intermolecular reaction. In an intramolecular reaction, however, this decrease due to the standard entropy of molecularity does not occur, because the one molecule containing the two reactants is already in a solvent cage diffusing through solution. This fact has the effect of increasing dramatically the standard entropy of activation for the intramolecular reaction relative to the intermolecular reaction. Because the standard entropy of molecularity is missing from the standard entropy of activation for the intramolecular reaction, owing to the fact that approximation has already been accomplished synthetically, the standard entropy of activation for the intramolecular reaction is necessarily greater than that for the intermolecular reaction.

These considerations can be expressed in equations. If the same reaction with the same changes in standard enthalpy and standard entropy were occurring once the reactants have entered the solvent shell, then the standard entropy of activation, $\Delta^{\ddagger}S^{\circ}_{intra}$, of the intramolecular reaction would be related to the standard entropy of activation, $\Delta^{\ddagger}S^{\circ}_{inter}$, of the intermolecular reaction by

$$\Delta^{\ddagger}S^{\circ}_{inter} = \Delta^{\ddagger}S^{\circ}_{intra} + \Delta^{\ddagger}S^{\circ}_{molec} \qquad (3\text{–}356)$$

Consequently

$$R\ln\left(\frac{k_{intra}}{k_{inter}}\right) = \Delta^{\ddagger}S^{\circ}_{intra} - \Delta^{\ddagger}S^{\circ}_{inter} = -\Delta^{\ddagger}S^{\circ}_{molec} \qquad (3\text{–}357)$$

Because $\Delta^{\ddagger}S^{\circ}_{molec} < 0$, $k_{intra} > k_{inter}$. Once the encounter complex has formed in the intermolecular reaction, however, the achievement of the transition state is quite different from that in the intramolecular reaction.

There is a standard entropy of rotational restraint affiliated with both an intramolecular reaction and an encounter complex of two molecules in a solvent shell. The **standard entropy of rotational restraint** is the decrease in standard entropy that is required to constrain a portion of the rotational motions within a solvent cage during the formation of a transition state to achieve the proper orientation of the atoms participating directly in the reaction. In the intermolecular reaction, the two reactants in the solvent cage are unattached and free to rotate independently. In the intramolecular reaction, where the two reactants are attached together, the standard entropy of rotational restraint arises from the fact that formation of the transition state during an intramolecular reaction requires that a portion of the internal rotational entropy in the molecule be eliminated because only a fraction, often only a small fraction, of the accessible rotational isomers can participate in the reaction productively. In both cases, a decrease in entropy is required to bring

these rotational motions into the conformation required for the transition state to form.

The **standard entropy of approximation** is the decrease in standard entropy that results when two reactants that are either free in solution or in covalent association are within a solvent cage with the alignments required to form the transition state for the reaction in which they participate. It is necessarily a negative number. The magnitude of the standard entropy of approximation is the sum of the standard entropy of molecularity and the standard entropy of rotational restraint[272]

$$\Delta^{\ddagger}S^{\circ}_{\text{approx}} = \Delta^{\ddagger}S^{\circ}_{\text{molec}} + \Delta^{\ddagger}S^{\circ}_{\text{rot}} \qquad (3\text{–}358)$$

The **magnitudes of each of these terms** can be discussed in turn.

The standard entropy of molecularity is the decrease in standard entropy that should accompany the change of an intermolecular reaction to an intramolecular reaction.[272] In the specific case of a bimolecular reaction in free solution, the two independent reactants have six translational and six external rotational degrees of freedom when moving through the solution, but the one encounter complex formed by the association of the two reactants should have only three translational and three external rotational degrees of freedom. The **change in standard entropy associated with the loss of just the three translational and three external rotational degrees of freedom** during this inescapable association, calculated for the situation in which the two reactants and the transition state or product are dissolved in a solution at 25 °C with a standard state of 1 M in solutes, has been estimated[272] to be between –160 and –210 J K^{-1} mol^{-1}.

It has also been estimated[272] that –190 to –220 J K^{-1} mol^{-1} is an adequate estimate for $\Delta^{\ddagger}S^{\circ}_{\text{approx}}$, the maximum decrease in standard entropy change expected from converting an intermolecular, bimolecular reaction into an encounter complex with the proper orientations to achieve the transition state, when molarities are used as units of concentration for **standard states**. This estimate can be compared to the standard entropy change observed for a simple bimolecular reaction between two rigid molecules to form a single rigid molecule entropically resembling a transition state, such as the dimerization of cyclopentadiene in the liquid phase, for which the standard entropy change is –130 to –170 J K^{-1} mol^{-1} with the same choice of standard state. The difference between the calculated and the observed standard entropy change in the particular instance of cyclopentadiene can be accounted for by the presence of low-frequency **vibrations** in the dimer that could not be present in the two monomers because of their smaller size. If corrected volume fractions[273,274] are used as units of concentration for standard states and the partial molar volumes of the reactants were 0.1 L mol^{-1}, which is about the volume of a normal small molecule, then the range expected for standard entropy of approximation for a bimolecular reaction would be –160 to –190 J K^{-1} mol^{-1}.

As the example of the dimerization of cyclopentadiene illustrates, an intramolecular reaction, because it usually involves a larger and more flexible molecule than any of the reactants in the intermolecular reaction with which it is being compared, can never realize all of this favorable standard entropy of approximation. Major factors in decreasing the portion of the standard entropy of approximation that an intramolecular reaction will enjoy are the internal rotations about the covalent bonds within the intramolecular reactant itself. These rotations decrease the probability that the necessary juxtaposition of reactive centers will occur. For example, in the case of the sulfonium ion in Equation 3–354, if its cyclopentane is for the moment assumed to be rigid, then the rotational orientation around two carbon–carbon bonds must be appropriate if the hydroxy oxygen is to be placed adjacent to the electrophilic carbon. It has been estimated[272] from the results of thermodynamic and kinetic measurements from a number of intramolecular reactions that the standard entropy of rotational restraint decreases by about 20 J K^{-1} mol^{-1} for every bond that lies between the two atoms participating directly in the reaction and about which free rotation can occur. This value is for reactions in which a covalent bond is formed between the two participants. Nevertheless, measurements of the effect of increasing the number of bonds between donor and acceptor on the standard free energy of formation of an intramolecular hydrogen bond between a hydroxy group and an acyl oxygen in $CDCl_3$ led to the conclusion that the standard entropy of rotational restraint also decreased by about 20 J K^{-1} mol^{-1} for every bond that lies between the two atoms participating directly in the hydrogen bond and about which free rotation can occur.[275]

The effect of approximation on the rate constant for an intramolecular reaction is usually significant only when the two central atoms that participate in the reaction become involved in a **five-membered or six-membered ring** in the transition state. A

four-membered ring is usually too strained, because of the normal bond angles of commonly encountered organic molecules, to provide any favorable approximation. A seven-membered ring, if there is free rotation about every bond, has too negative a value of $\Delta^{\ddagger}S^{\circ}_{\text{rot}}$ to exhibit a $\Delta^{\ddagger}S^{\circ}_{\text{approx}}$ negative enough to have a noticeable effect on rates. For example, even in the intramolecular nucleophilic catalysis of phenyl ester hydrolysis by a carboxy group,[271,276] a series of reactions unusually prone to intramolecular catalysis, phenyl adipate would show a rate of phenolate release due to nucleophilic catalysis only 4-fold greater than that for the same reaction of phenyl acetate in 1.0 M sodium acetate. Large, rigid molecules in which the two atoms that must react are more than five covalent bonds apart yet close enough to collide are difficult to synthesize, with the relevant exception of two reactants held in the proper orientation within the active site of a molecule of protein.

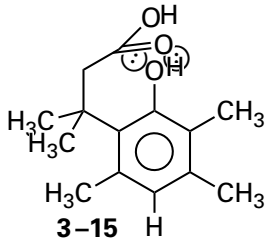
There are also **steric effects** that arise in an intramolecular reaction that are absent in the corresponding intermolecular reaction and that result from the structure of the covalent scaffold that connects the two reactive centers. These steric effects increase the standard free energy of activation and decrease the ratio between the rate constants for the intramolecular reaction and the intermolecular reaction. In the case of an enzyme, however, the two reactants are not covalently attached by a scaffold but juxtaposed by noncovalent forces, a situation in which disadvantageous steric effects may well be at a minimum as a result of natural selection.

If the magnitude of $\Delta\Delta^{\ddagger}S^{\circ}$, the actual difference between the standard entropies of activation, must be less than the magnitude of $\Delta^{\ddagger}S^{\circ}_{\text{approx}}$, then

$$T\Delta^{\ddagger}S^{\circ}_{\text{approx}} < -RT\ln\left(\frac{k_{\text{intra}}}{k_{\text{inter}}}\right) - \Delta\Delta^{\ddagger}H^{\circ} \qquad (3\text{–}359)$$

where k_{intra} and k_{inter} are the intramolecular and intermolecular rate constants. If the differences in the actual standard enthalpies of activation, $\Delta\Delta^{\ddagger}H^{\circ}$, are assumed to be zero, for the sake of argument, then the experimentally estimated **standard entropy of approximation is always an upper limit for the actual standard entropy of approximation**.

At least **three points can be drawn from the foregoing exercise**. First, the largest intramolecular increases in rate yet measured—with the educational exceptions of cases involving severe enthalpic,[277,278] compressive,[279] steric effects in the transition states engendered by methyl groups, such as during the intramolecular lactonization of



3–15

are of a magnitude significantly less than that expected simply for the transformation of an intermolecular reaction into an intramolecular reaction. Second, the larger the number of bonds about which rotation can occur between the atoms that must collide during an intramolecular reaction, the smaller will be the decrease in standard free energy of activation when an intermolecular reaction becomes an intramolecular reaction. Third, the maximum decrease in the standard free energy of activation to be expected when a bimolecular, intermolecular reaction is turned into a unimolecular, intramolecular reaction is –60 kJ mol^{-1} at 25 °C, which would produce a rate enhancement of 10^{10} M.

Both entropy of molecularity and entropy of rotational restraint are major contributors to the acceleration achieved by an enzyme.

The best way to understand the **effect of the standard entropy of molecularity on the rate of an enzymatic reaction** is to consider the equilibrium constant for formation of the encounter complex in a bimolecular reaction. If the standard entropy of molecularity[272] is assumed to be –180 J K^{-1} mol^{-1} and if the enthalpy change for formation of an encounter complex is ignored for the moment, then the equilibrium constant of association for formation of an encounter complex should be 10^{-9} M^{-1}. The rate constant for dissociation of an encounter complex should the quotient of the rate constant for its formation and its equilibrium constant of association. If the encounter-controlled rate constant for the collision of two reactants is 10^{10} M^{-1} s^{-1}, then the rate of dissociation for an encounter complex, the formation of which involves no change in standard enthalpy, should be 10^{19} s^{-1}, an unimaginably rapid rate. The reason that so few reactions are encounter-controlled is that an encounter complex has a vanishingly small lifetime. The few encounter complexes that have been observed directly

are charge-transfer complexes,[1391] which have significant standard enthalpies of formation. The fact that most encounter complexes have such short lifetimes is also why termolecular rates usually, if not always, involve preassociation of two of the reactants. The encounter complex between two previously unassociated reactants does not exist long enough for a third reactant to collide. The lifetime of a complex between an enzyme and its substrates, however, is on the order of milliseconds to seconds. Catalytic groups on amino acids and prosthetic groups are also assembled in this complex automatically so that, in the abstract, the complex is of an order greater than termolecular. Consequently, from the standpoint of entropy of molecularity, the acceleration achieved by an enzyme should be greater than what is observed.

The best way to consider the **effect of standard entropy of rotational restraint on the rate of an enzymatic reaction** is to consider what occurs in an encounter complex in a nonenzymatic reaction. For a reaction to occur in an encounter complex, the reactants themselves and the sites of reaction within those reactants must rotate from their random orientations in the initial encounter complex to the orientations necessary to accomplish the reaction. In almost every encounter, there is simply not enough time for this to occur. In the complex between an enzyme and its catalytic groups and substrates, as revealed by crystallography, the proper orientations of substrates and catalytic groups required for reaction are achieved by the simple act of association of the substrates with the active site, because the complex is designed to grasp the substrates in the proper orientation. Consequently, from the standpoint of standard entropy of rotational restraint, the acceleration achieved by an enzyme is not in the least surprising.

If the reaction catalyzed by an enzyme involves two or more reactants, as almost all enzymatic reactions do when catalytic acid–bases are included, then the standard entropy of approximation realized as the reactants associate with the active site decreases the intrinsic standard entropy of the reactants and brings the standard free energy of the reactants closer to that of the consecutive transition states for the reaction.[280] As a result, it is misleading to compare the catalytic constant of an enzymatic reaction and the rate constant of the respective intermolecular reaction, in spite of the apparently amazing aspects of the comparison. If the comparison were to be a valid one, then the change in standard free energy attributable to this standard entropy of approximation would have to be accounted for to obtain the **difference in the standard free energy of activation, $\Delta\Delta^{\ddagger}G^{\circ}$, that the active site is able to achieve by strategies other than simply juxtaposing the two reactants and the catalytic groups in the proper orientation**. If the apparent difference in standard free energy of activation, $\Delta\Delta^{\ddagger}G^{\circ}_{\text{app}}$, is that calculated from the difference between the rates of the uncatalyzed and enzymatically catalyzed reactions

$$-RT\ln\left(\frac{k_0}{k_{\text{uncat}}}\right) = \Delta\Delta^{\ddagger}G^{\circ}_{\text{app}} \tag{3–360}$$

and

$$\Delta\Delta^{\ddagger}G^{\circ} - \Delta\Delta^{\ddagger}G^{\circ}_{\text{approx}} = \Delta\Delta^{\ddagger}G^{\circ}_{\text{app}} \tag{3–361}$$

then

$$\Delta\Delta^{\ddagger}G^{\circ} = \Delta\Delta^{\ddagger}G^{\circ}_{\text{app}} - T\Delta^{\ddagger}S^{\circ}_{\text{approx}} \tag{3–362}$$

The conclusion from this equation is that the assistance that an active site provides to catalyze the reaction once the reactants are bound is far less than one might assume simply from comparing the rate of the uncatalyzed reaction to that of the enzymatically catalyzed reaction.

Enzymes usually **hold their substrates within the active site in a remarkably firm grip** that orients them rigidly and freezes internal rotation. There is experimental evidence supporting the conclusion that enzymatic active sites are able to hold substrates so tightly as to achieve alignments that are fixed in orientation to within 10 pm.[281] As a result of such a firm grip, rotational degrees of freedom within the substrates themselves, which would detrimentally increase the entropy of approximation accomplished by the enzyme, are inaccessible, just as rotational degrees of freedom for the side chains of amino acids in the interior of a molecule of protein are usually inaccessible. Consequently, an enzyme, in theory, should be able to realize the full acceleration in rate available in the standard entropy of approximation simply by binding its reactants.

The **theoretical acceleration expected from simply bringing the two reactants in a bimolecular reaction together on an active site** and holding them tightly in the proper orientation is a factor of

10^{10} M if, as is usually the case, the rate of the bimolecular reaction is expressed in units of molar^{-1} second^{-1} and the standard entropy of approximation is –200 J K^{-1} mol^{-1} with this standard state. In addition, the active sites of enzymes gather together catalytic side chains of their amino acids to replace the freely diffusing acids and bases in an aqueous solution, and standard entropies of approximation should apply also to these catalysts. Consequently, the question seems to be why the increases in rate are not larger. When it is examined from the other direction, this question becomes "Why are reactions in solution so slow?" The answer to this question seems far more obvious, but it is the same question.

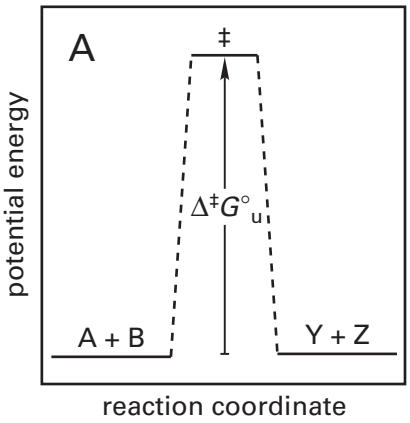
The almost exclusive contributor to the acceleration in rate accomplished by an enzyme is its ability to assemble reactants, prosthetic groups, and catalytic acids and bases within its active site firmly in the proper orientation. Consequently, the question of acceleration becomes moot. It follows that an active site, to the best of its abilities, must avoid hindering the reaction. The importance of this conclusion, which has been intentionally discussed before any other conclusions about an active site, cannot be overstated. There are, however, other strategies beyond approximation that can be employed and other requirements that must be satisfied by an active site to achieve effective catalysis.

The only observation that seems to contradict this obvious conclusion is the puzzling fact that the decrease in standard free energy of activation achieved by an enzyme results mainly from an apparent decrease in the standard enthalpy of activation for the reaction.[282,283] This apparent contradiction probably results from the fact that increases in entropy resulting from changes in solvation accompanying the association of reactants mask the entropy of approximation. The significant increase in entropy accompanying the hydrophobic effect that drives the association of reactants and that must mask the entropy of approximation is probably the most important contributor to the increase in entropy resulting from changes in solvation.

The standard entropy of approximation is overcome during the association of reactants with the active site. This decrease in the standard entropy of the substrates, which is caused by the disappearance of their respective translational and external rotational degrees of freedom relative to each other, represents an increase in intrinsic standard free energy that is paid for by favorable noncovalent interactions between each reactant and the active site. The consequent elimination of the standard entropy of approximation brings the standard free energies of the reactants closer to the standard free energies of the successive transition states through which the enzymatic reaction passes once the reactants have been assembled. For such a strategy to work, the associations between the enzyme and the reactants must be fast enough that they do not become excessively rate-affecting,* or even rate-limiting, even though a considerable decrease in translational and rotational entropy is occurring during these associations. Consequently, the concentrations of the reactants in the cytoplasm and their bimolecular rate constants of association must be high enough to prevent their associations from being close to rate-limiting. The association rate constants between active sites and substrates are usually quite large [$(0.01–10) \times 10^8$ M^{-1} s^{-1}],[263] and they often approach values expected for the encounter-controlled limit.[284] Such rapid rates of association, achieved by natural selection, are actually more remarkable than the enhanced rates of the chemical reactions once the substrates are bound.

These considerations can be summarized diagrammatically (Figure 3–26). In the absence of the enzyme (Figure 3–26A), reactant A collides with reactant B to produce a transition state of high standard free energy relative to the standard free energy of the reactants. The standard free energy of the transition state is higher than the standard free energy of the separated reactants by the standard free energy of activation of the uncatalyzed reaction, $\Delta^{\ddagger}G^{\circ}_{u}$, necessarily a positive number. If the enzyme were catalyzing the reaction only by approximation, the two steps encompassing association of the reactants, both proceeding rapidly with small standard free energies of activation, would bring the reactants into juxtaposition and proper alignment. The standard free energy of activation for the chemical transformation on the active site of the

*Although the term "rate-limiting step" has been unambiguously defined,[79] there is no accepted term for an elementary rate constant that simply appears in the kinetic equation governing a particular reaction and thus affects the rate of the reaction rather than being rate-limiting. From here on in this text, the term "**rate-affecting step**" will be used to describe any step in a kinetic mechanism the elementary rate constant of which appears in the equation governing the rate of a reaction other than the rate-limiting rate constant for that reaction. The terms "rate-controlling" and "rate-determining" have been used in various contexts, but at the present time these terms are considered to be synonymous with the term "rate-limiting", and hence cannot be used to convey what is here defined as "rate-affecting".



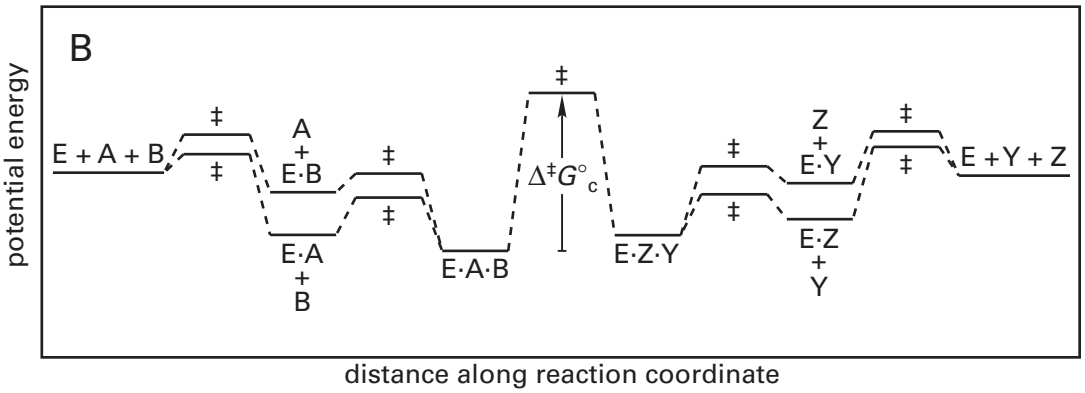


Figure 3–26: Diagrammatic representations of the difference in standard free energy of activation between a simple single-step reaction and the steps involved when that reaction occurs at the active site of an enzyme. **(A)** The steps involved in the reaction at the active site of the enzyme are the binding of the first reactant to the active site followed by the binding of the second to form the ternary complex, E·A·B; the conversion ($\Delta^{\ddagger}G^{\circ}_{c}$) of the ternary complex with the reactants and the active site into the ternary complex with the products and the active site, E·Z·Y; and the dissociation of the first product from the active site followed by the dissociation of the second. Each step has its own transition state, indicated by ‡. **(B)** In the respective bimolecular reaction uncatalyzed by the enzyme, the reactants pass through only one transition state ($\Delta^{\ddagger}G^{\circ}_{u}$) rather than the five transition states for the enzymatically catalyzed reaction.

enzyme, $\Delta^{\ddagger}G^{\circ}_{c}$, again a positive number, would be decreased relative to that of the bimolecular reaction (Figure 3-26B) because of the consequent elimination of the standard entropy of approximation, necessarily a negative number

$$\Delta^{\ddagger}G^{\circ}_{c} = \Delta^{\ddagger}G^{\circ}_{u} + T\Delta^{\ddagger}S^{\circ}_{approx} \qquad (3–363)$$

This decrease in the standard free energy of activation results from the fact that the standard chemical potential of the reactants has increased because a certain fraction of the standard free energy of noncovalent interaction between reactant and active site has been expended to compensate for loss of the translational and rotational entropy of the free reactants.

Weakening the grip of the active site on its reactants can cause decreases in the catalytic constant. The active site of an enzyme has evolved to associate with its specific substrates. The result of this evolution by natural selection is that it usually holds those particular molecules firmly. This firm grip permits the active site to perform the advantageous orientations of substrates, prosthetic groups, and catalytic side chains to enforce the maximum entropy of approximation.

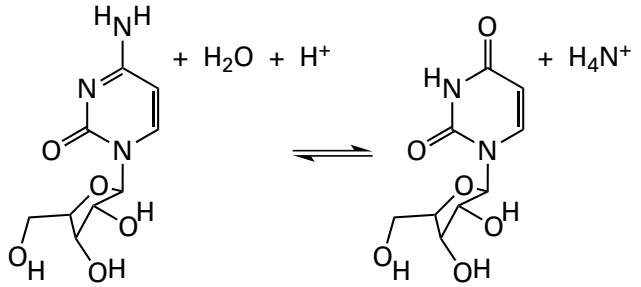
Altering the structures of the reactants at locations distant from the atoms at which the reaction occurs can cause the rate of the enzymatic reaction to decrease. For example, if acetyl-SCoA instead of acetoacetyl-SCoA is used as a substrate for porcine 3-oxoacid CoA-transferase

$$\text{3-oxoacyl-SCoA} + \text{succinate} + H^{+} \rightleftharpoons \text{3-oxocarboxylic acid} + \text{succinyl-SCoA} \qquad (3–364)$$

the specificity constant for the enzymatic reaction decreases by a factor of 600. It is easy to imagine that the active site would have a difficult time gripping an acetyl group tightly when it has evolved to grip a 3-oxoacyl group. In addition, the enzyme shows no detectable activity with either acetoacetylpantetheine or *S*-acetoacetyl-*N*-acetylcysteamine, each of which contains only a proximal fragment of coenzyme A. One possible explanation for this latter result is that the active site must extend its grip over the

entire acetoacetyl-SCoA molecule to align the substrate properly in the active site.[285] In the crystallographic molecular model of coenzyme A bound to the active site of the enzyme, the majority of the noncovalent interactions with coenzyme A are to the adenosine diphosphophosphate group and a portion of the pantetheinyl group,[286] a fact that is consistent with this conclusion.

Cytidine deaminase



3–16

(3–365)

catalyzes a reaction that occurs entirely within the pyrimidine base of its reactant, yet the removal of the 3′-hydroxy group from the ribosyl group of cytidine (**3–16**) decreases the catalytic constant of the enzyme from *E. coli*[287] by a factor of 370. The most reasonable explanation for this result is that removal of the 3′-hydroxy group deteriorates the fit between the active site and the reactant, loosens the grip of the active site on the reactant, and decreases the ability of the active site to orient the reactant productively within the complex.

These decreases in catalytic constant can be expressed as increases in the entropy of approximation. For example, when the nucleotide portion of coenzyme A is removed, the decrease in the catalytic constant of porcine 3-oxoacid CoA-transferase that results[288] is equivalent to an increase in the entropy of approximation achieved by the enzyme of +90 J K^{-1} mol^{-1} (Equation 3–357).

The active site does not have to fit the reactant tightly to observe changes in the turnover of an enzyme that result from alterations in the structure of the reactant distant from the site of catalysis. Thermolysin is an endopeptidase from *Bacillus thermoproteolyticus* that is required to hydrolyze peptide bonds between a glycine and a leucine in a broad array of different sequences. Consequently, it cannot fit its reactants too tightly beyond the peptide bond itself. Nevertheless, when a series of peptides was synthesized in which the substituents on either side of a central glycylleucine peptide bond were altered, the catalytic constant for hydrolysis of that glycylleucine peptide bond by the enzyme varied by a factor of 1000 while the K_m varied only by a factor of 21 (Table 3–6). If the three peptides with the smallest K_m are removed from consideration, K_m varies by only a factor of 2 while the catalytic constant still varies by a factor of 1000.[289] These observations are consistent with the conclusion that each of these distant alterations had its own particular effect on the rigidity, geometry, and orientation of the reactant in the immediate vicinity of the peptide bond being cleaved by the enzyme, and each of these effects was registered mainly in the catalytic constant.

Table 3-6: Effect of Changes in the Structure of the Reactant on the Kinetic Parameters[289] of Thermolysin[a]

peptide[b]	K_m[c] (mM)	k_0[d] (s^{-1})
Cbz[e]-Gly-Leu-D-Ala	16	5
Cbz-Gly-Leu-Gly-D-Ala	13	25

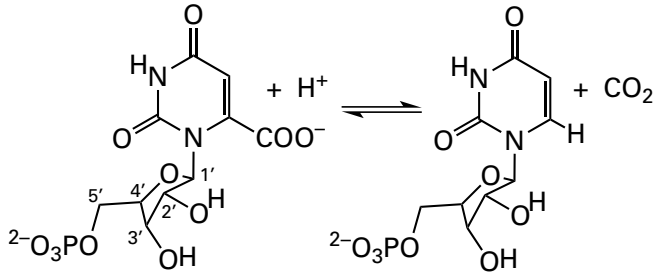
[c]From linear fits to double reciprocals. [d]$V[E]_t^{-1}$. [e]Cbz, benzyloxycarbonyl, which was historically given the name carbobenzoxy.

Mutating side chains of amino acids in the active site that are known to form contacts with a reactant distant from the atoms participating in the reaction also can decrease the catalytic constant of an enzyme.[290] For example, Aspartate 296 in murine adenosine deaminase forms a hydrogen bond with

nitrogen 7 of an analogue of adenosine in a crystallographic molecular model of the complex of the analogue with the enzyme, and presumably with nitrogen 7 of adenosine in the normal reaction of the enzyme.[291] When Aspartate 296 is mutated to alanine, the K_m for the enzymatic reaction increases by only 10-fold while the catalytic constant decreases more than 1000-fold. Aspartate 37 of orotidine-5′-phosphate decarboxylase

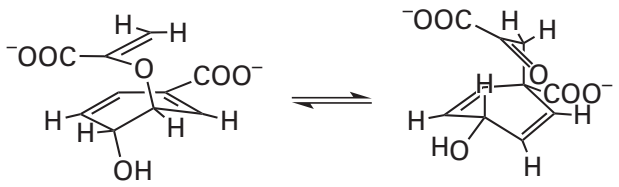


3–17

(3–366)

from *S. cerevisiae*, which forms a hydrogen bond to the 3′-hydroxy group of the 5′-phosphoribosyl group of orotidine 5′-phosphate (**3–17**) when it is in the active site and which is even farther from the location within the active site at which catalysis occurs, is mutated to alanine, the catalytic constant of the enzyme[292] decreases by a factor of 50. When Glutamate 91 of cytidine deaminase from *E. coli*, which forms a hydrogen bond to the 3′-hydroxy group group of cytidine (**3–16**) when it is in the active site, is mutated to alanine, the catalytic constant of the enzyme[287] decreases by a factor of 30. When Arginine 235 of orotidine-5′-phosphate decarboxylase from *S. cerevisiae*, which forms two hydrogen bonds to the 5′-phospho group of orotidine 5′-phosphate, is mutated to alanine, the catalytic constant of the enzyme[293] decreases by a factor of 100. Often the effect of such a mutation at a location distant from the site of catalysis is expressed exclusively as a decrease in catalytic constant.[294] Again, these decreases in catalytic constant can be explained as the result of a loosening of the grip of the enzyme on its reactant caused by the mutation.

The ability of an enzyme to hold its reactant in a firm grip and orient the reactants is often used to prevent undesirable side reactions from occurring. In this way, the reaction is directed exclusively to the desired product. For example, when the reaction catalyzed by chorismate mutase

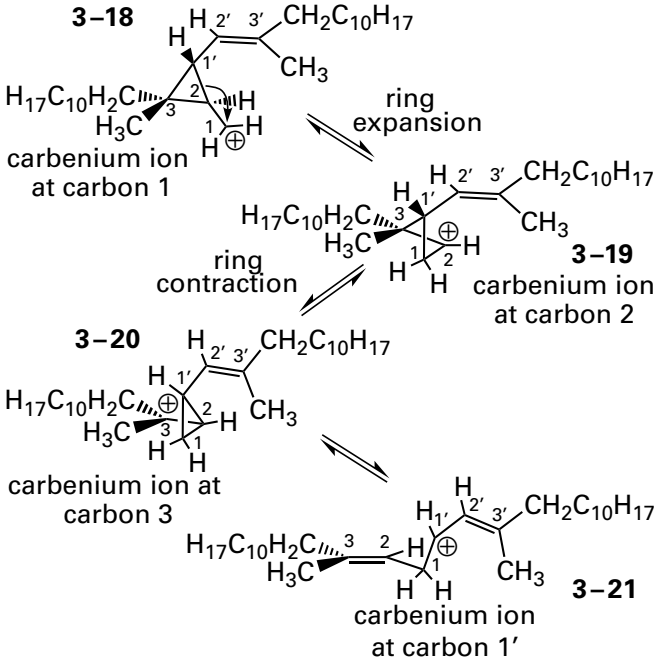


chorismate prephenate

(3–367)

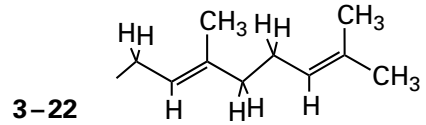
is performed nonenzymatically in a solvent of 2:1 methanol/water, 33% of the product is 4-hydroxybenzoic acid and pyruvate.[295] In both this elimination and the desired electrocyclic rearrangement, there is considerable cleavage of the carbon–oxygen bond, but in the former reaction, no formation of the carbon–carbon bond occurs. One way in which the enzyme prevents the elimination is to position carbon 2 of the 1-carboxyvinyl group immediately adjacent to carbon 1 of chorismate to increase the yield of the formation of this bond.

The intermediate (+)-presqualene diphosphate is formed on the active site of squalene synthase from the allyl carbenium ion that results from the dissociation of diphosphate from one molecule of (2*E*,6*E*)-farnesyl diphosphate (see Figure 1–26) and that then adds to the double bond between carbons 2 and 3 of another (2*E*,6*E*)-farnesyl diphosphate in an electrophilic addition that produces a cyclopropyl group. The carbenium ion **3–18**, resulting from the dissociation of (+)-presqualene diphosphate, is converted to squalene by squalene synthase through the rearrangement of the successive carbenium ions



(3–368)

where the numbering of the intermediates is that of the two constituent farnesyl groups and $C_{10}H_{17}$ is a geranyl group



When initial carbenium ion **3–18** is produced nonenzymatically in aqueous solution,[296] only 0.02% of the product results from the desired rearrangement to carbenium ion **3–19** because the carbenium ion **3–18** strongly prefers to rearrange (99%) to a carbenium ion at carbon 1′ in conjugation with the exocyclic double bond between carbons 2′ and 3′ or rearrange (1%) to a tertiary carbenium ion at carbon 3, the more saturated position in the cyclopropyl group. In the former rearrangement, the electrons in the bond between carbons 1′ and 2 swing away from carbon 1′ to form a double bond between carbons 1 and 2 rather than participating in a ring expansion, and in the latter rearrangement, the electrons in the bond between carbons 3 and 2 swing away from carbon 3 also to form a double bond between carbons 1 and 2. In fact, on the active site of botryococcene synthase from *Botryococcus braunii*, an enzyme related (45% identity; 1.3 gap percent) to squalene synthase, carbenium ion **3–18** does rearrange by the former, most favorable route on the way to its normal product, botryococcene.[297] Somehow the active site of squalene synthase has to prevent these unfavorable rearrangements from occurring.

The favored rearrangement in solution to the carbenium ion at carbon 1′ (99% yield) would be a rather devastating side reaction in the sequence of rearrangements (Equation 3–368) that must be catalyzed by the active site of squalene synthase during its production of squalene. This side reaction can be prevented by holding the π system of the exocyclic carbon–carbon bond between carbons 2′ and 3′ orthogonal to the *p* orbital of the potential carbenium ion at carbon 1′ to prevent its conjugation. In the crystallographic molecular model of the complex between (+)-presqualene diphosphate and the active site of human squalene synthase in which Tyrosine 73 was mutated to an alanine to decrease the enzymatic activity and Mn^{2+} was used as the required metallic dication to produce the proper conformation of the (+)-presqualene diphosphate,[298] the bond between carbons 1′ and 2 of the cyclopropyl ring is almost parallel to the plane of the carbon–carbon double bond between carbons 2′ and 3′ (23° out of plane). Consequently, the π system of this exocyclic double bond should end up almost fully orthogonal to the *p* orbital of a carbenium ion at carbon 1′ were the bond between carbons 1′ and 2 to dissociate from carbon 1′ rather than from carbon 2. The ability of the enzyme to grip its reactants tightly permits it to enforce this orientation and prevent the unfortunate rearrangement.

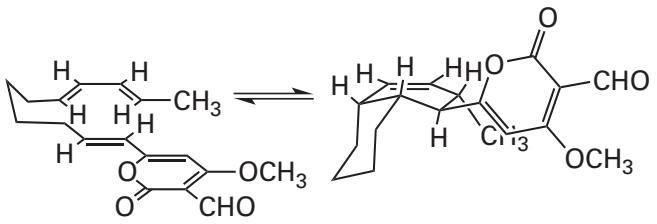
In the crystallographic molecular model, however, between (+)-presqualene diphosphate and 4,4′-diapophytoene synthase from *Staphylococcus aureus* in which Tyrosine 129 has been mutated to alanine to decrease its activity,[299] the bond between carbons 1′ and 2 of the cyclopropyl ring is almost perpendicular to the plane of the carbon–carbon double bond between carbons 2′ and 3′ (72° out of plane). This active site is required to perform the same rearrangements as the active site of squalene synthase (Equation 3–368). This orientation would favor the conjugation of the carbon–carbon double bond between carbons 2′ and 3′ with a developing *p* orbital of a carbenium ion at carbon 1′. Consequently this orientation significantly favors the side reaction. If this crystallographic molecular model actually replicates the normal conformation of the (+)-presqualene diphosphate in the active site, it seems hard to believe that the side reaction does not occur most of the time. The resulting allyl carbenium ion at carbon 1′, however, may well be a dead end, and eventually the proper carbenium ion at carbon 2

forms and the reaction proceeds. The allyl carbenium ion at carbon 1′ would be a dead end if the active site prevents any nucleophile from adding to it because there is no adjacent hydron that can depart to produce a stable neutral product. Nevertheless, the situation in the active site of 4,4′-diapophytoene synthase is not so clear as that in the active site of squalene synthase.

The other side reaction that is favored in solution (1% yield) and that would be detrimental to the proper reaction is the formation of the tertiary carbenium ion at carbon 3. In fact, in both crystallographic models, that for the complex of (+)-presqualene diphosphate with the active site of squalene synthase and that for the complex of (+)-presqualene diphosphate with the active site of 4,4′-diapophytoene synthase, this rearrangement seems to be favored. In both cases, the carbon–carbon bond between carbons 2 and 3 is more in-line (122° and 146°, respectively) with the carbon–oxygen bond between carbon 1 and the oxygen of the leaving diphosphate than the carbon–carbon bond between carbons 1′ and 2 (58° and 76°, respectively). If these two conformations of the (+)-presqualene diphosphate replicate the active conformation, it is hard to see how formation of the carbenium ion at carbon 3 is prevented by the active site. This rearrangement has the potential to be even more damaging because there is a hydron adjacent to this carbenium ion that can depart to give a remarkably stable side product with a double bond between carbons 3 and 1′. It would take a tight grip indeed to prevent carbon 3 from flattening to the trigonal configuration required of a carbenium ion.

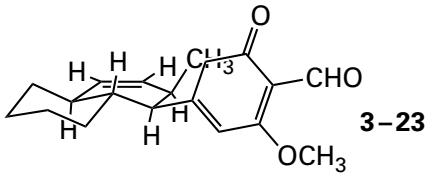
Once these difficulties are somehow surmounted, the rearrangement of carbenium ion **3–20** produces allyl carbenium ion **3–21**, so all the active site has to do is not hinder the formation of this last intermediate by ensuring that the double bond is not hindered from becoming oriented parallel to the *p* orbital of the carbenium ion.

When the cycloaddition catalyzed by prosolanapyrone-III cycloisomerase



(3–369)

is performed in the absence of the enzyme, the product from exo addition



3–23

which is the more stable isomer from the more stable transition state, predominates (87%).[300] When the purified enzyme from *Alternaria solani* catalyzes the reaction, however, enantiomerically pure solanapyrone A, resulting from endo addition (Equation 3–369), is the product.[301] This reversal of the stereochemistry performed by the enzyme results from the ability of the active site to align atoms in the reactant in such a way that only the endo transition state can form. This conclusion from the crystallographic molecular model is the most convincing evidence that the active site itself catalyzes this cycloaddition.[302]

Problem 3–23: The rate constant for the reaction between trimethylamine and phenyl acetate to produce the *N,N,N*-trimethylacetamide ion $[(CH_3)_3{}^+NCOCH_3]$ and phenoxide is 8×10^{-3} M^{-1} min^{-1} at 20 °C. The rate constant for the intramolecular aminolysis of phenyl 4-(*N,N*-dimethylamino)butyrate to yield *N,N*-dimethyl-2-oxopyrrolidinium and phenoxide is 10 min^{-1} at 20 °C.

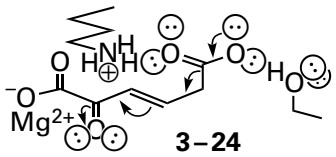
(A) Calculate the "effective molarity" of trimethylamine that would be required for the rate of the intermolecular reaction to equal the rate of the intramolecular reaction.
(B) Calculate an upper limit for $\Delta^{\ddagger}S^{\circ}_{approx}$ for the intramolecular reaction on the assumptions that the solvent for both of these reactions is water and that the standard enthalpies of activation are the same for the two reactions. First use molarity as the units for the second-order rate constant, and then use corrected volume fraction.

Strain

The examples of chorismate mutase (Equation 3–367), squalene synthase (Equation 3–368), and prosolanapyrone-III cycloisomerase (Equation 3–369) illustrate the ability of an active site to juxtapose particular atoms in a reactant to increase dramatically the probability that these locations will collide and to guarantee that the proper product results from the catalysis. To ensure that prephenate is the product of the reaction catalyzed by chorismate mutase (Equation 3–367), the distal carbon of the double bond of the *enol*pyruvyl group must collide with carbon 4 of the cyclohexadienyl group (Figure 1–30). To ensure that these two atoms are juxtaposed when the chorismate is bound in the active site, however, in addition to selecting the proper rotamer, the active site must also force the cyclohexadienyl group of chorismate to assume the conformation placing the oxygen of the *enol*pyruvyl group in an axial orientation.[303,304] The active site is constructed so that the axial conformer is the only one that can associate with it.[305,306] In this instance, the active site is sterically forcing the reactant to assume a less stable conformation. This steric enforcement is an example of the **ability of an active site to strain a substrate in the interest of catalysis**.

The equilibrium constant[307] for isomerization between the equatorial and axial conformers of the hexadienyl group in chorismate is 0.14 at 25 °C in aqueous solution. Consequently, as a result of forcing the hexadienyl group to assume the less stable conformer, an apparent acceleration of around 10-fold should be observed when the catalytic constant of the enzyme is compared to the rate constant of the uncatalyzed reaction. Between these two locations are two bonds about which full rotation can occur. Elimination of the entropy of internal rotation about these two bonds would translate into a modest 100-fold increase in the rate of the reaction.[272] The catalytic constant of the enzymatically catalyzed reaction is 2×10^6 times that of the nonenzymatic reaction in water at pH 7.5 and 37 °C. Together, freezing of internal rotations and enforcement of the axial conformation by the configuration of the active site should provide an acceleration of 10^3. This acceleration, however, can be achieved by the active site of the enzyme only if it is able to enforce both of these restrictions with high efficiency. If not, the full acceleration cannot be realized. If the full acceleration is actually achieved, a factor of only 10^3 remains unaccounted for.

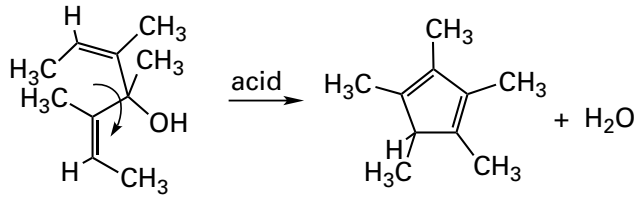
To catalyze the decarboxylation of the carboxylato group at carbon 6 of (3*E*)-2-oxohex-3-enedioate, the active site of 2-oxo-3-hexenedioate decarboxylase has to hold the bond between carbons 5 and 6 parallel to the π molecular orbital system encompassing the carboxylato group at carbon 1, the carbonyl group at carbon 2, and the double bond between carbons 3 and 4



3–24

so that this π molecular orbital system can withdraw electron density from it. In the crystallographic molecular model of the active site of the enzyme from *P. putida* occupied by 2-oxohexanedioate,[308] an analogue of the substrate, 2-oxohex-3-enedioate, both steric effects and hydrogen bonds to a lysine and a serine perform this orientation with precision and rigidity.

The ability to constrain a reactant in a conformation more similar to the transition state than the ground state is not an exclusive property of enzymes. There are also **synthetic examples of catalysts** that are able to do so. For example, there is a tetrahedral complex of four gallium atoms held at the vertices of a tetrahedron by six *N*,*N*′-bis(2,3-dihydroxybenzoyl)-1,5-diaminonaphthalenes, which form the limbs of the tetrahedron. This complex has a sizeable enclosed, nonpolar cavity at its center, and it can catalyze the cyclization



(3–370)

that results from rearrangement of a carbenium ion formed when the hydronated hydroxy group on carbon 4 of the reactant leaves. The bond that forms to produce the cyclohexadiene is a bond between carbons 2 and 6 of the diene that is the reactant. Consequently, there have to be rotations around the bonds between carbons 4 and 5 and between carbons 3 and 4 to bring carbons 2 and 6 close enough together for the bond to form. In addition, because the two double bonds in the reactant are both cis, the methyl groups of carbons 1 and 7 run into each other as carbons 2 and 6 approach each other and sterically hinder the molecule from assuming the proper conformation for the transition state.

The association of the reactant with the complex of the four galliums and the six *N,N′*-bis(2,3-dihydroxybenzoyl)-1,5-diaminonaphthalenes increases the rate of the reaction significantly.[309] One explanation for this observation is that the reactant binds within the nonpolar cavity in the catalyst and can fit in the cavity only when it has assumed the compact, globular conformation that brings carbons 2 and 6 next to each other on the way to the transition state. The catalyzed reaction has the same steady-state kinetics as an enzymatic reaction with a specificity constant of 0.4 M^{-1} s^{-1} and a catalytic constant of 0.016 s^{-1}. Because the rate constant for the uncatalyzed reaction is 8×10^{-9} s^{-1}, the acceleration observed is 2×10^6 or a decrease in $\Delta^{\ddagger}G^{\circ}$ of –36 kJ M^{-1}. This decrease is much larger than that expected for the freezing of two rotational degrees of freedom and suggests that some compression by the cavity of the compact conformer in the direction of the transition state is also occurring.

If, during the association of substrates with the active site on an enzyme, they are not only oriented properly to achieve a configuration appropriate to the transition state but also **contorted physically by the active site** of the enzyme into that configuration, then **catalysis by strain** results. In this situation, an additional fraction of the standard free energy of dissociation, beyond that used to overcome the entropy of approximation, is used to provide the energy necessary to contort the substrates toward the transition state. Catalysis by strain does not account for a large portion of the decrease in standard free energy of activation accomplished by an active site,[310] but it can contribute significantly to the decrease.

Catalysis by strain was originally defined in detail by Pauling in 1948 in the following credo:[311]

> I believe that an enzyme has a structure closely similar to that found for antibodies, but with one important difference, namely, that the surface configuration of the enzyme is not so closely contemporary [sic] to its specific substrate as is that of an antibody to its homologous antigen, but is instead complementary to an unstable molecule with only transient existence—namely, the "activated complex" [transition state] for the reaction that is catalyzed by the enzyme. The mode of action of an enzyme would then be the following: the enzyme would show a small power of attraction for the substrate molecule or molecules, which would become attached to it in its active surface region [its active site]. This substrate molecule, or these molecules, would then be strained by the forces of attraction to the enzyme, which would tend to deform it into the configuration of the activated complex, for which the power of attraction by the enzyme is the greatest. The activated complex would then, under the influence of ordinary thermal agitation, either reassume the configuration corresponding to the reactants, or assume the configuration corresponding to the products. The assumption made above that the enzyme has a configuration complementary to the activated complex, and accordingly has the strongest power of attraction for the activated complex, means that the activation energy for the reaction is less in the presence of the enzyme that in its absence, and accordingly that the reaction would be speeded up by the enzyme. My colleague Professor Carl Niemann and I are carrying out experiments on inhibition of enzyme activity designed to test this postulate, by the search for inhibitors that have a greater power of combination with the enzyme than have the substrate molecules themselves.

The crystallographic molecular models of lysozyme and other glycosidases provided early experimental evidence consistent with this hypothesis. Lysozyme is a glycosidase that normally catalyzes

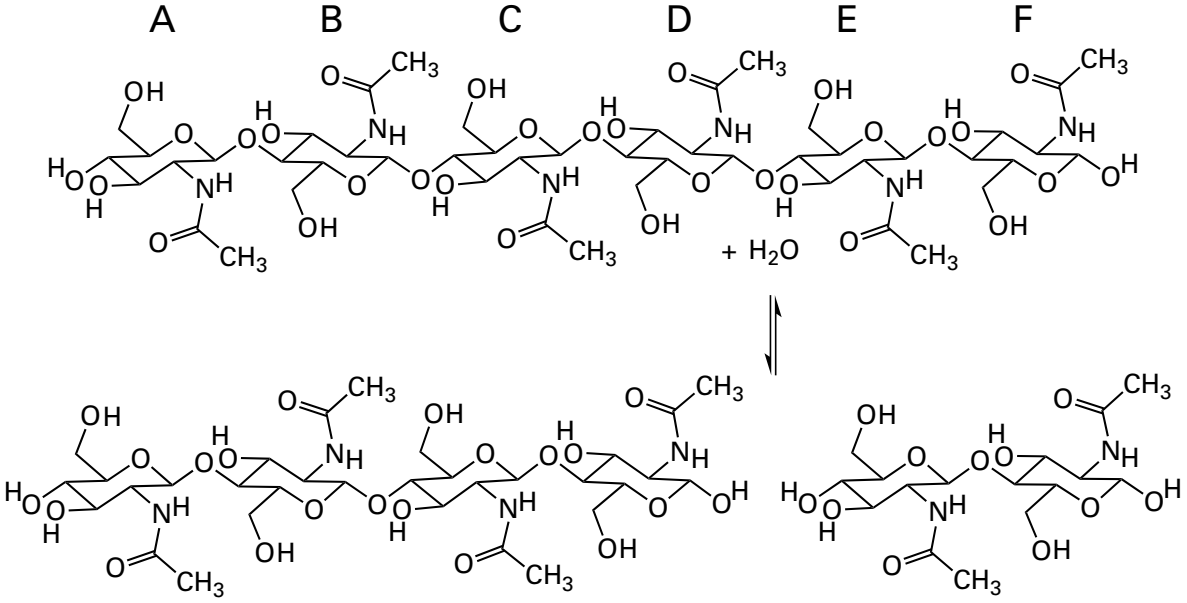


Figure 3–27: Hydrolysis of (β1,4)-hexa-*N*-acetylglucosaminopyranose to a molecule of (β1,4)-di-*N*-acetylglucosaminopyranose and a molecule of (β1,4)-tetra-*N*-acetylglucosaminopyranose, a reaction catalyzed by lysozyme from *G. gallus*.[312]

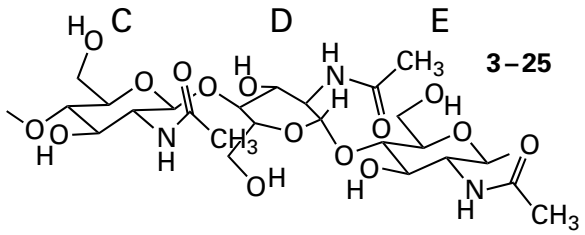
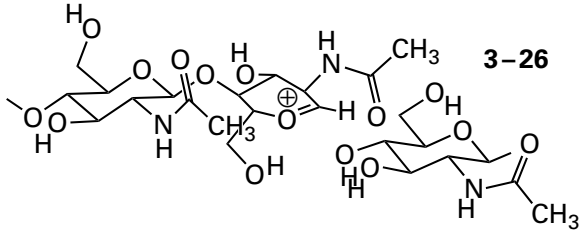
the hydrolysis of polysaccharides in bacterial outer membranes. It also catalyzes the hydrolysis of the hexasaccharide (β1,4)-hexa-*N*-acetylglucosaminopyranose (Figure 3–27).[312] Within the hexasaccharide, the cleavage occurs at monosaccharide D between the fourth and the fifth *N*-acetyl-D-glucosamines.[313] When lysozyme from *G. gallus* was crystallized with the trisaccharide (β1,4)-tri-*N*-acetylglucosaminopyranose occupying the active site and a map of difference electron density was computed, a crystallographic molecular model incorporating reasonable hydrogen bonds and lack of steric hindrance could be constructed for the complex between the trisaccharide and three subsites (A, B, and C) in the active site.[314] Three additional molecular models of the proper monosaccharides were added to the reducing end of the molecular model of the trisaccharide in the complex to produce the hexasaccharide. These last three monosaccharides could be placed in subsites D, E, and F in the active site. They could be linked in a similar array of hydrogen bonds and inserted without steric clashes[315] in these subsites only if the entire molecular model of the hexa-*N*-acetylglucosaminopyranose was **contorted from the all-chair conformation** shown in Figure 3–27. The contortion required to fit the last three monosaccharides into the active site required a flattening of monosaccharide D into the sofa configuration in which carbon 4, carbon 5, oxygen 5, carbon 1, and carbon 2 of monosaccharide D are all in the same plane[314,316]



3–25

On the basis of this rather primitive model-building, the crystallographers proposed that one way lysozyme catalyzes the hydrolysis is to use the energy of its association to contort the monosaccharide D into a form that accommodates the planar oxocarbenium ion that would be an intermediate in this acetal hydrolysis.[317]



3–26

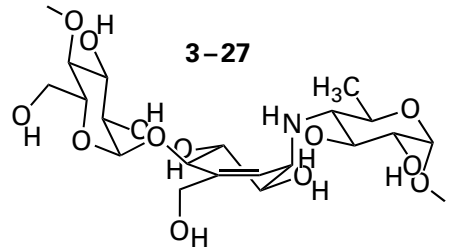
The most stable conformation for this oxocarbenium ion is one in which carbon 5, oxygen 5, carbon 1, and carbon 2 of the pyranose are all in the same plane. Such an oxocarbenium ion can be an intermediate of high energy in the hydrolysis of acetals and ketals. By the **Hammond postulate**,[318] the transition state between a reactant or reactants and

an intermediate of high energy should resemble the intermediate more closely than the reactant or reactants. Therefore, the conclusion was reached that lysozyme was catalyzing the reaction by **contorting the substrate in the direction of the transition state**.

Since this original conjecture, several crystallographic molecular models of complexes between lysozyme from *G. gallus* and various oligosaccharides have been reported in which the monosaccharide at the reducing end is actually located in the D site.[312,319] In each of these models, the monosaccharide in the D site has been distorted by the active site into a conformation in which carbon 5, oxygen 5, carbon 1, and carbon 2 are all in almost the same plane (Figure 3–28)[319] as required for the most stable conformation of oxocarbenium ion **3–26**.

A distortion of a monosaccharide at the reducing end of an oligosaccharide in the crystallographic molecular model of another endoglycosidase, cellulase from *Acetivibrio thermocellus,* also puts carbon 5, oxygen 5, carbon 1, and carbon 2 of the monosaccharide in the hydrolytic location in the same plane,[320] and an analogous distortion to achieve planarity also occurs in the crystallographic molecular model of a complex between the active site of exo-α-sialidase from *S. typhimurium* and 4-acetamido-2,4-dideoxy-D-*glycero*-D-*galacto*-α-octopyranosylphosphonic acid, an analogue of the *N*-acetyl-D-neuraminic acid in an α-glycosidic linkage in a sialylglycoside that is normally a substrate for the enzyme.[321] In several other crystallographic molecular models of endoglycosidases, however, the distortions observed do not put these four atoms in the same plane.[322,323]

When a decasaccharide that has (3*S*,4*S*,5*S*,6*R*)-3-amino-4,5,6-hydroxy-1-(hydroxymethyl)cyclohexenyl group

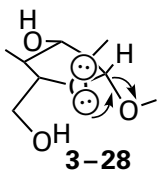


3–27

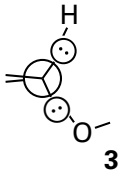
at two internal positions associates with a bacterial α-amylase, the planar carbon–carbon double bond in one of these rigid rings, in which four of the carbons are in the same plane, ends up, presumably by design, at the location in the active site at which hydrolysis of the oligosaccharide is usually catalyzed.[324]

It may[317,325,326] or may not[327] be the case that there is an oxocarbenium ion as an intermediate in the reaction catalyzed by these enzymes. One of the arguments routinely used to dismiss the existence of a glycosyl oxocarbenium ion as an intermediate in these active sites is that the lifetime of a glycosyl oxocarbenium ion in aqueous solution[328] has been estimated to be only 10^{-12} s. What is usually omitted in these dismissals is the statement that the carbenium ion has "short but significant lifetime in aqueous solution".[328] In other words, it is not that glycosyl oxocarbenium ion cannot exist but only that its existence is short. It was also emphasized when the estimate of the lifetime was presented that the lifetime is short in aqueous solution because when it is formed, there is always a molecule of water immediately adjacent to it with which it almost immediately reacts. In the active site of an enzyme, however, there would be no molecule of water adjacent to an oxocarbenium ion, so its lifetime could be prolonged indefinitely. None of these arguments either prove or disprove the existence of a glycosyl oxocarbenium ion as an intermediate in these enzymatic nucleophilic substitutions. Nevertheless, the alternative transition state in which a concerted nucleophilic substitution by a carboxylato group in the active site on the carbonyl carbon of the glycosyl group still requires the coplanarity of carbon 5, oxygen 5, carbon 1, and carbon 2.

Coincidently, the act of distorting the pyranose or the furanose of a glycoside into a planar conformation around an incipient oxocarbenium ion (Figure 3–28) performed by the active site of a glycosidase or a glycosylase also causes the cis lone pair of electrons on the oxygen to become parallel to the σ bond of the leaving group



3–28



3–29

and consequently increases the overlap between the two. This overlap provides **push ejecting the leaving group**.[329,330]

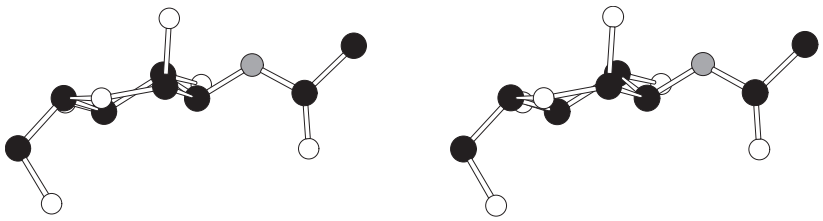


Figure 3–28: Crystallographic molecular model of the *N*-acetyl-D-glucosaminyl group at the reducing end of the tetrasaccharide (β1,4)-tetra-*N*-acetylglucosaminopyranose bound in the active site of a mutant of lysozyme from *G. gallus* in which the catalytic amino acid Aspartate 52 had been mutated to a serine.[319] Black atoms are carbons, white atoms are oxygens, and the small gray atom is a nitrogen. The mutant of lysozyme with an equimolar ratio of the hexasaccharide (β1,4)-hexa–*N*-acetylglucosaminopyranose and the enzyme was crystallized from the mixture over a period of 14 days at 16 °C. During that time, the almost inactive mutant enzyme nevertheless hydrolyzed the hexasaccharide to disaccharide and tetrasaccharide. A data set was collected from these crystals to a Bragg spacing of 0.2 nm. In the map of electron density calculated from this data set, electron density corresponding to the tetrasaccharide (β1,4)-tetra-*N*-acetylglucosaminopyranose was observed in the active site of the enzyme. A molecular model of the tetrasaccharide in the all-chair configuration was inserted into this electron density, and the entire molecular model was submitted to refinement. During the refinement, the *N*-acetylglucosaminyl group at the reducing end of the tetrasaccharide, which was located in the D subsite of the active site, gradually assumed the conformation shown in the drawing. The conformation the *N*-acetylglucosaminyl group assumed during the refinement was almost a perfect sofa conformation, in which carbons 1, 2, 4, and 5 and oxygen 5 all would have been in the same plane. The α isomer of the *N*-acetylglucosaminyl group was clearly designated by the electron density, and the oxygen of its 1-hydroxy group was axial in the final refined conformation.

Another example of an active site built to enforce a usually unstable conformation of a substrate is that of scytalone dehydratase from *Magnaporthe grisea*. From observations of the effect of site-directed mutations on the relative activities of the enzyme for three different substrates, it was concluded that the active site enforces boat conformations of each of the substrates, conformations causing the bonds to the hydroxy group that leaves as a molecule of water and the adjacent hydrogen that is removed as a hydron during the dehydration resulting from a *syn* elimination to be parallel to each other.[331]

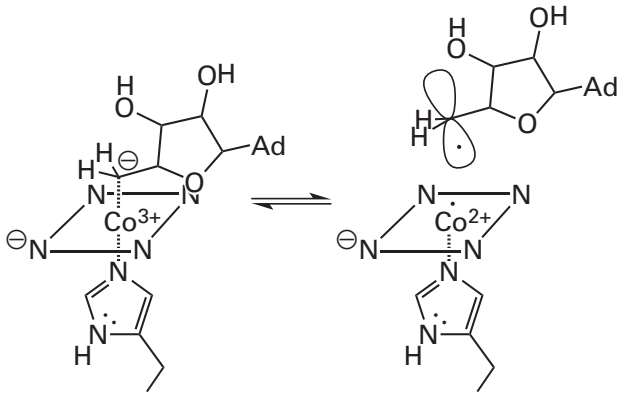
In the nucleophilic substitution catalyzed by orotate phosphoribosyltransferase

$$\begin{gathered}H^+ + \text{ orotidine 5′-phosphate } + \\ MgOPO_3PO_3^{2-} \rightleftharpoons \text{ orotate } + \\ \text{magnesium 5-phospho-}\alpha\text{-D-ribose 1-diphosphate}\end{gathered} \qquad (3\text{–}371)$$

with magnesium diphosphate as the nucleophile and orotate as the leaving group from carbon 1′ of the orotidine 5′-phosphate, the transition state is thought to be somewhere between the tight pentavalent intermediate of a concerted nucleophilic substitution and the intermediate oxocarbenium ion of a dissociative nucleophilic substitution. In either case, carbon 1′ of the intermediate is in the same plane as carbon 2′, the oxygen of the furanose ring, and the hydrogen on carbon 1′. Isotope effects on the association of [1′-^{3}H]orotidine 5′-phosphate with the active site of human orotate phosphoribosyltransferase are consistent with a distortion of this substrate by the active site as it associates that **flattens carbon 1′ in the direction of its planar conformation** in the transition state.[332]

A distortion such as the ones that occur in the active sites of chorismate mutase and lysozyme, in which **dihedral angles along covalent bonds are forcefully altered,** is one example of strain in catalysis.

Enzymatic active sites also seem to pull on covalent bonds to decrease their strength. For example, the homolytic dissociation of the carbon–cobalt bond of adenosylcobalamin



(3–372)

is catalyzed by both the active site of methylmalonyl-CoA mutase and the active site of glutamate mutase. In the crystallographic molecular model of cobalamin in the active site of methylmalonyl-CoA mutase from *P. freudenreichii*, the imidazolyl group of the histidine that is the axial ligand on the opposite side of the cobalt in the adenosylcobalamin is constrained sterically to be at a greater distance from the plane of the ring than it would be in an unconstrained situation. This displacement, exerted by the active site, in turn pulls the cobalt out of the plane of the corrin in the direction of the imidazolyl group and must lengthen and weaken the carbon–cobalt bond to the adenosyl group on the other side of the corrin in the prosthetic adenosylcobalamin.[333] Quantum mechanical calculations of the dissociation of the carbon–cobalt bond of adenosylcobalamin in the active site of glutamate mutase from *Clostridium cochlearium* lead to the conclusion that as the carbon–cobalt bond dissociates within the active site and the two incipient products of the dissociation, the 5′-adenosyl radical and the cob(II)alamin, move farther apart, they each are bound more and more tightly. In other words, the active site is constructed so that a long carbon–cobalt bond allows both the adenosyl group and the cobalaminyl group to be bound by the active site more effectively. In this way, the enzyme promotes the lengthening of the carbon–cobalt bond that pulls it apart homolytically.[334]

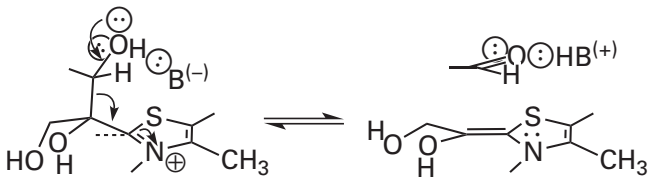
A carbon–cobalt bond is a weak covalent bond. Its bond dissociation energy (110 ± 10 kJ mol^{-1})[335] is only about 30% that of a carbon–carbon bond (370 kJ mol^{-1}). Because, however, it is still a covalent bond, when the active site pulls, it does not lengthen significantly enough to be registered in a crystallographic molecular model, but it is weakened nevertheless by the tug.

The process of distorting a dihedral angle, such as that occurring in lysozyme, or stretching a bond,

such as that occurring in glutamate mutase, **can be viewed dynamically**.[311] As the nuclei around the bond to be broken move by thermal motion in the direction of the configuration they must assume in the transition state, the hexa-*N*-acetyl-D-glucosamine or the adenosylcobalamin fits the respective active site more effectively, and the sum of the standard free energies of formation for noncovalent forces between hexasaccharide or adenosylcobalamin and the active site decreases accordingly. As the nuclei move by thermal motion away from the configuration they must assume in the transition state, each substrate fits the respective active site less effectively, and the standard free energy of formation for noncovalent forces increases accordingly. Both the active site and the substrate are rearranging at random as a result of thermal motion, but as the ensemble of conformations moves in the direction of the transition state, the sum of the standard free energy of noncovalent interactions decreases. Because the standard free energy of formation for the noncovalent forces decreases continuously as the respective reactant moves along the reaction coordinate toward the transition state, the standard free energy of activation is less than it would have been if the reaction were occurring in free solution, and the rate of the reaction is greater. The consequence of this process is that the standard chemical potential of the transition state is decreased by the additional standard free energy of noncovalent interaction realized along the trajectory.

An active site is also able to bend a covalent bond as well as stretch one. For example, the decarboxylation of 5-carboxy-4-hydroxy-3-methoxybenzoate (5-carboxyvanillate) by 5-carboxyvanillate decarboxylase from *Sphingomonas paucimobilis* is formally an electrophilic aromatic substitution of the 5-carboxylato group with a hydron. In the crystallographic molecular model of the enzyme in a complex with the unreactive analogue 4-hydroxy-3-methoxy-5-nitrobenzoate, in which an isosteric nitro group replaces the carboxylato group that is the electrophile that leaves as carbon dioxide in the normal substitution, the nitro group is bent out of the plane of the phenyl ring by 23°, even though the nitro group in free 4-hydroxy-3-methoxy-5-nitrobenzoic acid is coplanar with the ring.[336] Presumably, the 5-carboxylato on the reactant 5-carboxy-4-hydroxy-3-methoxybenzoate is also bent out of the plane by the active site, a conformation that favors the hydronation of carbon 5 to form 1,5-carboxy-3-methoxy-4-oxocyclohexa-2,6-diene, which is the intermediate in the electrophilic aromatic substitution. In this intermediate, carbon 5 is tetrahedral as a result of the hydronation, so bending the carboxylato group in the direction of tetrahedrality from trigonality promotes the hydronation and hence the substitution.

In the crystallographic molecular model of the adduct between the prosthetic thiamine diphosphate in the active site of transketolase from *E. coli* and the ketose, xylulose 5-phosphate,[337] the bond between carbon 2 of the thiazole ring and the α carbon of the adduct is **pulled out of the plane of the thiazole ring** so that the angle between it and the plane of the thiazole is 25°. The pull seems to be exerted on the portion of the xylulose 5-phosphate beyond carbon 2 by noncovalent interactions between this portion of the substrate and the active site, most notably the phospho group. Because carbon 2 in the adduct, which is participating in the aromatic thiazole ring, is sp^2-hybridized, the bond between carbon 2 and the α carbon would normally be in the plane of the ring. The bond between carbons 2 and 3 breaks in the next step of the enzymatic reaction



(3–373)

In the drawing, the dashed line represents the position of the bond were it in the plane of the thiazole ring. The fact that the active site is pulling on this bond vigorously enough to distort carbon 2 should also weaken it and make it easier to break.

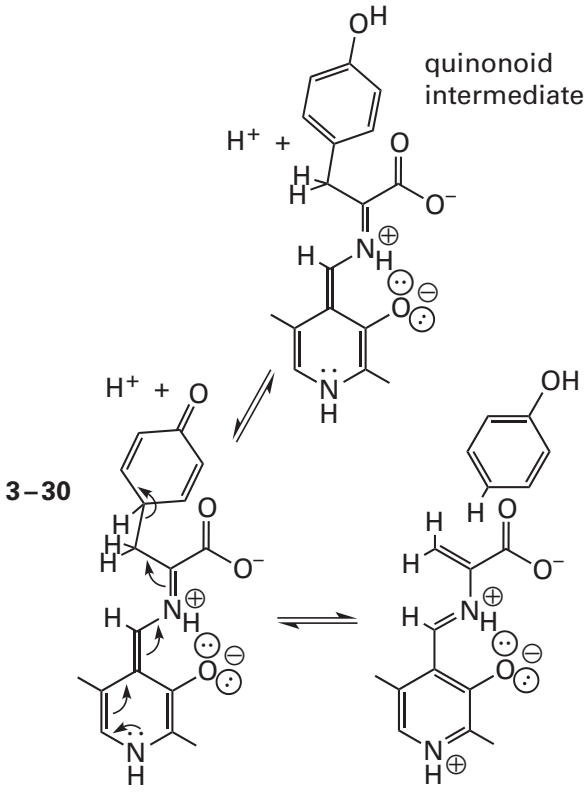
Orotidine-5′-phosphate decarboxylase (Equation 3–366) catalyzes an electrophilic substitution in which a carboxylato group, which leaves from carbon 6 of orotidine 5′-phosphate as carbon dioxide (an electrophile), is replaced by a hydron (also an electrophile).* In this electrophilic substitution, there is no reasonable anionic intermediate. For the lack of a reasonable intermediate, an unreasonable intermediate, in which carbon 6 is a carbanion with a σ lone pair of undelocalized electrons in the plane of the ring and jutting out from it, seems inescapable. Strangely enough, the active site also catalyzes the nucleophilic substitution of a hydroxide for the 6-cyano group in 6-cyanouridine 5′-phosphate, which leaves as a cyanide. When 6-cyanouridine

*This substitution is not an electrophilic aromatic substitution.

5′-phosphate is bound in the active site of orotidine-5′-phosphate decarboxylase from *Methanothermobacter thermautotrophicus*,[338] the cyano group is bent out of the plane of the pyrimidine ring by an angle of 30°, a distortion that should be required by a nucleophilic substitution. This bending accomplished by the active site is estimated to require about +30 kJ mol^{-1} of standard free energy. The 6-carboxylato group on orotidine 5′-phosphate should also be bent out of the plane of the ring upon its association with the active site, and this contortion should weaken the bond between carbon 6 and the carbon of the carboxylato group and increase the withdrawal of electron density in this bond by the acyl oxygen at carbon 4. A similar distortion is observed in a crystallographic molecular model of the active site occupied by orotidine 5′-phosphate in a mutant of orotidine-5′-phosphate decarboxylase from *M. thermautotrophicus* in which Aspartate 70 has been mutated to an alanine,[339] so the distortion does not seem to be accomplished by a steric interaction with this immediately adjacent side chain.[340] The distortion is not confined to molecules that are substrates for the enzyme. When 6-methyluridine 5′-phosphate occupies the active site,[341] the methyl group is bent out of the plane of the pyrimidine ring by 15°.

In the normal reaction catalyzed by orotidine-5′-phosphate decarboxylase, the carbanionic intermediate is hydronated by the ammonio group of Lysine 72. In a crystallographic molecular model of the complex between orotidine-5′-phosphate decarboxylase from *M. thermautotrophicus* and the substrate uridine 5′-phosphate,[342] carbon 6 in the uracil is also bent by the active site out of the plane of the ring by 0.01 nm by the 6-amino group of Lysine 72. When Lysine 72 is mutated to an alanine, the dissociation constant for uridine 5′-phosphate decreases by a factor of 10^5, a result consistent with Lysine 72 being responsible for the steric distortion of carbon 6 of the uridine 5′-phosphate. During catalysis, this distortion would result from the compression of one of the hydrogens on the ammonio group of Lysine 72 against carbon 6. In a crystallographic molecular model of the active site of the same mutant occupied by 6-cyanouridine 5′-phosphate, however, the cyano group is still bent out of the plane of the ring to the same degree as it is in the wild type by two fixed molecules of water occupying the same location as the lysine does in the wild-type active site.[338]

During the electrophilic aromatic substitution catalyzed by tyrosine phenol-lyase



(3–374)

carbon 1 of the 4-hydroxyphenyl group, upon its hydronation, changes its hybridization from sp^2 to sp^3, from trigonal planar to tetrahedral. In the crystallographic molecular model of the quinonoid intermediate of L-tyrosine in the active site of a mutant of tyrosine phenol-lyase from *Citrobacter freundii*,[343] the active site has pushed on the 4-hydroxyphenyl group, so carbon 1, although it remains trigonal, is no longer planar. In the active site, as a result of this push, the angle between the still planar, aromatic phenyl ring and the bond between carbon 1 and the β carbon has decreased from 180° to around 158°, on its way to the 125° that it has in hydronated intermediate **3–30**.

2′-Deoxypseudouridine is an inactive analogue of uridine, which is the natural substrate for the active site of uracil-DNA glycosylase. In the crystallographic molecular model of the active site of human uracil-DNA glycosylase occupied by 2′-deoxypseudouridine, which has swung out from the double-helical DNA in which it was incorporated, the 2′-deoxypseudouracil in the 2′-deoxypseudouridine has been twisted and the ring bent over so that it is almost coplanar with the ring of the ribose.[344] This bending of the 2′-deoxypseudouracil at the bond of the hemiaminal that connects the ribose and the nucleotide base brings the π molecular orbital system of the 2′-deoxypseudouracil almost parallel with the

σ bond between the 2′-deoxypseudouracil and the ribose, allowing the π molecular orbital system of the 2′-deoxypseudouracil to withdraw electron density from the σ bond and promote the heterolytic dissociation of this bond, which is the first step in the dissociative nucleophilic substitution of the 2′-deoxypseudouracil with a hydroxy group.

Active sites also force two atoms between which a covalent bond is to be formed into closer proximity than the sum of their van der Waals radii. This ability explains the compression of the ammonio group on Lysine 72 in orotidine-5′-phosphate decarboxylase against carbon 6 of the orotidine.

The first intermediate in the reaction catalyzed by the active site of porcine 3-oxoacid CoA-transferase (Equation 3–364) is a mixed anhydride[285,345,346] between Glutamate 305[347] and the 3-oxoacyl group of the 3-oxoacyl-SCoA resulting from a nucleophilic substitution at the acyl carbon of the 3-oxoacyl-SCoA of the carboxylato group of the glutamate for the sulfanyl group of coenzyme A. There is a crystallographic molecular model of a complex between a mutant of acetate CoA-transferase from *Acetobacter aceti*, in which the glutamate equivalent to Glutamate 305 in 3-oxoacid CoA-transferase is replaced with an alanine, and dethiaacetyl-CoA, an inert analogue of coenzyme A in which the sulfur of the thioacetyl group is replaced by a carbon.[346] When dethiaacetyl-CoA is superposed on a crystallographic molecular model of the wild-type enzyme, the carbonyl carbon of the dethiaacetyl-CoA, which is the analogue of the acyl carbon of acetyl-SCoA, is only 0.2 nm from the nearest oxygen of the carboxylato group of Glutamate 305, well within van der Waals contact. The new bond will be formed between this carbon and this oxygen. This compression, if it actually occurs in the active site during the normal reaction, would explain the fact that all the noncovalent interactions between acetoacetyl-SCoA and the active site of porcine 3-oxoacid CoA-transferase (Equation 3–364) are needed for it to perform its catalysis. This compression would validate the prediction that "the thiol ester group of the bound acyl-CoA is then clamped against the enzyme carboxylate group in a viselike grip that causes an increase in rate by decreasing the low frequency motions and entropy that must be lost to form a new covalent bond, and by destabilizing the bound thiol ester group relative to the transition state."[285] In the transition state for formation of the tetrahedral intermediate in anhydride formation, the distance between the oxygen of the glutamate and the acyl carbon of acetoacetyl-SCoA should be about 0.2 nm.

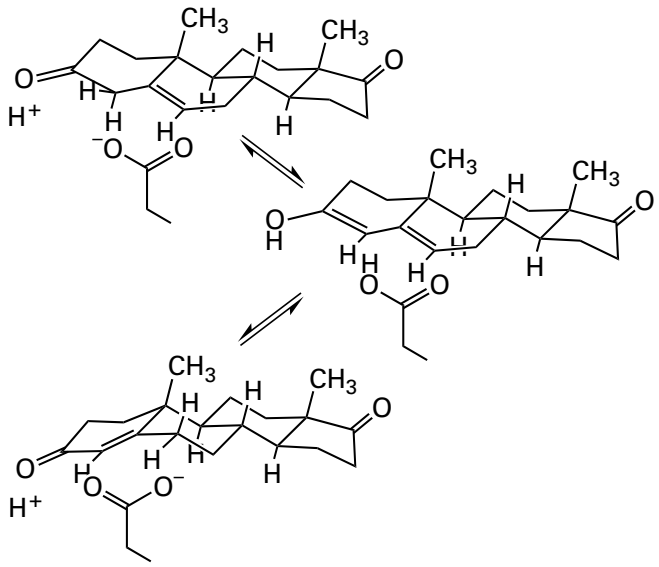
Alkaline phosphatase from *E. coli* catalyzes the hydrolysis of a large variety of phosphate monoesters. The promiscuity results from the fact that the enzyme associates only with the four oxygens of the phospho group and does not associate with the remainder of the alcohol taking part in the phosphoester. The enzyme uses the alkoxide of a serine in the active site, which is stabilized by a prosthetic Zn^{2+}, as a nucleophile in a nucleophilic substitution at phosphorus, with the alcohol as the leaving group, to form a phosphoserine as an intermediate in the reaction. A hydroxide from solution, which is stabilized by another prosthetic Zn^{2+}, then replaces the oxygen of the leaving alcohol and participates in a second nucleophilic substitution at phosphorus, in which the alkoxide of the serine is the leaving group and the product is phosphate. In the reverse direction, phosphate should associate with the active site, and a phospho group should be transferred to the alkoxide of the serine. The dissociation constant for the trianion of phosphate from the active site when serine is the nucleophilic alkoxide is $\geq 1 \times 10^{-7}$ M. When the serine is mutated to a glycine, the dissociation constant of the trianion of phosphate from the active site[348] is approximately 1×10^{-15} M. It was concluded that a portion (<-24 kJ mol^{-1}) of the dramatically large standard free energy of dissociation for the trianion of phosphate for the active site, which is revealed when the serine has been mutated to a glycine, has been used to push the phosphorus atom of the phosphate trianion up against the lone pair of electrons on the alkoxide of the serine. This alkoxide adds to the phosphorus atom during the formation of the phosphorane that is the intermediate in the nucleophilic substitution of the alkoxide of the serine for the hydroxide that is the leaving group in the reverse direction. The dissociation constant for the dianion of phosphate from the active site in which the serine is the alkoxide, however, which is the model for a phosphate ester, the ground state, increases only by a factor of 46 (4.4 kJ mol^{-1}) when the serine is replaced by a glycine.

Forcing of one atom of a reactant up against an atom of another reactant between which a covalent bond is to be formed can lead to **reactant antagonism**. Reactant antagonism occurs when one reactant decreases the dissociation constant for another reactant and vice versa. For example, the dissociation constant for 3-phospho-D-glyceroyl phosphate from human phosphoglycerate kinase

$$MgADP^- + \text{3-phospho-D-glyceroyl phosphate} \rightleftharpoons \text{3-phospho-D-glycerate} + MgATP^{2-} \quad (3\text{–}375)$$

increases from 0.03 μM when the active site is unoccupied to 0.9 μM when the active site is occupied by $MgADP^-$, and the dissociation constant for $MgADP^-$ increases from 8 μM when the active site is unoccupied to 100 μM when the active site is occupied by 3-phospho-D-glyceroyl phosphate.[349] One explanation for these observations is that the active site pushes the oxygen of the $MgADP^-$, to which the 1-phospho group of 3-phospho-D-glyceroyl phosphate is to be transferred, up against the phosphorus atom to catalyze the transfer and that this push is manifested in a steric effect that increases the respective dissociation constants.

Active sites also **force a base and a carbon from which a hydron is to be removed or an acid and a carbon to which a hydron is to be added into closer proximity** than the sum of their van der Waals radii. In effect, this property is a corollary to forcing together two atoms between which a covalent bond is to be formed. In a crystallographic molecular model between the active site of a mutant of steroid Δ-isomerase



(3–376)

from *Comamonas testosteroni* and its substrate androst-4-ene-3,17-dione (the product in Equation 3–376), the carboxylato oxygen of Aspartate 38, the catalytic base, is forced up against carbon 4 (0.27 nm) and carbon 6 (0.33 nm), the two carbons between which it transfers a hydron, closer than the sum (0.38 nm) of the van der Waals radii of a hydrogen (0.115 nm) and an oxygen (0.15 nm) and the length of a carbon–hydrogen bond (0.11 nm). When Proline 38, which is immediately adjacent to Aspartate 38, is mutated to a glycine, the side chain of Aspartate 38 is able to swing away from carbons 4 and 6 of androst-4-ene-3,17-dione, and the strain is relieved. This relief is manifest in the decrease of the dissociation constant for androst-4-ene-3,17-dione from the active site from 60 μM in the wild type to 1.1 μM for the mutant in which the proline has been replaced with glycine.[350] This difference in the standard free energy of dissociation for the substrate is presumed to be approximately equal to the standard free energy of dissociation for androst-4-ene-3,17-dione, which is used by the active site to force the carboxylato oxygen up against the two carbons.

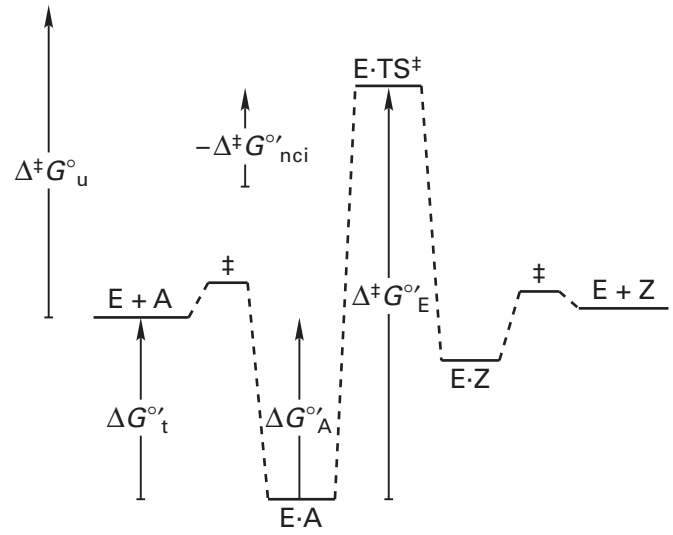
The standard free energy that accomplishes strain within an active site is provided by noncovalent interactions between the active site and the reactants. The **hydrophobic effect** accompanying the association of reactants with the active site results from the removal of hydrogen–carbon bonds both on the reactant and within the active site itself from contact with water.[52] In many active sites, a few of the hydrogen–carbon bonds on the reactant and within the active site may still be exposed to the water of the surrounding solution, but those that have been sequestered produce the favorable, negative standard free energy of the hydrophobic effect that accompanies the association. The hydrophobic effect is the main contributor to the standard free energy of dissociation and as such is responsible for assembling the reactants on the active site. The reactant and the active site of an enzyme almost always have complementary donors and acceptors for hydrogen bonds. There is little net standard enthalpy change when these **hydrogen bonds** form, however, because the donors and acceptors were participating in hydrogen bonds with the water before the complex between reactant and active site is formed, and there is usually no net change in the number of hydrogen bonds in the solution.[351] If, however, the donors and acceptors from water were not replaced by acceptors and donors in the active site, there would be an increase in standard free energy upon the association of a substrate with an active site. Once they are within the active site, the reactants engage in **van der Waals forces** with the functional groups within the active site. Again, there is little net standard enthalpy change resulting

from these interactions because both the functional groups in the active site and those on the reactants were engaged in van der Waals forces with the water of the solution before the reactants entered the active site.[352] After it has been occupied by the reactant, the active site also has associated with it a particular **electric potential energy** that arises from the disposition of the formal elementary charges and the orientation of the dipoles that it contains.

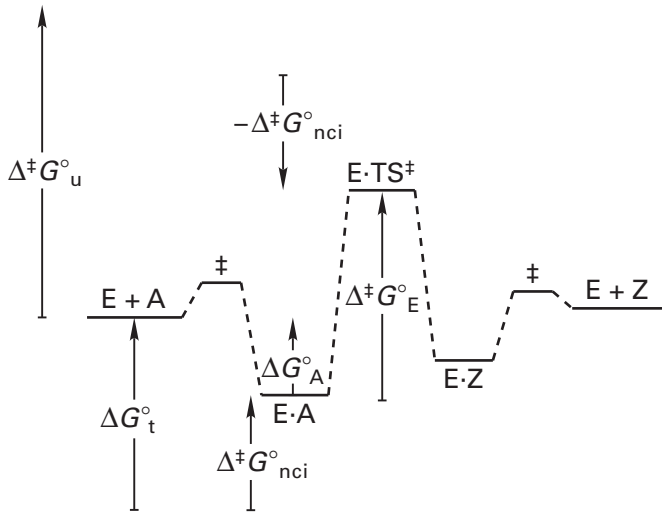
Because all or almost all of the hydrophobic effect is realized simply upon the dehydration of hydrogen–carbon bonds on the reactant and those in the active site, only the standard free energies of the hydrogen bonds, the van der Waals forces, and the electric potential change as the conformation of the occupied active site progresses from the ground state to the transition state. These interactions, in dramatic contradistinction to the hydrophobic effect, are critically dependent on the orientation and position of the participants.[351,352] When all three noncovalent interactions between the reactant and the active site are accomplished as favorably as possible, the maximum standard free energy of dissociation, ΔG°_{t}, which is composed of the **total available standard free energy of the noncovalent interactions and the electric potential** and which is always a positive number, is achieved.

These effects can be represented on **free energy diagrams** (Figure 3–29).[353] Suppose that the enzyme catalyzing the reaction had an active site constructed so that all these interactions that are subject to change—namely the hydrogen bonds, the van der Waals forces, and the electric potential—were completely engaged and the electric potential energy was at a minimum, and hence the sum of the standard free energies resulting from these interactions was **at the absolute minimum, when the ground states of the reactants were bound**. This situation would cause the reactants to be bound tightly, and its standard free energy of dissociation, $\Delta G^{\circ\prime}_{A}$, would equal $\Delta G^{\circ\prime}_{t}$, the maximum standard free energy of dissociation for the optimally aligned noncovalent interactions and the minimum of electric potential in this situation. The sum of the standard free energies for the formation of hydrogen bonds, the formation of van der Waals forces, and the electric potential would be at an absolute minimum when the reactants are bound. During the approach to the transition state, however, the standard free energy of these interactions would have to increase as the nuclei changed their configuration from the one they had in the ground states of the reactants. In this situation, the standard free energy of activation, $\Delta^{\ddagger}G^{\circ\prime}_{E}$, for the reaction on the active site of the enzyme would be increased relative to the standard free energy of activation for the uncatalyzed reaction, $\Delta^{\ddagger}G^{\circ}_{u}$ (corrected for entropy of approximation and changes in solvation between the water in the solution and the active site), by an amount of standard free energy, $\Delta^{\ddagger}G^{\circ\prime}_{nci}$ (in this case a positive number), equal in magnitude to the standard free energy of formation for the noncovalent interactions lost during the progress along the reaction coordinate. Under these circumstances, the enzyme would decrease the rate of the reaction after approximation has been accomplished.

Suppose, however, that the enzyme catalyzing the reaction has an active site constructed so that all these interactions that are subject to change—namely the hydrogen bonds, and the van der Waals forces—are completely engaged and the electric potential energy is at a minimum, and hence the sum of the standard free energies resulting from these interactions is **at the absolute minimum, only when the transition state is bound**. In this situation, the transition state is bound tightly, and its standard free energy of dissociation, $\Delta G^{\ddagger\circ}_{t}$, is equal to ΔG°_{t}, the maximum standard free energy of dissociation for the optimally aligned noncovalent interactions and the minimum of electric potential in this situation. The sum of the standard free energies for the formation of hydrogen bonds, the formation of van der Waals forces, and the electric potential are at an absolute minimum only when the transition state is achieved. During the approach to the transition state, however, the standard free energy for these interactions decreases as the nuclei change their configuration from the one they had in the ground states of the reactants. In this situation, the standard free energy of activation, $\Delta^{\ddagger}G^{\circ}_{E}$, for the reaction on the active site of the enzyme is decreased relative to the standard free energy of activation for the uncatalyzed reaction, $\Delta^{\ddagger}G^{\circ}_{u}$ (corrected for entropy of approximation and changes in solvation), by an amount of standard free energy, $\Delta^{\ddagger}G^{\circ}_{nci}$ (in this case a negative number), equal in magnitude to the standard free energy of formation gained and the decrease in the electric potential during the progress along the reaction coordinate. The sum of the standard free energies arising from all these interactions that change as the conformation of the occupied active site changes is at a minimum only when the transition state is reached. Under these circumstances, the enzyme increases the rate of the reaction after approximation has been accomplished.



enzyme that binds reactant efficiently



enzyme that binds transition state efficiently

Figure 3–29: Diagrammatic representation of the effect of binding the transition state more efficiently than the ground state on the standard free energy of activation for an enzymatic reaction. The free energy of activation for the uncatalyzed reaction, $\Delta^{\ddagger}G^{\circ}_{u}$, is for the uncatalyzed reaction once any free energy of approximation has been subtracted so that one can focus only on events that occur after association of reactant A with the active site. **(A)** An enzyme the active site of which binds the reactant most efficiently will have a large positive standard free energy of dissociation ($\Delta G^{\circ\prime}_{A} >> 0$) for the reactant, but it will bind the transition state poorly because standard free energies of dissociation for some of the noncovalent interactions are lost ($\Delta^{\ddagger}G^{\circ\prime}_{nci} < 0$) as the reactant is transformed to the transition state. It has been assumed that, without the loss of noncovalent interactions, the standard free energy of activation on the active site would be the same as the standard free energy of activation of the uncatalyzed reaction ($\Delta^{\ddagger}G^{\circ}_{u}$), corrected for standard free energy of approximation. Raising of the standard free energy of the E·TS‡ complex because some noncovalent interactions are lost causes the standard free energy of activation on the active site ($\Delta^{\ddagger}G^{\circ\prime}_{E}$) to be larger than the standard free energy of activation of the uncatalyzed reaction ($\Delta^{\ddagger}G^{\circ}_{u}$), after correcting for the standard free energy of approximation. **(B)** An enzyme the active site of which binds the transition state most effectively will still have a positive standard free energy of dissociation ($\Delta G_{A}^{\circ} > 0$) for the reactant, but it will bind the transition state strongly because standard free energies of dissociation for some of the noncovalent interactions are gained ($\Delta^{\ddagger}G^{\circ}_{nci} > 0$) as the reactant is transformed to the transition state. Lowering of the standard free energy of the E·TS‡ complex causes the standard free energy of activation on the active site ($\Delta^{\ddagger}G^{\circ}_{E}$) to be smaller than the standard free energy of activation of the uncatalyzed reaction ($\Delta^{\ddagger}G^{\circ}_{u}$), after correcting for the standard free energy of approximation.

Regardless of whether strain is occurring, the large increase in the rate of reaction that results simply from assembling and orienting the reactants on the active site would still apply. In one case, however, this increased rate would be decreased by the loss of noncovalent interactions on approach to the transition state. In the other case, it is increased by the gain in noncovalent interactions on approach to the transition state. Considered in this way, it seems almost to be a necessity that the full effect of noncovalent interactions not be exerted until the transition state is reached.

Another way to present the effects of binding upon the rate of an enzymatic reaction is a more general approach not confined simply to a consideration of noncovalent forces. In this approach, all the consequences associated with the binding of the transition state to the active site of an enzyme are included.[354,355] In the case of an enzyme that operates on two reactants, the following linkage box can be constructed[355]

$$\begin{array}{ccccc} \mathrm{E + A + B} & \overset{^{\ddagger}K_{u}}{\rightleftharpoons} & \mathrm{E + A{\cdot}B^{\ddagger}} & \xrightarrow{\dfrac{\kappa_{T,u}}{\delta_{u}}\left(\dfrac{k_{B}T}{2\pi^{\ddagger}m_{u}}\right)^{1/2}} & \mathrm{E + Z{\cdot}Y} \\ \Big\downarrow\Big\uparrow K_{dA} & & \Big\Vert\Big\Vert\, {}^{\ddagger}K_{d} & & \\ \mathrm{E{\cdot}A + B} & & & & \\ \Big\downarrow\Big\uparrow K_{dB} & & & & \\ \mathrm{E{\cdot}A{\cdot}B} & \overset{^{\ddagger}K_{E}}{\rightleftharpoons} & \mathrm{E{\cdot}A{\cdot}B^{\ddagger}} & \xrightarrow{\dfrac{\kappa_{T,E}}{\delta_{E}}\left(\dfrac{k_{B}T}{2\pi^{\ddagger}m_{E}}\right)^{1/2}} & \mathrm{E{\cdot}Z{\cdot}Y} \end{array} \qquad (3\text{–}377)$$

where K_{dA}, K_{dB}, and ${}^{\ddagger}K_{d}$ are the dissociation constants from the active site for reactant A, reactant B, and the transition state, respectively; $A{\cdot}B^{\ddagger}$ is the

transition state; $\kappa_{T,u}$, δ_u, and ${}^{\ddagger}m_u$ and $\kappa_{T,E}$, δ_E, and ${}^{\ddagger}m_E$ are transmission coefficients, lengths of the reaction coordinate at the transition state, and masses of the transition state for the uncatalyzed and enzymatically catalyzed reactions, respectively; and ${}^{\ddagger}K_u$ and ${}^{\ddagger}K_E$ are the equilibrium constants between the respective reactants and transition states.

Assume for the moment that expressions containing transmission coefficients, lengths of the reaction coordinates at the transition state, and masses of the transition states for the uncatalyzed and enzymatically catalyzed reactions are approximately equal.* Because

$$k_i = \frac{\kappa_{T,i}}{\delta_i}\left(\frac{k_B T}{2\pi {}^{\ddagger}m_i}\right)^{1/2} {}^{\ddagger}K_i \qquad (3\text{–}378)$$

it follows that

$$\frac{K_{dA}K_{dB}}{{}^{\ddagger}K_d} \cong \frac{k_0}{k_u} \qquad (3\text{–}379)$$

This expression states that, given all the rather bold assumptions that have been made, the quotient of the product of dissociation constants for the reactants and the dissociation constant for the transition state determines the ratio between the catalytic constant for the enzymatically catalyzed reaction and the rate constant for the uncatalyzed reaction. Therefore, to catalyze a reaction, **an enzyme must bind the transition state more tightly than the reactants**, and the degree of preference it displays for the transition state relative to the reactants determines entirely the increase in rate that is realized.

This statement alone, however—that an active site must bind the transition state more tightly than the reactants—although indisputable,[263] is uninformative. The informative observations are **the details of the explicit strategies** used by the active site to bind the transition state preferentially. One strategy is to design an active site in which noncovalent forces increase in strength and electric potential decreases as the configuration of the atoms in the reactants moves toward that of the transition state. In the transition state, covalent bonds are partially formed and partially broken between the reactants themselves, and the active site must associate with these shortened or elongated distances between particular atoms in the transition state more effectively than it does with the same atoms in the reactants. Another strategy is to provide appropriately located acids and bases. The transition states in most biochemical reactions involve hydrons in transit. A bare hydron leaving a shrinking lone pair of electrons in a reactant or a bare hydron being attracted to an enlarging lone pair of electrons in a reactant are hydrons in transit. They are structural features of the transition state that must be bound by the enzyme if the transition state is to be bound more tightly than the reactants, in which these peculiar situations do not exist. To stabilize and provide these hydrons in transit, acids and bases must be located appropriately within the active site but also compressed against the corresponding bases and acids in the reactants to approach the respective distances between the nuclei in the transition state. Finally, in many instances, prosthetic groups or metallic ions are incorporated in the active site to provide capabilities unavailable in a simple aqueous solution. All these features, and any others that apply to the interaction between the active site and the transition state, produce the difference in standard free energy of dissociation for the reactants in their ground state from the active site and the standard free energy of dissociation for the transition state from the active site.

It has been a widely accepted custom to quantify the catalytic proficiency of an enzyme[356] as the rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$. The ratio $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$, however, is a rate constant that is only indirectly related to the actual catalytic proficiency of the enzyme. The rate constant actually quantifying the catalytic proficiency of the enzyme is $k_0\,(K_{dA}K_{dB}\ldots)^{-1}$, a number that should be proportional to the association constant between the transition state and the active site (Equation 3–379) if several related enzymatically catalyzed reactions are compared for which the rate of the uncatalyzed reaction is the same—always with the caveat that all of the foregoing assumptions are valid. It is significantly more difficult, however, to measure the dissociation constant for a reactant than to measure its Michaelis constant. Consequently, the unmentioned assumption made to avoid this labor is that the Michaelis constant for a reactant is approxi-

*It is difficult to decide what the mass of the transition state is when the reaction is occurring within an active site because an indeterminate portion of that active site is actively in motion as the transition state is being approached. When the reaction occurs in solution, however, a significant portion of the solvation shell is also actively in motion as the transition state is being approached. It can be assumed, merely for the sake of the argument, that roughly the same mass of the active site is in motion as the mass of the solvation shell that is in motion.

mately the same as its dissociation constant, a rather tenuous assumption. It has also been decided that it is more gratifying to use a number indirectly related to the association constant for the transition state, ${}^{\ddagger}K_{\mathrm{d}}^{-1}$, rather than a number more directly related to the dissociation constant because it is always a number greater than 1 and therefore seems to indicate that the enzyme is increasing the rate of the reaction. Regardless of all these caveats, the custom of tabulating the rate constants $k_0\,(K_{\mathrm{mA}}K_{\mathrm{mB}}\ldots)^{-1}$ has become universal. One is forced to consider these ratios as more or less the same as the intended rate constants $k_0\,(K_{\mathrm{dA}}K_{\mathrm{dB}}\ldots)^{-1}$.

The rate constant $k_0\,K_{\mathrm{mA}_i}{}^{-1}$ can be used to obtain **information about the structure of the transition state in a particular enzymatic reaction from a series of reactants $\mathbf{A}_i$,** each of which can participate in the reaction catalyzed by the enzyme.[357,358] If a series of reactants A_i for an enzyme is examined in which all the rate constants for the uncatalyzed reaction are the same; if the reaction is being catalyzed only by the increase in standard free energy of dissociation of the transition state; and if the dissociation constants for the other reactants in the enzymatic reaction do not change as the identity of reactant A is changed, then the quantities $K_{\mathrm{dA}_i}\,k_0{}^{-1}$ will be proportional to the dissociation constants for the respective transition states from the active site (Equation 3–379). The rate constant $k_0\,K_{\mathrm{mA}_i}{}^{-1}$ may also be proportional to the association constants for the respective transition states from the active site. For example, a series of alkyl phosphates and a series of phenyl phosphates that differed in the $\mathrm{p}K_{\mathrm{a}}$ of the leaving groups in each case were used as reactants for alkaline phosphatase

$$\mathrm{ROPO_3^{2-}} + \mathrm{HOH} \rightleftharpoons \mathrm{ROH} + {}^{2-}\mathrm{O_3POH} \qquad (3\text{–}380)$$

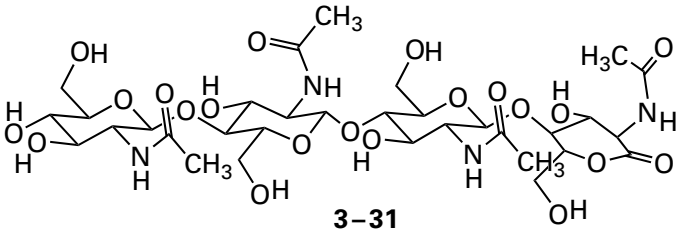
from *E. coli*, an enzyme in which the portion of the reactant beyond the phospho group hangs out into the solution. The values for the common logarithms of $k_0\,K_{\mathrm{m,phos}}{}^{-1}$ were plotted against the respective values of $\mathrm{p}K_{\mathrm{a}}$ for the leaving groups. The Brønsted coefficient for the phenyl phosphates was -0.77 ± 0.1, and that for the alkyl phosphates was -0.85 ± 0.1. From these values it was concluded that, in the transition states for the rate-limiting nucleophilic substitutions at phosphorus, the bond between oxygen and phosphorus is mostly dissociated.[359]

The rate constant $k_0\,K_{\mathrm{m}}{}^{-1}$ can be used to obtain information about the apparent change in the standard free energy of the dissociation constant for the transition state relative to the dissociation constant for the reactant from the active sites in **a series of site-directed mutations**. For example, the values of $k_0\,K_{\mathrm{m}}{}^{-1}$ for four mutations of orotidine-5′-phosphate decarboxylase from *S. cerevisiae*, both alone and in all fifteen combinations, were used to estimate the changes in standard free energies of activation for the enzymatic reaction produced by each mutation, and hence the contributions of the side chains of those amino acids to stabilization of the transition state relative to the ground state.[360]

One misunderstanding of the statement that the enzyme must bind the transition state more tightly than the reactants is the impression it leaves that the enzyme actually binds transition states present in the solution and that this ability would explain its catalysis. An enzyme binds otherwise unassociated and unactivated reactants, and the transition states are achieved within the active site. If an enzyme preferentially bound only transition states formed in solution, it could only decrease the rate of the reaction because, by definition, a transition state decomposes to products instantaneously. That the enzyme must bind the transition state more strongly than the ground state is only a thermodynamic argument, not something that actually occurs.

If a transition state has to be bound more tightly to an active site than the substrates, it should be possible, as proposed by Pauling in the credo cited above,[311] to design molecules the structures of which resemble the structures of the respective transition states and to demonstrate that they bind to the enzyme far more tightly than do the substrates. In most instances, transition states involve bond lengths and bond angles that cannot be reproduced in a stable molecule. By the **Hammond postulate**,[318] however, an intermediate of high energy encountered along a reaction coordinate, which by definition does have normal bond lengths and bond angles, resembles in its structure the transition states on either side of its well of potential energy more closely than do either the immediate reactant or the immediate product. Because one is rarely able to synthesize analogues for transition states, **analogues for intermediates of high energy** have been synthesized and shown to be potent inhibitors of enzymes, as predicted. In spite of the inaccuracy of the phrase, analogues for intermediates of high energy are often referred to as "transition-state analogues".

The trisaccharide *N*-acetylglucosaminopyranosyl-(β1,4)-*N*-acetylmuramopyranosyl-(β1,4)-*N*-acetyl-D-glucosamine binds to the active site of lysozyme from *G. gallus* in subsites A, B, and C (Figure 3–27) with a dissociation constant of 4 μM, while the tetrasaccharide *N*-acetylglucosaminopyranosyl-(β1,4)-*N*-acetylmuramopyranosyl-(β1,4)-*N*-acetylglucosaminopyranosyl-(β1,4)-*N*-acetylmuramate binds with a dissociation constant of 500 μM.[361] This increase in the dissociation constant for the tetrasaccharide relative to the trisaccharide is thought to be due to the fact that the more stable chair conformation of the pyranose of the additional *N*-acetylmuramate in the fourth position of the tetrasaccharide cannot fit into the subsite for the D-pyranose in the active site of the enzyme without being distorted into a half-chair conformation (Figure 3–28),[319] and this distortion increases the dissociation constant. The δ-lactone of (β1,4)-tri-*N*-acetylglucosaminopyranosyl-2-acetamido-2-deoxygluconate



3–31

however, binds to the active site of lysozyme with a dissociation constant of 0.2 μM.[362] All these results are consistent with the conclusion that at the reducing end of a tetrasaccharide that occupies the active site of lysozyme, rather than the chair conformation of a pyranose, a planar conformation at carbon 5, oxygen 5, carbon 1, and carbon 2, which is the case with the lactone, is the structure that fits in subsite D. On the basis of these observations, it was proposed that the δ-lactone resembles oxocarbenium ion **3–26**, an intermediate of high energy, or the planar arrangement at these atoms in the transition state of a concerted nucleophilic substitution by a carboxylato group that the active site has evolved to stabilize.

In the crystallographic molecular model obtained from a crystal of lysozyme in which the active site was occupied by tetrasaccharide **3–31**, the lactone was found to occupy the subsite in the active site for the D pyranose at the reducing end of the tetrasaccharide, and it was bound in the planar, sofa conformation, which is its usual unhindered conformation in solution.[316] Because the terminal δ-lactone definitely occupies this subsite when tetrasaccharide **3–31** is bound even though a pyranose in the chair conformation at this position in a tetrasaccharide might not occupy the same subsite, only an upper limit to the difference in the standard free energy of dissociation between a lactone and a pyranose from the D subsite can be calculated. This upper limit for $\Delta\Delta G^\circ$ is 20 kJ mol^{-1}.

A few **analogues for transition states** and many other **analogues for intermediates of high energy** have been synthesized and shown to have dissociation constants from the enzyme for which each was designed that are significantly smaller than those for the respective reactants (Table 3–7). For example, the inhibition constant K_i—which in general is assumed to be a dissociation constant—for the bicyclic dicarboxylate **3–33** (100 nM) is 100 times smaller than the Michaelis constant $K_{m,chr}$ for chorismate,[364] which in the absence of a dissociation constant for chorismate was assumed to be an approximation of its dissociation constant. Analogues for the respective transition states in an electrocyclic reaction (**3–32**), a 1,2-methyl migration (**3–34**), the dissociation of a nucleophile (**3–36**), and a dissociative nucleophilic substitution at phosphorus (**3–39**) have been reported. Analogues for intermediates of high energy such as carbenium ions (**3–41** and **3–43**), oxocarbenium ions (**3–45**, **3–47**, and **3–50**), enolates (**3–52**, **3–54**, **3–56**, **3–58**, and **3–60**), phosphoranes (**3–62**), unstable ketals (**3–64**), hemiaminals,[448,449] and tetrahedral intermediates (**3–66**) have also been reported. In the special case of tetrahedral intermediates in nucleophilic substitutions, sulfoximines (**3–67**), hemiaminals (**3–68**), boronates (**3–69**), hemiacetals and hemiketals (**3–70**), phosphonamidates (**3–71**), sulfonamides (**3–72**), phosphonates (**3–73**), phosphinates,[450-452] and phosphates[453] have been used as analogues.

Table 3-7: Analogues for Transition States and Intermediates of High Energy[a]

transition state	analogue[a]	references	intermediate	analogue	references
 **3–32**	 **3–33** K_i = 150 nM	303, 363-365	 **3–41**	 **3–42** K_i = 4 nM	366

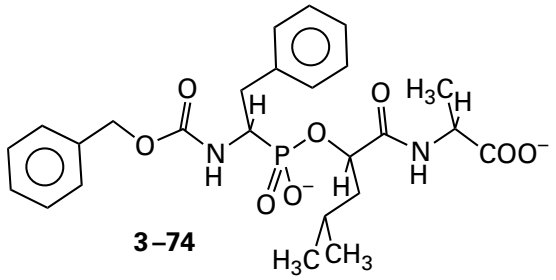
[a]The noted inhibition constant is for inhibition of only one of the enzymes inhibited by the analogue and is usually the smallest of the values observed when several enzymes or several different conditions were tested.

One peculiar property of a few of these analogues for intermediates of high energy, especially those that bind with the smallest dissociation constants, is that their **rates of association are quite slow** compared to those at which other ligands bind to the same active site.[454-456] For example, the analogue



3–74

for the tetrahedral intermediate in the hydrolysis of peptides catalyzed by thermolysin from *B. thermoproteolyticus* (Table 3–6) has a rate of association of only $470\ M^{-1}\ s^{-1}$ but a dissociation constant of 45 nM.[427] It may be that, in these peculiar instances, the active site in its ground state has evolved to associate rapidly with the reactants, yet the respective intermediate of high energy differs enough in structure and conformation from the ground state that a molecule mimicking it cannot associate efficiently.[455] In the case of analogue **3–74** of the tetrahedral intermediate in the active site of thermolysin, because it does not resemble the reactant, it binds slowly. This behavior should be distinguished from the situation in which an inhibitor associates with a normal, rapid second-order rate constant but appears to associate slowly because the approach to equilibrium is governed by its slow rate of dissociation[457] or the situation in which an inhibitor associates slowly because it forms a covalent adduct with the enzyme.[458]

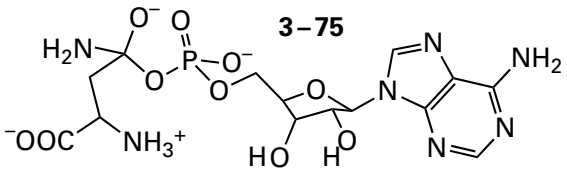
Such analogues for intermediates of high energy **should be distinguished from bisubstrate analogues.**[109,280] A bisubstrate analogue is a compound in which two of the substrates of an enzymatic reaction have been attached together synthetically. For example, *N*-(phosphonacetyl)-L-aspartate (**3–6**), a competitive inhibitor of aspartate carbamoyltransferase, combines the structures of carbamoylphosphate (**3–7**) and L-aspartate (**3–8**). The dissociation constant for carbamoyl phosphate from the empty active site of aspartate carbamoyltransferase from *E. coli* is 27 μM, and the dissociation constant for L-aspartate from the empty active site is 11 mM.[178] The respective standard free energies of dissociation, based on a standard state of corrected volume fraction,[273,274] are +33 and +18 kJ mol^{-1}. The inhibition constant K_i for *N*-(phosphonacetyl)-L-aspartate, when it is acting as a competitive inhibitor binding to the empty active site of aspartate carbamoyltransferase, is 30 nM, from which a standard free energy of dissociation of +48 kJ mol^{-1} can be calculated. The standard free energy of dissociation for the bisubstrate analogue is almost equal to the sum of the free energies of dissociation for the two substrates. Consequently, it cannot be an analogue of an intermediate of high energy. It is simply an example of free energy of approximation.

An inhibitor of phosphoribosylglycinamide formyltransferase from *E. coli* in which the substrates 10-formyltetrahydrofolate and N^1-(5-phospho-D-ribosyl)glycinamide have been joined together synthetically with a simple methylene[459] has a standard free energy of dissociation (+57 kJ mol^{-1}) that is almost equal to or less than the sum of the standard free energies of dissociation of 10-formyltetrahydrofolate (≥27 kJ mol^{-1}) and N^1-(5-phospho-D-ribosylglycinamide (≥34 kJ mol^{-1}).[460]

An analogue in which the 5′-hydroxy group of adenosine is covalently attached to the carbamoyl nitrogen of L-cysteinamide by a sulfonyl group is a strong inhibitor (K_i = 300 nM; K_d = 100 nM) of the nucleophilic substitution at phosphorus catalyzed by L-cysteine:1D-*myo*-inositol 2-amino-2-deoxy-α-D-glucopyranoside ligase from *Mycolicibacterium smegmatis*. Even though the analogue is isosteric with *O*-adenylyl-L-cysteine, a proposed intermediate of high energy in the enzymatic reaction; even though the dissociation constants for AMP and L-cysteine were not measured; and even though the Michaelis constants for $MgATP^{2-}$ and L-cysteine suggest that it may well be an analogue of that intermediate of high energy, the authors have decided that the analogue is simply a "bisubstrate analogue".[461,462] Such caution should probably be applied to all analogues in which portions of two substrates are combined.

The standard free energy of dissociation defines the difference between a bisubstrate analogue and an analogue of an intermediate of high energy. The standard free energies of dissociation for *N*-(phosphonacetyl)-L-aspartate and the inhibitor of phosphoribosylglycinamide formyltransferase, although they are large, are almost equal to but nevertheless less than the **sum of the standard free energies of dissociation** for their respective parts. Consequently, they are bisubstrate analogues and not analogues for intermediates of high energy. In fact, their designs were not intended to mimic a transition state or an intermediate of high energy.

The standard free energy of dissociation for an analogue of a transition state or an intermediate of high energy that coincidentally combines two substrates for the enzyme must be greater than the sum of the standard free energies of dissociation for each separate substrate. For example, an analogue for a proposed tetrahedral intermediate

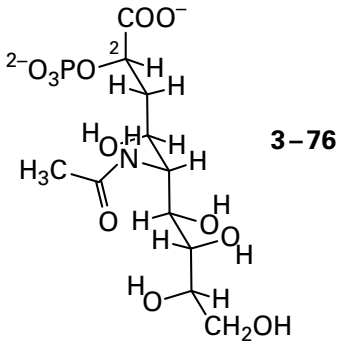


in the reaction catalyzed by aspartate—ammonia ligase from *E. coli*

$$\text{MgATP}^{2-} + \text{L-aspartate} + \text{NH}_4^+ \rightleftharpoons \text{AMP}^{2-} + \text{MgOPO}_3\text{PO}_3^{2-} + \text{L-asparagine} + 2\,\text{H}^+ \quad (3\text{–}381)$$

was synthesized using a sulfoximine (**3–67**) to substitute for the tetrahedral intermediate. This inhibitor has an inhibition constant of 70 nM,[456] which is impressive, but its standard free energy of dissociation (+44 kJ mol^{-1}) is not significantly greater than, and may be less than, the sum of the standard free energies of dissociation for L-aspartate (≥23 kJ mol^{-1}) and MgATP^{2-} (≥20 kJ mol^{-1}) from the enzyme. This comparison is ambiguous because the dissociation constant for AMP^{2-} was not measured. If AMP^{2-} binds weakly to the active site, the sulfoximine may well be an analogue of an intermediate of high energy. Nevertheless, the claim that an inhibitor is an analogue of an intermediate of high energy should require a demonstration that it is not merely a bisubstrate analogue.

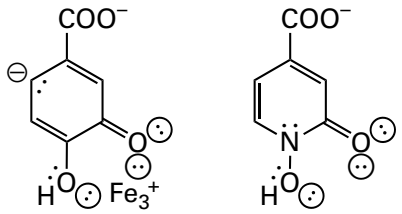
This caveat, however, does not mean that **useful information** cannot be obtained from a bisubstrate analogue. For example, the bisubstrate analogue



covalently attaches the properly positioned phospho group and carboxy group of phospho*enol*pyruvate, one substrate, and *N*-acetyl-D-mannosamine, the other substrate for *N*-acetylneuraminate synthase from *Neisseria meningitidis*. The fact that only the *R* isomer at carbon 2 of the analogue associates with the active site is consistent with a tetrahedral intermediate in the enzymatic reaction that has a particular sterochemistry. This intermediate, which forms between the carbon–carbon double bond of phospho*enol*pyruvate as a nucleophile, the carbonyl group of the *N*-acetyl-D-mannosamine as the electrophile, and a molecule of water as the second nucleophile, must have the *R* configuration at its carbon 2. Consequently, a crystallographic molecular model of the 2*R* analogue in the active site should reveal the orientation of the catalytic groups that occur around the actual tetrahedral intermediate.[463]

In several instances, a **bisubstrate analogue has been produced on the active site** of an enzyme rather than synthetically from one of the substrates that happens to be a nucleophile and an analogue for another substrate that incorporates an electrophilic carbon in the proper location[464] or from one of the substrates that happens to be an electrophile and an analogue for another substrate that incorporates a nucleophilic carbon in the proper location.[465]

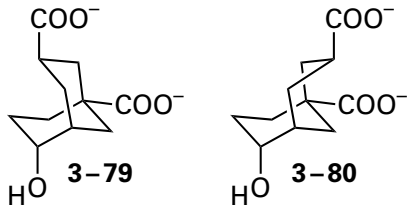
The existence of a particular inhibitor that binds tightly and noncovalently to a particular enzyme is often used as an argument in favor of a transition state or a particular intermediate in the mechanism of the enzyme. For example, to provide evidence for the existence of the anionic intermediate **3–77** in the reaction catalyzed by protocatechuate 3,4-dioxygenase from *P. aeruginosa*



the hydroxamate **3–78** was synthesized.[466] The inhibition constant K_i for this inhibitor (100 nM)[467] is 300 times smaller* than the Michaelis constant (30 μM) for protocatechuate.[468]

*The problem of whether or not the inhibitor is a bisubstrate analogue does not arise with an enzyme that has only one reactant.

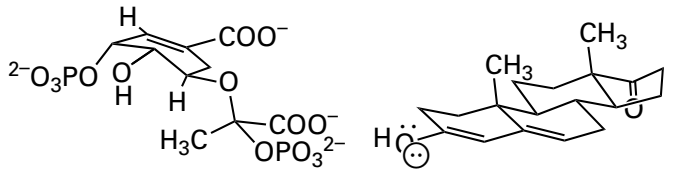
The inhibition effected by analogues for intermediates of high energy has also been used to distinguish between alternatives for the **conformation of the transition state** in a particular enzymatic reaction. For example, the transition state in the reaction catalyzed by chorismate mutase (Equation 3–367) could proceed through either an all-chair conformer of the transition state or a chair–boat conformer. The fact that *exo*-6-hydroxybicyclo[3.3.1]nonane-1,*exo*-3-dicarboxylate (**3–79**) was a reasonable competitive inhibitor of chorismate mutase from *E. coli* (K_i = 400 μM) while *exo*-6-hydroxybicyclo[3.3.1]nonane-1,*endo*-3-dicarboxylate (**3–80**) was not (K_i >10 mM)



3–79 **3–80**

has been used as an argument that the transition state in the enzymatic reaction is in the all-chair conformation.[363]

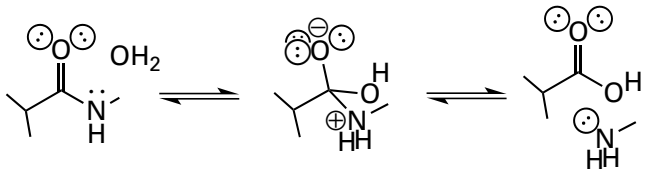
A compound thought to be the actual intermediate of high energy in an enzymatic reaction can sometimes be synthesized. If it binds tightly to the enzyme, this tight binding is presented as evidence for its participation in the reaction. For example, the phosphorylated hemiketal **3–81**



3–81 **3–82**

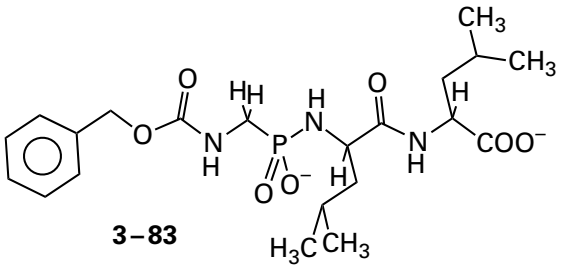
has a dissociation constant of less than 1 nM from 3-phosphoshikimate 1-carboxyvinyltransferase (Equation 3–262) from *E. coli*,[469] and the dienol **3–82** has a dissociation constant of 6 nM from a mutant of steroid Δ-isomerase from *C. testosteroni*.[470] These small dissociation constants are presented as evidence that these compounds are intermediates in these reactions.

Correlations between the dissociation constants of analogues for intermediates of high energy and the rate constants $K_m\ k_0^{-1}$ can provide information about both analogues and intermediates in the enzymatic reaction. Thermolysin hydrolyzes peptide bonds in polypeptides amino-terminal to hydrophobic side chains (Table 3–6) through a tetrahedral intermediate



(3–382)

Analogues for six of the peptides in Table 3–6 were synthesized that incorporate a phosphonamidate (**3–71**) in place of a peptide bond. For example, the phosphonamidate



3–83

is identical to the peptide Cbz-Gly-Leu-Leu (Table 3–6) with the exception that one of the acyl carbons has been replaced by the phosphorus and oxygen of the phosphonamidate. This compound inhibits thermolysin strongly as a competitive inhibitor (K_i = 9 nM).[426] Each of the six respective phosphonamidates was shown to be a potent competitive inhibitor of the hydrolytic reactions catalyzed by the enzyme.

If these phosphonamidates are bound to the active site of thermolysin as if they were the respective tetrahedral intermediates in the normal catalytic mechanism (Equation 3–382 and Table 3–7), then they should be bound with much of the standard free energy of the available interactions between the active site and transition state. The values of the competitive inhibition constants $K_{ic,phn}$ **for each competitive inhibitor in the series should be directly proportional to** $^{\ddagger}K_d$ **for the corresponding transition state** (Equation 3–377). If this is the case and k_u, the rate constant for the uncatalyzed hydrolysis of each peptide, is approximately the same for all the peptides in the series, the values for $K_{i,phn}$ should be proportional to the values for the product $K_{d,pep}\ k_0^{-1}$ (Equation 3–379). The values for the common logarithms of $K_{i,phn}$ should be a linear function for the respective values of the common logarithms for $K_{d,pep}\ k_0^{-1}$ with a slope equal to 1. When these values of the

common logarithms for $K_{i,phn}$ were plotted as a function of the common logarithms for $K_{m,pep}\ k_0^{-1}$, the slope of the line fit to the data was 0.87 ± 0.15 over a range for K_i from 9 to 1700 nM.[426] Such a correlation simultaneously provides evidence, in the case of thermolysin, for the existence of the tetrahedral intermediate in the enzymatic reaction, for the diversion of standard free energy of dissociation to lower the standard free energy of activation, and for the ability of a phosphonamidate to mimic the tetrahedral intermediate (Figure 1–10).

A similar, though more extensive, series of 14 tripeptides and tetrapeptides were synthesized in which a phosphonate (**3–73**) rather than a phosphonamidate replaced the peptide bond between their two carboxy-terminal alanines. These analogues for the respective tetrahedral intermediates were found to be competitive inhibitors of bovine carboxypeptidase A, an exopeptidase that hydrolyzes the peptide bond between the carboxy-terminal amino acid of a protein and its penultimate amino acid. Over three orders of magnitude, their competitive inhibition constants $K_{ic,pho}$ were proportional to the values of $K_{m,pep}\ k_0^{-1}$ for the respective peptides as reactants for the enzyme because the slope of the line fit to a plot of the common logarithms of $K_{ic,pho}$ as a function of the common logarithms of $K_{m,pep}\ k_0^{-1}$ is indistiguishable from 1 (Figure 3–30A).[213,471,472] In this instance, each of the 14 inhibitors had an inhibition constant $K_{i,pho}$ that was at least 1000 times smaller than the value for the corresponding Michaelis constant $K_{m,pep}$. Again, in addition to the conclusion that a portion of the standard free energy of dissociation of the respective reactants is used by the active site to distort the reactants in the direction of the transition state, this correlation provides evidence that the intermediate in the reaction catalyzed by carboxypeptidase A is a tetrahedral intermediate.

A **proportionality between K_i and $K_m\ k_0^{-1}$** (Figure 3–30A) is used as an argument that each member of a particular series of inhibitors resembles an intermediate of high energy or a transition state in the enzymatic reaction.[473] If the series of inhibitors fails this test, however, it cannot be concluded that its members are not analogues for intermediates or transition states[474,475] because the Michaelis constant K_{mA} is often uncorrelated with the dissociation constant for a particular reactant.

The same type of correlation can be made between the dissociation constants for the same analogue of an intermediate in an enzymatic reaction and the **values of $K_m\ k_0^{-1}$ for a series of mutants** of the enzyme of decreasing catalytic efficiency. For example, tungstate associates with the active site of alkaline phosphatase from *E. coli* and forms an adduct with the serine responsible for nucleophilically catalyzing the hydrolysis of phosphate esters. The fact that the dissociation constants for tungstate from the active sites of several site-directed mutants of the enzyme are almost proportional to the values of $K_m\ k_0^{-1}$ for the hydrolysis of methyl 4-nitrophenyl phosphate by the respective mutants (Figure 3–30B) is evidence for the conclusion that the adduct of tungstate is mimicking an actual intermediate of high energy in the enzymatic reaction. The crystallographic molecular model of that adduct demonstrates that it is a pentavalent, trigonal bipyramid isosteric with a phosphorane.[476] Consequently, these results are consistent with a phosphorane being an intermediate in the enzymatic reaction, which is reasonable because the nucleophile is a strong one and the leaving group is a poor one.

The structure of the active site of bovine carboxypeptidase A was also varied. Some of the aforementioned phosphonates were used as inhibitors of three mutants of carboxypeptidase A, with significantly different values of $K_{m,pep}\ k_0^{-1}$ from the wild type, to obtain 15 different values of $K_{i,pho}$ and $K_{m,pep}\ k_0^{-1}$ for the various combinations of inhibitors and mutant enzymes. Again, the common logarithms of the values of $K_{i,pho}$ were proportional (slope 1.03) to the common logarithms of $K_{m,pep}\ k_0^{-1}$ for the respective mutants hydrolyzing the respective peptides.[477]

Endo-1,4-β-xylanase from *C. fimi* hydrolyzes (β1,4)-D-xylosidic linkages in xylans. Three derivatives of D-xylosyl-(β1,4)-D-xyloside that place a planar lactam oxime, a planar imidazolyl group, and a lactam in the location of carbon 1 and the pyranose oxygen at the reducing end of this disaccharide are potent inhibitors (inhibition constants of 0.37 μM, 0.16 μM, and 0.33 μM, respectively) of the enzyme. When each is used as an inhibitor of a series of mutants of the enzyme, the common logarithms of the inhibition constants of each inhibitor were linearly related (slopes of 1.18, 1.20, and 1.31, respectively) to the values for the common logarithms of $K_m\ k_0^{-1}$ for

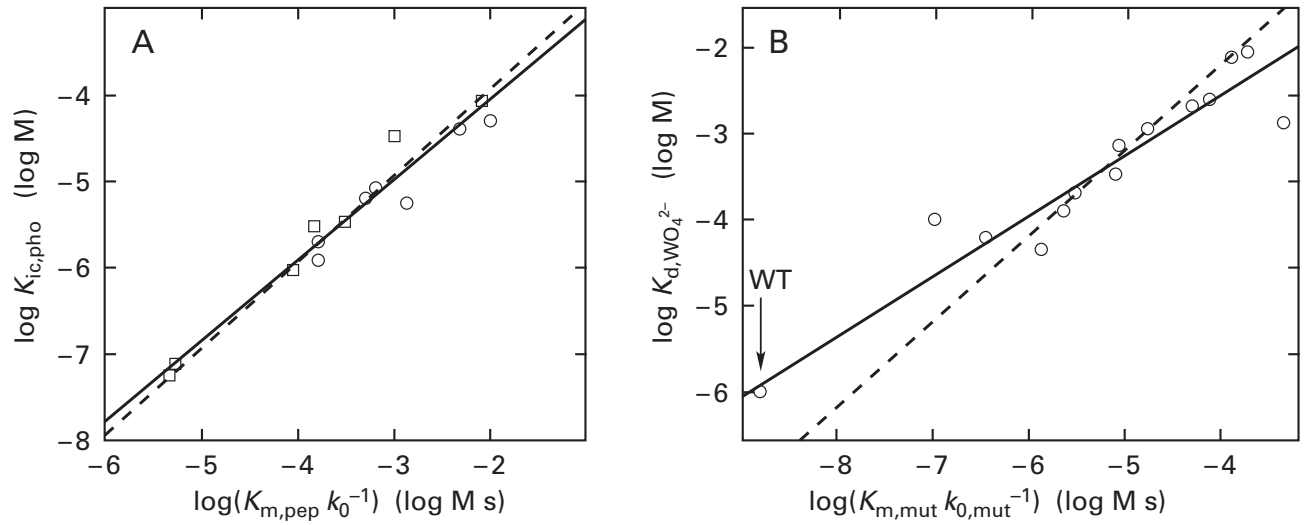


Figure 3–30: **(A)** Correlation between the dissociation constants, $K_{ic,pho}$, for a set of phosphonates from the active site of bovine carboxypeptidase A and the values of the steady-state rate constants, $K_{m,pep}$ k_0^{-1}, for the homologous reactants.[213] The reactants, listed in order of increasing values for $K_{m,pep}$ k_0^{-1}, were the peptides Cbz-Phe-Ala-Ala, Cbz-Ala-Ala-Ala, Cbz-D-Ala-Ala-Ala, Cbz-Leu-Ala-Ala-Ala, Cbz-Phe-Ala-Ala-Ala, Cbz-Gly-Ala-Ala, Pp-Ala-Ala-Ala, Pp-Ala-Ala-Ala-Ala, Cbz-Ala-Ala-Ala-Ala, Ac-Ala-Ala-Ala-Ala, Ac-Ala-Ala-Ala, Cbz-Ala-D-Ala-Ala-Ala, Ac-Ala-D-Ala-Ala-Ala, and Ac-D-Ala-Ala-Ala, where Cbz is benzyloxycarbonyl, Pp is 3-phenylpropanoyl, and Ac is acetyl. In each case, the peptide is cleaved by the enzyme at the peptide bond in the carboxy-terminal alanylalanine. An analogue of each peptide was synthesized in which a phosphonate (**3–73**) replaced the peptide bond between the carboxy-terminal alanylalanine as the phosphonamidate replaces the peptide bond in analogue **3–83**. Each analogue was assayed for its ability to inhibit carboxypeptidase A at pH 7.6, 27 °C, and an ionic strength of 0.5 M with the fluorescent reactant *N*-[3-(2-furyl)-acryloyl]-L-phenylalanyl-L-phenylalanine. The analogues were all competitive inhibitors of the enzyme. The common logarithms of the competitive inhibition constants, $K_{ic,pho}$ (molar), for tripeptides (□) and tetrapeptides (○) are plotted as a function of the common logarithms of their respective steady-state rate constants, $K_{m,pep}$ k_0^{-1} (molar second), determined previously at pH 7.6 and 27 °C.[471,472] The solid line is a least-squares linear fit to the data with a slope of 0.93 (r = 0.975), and the dashed line is a least-squares fit of a line of slope 1 to the data (r = 0.973). **(B)** Correlation between the dissociation constants, $K_{ic,WO_4^{2-}}$, for tungstate from the active sites of a set of mutants of alkaline phosphatase from *E. coli* and the values of the steady-state rate constants, K_m k_0^{-1}, for the hydrolysis of methyl 4-nitrophenyl phosphate at pH 8.0 by the respective mutant.[476] The mutants, listed in order of increasing values for K_m k_0^{-1}, were the wild type (WT), D101A, D153A, K328A, D153A/K328A, D101A, R166S/K328A, D101A/R166S, D101A/R166S/D153A, D153A/R166S, E322Y, D101A/D153A/R166S/K328A, and D153A/E322Y. The dissociation constants for tungstate from the various mutants were the values of the inhibition constant for competitive inhibition of each mutant by tungstate. The common logarithms of these inhibition constants, $K_{ic,WO_4^{2-}}$ (molar), are plotted as a function of the common logarithms of their respective steady-state rate constants, K_m k_0^{-1} (molar second). The solid line is a least-squares linear fit to the data with a slope of 0.7 (root mean square deviation = 0.28), and the dashed line is a least-squares fit of a line of slope 1 to the data (root mean square deviation = 0.41).

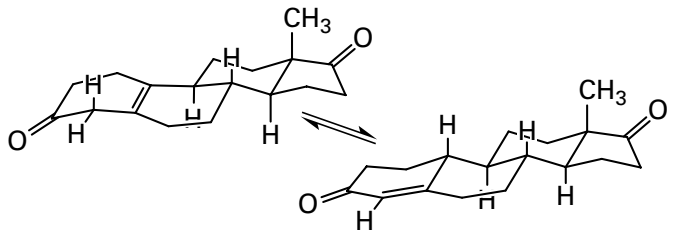
each mutant. The similarity of the slopes, the fact that the data span three orders of magnitude, and the quality of the correlations are arguments in favor of these three inhibitors being analogues of an intermediate or a transition state in the enzymatic reaction.[478] The lactam oxime and the imidazolyl group have carbon 2, carbon 1, the pyranosyl oxygen and carbon 5 in the same plane as would an oxocarbenium ion, and the lactam has carbon 2, carbon 1, and the pyranosyl oxygen in the same plane. These facts are consistent with an oxocarbenium ion as an intermediate in the reaction or an expanded, concerted nucleophilic substitution.

Such correlations can also be evidence that the standard free energies of dissociation for particular functional groups on substrates, even those distant from the site of catalysis, are being used by an active site to lower the standard free energy of the transition state relative to that of the ground state. For example, steroid Δ-isomerase from *P. putida* (Equation 3–376) also catalyzes the alternative isomerization



(3–383)

of estr-5(10)-ene-3,17-dione (ed). Cyclohex-3-en-1-one (co) is an analogue of the single ring in which the isomerization occurs. The value for $k_0\,K_{m,ed}^{-1}$ is 27,000 times greater than $k_0\,K_{m,co}^{-1}$. One interpretation of this large difference is that a portion of the standard free energy of dissociation for the rest of the estr-5(10)-ene-3,17-dione has been used to lower the standard free energy of the transition state for one or more rate-affecting steps in the enzymatic reaction.[479]

Two related enzymes (25% identity; 2.3 gap percent), 2-dehydro-3-deoxy-phosphogluconate/2-dehydro-3-deoxy-6-phosphogalactonate aldolase from *Saccharolobus solfataricus* and 2-dehydro-3-deoxy-phosphogluconate aldolase from *Picrophilus torridus*, each perform a retroaldol reaction on 2-dehydro-3-deoxy-6-phospho-D-gluconate (KDPG), but the value of $k_0\,K_{m,KDPG}^{-1}$ for the former enzyme is 2000 times greater than that for the latter. The enzyme from *S. solfataricus* has a cluster of amino acid side chains responsible for binding the 6-phospho group of 2-dehydro-3-deoxy-6-phospho-D-gluconate that is missing in the enzyme from *P. torridus*. It has been proposed that this difference permits the increased free energy of dissociation, exerted at a significant distance from the point at which the retroaldol cleavage occurs, to be used to lower the standard free energy of the transition state. This decrease in standard free energy increases catalytic activity of the former enzyme.[480]

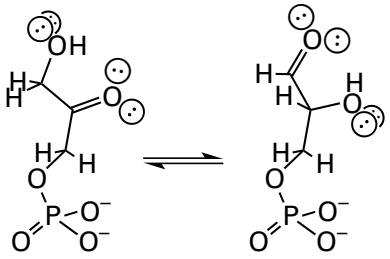
When the phospho group distant from the site of the substitution catalyzed by human orotidine-5′-phosphate decarboxylase (Equation 3–366) is removed from orotidine 5′-phosphate (**3–17**), the catalytic constant decreases[481] by a factor of 10^5. (1-β-D-Erythrofuranosyl)orotic acid (EO) is an analogue of orotidine 5′-phosphate with not just the phospho group but the entire phosphohydroxymethyl group at carbon 4′ replaced by a hydrogen. When it is used as a substrate for orotidine-5′-phosphate decarboxylase (Equation 3–366) from *S. cerevisiae*, the specificity constant $k_0\,K_{mEO}^{-1}$ at pH 7 and 25 °C is 0.02 $M^{-1}\,s^{-1}$, which is 4×10^8 times smaller than the specificity constant $k_0\,K_{mOMP}^{-1}$ ($1\times10^7\ M^{-1}\,s^{-1}$) for the natural substrate, orotidine 5′-phosphate (OMP). This observation is consistent with a decrease in the standard free energy of dissociation for the transition state relative to that of the ground state of –49 kJ mol^{-1}, as a result eliminating the phosphohydroxymethyl group (Equation 3–379).[482] When orotate (O) alone is used as a substrate for orotidine-5′-phosphate decarboxylase (Equation 3–366) from *S. cerevisiae*, the specificity constant $k_0\,K_{mO}^{-1}$ at pH 7 and 25 °C is $3\times10^{-10}\ M^{-1}\,s^{-1}$, which is 7×10^7 times smaller than the specificity constant $k_0\,K_{mEO}^{-1}$. This observation is consistent with a further decrease in the standard free energy of dissociation for the transition state relative to that of the ground state of –45 kJ mol^{-1} as a result of eliminating the β-D-erythrofuranosyl group. These apparent decreases in the standard free energy of dissociation for the transition state are, in turn, consistent with the conclusion that the free energy of dissociation for some or all of the noncovalent interactions of both the phosphohydroxymethyl group at carbon 4′ of orotidine 5′-phosphate and the ribose of orotidine 5′-phosphate is used by the active site to increase the standard free energy of dissociation for the transition state relative to that of the ground state by +94 kJ mol^{-1} and thereby lower the free energy of activation by –94 kJ mol^{-1} (Figure 3–29).[483]

When phosphite, HPO_3^{2-} (PHI), is present at saturation, however, the specificity constant $k_0\,K_{mEO}^{-1}\,K_{dPHI}^{-1}$ (Equation 3–379) is 1600 $M^{-1}\,s^{-1}$, where K_{dPHI} is the dissociation constant from the active site for the cosubstrate phosphite. This specificity constant is consistent with a restoration by the phosphite of +28 kJ mol^{-1} to the standard free energy of dissociation of the transition state relative to that of the ground state[482] and a consequent decrease of –28 kJ mol^{-1} in the standard free energy of activation for the reaction (Figure 3–29). Phosphite substitutes in part for the missing phosphohydroxymethyl group. Because, however, phosphite is not connected covalently to carbon 4′ of (1-β-D-erythrofuranosyl)orotic acid, the active site, by gripping it, cannot be decreasing the entropy of approximation at the site of catalysis. Both the large decrease in the standard free energy of dissociation for the transition state relative to the ground state when the phosphohydroxymethyl group is removed and the subsequent significant increase in the standard free energy of dissociation for the transition state relative to that of the ground state when a portion of that phosphohydroxymethyl group is restored are consistent with the association of the 4′-phosphohydroxymethyl group of orotidine 5′-phosphate,

which is distant from the site of the decarboxylation, nevertheless providing standard free energy to lower the standard free energy of activation.

A series of site-directed mutants of orotidine-5′-phosphate decarboxylase (Equation 3–366) from *S. cerevisiae* with different values for $k_0\,K_{mOMP}^{-1}$ were constructed. When the common logarithms of the rate constants $k_0\,K_{mEO}^{-1}\,K_{dPHI}^{-1}$ were plotted against the common logarithms of the respective rate constants $k_0\,K_{mOMP}^{-1}$, there was a linear correlation between the two, over five orders of magnitude, with a slope of 1.05 ± 0.08. This correlation is further validation of the conclusion that association of the phosphohydroxymethyl group at carbon 4′ of orotidine 5′-phosphate provides standard free energy used to lower the standard free energy of the transition state relative to that of the ground state for the reaction catalyzed by orotidine-5′-phosphate decarboxylase.[484]

A similar correlation (slope = 1.04 ± 0.3) was observed for the reactions catalyzed by a series of site-directed mutants of triose-phosphate isomerase

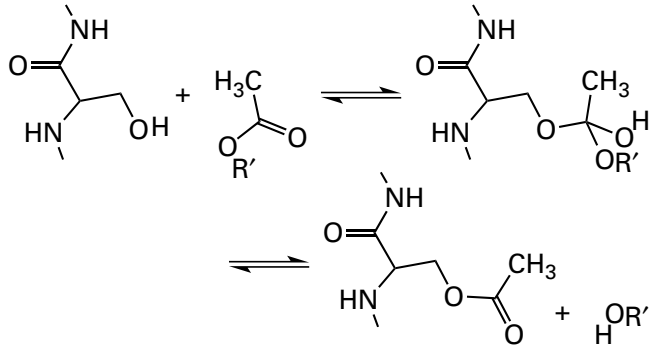


(3–384)

from *Trypanosoma brucei* between the common logarithms of $k_0\,K_{mGAP}^{-1}$, where the Michaelis constant is for D-glyceraldehyde 3-phosphate (GAP), and the common logarithms of $k_0\,K_{mGAP}^{-1}\,K_{dPHI}^{-1}$, where the Michaelis constant is for glycolaldehyde (GA), a truncated version of D-glyceraldehyde 3-phosphate in which the 2-phosphohydroxymethyl group is replaced by a hydrogen, and the dissociation constant is for phosphite (PHI). Again the conclusion is that standard free energy of dissociation for the phosphohydroxymethyl group of D-glyceraldehyde 3-phosphate is used to lower the standard free energy of the transition state relative to that of the ground state for the isomerization catalyzed by the enzyme.[485]

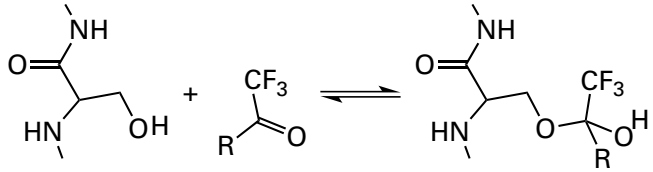
A decrease in the apparent standard free energy of dissociation for the transition state relative to that of the ground state (-35 kJ mol^{-1}) is observed for the reaction catalyzed by 1-deoxy-D-xylulose-5-phosphate reductoisomerase from *M. tuberculosis* when 1-deoxy-L-erythrulose (1-deoxy-D-xylulose-5-phosphate missing its phosphohydroxymethyl group) is used as a substrate, and a portion of the standard free energy of dissociation for the transition state relative to that of the ground state (+13 kJ mol^{-1}) can be restored when phosphite associates with the active site along with 1-deoxy-L-erythrulose.[486]

Thermolysin and carboxypeptidase A catalyze the hydrolysis of a peptide bond by activating water and catalyzing its direct addition to the amide. Another whole group of endopeptidases and esterases, such as trypsin, chymotrypsin, elastase, and acetylcholinesterase, catalyze hydrolyses of acyl compounds by forming covalent intermediates between serines in their active sites and the acyl carbons of the reactants (Figure 3–6). In the case of acetylcholinesterase, the covalent intermediate is an ester formed between a serine in the active site and the acetyl moiety of the reactant



(3–385)

Several trifluoromethyl ketones were synthesized to act as precursors to the respective hemiacetals formed from the serine in the active site[487]

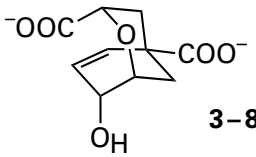


(3–386)

These hemiacetals, because they mimic the tetrahedral intermediate of the nucleophilic substitution catalyzed by acetylcholinesterase (Equation 3–385), are examples of analogues for intermediates of high energy **formed on the active site of the enzyme itself from a precursor**.[488] Because they can form such adducts, trifluoromethyl ketones are potent inhibitors of the enzymatic reaction. For example, the trifluoromethyl ketone that is an analogue for acetylcholine [R = $-(CH_2)_3N^+(CH_3)_3$] has an inhibition

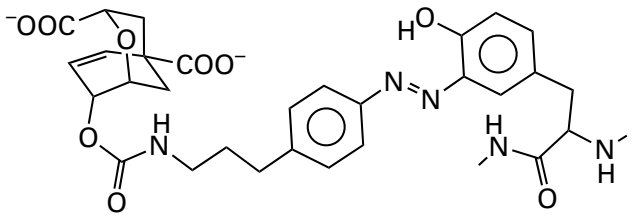
constant, K_i, of 0.06 nM for acetylcholinesterase from *E. electricus*.[487]

It has been pointed out by Jencks,[489] and implied by Pauling,[311] that if an active site catalyzes a reaction by binding the transition state or an intermediate of high energy more tightly than it does the substrates,[311] an immunoglobulin raised against an analogue for either a transition state or an intermediate of high energy, because it would bind the corresponding transition state or intermediate of high energy tightly, should catalyze the corresponding reaction. Such **catalytic immunoglobulins** have been produced. For example, monoclonal immunoglobulins were raised against an analogue[364]



3–84

of the transition state in the chorismate mutase reaction ($K_i = 0.1\ \mu M$) that had been attached as a hapten to a protein carrier through a tyrosine[490]



3–85

One of the monoclonal immunoglobulins produced was able to catalyze the chorismate mutase reaction enzymatically ($k_0 = 2.7\ min^{-1}$, $K_m = 260\ \mu M$ at 10 °C). Although this monoclonal immunoglobulin was not so efficient as chorismate mutase itself ($k_0 = 820\ min^{-1}$, $K_m = 290\ \mu M$ at 10 °C), its catalytic constant was 10^4 times that of the first-order, uncatalyzed reaction under the same conditions. It has already been noted that freezing rotation around the two exocyclic bonds of chorismate and forcing the exocyclic carbon–carbon double bond into the axial position could accelerate the reaction by a factor of 10^3. The same analogue for the transition state was used in other experiments[491] and a similar monoclonal antibody was isolated.

A number of these catalytic immunoglobulins have been produced. None has yet duplicated the acceleration of rate achieved by an enzyme. For example, the largest catalytic constants observed so far are in the range 20–100 min^{-1} at 25 °C[492-495] while enzymes usually have catalytic constants[264] between 10 and $10^6\ s^{-1}$. The advantage of such catalytic immunoglobulins, however, is that they can be designed to catalyze reactions not catalyzed by extant enzymes.[492,496-500]

The standard free energy of dissociation of the substrates can be exploited by an enzyme to alter the difference in standard free energy between reactants and products while they are bound at the active site. The equilibrium constant for the reaction catalyzed by L-lactate dehydrogenase (Equation 3–27) at pH 7, in the direction of reducing pyruvate to lactate and converting NADH to NAD^+ in free solution, is 2.5×10^4 in favor of NAD^+ and lactate because of the gain in aromaticity of the nicotinamide and the conversion of a π bond to a σ bond. When all the substrates, however, are within the active site of the porcine enzyme, the equilibrium constant for the same reaction is only 4.[501] This represents a shift in the standard free energy change for the reaction as written of +22 kJ mol^{-1} when it takes place on the active site. This shift can be explained with the following linkage box

$$\begin{array}{ccc} \mathrm{E + NAD^+ + lactate} & \underset{\Delta G^\circ_1}{\rightleftharpoons} & \mathrm{E + NADH + H^+ + pyruvate} \\ \Big\updownarrow \Delta G^\circ_2 & & \Big\updownarrow \Delta G^\circ_4 \\ \mathrm{E{\cdot}NAD^+{\cdot}lactate} & \underset{\Delta G^\circ_3}{\rightleftharpoons} & \mathrm{EH^+{\cdot}NADH{\cdot}pyruvate} \end{array} \qquad (3\text{–}387)$$

By observation

$$\Delta G^\circ_1 + 22\ \mathrm{kJ\ mol^{-1}} = \Delta G^\circ_3 \qquad (3\text{–}388)$$

It necessarily follows that

$$\Delta G^\circ_2 = \Delta G^\circ_4 + 22\ \mathrm{kJ\ mol^{-1}} \qquad (3\text{–}389)$$

and that pyruvate and NADH dissociate from the enzyme less readily, by +22 kJ mol^{-1}, than lactate and NAD^+. A standard free energy change of +22 kJ mol^{-1} must occur in the noncovalent forces holding the substrates in the active site as pyruvate and NADH are turned into lactate and NAD^+.

A similar effect is observed with isoleucine—tRNA ligase

$$MgATP^{2-} + \text{L-isoleucine} + tRNA^{Ile} \rightleftharpoons AMP^{2-} + H^+ + MgOPO_3PO_3^{2-} + \text{L-isoleucyl-}tRNA^{Ile} \quad (3\text{–}390)$$

from *E. coli*. When the substrates are on the active site,[502] the standard free energy change is +5 kJ mol^{-1} to form the amino acid adenylate that is the intermediate in the reaction; but, in solution,[502,503] the standard free energy change for the same reaction has been estimated to be between +20 and +40 kJ mol^{-1}.

Such shifts in the standard free energy change for an enzymatically catalyzed reaction, brought about by the **preferential association of reactants or the preferential association of products** to the active site, may be advantageous. It has been argued that when the standard free energy change for the reaction catalyzed by an enzyme is shifted sufficiently so that it has a value of 0 within the active site, the enzyme can catalyze the reaction with the highest efficiency.[504] This property is supposed to be essential when the role of that reaction in metabolism is to perform the net transformation of substrates either in one direction or in the other direction, depending on the demands of the moment, and to accomplish this feat, the enzyme must maintain its substrates at their equilibrium concentrations in the cytoplasm.[505] Several enzymes, such as arginine kinase from *Homarus vulgaris*, creatine kinase from *O. cuniculus*, phosphopyruvate hydratase from *S. cerevisiae*, glutamine synthetase from *E. coli*, phosophoglucomutase from *O. cuniculus*, and phosphoglycerate kinase (Equation 3–375) from *S. cerevisiae*,[506] all maintain their substrates at equilibrium in the cytoplasm and all shift the equilibrium constants on the active site to values close or considerably closer to 1.[507] The generality, however, of the conclusion that a perfect enzyme will maintain the equilibrium constant between reactants and products on its active site near a value of 1 has been questioned.[508]

(2016) Substrate distortion and the catalytic reaction mechanism of 5-carboxyvanillate decarboxylase, *J. Am. Chem. Soc. 138*, 826–836. https://doi.org/10.1021/jacs.5b08251

Problem 3–24: The catalytic subunit of aspartate carbamoyltransferase contains the active site that catalyzes the reaction of Equation 3–220.

(A) Write a mechanism for this reaction, involving a tetrahedral intermediate, as it would occur in the active site of the enzyme. Indicate the removals and additions of hydrons by acids and bases in the active site.

(B) Succinate is an inhibitor of the enzyme that competes with L-aspartate for the same corner of the active site. Draw the structures of succinate and aspartate side by side in the same orientation. What is the difference between the two?

When the catalytic subunit of aspartate carbamoyltransferase from *E. coli* is mixed with saturating concentrations of carbamoyl phosphate and succinate, a significant conformational change occurs in the enzyme that is associated with increased absorbance of the protein at 290 nm[178] and a 1.8% increase in the sedimentation coefficient.[509] Neither carbamoyl phosphate nor succinate alone causes this change in conformation; nor does it occur when the carbamoyl phosphate corner of the active site is occupied by $HOPO_3^{2-}$ and either L-aspartate or succinate occupies its corner. The following are dissociation constants for succinate and L-aspartate from the enzyme when it is saturated with either phosphate or carbamoyl phosphate.[178]

ligand	phosphate	carbamoyl phosphate
aspartate	6.7 mM	>20 mM
succinate	33 mM	0.74 mM

The conclusion that can be drawn from these measurements is that carbamoyl phosphate increases the affinity of the enzyme for succinate 50-fold but decreases the affinity of the enzyme for L-aspartate greater than 3-fold.

(C) Examine closely your mechanism for the enzymatic reaction and the structural difference between L-aspartate and succinate and explain values of the tabulated dissociation constants in terms of strain.

(D) Assume that the same noncovalent forces are involved in the binding of either L-aspartate or succinate to the enzyme and that the available noncovalent free energy for L-aspartate changes by the same amount as that for succinate when carbamoyl phosphate is substituted for phosphate. If these assumptions apply, how much free energy of association is apparently used by the enzyme to lower the free energy of activation for the reaction?

Problem 3–25:

(A) Write the chemical mechanism for the hydrolysis of a peptide bond, RCONHR′, when it is not catalyzed by an enzyme. Include all transfers of hydrons explicitly. Draw the reactants, all intermediates, and the products with proper stereochemistry.

A series of inhibitors has been synthesized for thermolysin from *B. thermoproteolyticus*[426]

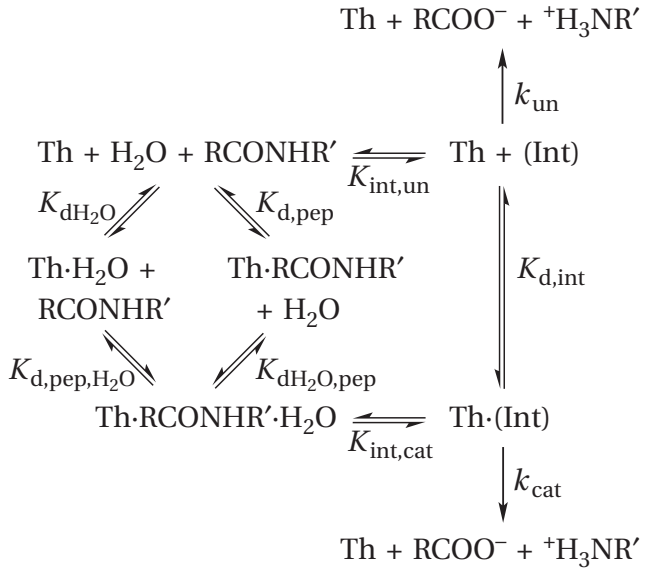
inhibitor	K_i (nM)
CbzNHCH$_2$PO$_2$-L-Leu-D-Ala	1700
CbzNHCH$_2$PO$_2$-L-Leu-amide	760
CbzNHCH$_2$PO$_2$-L-Leu-Gly	270
CbzNHCH$_2$PO$_2$-L-Leu-L-Phe	78
CbzNHCH$_2$PO$_2$-L-Leu-L-Ala	78
CbzNHCH$_2$PO$_2$-L-Leu-L-Leu	9.1

where Cbz is benzyloxycarbonyl.

(B) By drawing the appropriate structures, explain why these inhibitors (see Table 3–7) bind so much more tightly to the enzyme than their analogous substrates (Table 3–6).

(C) What is the central intermediate in the peptide hydrolysis catalyzed by thermolysin?

One way to write the mechanism of the reaction catalyzed by thermolysin and compare it to the mechanism of the nonenzymatic reaction is



where (Int) is the central intermediate in peptide hydrolysis, k_{un} and k_{cat} are rate constants for the dissociation of the intermediate into the two products in free solution or on the active site of the enzyme, Th is thermolysin

$$K_{int,un} = \frac{[(Int)]}{[RCONHR'][H_2O]}$$

$$K_{int,cat} = \frac{[Th\cdot(Int)]}{[Th\cdot RCONHR'\cdot H_2O]}$$

and all the other constants are dissociation constants.

It has been shown that the values of K_m (Table 3–6) for the reactants analogous to these inhibitors are approximately equal to their dissociation constants from the active site. These tabulated values are presumed to be apparent dissociation constants.

$$K_{d,pep,app} = \frac{([Th] + [Th\cdot H_2O])[RCONHR']}{[Th\cdot RCONHR'] + [Th\cdot RCONHR'\cdot H_2O]}$$

(D) Show that

$$K_{d,pep,app} = \frac{K_{d,pep,H_2O}\left(1 + \frac{K_{dH_2O}}{[H_2O]}\right)}{\left(1 + \frac{K_{dH_2O,pep}}{[H_2O]}\right)}$$

(E) Show that

$$K_{d,int} = \frac{K_{dH_2O}\, K_{int,un}\, K_{d,pep,app}\left(1 + \frac{K_{dH_2O,pep}}{[H_2O]}\right)}{K_{int,cat}\left(1 + \frac{K_{dH_2O}}{[H_2O]}\right)}$$

(F) Show that there should be a correlation among the values of inhibition constants, K_i, for the six inhibitors and the values of the dissociation constant, $K_{d,pep}$, and the catalytic constant, k_0, for the respective peptide if the following reasonable assumptions are made.

(a) The initial rate $v_0 = k_0[\text{Th}\cdot\text{RCONHR}'\cdot H_2O] = k_{cat}[\text{Th(Int)}]$ so that $k_0 = k_{cat}K_{int,cat}$.

(b) The rate constant, k_{cat}, is the same for all substrates.

(c) Both the enzymatic reaction and the uncatalyzed reaction proceed through the same central intermediate.

(d) The equilibrium constant, $K_{int,un}$, is the same for all the substrates because the differences among them are distant from the point of hydrolysis.

(e) The concentration of the reactant water is at saturation so that it is greater than the two dissociation constants, K_{dH_2O} and $K_{dH_2O,pep}$.

(f) The equilibrium constants, K_i and $K_{d,int}$, vary in direct proportion to each other as the substrates and their analogous inhibitors are varied in structure.

(G) Show that the results display this correlation.

Problem 3–26: The enzyme inorganic diphosphatase catalyzes the reaction

$$MgO_3POPO_3^{2-} + H_2O \rightleftharpoons MgO_3PO^- + HOPO_3^{2-} + H^+$$

where $MgO_3POPO_3^{2-}$ is the magnesium complex of inorganic diphosphate, $HOPO_3^{2-}$ is phosphate, and MgO_3PO^- is the magnesium complex of phosphate. From the following equilibrium constants[510]

$$\frac{[HOPO_3^{2-}]^2}{[H_2O_3POPO_3^{2-}]} = 2.7\times10^4\ \text{M}$$

$$\frac{[Mg^{2+}][HOPO_3^{2-}]}{[MgO_3PO^-]} = 5\times10^{-2}\ \text{M}$$

$$\frac{[Mg^{2+}][H_2O_3POPO_3^{2-}]}{[MgO_3POPO_3^{2-}]} = 2.7\times10^{-4}\ \text{M}$$

for the species at pH 7, calculate the equilibrium constant for this reaction as written. On the active site of the enzyme from *S. cerevisiae*, the equilibrium constant at pH 7 for the reaction catalyzed by the enzyme is 5. The ionization state of the reactants and products in the active site is unknown. Compare the two equilibrium constants, the one in solution with the one on the active site. Discuss their relative magnitudes in terms of approximation and strain.

Problem 3–27: These competitive inhibitors were designed as analogues for intermediates of high energy for the respective enzymes. Draw the inhibitor next to the intermediate of high energy in the reaction that it was designed to mimic in the same orientation as the drawing of the compound.

enzyme	inhibitor	K_{ic}
aconitate hydratase[511]		60 nM
isocitrate lyase[512]		<20 nM

orotidine-5′-phosphate decarboxylase[513]		10 pM
adenosine deaminase[514]		3 pM
acetylcholinesterase[515]		30 nM
glucose-6-phosphate isomerase[516]		0.3 μM
phosphopyruvate hydratase[517]		0.1 μM
adenosine deaminase (3.5.4.4)[400]		25 μM

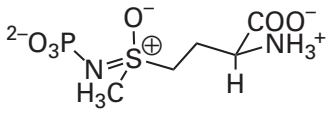
The reactions catalyzed by these enzymes can be learned at https://www.enzyme-database.org/.

Problem 3–28: Is the magnesium complex of *P*(1),*P*(5)-bis(5′-adenosyl) pentaphosphate a bisubstrate analogue or an analogue for an intermediate of high energy for adenylate kinase from *O. cuniculus*

$$AMP^{2-} + MgATP^{2-} \rightleftharpoons ADP^{3-} + MgADP^{-}$$

if its dissociation constant as a competitive inhibitor[518] is 3 nM while the dissociation constants from the active site for AMP^{-} and $MgATP^{2-}$ are 0.1 and 0.6 mM?

Problem 3–29: L-Methionine (*S*)-sulfoximine *N*-phosphate



forms a tight complex with ovine glutamine synthetase.[391,519] What does this fact suggest about the mechanism of the enzyme?

Crystallographic Studies of Active Sites

The initial step in a crystallographic study of the active site of an enzyme is to construct a **refined crystallographic molecular model of the enzyme in one of its forms** by the usual procedures of crystallization, diffraction of X-rays, collection of a data set, calculation of a map of electron density, construction of a molecular model, and refinement. For a protein that has just been crystallized and to which these methods are being applied, molecular replacement is always the first resort for calculating a map of electron density.

There are now so many crystallographic molecular models of so many proteins that one is often already available of a protein that is known from its sequence of amino acids to be homologous to the enzyme of interest.* In addition, methods of artificial intelligence can use the large and ever-growing collection of established crystallographic molecular models to learn how to construct a molecular model from the sequence of amino acids for a protein.[520] Either or both of these approaches can be used to create a hypothetical molecular model† for the purposes of molecular replacement of a protein that has been crystallized but for which a crystallographic molecular model is unavailable.

*It is now the case that the sequence of amino acids for any protein that has been purified and crystallized is almost always available from genomic sequencing.

†It should be pointed out that these methods provide a hypothetical molecular model of only the unoccupied protein and are as yet unable to provide a hypothetical molecular model of a form of the enzyme in which the active site is occupied by any ligand. Hence, crystallography is still required to examine the mechanism of an enzyme. It should also be kept in mind that these methods, because they do not rely on any understanding of the forces involved in protein folding, which are at best poorly understood, cannot provide any information about why a protein has a certain structure.

The crystallographic molecular model of a related protein or a hypothetical molecular model created by artificial intelligence is used as a starting point to apply molecular replacement to the observed reflections from a crystal of the enzyme of interest. **Molecular replacement** allows the crystallographer to initiate refinement without the need for the arduous tasks of discovering isomorphous replacements, locating the positions of the heavy atoms in those isomorphous replacements, and phasing the initial data set of observed reflections. Consequently, molecular replacement has had a significant impact on crystallography.

Molecular replacement uses **Patterson maps** to score its trials and errors. A Patterson map is calculated by the usual Fourier transform from squares of the amplitudes of reflections in an observed data set, but the phases for the reflections are all set at zero. A Patterson map provides a map of all the vectors between all the atoms in the unit cell rather than a map of electron density. Nevertheless, a Patterson map is indirectly related to the actual electron density within the unit cell.

If a known molecular model of a homologous protein is used as a starting point, a molecular model of the actual protein in the crystal with which to initiate refinement is then built from the molecular model of the homologous protein by placing each of its amino acids in the location of the homologous amino acid in the protein used to initiate the molecular replacement. When a hypothetical molecular model derived from artificial intelligence is used to initiate molecular replacement, it already has the correct sequence of amino acids.

Methods are available to **rotate and translate the homologous or hypothetical molecular model** of the protein within the unit cell of the crystal of the protein of interest for which a molecular model is not available.* The homologous or hypothetical crystallographic molecular model is rotated and translated until the calculated Patterson map of the rotated and translated molecular model in the unit cell containing the protein of interest has the highest correlation with the Patterson map calculated from the amplitudes of the reflections observed directly from the new crystal. When the best correlation is achieved, it is assumed that the orientation and position of the homologous or hypothetical crystallographic molecular model is as close as possible to the orientation and position of the actual molecule of the protein of interest in the unit cell of the crystal.

Once the molecular model in which the amino acids of the homologous protein have been replaced or the hypothetical molecular model has been positioned and oriented in the unit cell of the new crystal, a data set of reflections, F_c, and a data set of phases, α_c, is calculated from that oriented molecular model. These two data sets are used to initiate a refinement of the structure against the data set of the observed amplitudes of the reflections, F_o, from the crystal, again the only actual observations.

Gradually, under the influence of the observed data set, the map of electron density shifts from that of the initial molecular model to one for the actual molecule in the crystal. At first, the set of atoms that were present in the initial crystallographic molecular model positioned by the molecular replacement are continuously repositioned in the maps of electron density calculated during initial rounds of refinement as accurately as possible. When further adjustments of these atoms are no longer required, the positive electron density for any prosthetic groups in the active site or molecules of water or other ligands that are at any location in the protein in the crystal and that were not present in the anhydrous molecular model used to initiate the refinement will be at their most accurate resolution, and molecular models of these prosthetic groups, molecules of water, and ligands are placed within their respective electron densities. The more complete structure is then submitted to further refinement against the observed amplitudes, and molecules of water are added as they appear in the map of electron density.

In the initial crystallographic molecular model of the enzyme, the active site is usually unoccupied by substrates or inhibitors because neither substrates nor inhibitors were present in the solution from which the enzyme was crystallized. In many instances, however, **a form of the enzyme occupied by a substrate or an inhibitor** is the form chosen for the initial crystals, often because it crystallizes more readily. Such a salutary effect of a ligand on the crystallization is thought to be due to the rigidification of the active site produced by its association. Just as is done with molecules of water or prosthetic groups, as soon as the electron density of that substrate or inhibitor becomes definitive in one of the intermediate maps of difference electron density calculated during the refinement, a molecular model of it is

*Most unit cells have more than one molecule of protein within them. Each molecule of protein, however, is usually related to every other molecule of protein by the symmetry operations of the space group. As a result, rotation of the known crystallographic molecular model of the protein can be continuously coupled to rotation of other copies of that same known crystallographic molecular model within the new unit cell by these symmetry operations so that all copies rotate at the same time.

positioned within that electron density, and that molecular model of the ligand simply becomes a part of the overall molecular model of the enzyme submitted to further refinement.

In some instances, a protein, thought to be unoccupied, has been found to have a ligand bound to it other than any of the components in the solution used to crystallize the protein. When such unexpected features appear in its map of electron density, the unexpected ligand should then be identified by chemical analysis rather than just by guessing what it is.[521-523]

The initial crystals of the enzyme, either occupied or unoccupied; the data sets for the observed amplitudes of the reflections, F_o, the calculated amplitudes of the reflections, F_c, and the calculated phases for the reflections,* both α_o and α_c; the refined maps of electron density; and the fully refined crystallographic molecular model itself comprise the starting point in a study of the active site of a particular enzyme.

Although molecular models of substrates and inhibitors are often **docked computationally** with an empty active site to produce imaginary complexes, this practice is usually unreliable,[524] while crystallographic molecular models of actual complexes are definitive pictures of actual events.

Crystals of an enzyme, the active site of which is occupied by one or more substrates or inhibitors of interest that were not present in the initial crystals, can be prepared in at least two ways. The initial crystals of the enzyme with an unoccupied or otherwise occupied active site can be transferred to a solution containing one or more of these ligands of interest, which diffuse into the crystal and occupy the active sites. Often this **soaking** causes the crystals to shatter as adjustments in the structure of the protein occur in response to the occupation of the active site. Sometimes this shattering can be prevented by crosslinking the crystals, but this procedure can often prevent a conformational change required to produce the active conformation of the active site or even prevent the added ligands from occupying the active site. Preferably, **the ligands of interest can be present during crystallization** at concentrations adequate to saturate the active sites and become directly incorporated into the crystal while on the active site of the enzyme. This strategy, however, can lead to crystals that are not isomorphous with the original crystals and have a different space group from the original crystals simply because the enzyme is a different molecule when one or more ligands are bound than when no ligand or another ligand is bound. For example, while the unliganded α_2 dimer of equine alcohol dehydrogenase crystallizes in the $C222_1$ space group with a single protomer as the asymmetric unit, the form of the enzyme in which the active site is occupied by NADH crystallizes in the $P1$ space group with the entire α_2 dimer necessarily comprising the asymmetric unit.[525]

If crystals of the enzyme occupied with the substrate or inhibitor of interest have a **different space group from the initial crystals** of the unoccupied or otherwise occupied enzyme, they necessarily present an entirely new crystallographic problem. In almost all cases, however, this new problem can again be solved rapidly by molecular replacement using the initial molecular model of the protein of interest as a starting point.

If one is lucky and **the new crystals of the liganded enzyme are isomorphous** with the crystals that produced the initial crystallographic molecular model, a map of electron density can be calculated using the set of calculated phases, α_c, from the initial refined crystallographic molecular model and the observed data set of amplitudes for the reflections, F_o, collected from the new crystals. Were the phases of all the reflections from the new crystals the same as the phases of the reflections from the initial crystals, an unambiguous map of electron density could be calculated from this data set immediately, but they are not the same because the presence of new ligands has produced a different set of reflections with different phases from those collected from the initial crystals. Although the electron density for the polypeptide itself is almost the same as it was in the earlier refined map of electron density of the otherwise occupied or unoccupied enzyme, there are often differences, especially in the vicinity of the active site, resulting from changes in the conformation of the polypeptide elicited by the binding of substrates or inhibitors that now occupy the enzyme, and these changes must be incorporated during refinement. The alterations in electron density resulting from these changes in conformation become more definitive as the refinement against the data set of observed

*It is worth reminding the reader that the only observed data are the reflections from particular crystals and their amplitudes, which are tabulated both in the several data sets that are needed to calculate the phases and in the data sets F_o used with the phases to calculate maps of electron density. All the remaining data sets are for calculated data, including the euphemistically designated "observed phases", α_o, as well as the data sets for the phases, α_c, and the reflections, F_c, calculated from the various interim crystallographic molecular models built by the crystallographer in the computer during the cycles of refinement.

amplitudes progresses, and these alterations guide the necessary adjustments of the polypeptide. Again, the atoms present in the initial model are positioned in the new model as accurately as possible first, and then, either initially or as the refinement proceeds, molecular models of the novel ligand or ligands are inserted in the respective features of positive electron density.

There are, however, **problems with isomorphous crystals**. Isomorphous crystals may not have the enzyme in the proper conformation for catalysis. For example, when $MgATP^{2-}$ is diffused into crystals of a domain of myosin II from *Dictyostelium discoideum*, it is unhydrolyzed in the map of electron density calculated from the observed data set even though the domain would have rapidly hydrolyzed the $MgATP^{2-}$ were it in solution.[526] When Mg^{2+} is diffused into crystals of a complex between the *Eco*RV endonuclease from *E. coli* and a fragment of DNA, the DNA remains unhydrolyzed even though the Mg^{2+} associates in the active site adjacent to the phosphodiester that is normally hydrolyzed by the enzyme in the presence of Mg^{2+} when it is in solution.[527] Another disadvantage of trying to avoid molecular replacement by using isomorphous crystals is that it is difficult to eliminate bias toward the initial, unliganded structure. Often molecular replacement is still used to obtain an initial map of electron density from an isomorphous crystal to avoid these biases.

A refined crystallographic molecular model of **a complex between a protein that is not an enzyme and a ligand** that binds to that protein can also be obtained by these procedures. Strategically, this approach is a simpler problem than that of a complex between an enzyme and its substrates because a protein that simply binds a ligand does not alter the ligand covalently in a catalytic reaction. Examples of crystallographic molecular models for such naturally static complexes are those for hormone receptors and their hormones,[528] immunoglobulins and their antigens,[529] binding proteins that deliver metabolites to proteins catalyzing transport and their metabolites,[530-532] lectins and their oligosaccharides,[533,534] agglutinins and their oligosaccharides,[535,536] lipid-binding proteins and their lipids,[537-539] and histocompatibility antigens and their peptidic ligands.[540-542]

When the refinement of a crystallographic molecular model of the liganded enzyme is complete, an **omit map of difference electron density** is calculated**.** For the calculation of this omit map, the molecular model of a substrate, ligand, or inhibitor is omitted from a crystallographic molecular model, a data set is calculated from this molecular model, and refinement against the observed reflections is initiated and continued until the positive electron density for these omitted participants in the maps no longer changes This omit map of difference electron density and the value of R_{free} for the omit map are presented as validation and a measure of the accuracy, respectively, of the final orientations of all these essential groups (Figure 3–31).[543] In many instances, any prosthetic groups, molecules of water, and amino acid side chains judged to be essential to catalysis are omitted and consequently become features in the map. It is always the final omit map of difference electron density that provides the most accurate picture of the actual occupancy of the active site.

An active site or binding site that is unoccupied by substrates or ligands is filled with molecules of water. This observation is almost universal because empty space is always minimized in a condensed phase. Because a molecule of protein in its crystal is still entirely dissolved in water, and therefore still in a condensed phase, empty spaces larger than a molecule of water will usually be automatically filled with molecules of water. An active site is required to orient substrates so they can act as participants in the reaction catalyzed by the enzyme. The noncovalent interactions usually employed to perform this orientation are hydrogen bonds formed between the active site and the substrates. The donors and acceptors for those hydrogen bonds in the active site when it is unoccupied by substrates form hydrogen bonds with more or less rigidly held molecules of water.[511] In the map of electron density for the unoccupied active site, these fixed molecules of water appear as spheres of electron density. There are, however, in the map of electron density many apparently vacant areas, especially the spaces between the molecules of protein but those within the molecules of protein as well. Because nature abhors a vacuum, these apparent vacancies are areas in the actual crystal that are almost always filled with **molecules of disordered water**.

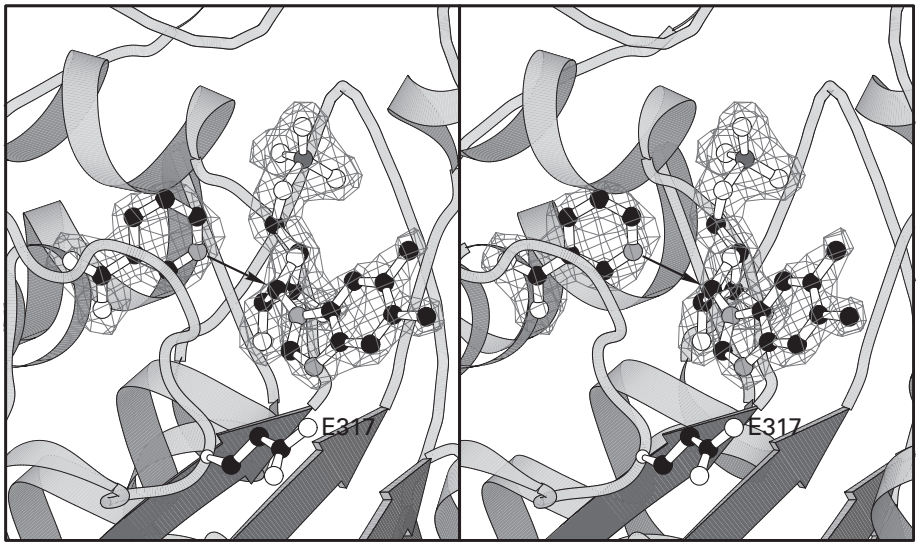


Figure 3–31: Map of difference electron density between nicotinate-nucleotide—dimethylbenzimidazole phosphoribosyltransferase from *S. typhimurium* with a vacant active site and the enzyme with its active site occupied by α-ribazole 5′-phosphate and nicotinate.[543] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large dark gray atom is phosphorus. Nicotinate-nucleotide—dimethylbenzimidazole phosphoribosyltransferase from *S. typhimurium* was crystallized in a buffer of ammonium phosphate containing the substrate 5,6-dimethylbenzimidazole. A refined crystallographic molecular model of the complex between the enzyme and 5,6-dimethylbenzimidazole was constructed from a data set gathered to Bragg spacing of 0.19 nm from crystals of this complex and several isomorphous replacements. Samples of these crystals were soaked in a solution of the substrate β-nicotinate D-ribonucleotide, and a new data set was gathered, again to Bragg spacing of 0.19 nm. A map of difference electron density was calculated from amplitudes of the reflections of this new data set and amplitudes and phases of the reflections calculated from the original refined crystallographic molecular model of the complex between the enzyme and 5,6-dimethylbenzimidazole from which the molecular models of the 5,6-dimethylbenzimidazoles, all the waters, and all the phosphate ions had been removed to completely empty the active sites. The map of electron density that resulted (features of isoelectronic density in the drawing) clearly demonstrated that β-nicotinate D-ribonucleotide and 5,6-dimethylbenzimidazole had been converted by the enzyme within its active site to nicotinate (to the left) and α-ribazole 5′-phosphate (to the right). Molecular models of these two substrates were inserted into the respective features of electron density, and their exact positions were determined by refinement. A ribbon drawing of the crystallographic molecular model of the protein surrounding the active site is included in the figure. Nitrogen 1 of the nicotinate can displace the 5,6-dimethylbenzimidazole of the α-ribazole 5′-phosphate in the nucleophilic substitution catalyzed by the enzyme (arrow) to produce β-nicotinate D-ribonucleotide, but the equilibrium within the active site favors the observed substrates nicotinate and α-ribazole 5′-phosphate. Glutamate 317 hydronates nitrogen 3 of the 5,6-dimethylbenzimidazole in α-ribazole 5′-phosphate to make it a better leaving group in the reaction catalyzed by the enzyme. In building the initial crystallographic molecular model of the enzyme, **fixed molecules of water*** are added to the molecular model as its refinement progresses, and they become obvious features of electron density. Consequently, the fully refined initial crystallographic molecular model, which forms the basis for calculating the maps of electron density for the various forms of the enzyme occupied by the various ligands, contains many molecules of water. This initial molecular model is to be the starting point for either molecular replacement or for calculating a new map of electron density from an isomorphous crystal. For these calculations, under the assumption that occupation of the active site changes the position and occupation of these sites for fixed molecules of water, even at distant locations, **all the molecules of water in the initial crystallographic molecular model are routinely discarded** before it is used as a starting point in the rotation and translation operations of molecular replacement and refinement. As the subsequent refinement of the liganded molecular model progresses, fixed molecules of water appear, not necessarily in the same places as the ones that were discarded, and they are added to the new structure during its refinement. If the active site in the initial model is occupied by any other ligand, that ligand is also removed before the set of phases used to initiate the refinement is calculated from the initial model properly positioned in the unit cell. An exception to this procedure is a tightly bound prosthetic group, which is usually retained in the active site under all conditions and is consequently retained in the stripped initial molecular model.

When a substrate, inhibitor, or ligand associates with an active site or a binding site, **it displaces the molecules of water that occupied the active site** in its absence. Because an active site often has a significant constellation of donors and acceptors ready to form hydrogen bonds with its substrates, there are usually quite a few fixed molecules of water within the active site in a crystallographic molecular model of the unoccupied enzyme. The displacement of these fixed molecules of water can be followed by examining crystallographic molecular models. For example, in the active site of streptogrisin A from *Streptomyces griseus*, there are 15 fixed molecules of water that are displaced when the competitive inhibitor chymostatin binds to the active site (Figure 3–32).[544] In the absence of the inhibitor 1-deoxynojirimycin, the donors and acceptors that will form hydrogen bonds to the four hydroxy groups of the 1-deoxynojirimycin when it occupies the active site of glucoamylase from *Aspergillus awamori* are occupied by four fixed molecules of water, which assume the same positions that the hydroxy groups of the inhibitor do.[545]

Large nonpolar pockets intended for purely hydrophobic portions of the substrates, even though they themselves are lined by hydrophobic amino acids, do not remain empty in the absence of substrates but are occupied by molecules of water, often fixed molecules of water. For example, when a molecule of oleate associates with the binding site for fatty acids in the intestinal fatty acid binding protein from *R. norvegicus*, its alkane displaces at least nine fixed molecules of water occupying that hydrophobic site in its absence.[546] As a ligand binds to the active site by occupying the donors and acceptors for hydrogen bonds and nonpolar pockets, the molecules of water that were occupying these locations must dissociate before the ligand can settle in.

Aside from occupying donors and acceptors for hydrogen bonds in an active site that will ultimately by occupied by acceptors and donors on a substrate and filling otherwise empty space that will be filled by atoms of the substrate, **a fixed molecule of water in the empty active site can itself wind up being a substrate for the enzyme.** For example, in the crystallographic molecular model of the empty active site of β-lactamase from *S. aureus*, there is a molecule of water fixed by hydrogen bonds to Glutamate 166 and Asparagine 170.[547] During the hydrolysis of β-lactams catalyzed by the enzyme, the acyl group of the lactam participates in a nucleophilic substitution in which the hydroxy group of Serine 70 replaces the amino group of the lactam to produce an intermediate ester. The molecule of water fixed by these two hydrogen bonds is positioned in the empty active site at a location where it can participate in a second nucleophilic substitution, replacing the hydroxy group of Serine 70 in this intermediate ester and releasing the hydrolyzed lactam. When Asparagine 170 is replaced with a glutamine, this water in the empty active site is displaced,[548] and the hydrolysis of the intermediate ester with Serine 70 is decreased by a factor of 800.

*As before, a fixed molecule of water is a molecule of water that has a fixed location in a map of electron density. This usage is not meant to imply that the same molecule of water occupies this location for any appreciable length of time; rather, these molecules of water are exchanging rapidly with molecules of water in the solvent. At any given instant, however, the site is occupied by a molecule of water.

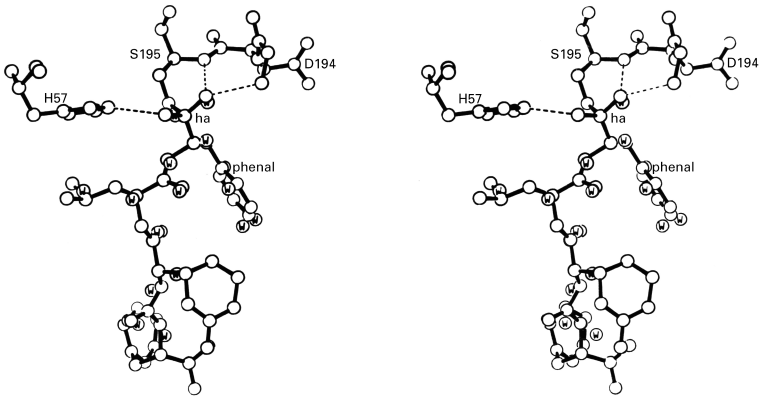

Figure 3–32: Crystallographic molecular model of the inhibitor chymostatin bound within the active site of streptogrisin A from *S. griseus*, including the molecules of water displaced from the active site by the inhibitor.[544] Streptogrisin A was crystallized (space group $P4_2$) from 1.3 M sodium phosphate at pH 4.1. A data set, F_{nat}, was collected to Bragg spacing of 0.18 nm. The phases of these reflections were estimated from four isomorphous replacements, and the initial crystallographic molecular model was refined to an *R*-factor of 0.14. This refined crystallographic molecular model contained 200 molecules of water. Crystals were soaked in mother liquor containing chymostatin, and a new data set, F_{chym0}, was then collected. The map of difference electron density ($F_{chym0} - F_{nat}$) was then calculated to locate the position of chymostatin in the unit cell. The inhibitor was found to overlap 18 of the molecules of water in the refined crystallographic molecular model of the unoccupied enzyme. These molecules of water were removed from the crystallographic molecular model, and a data set, F_c, was then calculated from it. The difference map of electron density ($F_{chym0} - F_c$) was then used to position the chymostatin as accurately as possible. This resulting molecular model was then refined against the data set F_{chym0}. The stereo drawing presents the final configuration of the chymostatin (P1–P4) and three of the amino acids in the active site (H57, S195, and D194). The aldehyde of the carboxy-terminal phenylalaninal (phenal) of the chymostatin has formed a hemiacetal (ha) with the hydroxy group of Serine 195. Fourteen of the 15 waters located within the active site of the unliganded crystallographic molecular model of streptogrisin A at locations overlapping that of the chymostatin, which are displaced by the chymostatin as it associates with the active site, are indicated as W. The final crystallographic molecular model of the occupied active site, in which the protein is positioned by the refinement itself and the substrates, inhibitors, or other ligands are positioned by the omit map, is used to draw conclusions about the mechanism of the enzymatic reaction. The crystallographic molecular model of an enzyme with its active site occupied by the full complement of substrates presents a challenging problem because an enzyme, by definition, catalytically interconverts its substrates. Consequently, most crystallographic studies of enzymatic active sites are performed in the absence of a full complement of substrates. The crystallographic molecular model of the active site of an enzyme occupied by one or more substrates or inhibitors, in which the entire complement of substrates is not present, is a static structure. Because it is a static structure rather than an active catalyst, the information gained about the catalytic mechanism of the enzyme from such a crystallographic molecular model **depends entirely upon the ligands that are chosen to occupy in the active site.**

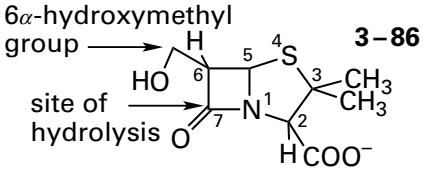
The simplest information gained from a crystallographic molecular model is the **location of the active site** in its structure. If the enzyme happens to contain a tightly bound prosthetic group involved in the catalytic mechanism, it will identify the location of the active site.[549] If an enzyme has only one reactant and one product or if one of the two reactants is water itself, which cannot be left out of the crystal, then **competitive inhibitors are often used to locate the active site**.[550,551] For example, 2-benzylsuccinate dianion is a competitive inhibitor of carboxypeptidase C from *S. cerevisiae* and is found in the crystallographic molecular model of its complex with the enzyme. The 1-carboxy group of the inhibitor forms hydrogen bonds to the side chains of Glutamate 145, Histidine 397, and Asparagine 51 and the amido group of Glycine 52, and its phenyl group is inserted into an adjacent nonpolar pocket. These donors and acceptors for hydrogen bonds and this nonpolar pocket together constitute the subsite within the active site at which the carboxy-terminal amino acid of a normal reactant for the enzyme is thought to bind.[552]

Crystallographic molecular models of the active sites of enzymes occupied by **inhibitors of pharmaceutical interest** can be used to design even more potent inhibitors that have even smaller dissociation constants.[553-555] For example, an examination of the crystallographic molecular model of the complex between exo-α-sialidase from influenza virus and the inhibitor 2-deoxy-2,3-dehydro-D-*N*-acetylneuraminic acid ($K_i = 1\ \mu M$) suggested that substitution of the 4-hydroxy group of the inhibitor with a guanidinio group would take advantage of four properly oriented acceptors in the protein for four of the five new donors for hydrogen bonds in the guanidinio group. The 4-guanidinio derivative was a far more tightly bound inhibitor ($K_i = 0.1$ nM), and its guanidinio group did occupy the acceptors as predicted.[556]

Examination of the crystallographic molecular model of an acyl intermediate between penicillanic acid and the active site of TEM-1β-lactamase, which hydrolyzes penicillins, suggested that adding a hydroxymethyl group to carbon 6 of the penicillanic acid would displace the water necessary to hydrolyze that acyl enzyme intermediate, just as mutation of the asparagine in the active site of β-lactamase from *S. aureus* to a glutamine displaced a molecule of water responsible for hydrolyzing the acyl enzyme intermediate in its enzymatic reaction.

6α-(Hydroxymethyl)penicillanic acid



3–86

was found to form a long-lived, inactive, covalent complex with the enzyme in which its hydroxy group does displace the hydrolytic water.[557] Crystallographic molecular models can also be used to locate binding sites on enzymes for inhibitors of pharmaceutical interest that do not mimic the substrates of the enzyme.[558-560]

Competitive inhibitors that are much closer **analogues for substrates** of the enzyme are usually used to define the complex between an enzyme and a lone substrate. For example, D-glucitol 6-phosphate, in which the 2-oxo group of the substrate D-fructose 6-phosphate has been reduced to the secondary alcohol, locates the active site in the crystallographic molecular model of its complex with D-psicose-6-phosphate 3-epimerase

D-psicose 6-phosphate $\rightleftharpoons$ D-fructose 6-phosphate (3–391)

from *E. coli*. In addition to identifying the active site, this crystallographic molecular model also defines the coordination of the actual substrate D-fructose 6-phosphate with a prosthetic Mg^{2+} and reveals a

pocket with a lining of amido groups from the backbone of the polypeptide and hydroxy groups from side chains that together form five hydrogen bonds to the three nonbridging oxygens of the 6-phospho group.[561]

Most enzymes catalyze reactions involving two or more reactants and two or more products. In such a situation, the active site and the subsite within the active site for a substrate can be located by **occupying it with only one of the two reactants or products**.[562-566] For example, a crystallographic molecular model of (2*E*,6*E*)-farnesyl diphosphate bound to protein farnesyltransferase from *R. norvegicus*, in the absence of its other reactant, a protein to which the enzyme transfers the (2*E*,6*E*)-farnesyl group, locates the active site on the enzyme and defines the snug nonpolar pocket into which the farnesyl group inserts.[567] Likewise, the crystallographic molecular model of UDP-galactose bound to bovine *β*-*N*-acetylglucosaminyl-glycopeptide *β*-1,4-galactosyltransferase in the absence of its other reactant, an oligosaccharide with *β*-*N*-acetyl-D-glucosamine at its nonreducing end, locates the subsite within the active site with which UDP-galactose associates and also defines the significant conformational change that occurs in the polypeptide surrounding the active site and that creates the site to which the oligosaccharide that is the other reactant binds after the UDP-galactose has associated.[568] The complex between the substrate uridine 5′-phosphate and the active site of orotidine-5′-phosphate decarboxylase (Equation 3–366) from *B. subtilis* in the absence of CO_2 **identifies the catalytic side chains surrounding the site** of the carboxylation.[569] Orotidine 5′-phosphate, the reactant corresponding to the product uridine 5′-phosphate, would be immediately decarboxylated if it were mixed with the enzyme.

Both $MgADP^-$ and $MgATP^{2-}$ were bound in separate experiments at the active site of crystalline equine phosphoglycerate kinase (Equation 3–375) by soaking crystals in solutions of the respective ligand. Both of these substrates, one a reactant and the other the respective product, were bound at the same location and in the same orientation in a pocket on the surface of the enzyme, and this observation both located the active site and **defined the noncovalent interactions** between the active site and an adenine nucleotide.[570] There are crystallographic molecular models of much higher accuracy and resolution[571] of $MgADP^-$ and $MgATP^{2-}$, respectively, occupying the active site of 5-(carboxyamino)imidazole ribonucleotide synthase from *Aspergillus clavatus*, in which the precise conformation of the nucleotides, their ligation by two Mg^{2+} ions, and the donors and acceptors for hydrogen bonds ensnaring them in the active site are clearly observed.

Many of the dehydrogenases using nicotinamide-adenine dinucleotides as coenzymes have been crystallized with either NAD^+, NADH, $NADP^+$, and NADPH occupying their active sites,[525,572-574] the so-called "holoenzyme", in the absence of the other respective nominal reactant or in the presence of an inhibitor that is competitive with the nominal reactant. In most instances, crystallographic molecular models of such "holoenzymes" have permitted the description of the extensive networks of hydrogen bonds that form between amino acids of the active site and NAD^+, NADH, $NADP^+$ or NADPH (Figure 3–33),[575,576] which are large molecules.

In a strategy similar to using just one of two reactants, for an enzyme that has three reactants, using **two of the three reactants** will often form a static complex. The crystallographic molecular model of this complex will not only locate the subsites in the active site for each of the two reactants but will also reveal the relative orientation of the reactants and allow one to imagine the corresponding orientation of the third reactant.[577]

The practice of using just one of two reactants or two of three reactants, however, can be misleading. For example, crystals of unliganded citrate (*Si*)-synthase (Equation 3–226) were soaked in solutions of citrate, and isomorphous crystals of the enzyme to which citrate is bound were obtained. When crystals were formed from enzyme to which both citrate and coenzyme A had been bound, however, the enzyme changed its conformation, causing the active site to rearrange and the details of the interactions between citrate and the amino acids around it to change significantly.[578]

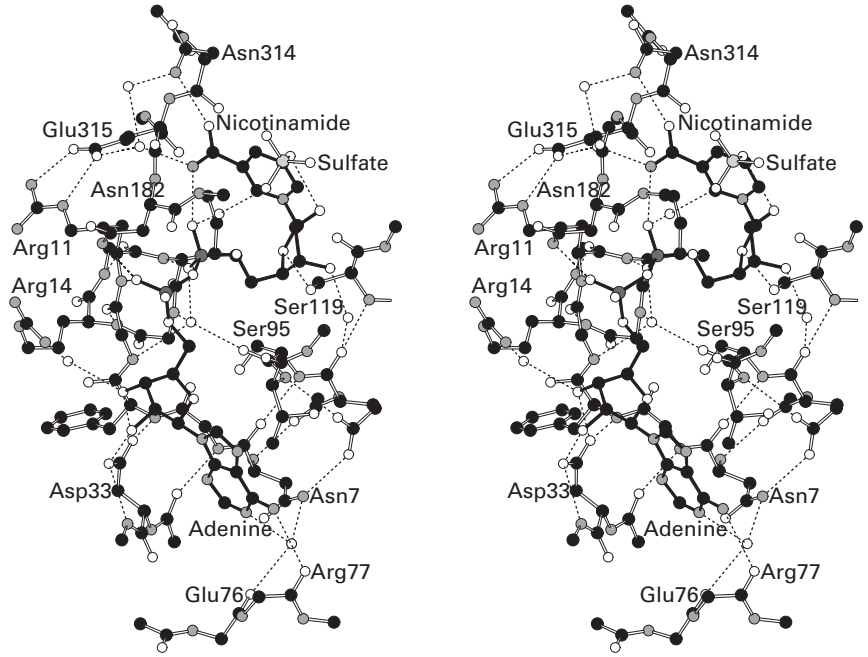


Figure 3–33: Stereodrawing[576] of the network of hydrogen bonds between NAD^+ and side chains of amino acids in the polypeptide surrounding the active site in the crystallographic molecular model of the complex between NAD^+ and glyceraldehyde-3-phosphate dehydrogenase from *G. stearothermophilus*.[575] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, the two large dark gray atoms are atoms of phosphorus, and the large light gray atom is a sulfur. The complex between glyceraldehyde-3-phosphate dehydrogenase and NAD^+ was crystallized from a phosphate buffer containing 1 mM NAD^+. In the final crystallographic molecular model from a data set gathered to Bragg spacing of 0.18 nm and data sets of several isomorphous replacements, the adenine ring (Adenine) of the NAD^+ in the active site participates in hydrogen bonds with the peptidic oxygen of Arginine 77 from the protein and a fixed molecule of water (white sphere). The O2′ and O3′ groups on the adenylyl ribose participate in hydrogen bonds with the carboxy group of Aspartate 33 and the latter with a molecule of water (white sphere). The two phospho groups participate in hydrogen bonds to the peptidic amido nitrogens of Arginine 11 and Isoleucine 12 and the amido nitrogen in the side chain of Asparagine 182 as well as several molecules of water (white spheres). The O4′ oxygen of the ribose of the nicotinamide nucleotide participates in a hydrogen bond with the hydroxy group of Serine 119. The O2′ and O3′ oxygens of the ribose of the nicotinamide nucleotide participate in hydrogen bonds to a sulfate and a molecule of water (white sphere). The nicotinamide participates in hydrogen bonds to the amido nitrogen in the side chain of Asparagine 314 and a molecule of water (white sphere). There is also an intramolecular hydrogen bond within the NAD^+ between the amido nitrogen of the nicotinamide and its phospho group.

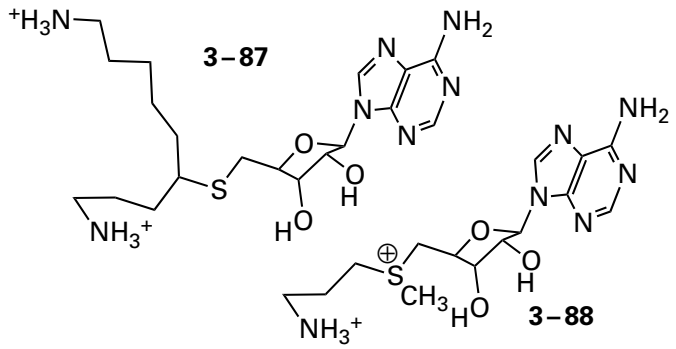
One way to occupy simultaneously both of the subsites on the active site of an enzyme and avoid the difficulty of these subsequent rearrangements when a second reactant associates is to effect these changes in conformation relevant to the enzymatic reaction by using a **bisubstrate analogue** as a ligand. For example, the bisubstrate analogue **3–87***



which combines the structural features of *S*-adenosyl-3-(methylthio)propylamine (**3–88**) and putrescine (1,4-diaminobutane), locates the subsites for these two reactants in the active site in the crystallographic molecular model[579] of its complex with spermidine synthase

S-adenosyl-3-(methylsulfanyl)propylamine + putrescine ⇌ spermidine + H^+ + *S*-methyl-5′-thioadenosine (3–392)

from *Thermotoga maritima*. Likewise, *N*-phosphonacetyl-L-aspartate (**3–6**), a bisubstrate analogue that combines the structural features of carbamoyl phosphate and L-aspartate, has been used to locate the active site and the catalytic side chains in a crystallographic molecular model of aspartate carbamoyltransferase (Equation 3–220) from *E. coli*.[580]

In a number of enzymatic reactions, **a small portion of one reactant is transferred to the other reactant**. In such cases, the reactant to which the group is transferred and the product from which the group has been transferred will often form an inactive dead-end complex defining the subsites for these substrates and the orientation in which the two substrates between which the group is transferred are held by the enzyme. For example, the **enzymatically inactive complex** between IMP dehydrogenase from *T. foetus* and the reactant xanthosine 5′-phosphate and the product NAD^+ lacks the hydride transferred from NADH to xanthosine 5′-phosphate during the enzymatic reaction, and the crystallographic molecular model of this complex defines the noncovalent interactions recognizing and orienting the two substrates as well as a significant conformational change in the enzyme that occurs upon the binding of substrates.[581]

The crystallographic molecular model of the enzymatically inactive complex (Figure 3–34)[582] between the active site of guanidinoacetate *N*-methyltransferase from *R. norvegicus* and the reactant guanidinoacetate (GuanAc) and the product *S*-adenosyl-L-homocysteine (SAHC) is missing the methyl group that is transferred by the active site back and forth from *S*-adenosyl-L-methionine to guanidinoacetate and from the resulting creatine to *S*-adenosyl-L-homocysteine, but the alignment of guanidinoacetate and *S*-adenosyl-L-homocysteine by the enzyme places the sulfur and the nitrogen between which the methyl group is transferred immediately adjacent to each other at a distance of 0.39 nm, in perfect orientation for a concerted nucleophilic substitution, and reveals the basic strategy employed by the active site.

A similar disposition of *S*-adenosyl-L-homocysteine and geranyl *S*-thiolodiphosphate, an analogue of geranyl diphosphate, is observed in a crystallographic molecular model of the active site of geranyl diphosphate 2-*C*-methyltransferase from *Streptomyces coelicolor*. In this instance, the distance between the carbon that would be methylated in geranyl diphosphate and the sulfur of the *S*-adenosyl-L-homocysteine is 0.55 nm. This enzyme catalyzes a concerted nucleophilic substitution that transfers the methyl group from *S*-adenosyl-L-methionine to carbon 2 in the nucleophilic carbon–carbon double bond between carbons 2 and 3 of geranyl diphosphate rather than to a guanidino nitrogen. In this latter molecular model, the π electrons on one side of the carbon–carbon double bond are pointed at the sulfur of the L-homocysteine just as the nucleophilic lone pair of electrons of the guanidino nitrogen is pointed at the sulfur in the active site of guanidinoacetate *N*-methyltransferase (Figure 3–34).

*From here on in this text, whenever possible, in drawings of chemical structures and in chemical equations, the substrates, analogues of substrates, analogues for intermediates of high energy, inhibitors, and side chains of amino acids participating in the respective enzymatic reactions will be drawn in the conformations and relative orientations they assume within their respective active sites in crystallographic molecular models. In these instances, molecular drawings have been chosen rather than drawings of the actual crystallographic molecular models to permit detailed explanations of the chemistry of the respective reactions.

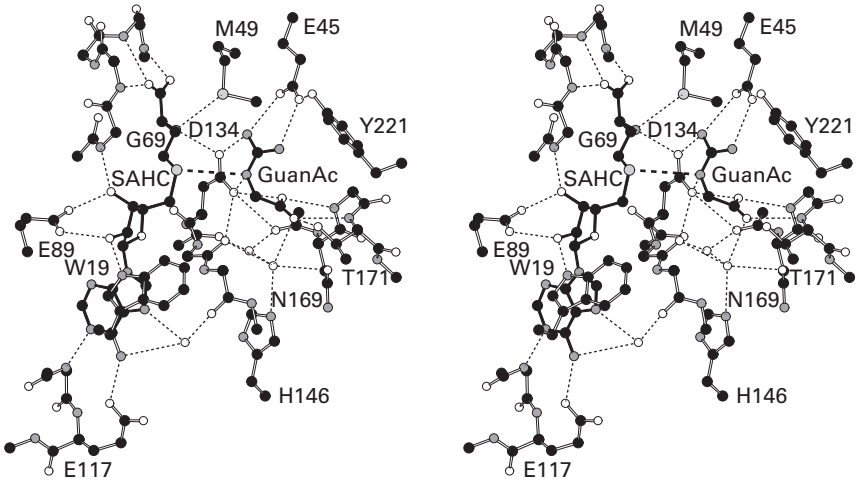


Figure 3–34: Stereodrawing[576] of the occupied active site in the crystallographic molecular model for the complex of guanidinoacetate *N*-methyltransferase from *R. norvegicus* and the reactant guanidinoacetate and the product *S*-adenosylhomocysteine.[582] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. Crystals of the enzyme were grown from a solution containing 1 mM *S*-adenosylhomocysteine and 2 mM guanidinoacetate. A data set was gathered at Bragg spacing of 0.20 nm, and a map of electron density was produced by molecular replacement using an earlier crystallographic molecular model of a complex between the enzyme and *S*-adenosylhomocysteine. Features in the initial map of electron density into which *S*-adenosylhomocysteine (SAHC) and guanidinoacetate (GuanAc) could be satisfactorily inserted were found in the region already assigned as the active site. Following the insertion, the crystallographic molecular model was submitted to refinement. A portion of the final refined molecular model is drawn. In a nucleophilic substitution, the enzyme transfers a methyl group back and forth between the sulfur in *S*-adenosylhomocysteine and the imido nitrogen of guanidinoacetate, which are connected by a thick dashed line in the drawing. The methyl group itself is missing in the crystallographic molecular model but can be imagined on the fly. There are a number of hydrogen bonds between donors and acceptors in the substrates, the polypeptide, and molecules of water (white spheres) orienting the two substrates in the active site. Tryptophan 19 stacks upon the adenine of the *S*-adenosylhomocysteine.

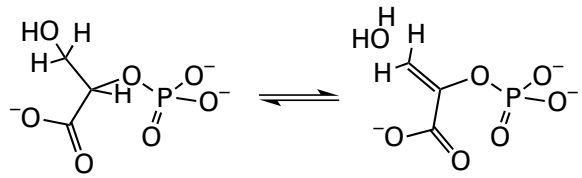
In both crystallographic molecular models, the line of centers between the nucleophile and the sulfur of *S*-adenosyl-L-homocysteine passes through one of the vertices of the tetrahedral sulfur, the location that would be occupied by the methyl group on the tetrahedral sulfonium ion were the *S*-adenosyl-L-homocysteine actually *S*-adenosyl-L-methionine. The alignment between the sulfur in the L-homocysteine and the As^{3+}, the methyl acceptor, is less ideal in the crystallographic molecular model of the occupied active site of arsenite methyltransferase from *Cyanidioschyzon*,[583] but it can be inferred that steric effects on the methyl group itself would complete the alignment.

An enzymatically inactive complex forms on the active site of rhamnulokinase from *E. coli* between the product $MgADP^-$ and the reactant β-L-fructofuranose, an alternative to the nominal reactant L-rhamnofuranose. This complex is missing the phospho group normally transferred from $MgATP^{2-}$ to the 1-hydroxy group of β-L-fructofuranose, but its crystallographic molecular model defines an extensive conformational change that occurs upon binding of substrates and shows how the reactants are oriented by the enzyme to achieve the phospho transfer.[584] One can readily imagine the missing phospho group on the fly between the oxygen of $MgADP^-$ and the oxygen of β-L-fructofuranose.

At times, one of the substrates in a formally unimolecular reaction is used as a ligand in crystallographic studies even though it is continuously transformed in the crystal by the enzyme. Usually, under these circumstances, only one of the two substrates, reactant or product, is observed in the active site, but occasionally the equilibrium constant for the reaction in the active site close enough to 1 that **both reactant and product, in equilibrium with each other, can be observed simultaneously in a crystallographic molecular model of the active site**. For example, the substrates in the reaction catalyzed by phosphopyruvate hydratase from *O. cuniculus*, 2-phospho-D-glycerate and phospho*enol*pyruvate and a molecule of water



(3–393)

are present in an almost equimolar mixture when they are in the active site.[507] Crystals of phosphopyruvate hydratase from *S. cerevisiae* were grown from a solution containing phospho*enol*pyruvate and the Mg^{2+} needed for catalysis, and a feature of

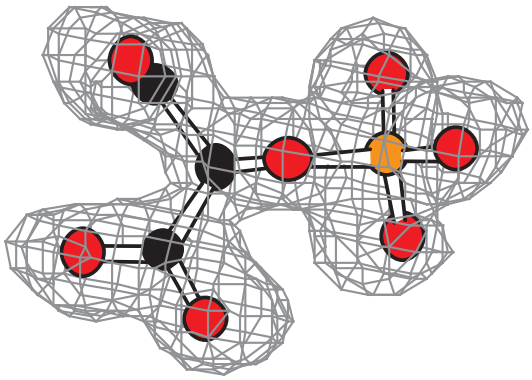


Figure 3–35: Equilibrium mixture of 2-phospho-D-glycerate and phospho*enol*pyruvate and a molecule of water (Equation 3–393) in the active site of phosphopyruvate hydratase from *S. cerevisiae*.[585] Black atoms are carbons, red atoms are oxygens, and the orange atom is a phosphorus. The purified enzyme was dissolved in a solution containing 2 mM phospho*enol*-pyruvate, 2 mM $MgCl_2$, 0.25 M KCl, and 50 mM 3-[4-(2-hydroxyethyl)piperazin-1-yl]propane-1-sulfonic acid at pH 8.0. The enzyme was crystallized from this solution, and a map of electron density was calculated from diffracted X-rays to Bragg spacing of 0.18 nm. In the active site of the enzyme, there was a feature of electron density that resembled either 2-phospho-D-glycerate or phospho*enol*pyruvate and a molecule of water. The substrates were intentionally omitted during the refinement, and the final omit map of electron density is presented as a cage of light gray lines. A molecule of 2-phospho-D-glycerate has been inserted into this map of electron density, but it is clear from the protrusion in the upper left-hand corner of the map that a molecule of phospho*enol*pyruvate and a molecule of water could just as easily been inserted. Reprinted with permission from reference 585. Copyright 1996 American Chemical Society. https://doi.org/ 10.1021/bi952859c

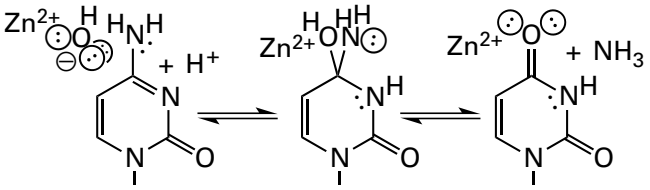
electron density was observed in the map that resembled a substrate. A refined omit map of difference electron density (Figure 3–35) has a continuous feature of electron density into which either 2-phospho-D-glycerate or phospho*enol*pyruvate and a molecule of water can be inserted,[585] consistent with the expectation that the substrates are both present in equilibrium with each other. An omit map of electron density within the active site of a complex between L-fucose and L-fucose mutarotase from *E. coli* demonstrates unequivocally that both reactant, α-L-fucopyranose, and product, β-L-fucopyranose, are present in an almost equimolar mixture,[586] presumably in equilibrium with each other. In the active site of UDP-glucuronic acid 4-epimerase from *Bacillus cereus*, both UDP-D-glucuronic acid and UDP-D-galacturonic acid, the reactant and product of the enzymatic reaction, are present in an equilibrium mixture.[587]

Phosphopyruvate hydratase from *S. cerevisiae* also crystallizes in a different space group in which the complete dimer is in the asymmetric unit. The **different environments** in this other crystal for the two subunits of the homodimer of the enzyme, which is symmetric in solution, **have altered the conformations of the two active sites** in such a way that the equilibrium constants between 2-phospho-D-glycerate and phospho*enol*pyruvate and a molecule of water are shifted in opposite directions. In the unit cell of this other crystal, in one of the active sites of the dimer, electron density for only 2-phospho-D-glycerate is observed, and in the other active site, electron density for only phospho*enol*pyruvate and a molecule of water is observed.[588] The same situation occurs in a crystal of dihydroorotase

(*S*)-dihydroorotate + H_2O $\rightleftharpoons$ H^+ + *N*-carbamoyl-L-aspartate (3–394)

from *E. coli*. The dimeric enzyme crystallizes in the space group $P2_12_12_1$ with the dimer as the asymmetric unit. The environments of the two subunits in the crystal are different enough that one subunit stabilizes (*S*)-dihydroorotate and water in its active site and the other subunit stabilizes *N*-carbamoyl-L-aspartate in its active site.[589]

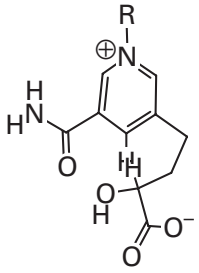
The equilibrium mixture of substrates in the active site of an enzyme that has two reactants and two products and catalyzes a bimolecular reaction can also be observed crystallographically. For example, cytidine deaminase catalyzes the hydrolysis of cytidine to uridine



(3–395)

A hydroxide on a Zn^{2+} in the active site is the nucleophile in a nucleophilic substitution at the acyl carbon of the amidine. The nucleophilic substitution passes through the usual tetrahedral intermediate. The omit map of electron density for the complex between murine cytidine deaminase and cytidine had a feature of electron density that was clearly a hybrid of a cytidine and a water (Figure 3–36A) and a uridine and an ammonia (Figure 3–36B) in an equilibrium ratio of 3:1.[590]

(3*S*)-5-(3-Carboxy-3-hydroxypropyl)nicotinamide-adenine dinucleotide (previously **1–78**)



3–89

R ≡ 5′-(adenosine-5′-diphosphoryl)ribosyl

is a bisubstrate analogue for L-lactate dehydrogenase (Equation 3–27). When this bisubstrate analogue is added to a solution of L-lactate dehydrogenase, the hydride is transferred back and forth intramolecularly between carbon 3 of the 3-carboxy-3-hydroxypropyl group and carbon 4 of the nicotinamide while it is in the active site, an observation demonstrating that one analogue effectively mimics two substrates. A crystallographic molecular model of the bisubstrate analogue occupying the active site of porcine L-lactate dehydrogenase, in crystals within which the hydride is presumably being transferred back and forth continuously, identifies the groups responsible for catalysis, in particular the imidazolyl group of Histidine 195 that is responsible for removing the hydron from the 3-hydroxy group during its oxidation to the 3-oxo group.[591]

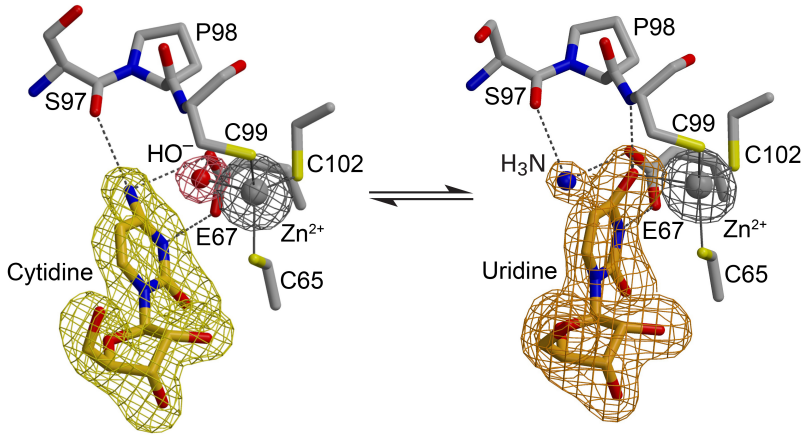


Figure 3–36: Omit maps of electron density for substrates bound in the active sites in crystallographic molecular models for **(A)** the complex of murine cytidine deaminase and the substrates cytidine and water and **(B)** the complex of murine cytidine deaminase and the substrates uridine and ammonia.[590] Crystals of the enzyme were grown from a solution containing 5 mM cytidine. A data set was gathered at Bragg spacing of 0.207 nm, and a map of electron density was produced by molecular replacement using an earlier crystallographic molecular model of human cytidine deaminase.[599] In the initial map of electron density, there were features in the active site that could be explained by the superposition of molecules of cytidine and water and molecules of uridine and ammonia with a ratio of occupancy of about 3:1. Three quarters of a molecule of cytidine, three quarters of a hydroxide, one quarter of a molecule of uridine, and one quarter of a molecule of ammonia were inserted into these hybrid features of electron density, and the resulting molecular model of these substrates at their respective partial occupancies and the enzyme were submitted to refinement. Following the refinement, omit maps of electron density (features of electron density in Panels A and B, respectively) were prepared for each pair of substrates by omitting their respective partial molecules and the equivalent fraction of a Zn^{2+} from the final crystallographic molecular model. Portions of the final crystallographic molecular model are drawn including, on the one hand (Panel A), the final positions of the molecules of cytidine and hydroxide (OH) and, on the other hand (Panel B), the final positions of the molecules of uridine and ammonia (N), as well as portions of the protein providing donors and acceptors of hydrogen bonds to the substrates and ligands for the Zn^{2+}. Arrows indicate the nucleophilic attack of hydroxide (Panel A) coordinated to Zn^{2+} on the cytosine of the cytidine and the nucleophilic attack of ammonia (Panel B) on the uracil of the uridine. One of the hydrogens on the ammonia participates in a hydrogen bond with the peptidic oxygen of Serine 97. The upper oxygen of the carboxy group of Glutamate 67 (which is behind the water in panel A and behind the molecule of ammonia in panel B) is close enough to the amido nitrogen on carbon 4 of the cytidine (0.30 nm) and the hydroxide on the Zn^{2+} (0.28 nm) in Panel A, and also close enough to the acyl oxygen on carbon 4 of the uridine (0.30 nm) and the ammonia (0.29 nm) in Panel B, to form hydrogen bonds with both functional groups and both nucleophiles. The lower oxygen of Glutamate 67 forms a hydrogen bond with nitrogen 3 of both the cytosine (0.29 nm) and the uridine (0.27 nm), facts which suggest that it is planted as the other oxygen pivots around it. The fact that **most crystals are frozen before a data set is collected may shift an equilibrium** one way or the other. For example, the equilibrium constant within the active site[136] at 30 °C for the reaction catalyzed by orotate phosphoribosyltransferase from *S. typhimurium* is 2 in favor of the products, orotidine 5′-phosphate and diphosphate. Nevertheless, the omit map of electron density within its occupied active site, from a data set gathered at –178 °C, is consistent with the presence of only the reactants, orotate and 5-phospho-α-D-ribose 1-diphosphate, with no indication of the presence of orotidine 5′-phosphate or diphosphate.[592] It must be the case that the equilibrium is shifted in favor of orotidine 5′-phosphate and diphosphate at the lower temperature. Even though the equilibrium constant in solution at 25 °C for the reaction catalyzed by isochorismate synthase is 0.84 in favor of the reactant chorismate,[593] the map of electron density calculated from a data set gathered from crystals of the enzyme from *E. coli* at cryogenic temperatures is consistent with the presence of only the product isochorismate in the active site.[594]

As is the case with orotate phosphoribosyltransferase and isochorismate synthase at cryogenic temperatures, for the majority, if not almost all, of the equilibria between substrates when they are in their respective active sites and when the enzymes are either in solution or in a crystal, **the equilibrium constant within the active site favors one of the outcomes**, often the outcome favored by the overall equilibrium for the reaction being catalyzed. If the equilibrium constant for the reaction within the active site is such that less than 10% of the substrates on one side of the equation for the enzymatic reaction are present, the electron density for the minor participants cannot be resolved from the electron density of the major participants. One reason for the presence of the substrates on only one side of the equilibrium, as was observed with the two different conformations of the subunits of phosphopyruvate hydratase and the two different conformations of the subunits of dihydroorotase in the respective crystals, can be that the conformation of the enzyme that has crystallized favors the substrates on only that side of the equation even though there may be other conformations in the solution favoring the substrates on the other side of the equation.

Complexes between an active site and a full complement of the substrates favored by the equilibrium existing in the active site in the crystal under the conditions at which the data set is gathered (often referred to ambiguously as a "complex with the products of the enzymatic reaction") can be crystallized.[595,596] The resulting complex will usually show no feature of electron density suggesting that the substrates unfavored by the equilibrium are also present in the active site even though they must be present at a ratio dictated by the equilibrium constant for the reaction as it occurs in the active site under the conditions of data collection. For example, within the active site of triose-phosphate isomerase (Equation 3–384) from *S. cerevisiae*, as in solution, the equilibrium favors glycerone phosphate.[597] In the map of electron density for the complex between glycerone phosphate and the enzyme (Figure 3–37),[598,599] there is a feature within the active site into which only a molecule of glycerone phosphate can be inserted.

Lanosterol synthase catalyzes an equilibrium

$$\text{(3}S\text{)-2,3-epoxy-2,3-dihydrosqualene} \rightleftharpoons \text{lanosterol} \qquad (3\text{–}396)$$

that in solution is heavily in favor of lanosterol. In the map of difference electron density from crystals of the complex between the human enzyme and lanosterol, there is no evidence for electron density arising from (3*S*)-2,3-epoxy-2,3-dihydrosqualene, only a clear feature of electron density for lanosterol.[600] Likewise, in the case of the complex between nicotinate-nucleotide—dimethylbenzimidazole phosphoribosyltransferase from *S. typhimurium*

$$\beta\text{-nicotinate D-ribonucleotide} + \text{5,6-dimethylbenzimidazole} \rightleftharpoons \text{H}^+ + \text{nicotinate} + \alpha\text{-ribazole 5′-phosphate} \qquad (3\text{–}397)$$

and its two substrates nicotinate and α-ribazole 5′-phosphate, there is no indication in the difference map of electron density for the presence of any β-nicotinate D-ribonucleotide or 5,6-dimethylbenzimidazole, but the orientation of the two substrates favored by the equilibrium positions them perfectly for the phosphoribosyl transfer catalyzed by the enzyme (Figure 3–31).[543] In the case of glutathione transferase, when it catalyzes the condensation of glutathione and phenanthrene 9,10-oxide, there are two reactants but only one product, 9-(*S*-glutathionyl)-10-hydroxy-9,10-dihydrophenanthrene. The reaction heavily favors this substrate, and the complex between it and the enzyme from *R. norvegicus* could be crystallized.[601]

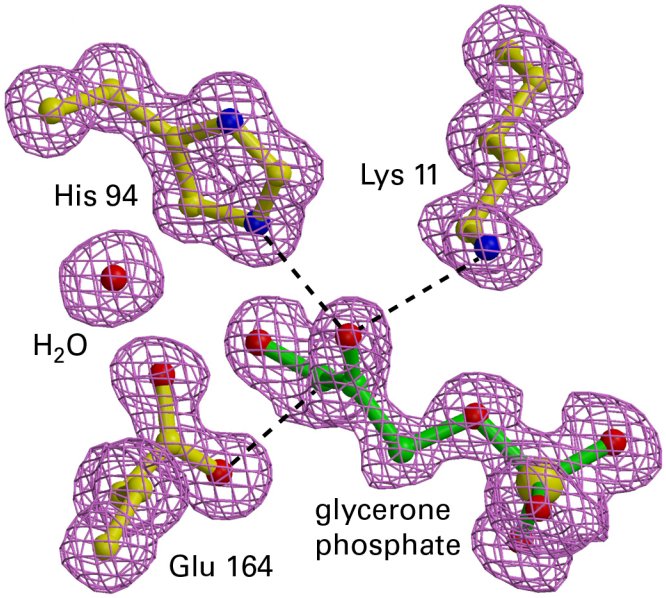

Figure 3–37: Omit maps of electron density for three catalytic side chains and glycerone phosphate bound in the active site of triose-phosphate isomerase from *S. cerevisiae*.[598] Crystals of a fully active double mutant of the enzyme in which Tryptophan 90 was mutated to a tyrosine and Tryptophan 157 to a phenylalanine were soaked in a solution of glycerone phosphate. The crystals gradually disappeared and new crystals gradually appeared that were monoclinic and of space group $P2_1$. A data set was gathered from these monoclinic crystals at Bragg spacing of 0.12 nm, and a map of electron density was produced by molecular replacement using an earlier crystallographic molecular model of the enzyme.[599] In the refined map of electron density, there was a feature of electron density into which a molecular model of glycerone phosphate could be inserted. Following the refinement, omit maps of electron density were prepared by omitting glycerone phosphate and the side chains of Lysine 11, Histidine 94, and Glutamate 164. The drawing is of the electron density in that omit map filled with molecular models of glycerone phosphate and the side chains. Dashed lines for Lysine 11 and Histidine 94 are for hydrogen bonds that they form with the carbonyl oxygen of the glycerone phosphate. The dashed line from one of the carboxylato oxygens of Glutamate 164 to carbon 3 of the glycerone phosphate indicates its role as a base that removes a hydron from that carbon in the enzymatic reaction. Reprinted with permission from reference 598. Copyright 2003 National Academy of Sciences, U.S.A. https://doi.org/10.1073/pnas.0233793100

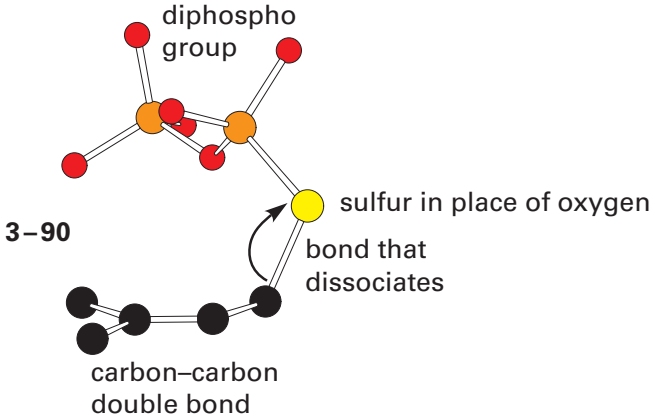
When neither a complex between an enzyme and an equilibrium mixture of substrates nor one between the enzyme and the set of substrates favored by the equilibrium as it occurs on the active site can be crystallized, it is often possible to produce a complex closely resembling the natural complex by using an almost identical but inactive analogue in place of one of the substrates.[602]

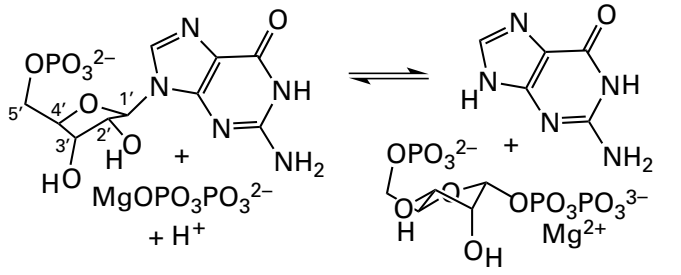
Isoprene synthase catalyzes the dissociation of diphosphate from 3,3-dimethylallyl diphosphate to produce the 3,3-dimethylallyl carbenium ion (**1–99** in Figure 1–26) as an intermediate in the reaction. The transfer of a hydron from one of the methyl groups of the dimethylallyl carbenium ion produces isoprene, 2-methylbuta-1,3-diene, which is the product of the enzymatic reaction. 3,3-Dimethylallyl *S*-thiolo diphosphate



is an inactive analogue of dimethylallyl diphosphate in which the oxygen between the dimethylallyl group and the diphospho group, which would leave the dimethylallyl group in the normal reaction

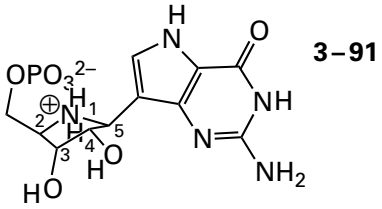
catalyzed by the enzyme, has been replaced with a sulfur. In a crystallographic molecular model of the active site of isoprene synthase from *Populus canescens*,[603] the analogue is forced by the active site to assume a conformation in which the bond between carbon and sulfur, which would be the bond that dissociates in 3,3-dimethylallyl diphosphate (**1–99** in Figure 1–26), is parallel to the *p* orbitals that form the π molecular orbital system of the carbon–carbon double bond of dimethylallyl diphosphate (as in **3–90**). Consequently, the two electrons in the occupied π molecular orbital of the carbon–carbon bond can push on the carbon–oxygen bond of the substrate and enhance the dissociation. One of the oxygens of the distal phospho group is also positioned by the active site to remove the hydron from the cis methyl group of the dimethylallyl carbenium ion to produce the isoprene. This oxygen is oriented by the active site so that it is on a line with the carbon of the methyl group that is perpendicular to the plane of the carbon–carbon double bond. In this orientation, it is able to remove the hydron in a carbon–hydrogen bond on the methyl group when that bond is parallel to the π molecular orbital system of the allyl carbenium ion, which withdraws the two electrons in that bond into itself.

Hypoxanthine phosphoribosyltransferase, which is able to catalyze the nucleophilic substitution at the carbon of the hemiaminal in the ribose of the alternative substrate, guanosine 5′-phosphate



(3–398)

is inhibited by the pyrrolidinium ion



3–91

In a crystallographic molecular model of a complex between the human enzyme and magnesium diphosphate, Mg^{2+}, and pyrrolidinium **3–91** (Figure 3–38),[604,605] the Mg^{2+} of the magnesium diphosphate has two of the nonbridging oxygens as ligands. The other Mg^{2+} in the active site has two other nonbridging oxygens of the diphosphate and the 3-hydroxy group and the 4-hydroxy group of pyrrolidinium **3–91** as ligands. This network of ligation creates a rigid structure of two five-membered rings and two six-membered rings that holds the oxygen of the diphosphate that is the acceptor of the phosphoribosyl group in the nucleophilic substitution catalyzed by the enzyme immediately adjacent to carbon 2 of the pyrrolidinium **3–91** (Figure 3–38). Carbon 2 is the homologue of the electrophilic carbon 1′ of the ribose in the guanosine 5′-phosphate (Equation 3–398). The crystallographic molecular model demonstrates that hydronation of nitrogen 9 of the guanine in guanosine 5′-phosphate increases the electrophilicity of carbon 1′ by improving the leaving group in the nucleophilic substitution. In the transition state of the enzymatic reaction, the nonbridging oxygen of the diphosphate that is immediately below (dotted line in the figure) the oxygen in the intermediate oxocarbenium ion of the ribosyl group, represented in the analogue by the ammonio nitrogen, stabilizes its positive elementary charge.[606]

In a similar complex with a similar inhibitor in the active site of purine-nucleoside phosphorylase from *E. coli*, the phosphate that normally attacks carbon 1′ of ribose in the nucleoside is held in position by hydrogen bonds from the six ω nitrogen–hydrogens of three guanidinio groups from three arginines instead of two Mg^{2+}, but these hydrogen bonds also form a network of rigid five-membered rings.[607]

In the case of enzymes that have two identical reactants, such as porphobilinogen synthase from *P. aeruginosa*, which condenses two 5-aminolevulinates, the same enzymatically inactive analogue of these two reactants can be used to occupy each of the two respective subsites in the active site.[608]

Complexes between **two substrates and an analogue of the third substrate** and an enzyme catalyzing a reaction with three reactants and three products have also been crystallized, and the alignment of the three ligands defines the orientation of the three substrates in the normal reaction.[609]

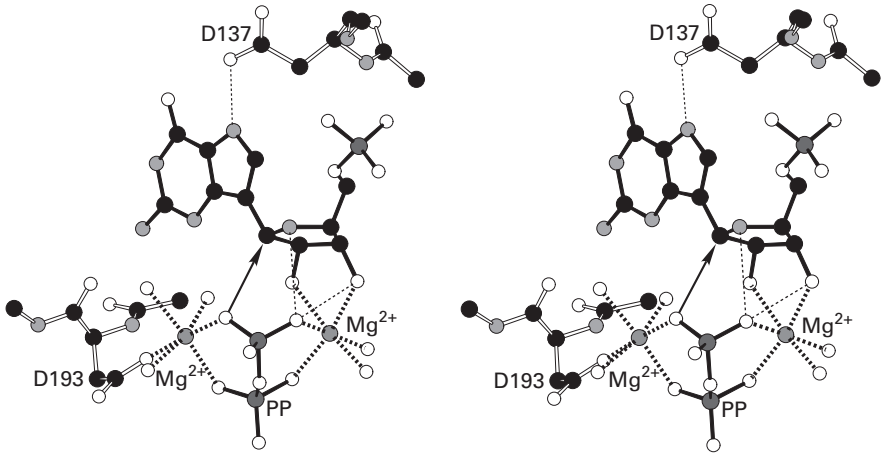


Figure 3–38: Stereodrawing[576] of the crystallographic molecular model of the active site in the complex of human hypoxanthine phosphoribosyltransferase, its substrate magnesium diphosphate, and the pyrrolidinium **3–91**, which is an inhibitor of the enzyme.[604] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, large dark gray atoms are atoms of phosphorus, and the two small dark gray spheres are magnesium ions. The enzyme was crystallized from a solution containing an equimolar concentration of pyrrolidinium **3–91** and an excess of magnesium diphosphate. A data set was gathered from the crystals at Bragg spacing of 0.20 nm, and a map of electron density was produced by molecular replacement using an earlier crystallographic molecular model of hypoxanthine phosphoribosyltransferase from *T. gondii*.[605] In the initial map of electron density, there were features in the active site into which molecular models of molecules of magnesium diphosphate and pyrrolidinium **3–91** could be unambiguously inserted. The molecular models of the pyrrolidinium, Mg^{2+}, and the diphosphate (PP) in the final refined crystallographic molecular model are drawn. The arrow indicates the nucleophilic attack of the closest oxyanion in the magnesium diphosphate that would occur during the reaction catalyzed at the active site on carbon 1 of guanosine 5′-phosphate, the normal substrate for the enzyme, which is represented by carbon 5 of the inhibitor. The nearly vertical, thin dashed line indicates a hydrogen bond between the quaternary ammonium of the pyrrolidinium and another oxyanion of the diphosphate. This hydrogen bond represents an ionic interaction between the oxygen atom of the normal oxocarbenium ion intermediate and this oxyanion in the nucleophilic substitution catalyzed by the enzyme. The second Mg^{2+}, in addition to the one brought into the active site on the diphosphate, is also coordinated by the diphosphate. In addition to five molecules of water (white spheres) and ligands from the diphosphate and the two hydroxy groups on pyrrolidinium **3–91** that provide ligands to the two Mg^{2+}, Aspartate 193 from the enzyme provides a ligand to one of the magnesium ions.

Magnesium 5′-adenylic methylenediphosphonic anhydride (**3–5**), in which the bridging oxygen to the γ-phospho group of $MgATP^{2-}$ has been changed to a methylene group; magnesium 5′-adenylic imidodiphosphonic anhydride ($MgAMPPNP^{2-}$), in which the bridging oxygen to the γ-phospho group of $MgATP^{2-}$ has been changed to an imino group; and magnesium adenosine 5′-(3-thiotriphosphate), in which one of the nonbridging oxygens on the γ-phospho group of $MgATP^{2-}$ has been changed to sulfur, are **analogues often used in place of $MgATP^{2-}$**. These analogues are widely used because there are so many enzymes that have $MgATP^{2-}$ as a substrate. They cannot participate in the enzymatic reaction, yet they often form ternary complexes with an active site and the substrate to which and from which the γ-phospho group of $MgATP^{2-}$ is transferred during the normal nucleophilic substitution at phosphorus catalyzed by an enzyme that has $MgATP^{2-}$ as a substrate. Examples of cosubstrates to which γ-phospho groups are transferred from $MgATP^{2-}$ in such active sites are shikimate,[610] adenosine,[611] uridine 5′-phosphate,[612] formylglycinamide ribonucleotide,[613] flavin mononucleotide,[614] the hydroxy group of serine in a peptide,[615] and fructose 6-phosphate (Figure 3–39).[616] In crystallographic molecular models of ternary complexes with the respective active sites for each substrate, as in that for human 6-phosphofructo-2-kinase (Figure 3–39), the oxygen of the cosubstrate to be phosphorylated is nestled against the γ phosphorus of the analogue of $MgATP^{2-}$ and surrounded by the three terminal nonbridging oxygens and aligned for an in-line nucleophilic substitution at the γ phosphorus of $MgATP^{2-}$. In this orientation, there is considerable electron repulsion between the lone pairs of electrons on the oxygen receiving the phospho group and the lone pairs of electrons on three nonbridging oxygens, and this electron repulsion must be overcome by pushing the oxygen against the phosphorus.

An enzymatically inactive ternary complex that mimics the complex between the actual substrates in an active site can be produced between **an analogue that lacks a nucleophilic heteroatom and the other substrate** participating in a nucleophilic substitution. For example, for an enzyme catalyzing a phospho transfer to and from $MgATP^{2-}$, an analogue of the cosubstrate that is missing just the oxygen to and from which the phospho group is transferred can be used to produce a complex in a crystallographic molecular model of the active site of an enzyme. The inactive complex mimics the actual complex in which the nucleophilic substitution at phosphorus takes place.[215,216,617] It was possible to crystallize a complex between a galactosyl transferase from *N. meningitidis* and UDP-galactose and an analogue of the oligosaccharide that would normally accept the galactosyl group but that is missing the hydroxy group to which the galactosyl group is transferred, and a crystallographic molecular model of this complex could be obtained.[618]

Succinate, which is an analogue of L-aspartate missing the α-amino group to which a carbamoyl group is transferred from carbamoyl phosphate by aspartate carbamoyltransferase (Equation 3–220), can be used to form an inactive complex with the enzyme and carbamoyl phosphate. The succinate and the carbamoyl phosphate are tightly held and oriented by the active site in the crystallographic molecular model of the complex (Figure 3–40).[580,619] When L-aspartate is superposed on the succinate in the crystallographic molecular model, its amino nitrogen ends up 0.21 nm from the carbamoyl carbon of the carbamoyl phosphate, well within van der Waals contact (0.33 nm) and in an orientation placing it in the location of the large central lobe in the lowest unoccupied molecular orbital of the π system of the carbamoyl group. Considering how short this distance is, it is easy to imagine the amino group of the L-aspartate forcefully pushed up against the carbamoyl carbon of the carbamoyl phosphate by the active site to promote the reaction.

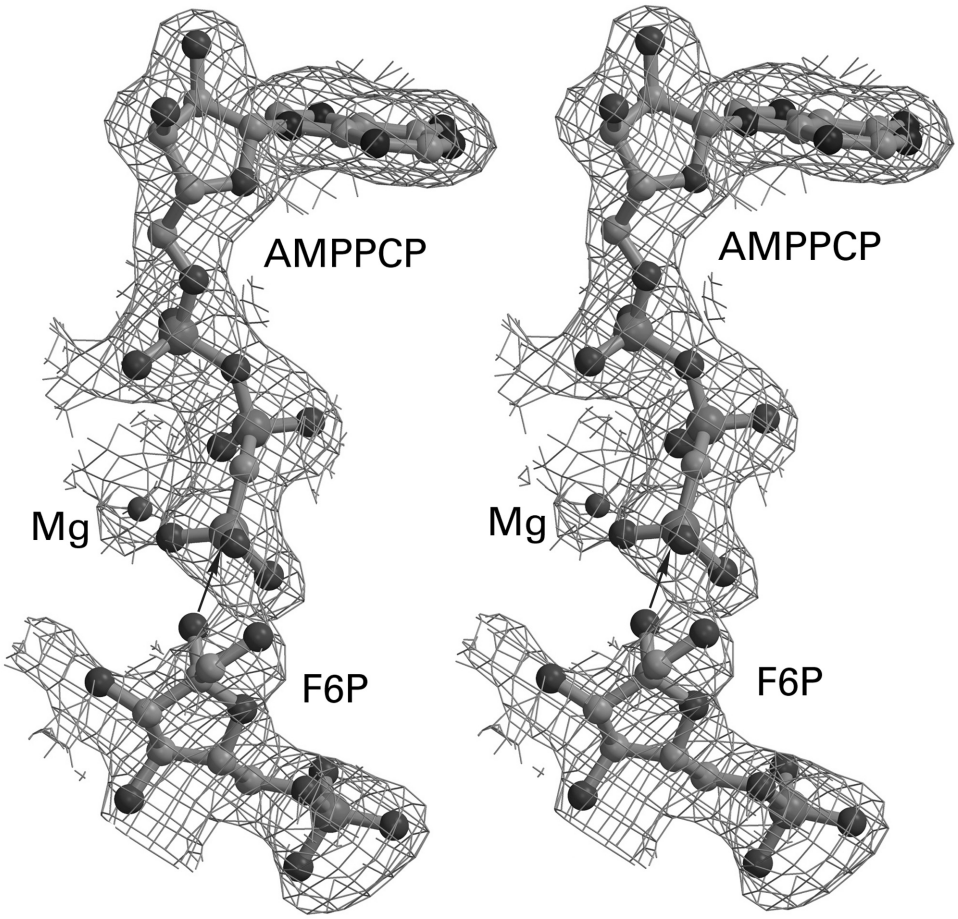

Figure 3–39: Omit map of electron density for the ligands bound in the active site in a crystallographic molecular model for the complex of human 6-phosphofructo-2-kinase, its substrate β-D-fructose 6-phosphate, and the inhibitor $MgAMPPCP^{2-}$ (**3–5**).[616] Crystals of the enzyme were transferred to a solution containing 0.2 mM β-D-fructose 6-phosphate, and 0.2 mM $MgAMPPCP^{2-}$. After one hour, a data set was gathered from the crystals at Bragg spacing of 0.27 nm, and a map of electron density was produced by molecular replacement using an earlier crystallographic molecular model of human 6-phosphofructo-2-kinase from which all ligands and molecules of water had been stripped. In the initial map of electron density, there were features in the active site into which molecular models of molecules of β-D-fructose 6-phosphate and $MgAMPPCP^{2-}$ could be unambiguously inserted. Following refinement, an omit map of electron density (features of electron density in the drawing) was prepared by omitting the molecules of β-D-fructose 6-phosphate and $MgAMPPCP^{2-}$. The molecular models of the molecules of β-D-fructose 6-phosphate (F6P), and $MgAMPPCP^{2-}$ in the final crystallographic molecular model are drawn. The arrow indicates the nucleophilic attack of the 2-hydroxy group of β-D-fructose 6-phosphate on what would be the γ-phospho group of $MgATP^{2-}$ in the normal reaction catalyzed by the enzyme. Reprinted from reference 616 with permission from Elsevier. https://doi.org/10.1016/j.jmb.2007.03.038

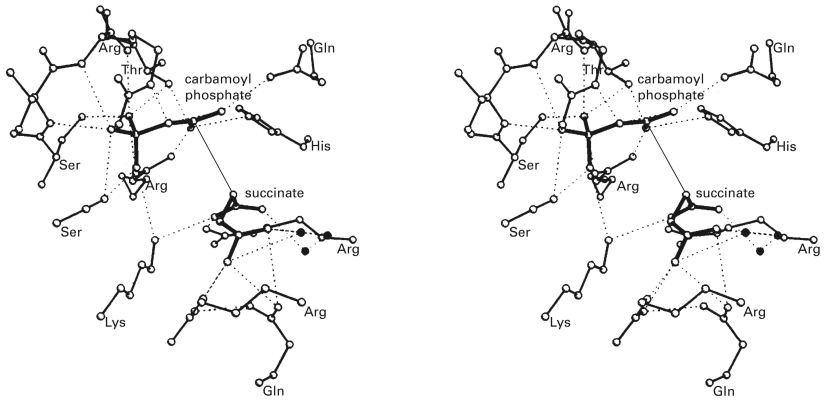

Figure 3–40: Crystallographic molecular model of the active site in the complex between aspartate carbamoyltransferase from *E. coli* and succinate and carbamoyl phosphate.[619] Crystals of the enzyme, in which the active sites had been occupied with *N*-phosphonacetyl-L-aspartate (**3–6**) to promote crystallization of the enzyme in its active conformation, were soaked for 60 h in a solution of 20 mM carbamoyl phosphate and 30 mM succinate at pH 5.9 and 20 °C. A data set was gathered from the resulting crystals to Bragg spacing of 0.26 nm. The molecular model used to initiate refinement was a crystallographic molecular model of the enzyme, determined from crystals in which the active site was occupied by *N*-phosphonacetyl-L-aspartate.[580] This provisional molecular model had water and *N*-phosphonacetyl-L-aspartates removed from it before it was inserted into the unit cell. A map of electron density was produced by using the data set of the phases calculated from this provisional model in the unit cell and the data set of observed phases gathered from the crystals in which the active site was occupied by succinate and carbamoyl phosphate. As the refinement of this initial model progressed, features appeared in the map of electron density within the known active site and became more distinct. Eventually, molecular models of succinate and carbamoyl phosphate could be unambiguously inserted into these features and the refinement was continued. The drawing is of the succinate and the carbamoyl phosphate in the final refined crystallographic molecular model. The dashed lines, as usual, indicate hydrogen bonds, and a thin solid line has been drawn from carbon 2 of the succinate, the carbon on which the amino group would be located on (2*S*)-2-aminosuccinate (L-aspartate), and the carbamoyl carbon of the carbamoyl phosphate. This line would intersect with the nitrogen atom in (2*S*)-2-aminosuccinate were it occupying the active site and is at an acceptable angle with respect to the plane of the carbamoyl group for nucleophilic addition to its π system. The hole for the oxyanion of the tetrahedral intermediate in the nucleophilic substitution at the carbamoyl carbon can be identified in the crystallographic molecular model of the complex between the enzyme and *N*-phosphonacetyl-L-aspartate.[580] The oxyanion hole is for the oxygen atom at the back of the drawing of carbamoyl phosphate in the figure. This oxyanion hole is formed by the hydrogen on the hydroxy group of threonine, the guanidino group of arginine, and the hydronated imidazolyl group of histidine.

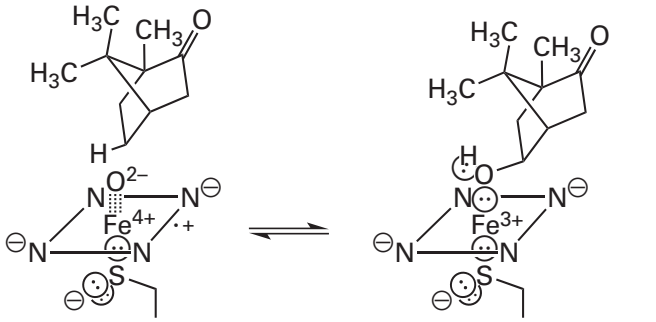
A similar way to form an enzymatically inactive complex that closely resembles the catalytically active complex between substrates and the active site is available if the enzyme catalyzes electron transfer. In this instance, instead of removing a functional group, an electron is added or subtracted. If an **incorrect oxidation state of the active site and the substrates** is chosen, the electron transfer cannot proceed. For example, when the heme in camphor 5-monooxygenase from *P. putida* is in the ferric form rather than the ferrous form, the enzyme is unable to hydroxylate camphor, and a crystallographic molecular model of the complex between camphor and the enzyme shows the orientation of the camphor accomplished by the active site, with its carbon 5 the distance of one oxygen atom away from the iron and at an angle appropriate for hydrogen abstraction by the oxoiron(IV) porphyrin$^{\bullet+}$ (previously Equation 2–252)



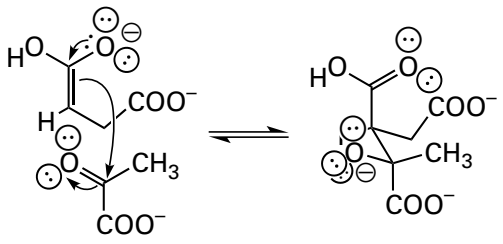
(3–399)

that is the normal intermediate in the active form of the enzyme.[620]

An almost identical, inactive form of an enzyme can also be obtained by **mutating one of the side chains of the amino acids shown to be in the active site** in an earlier crystallographic molecular model of the enzyme.[621-625] For example, in the crystallographic molecular model of a complex between the substrates pyruvate and succinate and an inactive (<1% activity) mutant of methylisocitrate lyase from *E. coli*

succinate + pyruvate $\rightleftharpoons$ (2*S*,3*R*)-3-hydroxybutane-1,2,3-tricarboxylate (3–400)

in which Cysteine 123 had been mutated to serine,[626] the hydroxy group of the serine is immediately adjacent to carbon 2 of the succinate, from which the cysteinate would normally remove a hydron to form the enolate, and the carbonyl carbon of the pyruvate is immediately adjacent to the other side of carbon 2 of succinate, oriented perfectly to participate in a nucleophilic addition with the resulting enolate of succinate



(3–401)

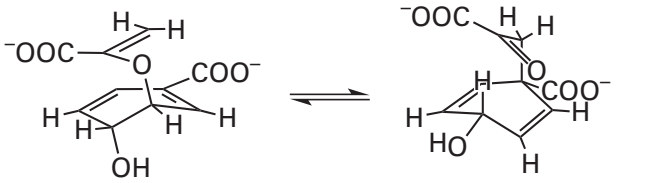
to produce (2*S*,3*R*)-3-hydroxybutane-1,2,3-tricarboxylate in the normal enzymatic reaction.

Mutating one or another of the amino acids in the active site often enables a crystallographic molecular model of the **active site occupied by an intermediate** that would otherwise be evanescent and unable to be observed.[571] For example, when Glutamate 166 in the active site of β-lactamase from *M. tuberculosis* is mutated to an alanine, the transient acyl intermediate in the enzymatic reaction can no longer be hydrolyzed and becomes stable, and the acyl intermediate of the substrate cefamandole can be observed in a crystallographic molecular model of the active site.[627]

A mutant of the enzyme can also **reveal a Michaelis complex** between the reactant and the active site that would otherwise be rapidly converted to product. When Lysine 73 in the active site of β-lactamase from *M. tuberculosis* is mutated to an alanine, the initial Michaelis complex in the enzymatic reaction between the active site and unaltered cefamandole, a reactant for the enzyme, becomes stable and can also be observed crystallographically.[627] A mutant of nicotinamidase from *S. pneumoniae* stabilizes the acyl intermediate in its reaction, and another mutant stabilizes the Michaelis complex with its substrate nicotinamide so that crystallographic molecular models could be constructed of these complexes.[628] Mutating Histidine 187 in the active site of mannuronate-specific alginate lyase from *Defluviitalea phaphyphila* prevented the normal cleavage of alginate and permitted a complex to be formed in the crystal in which all five of the D-mannurates of intact [(α1,4)-D-mannuronate]$_5$ are bound in the active site, and this Michaelis complex spans the location in the active site at which the cleavage of the oligomer would normally occur. When the same substrate was bound in the active site of the native alginate lyase in the crystal, the [(α1,4)-D-mannuronate]$_5$ is cleaved, only three

of the sites are occupied, and the nonreducing end of the trimer sits at the point of cleavage,[629] as was the case in the original crystallographic molecular model of the occupied active site of lysozyme.

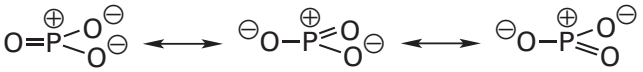
Unquestionably, the most informative ligands that can be chosen for crystallographic studies of the active site of an enzyme are analogues of transition states or analogues for intermediates of high energy.[316] For example, a crystallographic molecular model of a complex between analogue **3–84** for the transition state of chorismate mutase (previously Equation 3–167)



(3–402)

from *B. subtilis* and the enzyme identifies the amino acids creating the active site and confining the transition state to the proper geometry for the electrocyclic reaction.[365]

Crystallographic molecular models of complexes between **analogues for intermediates of high energy** are more numerous than those for analogues of transition states. **Nitrate** (NO_3^-) is isosteric and isoionic with monomeric metaphosphate anion*



3–92

In the omit map of electron density generated from crystals of the complex between arginine kinase

$$\text{L-arginine} + MgATP^{2-} \rightleftharpoons H^+ + MgADP^- + \text{L-arginine phosphate} \quad (3–403)$$

from *Limulus polyphemus* and L-arginine, $MgADP^-$, and nitrate, the electron density for nitrate is clearly observed (Figure 3–41).[630] The plane of nitrate is normal to a line drawn between one of the nonbridging β-oxygens of $MgADP^-$ and one of the ε amido nitrogens of L-arginine with the nitrogen of nitrate on the line. This orientation of the nitrate mimics monomeric phosphate as an intermediate in the reaction on the fly between these two atoms in the nucleophilic substitution at phosphorus normally catalyzed by the enzyme. In this instance, because both L-arginine phosphate and $MgATP^{2-}$ are phosphate esters of high energy, the nucleophilic substitution should be dissociative, and monomeric metaphosphate should be mimicking an intermediate instead of a transition state. The orientation of the guanidino group of L-arginine, the nucleophile, suggests that the nucleophilic electrons that participate in the reaction are those in the highest occupied molecular orbital of its π molecular orbital system.

Another **analogue of monomeric metaphosphate**, which resembles it in planarity and charge number, is MgF_3^-. It has already been noted that MgF_3^- was used in a crystallographic description of the steps in the mechanism of cAMP-dependent protein kinase,[631] where it was located in a crystallographic molecular model on the line of centers between the hydroxy group of the serine normally phosphorylated by the enzyme and one of the nonbridging β-oxygens of $MgADP^-$, just as nitrate is located in the crystallographic molecular model of the active site of arginine kinase on the line of centers between the two atoms to and from which the phospho group is transferred (Figure 3–41). In a crystallographic molecular model[632] of a complex between the active site of β-phosphoglucomutase from *Lactococcus lactis* and β-D-glucose 6-phosphate and MgF_3^-, the atom of magnesium is located on the line of centers between the 1-hydroxy group of β-D-glucose 6-phosphate and the carboxy oxygen of an aspartate in the active site. In the reaction catalyzed by the enzyme, a phospho group is transferred back and forth between these two oxygens.

One of the **phosphonamido inhibitors** of thermolysin, phosphonamidate **3–83**, is based on the reactant Cbz-Gly-Leu-Leu (Table 3–6). Crystals of thermolysin from *B. thermoproteolyticus* soaked in a solution of phosphonamidate **3–83** were used to generate a refined crystallographic molecular model of the active site occupied by this analogue for the tetrahedral intermediate in the enzymatic reaction (Figure 3–42).[633] Aside from identifying all the important catalytic side chains, the crystallographic molecular model defines the noncovalent interactions holding the analogue in the active site along its entire length.

*Recall that phosphorus is immediately below nitrogen on the periodic table.

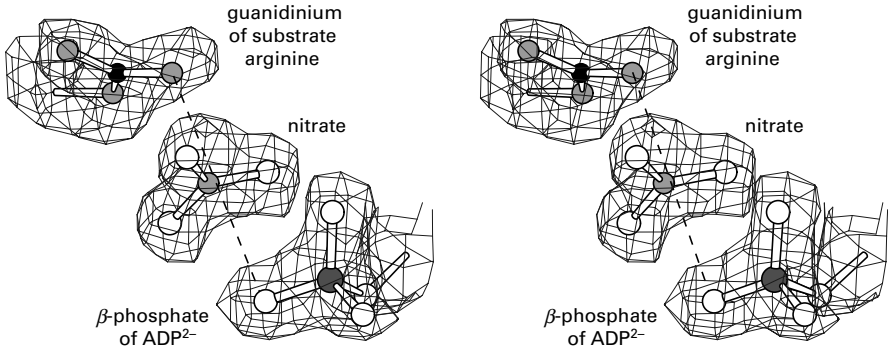


Figure 3–41: Omit map of electron density for the ligands bound in the active site in a crystallographic molecular model of the complex formed from arginine kinase from *L. polyphemus*, its substrates L-arginine and $MgADP^-$, and nitrate.[630] White atoms are oxygens, small gray atoms are nitrogens, and the large dark gray atom is a phosphorus. The enzyme was crystallized from a solution containing 53 mM $MgCl_2$, 2 mM ADP^{2-}, 25 mM KNO_3, and 10 mM L-arginine. A data set was gathered from the crystals at Bragg spacing of 0.186 nm, and a map of electron density was produced using phases estimated by a combination of molecular replacement and isomorphous replacement. In the initial map of electron density, there were features in the active site into which molecular models of molecules of ADP^{2-}, NO_3^- (nitrate), and L-arginine could be unambiguously inserted. Following refinement, an omit map of electron density (features of electron density in the drawing) was prepared by omitting these three ligands. The molecular models of NO_3^- and portions of the molecules of ADP^{2-} and L-arginine in the final crystallographic molecular model are drawn. The dashed line indicates the axis of the nucleophilic substitution at phosphorus that would occur in the normal reaction, in which monomeric metaphosphate takes the place of nitrate. Figure 3–42: Stereodrawing[576] of the occupied active site in the crystallographic molecular model of the complex between thermolysin from *B. thermoproteolyticus* and phosphonamidate **3–83**.[633] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, the large dark gray atom is a phosphorus, and the small dark gray sphere is a zinc ion. A data set from crystals of unliganded thermolysin was gathered to Bragg spacing of 0.16 nm, and a crystallographic molecular model refined against this data set served as the starting point of the study. Crystals of thermolysin were soaked in a 10 mM solution of the phosphonamidate for several days. A data set, $|F_{\text{complex}}|$, was gathered to Bragg spacing of 0.16 nm from these crystals. From maps of difference electron density, the general location occupied by the phosphonamidate in the active site could be defined. All molecules of water overlapping this location in the refined crystallographic molecular model were removed, and a data set, $|F_{\text{nat,calcd}}|$, and a set of phases, $a_{\text{nat,calcd}}$, were calculated from this dehydrated model to Bragg spacing of 0.16 nm. A map of difference electron density ($F_{\text{complex}} - F_{\text{nat,calcd}}$) was calculated from these two data sets and the set of phases. A molecular model of the phosphon-amidate was inserted into the large feature of positive electron density found in the active site. The initial crystallographic molecular model of phosphonamidate in the active site was refined against the observed data set $|F_{\text{complex}}|$, and a drawing of the phosphonamidate (PhAm; black bonds) in the active site (white bonds) in the final refined crystallographic molecular model is presented. The carbobenzoxy group (Cbz) of the phosphonamidate is labeled to orient the drawing.The Zn^{2+} of the metalloenzyme is included in the drawing. Molecules of water (white spheres) involved in the network of hydrogen bonds in the active site are included.

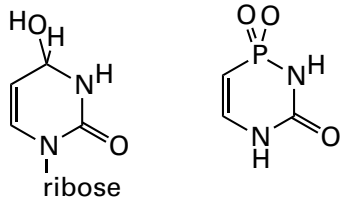
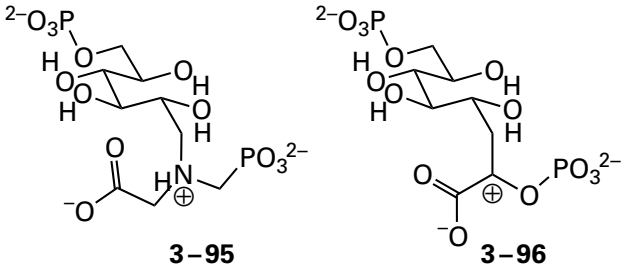
The hydrate of pyrimidin-2-one ribonucleoside (**3–93**)



3–93 **3–94**

is an analogue for the tetrahedral intermediate in the reaction catalyzed by cytidine deaminase (Equation 3–395). The same arrangement of catalytic groups and Zn^{2+} around analogue **3–93** is observed in a crystallographic molecular model of the active site of cytidine deaminase from *E. coli*[634] as is observed (Figure 3–36) for the equilibrium mixture cytidine and uridine in the active site of murine cytidine deaminase (28% identity; 2.7 gap percent). Phosphonocytosine (**3–94**) is an analogue for the tetrahedral intermediate in the reaction catalyzed by cytosine deaminase, an enzyme apparently evolutionarily unrelated to cytidine deaminase. In the crystallographic molecular model of phosphonocytosine in the active site of cytosine deaminase from *E. coli*, a similar but distinct distribution of catalytic functional groups around the analogue is observed.[635] A hydroxide on Zn^{2+} is still the nucleophile, but an aspartate takes the place of the glutamate in the active site of cytidine deaminase. The cytosine is flipped over relative to the cytosine ring in the active site of cytidine deaminase (Figure 3–36), so a second carboxy group is required to hydronate nitrogen 3. Finally, the hydrogen bond to the acyl oxygen is provided by a histidine rather than the amido nitrogen–hydrogen of Cysteine 99.

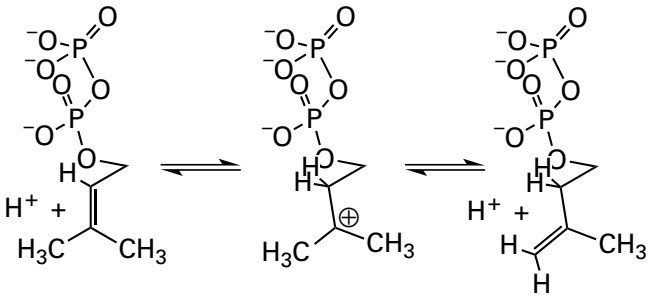
The trialkylammonium **3–95**



3–95 **3–96**

is an **analogue of carbenium ion 3–96**, another intermediate of high energy. Carbenium ion **3–96** is the initial intermediate in the condensation between phospho*enol*pyruvate and D-arabinose 5-phosphate catalyzed by 3-deoxy-8-phosphooctulonate synthase. Crystallographic molecular models of the complexes between trialkylammonium **3–95** and the 3-deoxy-8-phosphooctulonate synthases from *E. coli* and *Aquifex aeolicus* identify the side chains of the amino acids that orient the two reactants within the respective active sites.[636,637] The relative orientation of the groups that mimic D-arabinose 5-phosphate on the one end and phospho*enol*pyruvate on the other end of the analogue explains the stereochemistry determined previously for the condensation.[637]

It has been proposed that the reaction catalyzed by isopentenyl-diphosphate Δ-isomerase from *S. cerevisiae* proceeds through a tertiary carbenium ion resulting from the hydronation of either substrate on carbon



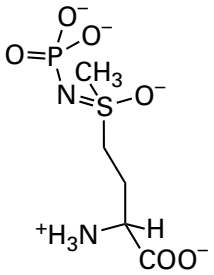
(3–404)

This proposal is based on the fact that the enzyme is inhibited by 2-(dimethylamino)ethyl diphosphate, a tertiary ammonium analogue of this carbenium ion, in which the ammonio nitrogen replaces the carbon of the carbenium ion.[638] In crystallographic molecular models of a complex between isopentenyl-diphosphate Δ-isomerase from *E. coli* and 2-(dimethylamino)ethyl diphosphate[551] and a complex of human isopentenyl-diphosphate Δ-isomerase (26% identity; 3.3 gap percent) and 2-amino-1-ethyl diphosphate,[639] the candidates for the respective catalytic acids performing these hydronations can be identified.

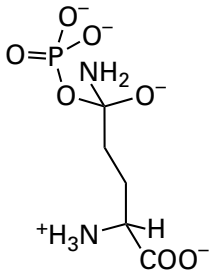
Analogues for intermediates of high energy can also be **formed on the active site of an enzyme** and observed in a crystallographic molecular model. For example, glutamine synthetase from *M. tuberculosis*

$$\text{L-glutamate} + NH_3 + MgATP^{2-} \rightleftharpoons MgADP^- + HOPO_3^{2-} + \text{L-glutamine} \quad (3\text{–}405)$$

was mixed with the sulfoximine (**3–67**) of L-methionine and $MgATP^{2-}$ and then crystallized. In the crystallographic molecular model, the adduct **3–97**



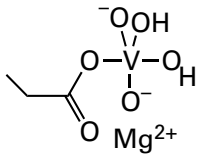
3–97



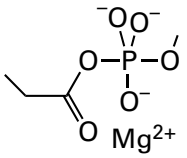
3–98

was observed occupying the active site[640] along with $MgADP^-$. Adduct **3–97** is an analogue of the tetrahedral intermediate **3–98**, which forms on the active site when ammonia attacks the 5-phospho-L-glutamate produced by the phosphorylation of the carboxylato group of L-glutamate by $MgATP^{2-}$ during the step in the mechanism in which there is a nucleophilic substitution of the phospho group for an amido group catalyzed by the active site. The position of the methyl group of adduct **3–97** occupies the site at which ammonia normally binds,[641] the sulfoximido oxygen identifies the guanidinio group of an arginine that is the donor in a hydrogen bond stabilizing the oxyanion of intermediate **3–98**, the $MgADP^-$ assumes an orientation appropriate for the initial transfer of the phospho group to the carboxylato group of L-glutamate, and the three Mg^{2+} ions that orient the three phospho groups and the carboxylato group of the L-glutamate that is phosphorylated are clearly defined in the crystallographic molecular model.

An enzyme catalyzing a **nucleophilic substitution at the phosphorus in a monoester of phosphoric acid** is the phosphatase encoded by the BT4131 gene of *Bacteroides thetaiotaomicron*. This enzyme first performs a nucleophilic substitution at a phosphate monoester in which the alcohol of the phosphoester is the leaving group and the magnesium carboxylato group of Aspartate 8 in the active site is the nucleophile. The enzyme then catalyzes a second nucleophilic substitution at the same phosphate group in which the magnesium carboxylato group of Aspartate 8 is the leaving group and water, under general base catalysis by Aspartate 10, is the nucleophile (Figure 3–43).[643] Vanadate (Table 3–7) forms, with the carboxylato group of Aspartate 8, an analogue (**3–99**) for the phosphorane (**3–100**) formed during the normal reaction in the active site



3–99



3–100

This phosphorane is an intermediate in the nucleophilic substitution of the magnesium carboxylato group of this Aspartate 8 with a hydroxy group from water catalyzed by the enzyme.[642] In the crystallographic molecular model of the complex between the enzyme and vanadate, a hydrogen bond between the carboxylato group of Aspartate 10 and the axial hydroxy group of the vanadate identifies Aspartate 10 as the catalytic base that removes a hydron from the molecule of water.

The goal of the approaches discussed so far is to obtain experimentally a single accurate crystallographic molecular model in which details of the catalytic mechanism are unveiled.

There are also computational approaches to creating a molecular model of the fully occupied active site. These approaches are not so satisfying as having a single informative crystallographic molecular model, but they can be provocative nevertheless.

A molecular model of the complex between the active site of an enzyme and its several reactants can be computed by **superposing separate crystallographic molecular models** of complexes between the enzyme and each reactant by itself.[644,645] For example, the crystallographic molecular model of a complex between the active site of human galactosylgalactosylxylosylprotein 3-β-glucuronosyltransferase and $MgUDP^-$ and the trisaccharide 3-β-D-galactosyl-4-β-D-galactosyl-*O*-β-xylose was superposed on a crystallographic molecular model of a complex between the active site and UDP-glucuronate. In the superposition, the 3-hydroxy group of the terminal D-galactose of the trisaccharide, to which the glucuronosyl group is transferred during the enzymatic

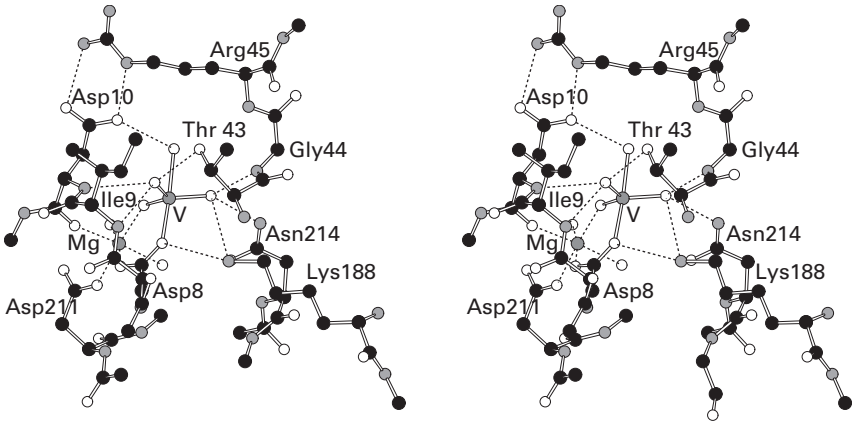


Figure 3–43: Stereodrawing[576] of the occupied active site in the crystallographic molecular model of the complex between the phosphatase encoded by the BT4131 gene of *B. thetaiotaomicron* and a vanadate.[642] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the small dark gray sphere is a magnesium ion. Crystals of the enzyme were grown from a solution containing 10 mM $MgCl_2$ and 5 mM sodium orthovanadate. A data set was gathered at Bragg spacing of 0.1 nm, and a map of electron density was produced by molecular replacement using an earlier crystallographic molecular model of the phosphatase from which all the ligands and molecules of water had been stripped. A feature of electron density was found in the active site immediately adjacent to the electron density for one of the oxygens in the carboxy group of Aspartate 8. An atom of vanadium and four atoms of oxygen could be inserted into this trigonal pyramidal distribution of electron density, and a bond was made between vanadium and the oxygen of Aspartate 8. A sphere of electron density consistent with a Mg^{2+} was found adjacent to the electron density assigned to the vanadate, and a magnesium atom was inserted in this sphere. The initial molecular model with these insertions was submitted to refinement. The drawing of the final refined structure includes the vanadyl group centered on the atom of vanadium (V), the Mg^{2+}, and most of the amino acids in the surrounding polypeptide providing hydrogen bonds to vanadate and amino acids and the molecules of water (white spheres) providing ligands to Mg^{2+}.

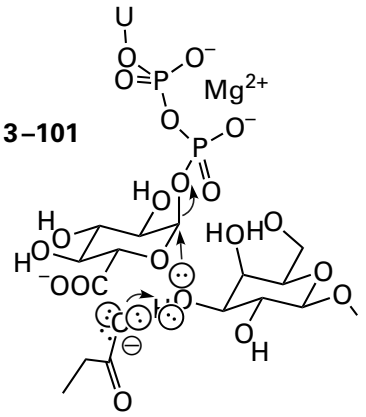
reaction, ends up on the opposite side of carbon 1 of the glucuronosyl group of UDP-glucuronate from the phosphate group of $MgUDP^-$ that leaves during the nucleophilic substitution catalyzed by the enzyme[646]

3–101



in line for the nucleophilic substitution.

When the crystallographic molecular model of the complex between shikimate kinase from *M. tuberculosis* and shikimate 3-phosphate and $MgADP^-$ is superposed on the crystallographic molecular model of the complex between the enzyme and $MgATP^{2-}$, the three nonbridging oxygens of the phosphate on shikimate phosphate superpose on the three nonbridging oxygens of the γ-phospho group of $MgATP^{2-}$, and the in-line nucleophilic substitution with inversion of configuration at the phosphorus that transfers the phospho group from $MgATP^{2-}$ to the hydroxy group of shikimate is easily imagined.[647]

(2*E*,6*E*)-Farnesyl diphosphate synthase

magnesium isopentenyl diphosphate +
magnesium geranyl diphosphate $\rightleftharpoons$
$MgOPO_3PO_3^{2-}$ + H^+ +
magnesium (2*E*,6*E*)-farnesyl diphosphate
(3–406)

catalyzes the alkylation of the isopentenyl alkene by the same mechanism as that of dimethylallyl-*trans*transferase (Figure 1–26), in which the allyl carbenium ion formed from geranyl diphosphate, instead of 3,3-dimethylallyl diphosphate, adds to the carbon–carbon double bond in isopentenyl diphosphate. Two crystallographic molecular models were superposed. One was a model of the complex between (2*E*,6*E*)-farnesyl diphosphate synthase from *E. coli*[648] and isopentenyl diphosphate and *S*-diphospho-1-sulfanyl-3-methyl-2-butene, an inactive analogue of the substrate geranyl diphosphate. The other was a model of a complex of the closely related (42% identity; 1.3 gap percent) enzyme farnesyl*trans*transferase

magnesium isopentenyl diphosphate +
magnesium (2*E*,6*E*)-farnesyl diphosphate
$\rightleftharpoons$ $MgOPO_3PO_3^{2-}$ + H^+ +
magnesium geranylgeranyl diphosphate
(3–407)

from *Sinapis alba* with geranylgeranyl diphosphate, which is the product of its reaction as written and which is homologous to (2*E*,6*E*)-farnesyl diphosphate.

The superposition of these two crystallographic molecular models (Figure 3–44)[648,649] clearly shows how the atoms involved in the reaction move as reactants are converted to products in the respective, mechanistically identical reactions catalyzed by these two different enzymes. The steps of the alkylation are indicated by the numbers. First, the bond between the allylic carbon 1 of the respective polyisoprenoid and the oxygen of trimagnesium diphosphate dissociates heterolytically to produce the allyl carbenium ion. Second, the double bond of the isopentenyl diphosphate, the alkene, acting as a nucleophile in the alkylation, reacts with the carbenium ion to form the new carbon–carbon bond in the adduct. Third, the hydron at carbon 2 of the former isopentenyl diphosphate immediately adjacent to the carbenium ion at carbon 3 of the former isopentenyl diphosphate is removed by one of the oxygens of trimagnesium diphosphate, which is the product of the dissociation that occurred in the first step, to produce the double bond between carbons 2 and 3 in the product.

If a crystallographic molecular model of the active site of an enzyme occupied by one of the substrates and an inactive, competitive inhibitor of the other substrate that happens to contains the other substrate as part of its structure has been constructed, the actual substrate can be inserted in place of the portion of the inhibitor that is in common and the resulting **hypothetical molecular model can be submitted to energy minimization**. For example, there is a crystallographic molecular model of the active site of malate dehydrogenase from *E. coli* occupied by NAD^+ and citrate, which is an inactive inhibitor of the enzyme that contains all the atoms of the normal substrate, (*S*)-malate, except the hydride that would be transferred to NAD^+ in the normal reaction.

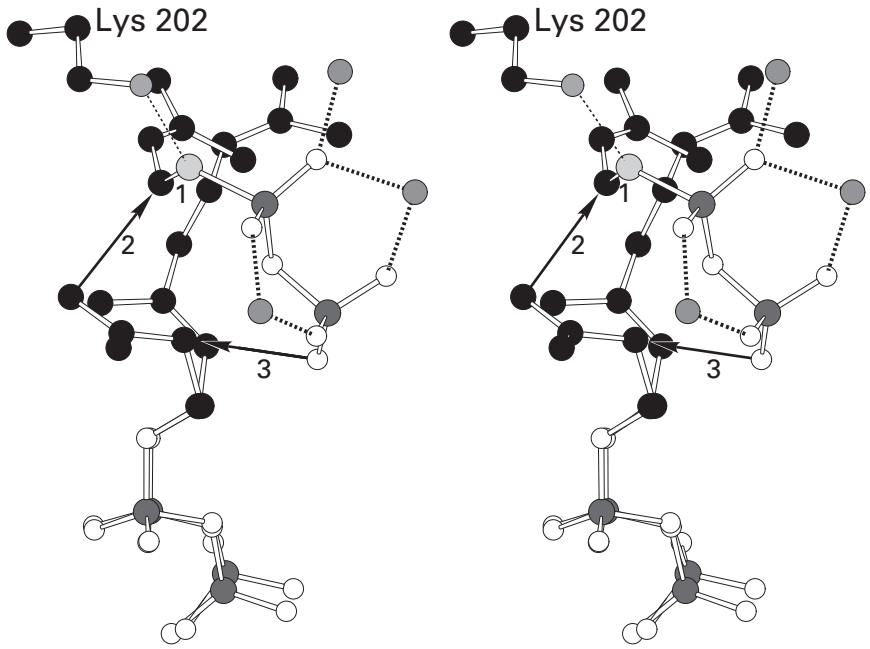


Figure 3–44: Superposition of the molecular models of isopentenyl diphosphate and *S*-diphospho-1-sulfanyl-3-methylbut-2-ene in the active site of the crystallographic molecular model of their complex with (2*E*,6*E*)-farnesyl diphosphate synthase from *E. coli*[648] upon the molecular model of geranylgeranyl diphosphate in the active site of the crystallographic molecular model of its complex with farnesyl*trans*transferase from *Sinapsis alba*.[649] Black atoms are carbons, white atoms are oxygens, gray atoms are nitrogens, the large light gray atom is a sulfur, the large dark gray atoms are atoms of phosphorus, and the three small dark gray spheres are magnesium ions that are ligands to the diphospho group of the geranylgeranyl diphosphate. The *S*-diphospho-1-sulfanyl-3-methylbut-2-ene in the former crystallographic molecular model is an inactive analogue of the first five carbons of the normal substrate, geranyl diphosphate. The superposition describes the conversion of the two respective reactants into the two respective products catalyzed by each of these enzymes, which are closely related and catalyze alkylations that have identical mechanisms (see Figure 1–26).

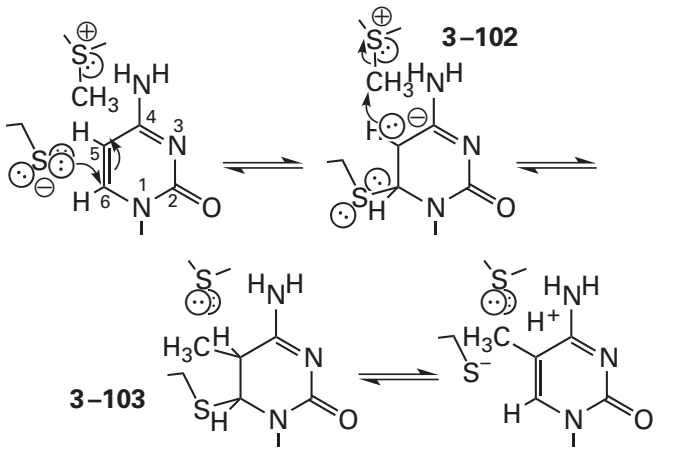
A molecular model of (*S*)-malate was inserted into the electron density for the citrate, and the resulting molecular model of the occupied active site was submitted to energy minimization. The **computed structure** places electrophilic carbon 4 of the NAD^+ 0.35 nm from carbon 2 of the malate, from which it would normally abstract a hydride in the reaction catalyzed by the enzyme, and in a favorable orientation for such an abstraction.[650]

A series of crystallographic molecular models of strategically designed complexes between an enzyme and various ligands can represent the complete sequence of events in its catalytic cycle.[651-653] For example, DNA (cytosine-5-)-methyltransferase is responsible for using *S*-adenosyl-L-methionine to methylate carbons 5 in cytosines



(3–408)

at particular positions in the double-stranded DNA of a bacterium to protect it from its own restriction endonucleases.

Three crystallographic molecular models represent the three steps in the enzymatic reaction. The crystallographic molecular model of a complex between the enzyme from *Haemophilus parahaemolyticus* and *S*-adenosyl-L-homocysteine, which is *S*-adenosyl-L-methionine missing the methyl group, and a segment of DNA containing a deoxycytidine that can be methylated by the enzyme illustrates the first step in the reaction, in which the deoxycytidine is flipped out of the double helix into the active site of the enzyme. When a segment of DNA containing the deoxycytidine to be methylated, which has been modified by fluorination at carbon 5, is mixed with the enzyme and *S*-adenosyl-L-methionine, the active site methylates carbon 5 of this 5-fluorodeoxycytidine, but there is a fluorine in place of the hydrogen at carbon 5 in the equivalent of adduct **3–103,** so the reaction cannot proceed to the next step. The crystallographic molecular model of this stalled complex and *S*-adenosyl-L-homocysteine occupying the active site[654] identifies the 5-fluorinated form of adduct **3–103**. Unfluorinated adduct **3–103** in the normal reaction results from the methylation at carbon 5 of carbanion **3–102** that in turn is produced by the nucleophilic addition of the sulfido group of Cysteine 81 in the active site to carbon 6 of the flipped-out deoxycytidine. The crystallographic molecular model of the complex between the products *S*-adenosyl-L-homocysteine and the segment of DNA containing the methylated deoxycytidine represents the final step in the reaction.[655]

cAMP-Dependent protein kinase catalyzes a nucleophilic substitution at phosphorus during which a phospho group is transferred from $MgATP^{2-}$ to the hydroxy group of a serine in one of its protein substrates to form a phosphomonoester. The molecular details of the steps in the reaction that occurs in its active site can be followed in crystallographic molecular models of the active sites of the enzymes from *Mus musculus* and *O. cuniculus* in three complexes: a complex with $CaATP^{2-}$ and a peptide in which the serine that is usually phosphorylated has been replaced by a cysteine; a complex of $MgADP^-$, the unmodified seryl peptide, and MgF_3^-, a trigonal mimic of monomeric metaphosphate (see the homologous complex **3–40** with aluminum); and a complex of $MgADP^-$ and the phosphorylated seryl peptide.[631]

In the case of inorganic diphosphatase from *S. cerevisiae*, complexes of wild-type enzyme and two mutants with phosphate, diphosphate, and various divalent metallic ions provide crystallographic molecular models for the reactants and products of six steps in the enzymatic reaction that comprise the complete catalytic cycle.[656]

A data set suitable for calculating a map of electron density can also be gathered over intervals as short as picoseconds by using intense short flashes of X-rays. As already noted, this procedure has been used to follow events in the active sites of bacteriorhodopsin,[657,658] photosystem II,[659-661] and photoactive yellow protein.[662-664] In each case, the reaction within the active site could be initiated by a strong flash of light of the proper wavelength, and the changes in the active site could then be followed by the flashes of X-rays at appropriate intervals. This procedure has seldom been applied to enzymatic reactions because in the active sites of most enzymes, few ways have been developed to initiate the reaction in a crystal in such a way that all the

active sites proceed in concert through the reaction. In the case of haloacetate dehalogenase from *Rhodopseudomonas palustris*, however, this problem was solved by soaking the crystals of the enzyme in a solution of 2-(4-hydroxyphenyl)-2-oxoethyl 2-fluoroacetate, which upon photolysis rapidly releases 2-fluoroacetate, a reactant for the enzyme. The photolytically released 2-fluoroacetate immediately associates with a significant proportion of the active sites in the crystal, and the dehalogenation then proceeds. Data sets could be collected at intervals from 30 ms to 30 s following the initiation of the reaction to follow the steps in the catalytic mechanism.[665]

The structure of the active site itself; the conformations, orientations, and positions of the substrates, analogues of substrates, and analogues of transition states and intermediates of high energy within an active site; and the distances among their atoms and atoms of the active site are the only facts revealed by a crystallographic molecular model. Each of these purely stereochemical features in this static structure is the consequence of noncovalent interactions. It follows that the information provided by the crystallographic molecular model also defines these noncovalent interactions. They are hydrogen bonding,[351] electric fields that arise from both ionic and dipolar forces, the hydrophobic effect,[666] and van der Waals forces.[352]

Most of the hydrogen bonds that are formed between an enzyme and its substrates and other ligands occupying the active site are participants in networks of hydrogen bonds that ensnare those substrates and ligands (Figures 3–33, 3–34, 3–40, and 3–42). These networks of hydrogen bonds are revealed in a crystallographic molecular model in which the active site is occupied by substrates, analogues of substrates, or analogues of transition states or intermediates of high energy. The networks of hydrogen bonds between substrates and ligands and an active site or a binding site, as with the networks of hydrogen bonds within the protein itself, have been **the most compelling features of crystallographic molecular models** from the beginning of their revelation, no doubt because of the emphasis on hydrogen bonding in the early models of the α helix and β structure that were published[667,668] before any crystallographic molecular models of proteins had been revealed. The fact that hydrogen bonds are blatant in crystallographic molecular models has led to the mistaken impression that they provide standard free energy of association for a substrate or a ligand during its association with an active site or a binding site. As has already been discussed, however, because of the properties of liquid water in which the substrates, the ligands, and the active site are dissolved before they associate, the only noncovalent interaction that can provide significant, favorable standard free energy of association is the hydrophobic effect.

One of the more paradigmatic examples of hydrogen bonding between a ligand and its site is found in the crystallographic molecular model of the complex between β-D-galactose and the periplasmic D-glucose/D-galactose-binding protein from *E. coli* (Figure 3–45).[669-671] Of the 17 donors and acceptors for hydrogen bonds on the β-D-galactose, 11 are occupied by acceptors and donors from the amino acids surrounding the site and two are occupied by the acceptors of a tightly bound molecule of water. Every donor for a hydrogen bond on the D-galactose is associated with an acceptor.

Not all the hydrogen bonds in these networks are provided by the folded polypeptide. As the complex between β-D-galactose and the periplasmic D-glucose/D-galactose-binding protein illustrates, **molecules of water fixed by hydrogen bonds** within the active site or within a binding site often provide donors and acceptors for hydrogen bonds to the substrates or ligands when they are bound (Figures 3–33, 3–34, and 3–42).[464,672] For example, in the crystallographic molecular model of the complex between asparagine—tRNA ligase from *Pyrococcus horikoshii* and the intermediate asparaginyl-adenylate, a molecule of water provides an acceptor for a hydrogen bond with the primary carbamoyl nitrogen–hydrogen of the side chain of the asparaginyl group that was the substrate L-asparagine, and another molecule of water provides a donor for a hydrogen bond to the acyl oxygen of the carbamoyl group[673]

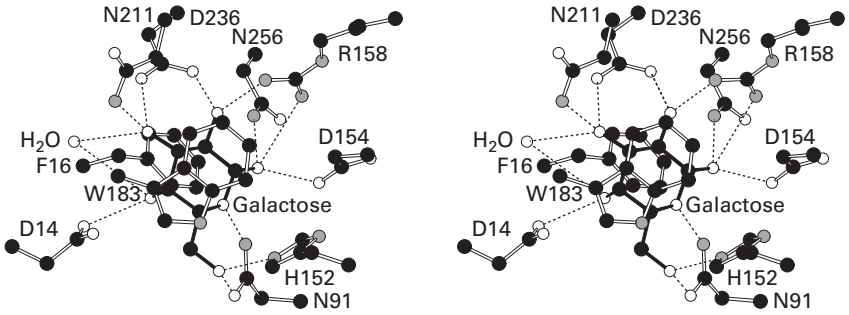


Figure 3–45: Stereodrawing[576] of the networks of hydrogen bonds formed between β-D-galactose and the various donors and acceptors surrounding it in the binding site within the crystallographic molecular model of the complex between β-D-galactose and the periplasmic D-glucose/D-galactose-binding protein from *E. coli*.[669,670] Black atoms are carbons, white atoms are oxygens, and gray atoms are nitrogens. The tightly associated β-D-glucose that is bound to the binding site in the protein in the cell and that copurifies with it was replaced by β-D-galactose,[671] and the complex was then crystallized. A data set was gathered to Bragg spacing of 0.2 nm, and a map of electron density was calculated using phases calculated from an earlier crystallographic molecular model of the protein to which β-D-glucose was bound and from which the molecular models of β-D-glucose and the waters had been removed. In an initial map of difference electron density, a feature that could be unambiguously identified as that of a molecule of β-D-galactose in the binding site was observed. The side chains of each amino acid that forms hydrogen bonds to β-D-galactose in the refined crystallographic molecular model are drawn, as well as a fixed molecule of water that provides two hydrogen bonds. The side chains of Tryptophan 183 and Phenylalanine 16 sandwich the two hydrophobic faces of β-D-galactose.

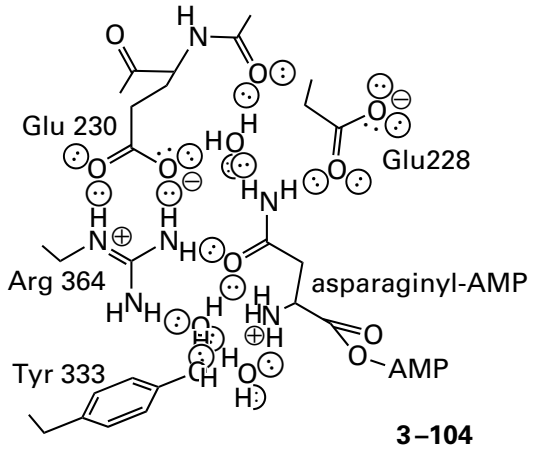


3–104

To ensure that the former molecule of water provides only an acceptor, its two donors are occupied with hydrogen bonds to the peptidyl acyl oxygen of Leucine 229 and the carboxylato group of Glutamate 230. These two molecules of water are responsible in part for identifying the L-asparagine that is the substrate for the enzyme, a role that is critical to avoiding rather catastrophic misacylation of the transfer RNA.

In a crystallographic molecular model of the active site of DNA-directed DNA polymerase from Escherichia phage RB69 occupied by a synthetic fragment of DNA that is a substrate for the enzyme, a cluster of five fixed molecules of water is used to provide donors and acceptors for hydrogen bonds for the acceptors and donors in the minor groove of the double-helical portion of the DNA.[674] The buried molecules of water in this crystallographic molecular model calculated from a data set to Bragg spacing of 0.18 nm are tetrahedrally aligned with each other as in the iceIh lattice, and the hydrogen bonds to the acceptors and donors in the minor groove are also tetrahedrally arrayed around each molecule of water.

In the binding site of sialic acid-binding periplasmic protein SiaP from *Haemophilus influenzae*, a cluster of five fixed molecules of water provides three donors of hydrogen bonds that recognize a molecule of the substrate sialic acid. When this cluster is disrupted by mutating a nearby alanine to an asparagine, the dissociation constant for sialic acid decreases[675] by a factor of 1400.

The crystallographic molecular model of the enzymatically inactive complex between human glutathione-disulfide reductase and its oxidized substrates glutathione disulfide and $NADP^+$ represents an extreme example of the participation of fixed molecules of water in identifying the substrate for an enzyme. There are 13 molecules of water that are fixed by 17 donors and acceptors for hydrogen bonds from the protein and that in turn provide 17 donors and acceptors to just the bound glutathione disulfide.[676]

In the case of D-glucose/D-galactose-binding protein (Figure 3–45), the binding site completely surrounds its ligand, preventing any contact with the bulk solution that surrounds the protein. An active site or a binding site on a protein, however, is often merely a depression or a crevice on its surface. In such a site, several of the donors and acceptors for hydrogen bonds on a bound substrate or a bound ligand can remain occupied by fixed molecules of water that occupied those donors and acceptors for hydrogen bonds when they were free in solution, and those **fixed molecules of water can still be in contact with molecules of water in the bulk solution.**

In almost all instances, the formation of a hydrogen bond between an acceptor or a donor on a functional group from the active site and a donor or an acceptor on a ligand, respectively, should be **an almost isenthalpic reaction**[677,678] because the concentration of hydrogen bonds in the solution does not increase significantly during the reaction.[351,679] This conclusion results from the fact that when the active site is unoccupied and the substrates are free in solution before they associate with the active site, a donor or an acceptor for a hydrogen bond in the active site or on a substrate is occupied most of the time with an acceptor or a donor from a molecule of water. When the substrates associate with the active site, if these donors and acceptors that were participating in hydrogen bonds with molecules of water do not find partners in the occupied active site, the number of hydrogen bonds in the solution decreases. When they do find partners, the number of hydrogen bonds in the solution does not change significantly, so the standard enthalpy of the solution remains approximately the same. Consequently, it is not because hydrogen bonds in an active site have favorable standard free energies of formation that there are so many of them; but it is because **whenever a donor or an acceptor for a hydrogen bond leaves water it must find an acceptor or the change in standard free energy is positive and unfavorable**.

Even though the formation of a hydrogen bond in an active site is almost isenthalpic, it so happens that, as in the case of the occupied site on D-glucose/D-galactose-binding protein (Figure 3–45), there is an imbalance between the occupation of donors and the occupation of acceptors for hydrogen bonds in a fully occupied active site. Although accep-

tors often do not find donors, **all or almost all of the donors for hydrogen bonds usually participate in hydrogen bonds** with acceptors in an occupied active site. This feature of the association of substrates, coenzymes, and prosthetic groups with an active site results from a historical fact. In a concentrated solution of protein, such as the cytoplasm in which most enzymes have evolved, acceptors always outnumber donors for hydrogen bonds because the polypeptide backbones of the proteins in that solution have two acceptors for hydrogen bonds on each acyl oxygen but only one donor on each amido nitrogen.[680] A donor for a hydrogen bond on a ligand or on the surface of the active site, when they are dissolved in cytoplasm, will always be occupied by an acceptor on a molecule of water in free solution. Whenever that donor is vacated by that molecule of water upon association of the ligand with an active site and does not participate in a hydrogen bond with an acceptor from the active site or another ligand or within the ligand itself, there is an inescapable positive change in the standard enthalpy of the solution as a whole because a net of one hydrogen bond is lost. In cytoplasm, however, this loss does not occur for an acceptor. If an acceptor for a hydrogen bond is not occupied by a donor following association of the ligand, there is no change in the number of hydrogen bonds in the solution because the donor on the molecule of water that dissociates from the acceptor can always find another unoccupied acceptor. It follows that during the association of substrates, coenzymes, and prosthetic groups with the active site on an enzyme, which has evolved over its entire history under these conditions, the maximum possible number of hydrogen bonds will form with donors, both on the ligands and on functional groups from the active site.*

A hydrogen bond between a donor and an acceptor in free aqueous solution always has a positive standard free energy of formation because of the competition of molecules of water for the donor and the acceptor,[678] but the formation of a hydrogen bond between an acceptor or a donor on an otherwise rigidly held ligand and a rigidly fixed donor or acceptor on a functional group from the active site involves significant **standard entropy of approximation**. Consequently, its formation in fact might display a negative standard free energy of formation. Nevertheless, if there are rigidly oriented hydrogen bonds in active sites that do have a negative free energies of formation, those standard free energies are probably not greatly negative.

There have been **many experiments that have been designed to discover a hydrogen bond in an occupied active site that has a negative standard free energy of formation**. In most of these experiments, rather small differences in thermodynamic state functions form the basis of the argument. It turns out, however, that it is difficult if not impossible to derive the standard free energy of formation of the hydrogen bond in question from these small, indirect effects. Perhaps it is educational to examine one of the more rigorous attempts to do so.

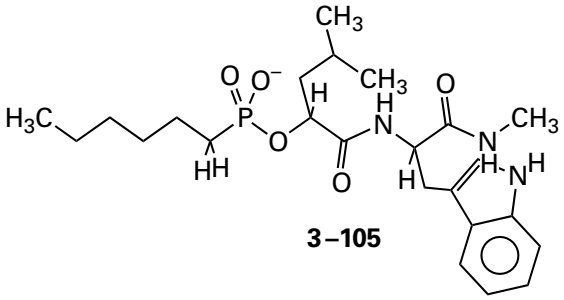
Two series of analogues for the tetrahedral intermediate in the hydrolytic reaction catalyzed by thermolysin from *B. thermoproteolyticus* have been synthesized. The various analogues in the first series were phosphonates (**3–73**), and the various analogues in the second series were the corresponding phosphonamidates (**3–71**). Each phosphonate was homologous to one of the phosphonamidates, each phosphonamidate was homologous to one of the phosphonates, and each pair of homologues was homologous to one of the peptides in a series of reactants for the enzyme (see **3–83** and Table 3–6). When the dissociation constants (K_i) for each phosphonamidate and its corresponding phosphonate, all acting as competitive inhibitors of thermolysin, were compared, a consistent difference, equivalent to a difference in free energy of dissociation of +16.7 ± 0.4 kJ mol^{-1}, was observed.[681] Each phosphonamidate had the larger free energy of dissociation (a smaller dissociation constant) relative to the corresponding phosphonate.

Between the refined crystallographic molecular models of the complex between a phosphonate and the enzyme and the complex between the corresponding phosphonamidate and the enzyme, no difference in the orientations or the positions of the two respective inhibitors or amino acids within the

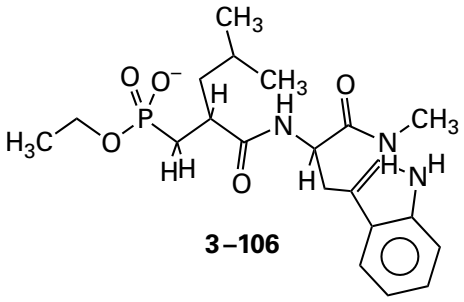
*In a dilute solution of protein and a reasonably concentrated solution of reactants, such as the situation when steady-state kinetics or equilibrium binding is assessed experimentally, the solutes will determine whether donors or acceptors are in excess in the solution. If acceptors are in excess, as in cytoplasm, whenever a hydrogen bond between a donor and an acceptor on a molecule of water dissociates because the donor has lost contact with the water in the solution, there will be a net loss of one hydrogen bond if the donor fails to find an acceptor in the active site because the acceptor on the molecule of water released will not find an unoccupied donor. If, however, donors are in excess, whenever a hydrogen bond between a donor and an acceptor on a molecule of water dissociates because the donor has lost contact with the water, there will be no net loss of a hydrogen bond if the donor fails to find an acceptor in the active site because the molecule of water released will find another donor. These considerations, however, are irrelevant to natural selection, which has always operated in a cytoplasm with excess acceptors.

active site could be observed.[682] In the model of the phosphonamidate bound in the active site, the nitrogen of the nitrogen–hydrogen bond of the phosphonamidate is 0.30 nm from the acyl oxygen of the peptide bond of Alanine 113 with a reasonable orientation for a hydrogen bond (Figure 3–42). One difference between the complex of a phosphonate with the active site and the complex of the corresponding phosphonamidate with the active site is the existence of this hydrogen bond. If this hydrogen bond were the only difference, the free energy of formation of this rigidly oriented hydrogen bond, relative to the hydrogen bond between the same nitrogen–hydrogen and a molecule of water when it was free in solution, would be –17 kJ mol^{-1}, which could be attributed to the entropy of approximation. There are, however, at least two other differences.

First, the ester oxygen of each phosphonate is forced to reside next to the acyl oxygen of Alanine 113 in the complex between a phosphonate and the active site, and this juxtaposition should engender an electron repulsion. To test this possibility, two competitive inhibitors of thermolysin, both of which were phosphonates



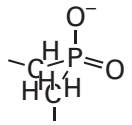
3–105



3–106

were synthesized.[683] The difference between the two was that the oxygen and the carbon of the phosphonate were interchanged. At the active site, this interchange would have replaced the oxygen with a carbon and a hydrogen, yet no difference in dissociation constant between these two competitive inhibitors was observed. The advantage of this experiment was that solvation of the two inhibitors in free solution should have been the same around the phosphorus, but in the active site, the oxygen would be replaced by the methylene. This result seems to suggest that electron repulsion is insignificant, but it would be surprising if there were not steric repulsion in the case of the methylene at least equivalent in magnitude to the electron repulsion of the oxygen because the distance that should exist between the carbon of the methylene and the oxygen of the peptide bond (0.30 nm) is well within the sum of the van der Waals radii of a hydrogen (0.115 nm) and an oxygen (0.15 nm) and the length of a carbon–hydrogen bond (0.11 nm), so this result is also inconclusive.

Second, the two free, nonbridging anionic oxygens of a phosphonate are less basic than the analogous anionic oxygens of a phosphonamidate and should bind less strongly to the zinc in the active site (Figure 3–42). This difference in pK_a could account for some or all of the difference in free energy of dissociation that was observed. To test this possibility, two sets of phosphonamidates (**3–71** and **3–83**), phosphonates (**3–73**), and phosphinates (**3–107**)



3–107

were synthesized, where each set is analogous to a peptide cleaved by thermolysin.[683] The phosphinates had the same pK_a as the phosphonamidates, but the values of pK_a for the analogous phosphonates were about 1.65 units lower. When the dissociation constants of the phosphonamidates and phosphinates were compared, the free energies of dissociation differed by only +6 kJ mol^{-1}, while the free energies of dissociation between phosphonamidates and phosphonates differed, as before, by +17 kJ mol^{-1}. When comparisons between phosphinates and phosphonamidates were made with the same series of peptide analogues used in the original comparisons between phosphonamidates and phosphonates,[684] the difference in free energy of dissociation between phosphonamidates and phosphinates was even less, +0.5 kJ mol^{-1}. From these observations, it might be concluded that the majority of the difference in free energy of dissociation between phosphonamidate and phosphonate is due not to the hydrogen bond but to the difference in basicity, which causes the oxygens of the phosphonamidate to bind more tightly to the zinc. When a series of arylphosphonate inhibitors of thermolysin that differed in the basicity of the phosphonate were examined, however, no

differences in dissociation constant were observed.[684] Again the observations are inconclusive.

From comparisons of the dissociation constants of all these phosphonamidates, phosphonates, and phosphinates, it can be concluded that the various differences in observed free energies of dissociation resulted from some combination of several factors: (1) the difference in hydrogen bonding in free solution between water and the nitrogen–hydrogen of the phosphonamidate or the oxygen of the phosphonate; (2) the difference in hydrophobic effect of the methylene in the phosphinates, the oxygen of the phosphonates, or the nitrogen–hydrogen of the phosphonamidates; (3) the difference in electron repulsion or steric repulsion between the acyl oxygen of Alanine 113 and the oxygen of the phosphonates or the methylene of the phosphinates; (4) the difference in basicity between the phosphinates, the phosphonamidates, and the phosphonates; and (5) the hydrogen bond itself. These experiments, at face value so simple, illustrate the difficulty of dissecting the various contributions of standard free energy to observed dissociation constants.

The most optimistic assessment of the results of these experiments is that the difference in standard free energy of formation between the hydrogen bond in the complex of a phosphonamidate with the active site of thermolysin and the hydrogen bond of the same phosphonamidate with water in free solution is greater than –17 kJ mol^{-1}; the most pessimistic is that it is in the neighborhood of 0 kJ mol^{-1}. The two states that differ by these amounts of free energy of formation are the nitrogen–hydrogen bond of the phosphonamidate in a hydrogen bond as a donor intramolecularly to the acyl oxygen of Alanine 113 and the nitrogen–hydrogen bond of the phosphonamidate as a donor intermolecularly to water. As the values of pK_a for the hydronated oxygen of water and the hydronated acyl oxygen of a peptide bond are essentially the same, no difference in enthalpy should exist between these two states. The lone pair of electrons on the peptide oxygen fixed and oriented adjacent to the nitrogen–hydrogen of the bound phosphonamidate, however, acts as if its entropy of approximation is no more negative than –50 J K^{-1} mol^{-1} relative to the entropy of approximation associated with the one mole fraction of water surrounding the unbound inhibitor and is probably much less negative.

In other, more equivocal experiments, the free energies of formation of single hydrogen bonds between amino acids in the active site of tyrosine-tRNA ligase from *Geobacillus stearothermophilus* and donors and acceptors on a bound substrate was estimated[679] to be about –4 kJ mol^{-1}. In these experiments, amino acids in the active site were replaced systematically by site-directed mutation, a procedure that involves significant and unpredictable steric effects. Similar results have been reported in other site-directed mutations.[685]

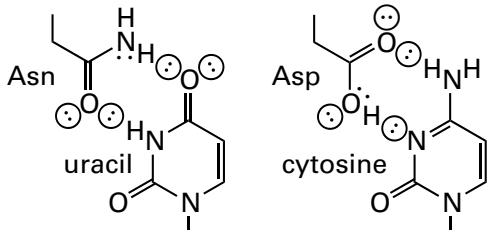
In any case, there seems to be agreement among those who have examined this question in detail that **it is possible for entropy of approximation to be of sufficient magnitude** to overcome the competition by water and provide a small favorable free energy of formation to one or more, but usually not the majority, of the hydrogen bonds in a complex between a ligand and a site on a protein. It should be kept in mind, however, that the entropy of approximation had to be paid for by the hydrophobic effect, so even if formally the formation of the hydrogen bond on the active site were to have a negative standard free energy of formation, a greater amount of negative standard free energy would have to be provided by the hydrophobic effect during the association of the substrate with the active site to accomplish the approximation. There is no doubt that when a donor or an acceptor for a hydrogen bond on a substrate cannot find an acceptor or a donor, respectively, in the active site, the standard free energy of formation between that donor or acceptor and a molecule of water is lost[678] and has to be paid for somehow.

Rather than to provide standard free energy of dissociation, the critical role of the hydrogen bonds that form between a substrate and an active site on an enzyme is to **orient the substrates relative to each other, to orient the substrates relative to the catalytic groups and prosthetic groups that perform the catalysis, and to recognize the substrates and ligands in the first place**. One important way that an enzyme or a protein that binds a particular substrate or ligand recognizes that substrate or that ligand is by providing donors and acceptors for hydrogen bonds positioned in space to complement the acceptors and donors, respectively, on the substrate or the ligand (Figures 3–33, 3–34, 3–36, 3–38, 3–40, and 3–42). One of the more unusual examples of such hydrogen bonding is that between the active site of haloacetate dehalogenase from *R. palustris* and its substrate.[686] This enzyme has a catalytic constant for hydrolyzing fluoroacetate that is 5 times larger than that for chloroacetate even though the bond dissociation energy of a carbon–fluorine bond is 1.35 times that of a carbon–chlorine bond. In the crystallographic molecular model of the

complex between an inactive mutant of the enzyme and fluoroactetate, the fluorine atom of the fluoroacetate is the acceptor for three hydrogen bonds, from Tyrosine 219, Histidine 155, and Tryptophan 156. These hydrogen bonds are all of reasonable length (0.30-0.33 nm), and they position the carbon on which the fluorine resides in the optimal alignment with the carboxylato group on Aspartate 110 that acts as a nucleophile in the nucleophilic substitution of the fluorine for one of the carboxylato oxygens. When chloroacetate occupies the active site, the larger radius of the chlorine atom causes it to fit improperly in this pocket, and it is pushed over, twisting the carbon–chlorine bond out of proper alignment and causing the catalytic constant for chloroacetate to be 5 times smaller than that for fluoroacetate. When the histidine is mutated to an asparagine, increasing the size of the pocket but retaining the donor for a hydrogen bond, the enzyme has a catalytic constant for chloroactetate that is 8 times larger than that for fluoroacetate.

Of even more importance than recognizing the proper substrate, however, is **the requirement that the arrangement of donors and acceptors for hydrogen bonds in the active site not complement the arrangement of acceptors and donors on closely related metabolites** in the cytoplasm or the environment that are not substrates or ligands for the enzyme or the protein. When an incorrect metabolite associates with an active site or a binding site, some of its acceptors and donors lose the donors and acceptors for hydrogen bonds provided by molecules of water when it is in solution and remain vacant while they are on the site, and some of the donors and acceptors in the active site or the binding site also lose the acceptors and donors provided by molecules of water in the empty active site and remain vacant in the complex. For each hydrogen bond lost in the overall solution, there will be an increase in standard free energy. For example, double-stranded uracil-DNA glycosylase from herpes simplex virus type 1 must distinguish a uracil from a cytosine. The active site focuses on the amido oxygen at carbon 4 of the uracil. At carbon 4 of cytosine, there is an amido group rather than an acyl oxygen. The active site provides two amido nitrogen–hydrogens, one from the side chain of an asparagine and the other from the polypeptide backbone, to form hydrogen bonds with the acyl oxygen of uracil.[687] Were cytosine to occupy the same location in the active site, the amido group at carbon 4 would lose its hydrogen bonds to two molecules of water, its amido group would displace the waters providing hydrogen bonds to the two amido nitrogen–hydrogens of the active site, no compensating hydrogen bonds would be formed, and four donors for hydrogen bonds in the overall solution would be vacated. The loss of the hydrogen bonds between these donors and molecules of water provides the positive standard free energy excluding cytosine from the active site, in addition to the steric overlaps of the four hydrogens in the incorrect complex. In this instance, the two donors are from amido groups, the values of pK_a (17) for which prevents them from dehydronating and becoming acceptors.

In the active site of thymidylate synthase from *Lactobacillus casei*, the side chain of an asparagine recognizes the acyl oxygen at position 4 of the 2′-deoxyuridine monophosphate (dUMP) that is its substrate with one of its carbamoyl nitrogen–hydrogens, and it recognizes the amido nitrogen–hydrogen of dUMP with its carbamoyl oxygen (**3–108**)

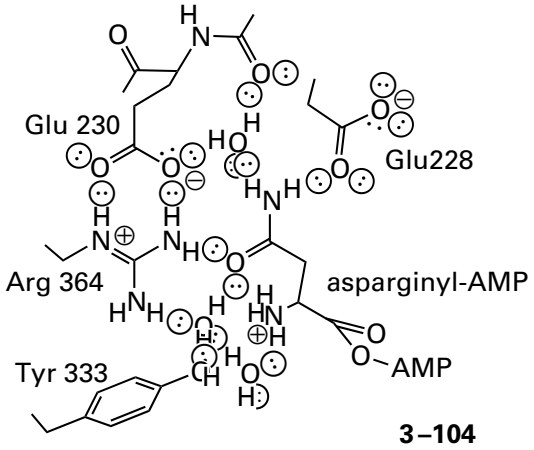


3–108 **3–109**

When the asparagine is mutated to an aspartic acid so that a donor for a hydrogen bond is converted into an acceptor (**3–109**), the mutant enzyme, unlike the wild-type enzyme, is able to methylate 2′-deoxycytidine monophosphate (dCMP) with a catalytic constant 0.06 times that of the catalytic constant for the wild-type enzyme when it is methylating dUMP.[688,689] Mutating the histidine that normally forms a hydrogen bond to the other lone pair of electrons on the acyl oxygen on carbon 4 of dUMP, which would sterically clash with the nitrogen–hydrogen bond on that side of the amido group on dCMP and assist in excluding it from the active site, increased the catalytic constant for the methylation[690] of dCMP by the aspartyl mutant by a further factor of 5.

Asparagine-tRNA ligase must distinguish aspartyl-AMP, the incorrect substrate, from asparaginyl-AMP, the correct substrate. The only difference between them is that an asparaginyl group has two donors and two acceptors for hydrogen bonds on its carbamoyl group, and an aspartyl group has at most only one donor and at least three acceptors in its β-carboxy group. The active site of the enzyme

from *P. horikoshii* provides two acceptors and two donors for hydrogen bonds



3–104

at the proper locations to complement the carbamoyl group of asparaginyl-AMP.[673] If the aspartyl group in aspartyl-AMP, rather than an asparaginyl-AMP, were to bind as the unhydronated β-carboxylato group, both Glutamate 228 and Glutamate 230 in the active site would have to be hydronated for the four acceptors on the β-carboxylato group to find four donors for hydrogen bonds properly positioned in the site. If, however, the aspartyl group in aspartyl-AMP were to bind as the hydronated β-carboxy group, then only one of the two glutamates in the active site would have to be hydronated for the single donor and the three acceptors for hydrogen bonds on the β-carboxy group to find one acceptor and three donors properly positioned in the site. The sum of the positive standard free energies for one or the other of these two unfavorable states of hydronation permits the enzyme, in part, to distinguish between aspartyl-AMP and asparaginyl-AMP.

A phospho group is usually recognized in an active site by a cuplike structure lined with an array of as many as ten donors for hydrogen bonds positioned to chelate its three nonbridging oxygens.[691] Each of the three formal oxyanions in the phospho group bound in the cup can be coordinated by as many as four donors for hydrogen bonds.[692] Usually there are three donors for hydrogen bonds for two of the oxyanions, and these donors are arranged roughly at three of the vertices of a tetrahedron, with a bond between phosphorus and the oxygen at the fourth vertex (see two of the vanadyl oxygens in Figure 3–43). The third oxyanion participates in only two or even one hydrogen bond.[692] Remarkably, this arrangement is contrary to the orientation of donors to oxyanions of phospho groups in crystallographic structures of small molecules,[693] in which the donors are arranged trigonally around each oxygen.* In the absence of a phospho group, the cup is filled with molecules of water. If any other ligand displaces even one of these waters without providing acceptors for any donors for hydrogen bonds vacated, there is a positive change in standard free energy that excludes that other ligand. The large number of properly positioned donors for hydrogen bonds in the cup are arrayed to fit the acceptors on a phospho group rather than the acceptors on any possible cluster of molecules of water. In the unoccupied state, some of these donors must be vacant, but they become occupied when the phospho group associates. Furthermore, there must be significant entropy of approximation favoring the association of the phospho group because so many properly aligned hydrogen bonds form at once. Consequently, a phospho group associates tightly with this array by extensive chelation and strongly anchors within an active site or a binding site the rest of the substrate or the ligand to which it is attached. The strength of this interaction explains why phosphate or other phosphorylated compounds at high concentration often act as inhibitors of enzymes that catalyze reactions involving phosphorylated substrates and consequently have one of these cups. The strength of these interactions may also be a reason, in addition to the ability of a phospho group to confine the metabolite to the cytoplasm, that phosphorylated substrates have been selected by evolution for most of the reactions in glycolysis.

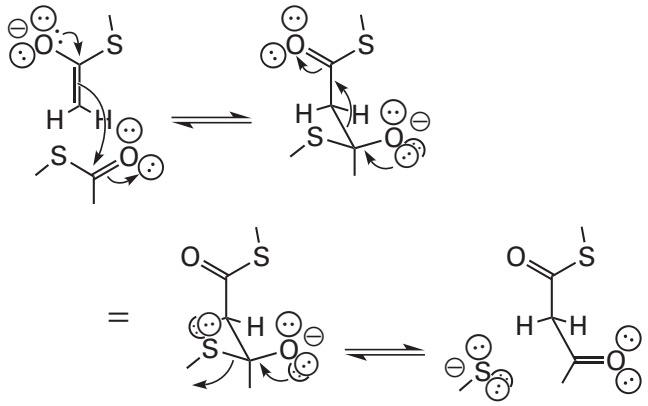
The crystallographic molecular model of the phosphatase encoded by the BT4131 gene of *B. thetaiotaomicron* (Figure 3–43) introduces the oxyanion hole, one of the frequently encountered features of an active site that can be revealed in a crystallographic molecular model by an analogue of an intermediate of high energy. The three equatorial oxygens of the vanadate are three equatorial oxyanions in the intermediate phosphorane. Two of these three oxygens form hydrogen bonds to the α-amido groups of Isoleucine 9, Aspartate 10, and Glycine 44, the hydroxy group of Threonine 43, the 6-amino group of Lysine 188, and the γ-amido group of Asparagine 214. These six donors for hydrogen bonds stabilize the single negative elementary charges on the two oxyanions and consequently the phosphorane itself. It is remarkable that the donors are arranged

*In some of these cups, there are trigonal arrays of donors around one of the oxygens.[694] Either arrangement is consistent with the requirement that the molecular orbitals of the phospho group have its overall symmetry.

tetrahedrally* around each oxygen, as the three lone pairs of electrons on each of them would be if they actually are hybridized sp^3.

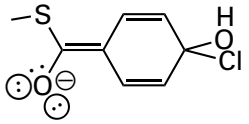
An **oxyanion hole is an arrangement of donors for hydrogen bonds that associates with an oxyanion in a substrate or intermediate** in an enzymatic reaction, but usually it stabilizes an oxyanion in an intermediate.[412] In addition to stabilizing oxyanions in a phosphorane, an intermediate of high energy, oxyanion holes are usually found in enzymes that hydrolyze peptide bonds through oxyanionic tetrahedral intermediates (Figures 1–10B and 3–6). The single oxyanion holes in subtilisin,[412] chymotrypsin,[695] streptogrisin A (Figure 3–32),[544] carboxypeptidase D from *Triticum aestivum*,[696] and bovine thrombin,[697] which in each enzyme is formed from two **α-amido groups of the polypeptide backbone**, can be identified in crystallographic molecular models of the complexes between the enzymes and the respective analogues for the tetrahedral intermediates.[412] Each analogue places an oxygen at the position of the oxyanion in the actual intermediate (Figure 3–32). In many of these structures, one of the two donors for hydrogen bonds is part of a stable six-membered ring that incorporates a nucleophilic serine and the tetrahedral intermediate (Figure 3–32).†

There are a number of other active sites that catalyze reactions other than a nucleophilic substitution at phosphorus or the hydrolysis of a peptide bond and yet use two α-amido groups from the polypeptide to form an oxyanion hole. For example, β-lactamase from *Enterobacter cloacae* hydrolyzes an amide through an oxyanionic tetrahedral intermediate,[698] and acetylcholinesterase from *T. californica* hydrolyzes an ester through an oxyanionic tetrahedral intermediate,[227] and the active site in each enzyme has an oxyanion hole formed from two α-amido groups from the polypeptide. β-Ketoacyl-[acyl-carrier-protein] synthase III from *M. tuberculosis* transfers an acyl group from the sulfanyl group of coenzyme A to the sulfanyl group of a cysteine in the protein and then transfers the acyl group from the cysteine to the enolate of acetyl-SCoA (previously Equation 1–118)



(3–409)

that is formed by the decarboxylation of malonyl-SCoA. Each of the two nucleophilic substitutions transferring the acyl group from the respective sulfanyl group proceeds through a tetrahedral intermediate at the acyl carbon, and the oxyanion of this tetrahedral intermediate is accommodated in an oxyanion hole formed by two α-amido groups from the polypeptide.[621] In the nucleophilic aromatic substitution catalyzed by 4-chlorobenzoyl-CoA dehalogenase from *Pseudomonas*, the oxyanion of the usual intermediate



3–110

in such a substitution in a thiobenzoate sits in an oxyanion hole formed from two α-amido groups from the polypeptide.[699]

There are other oxyanion holes, however, that are **not formed from two α-amido groups**. In the active site of aspartate carbamoyltransferase (Figure 3–40), the oxyanion hole for the tetrahedral intermediate at the carbamoyl carbon is formed by the hydroxy group of a threonine, the guanidinio group of an arginine, and the hydronated imidazolyl group of a histidine. In the active site of thermolysin (Figure 3–42), the oxyanion hole for the tetrahedral intermediate is formed by the carboxy group of a glutamic acid and a molecule of water. In acetyl-CoA *C*-acetyltransferase from *Zoogloea ramigera*, which catalyzes almost the same reaction as that catalyzed by β-ketoacyl-[acyl-carrier-protein] synthase III (Equation 3–409), one of the oxyanion holes is formed instead by the imidazolio group of a histidine and a molecule of water.[700]

In the active site of acetyl-CoA *C*-acetyltransferase from *Z. ramigera* there are **two oxyanion holes**. The

*It is also the case, however, that a tetrahedral arrangment minimizes the steric interactions among the donors of the hydrogen bonds.

†The six-membered ring in Figure 3–32 is formed by the amido nitrogen of Serine 195, its α and β carbons, its γ oxygen, the carbon of the hemiacetal (ha), and the oxygen of the hemiacetal that forms the hydrogen bond with the amido nitrogen of Serine 195.

enzyme performs a Claisen condensation (Equation 3–409) in which the enolate of an acetyl group on a cysteine in the active site is condensed with an acyl-SCoA. The oxyanion hole for the oxyanion of the enolate is provided by the fixed molecule of water and the imidazolio group of a histidine, and the oxyanion hole for the oxyanion in the tetrahedral intermediate in the nucleophilic substitution is provided by two amido nitrogen–hydrogen bonds from the backbone of the polypeptide.[701]

When amino acids that provide donors for hydrogen bonds in oxyanion holes are mutated, the rate constants for the enzymatic reaction usually decrease.[702] For example, in the active site of carboxypeptidase A from *R. norvegicus*, which hydrolyzes a peptide bond through an oxyanionic tetrahedral intermediate, the *ω*-guanidinio group of Arginine 127 and a Zn^{2+} form the oxyanion hole.[703] When Arginine 127 is mutated to a methionine, the specificity constant of the enzyme for its substrate decreases by a factor of 9000.[704]

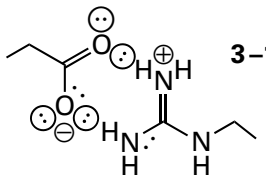
It has been pointed out that when a reaction that is catalyzed by an enzyme in which an oxyanion is formed as an intermediate occurs in aqueous solution, water invariably provides donors for the oxyanion. That water is required to provide these donors can be inferred from the fact[705] that when the catalytic base that removes the hydron during the enolization of acetone is bulky enough to bump off one of the molecules of water solvating the carbonyl oxygen that becomes the oxyanion of the enolate, the rate of enolization decreases by a factor of 10. Consequently, if the reaction is brought into an active site, the active site has to provide the donors for hydrogen bonds that water provides outside or it will actually decrease the rate of the reaction. Nevertheless, there may be advantages to providing **fixed donors for hydrogen bonds in the proper orientation**. In most of the situations in which an oxyanion forms during the enzymatic reaction, the oxygen begins as a trigonal acyl or carbonyl oxygen on a trigonal carbon and becomes a tetrahedral oxyanion on a tetrahedral carbon as the intermediate forms. This rehybridization usually perfects the fit of the oxygen within the oxyanion hole. To the extent that the hydrogen bonds in the occupied oxyanion hole come into existence or become more stable during this rehybridization, the increase in standard free energy of formation they experience must **lower the standard free energy of activation for the reaction**. When amino acids around the oxyanion hole in steroid Δ-isomerase from *P. putida* were mutated so that there was enough room in the active site for disorganized molecules of water to solvate the oxyanion rather than the fixed donors for hydrogen bonds provided normally by the enzyme,[706] the rate of the reaction decreased by a factor of 1000. Consequently, the hydrogen bonds achieved by the donors from the active site in an occupied oxyanion hole may be examples of hydrogen bonds that, during their formation or their increase in stability as the transition state is achieved, lower the standard free energy of activation of the reaction catalyzed by the enzyme.

The role of ionic interactions in the formation of complexes between substrates and active sites is difficult to assess. In part, this difficulty results from the fact that water solvates elementary charges so effectively. The change in standard enthalpy when two opposite elementary charges that were in free solution are juxtaposed in an active site during the association of a substrate is probably always positive because this solvation is lost in the process.[707] This endergonic change is the reason that ion pairs are usually unstable relative to the separated, independent ions in aqueous solution, and it forms the basis for the ionic theory of solution.

The main reason it is difficult to evaluate the importance of ionic interactions is that there are almost never fixed elementary charges in biochemical metabolites. The **charged molecules in biochemistry are almost always cationic acids or anionic bases** that can be neutralized in acid–base reactions and that have multiple donors and acceptors for hydrogen bonds. It is difficult to distinguish a hydrogen bond between a donor and an acceptor that just happen to be oppositely charged from an interaction due solely to ionic attraction. An example of this difficulty is the **charged hydrogen bonds** in the crystallographic molecular models of the adducts between the prosthetic pyridoxal phosphate and either aspartate or glutamate in the active site of aspartate transaminase (previously Equation 2–29)

$$\text{L-aspartate} + \text{2-oxoglutarate} \rightleftharpoons \text{oxaloacetate} + \text{L-glutamate} \qquad (3\text{–}410)$$

from *G. gallus*.[708,709] Each pair of charged hydrogen bonds between a guanidinio group and a carboxylato group is canonical



Are these hydrogen bonds or ionic interactions? When a fatty acid is bound to intestinal fatty acid binding protein from *R. norvegicus*, its carboxylato group forms two hydrogen bonds to two guanidinio nitrogen–hydrogens of an arginine side chain, but the geometry of the hydrogen bonding in the crystallographic molecular model seems more important than the balance of elementary charges.[710]

In the one instance that had always been presented as a purely ionic interaction,[711] that between the trimethylammonio group in acetylcholine and acetylcholinesterase, it has now been concluded that the noncovalent interaction that causes the quaternary ammonium to associate with the active site arises from the hydrophobic effect as well as electric forces (cation–π interactions) between the π molecular orbital system of uncharged aromatic side chains and the fixed cation.[226,229] A similar combination of the hydrophobic effect and cation–π interactions with two phenylalanines is involved in recognizing the sulfonium ion of *S*-adenosyl-L-methionine in the active site of human adenosylmethionine decarboxylase.[712] In this instance, the positively charged sulfur atom is covalently surrounded in the *S*-adenosyl-L-methionine itself by a methyl group, the β- and γ-methylenes of the L-methionine, and the methylene of carbon 5 of the ribosyl group, all of which insulate it. Contrariwise, in the case of the SH2 domain of the non-specific protein-tyrosine kinase from avian leukosis virus RSA, the phenyl ring of the phospho-L-tyrosine that is a ligand for the binding site in this domain is sandwiched between the guanidinio nitrogen of an arginine and the 6-ammonio group of a lysine in the crystallographic molecular model in what also appear to be cation–π interactions rather than ionic interactions.[713]

In the instance of the positively charged guanidinio group of an arginine involved in binding or catalysis, it has been proposed that ionic interactions can be dissected from hydrogen bonding by **mutating an arginine to a citrulline**. For example, in the crystallographic molecular model of the complex between the active site of chorismate mutase (Equation 3–402) from *B. subtilis* and analogue **3–84** for the transition state in the electrocyclic rearrangement catalyzed by the enzyme, one of the ω-amido nitrogen–hydrogens in the positively charged guanidinio group of Arginine 90 engages in a hydrogen bond with the ether oxygen of the analogue. This oxygen in the analogue is the homologue of the ether oxygen in chorismate that becomes the carbonyl of the prephenate.[365] When Arginine 90 is mutated to a citrulline, in effect replacing one of the ω-amido groups with a carbonyl oxygen as well as eliminating the single positive elementary charge that was on the guanidinio group of the arginine, the specificity constant for chorismate decreases by a factor of 20,000. This observation was presented as evidence that the positive elementary charge on the guanidinio group in the unmutated active site stabilizes the actual transition state in the reaction.[714] This conclusion was consistent with the fact that only mutants of the enzyme that have the guanidinio group of an arginine or the ammonio group of a lysine in the immediate vicinity of the ether oxygen in chorismate are enzymatically active.[715] In another instance, where the substitution of each of the two arginines in an active site with citrullines has been performed, there is no crystallographic evidence of the disposition of these arginines in a complex between the active site and either a substrate or an analogue, so it is difficult to evaluate the decreases of greater than 5000 in the catalytic constant that are observed when both arginines are mutated to citrullines. Nevertheless, the decrease was attributed to the loss of the positive elementary charges.[716]

During the substitution of citrulline for arginine, in addition to elimination of the charge, two nitrogen–hydrogens on an amido group are converted to two lone pairs of electrons; as a result, two donors for hydrogen bonds are converted to two acceptors. There are at least two problems with this substitution. First, the ω-carbamoyl nitrogen of the arginine in the unmutated active site that does not form the hydrogen bonds to the substrate that are the focus of attention may not actually end up in the occupied active site as the ureido oxygen of the citrulline, as is desired. If it does not, then the ω-carbamoyl nitrogen that does provide the hydrogen bond will be replaced by the ureido oxygen that cannot provide a hydrogen bond but would direct a lone pair of electrons at the lone pair of electrons in the acceptor of the substrate. For example, in the particular case of chorismate mutase, in the complex between the active site and the analogue of the transition state, the nitrogen atom of the other ω-amido group of the arginine that does not form the hydrogen bond with the oxygen of the substrate is sandwiched

between one of the carboxylato oxygens of Glutamate 78 (0.32 nm), and the sulfanyl group of Cysteine 88 (0.32 nm).[365] It is entirely possible that this intimate interaction is exclusive for a carbamoyl group and that in the mutated enzyme the acyl oxygen, rather than being sandwiched between these two atoms as is desired, is directed toward the oxygen of the substrate, which would certainly disrupt the reaction. Second, in most instances the amido group that does not form a hydrogen bond with the substrate engages with other side chains in the active site, and the mutation must interfere with these interactions, disrupting the alignment of the ureido group of the citrulline. This interference could well explain much if not all of the decrease in a specificity constant.

Most substrates of enzymatic reactions or ligands for binding proteins bear elementary charges at neutral pH and probably enter an active site or a binding site as charged molecules. In crystallographic molecular models of the resulting complexes, however, there is no obvious pattern in which each formal elementary charge on the substrate or ligand is exactly balanced by an amino acid bearing the opposite elementary charge in the site. Rather, the **distributions of elementary charges over occupied active sites or binding sites are far more disorganized and unpredictable** (Figures 3–33, 3–34, 3–40, 3–42, and 3–45). An example of an active site in which no cationic amino acid is located adjacent to a negative elementary charge on a substrate is found with tryptophan synthase. In the crystallographic molecular model of the active site of the enzyme from *S. typhimurium* occupied by the competitive inhibitor propane phosphate, the negatively charged phosphate is surrounded only by uncharged donors and acceptors for hydrogen bonds.[717] In the case of the phospho group of deoxyuridine phosphate, however, when it is bound in the active site of thymidylate synthase from *L. casei*, there are four arginines forming hydrogen bonds with its oxygens, so its maximum of two negative elementary charges is surrounded by four positive elementary charges.[718] The orientation by the active site of the seven donors for these hydrogen bonds creates the cup into which the three nonbridging oxygens of the phospho group fit perfectly.

There is another example of a complex of a positively charged substrate with a negatively charged amino acid in an active site that has been cited as a simple ionic interaction. Trypsin is an endopeptidase that cleaves peptide bonds (Figure 3–6) to the carboxy-terminal side of lysines and arginines exclusively. The enzyme was thought to be confined to cleave at these locations because, in the region of its active site where the side chain of the amino acid to the amino-terminal side of the susceptible bond is bound, there is a strategically placed aspartate,[719] Aspartate 171 in bovine α-trypsin, that would provide a compensating elementary charge. Before refined crystallographic molecular models (Figure 3–46)[720] of complexes between inhibitors and bovine trypsinogen, the precursor of bovine trypsin, were available, the interaction between trypsin and the lysines or arginines on its reactants was thought to be ionic. It turns out, however, that at least in this instance, it is **difficult if not impossible to distinguish the importance of hydrogen bonding from the importance of ionic interaction.**

In crystallographic models of complexes between trypsinogen and small inhibitory proteins in which either lysine or arginine in the respective protein occupies the pocket for the targeted amino acid in the reaction catalyzed by the enzyme, it is clear that either the lysine or the arginine, in turn, participates in a complex network of hydrogen bonds rather than participating only in an ionic interaction. This observation is remarkable because the arrangement of the donors for hydrogen bonds in lysine and the donors for hydrogen bonds in arginine are so different. Nevertheless, acceptors for hydrogen bonds are arranged within the binding site with great precision so as to accommodate either side chain. When lysine is bound, the three tetrahedrally arrayed donors on its ammonio group find three tetrahedrally arrayed acceptors for hydrogen bonds: Water 416, Water 414, and the peptidic acyl oxygen of Serine 172 within the polypeptide (Figure 3–46). The carboxy group of Aspartate 171 is not directly bound to lysine because its side chain is too short, but it forms a hydrogen bond to one of the actual ligands, Water 414. Arginine, however, is longer, by one atom, than lysine, and arginine forms a canonical bis-hydrogen bond (**3–111**) with Aspartate 171 directly. The other three donors of the planar guanidinio group in the arginine form hydrogen bonds with the acyl oxygen of Glycine 196, Water 416, and Water 403. Only one of these five acceptors for hydrogen bonds, Water 416, is also used in the complex with lysine. When arginine is bound, Water 414 is displaced and the acceptor for a hydrogen bond on the acyl oxygen of Serine 172 is vacant. When lysine is bound, the acceptor on Water 403 and the lone pair on Aspartate 171 are vacant.

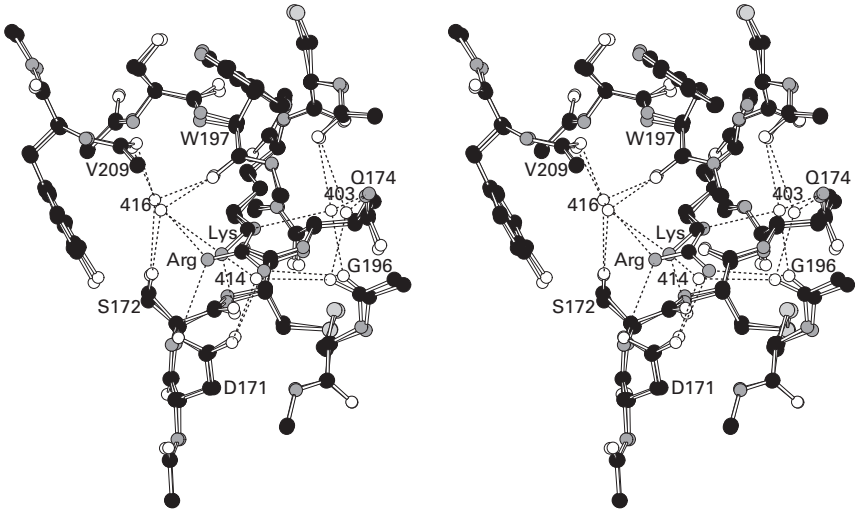


Figure 3–46: Superposed stereodrawings[576] of crystallographic molecular models of the binding of either lysine or arginine to the portion of the active site of trypsin, the specificity pocket, that determines its specificity for lysines and arginines.[720] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. The two crystallographic molecular models are superposed to show that the same conformation of the specificity pocket accommodates both side chains and that the side chains themselves superpose closely at each of their common atoms. The two crystallographic molecular models from which these regions come are those of the complex between native bovine pancreatic trypsin inhibitor (58 aa) and bovine trypsinogen, the precursor to bovine trypsin, in which a Lysine 15 of the inhibitor occupies the specificity pocket, and the complex between bovine trypsinogen and bovine pancreatic trypsin inhibitor, in which Lysine 15 has been replaced with an arginine. In the models, the side chain of the lysine occupies exactly the same location as that of arginine, with the 6-amino group of the lysine occupying the location of the guanidino carbon of the arginine. Water 414, Water 416, and the acyl oxygen of Serine 172 form a triangular array of hydrogen-bond acceptors for the three donors on the lysine. Aspartate 171, Water 403, Water 416, and the acyl oxygen of Glycine 196 form a planar array of hydrogen-bond acceptors for the five donors on the arginine.

In these two instances, the vacant acceptors in a given complex that are used to bind the other reactant in the other complex are enthalpically inconsequential in the wild. It is noteworthy, however, that every donor for a hydrogen bond on the respective side chain ends up in a hydrogen bond when it is bound at the active site.

The complexity of the hydrogen bonding in this subsite within the active site of trypsin when it is associating with a lysyl or an arginyl side chain in a substrate clearly reveals the naiveté of the expectation that changing Aspartate 171 to lysine would reverse the specificity of trypsin from peptide bonds carboxy-terminal to lysines and arginines to peptide bonds carboxy-terminal to aspartates and glutamates.[721] In the case of the active site of aspartate transaminase from *E. coli*, however, L-aspartate, the exclusive substrate for the enzyme, seems to be recognized mainly by the canonical pair of hydrogen bonds (**3–111**) between its γ-carboxylato group and Arginine 292. Mutating Arginine 292 to an aspartate did reverse the specificity of the transaminase from L-aspartate (7×10^5) in the native enzyme to L-arginine (7) in the mutant, but the specificity constant of the mutant for L-arginine was only 2×10^{-5} that of the wild type for L-aspartate.[722] The specificity was reversed, but the activity of the mutant for L-arginine was minuscule. Similar changes in specificity and activity were observed when an attempt was made to change the specificity of trypsin from *R. norvegicus* from hydrolyzing peptide bonds carboxy-terminal to arginines and lysines to the preference shown by the related enzyme chymotrypsin (38% identity; 2.8 gap percent) for aromatic side chains by mutating Aspartate 171 to the serine found at that location in chymotrypsin.[723]

The manifestation of the hydrophobic effect in a crystallographic molecular model is less apparent than the hydrogen bonds and ionic interactions. Nevertheless, because it is directly proportional to the number of hydrogen–carbon bonds removed from contact with the solution,[52] the magnitude of the hydrophobic effect affiliated with the association of ligand with an active site can be estimated by counting up the number of hydrogen–carbon bonds that are exposed to the solution in the unbound substrates, in the unbound coenzymes, and in the empty active site itself in the crystallographic molecular model of the unoccupied enzyme and then counting up the number of those same hydrogen–carbon bonds that remain in contact with the solution in the crystallographic molecular model of the fully occupied active site. The difference between these two tallies is an indication of the strength of the hydrophobic effect elicited by the association.

A crystallographic molecular model, however, leaves one with the false impression that where a particular hydrogen–carbon bond ends up once a substrate associates with an active site is somehow consequential to the hydrophobic effect. The only significant contribution to the hydrophobic effect is the behavior of the water that occurs after the hydrogen–carbon bond leaves. No interaction that occurs between that hydrogen–carbon bond and the environment that surrounds it in the active site is of importance.[352] It follows that observing the situation of a particular hydrogen–carbon bond within the active site provides no information about the magnitude of the hydrophobic effect in which it has participated.

Hydrogen–carbon bonds that have been removed from contact with water are always observed in a crystallographic molecular model of a substrate or a ligand bound in an active site or a binding site, and hydrogen–carbon bonds on functional groups from the active site that have been removed from contact with water upon the association of a substrate or a ligand are also always observed. For example, the hydrogen–carbon bonds of the three methylenes, of the ribosyl group, and of the adenine ring are all removed from contact with water upon formation of the complex between the active site of guanidinoacetate *N*-methyltransferase and *S*-adenosyl-L-homocysteine (Figure 3–34). In the crystallographic molecular model of the complex between porcine L-lactate dehydrogenase (Equation 3–27) and NAD^+, the planar π system of the adenine ring of NAD^+ is sandwiched between an alanine, an isoleucine, a valine, and a glycine on one side and two valines and a leucine on the other,[591] and the hydrogen–carbon bonds on these side chains that sandwich the adenine ring are removed from contact with water after intimately contacting the π molecular orbital system of the adenine upon formation of the complex.

In the case of side chains in the active site, the situation is somewhat ambiguous. The hydrophobic effect is the negative standard free energy change that occurs when a hydrogen–carbon bond is removed from bulk water. Because of the coordinated behavior of molecules of water in bulk, the magnitude of the hydrophobic effect may well depend on the behavior of the molecules of water beyond those immediately in contact with the hydrogen–carbon bond. In the active site of an enzyme, the hydrogen–carbon

side chains of the amino acids that are in contact with water before a substrate binds are usually in contact with molecules of water that are more or less isolated from the bulk phase, so the hydrophobic effect arising from their dehydration may be significantly less than the hydrophobic effect of removing a hydrogen–carbon bond from the bulk solution.

In most instances, the hydrophobic side chains in an unoccupied active site are surrounded by molecules of water because there is usually little vacant space in a condensed phase. In maps of electron density for the unoccupied active site of thermolysin from *B. thermoproteolyticus*, when those maps are calibrated to absolute electron density, there is no detectable electron density in the hydrophobic pocket formed from Phenylalanine 130, Leucine 133, Valine 139, Isoleucine 188, Valine 192, Leucine 202, and the π faces of the amides in the polypeptide backbone between positions 138 and 140, 188 and 189, and 112 and 113. This pocket is occupied by the leucine adjacent to the site of hydrolysis in the crystallographic molecular model in Figure 3–42. Consequently, there is no water adjacent to the hydrophobic side chains that form this empty hole in the unoccupied active site, and the situation is not complicated by the ambiguity accompanying the dehydration of those side chains. A series of otherwise identical phosphonamidates (see **3–71** in Table 3–7), which are analogues of the tetrahedral intermediate in the enzymatic reaction, were synthesized that place a methyl group, an isopropyl group, or an isobutyl group in this vacant subsite, and their free energies of association were measured.[724] The free energies of association for these three inhibitors decrease with a slope of -2.35 ± 0.03 kJ (mol of hydrogen–carbon bonds)$^{-1}$. This value is quite close to the value of -1.9 ± 0.2 kJ (mol of hydrogen–carbon bonds)$^{-1}$ that is the standard free energy for the removal of a hydrogen–carbon bond from water into a condensed phase of alkane based on units of molarity.[52] The small difference in the two values may result from the fact that during transfer between two isotropic condensed phases, which is the standard measure of the hydrophobic effect, a hole has to be made in the nonpolar phase, a process with a positive change in standard free energy. In the case of inhibitors associating with the active site of thermolysin, however, the hole is already there. In any case, this result for the association of these inhibitors with thermolysin is a rather unambiguous demonstration of the favorable standard free energy that is gained from the hydrophobic effect during the removal of hydrogen–carbon bonds from contact with water when a substrate enters the active site of an enzyme.

Although this fact is seldom emphasized, as is the case for the four hydrogens in the ring of the ribosyl group in *S*-adenosyl-L-homocysteine, **monosaccharides have two hydrophobic axial surfaces** opposite each other on the ring, each containing two to five hydrogen–carbon bonds.[725] For example, cyclodextrins, which are cyclic, cylindrical rings of D-glucosyl groups, have structures that turn an axial face of each monosaccharide, in which there are two hydrogen–carbon bonds, toward the axis of the cylinder, and together they form a significantly hydrophobic pocket.

In the refined crystallographic molecular model of the complex between β-D-galactose and the D-glucose/D-galactose-binding protein from *E. coli*, the β-pyranose of β-D-galactose is flush against the π molecular orbital system of a tryptophan on its axial face containing five hydrogen–carbon bonds, and one of the two hydrogen–carbon bonds on its other axial face is flush against the π molecular orbital system of a phenylalanine (Figure 3–45). The monosaccharide bound in the B subsite in lysozyme has one of its axial faces, containing three hydrogen–carbon bonds, flush against the π molecular orbital system of Tryptophan 62.[314] In the crystallographic molecular model of the complex between chitinase from *Ostrinia furnacalis* and the two products of the hydrolysis of $[(\beta 1,4)$-*N*-acetyl-D-glucosamine$]_7$, four of the five *N*-acetylglucosaminyl groups encompassing the site of hydrolysis each have one of their hydrophobic faces flush against the indolyl group of a tryptophan.[726,727] In the crystallographic molecular model of the complex between the maltodextrin-binding protein from *E. coli* and maltose, one of the glucosyl groups in the maltose is sandwiched between the π molecular orbital systems of a tyrosine and a tryptophan on one axial face and the π molecular orbital system of another tryptophan on the other axial face, and the other glucosyl group of the maltose is sandwiched between the edge of the indolyl group of a tryptophan on one side and the π molecular orbital system of another tryptophan on the other side.[728] In each instance, all the hydrogen–carbon bonds on the axial surfaces of the monosaccharides are removed from contact with the solution when the respective complex is formed. The π molecular orbital systems in these instances provide convenient flat surfaces to cover up the hydrogen–carbon bonds without also sequestering donors for hydrogen bonds in the process.

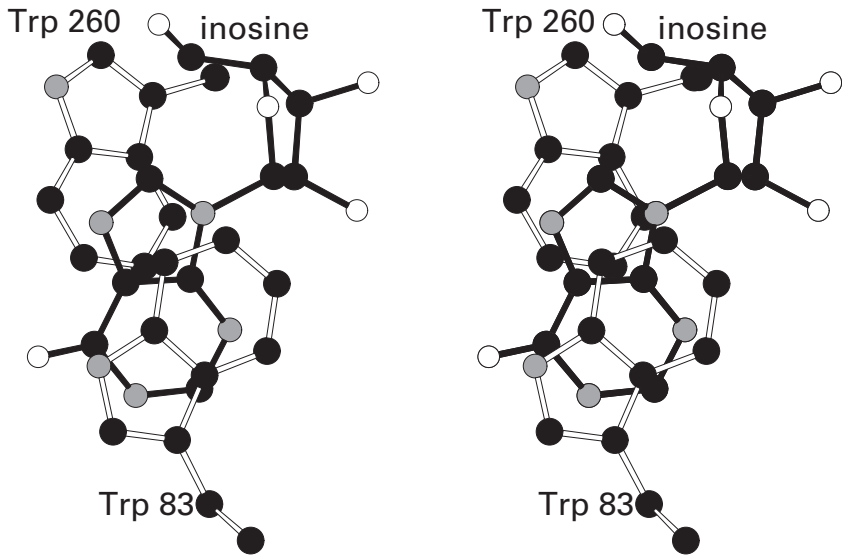

Figure 3–47: Stereodrawing[576] of hypoxanthine sandwiched between two tryptophans in the crystallographic molecular model of the complex between the active site of a mutant of purine nucleosidase from *T. vivax* and inosine, a substrate for the enzyme.[729] Black atoms are carbons, white atoms are oxygens, and gray atoms are nitrogens. To produce the mutant, Aspartate 10 in the active site was mutated to an alanine. The mutant enzyme is virtually inactive, which allowed a data set to be gathered before the inosine in the active site was hydrolyzed. Crystals of the mutant enzyme were soaked in a solution containing 50 mM inosine at pH 7.5 for 3 min and then frozen. A data set was gathered from the frozen crystals to Bragg spacing of 0.16 nm. The refinement of the crystallographic molecular model was initiated by using the amplitudes of the reflections in this data set and a data set of phases calculated from a crystallographic molecular model of the native enzyme in a complex with the inhibitor 3-deazaadenosine, from which all ligands, in particular the 3-deazaadenosine, and molecules of water had been removed. The crystal from which this initial crystallographic molecular model was solved was isomorphous with the crystal of the mutant in complex with the normal substrate, inosine. As the refinement progressed, electron density consistent with a molecule of inosine appeared in maps of electron density in the same location at which 3-deazaadenosine was found in the initial crystallographic molecular model. The drawing contains only the molecule of inosine that was inserted into this electron density and the side chains of the two tryptophans between which the inosine is sandwiched.

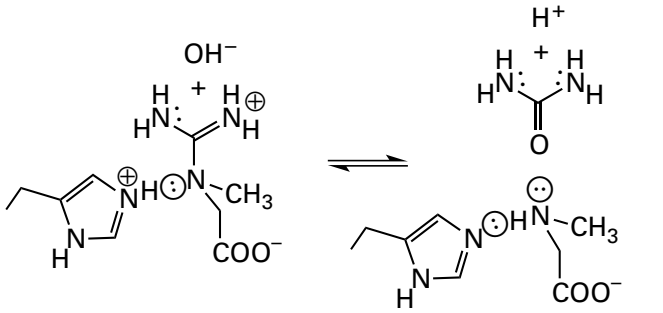
Because of the high frequency with which hydrophobic amino acids and the hydrophobic portions of hydrophilic amino acids line the surfaces of enzymatic active sites in crystallographic molecular models, **a significant hydrophobic effect must be involved in the association of any ligand**, other than an inorganic ion, with the active site of an enzyme.

There are many examples of **π molecular orbital systems within substrates and ligands for enzymes and proteins ending up sandwiched between π molecular orbital systems or stacked upon π molecular orbital systems of amino acids** forming the sites for those substrates and ligands. For example, in the crystallographic molecular model of the complex between a mutant of purine nucleosidase from *Trypanosoma vivax* and inosine, the hypoxanthine ring is sandwiched between two tryptophans (Figure 3–47).[729,730] In the complex between dihydrolipoyllysine-residue acetyltransferase from *Azotobacter vinelandii* and its substrate coenzyme A, however, the π molecular orbital system of the adenine ring is stacked upon the π molecular orbital system of the peptide bond between Glycine 561 and Histidine 562.[731] Because surfaces created by π molecular orbital systems do not display a hydrophobic effect when they are removed from water,[52] if such stacking is energetically advantageous rather than simply sterically advantageous, it must involve favorable van der Waals forces arising from the polarizability of the π molecular orbital systems.[732]

In the case of the complex between purine nucleosidase from *T. vivax* and inosine (Figure 3–47), it has been argued that the stacking of the two tryptophans above and below the inosine serves the purpose of raising the pK_a of the hydron on nitrogen 7 in the imidazolio group of the conjugate acid of the hypoxanthine and consequently promoting its hydronation during the enzymatic reaction. This hydronation would increases the capacity of the hypoxanthine to be a leaving group in the reaction.[730] If this is the case, in this instance the stacking has a **catalytic purpose** beyond possibly providing standard free energy of association.

In the crystallographic molecular model of a complex between an enzyme and its substrates or inhibitors, distortions of a reactant by the active site in the direction of the transition state (Figure 3–28) can often be observed.[733] For example, in the crystallographic molecular model of the complex between creatinase from *P. putida* and its substrate creatine, the planar guanidinio group of the creatine has been twisted by the active site so that the lone pair of electrons on the nitrogen that is the leaving group in the reaction



(3–411)

is almost orthogonal to and no longer conjugated to the amidino π molecular orbital system. Because it is now a basic σ lone pair of electrons rather than a delocalized π lone pair of electrons, it can be readily hydronated by an adjacent imidazolium from a histidine to enhance its ability to leave.[734] In the crystallographic molecular model of the complex between 3-deoxy-7-phosphoheptulonate synthase from *E. coli* and the substrate phospho*enol*pyruvate, the normally coplanar phospho*enol* group is twisted by the active site 30° with respect to the plane of the carboxylato group to prevent conjugation between the intermediate enolate and the carboxylato group, which would destabilize the enolate.[735] Although many of the distortions such as these are assisted by the appropriate orientation of donors and acceptors so that they complement acceptors and donors for hydrogen bonds in the distorted conformation of the reactant, the major force accomplishing such a distortion is often a steric effect.

Far and away the most reliable way to control a chemical reaction is to use a steric effect, and this fact has not been overlooked in the evolution of active sites. A steric effect is accomplished when a portion of the structure of the protein in the active site occupies the same location that some portion of the reactant in its most stable conformation would occupy when it associates with the site, and the conformation of the reactant must change to accommodate the obstacle.

There are five similar enzymes that bind to double-helical DNA substrates: DNA (cytosine-5-)-methyltransferase from *H. parahaemolyticus*,[654,655] human thymine-DNA glycosylase,[736] human uracil-DNA glycosylase,[737,738] human methylated-DNA—[protein]-cysteine *S*-methyltransferase,[739] and human DNA-(apurinic or apyrimidinic site) lyase.[740,741] In

each crystallographic molecular model of the complexes between these enzymes and their double-helical DNA substrates,* a base—cytosine, thymine, uracil, *O*-alkylguanine, or 8-oxo-7,8-dihydroguanine, respectively—has swung out of the stack of base pairs into the catalytic region of the active site. The positions in the double-helical DNA that were occupied by each of the flipped bases are now occupied by one or two amino acid side chains from the active site—glutamine and serine, arginine, leucine, arginine, and asparagine and arginine, respectively.

There are two ways to interpret these observations. As the double-helical DNA associates with the active site, the amino acid side chains are unavoidable obstacles in part responsible for pushing the flipped bases out of the double helix. Alternatively, as the bases flip out of the double helix by simple thermal agitation, the amino acid side chains swing into the slot vacated by the respective base and sterically prevent the substrate from leaving the active site and the base pair from reentering the double helix. The actual sequence of events is probably some combination of these scenarios.

Steric effects are also the most **dependable way to exclude the incorrect reactant** from the active site of an enzyme. For example, editing is the process by which a tRNA that has been aminoacylated by an incorrect amino acid is recognized and the incorrect amino acid is removed by hydrolysis.[742] Editing ensures that no misacylated tRNA arrives at a ribosome. When site-directed mutations are made in the active site for hydrolyzing misacylated L-valyl-tRNA^{Ile} in isoleucine-tRNA ligase from *E. coli*, the rate of hydrolysis of L-valyl-tRNA^{Ile} decreases dramatically and the amount of L-valyl-tRNA^{Ile} produced by the enzyme increases dramatically.[743] The nonpolar pocket in the active site for editing in isoleucine-tRNA ligase from *Thermus thermophilus*, which recognizes a misacylated L-valine so it can be excised, is just large enough for the isopropyl group of the L-valine but too small for the 2-butyl group of a correctly acylated L-isoleucine.[744] The 2-butyl group, and hence the properly acylated L-isoleucyl-tRNA^{Ile}, is successfully excluded from the active site responsible for editing and not subject to the hydrolysis performed by this site. In many of the tRNA ligases, the most reliable way to ensure that the correct amino acid is aminoacylated to a tRNA is to use steric effects. Amino acids larger than the correct one, such as L-methionine in the case of isoleucine-tRNA ligase, are excluded from the site for aminoacylation by steric effects; amino acids smaller than the correct one, such as L-valine, are removed by hydrolysis at the site for editing; and the correct amino acid is excluded from the site for editing by steric effects.

DNA-Directed DNA polymerase from *Escherichia* phage RB69 shows a greater than 10,000-fold preference for 2′-deoxyribonucleoside triphosphates over ribonucleoside triphosphates. In the crystallographic molecular model of the active site of the enzyme occupied by a template and magnesium 2′-deoxycytidine triphosphate, the π system on one surface of the 4-hydroxyphenyl group of Tyrosine 216 is flush against carbon 2′, the deoxy carbon.[674] If there were a hydroxy group on carbon 2′, as there is in cytidine triphosphate, it would overlap the 4-hydroxyphenyl ring of the tyrosine. The dissociation constant for magnesium cytidine triphosphate from the active site decreases from 16 to 0.52 mM and the catalytic constant for its incorporation into DNA increases from 0.74 to 8.6 s^{-1} when this tyrosine is mutated to an alanine. In contrast, the dissociation constant for the normal substrate, magnesium 2′-deoxycytidine triphosphate, from the active site remains 0.07 mM and the catalytic constant for its incorporation into DNA decreases from 200 to 22 s^{-1}. These two facts are consistent with the conclusion that the 4-hydroxyphenyl ring provides a steric effect that excludes ribonucleoside triphosphates from the active site.[745]

In the crystallographic molecular model of a complex between proline dehydrogenase from *E. coli* and tetrahydrofuran-2-carboxylic acid,[746] which is an analogue of the substrate L-proline, Tyrosine 540 is fixed in a location that would sterically overlap the hydroxy group of *trans*-4-hydroxy-L-proline, a metabolite present in the cytoplasm of the cell. This steric effect should prevent *trans*-4-hydroxy-L-proline from associating with the enzyme, just as Tyrosine 216 in DNA-directed DNA polymerase from *Escherichia* phage RB69 prevents ribonucleoside triphosphates from associating with its active site. Mutation of Tyrosine 540 to an alanine[747] decreases the ratio of the specificity constants for L-proline and *trans*-4-hydroxy-L-proline by a factor of 50.

A steric effect can also be used experimentally to **modify the reaction catalyzed by an enzyme**. When Asparagine 170 in the active site of β-lactamase from *S. aureus* is mutated to a glutamine, the resulting steric effect pushes the molecule of water responsible

*In the case of DNA (cytosine-5-)-methyltransferase, the double-helical substrate was fluorinated.

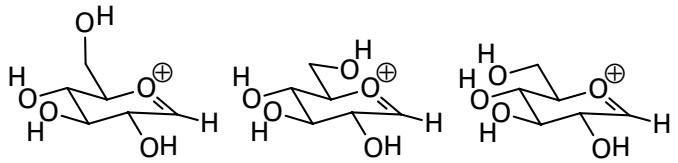
for the hydrolysis catalyzed by the enzyme away from the acyl group it must attack, and the rate of hydrolysis decreases more than 800-fold.[548]

One way to consider the steric effects exerted by an active site is to imagine that the active site is a more or less rigid mold into which a substrate must insert by adopting a conformation complementary to the mold. For example, when creatine binds to creatinase (Equation 3–411) from *P. putida*,[734] its methyl group fits into a nonpolar pocket; its amidino group fits into a pocket formed by the edge of a histidine, a valine, and two glutamates and two molecules of water that provide acceptors for the donors for hydrogen bonds on the amidino group; and its carboxymethyl group fits into a pocket formed by an isoleucine, the π molecular orbital system of another histidine, and two arginines that provide donors for the acyl oxygen. A creatine will fit into the mold created by these three pockets only if its central nitrogen is tetrahedral and twisted so that its lone pair of electrons is in the plane of the amidino group that is now unconjugated to it.

Many of these molds can be quite rigid. The **rigidity of the mold** formed by the active site of steroid Δ-isomerase from *P. putida* prevents the hydrogen bonds between its oxyanion hole and a phenolate from shortening as it should when 2,6-difluorophenolate is the ligand instead of phenolate.[281]

The mold is also able to **hold functional groups apart from each other** to prevent unfavorable reactions from occurring. For example, the 6-ammonium of a lysine in β-ketoacyl-[acyl-carrier-protein] synthase must be held close enough to the acetyl enolate formed during the decarboxylation of malonyl acyl-carrier protein to stabilize it but far enough away from it to prevent it from hydronating the enolate.[748]

The mold can also hold functional **groups in the reactant near the site of catalysis** in conformations that favor the catalysis. For example, there are three conformations of the hydroxymethyl group at carbon 5 of a pyranose



gauche,gauche **3–112** *gauche,trans* **3–113** *trans,gauche* **3–114**

Studies of the hydrolysis of fused rings that lock carbon 6 in one or the other of these conformations have demonstrated that gauche,gauche D-glucosyl glycosides hydrolyze 1.5 times more rapidly than gauche,trans D-glucosyl glycosides and 3.5 times more rapidly than trans,gauche D-glucosyl glycosides because in the gauche,gauche conformation at carbon 6, the carbon–oxygen bond is parallel to the π molecular orbital system of the intermediate oxocarbenium ion that is an intermediate and can donate electron density to it. Although these differences are quite small, nevertheless, in crystallographic molecular models of the occupied active sites of most glucosidases (94%), the mold holds the hydroxymethyl groups in the *gauche,gauche* conformation.[749] If this orientation is the result of natural selection, it illustrates the fact that natural selection operating for two billion years over the surface of the earth can respond to even small increases in enzymatic rate.

The mold can force a functional group in the reactant into an **environment that promotes catalysis**. For example, it has already been noted that decarboxylations occur far more rapidly in nonpolar solvents than in water.[750,751] In the active site of methylmalonyl-CoA decarboxylase from *E. coli*, the mold forces the polar carboxylato group of methylmalonyl-SCoA into a nonpolar pocket lined by three leucines, a valine, an edge of the phenyl ring of a tyrosine, a glycine, and a proline.[752]

The mold formed by an active site can **determine the specificity of the enzyme for its reactant** as well as **preventing the enzyme from converting the incorrect reactant**. For example, the deep nonpolar pocket in protein farnesyltransferase from *R. norvegicus* should be able to bind several different shorter isoprenoid diphosphates, but only when the (2*E*,6*E*)-farnesyl group of (2*E*,6*E*)-farnesyl diphosphate snugly fills the pocket is carbon 1 of the isoprenoid diphosphate properly positioned for the nucleophilic substitution catalyzed by the enzyme that takes place at this carbon.[567] Shorter isoprenoid diphosphates descend into the hole so far that their carbons 1 are improperly located relative to the catalytic groups; longer isoprenoid diphosphates spill out of the active site.

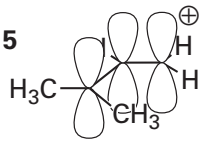
In a crystallographic molecular model of (2*E*,6*E*)-farnesyl diphosphate synthase from *G. gallus*,[753] there is a nonpolar pocket that snugly fits the geranyl group of a molecular model of the substrate geranyl diphosphate. The active site produces a geranyl carbenium ion and then alkylates it with isopentenyl diphosphate (see Figure 1–26). The

enzyme is specific for the geranyl group of geranyl diphosphate ($k_{gpp} = 5\ \mu M^{-1}\ s^{-1}$) and only reluctantly adds isopentenyl diphosphate to the farnesyl carbenium ion of farnesyl diphosphate ($k_{fpp} = 0.001\ \mu M^{-1}\ s^{-1}$), presumably because the longer farnesyl chain cannot fit in the pocket. Phenylalanine 112 and Phenylalanine 113 form the floor of the pocket. When they are mutated to an alanine and a serine, respectively, the specificity constant for farnesyl diphosphate, k_{fpp}, increases to $4.5\ \mu M^{-1}\ s^{-1}$, indistinguishable from that for geranyl diphosphate for the native enzyme.[754] Although the specificity constant of the mutant for geranyl diphosphate remains the same ($k_{gpp} = 3\ \mu M^{-1}\ s^{-1}$), the catalytic constant decreases by a factor of 20, presumably because the geranyl diphosphate no longer fits snugly in the pocket. Furthermore, in addition to producing the tetraisoprenoid geranylgeranyl diphosphate from farnesyl diphosphate and isopentenyl diphosphate, the enzyme now produces pentaisoprenoids, hexaisoprenoids, heptaisoprenoids, and octaisoprenoids because there is now no bottom to the nonpolar pocket, which has become a long nonpolar tube.

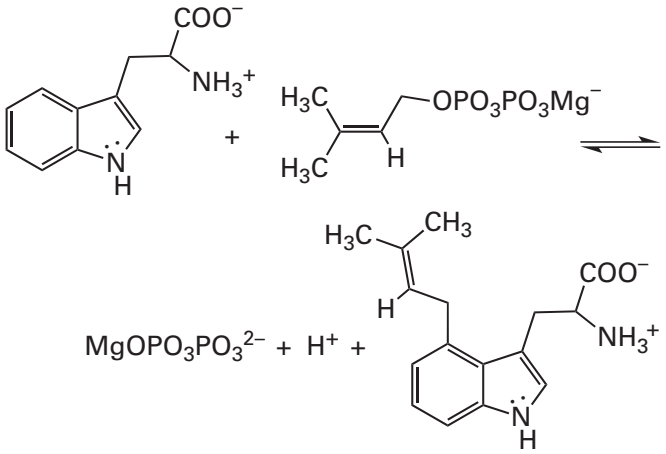
If the mold dictates the reactant for the enzymatic reaction, then it necessarily follows that the structure of the mold **determines what product is formed** in the enzymatic reaction because a reactant in one direction is a product in the other. For example, nonspecific monooxygenase 4B1 from *O. cuniculus* is an enzyme containing a heme P450 that preferentially hydroxylates carbon 1 of octane (90%) rather than carbon 2 (10%), which should be significantly more reactive to hydrogen abstraction. In the active site of the enzyme, there is a long hydrophobic tube into which octane fits snugly. Because the free energy of association is maximized when the entire octane molecule associates with the tube, only carbon 1 is accessible at the end of the tube where the oxoiron(IV) porphyrin$^{\bullet+}$ that performs the hydroxylation is located. Consequently, oxoiron(IV) porphyrin$^{\bullet+}$ usually removes a hydrogen from carbon 1 to initiate the hydroxylation rather than carbon 2.[755] In this instance, the mold **determines the regioselectivity of the reaction**. The chemistry of the reaction is the same, it is only where on the reactant the chemistry occurs that is controlled.

There is a family of enzymes that catalyze the prenylation of the indolyl group in either L-tryptophan or derivatives of L-tryptophan modified at its α-amino or α-carboxy group or both of them. Each reaction catalyzed by these enzymes is initiated by the dissociation of 3,3-dimethylallyl diphosphate (Figure 1–26) to produce dimethylallyl carbenium ion (previously **1–99**)

3–115



the primary carbon of which or the tertiary carbon of which then adds to either nitrogen 1 or to carbon 2, 3, 4, 5, 6, or 7 of the respective indolyl group.[756,757] Consequently, in theory, there are 14 possible products. An example of one specific regioselectivity would be the electrophilic aromatic substitution at carbon 4 catalyzed by 4-dimethylallyltryptophan synthase (previously Equation 1–155)



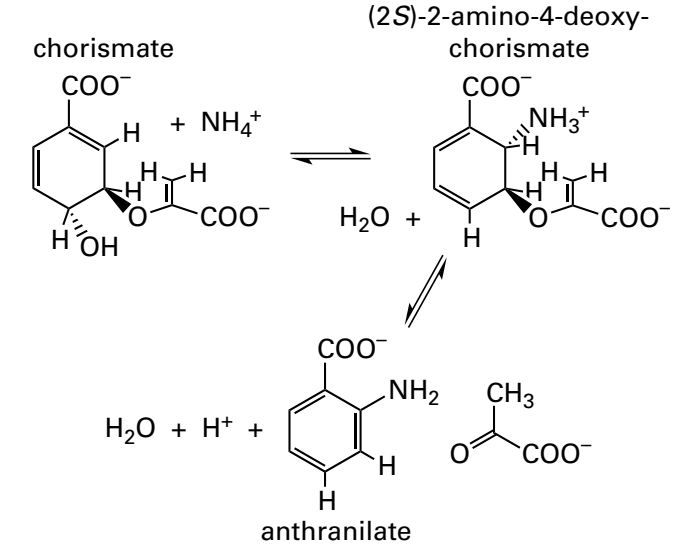
(3–412)

In this instance, the primary carbon of dimethylallyl carbenium ion **3–115**, the least reactive carbon, adds to the indolyl group. Each enzyme in this set catalyzes the electrophilic aromatic substitution or the electrophilic aromatic addition of only one of the two possible carbenium centers at only the nitrogen or only one of the six carbons with strict regiochemistry. All the enzymes in this set are homologous to each other, their sequences of amino acids can be aligned, and the same catalytic amino acids are found in the aligned sequences, in particular a glutamate the carboxylato group of which is the acceptor for a hydrogen bond from the indolyl nitrogen–hydrogen, a tyrosine that is responsible for hydronating the leaving oxygen of the diphosphate during the dissociation that produces dimethylallyl carbenium ion **3-115,** and several invariant amino acids that provide donors for hydrogen bonds to the diphosphate,[757] yet the regioselectivity of each active site is unique. The mold of the particular active site accomplishes the regioselectivity.

N^1-(1,1-Dimethylprop-2-enyl)tryptophan synthase from *Salinispora arenicola* adds the carbenium center situated on the tertiary carbon of the dimethylallyl carbenium ion **3–115** to nitrogen 1 of the indolyl group. In a crystallographic molecular model of the active site occupied by L-tryptophan and dimethylallyl *S*-thiolodiphosphate, which is an analogue of dimethylallyl diphosphate in which the leaving oxygen is replaced by a sulfur, the planar 3-methylprop-1-enyl group of the dimethylallyl diphosphate is sandwiched between the indolyl group of the L-tryptophan to which the tertiary carbon of dimethylallyl carbenium ion **3–115** adds and the indolyl group of Tryptophan 148, which is not modified during the reaction.[757] All the other enzymes in the set have either a tryptophan or a tyrosine at the position homologous to that of Tryptophan 148, so they all presumably form an analogous sandwich in which the three planes are parallel to each other. The tertiary carbon of the dimethylallyl *S*-thiolodiphosphate and the indolyl nitrogen of the L-tryptophan sit 0.34 nm apart on a line almost normal (104°) to the planes of the sandwich. In other words, the active site determines the regiochemistry of the reaction by placing the carbenium ion on the tertiary carbon of dimethylallyl carbenium ion **3–115** immediately adjacent to the atom in the L-tryptophan to which it is supposed to add and in the proper orientation for the electrophilic addition. The regiochemistry of all the other prenyltransferases in this set of enzymes is presumably determined in the same way; the active site positions carbon 1 or carbon 3 in the dimethylallyl diphosphate immediately adjacent to and on a line with the atom in the indolyl group to which it is to add, normal to the planes of the sandwich, to give the product produced by that particular enzyme. The active site of each enzyme sterically shifts the dimethylallyl diphosphate within the sandwich so that the proper orientation is achieved.

Enzymes in this family that add the carbenium ion to nitrogen 1, carbon 2, or carbon 3 of the indolyl group add either the tertiary carbon or the primary carbon of dimethylallyl carbenium ion **3–115**, but enzymes in this set that add the carbenium ion to carbons 4, 5, 6, or 7, always add the primary carbon of the allylic carbenium ion to the respective carbons of the indolyl group. This general regiochemistry can be explained by the fact that, in the crystallographic molecular model of N^1-(1,1-dimethylprop-2-enyl)tryptophan synthase, carbon 1 of the dimethylallyl *S*-thiolodiphosphate, which will become the primary carbon, sits against the phenyl ring of the indolyl group and carbon 3, which will become the tertiary carbenium ion, sits against the pyrrolyl group.

There are two related (25% identity; 3.2% gap percent) enzymes, 2-amino-4-deoxychorismate synthase from *Burkholderia lata* and anthranilate synthase from *Serratia marcescens*, that both convert chorismate to (2*S*)-2-amino-4-deoxychorismate



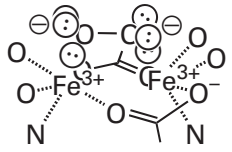
(3–413)

in an elimination followed by an addition. In the active site of anthranilate synthase, (2*S*)-2-amino-4-deoxychorismate undergoes the further elimination of an *eno*lpyruvate anion and a hydron to form anthranilate, the nominal product of its reaction. In the active site of 2-amino-4-deoxychorismate synthase, this elimination does not occur and 2-amino-4-deoxychorismate, the nominal product of its reaction, dissociates from the active site.

There are crystallographic molecular models of each active site occupied in both cases by benzoate, Mg^{2+}, and pyruvate. When the molecular models of benzoate and pyruvate in each active site are replaced by a molecular model of 2-amino-4-deoxychorismate and the resulting structures are submitted to energy minimization, it can be seen that the molds created by the two active sites differ in one significant way. The mold formed by the active site of 2-amino-4-deoxychorismate synthase sterically forces 2-amino-4-deoxychorismate into a conformation in which the hydron at carbon 2, the amino carbon, is locked into an equatorial position, preventing its overlap with the neighboring π molecular orbital system of the cyclohexadiene. Forcing the hydrogen to adopt an equatorial position prevents the elimination, which requires it to be in an axial position, and also

tilts it away from the amino group of the lysine homologous to the lysine that removes the hydron in anthranilate synthase. In the mold formed by the active site of anthranilate synthase, however, the molecular model of 2-amino-4-deoxychorismate assumes a conformation that places the hydrogen on carbon 2 in an axial position, ensuring both its overlap with the neighboring π molecular orbital system and its juxtaposition with the amino group of the lysine responsible for its removal as a hydron.[758] Again, the final product of an enzymatic reaction is dictated by the conformation that the mold of the active site forces the substrates or intermediates to assume.

In the crystallographic molecular model of stearoyl-SCoA occupying the active site of murine stearoyl-CoA 9-desaturase, the octadecanoyl group of the stearoyl-SCoA snugly occupies a mold just long enough to contain it. The mold, when it is fully occupied, places carbons 9 and 10 of the octadecanoyl group immediately adjacent to the diferrous diiron cluster that is also in the active site.[759] These two nonheme Fe^{2+}, along with a molecule of oxygen, produce the peroxydiiron(III) (previously **2–135**)



3–116

This structure is the precursor to the high-valent oxoiron intermediate that performs the actual desaturation, producing the double bond between carbons 9 and 10. The mold itself is bent into an acute angle so that when the octadecanoyl group occupies the mold, it is bent by the mold at both carbon 9 and carbon 10, forcing the bond between them into a less stable gauche conformation that is closer to the geometry of the cis double bond in the product than the more stable trans conformation. Consequently, in addition to determining the specificity of the enzymatic reaction for a stearoyl-SCoA, the rigid mold in stearoyl-CoA 9-desaturase also ensures that the desaturation occurs between carbons 9 and 10 and that the product contains a cis double bond rather than the more stable trans double bond.

A kink, albeit on a much larger scale, occurs in the crystallographic molecular model of human DNA ligase (ATP) in complex with a double helix containing 20 base pairs that is nicked on one strand in the middle. The 5′ end in the nick in this double helix has been adenylylphosphorylated on the 5′-hydroxy group to mimic exactly the adenylylphospho intermediate in the enzymatic reaction, but the 3′ end is lacking the 3′-hydroxy group, so the intermediate cannot proceed further in the normal ligation. The mold formed by the active site, which completely surrounds the double helix over nine of its base pairs, physically distorts the double helix, unwinding it to produce a kink that offsets the helical axis on one side of the kink by 0.5 nm from the helical axis on the other side. This kink opens up the double helix around the nick to allow the catalytic side chains in the active site to approach the phospho group at which the nucleophilic substitution at its phosphorus occurs as well as the 3′-hydroxy group that is the nucleophile and the adenylyl leaving group.[760] The product of the nucleophilic substitution is the repaired, intact double helix. In this instance, **the mold formed by the active site distorts the reactant to provide access to the site of the reaction.**

Rather than kink double-helical DNA at a site at which a base has been removed by a DNA glycosylase that recognizes damaged bases, the mold of the active site of human exodeoxyribonuclease III physically bends the DNA at the site of the apurinic or apyrimidinic deoxyribosyl group. The bend is quite abrupt, and the axes of the double helix at the two sides of the bend are at an angle of 35° to each other and are also displaced from each other by 0.5 nm. This bend extrudes the deoxyribosyl group from the double helix and permits both the deoxyribosyl group and the phospho groups at its 5′ and its 3′ end to enter the site at which the hydrolysis of these two phosphodiesters occurs, excising the apurinic or apyrimidinic deoxyribose.[761] The bend produced by the mold of the active site in double-helical DNA by the active site of type II site-specific deoxyribonuclease from *E. coli* is much smoother and less abrupt, but again the catalytic portion of the active site responsible for the hydrolysis is at the center of the bend. The major groove in the DNA is on the convex side of the bend, and at the center of the bend, the major groove is occupied by a loop of polypeptide. The seven side chains in this loop are responsible for recognizing the sequence of nucleotides in the DNA in the center of which the hydrolysis is to occur by reading the donors and acceptors for hydrogen bonds and the shapes of the base pairs along the major groove.[527] Again, in both of these instances, the mold provides access of the portion of the substrate to be hydrolyzed, rather than ligated, to the site of the hydrolysis.

Enzymes such as the fatty-acid synthase system

$$\text{acetyl-SCoA} + n\text{-malonyl-SCoA} + 2n\,\text{NADPH} + (3n-1)\,H^+ \rightleftharpoons 2n\,\text{NADP}^+ + n\,CO_2 + (n+1)\,\text{HSCoA} + CH_3(CH_2CH_2)_nCOO^- \quad (3\text{–}414)$$

or the polyketide synthases condense enolates of acetyl-SCoA formed by the decarboxylation of malonyl-SCoA, one after the other, to produce an elongating sequence of products. The ultimate length of **the final product is dictated by the volume of the mold in a portion of the active site** in which the elongating portion of the intermediate is situated. For example, chalcone synthase from *Medicago sativa* adds three acetyl units from three malonyl-SCoA, in equivalent Claisen condensations, one after the other, to 4-coumaryl-SCoA (analogous to the acetyl-SCoA in Equation 3–414) to produce naringenin. The volume of the portion of the active site in which the elongating polyketide ends up[762] causes the reaction to cease at three acetyl units when that volume has been filled. If the volume of that portion of the active site is decreased by mutating a glycine to a leucine, the enzyme produces bis-noryangonin, which results from the condensation of only two acetyl groups instead of three.[763]

Changing the shape of the mold by mutation can also change the identity of the product more significantly. For example, cyclohexanone monooxygenase from *Thermocrispum municipale* performs a Baeyer–Villiger oxidation (Figure 2–47) of the unnatural reactant 4-phenyl-2-butanone, for which the product is 2–phenylethyl acetate (<99%). When a leucine, phenylalanine, threonine, and leucine in the active site are mutated to glycine, glycine, phenylalanine, and threonine, respectively, the regiochemistry of the reaction is reversed, and the product of the oxidation of 4-phenyl-2-butanone is ethyl phenylacetate (98%).[764] The ester oxygen ends up on the other side of the original carbonyl group.

The role of the mold in determining the product of the reaction is **exploited most dramatically in the family of terpene cyclases.** Terpene cyclases are enzymes that cyclize geranyl diphosphate (two isoprene units), (2*E*,6*E*)-farnesyl diphosphate (three isoprene units), or geranylgeranyl diphosphate (four isoprene units) to produce monoterpenes, sesquiterpenes, or diterpenes, respectively. Each terpene cyclase cyclizes the particular isoprenoid diphosphate that is its substrate to form its particular unique terpene or its characteristic distribution of two or three terpenes. These enzymes as a group produce a vast array of terpenes from only the three respective isoprenoid diphosphates. The set of sesquiterpene synthases alone, the structurally related enzymes that use only (2*E*,6*E*)-farnesyl diphosphate as a substrate, produces over 300 different products, each from the same precursor.[765] Each active site in a terpene cyclase contains a mold that guides the reaction to the terpene or the two or three terpenes the enzyme is designed to produce.[765-768] The portion of a terpene controlled by the mold in a terpene cyclase is its polyisoprenyl group, which is entirely hydrocarbon. Consequently, hydrogen bonding is irrelevant and only the mold itself is guiding the reaction as it progresses.

The reaction of each of the hundreds of terpene cyclases begins with the heterolytic dissociation of the diphosphate from geranyl diphosphate, (2*E*,6*E*)-farnesyl diphosphate, or geranylgeranyl diphosphate to produce an **allylic carbenium ion**. In the active site of several if not most of the sesquiterpene synthases[765,769,770] and monoterpene synthases,[770,771] the diphospho group on the (2*E*,6*E*)-farnesyl diphosphate that enters the active site with at least one Mg^{2+} as a ligand is further liganded with two more Mg^{2+}. The result of such ligation is that it becomes a trimagnesium diphospho group with a cumulative charge number in its completely unhydronated state of +3. This excess positive elementary charge makes the trimagnesium diphospho group an excellent leaving group, but the trimagnesium diphosphate dication that results from its leaving should be inert to further participation in the reaction as either an acid or a base. The allylic carbenium ion of the geranyl group, the (2*E*,6*E*)-farnesyl group, or the geranylgeranyl group that results from the dissociation of the trimagnesium diphosphate then rearranges through a sequence of steps involving **carbon–carbon bond formation by intramolecular alkylation** (see Figure 1–26), leading to cyclization and the usual rearrangements of carbenium ions such as **hydride migrations and 1,2-methyl migrations**. The culmination of this sequence of reactions is usually the loss of a hydron to give a cyclic hydrocarbon, the terpene, that is the product of the reaction. A paradigmatic example of such a sequence of events is the one that proceeds in the active site of aristolochene synthase during the conversion of (2*E*,6*E*)-farnesyl diphosphate into (+)-aristolochene (Figure 3–48).[770,772-775]

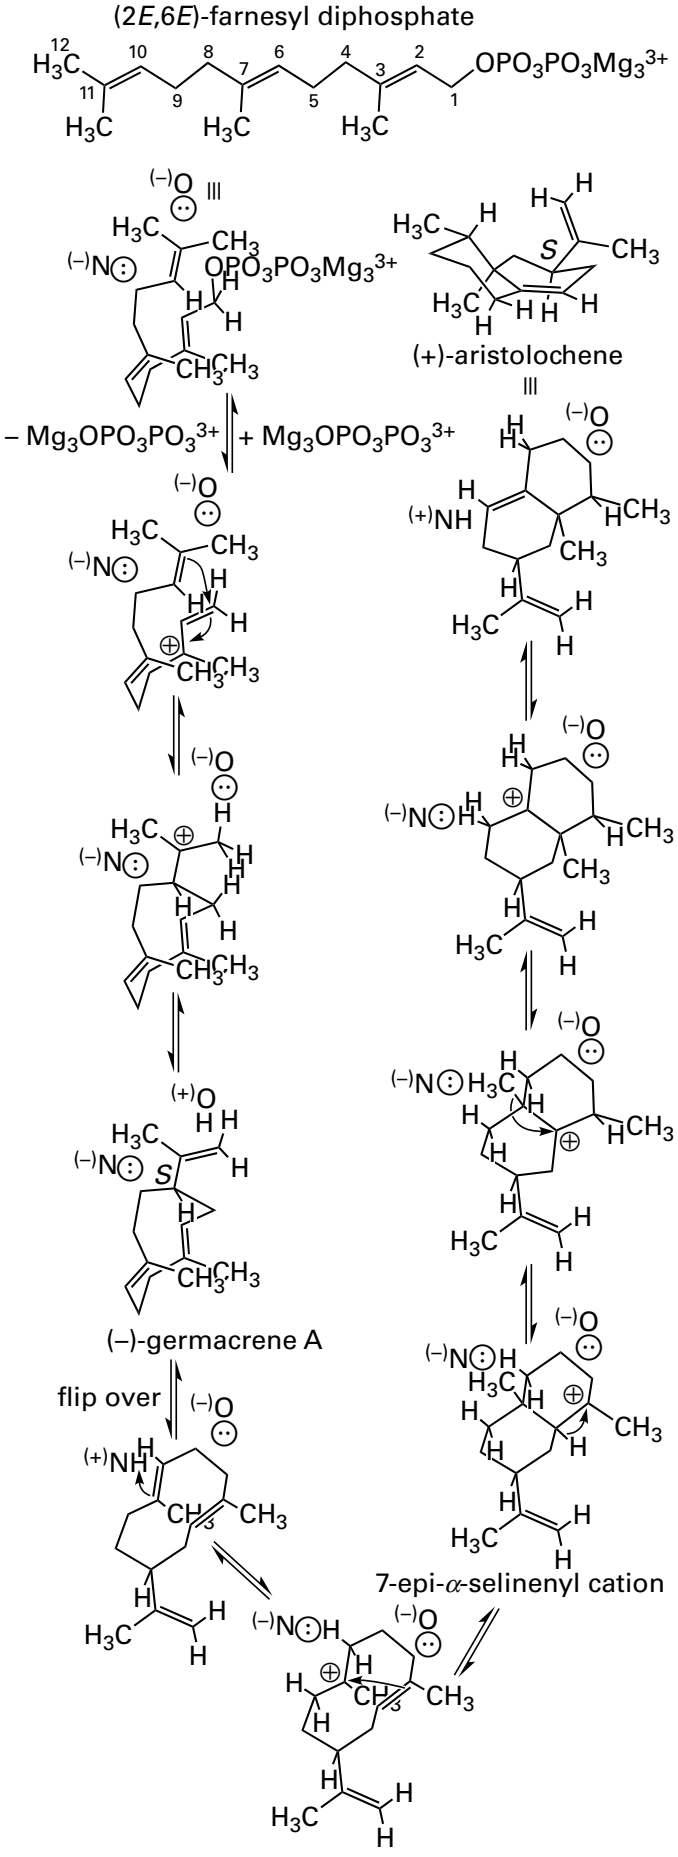


Figure 3–48: Mechanism of the conversion of magnesium (2*E*,6*E*)-farnesyl diphosphate into (+)-aristolochene, a sesquiterpene, catalyzed by aristolochene synthase.[772,773] In the active site of the enzyme, there are two Mg^{2+} ions that are ligands to the diphospho group in addition to the Mg^{2+} that enters the active site with (2*E*,6*E*)-farnesyl diphosphate.[775] The first step is the dissociation of trimagnesium diphosphate as a leaving group, which produces an allyl carbenium ion, the predominant resonance form of which is drawn. The predominance of this resonance form, which fixes the configuration at carbon 1, as well as the immediate alkylation in the next step explains the fact that the reaction proceeds with inversion of configuration at that carbon[774] even though it is a dissociative nucleophilic substitution (see the orientation in Figure 3–49A). The fact that this resonance form predominates explains how rotation about the bond between carbons 2 and 3 of the allylic carbenium ion can occur, as required, in certain terpene cyclases.[770] The double bond between carbons 10 and 11 as a nucleophile adds to the electrophilic carbon 1 of the allylic carbenium ion, forming a single bond between carbon 1 and carbon 10. During this cyclic alkylation, the carbocation ends up at carbon 11, as a tertiary carbenium ion. A base, $^{(-)}O\odot$, then removes a hydron from one of the methyl groups on carbon 11 to produce the neutral molecule (–)-germacrene A, (1*E*,5*E*,8*S*)-1,5-dimethyl-8-prop-1-en-2-yl-cyclodeca-1,5-diene, as an intermediate. The (–)-germacrene A then flips over in the active site to assume the orientation defined in Figure 3–49B. The double bond that was originally between carbons 6 and 7 of (2*E*,6*E*)-farnesyl diphosphate is then hydronated by a strong acid, $^{(+)}NH$, to produce the tertiary carbenium ion at original carbon 7. The double bond between the original carbons 2 and 3 then adds to this electrophilic carbenium ion, and the resulting cyclic alkylation produces the tertiary 7-*epi*-α-selinenyl cation in which the original carbon 2 forms a bond with the original carbon 7. The hydrogen that was on the original carbon 2 then migrates to the tertiary carbenium carbon of the 7-*epi*-α-selinenyl cation from its anterior position, as drawn, to produce the *S*-configuration at the original carbon 3. The methyl group that was on the original carbon 7 then migrates to the resulting tertiary carbenium carbon from the posterior position, as drawn, to produce the *R*-configuration of a quaternary carbon at the original carbon 2. The removal of a hydron by a base, $^{(-)}N\odot$, from the original carbon 8 produces the product (+)-aristolochene.

The inhibitor (2*E*,6*E*)-farnesyl *S*-thiolodiphosphate is an analogue of the substrate (2*E*,6*E*)-farnesyl diphosphate that cannot participate in the reaction because the oxygen in the trimagnesium diphospho group that leaves carbon 1 of (2*E*,6*E*)-farnesyl diphosphate has been replaced synthetically with a sulfur. This difference is the only one between the two molecules. In a crystallographic molecular model of the active site of aristolochene synthase from *Aspergillus terreus* occupied by magnesium (2*E*,6*E*)-farnesyl *S*-thiolodiphosphate (Figure 3–49A),[775] the mold into which the farnesyl group of the analogue has inserted causes it to assume a conformation favorable to the reaction that the enzyme

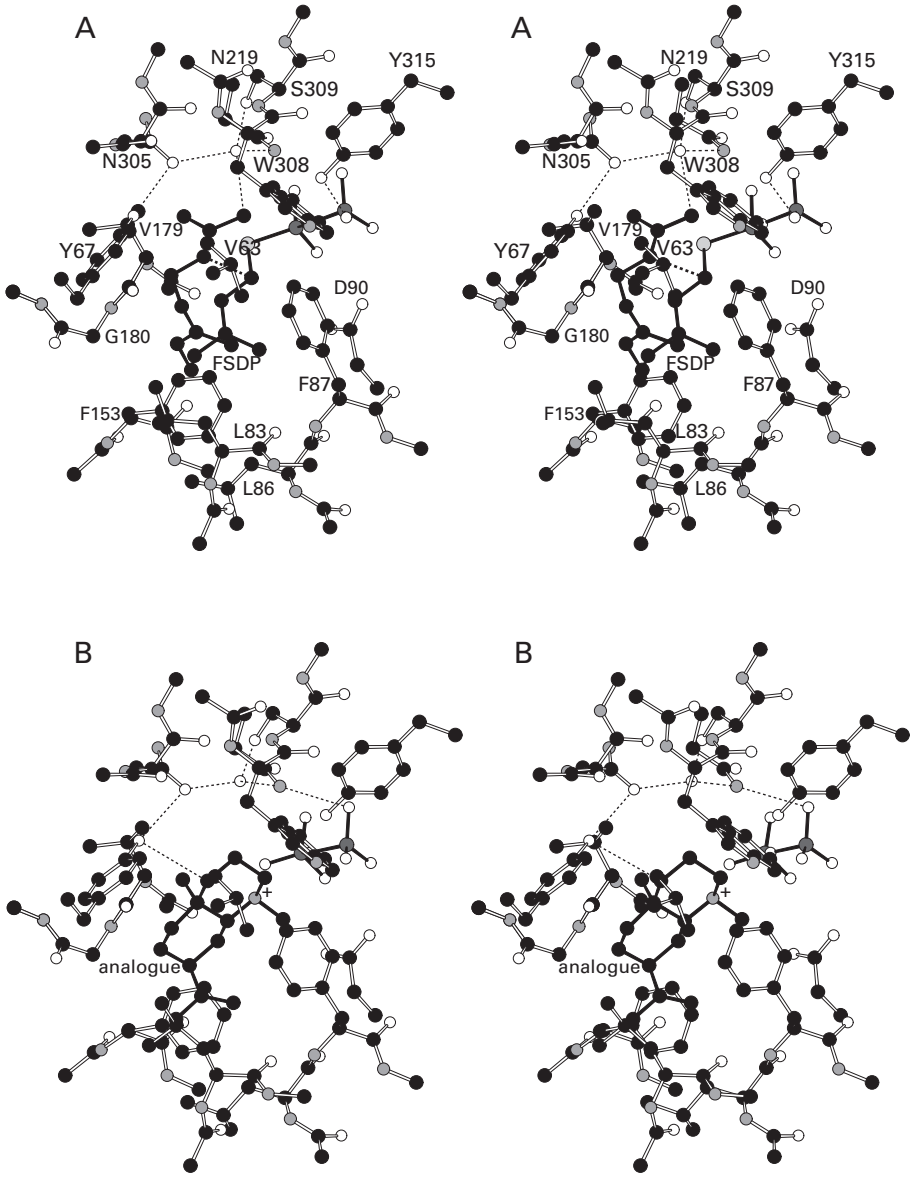

Figure 3–49: Stereodrawing[576] of the mold for the farnesyl group of (2*E*,6*E*)-farnesyl diphosphate created by side chains of the amino acids and the polypeptide backbone within the active site of aristolochene synthase from *A. terreus* that ensures the production of (+)-aristolochene.[775] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, large light gray atoms are sulfurs, and large dark gray atoms are atoms of phosphorus. **(A)** Initial Michaelis complex between the active site and magnesium (2*E*,6*E*)-farnesyl diphosphate. Crystals were grown from a solution containing 0.15 mM active sites of aristolochene synthase, 1.0 mM $MgCl_2$, 60 mM NaCl, 0.8 mM sodium diphosphate, and 0.75 mM (2*E*,6*E*)-farnesyl-*S*-thiolodiphosphate at pH 6.5. In the map of electron density calculated from a data set to Bragg spacing of 0.19 nm, there was a feature of electron density located in the active site into which a molecular model of (2*E*,6*E*)-farnesyl-*S*-thiolodiphosphate (FSDP) could be confidently inserted, and there were three features of electron density consistent with three Mg^{2+} ions coordinated by the diphospho group. The mold into which the farnesyl group of the inactive analogue of the substrate (2*E*,6*E*)-farnesyl diphosphate inserts, and presumably the substrate itself, is featured in the drawing. It is formed by two phenylalanines, two tyrosines, a tryptophan, two leucines, two valines, a glycine, and an asparagine, as well as portions of the polypeptide backbone. The farnesyl group of the inactive analogue folds into this mold with carbon 1 only 0.40 nm from carbon 10 (dashed line). **(B)** Complex between the active site and the 7-*epi*-α-selinenyl cation. Crystals were grown from a solution containing 0.15 mM active sites of aristolochene synthase, 1.0 mM $MgCl_2$, 60 mM NaCl, 0.8 mM sodium diphosphate, and 1.5 mM (1*R*,4a*S*,7*S*,8a*R*)-1,4a-dimethyl-7-(prop-1-en-2-yl)decahydroquinolinium at pH 6.5. (1*R*,4a*S*,7*S*,8a*R*)-1,4a-Dimethyl-7-(prop-1-en-2-yl)decahydroquinolinium is an analogue of the 7-*epi*-α-selinenyl cation that is an intermediate in the enzymatic reaction in which the carbenium carbon has been replaced by a tertiary ammonium ion. In the map of electron density calculated from a data set to Bragg spacing of 0.19 nm, there were two features of electron density located in the active site into which a molecular model of (1*R*,4a*S*,7*S*,8a*R*)-1,4a-di-methyl-7-(prop-1-en-2-yl)-decahydroquinolinium and a molecular model of a diphosphate could be confidently inserted, and there were three features of electron density consistent with three Mg^{2+} ions coordinated by the diphospho group. The drawing is in the same orientation as that in Panel A and is composed of the same side chains and strands of polypeptide.

catalyzes. The distance between carbons 1 and 10 of (2*E*,6*E*)-farnesyl *S*-thiolodiphosphate, the atoms between which the first carbon–carbon bond would be formed in (2*E*,6*E*)-farnesyl diphosphate (Figure 3–48), is 0.40 nm, which is close to the distance expected of van der Waals contact (0.42 nm).

Intramolecular alkylations other than this first one, however, must be prevented by the mold. The carbenium ion at carbon 3 must be prevented from adding to carbon 10, and the distance between these two carbons is 0.47 nm, and they are held in an unfavorable orientation. The allyl carbenium ion that is formed in the first step must also be prevented from adding to the double bond between carbons 6 and 7, which would be the more favorable cyclization in solution. In the conformation in which the farnesyl group is held by the active site, the distance between carbons 3 and 6 is 0.30 nm, the distance between carbons 1 and 6 is 0.46 nm, and the distance between carbons 3 and 7 is 0.35 nm. Even though they are immediately adjacent to each other, if carbon 3 were to add to carbon 6, an unfavorable four-membered ring would form, an outcome ruling out this cyclization. The pair of carbons 1 and 6 and the pair of carbons 3 and 7, both suitable candidates for alkylation, are oriented by the mold in conformations unsuitable for addition.

The inhibitor (1*R*,4a*S*,7*S*,8a*R*)-1,4a-dimethyl-7-(prop-1-en-2-yl)decahydroquinolinium ion is an analogue of the 7-*epi*-α-selinenyl cation that is an intermediate in the enzymatic reaction (Figure 3–48). It is identical in structure to the 7-*epi*-α-selinenyl cation with the exception that the positively charged carbon of the carbenium ion is replaced by a positively charged ammonio nitrogen. In a crystallographic molecular model of the active site of aristolochene synthase from *A. terreus* occupied by (1*R*,4a*S*,7*S*,8a*R*)-1,4a-dimethyl-7-(prop-1-en-2-yl)decahydroquinolinium ion and magnesium diphosphate (Figure 3–49B),[775] it can be seen that the **intermediate has flipped over** in the active site relative to the initial orientation of the (2*E*,6*E*)-farnesyl group. One might ask why this should be the case.

The most difficult step in the reaction catalyzed by the active site of aristolochene synthase is the **hydronation of the carbon–carbon double bond** in (–)-germacrene A (Figure 3–48). Such a hydronation requires a strong acid, and an acid that is strong enough is hard to come by in the active site of an enzyme. The hydron that departs from original carbon 12 of the (2*E*,6*E*)-farnesyl diphosphate in the third step of the mechanism, as with any hydron that departs from a carbon adjacent to a carbenium ion, is a strong acid. The feat is to **somehow transfer that strongly acidic hydron** from original carbon 12 to original carbon 6 without losing its acidity.

This acidic hydron is removed from original carbon 12 by a molecule of water held tightly in position by Asparagine 219 (0.28 nm), Asparagine 305 (0.28 nm), and Serine 309 (0.27 nm). These three tetrahedrally arrayed hydrogen bonds force a lone pair of electrons on the molecule of water against carbon 12 of (2*E*,6*E*)-farnesyl *S*-thiolodiphosphate at a distance of 0.31 nm, well within van der Waals contact (0.38 nm), and in precisely the orientation required for removing a hydron in a hydrogen–carbon bond parallel to the vacant *p* orbital on an adjacent carbenium ion on original carbon 11.

An acidic hydron is added to original carbon 6 in (–)-germacrene A, after it has flipped over in the active site, by the 4-hydroxy group of Tyrosine 67. In the complex between the active site and (1*R*,4a*S*,7*S*,8a*R*)-1,4a-dimethyl-7-(prop-1-en-2-yl)decahydroquinolinium ion (Figure 3–49B), the equatorial hydrogen on the carbon of the analogue of the 7-*epi*-α-selinenyl cation equivalent to original carbon 6 lies on the line of centers between the oxygen of this 4-hydroxy group and the carbon, and the distance between oxygen and carbon is 0.36 nm, within the sum (0.38 nm) of the van der Waals radii for hydrogen and oxygen and the length of a carbon–hydrogen bond. The distances and orientations leave little doubt that these two acid–bases, the molecule of water and the 4-hydroxy group of the tyrosine, are responsible for the respective dehydronation and hydronation.

Connecting the fixed molecule of water that acts as a base and the 4-hydroxy group of Tyrosine 67 that acts as an acid in each crystallographic molecular model is a network of oxygens participating in hydrogen bonds. The hydroxy group of Serine 309, the molecule of water, the acyl oxygen of Asparagine 305, and the phenolic 4-hydroxy group of Tyrosine 67 comprise this network. The values of pK_a for the hydronated forms of these four oxygens are –3, 0, –0.5, and –6, respectively. Each oxygen becomes a strong acid, in turn, when it is hydronated, and as judged from the individual values of pK_a, each is capable of **conserving the acidity of the hydron** removed by the molecule of water from original carbon 12 adjacent to the carbenium ion on original carbon 11. A hydron can be readily distributed among them through the hydrogen bonds creating the network. None of these participants, however, is able to hydronate the double bond between original carbons 6 and 7 in the initial con-

formation of the (2*E*,6*E*)-farnesyl diphosphate as it folds into the active site (Figure 3–48). Only after the neutral molecule of (–)-germacrene A, which is a stable intermediate and not evanescent as are the various carbenium ions, flips over in the active site is the carbon–carbon bond positioned for hydronation by the hydronated, cationic 4-hydroxy group of Tyrosine 67 ($pK_a = -6$) bearing the relayed, strongly acidic hydron. The fact that the plane of the phenyl ring is normal to the line of centers between the oxygen and the carbon is not consequential because hydronation of the 4-hydroxy group to produce an acid strong enough to hydronate the carbon–carbon bond would unconjugate the oxygen from the π system of the ring.*

Site-directed mutations reinforce the conclusion that these amino acids are involved in the hydron transfers that produce, in turn, the (–)-germacrene A and the 7-*epi*-α-selinenyl cation. When the homologue of Tyrosine 67 in aristolochene synthase from *Penicillium roqueforti* is mutated to a phenylalanine[777] or an alanine[778], the specificity constant for (2*E*,6*E*)-farnesyl diphosphate decreases by a factor of 1000, and 44% or 100%, respectively, of the terpenes produced by the active site are those expected if the reaction cannot proceed beyond (–)-germacrene A. When Serine 309 is mutated to an alanine, although the specificity constant for the production of (+)-aristolochene is unaffected, the mutant produces (–)-germacrene A as a product (10%), a fact suggesting that the hydronation of the (–)-germacrene A in the active site has been hampered because the molecule of water is no longer so rigidly fixed. When Asparagine 305 is mutated to alanine, the specificity constant for production of (+)-aristolochene decreases by a factor of 20, and half of the product produced is now (–)-germacrene A, again indicating a failure to hydronate the (–)-germacrene A while it is in the active site. When both Serine 309 and Asparagine 305 are mutated to alanines, the specificity constant for production of (+)-aristolochene decreases by a factor of 400, and 95% of the product is a mixture of (–)-germacrene A and (2*E*,6*E*)-farnesol, and (*E*)-nerlolidol.[776] These are products expected from an almost complete failure to hydronate (–)-germacrene A in the active site and either its release into the solution or the hydration of precursors to it, respectively. This last result is consistent with the rigidly oriented network of hydrogen bonds being replaced by a more disorganized collection of molecules of water in the empty space that is created by the two mutations to alanine and that is much less efficient at retaining the strongly acidic hydron and transferring it from one carbon to the other. In addition to indicating that the network of hydrogen bonds is responsible for the dehydronation to form the (–)-germacrene A and its subsequent hydronation, all these results are also consistent with the intermediate dehydronation and hydronation becoming the rate-limiting step of the reaction in the mutants rather than the dissociation of the trimagnesium diphosphate.

A comparison of the two crystallographic molecular models (Figure 3–49) suggests that **the mold formed by the active site is not completely rigid and has a degree of plasticity**. For example, the side chains of Leucine 83, Leucine 86, and Phenylalanine 87 have assumed different conformations in the two molecular models in which the unflipped and flipped orientations of the intermediate are observed. This observation suggests that the ability of the mold to change shape in certain locations in a certain way is also critical to determining the product of a specific cyclase.

All these observations, albeit made on only one of the terpene cyclases, lead to the following view of the mechanism common to the enzymes in this family. The first step in the reaction catalyzed by the active site of a terpene cyclase is the dissociation of diphosphate from the linear isoprenoid diphosphate to produce an allylic carbenium ion. Following the production of the allylic carbenium ion, the mold in which it finds itself determines which cyclizations, alkylations, rearrangements, hydronations, and dehydronations of the carbenium ion occur. During these processes, it is unlikely that the evolving carbenium ion reorients in the mold because it is so evanescent, but a stable intermediate terpene can reorient in the mold. Consequently, the mold must be plastic enough to tolerate not only the changes in shape of the evolving carbenium ion but

*Despite the desire that it be so,[776] it is unlikely that the trimagnesium diphosphate that is the leaving group in the first step of the reaction participates as an acid or a base in any of the hydronations or dehydronations that occur during the enzymatic mechanism of aristolochene synthase. First, it would be almost impossible to hydronate any of the oxygens of the trimagnesium phosphate because in its completely unhydronated state it has a formal charge number of +2. Second, the only connection between the water that removes a hydron from original carbon 12 and the hydronated 4-hydroxy group that hydronates (–)-germacrene A is two hydrogen bonds to the amido group of Asparagine 219. An amido group is a very poor base that cannot be hydronated in the orientation in which it is firmly fixed in both crystallographic molecular models. This amido group is responsible for rigidly fixing the molecule of water rather than any hydron transfers.

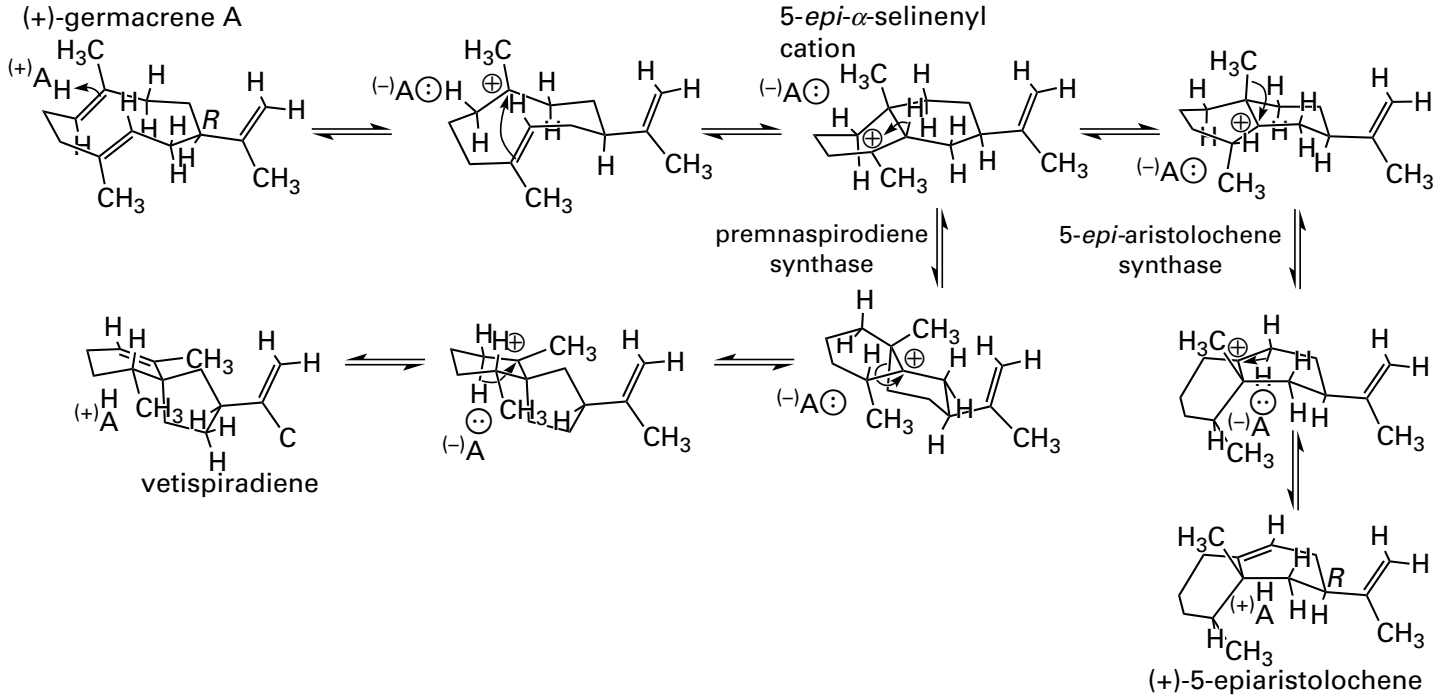

Figure 3–50: Enforcing the conformations of (+)-germacrene A that lead to 5-*epi*-aristolochene and vetispiradiene. These conversions proceed to completion within the active sites of 5-*epi*-aristolochene synthase and vetispiradiene synthase, respectively, and each passes through the same two intermediates, the sesquiterpene (+)-germacrene A and the 5-*epi*-α-selinenyl cation, which is produced in both active sites by hydronation of (+)-germacrene A and carbon–carbon bond formation across the center of the ring. The reactions diverge at the point where migration occurs across the central bond in the 5-*epi*-α-selinenyl cation. One way to control this migration conformationally is to control whether the methyl group or the carbon–carbon bond is parallel to the *p* orbital of the carbenium ion in the 5-*epi*-α-selinenyl cation. This conformational difference is prefigured in the angle enforced by the mold of the respective active site between the two endocyclic double bonds in (+)-germacrene A. If they are held in a conformation in which they are parallel, the methyl group will eventually end up parallel to the cation; if they are held in a conformation in which they are inclined at 60° to each other, the carbon–carbon bond will eventually end up parallel to the cation. It is also possible that bulky groups in the active sites of 5-*epi*-aristolochene synthase and vetispiradiene synthase sterically prevent the migration of the carbon–carbon bond and the methyl group, respectively, of the 5-*epi*-α-selinenyl cation.

also the reorientation of a stable intermediate. The shape of the active site and the plasticity that is inherent in the composition of the amino acids forming it determine the ultimate product or products of the reaction. In this way, basically the same chemical reaction can lead to the terpene, or the small number of terpenes, particular to that enzyme while the family of terpene cyclases, each with its own particular mold, can produce hundreds of different terpenes.

Site-directed mutation of amino acid side chains within the mold formed by the active site can change the product of the reaction catalyzed by one of these terpene cyclases. For example, nine different amino acids in the active site of *epi*-isozizaene synthase from *S. coelicolor* were mutated to create a set of 26 different mutants. Ten different sesquiterpenes that are not produced by the wild-type enzyme were produced by one or more of these mutants. Three different sesquiterpenes that were produced as minor products by the wild type were major products produced by one or more of the mutants.[779] When a single phenylalanine in the active site was mutated to seven different amino acids, each mutant produced one of five different sesquiterpenes, all different from *epi*-isozizaene.[780]

5-*Epi*-aristolochene synthase converts the farnesyl allylic carbenium ion, formed when trimagnesium diphosphate dissociates from trimagnesium (2E,6E)-farnesyl diphosphate, to the sesquiterpene 5-*epi*-aristolochene (Figure 3–50). It has a 5-*epi*-α-selinenyl cation as an intermediate, rather than a 7-*epi*-α-selinenyl cation, because the intermediate that is hydronated in its active site is (+)-germacrene A rather than (–)-germacrene A.[781] The reaction proceeds through an intramolecular, electrophilic alkylation that forms a carbon–carbon bond followed

by the transfer of a hydron, just as in the first steps of the mechanism of aristolochene synthase (Figure 3–48), but the mold in 5-*epi*-aristolochene synthase dictates the formation of an *R* configuration at original carbon 10 instead of an *S* configuration. The resulting stable intermediate, (+)-germacrene A, is also locked in the mold in a conformation that causes the two carbon–carbon double bonds within its ring to assume opposite orientations instead of the same orientation as they do in the active site of aristolochene synthase (Figure 3–49A) so that a 5-*epi*-α-selinenyl cation is formed as an intermediate. A hydride migration, a 1,2-methyl migration, and a dehydronation produces (+)-5-*epi*-aristolochene rather than (+)-5-aristolochene. A crystallographic molecular model of a complex between the enzyme from *Nicotiana tabacum* and magnesium 2-fluoro-(2*E*,6*E*)-farnesyl diphosphate, an inactive analogue of magnesium (2*E*,6*E*)-farnesyl diphosphate, has been reported.[766,769]

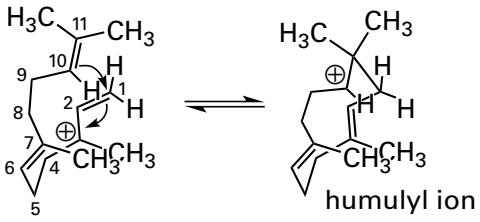
There is a terpene cyclase closely related to 5-*epi*-aristolochene synthase from *N. tabacum*, vetispiradiene synthase from *Hyoscyamus muticus* (75% identity; 0.9 gap per cent), that converts (2*E*,6*E*)-farnesyl diphosphate to vetispiradiene (97%) rather than (+)-5-*epi*-aristolochene, also through an intermediate 5-*epi*-α-selinenyl cation (Figure 3–50). When the nine amino acids that form the mold enforcing the rearrangement of (2*E*,6*E*)-farnesyl diphosphate to (+)-5-*epi*-aristolochene (in 90% yield) in the active site of 5-*epi*-aristolochene synthase are mutated to the amino acids occupying those locations in vetispiradiene synthase, to create a mold dictating the production of vetispiradiene, the mutant 5-*epi*-aristolochene synthase produces vetispiradiene (in 75% yield) instead of (+)-5-*epi*-aristolochene (in 3% yield).[782] A mutant in which only two of the nine amino acids have been mutated has a mold that dictates yet another sesquiterpene, *epi*-eremorphilene (70%). These observations demonstrate that, on the same superstructure, **the mold can be remachined by natural selection to change the products** of the enzymatic reaction, and they also further explain the raft of products produced by the various terpene cyclases.

The triterpene cyclase cycloartenol synthase from *A. thaliana*

(*S*)-2,3-epoxysqualene $\rightleftharpoons$ cycloartenol (3–415)

was mutated at random rather than at specific positions in its sequence of amino acids, and the mutants were selected for their ability to produce another triterpene, lanosterol, from (3*S*)-2,3-epoxy-2,3-dihydrosqualene. It was found that either the mutation of an amino acid in the lining of the mold or the **mutation of an amino acid in the protein outside the mold** in this enzyme could change the shape of the mold sufficiently to cause it to dictate the production of lanosterol instead of cycloartenol.[783,784] In the case of two related (54% identity; 0.6 gap percent) triterpene synthases, lupeol synthase from *Olea europaea* and β-amyrin synthase from *Panax genseng*, the mutation of leucine to tryptophan or the mutation of tryptophan to leucine at the respective homologous positions in the sequences of amino acids caused the lupeol synthase to produce β-amyrin (>99%) and the β-amyrin synthase to produce lupeol (66%).[785]

The terpene cyclizations described in detail in Figures 3–48 and 3–50 leave the impression that the intermediate carbenium ions in such cyclizations are always allyl or tertiary carbenium ions and that the mold cannot overcome the significant instability of **secondary carbenium ions** relative to allyl or tertiary carbenium ions. In the majority of terpene cyclizations, the intermediates are either allyl or tertiary carbenium ions, a realistic preference, but there are terpene cyclases in which the mold is able to dictate that a secondary carbenium ion be an intermediate. For example, in the initial cyclization in the active site of pentalenene synthase, a secondary carbenium ion is the intermediate



(3–416)

in an intramolecular alkylation of an alkene that is analogous to the first step in the alkylation catalyzed by aristolochene synthase (Figure 3–48), except for its regioselectivity. The mold of the active site dictates that the allyl carbenium ion cyclize to a humulyl ion, which is a secondary carbenium ion, rather than the tertiary germacradienyl ion. In the active site of pentalenene synthase from *Streptomyces exfoliatus* in a complex with 12,13-difluorofarnesyl diphosphate, an inactive analogue of farnesyl diphosphate, the mold holds carbon 1 of farnesyl diphos-

phate 0.03 nm closer to carbon 11 than to carbon 10, and one face of the π molecular orbital system of the phenyl group of a phenylalanine is pushed up against carbon 10 and the hydrogen on carbon 9. This phenyl group should be able to stabilize the secondary carbenium ion on carbon 10 by a cation–π interaction and orient the carbon–hydrogen bond on carbon 9 so that it is parallel to the vacant *p* orbital on the carbenium ion to provide hyperconjugation.[786] These features of the mold are thought to overcome the instability of the secondary carbenium ion.

There is a synthetic cavity that is able to enclose various derivatives of (*E*)-geraniol that have been activated by attaching leaving groups competent to form the geranyl carbenium ion. The resulting enclosed carbenium ion rearranges to produce one of a set of various monoterpenes. In this instance, the cavity remains the same; the distribution of monoterpenes produced depends on steric effects resulting from the different sizes of the appended leaving groups but also the time during which the rearrangement takes place.[787]

It is also possible to reconfigure the mold in an active site by mutation so that it will accept a chemical compound that is not present in the biological collection of metabolites and thereby use an enzyme, evolved for a different substrate, to perform a nonbiochemical reaction desired by a synthetic organic chemist.[779]

So far, the rigidity of the mold and its ability to grip substrates and intermediates in fixed orientations to select the proper reactant and determine the proper product have been stressed. In at least one instance, however, it was demonstrated that changing the structure of a fatty acyl group in the reactant for a monooxygenase, by changing one of its methylene carbons to an oxygen, caused the fatty acyl group to slide over in the active site so that the oxygenation occurred at the carbon adjacent to the one normally oxygenated.[788,789] This observation suggests that functional groups of substrates, especially alkanes, **are not always held that immovably** in their subsites.

The orientation of substrates and intermediates accomplished by the more or less rigid mold comprising an active site is the exploitation by natural selection of the principle of least nuclear motion. The principle of least nuclear motion[790] is that those elementary reactions will be favored that involve the least change in atomic position.[791] A corollary of this principle is that the less change in atomic position a reaction involves, the lower will be the standard free energy of activation and the faster will the reaction proceed.

Active sites follow this corollary by providing a mold that not only is complementary to the transition state or the transition states in a reaction but also **positions reactants and products such that their atoms are as close as possible to the positions occupied by respective atoms in the transition state**. This aspect of a mechanism proceeding in the active site of a particular enzyme can be appreciated by superposing crystallographic molecular models representing complexes between the active site and reactants, intermediates, and products.[792] For example, superposition of crystallographic molecular models of complexes between L-methionine adenosyltransferase from *E. coli*

$$\begin{aligned} MgATP^{2-} + \text{L-methionine} + \\ H_2O \rightleftharpoons \textit{S}\text{-adenosyl-L-methionine} + \\ MgOPO_3PO_3^{2-} + HOPO_3^{2-} + H^+ \end{aligned} \qquad (3\text{–}417)$$

and magnesium 5′-adenylic imidodiphosphonic anhydride ($MgAMPPNP^{2-}$) and L-methionine, on the one hand, and *S*-adenosyl-L-methionine and magnesium phosphoric imidodiphosphonic anhydride, on the other, shows that the atoms in the reactants move less than 0.1 nm during the transition to products (Figure 3–51).[793] The omit map of electron density (Figure 3–35) for the equilibrium mixture of 2-phospho-D-glycerate and phospho*enol*pyruvate and the molecule of water in the active site of phosphopyruvate hydratase illustrates how small the movements are in the positions of the atoms when reactant is converted to product.

The superposition of crystallographic molecular models of complexes between human double-stranded uracil-DNA glycosylase and an analogue of the reactant, an analogue for the intermediate oxocarbenium ion, and the products of the reaction show that the only atom that moves more than 0.1 nm during the reaction is the 1′-glycosidic carbon of the ribose in the uridylyl group.[794] An identical conclusion was reached about the respective 1′-glycosidic carbons and the other atoms in the substrates from crystallographic molecular models

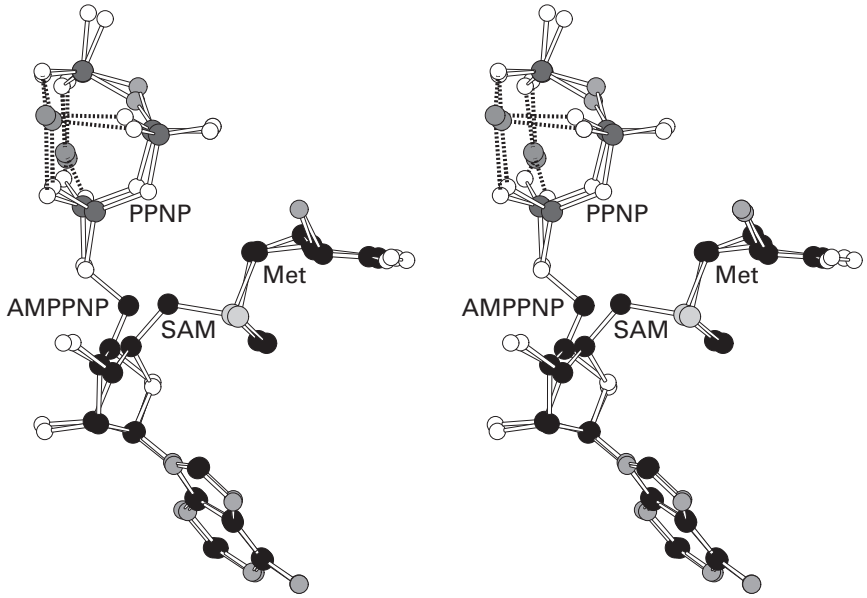


Figure 3–51: Superposition of stereodrawings[576] of molecular models of ligands in the active site in two crystallographic molecular models of complexes of methionine adenosyltransferase from *E. coli*. One molecular model is for the complex of the enzyme with its substrate L-methionine and the inhibitor $MgAMPPNP^{2-}$, and the other molecular model is for the complex of the enzyme with its substrate *S*-adenosyl-L-methionine (SAM) and the inhibitor magnesium phosphoric imidodiphosphonic anhydride (PPNP).[793] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, large light gray atoms are sulfurs, and large dark gray atoms are atoms of phosphorus. The enzyme was dissolved in a solution containing 5 mM $MgAMPPNP^{2-}$, 10 mM L-methionine, and 5 mM $MgCl_2$ at pH 8.0. After 60 min at 37 °C, the protein was crystallized. In the map of electron density calculated from a data set to Bragg spacing of 0.25 nm and calculated by imposing noncrystallographic 222(D_2) symmetry on the tetramer of the enzyme, the resulting feature of electron density located in the active site could be shown to be the sum of electron density arising from molecules of L-methionine and $MgAMPPNP^{2-}$ and electron density arising from molecules of *S*-adenosyl-L-methionine and magnesium phosphoric imidodiphosphonic anhydride. The latter pair of molecules arose from the nucleophilic transfer of an adenylyl group from $MgAMPPNP^{2-}$ to L-methionine catalyzed at the active site by the enzyme. Consequently, the molecular models of the former pair of molecules and the latter pair of molecules were each inserted into this feature of electron density at half occupancy, and the resulting molecular model was submitted to refinement. The final refined positions of the two pairs of substrates are superposed in the drawing. Two features of electron density consistent with Mg^{2+} were found to be coordinated by 5′-adenylic imidodiphosphonic anhydride, and phosphoric imidodiphosphonic anhydride, and those two Mg^{2+} (gray spheres) are included in the drawing. The 5′-carbon of the ribosyl group in the adenylyl group, at which the nucleophilic substitution catalyzed by the enzyme occurs, moves 0.13 nm during the substitution, and the 4′-carbon moves 0.06 nm.

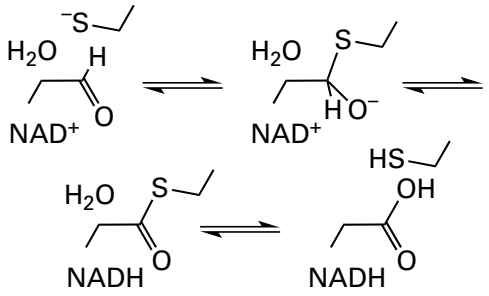
for complexes of bovine purine-nucleoside phosphorylase,[795] uridine phosphorylase from *E. coli*,[796] and adenine phosphoribosyl transferase from *Giardia intestinalis*.[797] All these observations emphasize that enzymes are usually designed to minimize changes in atomic position as their reactions proceed.

The active site must also accommodate both the reactants and the products of the enzymatic reaction. In cases in which the reaction requires only minimal alterations in the reactants during their conversion to products, the principle of least nuclear motion can be satisfied during the conversion. In more complicated reactions, however, rather significant shifts, such as the flipping over of (–)-germacrene A (Figure 3–48), have to occur in the bound substrates and intermediates for the reaction to proceed successfully from reactants to products. For example, in the reaction catalyzed by aldehyde dehydrogenase (NAD^+)



(3–418)

there are three consecutive steps with quite different chemistry: nucleophilic addition of the sulfanyl group of a cysteine in the active site to the carbonyl, dehydrogenation of the resulting thiohemiacetal by NAD^+, and hydrolysis of the resulting thioester. In the crystallographic molecular model of the active site of human aldehyde dehydrogenase (NAD^+) occupied by NAD^+, the nicotinamide ring of NAD^+ is in the location expected for removal of the hydride from the thiohemiacetal, but when the active site is occupied by NADH, the nicotinamide ring has withdrawn from its former location. The adenosyl group remains fixed in place as the reduced nicotinamide and its ribosyl group are displaced by about 0.4 nm from their position in the complex with NAD^+. It has been proposed that the purpose of this withdrawal of the nicotinamide ring performed by the active site is to provide room for the hydrolysis to proceed.[798] At the beginning of the reaction, the NAD^+ assumes the former conformation as it associates with the active site, and at the end of the reaction, the NADH is in the latter conformation, having shifted as the reaction progresses.

In the active site of **photoactive yellow protein** from *Halorhodospira halophila,* when the chromophore, (*E*)-4-hydroxycinnamic acid, photoisomerizes to (*Z*)-4-hydroxycinnamic acid, which is the photochemical product, hydrogen bonds to the chromophore break initially, but within 100 ps the rigidity of the active site causes them to re-form. Nevertheless, the active site is flexible enough to accommodate the *Z* carbon–carbon double bond, an accommodation that requires shifts in the mold of up to 0.1 nm.[664]

As the example of the subsite in trypsin responsible for its specificity has illustrated (Figure 3–46), the mold provided by the active site must sometimes be designed so that a subsite within it is able to recognize two different reactants. This accommodation can be accomplished by having a mold either large enough or flexible enough to achieve it. There are many other examples of **subsites within active sites that must recognize more than one functional group**. For example, unlike double-stranded uracil-DNA glycosylase from herpes simplex virus type 1, which must exclude cytosine from the active site, cytidylate kinase from *D. discoideum* must phosphorylate both cytidine phosphate and uridine phosphate, so the active site must be able to accommodate both substrates. The active site uses a molecule of water that is not controlled by other donors and acceptors, as is the one in double-stranded uracil-DNA glycosylase, to act as a donor for a hydrogen bond to the acyl oxygen at position 4 of the uracil and as an acceptor for a hydrogen bond from the carbamoyl nitrogen–hydrogen at position 4 of the cytosine.[799]

A significantly greater requirement for accommodation is satisfied by the active site of branched-chain-amino-acid transaminase from *E. coli*

L-leucine + 2-oxoglutarate ⇌
4-methyl-2-oxopentanoate + L-glutamate

(3–419)

The same subsite in the active site must recognize both the polar side chain of glutamate and the nonpolar side chain of leucine as well as those of isoleucine and valine. The subsite is a hydrophobic tube into which the isobutyl, 2-butyl, and isopropyl groups of leucine, isoleucine, and valine, respectively, can insert, as well as the two methylenes of the glutamate, and the tube has four donors at its

end that form hydrogen bonds with the carboxylato group of the glutamate when it is in the subsite or among themselves and molecules of water when it is not.[800]

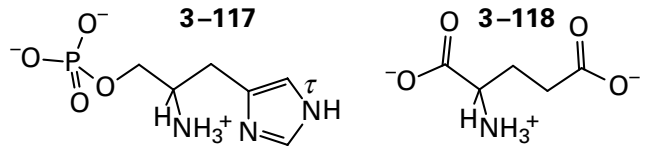
Thermolysin catalyzes the hydrolysis of peptide bonds to the amino-terminal side of hydrophobic amino acids such as alanine, valine, leucine, isoleucine, and phenylalanine almost exclusively.[801,802] The reliability of this specificity results from the expandable, exclusively hydrophobic pocket observed in the crystallographic molecular model at the location in the active site where the side chain on a reactant associates on the carboxy-terminal side of the point of cleavage (Figure 3–42). Phospholipase A_2 from *Naja atra* must recognize phospholipids that have the usual heterogeneous mixture of fatty acyl substituents at oxygens 2 and 3 of the glycero group. Consequently, it has a deep, flexible pocket lined entirely by hydrophobic side chains to accommodate indiscriminately the long alkyl and alkenyl chains.[447]

The **transaminases** that use pyridoxal phosphate as a prosthetic group are particularly good examples of active sites that must recognize two substrates at the same subsite of the complete mold. During transamination, an amino group is transferred from an amine to a 2-oxo acid, usually 2-oxoglutarate. The 2-oxo acid becomes an α-amino acid, usually L-glutamate, and the amine becomes the respective ketone, in which the oxygen of a carbonyl group replaces the amino group, just as the amino group replaced the oxygen of a carbonyl on the 2-oxo acid. The order of the steps in the forward reaction is mechanistically the same as the order of the steps in the reverse reaction. Because of this symmetry, a subsite within the active site has to accommodate equivalently both ketones and both amines and their respective adducts with pyridoxal phosphate. For example, LL-diaminopimelate aminotransferase transfers an amino group from LL-2,6-diaminoheptanedioate to 2-oxoglutarate to produce L-glutamate, which is L-2-aminopentanedioate, and L-2-oxo-6-aminoheptanedioate. The reaction takes place in LL-2,6-diaminoheptanedioate and L-glutamate at the 2-amino groups and in the respective ketones at the 2-oxo groups, but the functional groups attached to the carbons 2, a 4-amino-4-carboxybutyl group and a 2-carboxyethyl group, respectively, differ significantly in length and substitution. Nevertheless, they must be accommodated by the same subsite in the active site.

In contrast to the subtle arrangement of acceptors for hydrogen bonds necessary to recognize both arginines and lysines in the specificity pocket of trypsin, the arrangement of donors for hydrogen bonds necessary to recognize both L-glutamate and LL-2,6-diaminoheptanedioate in the specificity pocket of LL-diaminopimelate aminotransferase from *A. thaliana*[803] is more straightforward. The 6-carboxylato group in the substrate LL-2,6-diaminoheptanedioate and its various adducts with pyridoxal phosphate is two methylenes further away from its carbon 2 than the 4-carboxylato group in the substrate L-glutamate is from its carbon 2, and there is the additional ammonio group in the former. Nevertheless, the same donors to the 6-carboxylato group in LL-2,6-diaminoheptanedioate and its adducts, two tyrosines and a lysine, are used in the same roles to the 4-carboxylato group of L-glutamate and its adducts. The two extra methylenes in LL-2,6-diaminoheptanedioate are accommodated by kinking the longer alkane. The additional 6-ammonio group in LL-2,6-diaminoheptanedioate, immediately adjacent to the 6-carboxylato group, occupies a pocket that is occupied by disordered molecules of water when L-glutamate is in the active site. Two of these disordered molecules of water become fixed as acceptors for hydrogen bonds from the ammonio group, and the third nitrogen–hydrogen of the ammonio group forms a hydrogen bond with the carbamoyl group in the side chain of an asparagine. This carbamoyl group was hydrated in the complex with L-glutamate by the disordered molecule of water taking the place of the ammonio group in LL-2,6-diaminoheptanedioate.

In a much less dramatic example, the same arginine, with the same canonical hydrogen bonds (**3–111**), recognizes both the β-carboxylato group of L-aspartate and its adducts and the γ-carboxylato group of L-glutamate and its adducts in the active site of aspartate transaminase (Equation 3–410).[709]

Because it transfers the amino group from L-histidinol phosphate (**3–117**) to 2-oxoglutarate to produce 3-(imidazol-4-yl)-2-oxopropyl phosphate and L-glutamate (**3–118**)



histidinol-phosphate transaminase has to accommodate both the substrate L-histidinol phosphate and its adducts, as well as L-glutamate and its adducts. In the active site of the enzyme from *E. coli*, the guanidinio group of Arginine 386 forms canonical hydrogen bonds (**3–111**) with the α-carboxylato

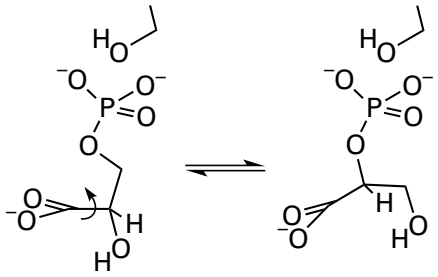
group of L-glutamate and donates the same nitrogen–hydrogens to two of the oxyanions of the phospho group in L-histidinol phosphate. An amido nitrogen–hydrogen from the carbamoyl group of Asparagine 194 donates a second hydrogen bond to one of the oxyanions of the α-carboxylato group of L-glutamate and donates a second hydrogen bond to the oxyanion of the phospho group of L-histidinol phosphate that ends up in the same location. A molecule of water fixed in position by Aspartate 109 acts as a donor in a hydrogen bond with the 4-carboxylato group of L-glutamate, and Aspartate 109 by itself acts as an acceptor to the τ-nitrogen of the imidazolyl group of L-histidinol phosphate. Because L-histidinol phosphate has more donors and acceptors for hydrogen bonds than L-glutamate, the remainder of the donors and acceptors to L-histidinol phosphate and its adducts are unique. A reasonable cup for the phospho group, with two donors for each oxyanion, and two acceptors for the two donors on the imidazolio group are provided by the active site.[804]

In the case of transaminases, because two different amines or amino acids have to engage in the same nucleophilic addition to the internal pyridoximine, the subsite that recognizes one of the substrates must recognize the other substrate but also exclude other amines and amino acids. The active sites in these enzymes have evolved to employ a strategy where the prosthetic pyridoxal phosphate remains in a fixed location in the active site while the different substrates add to it from within the same subsite. If, however, the substrates that are required to participate in reactions with a prosthetic group are dramatically different in structure, the active site may be constructed in such a way that **the prosthetic group moves between two subsites** for the substrates, rather than the two substrates occupying the same subsite. For example, the reduced prosthetic flavin in the active site of L-ornithine N^5-monooxygenase (NADPH)

$$\text{L-ornithine} + O_2 + \text{NADPH} \rightleftharpoons N^5\text{-hydroxy-L-ornithine} + H_2O + \text{NADP}^+ \quad (3\text{–}420)$$

becomes oxidized during the hydroxylation of L-ornithine and must be rereduced by NADPH, two substrates that differ considerably in structure. In crystallographic molecular models of the active site of the enzyme from *Kutzneria* occupied by various substrates, a significant movement of 0.6 nm within the active site of the 7,8-dimethylisoalloxazine of the prosthetic flavin adenine dinucleotide was observed that shifts it back and forth between the subsite with which NADPH associates and the subsite with which L-ornithine associates.[805]

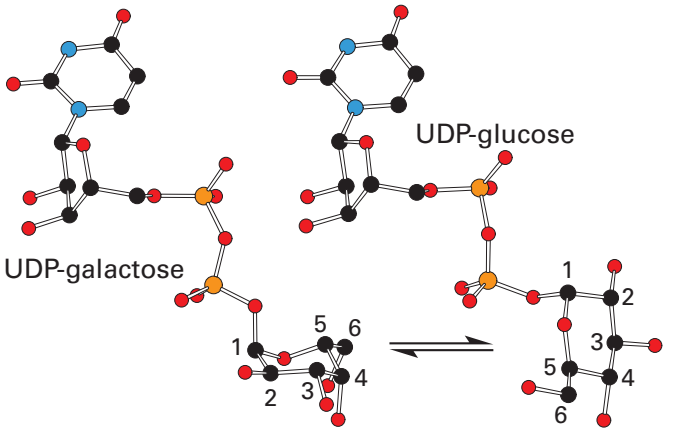
As is illustrated by the active site of aristolochene synthase (Figure 3–49), there are also **subsites within certain active sites that must accommodate two orientations of the same intermediate**. For example, in the crystallographic molecular model of phosphoglycerate mutase from *Leishmania mexicana*, the active site is occupied by an equilibrium mixture of the sole reactant 3-phospho-D-glycerate and the sole product 2-phospho-D-glycerate. In this equilibrium mixture within the active site, the reactant and the product differ in their conformation and orientation only by a 120° rotation around the bond between carbons 1 and 2 while the carboxylato group remains fixed in position. The rotation is accompanied by a tilt that nevertheless retains the position of the two carboxylato oxygens



3-phospho-D-glycerate 2-phospho-D-glycerate (3–421)

but brings the phospho group on carbon 2 of 2-phospho-D-glycerate into the same position it occupies on carbon 3 of 3-phospho-D-glycerate.[806] In the enzymatic reaction, the phosphate is transferred from oxygen 3 to Serine 75 to give the intermediate D-glycerate, the rotation and the tilt of the intermediate D-glycerate take place, and the phospho group is then transferred to oxygen 2 from Serine 75.

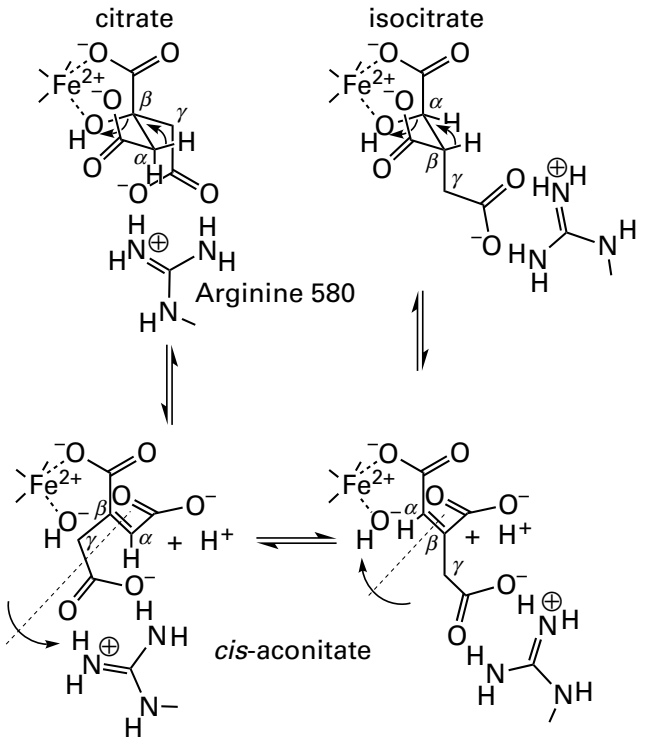
In the active site of UDP-glucose 4-epimerase (previously Equation 1–88)



(3–422)

a hydride is removed from carbon 4 of UDP-galactose by the prosthetic NAD^+ in the active site, and the resulting 4-oxoglucopyranosyl group of UDP-4-dehydroglucose pivots so that the hydride can be added by the stationary NADH to the side of the 4-oxo group opposite the side from which it was removed to produce UDP-glucose.* Carbon 4 of the hexose and its hydroxy group are held in exactly the same orientation and position by the active site in both UDP-galactose and UDP-glucose (Equation 3–422). This reorientation of the intermediate 4-oxopyranose is defined by crystallographic molecular models of complexes between an inactive mutant of the enzyme from *E. coli* and either UDP-galactose or UDP-glucose (Equation 3–422).[807] In a related (28% identity; 3.0 gap percent) enzyme, UDP-glucuronic acid 4-epimerase from *B. cereus*, when crystallographic molecular models of the active site occupied by the reactant and product, UDP-D-glucuronic acid and UDP-D-galacturonic acid, which in the active site in the crystal are in equilibrium with each other, are superposed, the epimeric carbons 4 in the two substrates occupy identical positions even though the two pyranoses have flipped over.[587]

In a crystallographic molecular model (Figure 3–52)[808] of the complex between porcine aconitate hydratase



(3–423)

and isocitrate, the isocitrate coordinates only one of the iron ions, a Fe^{2+},[809] in a prosthetic [4Fe–4S] iron–sulfur cluster with its α-hydroxy group and one of the oxygens* in its α-carboxylato group (upper right structure in Equation 3–423).[810] In the crystallographic molecular model between citrate and an inactive mutant of bovine aconitate hydratase in which Serine 642† has been changed to alanine, one of the oxygens of the β-carboxylato group and the β-hydroxy group of the citrate occupy the same two coordination sites on the Fe^{2+}.[811] In each case, the hydroxy group that is bound to Fe^{2+} is the one that leaves as ferrous hydroxide from both isocitrate and citrate, respectively, to produce *cis*-aconitate.

The *cis*-aconitate then must reorient in the active site, switching its coordination from its α-carboxy group to its β-carboxy group or vice versa (lower equilibrium in Equation 3–423). During this change in ligation, the *cis*-aconitate, when it is unliganded to the iron, pivots on the two σ bonds between the carbon–carbon double bond and the γ-carboxylato group while the γ-carboxylato group remains fixed

*Convince yourself that, in the drawing of UDP-galactose and UDP-glucose in Equation 3–422, the hydrogen on carbon 4 has the opposite stereochemistry even though it is pointed in the same direction, namely, the direction of the nicotinamide.

*This coordination resembles the coordination of the molybdenum ion in the [Mo–7Fe–9S–C] cluster of dinitrogenase by homocitrate (Figure 2–62).

†The hydroxy group of Serine 642 is equidistant (0.34–0.36 nm) from one oxygen in each of the three carboxy groups of isocitrate (Figure 3–52) but does not seem to form a hydrogen bond with any of them.

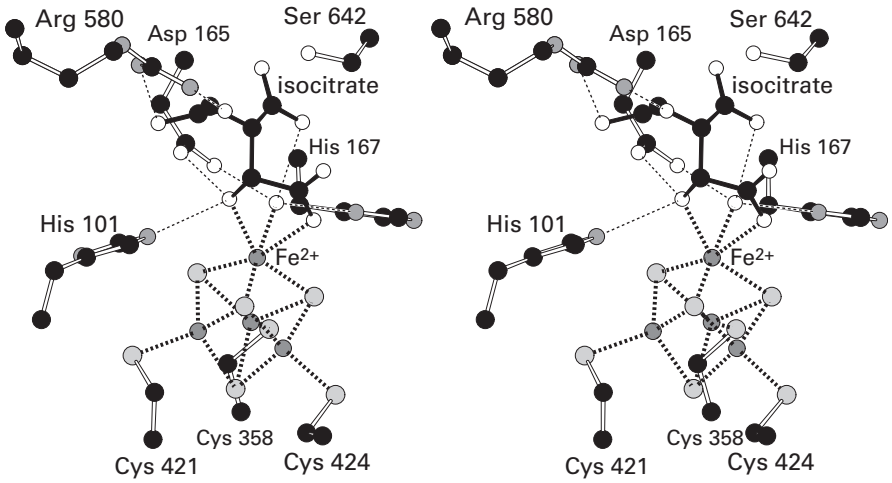


Figure 3–52: Stereodrawing[576] of the crystallographic molecular model of the active site of unmodified, enzymatically active porcine aconitate hydratase occupied by the substrate isocitrate.[808] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. In the iron–sulfur clusters, large light gray spheres are sulfides and small dark gray spheres are iron ions.The enzyme was purified from porcine heart, activated with 2 mM ferrous ammonium sulfate and 2 mM sodium dithionite, and crystallized in 2.4 M ammonium sulfate, 15 mM 1,2,3-tricarboxypropane, 20 mM citrate, and 60 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol at pH 7.8. A data set to Bragg spacing of 0.20 nm was collected. Electron density consistent only with isocitrate was observed in the active site even though the enzyme was crystallized in the presence of only citrate. The isocitrate was a ligand to the iron ion in the [4Fe–4S] iron–sulfur cluster that lacks a cysteine as a fourth tetrahedral ligand (iron at top corner) while all the other iron ions have a cysteine as their fourth ligands. This iron ion is hexacoordinate rather than tetrahedral as the others are, and it is a ferrous ion.[809] Three of its open coordination sites are filled by the three sulfides of the cluster. The isocitrate provides two ligands to the hexacoordinate Fe^{2+}: its 2-hydroxy group and its 1-carboxylato group. The final ligand to the Fe^{2+} is a molecule of water that acts as a Brønsted acid that hydronates the 3-carboxylato group of the isocitrate by relaying the acidity of Aspartate 166 or Histidine 167. *cis*-Aconitate performs a pivot in the active site so that its 1-carboxylato group (the α-carboxylato group in Equation 3–423) is replaced as a ligand to the hexacoordinate Fe^{2+} by its 3-carboxylato group (the β-carboxylato group in Equation 3–423). Following the pivot, the 1-carboxylato group of *cis*-aconitate that left the Fe^{2+} ends up with its two oxygens in the same pocket that was occupied by the two oxygens of the 3-carboxylato group that is now on the Fe^{2+}. This retention of position can be visualized by moving in your imagination the carboxymethyl group from carbon 2 of the isocitrate to carbon 3, thus creating citrate, and rotating the carboxymethyl group until its two oxygens end up in the same place that they were before you moved the carboxymethyl group.

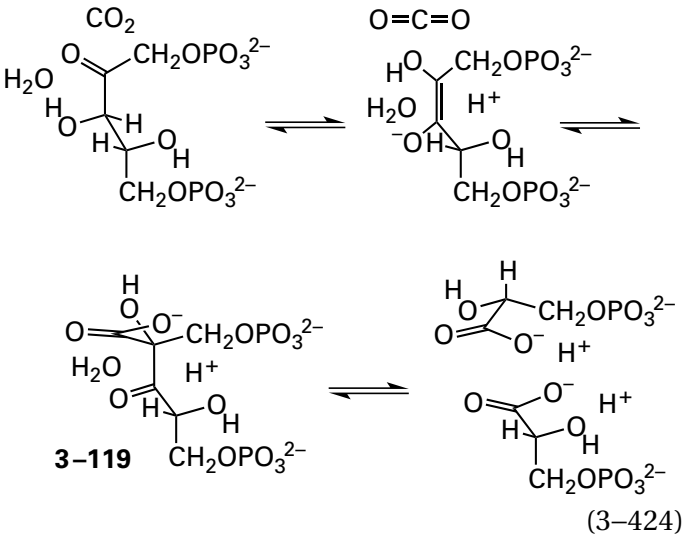
by the two canonical hydrogen bonds between its two oxygens and the two ω-amido nitrogens of Arginine 580 as well as four other donors. After the pivot, the hydroxy group of the ferrous hydroxide can be added to the other end of the carbon–carbon double bond so that isocitrate can be turned into citrate or citrate can be turned into isocitrate. Both before and after the pivot, the two oxygens of the α-carboxylato group in citrate and the two oxygens of the β-carboxylato group in isocitrate, respectively—in each case the carboxylato group that is neither a ligand to the Fe^{2+} nor the acceptor for the hydrogen bonds from Arginine 580—end up in the same pocket in the active site. In this pocket, the two oxygens of the α-carboxylato group before the pivot or the β-carboxylato group after the pivot are acceptors in six hydrogen bonds. While it is pivoting and neither of these carboxylato groups is associated with this pocket or with the Fe^{2+}, the loosely held *cis*-aconitate often leaves the active site, so there is always a significant concentration of *cis*-aconitate in the solution or the cytoplasm, and it enters and leaves the active site while the net conversion of citrate to isocitrate or the net conversion of isocitrate to citrate is proceeding.

The crystallographic molecular models of complexes between an enzyme and its substrates, prosthetic groups, or inhibitors define the boundary of the active site within which the reactants associate and at which they are converted to products. This active site will usually be a crevice, closed box, or tubular hole[812] deep enough, wide enough, and long enough to accommodate all the reactants when they are bound to the enzyme simultaneously. Its walls—from which protrude the functional groups that recognize the substrates, provide free energy of association, and catalyze the reaction—are formed from strands of the polypeptide comprising the protein. Although there are multienzymatic complexes that have active sites for more than one catalytic activity,[813] such as the multienzymatic complexes for fatty acid synthesis, the active sites of most enzymes are constructed to catalyze only one reaction or two or more closely related reactions.

In a monomeric enzyme, each molecule of the protein has an active site at a unique location on its surface or in its interior. Almost all enzymes, however, are oligomers formed from two or more protomers. In an oligomeric enzyme, each molecule of **the oligomer almost always contains as many active sites as there are protomers**. Usually, the active sites are all identical to each other, they are formed from strands of polypeptide that are all from the same protomer, and they are distributed over the surface or the interior of the oligomer by the same symmetry operations that govern the arrangements of the protomers themselves.[814] There are, however, many examples in which an active site in an oligomeric protein is constructed from strands of polypeptide from more than one of the protomers. In most of these instances, strands of polypeptide from two protomers form the active site, but in rare cases, an active site is constructed from strands of polypeptide from three protomers,[815-817] and in at least one instance, an active site is formed from strands of polypeptide from four of its protomers.[818,819] In such situations, the active site, by definition, lies within an interface or interfaces in the oligomer.

When an **active site is formed from strands of polypeptide from more than one protomer**, there can be two outcomes. The two or three protomers that form the interface or interfaces within which the active site is located are almost always related to each other by a twofold rotational axis of symmetry[820] or a threefold rotational axis of symmetry,[821] respectively. If the rotational axis of symmetry runs through the active site, it necessarily follows that the same amino acids from each protomer form the active site, and therefore there can only be one active site that is formed by the two or three protomers. In such a situation, the number of active sites in the oligomer will be equal to half or a third the number of protomers, respectively. If, however, the active site is formed from strands of polypeptide from only two of the protomers in the oligomer and the twofold rotational axis of symmetry relating them is far enough from the active site that all the strands of polypeptide forming an active site are unique, then there will be two active sites in the interface between the two protomers related by the axis of symmetry. In this instance, the number of active sites in the oligomer will be equal to the number of protomers. This equivalence is the usual case because an active site with an axis of symmetry running through it has difficulties associating with asymmetric substrates.

Ribulose-bisphosphate carboxylase[812]



(3–424)

from *Spinacia oleracea* is composed of eight copies of a folded α polypeptide (475 aa) and eight copies of a folded β polypeptide (123 aa). The octamer contains four α_2 dimers arranged around a fourfold rotational axis of symmetry, and the two twofold rotational axes of symmetry relating the subunits within the α_2 dimers are both normal to, and intersect perpendicularly at, the fourfold rotational axis of symmetry. Only the β subunits link the four α_2 dimers together around the fourfold axis of symmetry, so each α_2 dimer is an independent unit of the higher structure. Each α_2 dimer of ribulose-bisphosphate carboxylase contains **two active sites symmetrically displayed on opposite sides of the twofold rotational axis of symmetry** of that α_2 dimer. These two identical and symmetrically related active sites both lie within the interface between the two α subunits. The amino acids that form each of the two active sites (Figure 3–53)[812] are Threonine 171, Lysine 173, Lysine 175, Threonine 198, Aspartate 200, Glutamate 202, Histidine 292, Arginine 293, Histidine 325, Lysine 332, Leucine 333, Serine 377, Glycine 378, Glycine 379, Glycine 401, and Glycine 402 from one subunit (designated A in the figure) and Glutamate 58, Threonine 63, Tryptophan 64, and Asparagine 121 from the adjacent subunit across the interface (designated B in the figure). In no case is the same amino acid from both subunits present in the same active site, so there can be two active sites in each α_2 dimer.

This catalogue of the amino acids forming the active site of ribulose-bisphosphate carboxylase illustrates the fact that an active site is formed from **a cluster of neighboring amino acids in the structure of the protein, regardless of their covalent affiliation.** The only purpose for which the polypeptide has folded to form a globular structure and for which this globular structure has been created by natural selection is to gather these amino acids in proper alignment to catalyze the enzymatic reaction. Because the polypeptide folds into a complexly ordered, globular structure, amino acids distant in the sequence of amino acids or from different polypeptides are brought together opportunistically to form an active site.[822]

If it is unknown, but suspected for some reason, that an active site is composed of amino acids from two different subunits, this suspicion can be examined by **complementation**. An oligomer of an enzyme that has been mutated at one amino acid so that it is enzymatically inactive is mixed, under conditions where the subunits or the oligomer can interchange, with an inactive oligomer of the same enzyme that has been mutated at a different amino acid. If the enzymatic activity returns, one explanation is that the unmutated amino acid on the one subunit has joined the unmutated amino acid on the other in a now unmutated active site. For example, when Histidine 68 in the active site of adenylosuccinate lyase from *B. subtilis* is mutated to a glutamine or Histidine 141 is mutated to an alanine, the resulting mutants are each enzymatically inactive. When equal amounts of the two inactive mutants are mixed together in 20 mM NaCl at pH 7 and 25 °C for 12 h, enzymatic activity returns. The final level of reconstituted activity is equal to 15% of the level expected for the concentration of active sites present. If Histidine 68 from one subunit and Histidine 141 from an adjacent subunit are part of the same active site at the interface between the two subunits in adenylosuccinate lyase, the probability that unmutated Histidine 68 from one subunit and unmutated Histidine 141 from the other subunit end up in the same active site, if the subunits interchanged completely and at random, should be 25%, close to the observed value.[823] A yield of 25% has been observed in another complementation.[824]

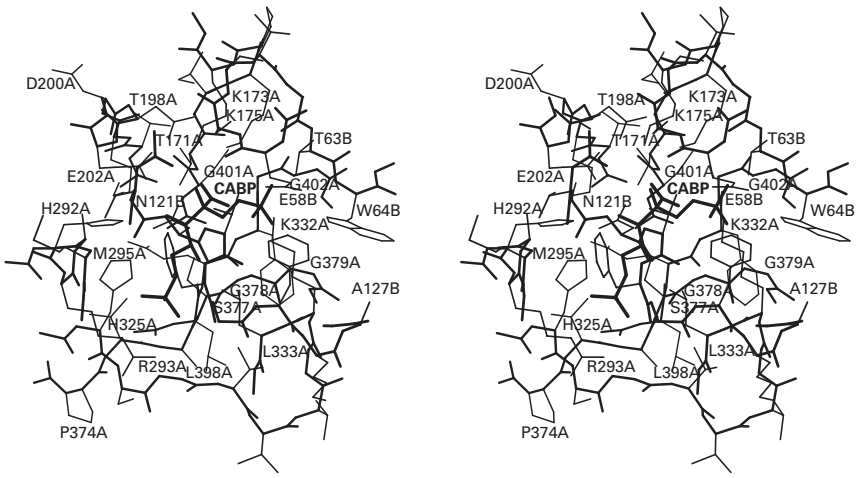


Figure 3–53: Stereodrawing[576] of the crystallographic molecular model of the active site of ribulose-bisphosphate carboxylase from *S. oleracea* occupied with 2-carboxy-D-arabinitol 1,5-bisphosphate, an analogue for intermediate **3–119** in the enzymatic reaction (Equation 3–424).[812] The complex between ribulose-bisphosphate carboxylase and 2-carboxy-D-arabinitol 1,5-bisphosphate was crystallized from a solution of ammonium sulfate. The phases of the reflections were determined by multiple isomorphous replacement with three derivatives. A model of the polypeptide was inserted into the initial map of electron density, and the resulting molecular model was used to initiate refinement. After several cycles of refinement, a molecular model of 2-carboxy-D-arabinitol 1,5-bisphosphate (CABP) was inserted into the difference map of electron density within a feature of positive electron density that was unmistakably the correct size and shape. Refinement then proceeded to a final *R*-factor of 0.24. The view is of the analogue (in thick lines) surrounded by segments of the polypeptide creating the active site. The polypeptide backbone is drawn with lines of intermediate width, and the side chains are drawn with thin lines. In the final crystallographic molecular model, the active site is a blind tube, open at one end to the solution, into which the 2-carboxy-D-arabinitol 1,5-bisphosphate has inserted. It is formed from eight strands of polypeptide, six from one subunit (designated A) and two from an adjacent, identical subunit related to the first by a twofold rotational axis of symmetry (designated B).

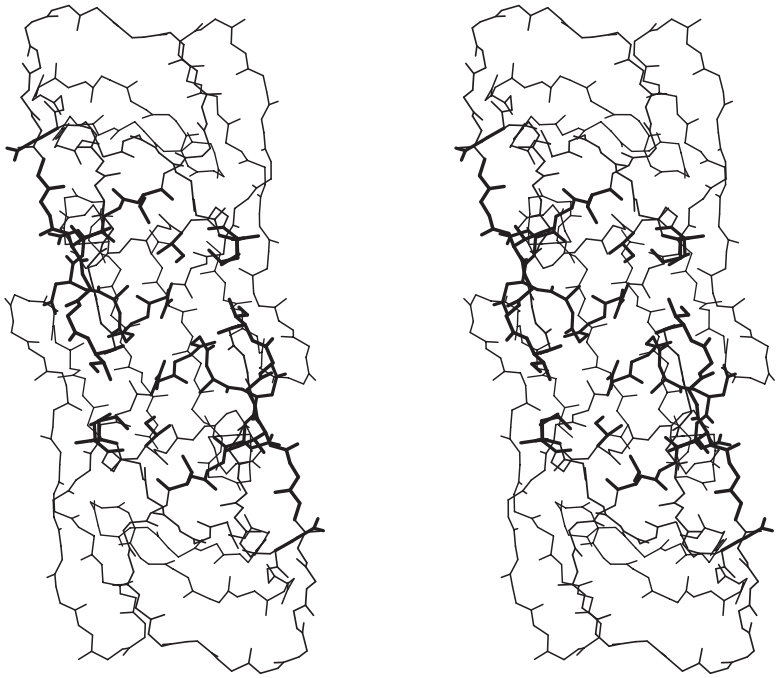

Figure 3–54: Stereodrawing[576] of the crystallographic molecular model of the α_2 dimer of aspartic endopeptidase from human immunodeficiency virus type 1 group M subtype B (isolate BH10).[825-828] The viral enzyme was expressed in *E. coli* and crystallized. The space group of the crystals was $P4_12_12$ with a single folded polypeptide in the asymmetric unit and related to an immediately adjacent asymmetric unit by an exact crystallographic twofold rotational axis of symmetry. Together these two folded, symmetrically related polypeptides form one molecule of the enzyme. The phases of the reflections to 0.3 nm were determined by molecular replacement using a previous crystallographic molecular model of the protein, and the resulting crystallographic molecular model was refined against a data set with Bragg spacing to 0.14 nm. The drawing is of the polypeptide backbones (thin lines) of the two folded polypeptides in the refined crystallographic molecular model of the complete molecule of the enzyme. The exact twofold rotational axis of symmetry of the molecule is normal to the plane of the page. Those portions of the polypeptide backbones and those side chains of the amino acids that make contact with peptide in complexes between the enzyme and substrates or peptidic inhibitors[829,830] are highlighted by thicker lines. The active site that is defined by these thicker lines runs diagonally across the enzyme as drawn from top left to bottom right. The active site makes contact with as many as ten amino acids in the polypeptide that it cleaves, which stretches in an elongated conformation across the active site. Two symmetrically displayed flaps of polypeptide form two symmetric arches enclosing the active site and the substrate.

One of the more unusual active sites is that in the aspartic endopeptidase from human immunodeficiency virus type 1 (Figure 3–54).[822,825-830] The protein is an α_2 dimer composed of two identical polypeptides (99 aa). It is a member of a family of aspartic endopeptidases that includes the pepsins from animals. Most of the other members of the family, however, are composed of folded polypeptides at least twice as long. These larger proteins all have an internal duplication that resulted from a gene duplication, and the two internally repeating domains, each of which is superposable on a single subunit of the dimeric viral enzyme, are arranged around a twofold rotational axis of pseudosymmetry that passes through the one protomer. In the large aspartic endopeptidases, this axis of pseudosymmetry passes through the one active site formed by the single folded polypeptide. In the viral aspartic endopeptidase, however, each of the two identically folded polypeptides assume the same position as one of the two domains in a larger aspartic endopeptidase, the protein is an α_2 dimer containing only one active site, the two folded polypeptides are arranged around a twofold rotational axis of symmetry, and **the twofold rotational axis of symmetry in the α_2 dimer passes through the center of the single active site** (Figure 3–54).

The peculiar aspect of this situation is that although the active site of the viral aspartic endopeptidase is symmetric in the unoccupied enzyme, its reactant, a strand of polypeptide that it is designed to cleave, is completely asymmetric, a fact that presents the difficulty already noted. When the reactant associates with the active site, the conformation of each subunit changes to complement the distinct sequence of five amino acids with which it associates on its side of the point of cleavage, so in the complex the conformations of the two protomers have become different from each other.[829,830] This plasticity within the active site contrasts with the rigidity of the active site in a terpene synthase but is a common feature of an endopeptidase that must accept many different sequences of amino acids. The symmetry of the unoccupied active site, however, can be exploited in designing inhibitors for a viral aspartic endopeptidase. A twofold rotationally symmetric inhibitor was synthesized that was bound tightly ($K_i = 5$ nM) to the aspartic endopeptidase from human immunodeficiency virus type 1.[831]

The larger, internally duplicated aspartic endopeptidases are examples of one of the **outcomes that can result from gene duplication**. As with these endopeptidases, the active site of diaminopimelate epimerase from *H. influenzae* also sits at the twofold rotational axis of pseudosymmetry in a monomeric protein that has two internally repeating domains.[832] Lactoylglutathione lyase from *S. cerevisiae*, however, has two internally repeating domains, each of which forms its own active site, so there are two functional active sites on each monomer of this enzyme, each catalyzing the same reaction.[833] Some of the internally duplicated hexokinases have one functional active site on each of the two internally repeating domains, two for each folded polypeptide, while in others, one of the active sites has become defunct.[834]

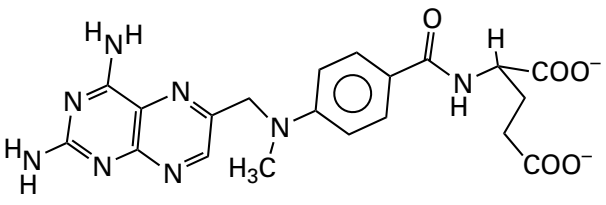
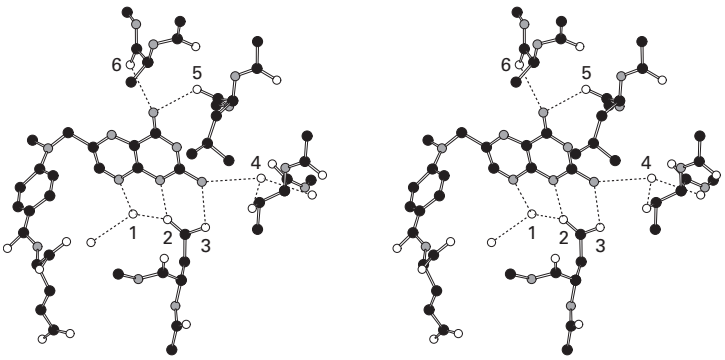
Problem 3–30: Methotrexate



is a strong inhibitor of dihydrofolate reductase that is competitive with respect to dihydrofolate, which it closely resembles. A view of a portion of the crystallographic molecular model of the complex between methotrexate and the active site of dihydrofolate reductase from *L. casei* is presented in the following figure. There are six hydrogen bonds, indicated with dashed lines, between the pteridinyl group of the inhibitor and the active site.



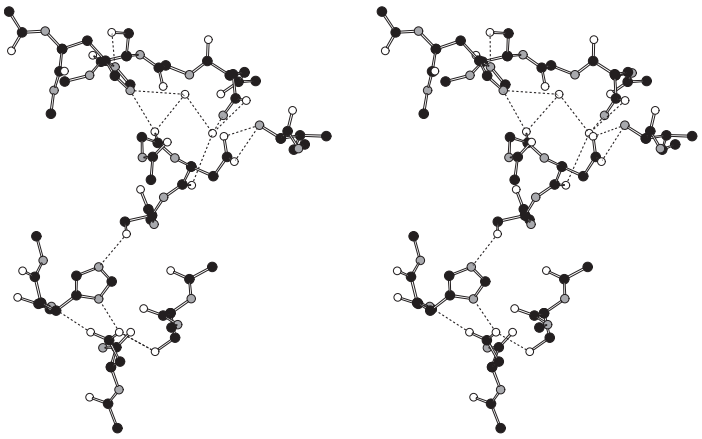
(A) Identify by their numbers the donor or acceptor to the methotrexate in each of the six hydrogen bonds. Identify the amino acid side chain by naming the amino acid, identify an atom from the peptide backbone by naming the functional group, and identify any other donor or acceptor by its name.

(B) Draw the σ structure of only the pteridinyl group of methotrexate. Include all σ lone pairs of electrons and acidic hydrons in their proper orientations. As an afterthought, to make your drawing more familiar, add π electrons distributed as they would be in one of the resonance structures.

(C) Around the pteridine ring in your drawing, place the functional groups that form the hydrogen bonds seen in the figure. Draw each functional group fully enough so that it is clear what it is. Draw each functional group with the proper size to match your drawing of the pteridine ring. Orient each functional group so that an ideal hydrogen bond is formed in each instance. Put σ lone pairs on the acceptors for hydrogen bonds in the proper orientations. Put acidic hydrogens on the donors for hydrogen bonds in the proper orientations. Choose one of the resonance hybrids of the functional groups.

(D) Two of the hydrogen bonds as they are formed in the crystallographic molecular model are not in the ideal configuration. Which two are they and why are they not ideal? Why does it not matter?

The following figure is a view of the active site in the crystallographic molecular model of bovine chymotrypsin.[835] The narrow dashed lines are supposed to indicate hydrogen bonds.



(E) Make a list identifying both the donor and the acceptor in each of the 14 hydrogen bonds. Identify the amino acid side chain by naming the amino acid, identify an atom from the peptide backbone by naming the functional group, and identify any other donor or acceptor by its name.

(F) Attempt to draw out each hydrogen bond with the care you exercised in your answer to part B.

(G) If you have done your work carefully enough, you will have found at least three hydrogen bonds indicated in the figure that are formally impossible for electronic or steric reasons. Identify each formally impossible hydrogen bond and describe why each is impossible.

(H) Assume that the crystallographer knew these were impossible as written and meant to indicate a different arrangement from single hydrogen bonds. Provide a reasonable explanation for what may be happening at each formally impossible location.

Problem 3–31: What information would be obtained from the crystallographic molecular model of the complex between *P*1,*P*5-bis(5′-adenosyl) pentaphosphate and adenylate kinase?[836]

Problem 3–32: What information can be gained from a crystallographic molecular model of the complex between deoxyuridine 5′-diphosphate and dUTP diphosphatase?[837]

$$MgdUTP^{2-} + H_2O \rightleftharpoons dUMP^{-} + MgOPO_3PO_3^{2-} + H^+$$

Problem 3–33: Draw the structures of the two reactants that the bisubstrate analogue **3–87** for spermidine synthase combines into one molecule. Draw them next to a drawing of bisubstrate analogue **3–87** so that it is clear which parts of the analogue mimic which reactant.

Problem 3–34: (1*S*)-1-Diphospho-(2*R*,3*R*)-dihydroxy-(4*S*)-4-(phosphoryloxymethyl)cyclopentane[838] forms inactive complexes with phosphoribosyl transferases and the acceptor to which the phosphoribosyl group is transferred. These complexes can be crystallized, and in the crystallographic molecular models the alignment of the acceptor and the analogue producing the phosphoribosyl transfer can be observed.[839] Why is this analogue inactive in the enzymatic reaction?

Problem 3–35: Tartrate dehydrogenase catalyzes three different reactions:[41]

$$(R,R)\text{-tartrate} + NAD^+ \rightleftharpoons (R)\text{-oxaloglycolate} + NADH + H^+$$

$$(R,S)\text{-tartrate} + NAD^+ + H^+ \rightleftharpoons CO_2 + (R)\text{-glycerate} + NAD^+$$

$$(R)\text{-malate} + NAD^+ \rightleftharpoons CO_2 + \text{pyruvate} + NADH$$

The enzyme has a Mn^{2+} as a prosthetic group in its active site.

(A) Draw each reactant in a sawhorse representation, with the *R* carbon of each reactant in front and in the same orientation. Draw the carbon in back of your structures of (*R*,*R*)-tartrate and (*R*,*S*)-tartrate with the hydroxy group in the orientation in which it can share the Mn^{2+} in the active site with the carboxy group on the front carbon in a metallocyle with six atoms.

(B) Explain the results of the three reactions in terms of these three structures that you just drew by making your mechanisms as similar as possible, aligning orbitals to permit the required overlap, and completing each reaction with least nuclear motion.

Problem 3–36: One way to verify that an active site is formed from strands of polypeptide from two different protomers in an oligomer is to perform a hybridization of mutants to assess complementation.[840-843] Suppose that Tyrosine 85 from one protomer and Lysine 273 from another protomer in an oligomeric enzyme participate in the same active site. Tyrosine 85 can be mutated to alanine (Y85A) and Lysine 273 can be mutated to alanine (K273A), and oligomers with only Y85A protomers and oligomers with only K273A protomers are both completely inactive.

(A) If equimolar amounts of each mutant oligomer are mixed together, the oligomers dissociate into monomers, and the monomers then reassociate into oligomers at random. What are the four different types of active sites that would result from the hybridization?

(B) In what ratio would these four different active sites be present in the final hybrids?

(C) What would be the enzymatic activity of this final mixture of hybrids relative to that of the unmutated, wild-type enzyme?

(D) Suppose a constant concentration of Y85A homooligomer is mixed with increasing concentrations of K273A homooligomer, the oligomers dissociate, and the monomers reassociate at random. Derive an equation for the fraction of Y85A protomers that would be associated with K273A homooligomers in the final mixture of hybrids.[844]

(E) In the experiment described in part D, what would be the enzymatic activity for each mole of Y85A protomer relative to the enzymatic activity for each protomer in the wild-type enzyme at infinite concentration of K273A?

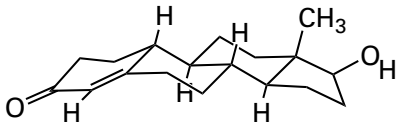
Physical Measurements of Complexes between Enzymes and Ligands

The **same stable complexes between enzymes and substrates and inhibitors** that can be studied crystallographically and that were just discussed at length can also be probed by physical measurements. The most commonly used physical methods for this purpose are infrared spectroscopy, ultraviolet and visible spectroscopy, and nuclear magnetic resonance spectroscopy.

Infrared spectroscopy is used to monitor changes in vibrational modes in a substrate or the analogue of a substrate when it associates with an active site. Although other molecular vibrational modes, such as those of the phosphorus–oxygen bonds in nucleotides and other substrates with phosphate groups,[845,846] can be followed, the strong, characteristic stretching frequency of the carbon–oxygen double bond of a carbonyl group or an acyl group in a substrate or an inhibitor bound in an active site is most often monitored by infrared spectroscopy. When a substrate or an inhibitor is bound in the active site, its infrared vibrational modes overlap those of the protein, so either Fourier transform infrared spectroscopy or Raman infrared spectroscopy, in both of which peaks of absorbance are significantly narrowed, is used for measurements. In addition, in both instances a difference spectrum between a solution of the enzyme alone and a solution of the same concentration of enzyme with the active site occupied by the substrate or inhibitor is used to isolate the vibrational modes of the ligand.

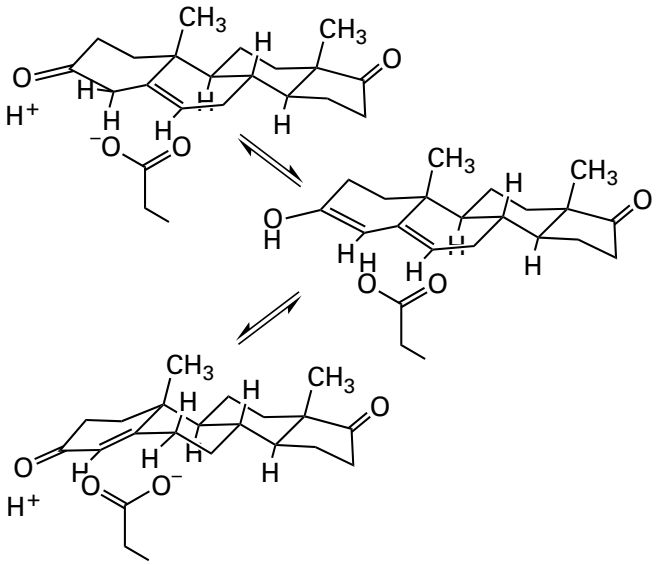
When glycerone phosphate associates with triosephosphate isomerase (Equation 3–384) from *G. gallus*, the stretching frequency of its carbonyl group[847] in a **difference Fourier transform infrared spectrum** between a solution of the enzyme alone and a solution of the enzyme with the active site occupied by glycerone phosphate has a maximum of absorbance at 1713 cm^{-1}. This stretching vibration has been assigned to the carbonyl group of glycerone phosphate when it occupies the active site in its productive orientation. In free solution, the same absorption has a maximum of absorbance at 1732 cm^{-1}. Consequently, there is a shift of –19 cm^{-1} in this absorption upon association of glycerone phosphate with the active site. By site-directed mutation, this shift could be shown to result from the presence of the imidazolyl group of the histidine in the active site[848] that is immediately adjacent to, and that forms a hydrogen bond with, the carbonyl oxygen of glycerone phosphate in the crystallographic molecular model of the occupied active site (Figure 3–37).

19-Nortestosterone is an enone



3–120

that is a competitive inhibitor of steroid Δ-isomerase



(3–425)

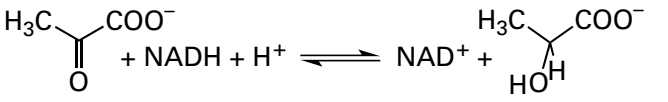
with respect to the substrate androst-5-ene-3,17-dione.[849] A difference Fourier transform infrared spectrum was recorded for 19-nortestosterone when it is occupying the active site of steroid Δ-isomerase from *P. putida*.[850] Upon association of the inhibitor with the active site from the solution, the maximum of absorbance for the stretching frequency of its carbonyl group shifts –46 cm^{-1}, from 1634 to 1588 cm^{-1}.

In a low-resolution structure of the active site of steroid Δ-isomerase from *C. testosteroni* occupied by the succinyl ester of nortestosterone, obtained by two-dimensional nuclear magnetic resonance spectroscopy, both the carboxy group of Aspartate 99 and the hydroxy group of Tyrosine 14 are immediately adjacent to the carbonyl oxygen of the inhibitor.[851] In a high-resolution crystallographic molecular model of the same active site occupied by equilenin, an inhibitor with the same carbon skeleton as 19-nortestosterone in which the two rings to the left in the drawing of **3–120** are aromatic, one of the carboxy oxygens of Aspartate 99 and the hydroxy

group of Tyrosine 14 form compressed (0.26 nm) hydrogen bonds with the hydroxy group that takes the place of the carbonyl carbon of 19-nortestosterone.[852] One of the oxygens of the homologous carboxy group in Aspartate 103 and the homologous hydroxy group in Tyrosine 16 in the active site of the enzyme from *P. putida* form short (0.26 nm) hydrogen bonds with the carbonyl oxygen of 19-nortestosterone (**3–120**) in the crystallographic molecular model of its occupied active site.[853]

When Aspartate 103 of the enzyme from *P. putida* is mutated to a leucine, the maximum of absorbance for the stretching frequency of 19-nortestosterone in the active site shifts +32 cm^{-1} to 1626 cm^{-1}. When Tyrosine 16 is mutated to a phenylalanine,[850] the maximum of absorbance for the stretching frequency shifts +61 cm^{-1} to 1649 cm^{-1}, a value larger than that of the stretching vibration of 19-nortestosterone in solution but not so large as its value in hexane (1690 nm). Both of these results suggest that the red shift observed when 19-nortestosterone associates with the enzyme is **due to both of these hydrogen bonds** and also that the 19-nortestosterone is in a nonpolar environment.

Isotopic editing can be used to assign absorptions in difference Fourier transform infrared spectra. For example, replacing a carbon-12 in a molecule, either synthetically or biosynthetically, with a carbon-13 increases the mass of that atom. The force constants of the bond remain the same, but the increase in mass causes the vibrational modes in which that carbon atom participates to shift to a lower frequency. These shifts in frequency can then be used to identify the absorptions that arise from the vibrational modes in which this carbon participates. For example, when [2-^{12}C]pyruvate is bound in the active site of the complex between NADH and porcine L-lactate dehydrogenase

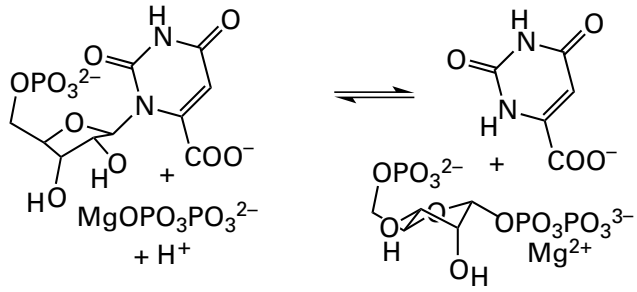


(3–426)

there is a maximum of absorbance in the difference Fourier transform infrared spectrum[854] of the resulting ternary complex at 1679 cm^{-1}. When [2-^{13}C]pyruvate associates with the same complex, the absorption with a maximum of absorbance at 1679 cm^{-1} is no longer present in the difference spectrum and is replaced with an absorption with a maximum of absorbance at 1640 cm^{-1}. The magnitude of the shift to lower frequency is that expected for the shift of the stretching vibration of a carbonyl group as a result of the increase of 1.00 g mol^{-1} in the molar mass of the carbon. Consequently, the maximum of absorbance at 1679 cm^{-1} was assigned to the stretching frequency of the carbonyl group in the [2-^{12}C]pyruvate occupying the active site. The frequency of the maximum of absorbance for the stretching vibration of the carbonyl in [2-^{12}C]pyruvate, which was assigned by isotopic editing, shifts –31 cm^{-1}, from 1710 to 1679 cm^{-1}, when the pyruvate enters the active site from the solution.

By recording a complete difference spectrum between the ternary complex of [2-^{12}C]pyruvate and that of [2-^{13}C]pyruvate with the active site occupied by NADH, **other vibrational modes in which this carbon participates** could also be identified, including a complex vibrational mode in which atoms from both pyruvate and the nicotinamide of NADH participate. This latter result is consistent with the obvious fact that pyruvate and NADH are intimately associated with each other in the active site.

Isotopic editing was also used to identify the stretching vibration of the ureido carbon–oxygen double bond at carbon 2 of orotidine 5′-monophosphate and the stretching vibration of the acyl carbon–oxygen double bond at carbon 4 of orotidine 5′-monophosphate when this substrate occupies the active site of orotate phosphoribosyltransferase



(3–427)

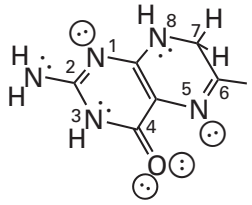
from *Plasmodium falciparum* in the absence of magnesium diphosphate. On the basis of these identifications, it could be unambiguously demonstrated that the frequencies of the maxima of absorbance for both absorptions shift to lower values by –20 cm^{-1} when orotidine 5′-monophosphate associates with the active site. In the crystallographic molecular model of the complex between the enzyme from *S. cerevisiae* and orotidine 5′-monophosphate, the oxygen at carbon 4 participates in two **short (0.26 nm) in-plane hydrogen bonds, trigonal at the oxygen**, with the nitrogen–hydrogen of an ω-guanidinio nitrogen of an arginine and an amido nitrogen–

hydrogen from the polypeptide, and the oxygen on carbon 2 participates in two out-of-plane hydrogen bonds with two fixed molecules of water.[855] Isotopic editing can also be used to identify absorptions from vibrational modes in phospho groups.[846]

Difference Raman infrared spectroscopy can be used to monitor the stretching frequency of the carbon–oxygen double bond of a carbonyl group or an acyl group in a substrate when it is bound in the active site of an enzyme. Again, the difference spectrum is between the spectrum of the unoccupied enzyme and the spectrum of the enzyme occupied by a substrate or an inhibitor. When pyruvate associates with the active sites of L-lactate dehydrogenases (Equation 3–426) from *G. stearothermophilus*, *Squalus acanthias*, and *Sus scrofa*,[856,857] each of which is already occupied by NAD^+, the stretching vibration of its carbonyl group in a difference Raman infrared spectrum decreases by $-42\ cm^{-1}$, from 1710 to $1668\ cm^{-1}$. Isotopic editing was used in this instance to validate the assignment of the absorptions. In the crystallographic molecular model of the complex between the active site of porcine L-lactate dehydrogenase and (3*S*)-5-(3-carboxy-3-hydroxypropyl)-nicotinamide-adenine dinucleotide (**3–89**), there are hydrogen bonds from the hydronated imidazolyl group of Histidine 195 and one of the ω-guanidinio nitrogens of Arginine 109 to the oxygen that is analogous to the carbonyl oxygen of pyruvate.[591]

Within a set of nine seryl-acyl enzyme intermediates (Equation 3–91) for three different serine endopeptidases, the common logarithm of the rate constant for the step in which the acyl intermediate is hydrolyzed (k_3 in Equation 3–91) was a linear function of the observed stretching frequencies (centimeters^{-1}) in the difference resonance Raman infrared spectra for the acyl carbon–oxygen double bond within the active site. As the stretching frequency of the substrate in the active site decreased, the common logarithm of the rate constant increased.[858,859] Each active site has an **oxyanion hole** into which the acyl oxygen in these acyl intermediates fits in the tetrahedral intermediates preceding and following the respective acyl intermediates. The correlation suggests that as the ability of an oxyanion hole to withdraw electron density from the carbon–oxygen double bond increases and the electrophilicity of the carbon increases, the rate of the hydrolysis of the acyl enzyme increases.

An advantage of difference Raman spectroscopy is that **many other infrared absorptions** can be observed in addition to the strong absorption of a carbon–oxygen double bond. For example, the absorptions in a difference Raman spectrum with absorbance maxima at 1650 and $1675\ cm^{-1}$ have been assigned to the stretching vibrations for the bond between unhydronated nitrogen 5 and carbon 6 of the pteridine ring in dihydrofolate and hydronated nitrogen 5 and carbon 6, respectively



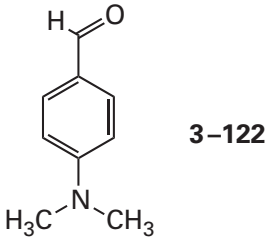
3–121

These absorptions shift reciprocally in relative absorbance with pH when dihydrofolate is in the active site of dihydrofolate reductase (previously Equation 1–89)

$$\text{NADPH} + \text{7,8-dihydrofolate} + H^+ \rightleftharpoons \text{5,6,7,8-tetrahydrofolate} + NADP^+ \quad (3\text{–}428)$$

from *E. coli*, and these reciprocal shifts in absorbance can be used to measure the pK_a of nitrogen 5 when the folate is in the active site.[860]

In the case of the stable ternary complex between equine alcohol dehydrogenase, an enzyme with a prosthetic Zn^{2+} in its active site, and NADH and 4-dimethylaminobenzaldehyde



3–122

which is a substrate for the enzyme, a complete difference Raman spectrum for the bound 4-dimethylaminobenzaldehyde could be collected from 300 to $1700\ cm^{-1}$ in which the 16 absorptions create a fingerprint for the substrate. This fingerprint was almost identical to that for the complex between Zn^{2+} and 4-dimethylaminobenzaldehyde in dichloromethane, which was proposed to mimic the situation of the substrate in the active site.[861]

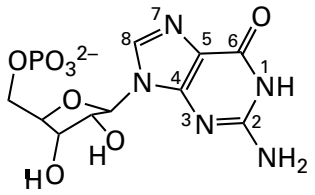
A **resonance Raman infrared spectrum** is observed when a chromophore in the active site is excited by passing a beam of light with a wavelength that is absorbed by that chromophore through the sample perpendicular to the beam from

the laser that is registering the Raman spectrum. The excitation of the chromophore by this perpendicular beam of light enhances the intensity of the absorptions from oscillators in the vicinity of the excited chromophore. For example, there is an oxidized, inactive form of murine cysteine dioxygenase

$$\text{L-cysteine} + O_2 \rightleftharpoons \text{3-sulfino-L-alanine} + H^+ \qquad (3\text{–}429)$$

that has mononuclear, nonheme Fe^{3+} in its active site rather than the Fe^{2+} present in the active enzyme. The complex between the substrate L-cysteine and the oxidized active site has a blue color resulting from an absorption with a maximum of absorbance at 640 nm. When this stable, inactive complex is excited by a perpendicular beam of light from a laser at a wavelength of 647 nm, two absorptions, with maxima of absorbance at 340 and 292 cm^{-1}, are enhanced sufficiently that they dominate the Raman spectrum in a region containing many overlapping unenhanced absorptions.[862] These enhanced absorptions were assigned to a stretching vibration of the bond between the Fe^{3+} and the sulfur of L-cysteine, which has become one of its ligands in the active site, and a bending vibration at the β carbon of that L-cysteine.

When the guanine (λ_{max} = 253 nm) in guanosine monophosphate



3–123

bound in the active site of human hypoxanthine phosphoribosyltransferase (Equation 3–398) is excited with a laser emitting light of wavelength 263 nm, eight vibrational modes in the guanine are enhanced and dominate the Raman infrared spectrum. Most of these vibrational modes are shifted relative to their positions in the infrared spectrum of guanosine monophosphate in free solution.[863] The maximum of absorbance for the stretching vibration at 1682 cm^{-1} of the acyl carbon–oxygen double bond at carbon 6 decreases in frequency by –40 cm^{-1}, and maxima of absorbance for two complex vibrational modes at 1538 and 1577 cm^{-1}, each involving both the nitrogen–hydrogen bond at nitrogen 1 and the amido group at carbon 2 in the guanidino group of the guanine, decrease in frequency by –11 cm^{-1}. In the crystallographic molecular model of the active site of human hypoxanthine phosphoribosyltransferase occupied by guanosine monophosphate,[864] Lysine 165 forms a hydrogen bond to the acyl carbon–oxygen bond at carbon 6 of the guanosine monophosphate, the acyl oxygen of the peptide bond of Valine 187 forms hydrogen bonds with the nitrogen–hydrogen bond of nitrogen 1 and one of the amido nitrogen–hydrogen bonds in the amido group on carbon 2, and the acyl oxygen of the peptide bond of Aspartate 193 forms a hydrogen bond with the other nitrogen–hydrogen bond of the amido group on carbon 2.

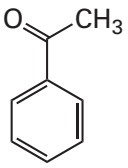
The absorption of the bending vibration at 1468 cm^{-1} of the nitrogen–hydrogen bond at nitrogen 1 of inosine monophosphate, observed in the resonance Raman infrared spectrum resulting from excitation at 260 nm, shifts by +5 cm when inosine monophosphate associates with the active site of adenylosuccinate synthase from *Methanocaldococcus jannaschii*.[865] This shift is consistent with a shift in the equilibrium between hydronated and unhydronated nitrogen 1 of the inosine monophosphate, the pK_a of which in solution is 12.5. The first step in the enzymatic reaction is the phosphorylation of the adjacent acyl oxygen in the amido group that includes nitrogen 1 by $MgATP^{2-}$. The dehydronation of nitrogen 1 by the carboxylato group of the aspartate with which it forms a hydrogen bond in the crystallographic molecular model[866] of murine adenylosuccinate synthase (26% identity; 1.8 gap percent) should be required to make the acyl oxygen sufficiently nucleophilic to engage in the nucleophilic substitution at phosphorus, even at the γphosphorus of $MgATP^{2-}$, and the shift in the absorption is consistent with this expectation.

Most authors of the foregoing infrared spectroscopic observations of the stretching vibrations of a carbon–oxygen double bond have proposed that the decreases in frequency for absorptions of the vibrational modes for carbon–oxygen double bonds that were observed upon association of the substrates or inhibitors with the respective active sites resulted from a weakening of those double bonds by the hydrogen bonds that are formed between the oxygen and the donors observed in the respective crystallographic molecular models. This weakening of the double bond would be brought about by a shifting of the electron density in the occupied π molecular orbital of the carbon–oxygen double bond toward the oxygen and thus in the direction of a configuration represented by the usually unfavored resonance

structure in which the oxygen bears a full negative formal charge, the carbon bears a full positive formal charge, and the double bond is broken. Consequently, in this view, the function of the donors for hydrogen bonds aligned by the active site would be to destabilize the ground state of the substrate relative to the immediate transition state by causing this shift in electron density.

This explanation of the shifts in the maxima of absorbance, however, is probably mistaken. First, the oxygen of each carbon–oxygen double bond accepts hydrogen bonds from molecules of water when it is free in solution, so the replacement of these hydrogen bonds by hydrogen bonds in the active site should be relatively inconsequential. Second, there are calculations suggesting that quite large local electric fields, larger than those that can be created by an active site, are required to produce significant shifts in electron density in the occupied π molecular orbital of a carbon–oxygen double bond.[850,867] Finally, it has been shown that **similar red shifts in the maximum of absorbance for a carbon–oxygen double bond do not result from decreases in its force constant**, as would be required if the active site were actually polarizing the occupied π molecular orbital significantly.

When acetophenone



3–124

is dissolved in nine different solvents, the frequency of the stretching vibration of the double bond of its carbonyl group shifts over a similar range (30 cm^{-1}) to the shifts observed in active sites, albeit increasing from water to hexane, from polar to nonpolar solvent, rather than decreasing as usually occurs when the carbonyls already discussed associate with the respective active sites from an aqueous solution. Nevertheless, similar shifts in infrared spectra of the stretching vibrations of carbon–oxygen double bonds in carbonyl and acyl groups upon changing solvent have often been invoked as a model for the shifts observed upon the association of a substrate with an active site. It has been demonstrated experimentally that the shifts in the observed frequency for the maximum of absorbance for the stretching vibration for the carbonyl group in acetophenone in these several solvents are not due to changes in the force constant of the bond, and hence its weakening, because the anharmonicity of the stretching vibration does not shift in concert with the shift in frequency of the absorption, as it must if the shift were due to a change in force constant, but remains unaltered within the resolution of the measurement.[868]

When a carbon–oxygen double bond is free in solution, **its fixed dipole induces an electric field in the solvent** surrounding it. The magnitude of this induced electric field can be estimated from known properties of the solvent.[869] When the shifts in the infrared absorptions of acetophenone in the same set of solvents used for the measurements of anharmonicity are plotted as a function of these calculated induced electric fields, a linear correlation is observed.[868,870] A similar linear correlation between the calculated values of the induced electric fields and the shift in infrared absorptions for 19-nortestosterone (**3–120**) was observed for the same set of solvents.[850]

The **sign on the component of an electric field at a carbon–oxygen bond and parallel to it** has been chosen so that the fixed electric field of the dipole of the carbon–oxygen bond in the ground state is positive, with oxygen at the negative end and carbon at the positive end. Since the induced electric field in water and the other solvents is, by definition, in the direction opposite to the fixed electric field of the dipole of the carbonyl group, the induced field has a negative sign.[871] As the induced local electric field becomes more negative, the stretching frequency of the carbon–oxygen double bond decreases. This convention for the sign of a local electric field in the vicinity of a carbon–oxygen double bond, based on the direction of its dipole, will be used from here on. A field with a negative sign is one that would be created by fixed positive formal charge in the surroundings that is closer to the oxygen than it is to the carbon or by a dipole oriented so that its positive charge is closer to the oxygen than it is to the carbon.

On the basis of the correlations between the induced local electric field in the adjacent solvent and the frequency for the maximum of absorbance, it has been proposed that the shifts in the maxima of absorbance for the stretching vibrations of carbon–oxygen bonds observed in the different solvents are the result of a vibrational Stark effect, rather than any change in the force constant or strength of the carbon–oxygen double bond.[870]

A **vibrational Stark effect** is a shift in the frequency of the maximum of absorbance for a vibrational mode produced by an electric field, either applied

externally to the entire solution or existing only in the immediate vicinity of the atoms participating in that vibrational mode.[871] It results from the fact that the lengths of the bonds participating in a particular vibrational mode increase in the excited state. Because the bond lengths increase, their dipoles increase, and the effect of the local electric field in their vicinity is greater in the excited state than in the ground state. In the particular case of the stretching vibration of a carbon–oxygen double bond in a carbonyl or acyl group, the dipole moment of the bond is large because of the difference in electronegativity between oxygen and carbon, and as a result, the difference in dipole moment between the ground state and the excited state is also significant. The local electric field, depending on its direction, may stabilize the excited state relative to the ground state and produce a red shift of the frequency of the maximum of absorbance to lower wavenumbers (lower energy), or it may destabilize the excited state relative to the ground state and produce a blue shift of the frequency of the maximum of absorbance to higher wavenumbers (higher energy). The important point in this description is that a vibrational Stark effect arises from a difference between the effect of the electric field on the excited state and its effect on the ground state and is a **property of only the spectroscopy and not a property of the bonds participating in the vibrational mode in the ground state** of the molecule. In other words, the force constants, and hence the strengths of the bonds themselves that are participating in the vibrational mode, can be unaffected by the electric field induced in the surroundings, but the presence of the field will nevertheless shift the frequency of the maximum of absorbance.

If the shifts in the stretching frequencies of the maxima of absorbance that are observed for its carbon–oxygen double bond when a carbonyl or acyl group enters an active site arise from the same physical process as these shifts in frequency in the various solvents, then they also should result from a vibrational Stark effect. Consequently, in practice, **the frequency of the maximum of absorbance in an infrared spectrum for the stretching vibration of a carbon–oxygen bond on a substrate or an inhibitor within an active site is a monitor of the local static electric field at the location of the carbon–oxygen bond created by the active site itself**.

There are a couple of **problems with using this shift in the frequency of the maximum of absorbance quantitatively to assess the local electric field in an active site**.[850,870,871] First, the slopes of the lines relating the shifts in frequency of the maximum of absorbance for both acetophenone (**3–124**)[868,870] and 19-nortestosterone (**3–120**)[850] and the calculated induced, microscopic electric fields in the various solvents, 0.41 and 0.70 cm^{-1} $(MV\,cm^{-1})^{-1}$, are considerably smaller than the slopes of the lines for the shifts in frequency for the maxima of absorbance in a fixed, applied, macroscopic electric field, 1.1 and 1.4 cm^{-1} $(MV\,cm^{-1})^{-1}$, respectively. It is unclear which of these coefficients should be used to estimate the fixed, microscopic electric field in an active site from shifts observed in infrared absorptions. Second, a carbon–oxygen double bond does not monitor the magnitude of the actual net local electric field, E_{loc}, at its position in the active site; it monitors only the component of the local electric field, $E_{loc}\cos\theta$, parallel to its fixed dipole, where θ is the angle between the net local electric field and the fixed dipole. Consequently, the actual electric field in its vicinity could be significantly larger than what it reports and not necessarily aligned with the carbon–oxygen double bond.* For both reasons, these measurements should be evaluated qualitatively.

Although reliable estimates of the absolute magnitude and direction of the electric field at the location of a carbon–oxygen double bond in a substrate or an inhibitor within an active site cannot be made by vibrational Stark effects, it nevertheless seems to be the case that **the shift in the frequency of its maximum of absorbance is linearly related to the magnitude of the component of the electric field parallel to the dipole of that carbon–oxygen bond**. A series of mutants of steroid Δ-isomerase (Equation 3–425) from *P. putida* were made in which Aspartate 103 was mutated to leucine or asparagine; Tyrosine 16 was mutated to phenylalanine, serine, or 3-chlorotyrosine; and Tyrosine 57 and Tyrosine 32, which participate in a network of hydrogen bonds with Tyrosine 16, were mutated to 3-chlorotyrosines. The frequencies of the maxima of absorbance of 19-nortestosterone (**3–120**) in the active sites of eight of these single and double mutants were linearly related to the common logarithm of their catalytic constants for the substrate androst-5-ene-3,17-dione.[850,853] As the frequency of the maximum of absorbance increases, and hence the red shift experienced when 19-nortestosterone enters the active site decreases, the common logarithm of the catalytic constant decreases. This linear

*In the case of steroid Δ-isomerase, however, calculations suggest that the static local electric field of the active site is aligned with the carbon–oxygen double bond.[872]

correlation is the one expected from the effect of an electric field on a particular standard free energy.

As the reaction catalyzed by steroid Δ-isomerase approaches its transition state, the electron density in the occupied π molecular orbital of the carbon–oxygen double bond is shifting onto the oxygen to become one of the lone pairs of electrons on the hydroxy group of the γ,δ-unsaturated enol that is the immediate intermediate (Equation 3–425). This shift in electron density is the result of the unfolding reaction, not a shift in the ground state prior to the onset of the reaction. This inescapable **shift in electron density onto the oxygen in the transition state** causes the negative elementary charge on the oxygen to increase, and this increase in negative charge in the transition state is favored by the component of the fixed, local negative electric field created by the distribution of formal charge and dipoles within the active site parallel to the dipole of the initial carbon–oxygen bond. A decrease in this component of the field, which results in a directly proportional decrease in the electric potential energy experienced by the transition state, should be linearly related to the standard free energy of activation, as is observed, because electric fields exert their influence on standard free energies in direct proportion. It has already been noted that a similar correlation exists between the frequencies of maximum absorption of the carbon–oxygen double bond in a series of seryl-acyl enzyme intermediates in the active sites of three endopeptidases and the common logarithms of the rate constants for their hydrolysis. Each result suggests that **the local electric field established by the active site can participate directly in catalyzing an enzymatic reaction.**

As is the case with the active site of steroid Δ-isomerase, in almost all the other examples of carbon–oxygen double bonds discussed earlier, because they involve red shifts when the substrate or inhibitor enters the active site, the local, fixed electric fields created by the respective active sites and experienced by the carbon–oxygen bonds upon their association with the active site must be more negative than the local electric fields induced by these same carbonyl and acyl groups when they are in water. In the active sites of triose-phosphate isomerase, L-lactate dehydrogenase, and serine endopeptidases, the negative elementary charge on the oxygen of the carbon–oxygen double bond increases in the respective transition state in the reaction. Consequently, a fixed, negative electric field existing in the ground state along the respective carbon–oxygen bond that is greater than the negative electric field induced in the surrounding water when the reactant is in solution provides greater stabilization of the transition state than does water and favors catalysis. In the active sites of orotate phosphoribosyltransferase and hypoxanthine phosphoribosyltransferase, either orotate or guanine is the **leaving group in the nucleophilic substitution**, so local negative electric fields at the respective carbon–oxygen bonds should stabilize excess negative charge accumulating on the oxygens in the transition state as orotate or guanine is leaving.

Mutation of an amino acid acting as a donor in a hydrogen bond with the oxygen of a carbon–oxygen double bond in a crystallographic molecular model of an occupied active site causes the frequency of the maximum of absorbance for its stretching vibration to increase by +20 to +60 cm^{-1}. In fact, the +61 cm^{-1} shift that occurs upon mutation of Tyrosine 16 in the active site of steroid Δ-isomerase[850] shifts the frequency of the maximum of absorbance of the carbon–oxygen bond by +20 cm^{-1} relative to its value in water. These results suggest that **the major contributors in an active site to the negative electric field along the axis of a carbon–oxygen bond in the ground state are the donors for hydrogen bonds to the oxygen**.[871] This conclusion seems reasonable. Each donor has a dipole moment that is positive at the hydrogen in the hydrogen bond and negative at the respective heteroatom on which the hydrogen is located. Each dipole producing these dipole moments is as intimate to the oxygen of the carbon–oxygen bond as possible because a hydrogen bond always brings the atoms participating much closer together than the sum of their van der Waals radii and covalent bonds.

Even though the oxygen of the carbon–oxygen bond is an acceptor for hydrogen bonds from water when it is in solution, the relative permittivity of an aqueous solution (80) is large while the relative permittivity of an occupied active site is much smaller. The strength of the electric field created by a fixed dipole is inversely proportional to the relative permittivity of the surroundings, so a smaller relative permittivity increases the strength of the electric field produced by each donor for a hydrogen bond even if their dipole moments are the same as that of a molecule of water. There may also be a contribution to the electric field that results from the donors being rigidly oriented by the active site. In any case, the donors for hydrogen bonds, although they probably do not significantly shift the electron density of the carbon–oxygen bonds in the ground state, do provide the electric field that stabilizes the

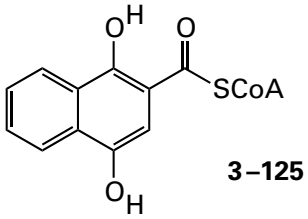
shift of electron density onto the oxygen that occurs in the respective transition states. In effect, the explanation of the effect is quite different even though the origin of the effect, the hydrogen bonds, is the same.

The frequency of the maximum of absorbance for a carbon–oxygen bond can also demonstrate a **blue shift** relative to the frequency for the maximum of its absorbance in water. When an phenacyl group, spectrally equivalent to acetophenone, is substituted synthetically for Phenylalanine 8 in bovine ribonuclease S, the frequency of the maximum of absorbance for the stretching frequency of its carbonyl group (1688 cm^{-1}) experiences a blue shift of +19 cm^{-1} relative to that for the same phenacyl group in water (1669 cm^{-1}).[870] In the crystallographic molecular model of bovine ribonuclease S,[873] Phenylalanine 8 is in a nonpolar pocket, but its π molecular orbital system is in van der Waals contact with the imidazolyl group of Histidine 12. Consequently, the blue shift in the maximum of absorbance for the phenacyl group is not so large as the one observed when it is transferred from water to hexane, +27 cm^{-1}, which represents a completely nonpolar environment. The blue shift (+11 cm^{-1}), however, observed in the frequency of the maximum of absorbance for the stretching vibration for the carbonyl of pyruvate bound in the active site of L-lactate dehydrogenase when it is occupied by NADH, relative to the active site when it is occupied by NAD^+. This blue shift results from the fact that the positive elementary charge on NAD^+, because it is immediately adjacent to the carbon of the carbon–oxygen bond rather than the oxygen, causes the local electric field experienced by the carbon–oxygen bond to be more negative.

Ultraviolet and visible absorption spectra are also used to examine the environment of chromophores on substrates or inhibitors when they are bound to active sites. For example, when 19-nortestosterone (**3–120**) is bound to steroid Δ-isomerase from *C. testosteroni*, the maximum of absorbance for the enone in the ultraviolet absorption spectrum shifts[849] from 248 to 260 nm. When 19-nortestosterone ($pK_{a,C=OH^+} = -2.3$) is dissolved in 10 M sulfuric acid, almost the same shift, from 248 to 258 nm, is observed.[874] The compressed hydrogen bonds (0.26 nm)[853] formed between the carbonyl oxygen of 19-nortestosterone and Aspartate 99 and Tyrosine 14 in the active site of the enzyme from *C. testosteroni* may mimic the hydronation that occurs in 10 M sulfuric acid.

Neither of these donors for hydrogen bonds, however, is anywhere near so strong an acid as a hydronium. The shift observed may in part be the result of the local electric field caused by the dipoles of these two donors that was detected by the Stark effect on infrared spectra of 19-nortestosterone when it is bound to the active site of steroid Δ-isomerase (Equation 3–425) from *P. putida*. It has been shown that a shift of the same magnitude in the ultraviolet spectrum of steroids closely related to 19-nortestosterone can be produced in a nonpolar environment by the dipole of an adjacent hydroxy group that is incapable of forming a hydrogen bond with the oxygen.[875] If the delocalized electrons in the π molecular orbital system are shifted toward the oxygen by the local electric field of the oxygen–hydrogen bond in the carboxy group of Aspartate 99 and the hydroxy group of Tyrosine 14, which are participating in hydrogen bonds with the oxygen, more than they are by the donors for hydrogen bonds from molecules of water in the solution, there should be a greater separation of charge in the molecule than it has in solution. Zwitterionic molecules, such as a pyridoximine of pyridoxal phosphate, in which the two opposite formal charges are on atoms that are conjugated to each other by a π molecular orbital system, have absorbances that are red-shifted relative to their conjugate acids and conjugate bases (Figure 2–1)[876] or to nonzwitterionic analogues with an isoelectronic π molecular orbital system. There must also be a contribution to the red shift observed in the wavelength for the maximum of absorbance from the decrease in relative permittivity experienced when the enone leaves the solution and enters the active site. The wavelength for the maximum of absorbance for an unconjugated carbonyl group shifts to higher wavelength as the relative permittivity of the solvent in which it is dissolved decreases, and the range of wavelengths over which this red shift occurs (about 10 nm) in mixed solvents from water to dioxane[877] is the same as the red shift that is observed when 19-nortestosterone associates with the active site.

A larger red shift in the maximum of absorbance, from 368 to 408 nm, is observed in the ultraviolet spectrum of 1-hydroxy-2-naphthoyl-SCoA, an analogue of the product 1,4-dihydroxy-2-naphthoyl-SCoA

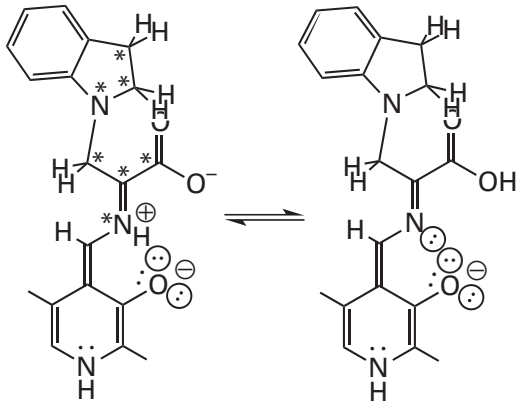


3–125

when it associates with the active site of 1,4-dihydroxy-2-naphthoyl-CoA synthase from *E. coli*. In this instance, however, the shift was attributed to dehydronation of the 1-hydroxy group by a base on the active site.[878] The dehydronation increases the conjugation of the oxygen of the thiocarboxy group on carbon 2 with the naphthoyl group, resulting in a shift of its maximum of absorbance to longer wavelengths, the same reason that dehydronation of a tyrosine in a protein shifts its maximum of absorbance from 275 to 293 nm.[879]

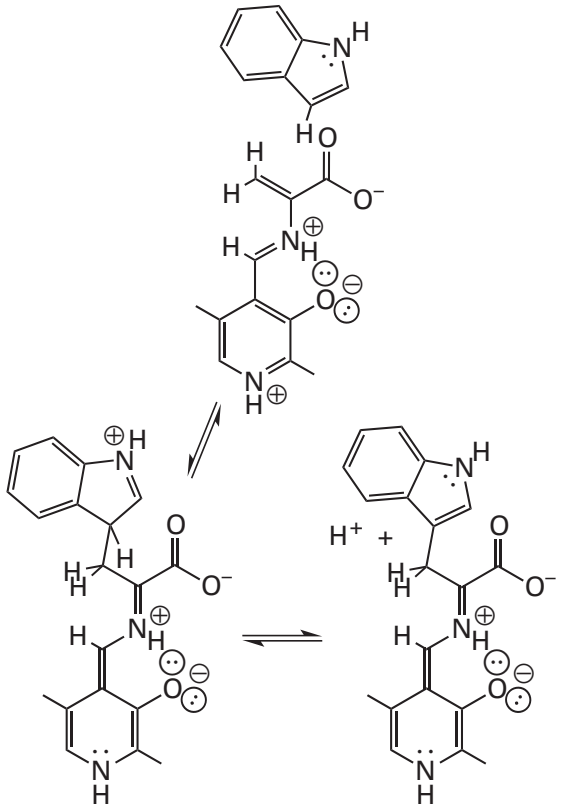
Nuclear magnetic resonance spectroscopy is used to examine the environment experienced by a nucleus of nonzero spin such as carbon-13, nitrogen-15, or fluorine-19* that has been incorporated into a substrate or inhibitor when it is bound to an active site. For example, deoxyuridine monophosphate labeled with **carbon-13** at carbon 2 or at carbon 4 both register the dehydronation of nitrogen 3 ($pK_a = 9.2$), which sits between them, by a downfield shift in their absorptions in a nuclear magnetic resonance spectrum of 8 parts per million (ppm). When either isotopically labeled deoxyuridine monophosphate is in solution, nitrogen 3 is hydronated, but after each of them has associated with the active site of thymidylate synthase (FAD) from *T. maritima*, nitrogen 3 is unhydronated. Site-directed mutation identifies the guanidinio group of Arginine 174 as the functional group in the active site responsible for the fact that deoxyuridine monophosphate is unhydronated following its association.[880] Whether the active site preferentially associates with the conjugate base or is itself responsible for the dehydronation is not clear, but it is possible to observe the dissociation of the hydron that occurs upon the association with an indicator of pH.

Labeling of indolene and L-serine with both carbon-13 and **nitrogen-15** at the locations marked with asterisks has been used to assign the tautomeric equilibrium in the quinonoid intermediate



(3–430)

that indolene forms on the active site for tryptophan synthase (indole-salvaging) within tryptophan synthase from *S. typhimurium*. This saturated quinonoid intermediate results from addition of the anilino nitrogen of the indolene ($pK_a \cong 29$) to the external pyridoximine of 2-aminoacrylate rather than the aromatic π electrons of unsaturated, aromatic indole. This adduct is an analogue of the quinonoid intermediate formed by electrophilic aromatic substitution on the indole by the electrophilic external pyridoximine of 2-aminoacrylate produced from L-serine in the normal enzymatic reaction



(3–431)

In this instance, an equilibrium between two different molecules (Equation 3–430) is being monitored by the physical method.

*Carbon-13 (1.1%) and nitrogen-15 (0.4%) are rare isotopes of carbon and nitrogen, but fluorine-19 is the naturally abundant isotope (100%) of fluorine.

The three **fluorine-19** atoms in MgF_3^-, an analogue of monomeric metaphosphate, when it associates with the complex between the active site of unphosphorylated β-phosphoglucomutase from *L. lactis* and the substrate β-D-glucose 6-phosphate, each have unique maxima of absorbance at −147, −152, and −159 ppm, respectively. Each peak reflects the **shielding** or **deshielding** that the unique electric field in the vicinity of its fluorine nucleus produces. There is no $[^{19}F]MgF_3^-$ in the solution in the absence of enzyme because it only forms on the active site, which is constructed to bind PO_3^- tightly, but if there were, its three fluorines would all be identical.

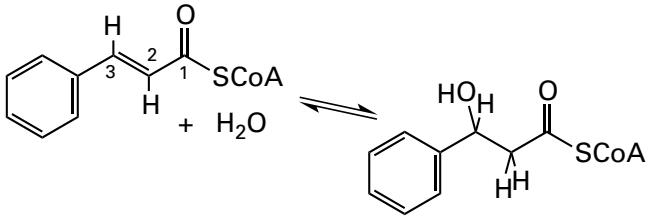
There are certain alterations in double-stranded DNA that convert a cytosine into a thymine with the result that a thymine is paired with a guanine, a mispairing that can lead to mutations. Thymine-DNA glycosylase recognizes these mispairings and hydrolyzes the hemiaminal between ribose and thymine. As has already been mentioned, in the first step in this hydrolysis, the thymine swings out of the stack of bases into the catalytic portion of the active site. The absorption of 2′-fluoro-*arabino*-deoxythymidine, which has been incorporated into duplex DNA so that its thymine is mispaired with a guanine, shifts upfield by −7 to −11 ppm from its absorption at −115 ppm in the stacked conformation, which predominates in solution, when it associates with the active site of human thymine-DNA glycosylase and flips out of the stack. The equilibrium constants between stacked and flipped conformations when the DNA is in the active site of the enzyme for four different double-stranded DNAs is proportional to the catalytic constant for the hydrolysis of hemiaminal in the active site.[881]

Nuclear magnetic resonance spectroscopy can also be used to obtain information about the electric field created by the active site and experienced by a **carbon–oxygen double bond** in a substrate or an inhibitor. The substrate or inhibitor can be synthesized, either chemically or enzymatically, in such a way that the carbon in the carbon–oxygen double bond is carbon-13 rather than carbon-12 while all the other carbons are normal carbon-12. A complex can then be formed with the modified substrate or inhibitor, and the carbon-13 nuclear magnetic resonance spectrum can be taken. For example, in a solution of 3 mM active sites of porcine citrate (*Si*)-synthase

$$\text{oxaloacetate} + \text{acetyl-SCoA} + H_2O \rightleftharpoons H^+ + \text{HSCoA} + \text{citrate} \qquad (3\text{–}432)$$

containing 3 mM carboxymethyl-SCoA, an analogue of the enolate of acetyl-SCoA,* and 3 mM [2-^{13}C]oxaloacetate, the active sites are saturated with carboxymethyl-SCoA and [2-^{13}C]oxaloacetate, and very little of either ligand remains free in solution. In the carbon-13 nuclear magnetic resonance spectrum, the carbon-13 at the carbonyl carbon in [2-^{13}C]oxaloacetate has a maximum of absorbance at 206.6 ppm, shifted downfield +7 ppm from its maximum of absorbance in free solution (199.9 ppm).[882] In the crystallographic molecular model of the same complex, the imidazolyl group of Histidine 320 and one of the ω-nitrogen–hydrogens of the guanidinio group of Arginine 329 are donors for two in-plane, trigonally arrayed hydrogen bonds (0.29 and 0.26 nm, respectively) to the carbonyl oxygen of the oxaloacetate.[883] When Histidine 320 is mutated to a glycine,[884] the maximum of absorbance for carbon-13 is at 200.7 ppm, only +1 ppm from its maximum of absorbance in free solution.

Cinnamoyl-SCoA, a substrate for the addition to a carbon–carbon double bond catalyzed by enoyl-CoA hydratase



(3–433)

can be synthesized in three isotopically labeled forms: [1-^{13}C]cinnamoyl-SCoA, [2-^{13}C,2-^{2}H]cinnamoyl-SCoA, and [3-^{13}C,3-^{2}H]cinnamoyl-SCoA. Carbon-13 nuclear magnetic resonance spectra of complexes between the active site of bovine enoyl-CoA hydratase and each labeled substrate in turn were obtained. The chemical shift of the maximum of absorbance for carbon 1 (201.0 ppm) was situated downfield by +5.1 ppm relative to its chemical shift in solution (195.9 ppm); that of carbon 2 (126.1 ppm) was situated upfield by −0.8 ppm relative to its chemical shift in solution (126.98 ppm); and that of carbon 3 (147.2 ppm) was

*The enolate is an intermediate in the enzymatic reaction. It is the nucleophile in the nucleophilic addition to the carbonyl group of oxaloacetate (see Equation 3–409) catalyzed by the enzyme.

situated downfield by +3.2 ppm relative to its chemical shift in solution (144.0 ppm).[885] In the crystallographic molecular model of enoyl-CoA hydratase from *R. norvegicus* occupied by 4-dimethylaminocinnamoyl-SCoA,[886] there are two amido groups from the polypeptide forming an oxyanion hole for the acyl oxygen of the cinnamoyl group, one at a location normal to the plane of the cinnamoyl group and the other near a tetrahedral position around the oxygen relative to the first.

The downfield shifts experienced by the [^{13}C]carbonyl carbons in oxaloacetate and cinnamoyl-SCoA result from **deshielding of the respective carbons**. As such, they indicate that electron density has shifted away from the carbon-13 of the carbonyl group. In oxaloacetate, this shift in electron density must be onto the oxygen of the carbonyl. In the extended π molecular orbital system of the cinnamoyl group, there is no necessity that it should be so, but it has been calculated that the shift of electron density from the carbon is also onto the oxygen.

These more or less unambiguous conclusions that **electron density in the respective π molecular orbital systems shifts from carbon to oxygen in the ground state** appear to contradict the proposal that electron density in the highest occupied π molecular orbitals of a carbon–oxygen double bond in a carbonyl or acyl group, when it enters an active site, is not displaced sufficiently in the direction of the oxygen to change the force constant of the carbon–oxygen bond. That the deshielding observed in the nuclear magnetic resonance spectrum of cinnamoyl-SCoA must result from a shift in electron density in the highest occupied π molecular orbital follows from the fact that the deshielding is also experienced by carbon 3, which has a lobe over it in the highest occupied π molecular orbital, but not by carbon 2, which has a node at its location. In the case of cinnamoyl-SCoA, however, it has been estimated that a shift in electron density at carbon 1 in the cinnamoyl group onto the oxygen atom equal to only about 0.02–0.05 of an elementary charge can account for the deshielding of +5.1 ppm, or about 1–2% of the electron density in the highest occupied molecular orbital. Since the deshielding is about the same (+7 ppm) at carbon 2 in [2-^{13}C]oxaloacetate, in the active site of citrate (*Si*)-synthase, the shift in electron density should also be about the same.[887] These shifts are fairly small and could well not measurably affect the force constant for the stretching frequency of a carbon–oxygen double bond yet cause an easily measurable increase in chemical shift.

The shift of electron density onto the oxygen in both oxaloacetate and cinnamoyl-SCoA that is registered by the deshielding results from the component of the local electric field along the carbon–oxygen bond created by the donors for hydrogen bonds to the respective oxygens. This component of the electric field in each case must have a negative sign to explain the deshielding. In the transition states of both enzymatic reactions, negative charge increases on these oxygens. Consequently, these local electric fields will stabilize the respective transition states relative to the ground states and contribute favorably to the catalysis.

By examining the two- and three-dimensional spectra of an unbound substrate or inhibitor in the solution surrounding an enzyme, it is possible to observe the residua of **nuclear Overhauser effects** between two hydrogen-1 atoms, a proton on the enzyme, substrate, or inhibitor and another proton on the substrate or inhibitor. These nuclear Overhauser effects were initiated while the substrate or inhibitor was associated with the active site of an enzyme, and they persist after its dissociation. The **transfer of saturation between two protons** that is accomplished while a substrate or inhibitor is bound to the active site of an enzyme persists for an interval long enough for the substrate or inhibitor to dissociate because relaxation is slow in nuclear magnetic resonance spectroscopy. If the substrate or inhibitor usually dissociates from the active site before relaxation has occurred, then the population of unbound ligand in the solution will contain a significant subpopulation of recently released individuals that retain the transfer of saturation that they gained while they were bound, and this subpopulation of unbound ligands will experience a nuclear Overhauser effect in the absorption of each proton to which saturation was transferred. This nuclear Overhauser effect will be manifested in the nuclear magnetic resonance spectrum of the entire population of unbound ligands at the chemical shift that the proton has when it is on the unbound ligand free in solution. It follows that, to observe such **transferred nuclear Overhauser effects**, the substrate or inhibitor must be in rapid exchange between the site and the solution, with a rate constant for dissociation from the site greater than the rate constant for the relaxation of its saturation.

Transferred nuclear Overhauser effects[888] can be produced by transfer of saturation either between a proton on a side chain in the active site and a proton on a substrate or inhibitor[889,890] or between two protons on the substrate or inhibitor while it is

bound in a particular conformation in the active site.[891] Saturation transfer produces negative nuclear Overhauser effects; a population of protons to which saturation has been transferred does not absorb so strongly as an equivalent population to which saturation has not been transferred. Because negative nuclear Overhauser effects are usually not observed between protons in a rapidly rotating small molecule in free solution, negative nuclear Overhauser effects observed for peaks of absorption of protons in a substrate or inhibitor in rapid equilibrium with an active site can be confidently assigned to saturation transfer that occurs when the substrate or inhibitor is bound to the site, and these negative nuclear Overhauser effects indicate that the two protons, one that has been saturated and one to which this saturation has been transferred, were close to each other in the conformation of the ligand bound to the site.

In several instances, the proximities between protons producing transferred nuclear Overhauser effects have been checked against crystallographic molecular models of the respective complexes and found to be consistent.[891-893] For example, the seven negative, transferred nuclear Overhauser effects observed in two-dimensional nuclear magnetic spectra of the hexapeptide Thr-Pro-norVal-*N*-methyl-Leu-Tyr-Thr, when it is in solution with porcine elastase and rapidly entering and leaving the active site, arise from pairs of protons on the peptide that are 0.2–0.4 nm apart in the crystallographic molecular model of the complex between this inhibitor and the enzyme.[894]

The **agreement of observed transferred nuclear Overhauser effects between protons with the proximities of the hydrons in crystallographic molecular models** of appropriate complexes provides reassurance that transferred nuclear Overhauser effects are informative in situations for which crystallographic molecular models are not available. For example, transferred nuclear Overhauser effects for acetylcholine in complex with acetylcholine receptor from *T. californica*[895] and for micellar 1-(hexylthio)-2-(nonanoylamino)-1,2-dideoxy-*sn*-glycero-3-phosphocholine in complex with phospholipase A_2 from *N. atra*[896] have been used to define the conformations adopted by this ligand and this inhibitor, respectively, when they are bound by their respective sites. Crystallographic molecular models were unavailable at the time for either complex.

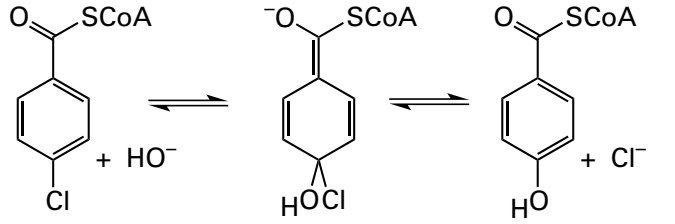
Nuclear magnetic resonance spectroscopy can provide other **information that cannot be obtained by crystallography**. For example, the hydronation state of amino acid side chains in a crystallographic molecular model, which usually can be determined only by neutron diffraction, can be established from two-dimensional nuclear magnetic resonance spectra of the same complex between the enzyme and the particular ligand of interest.[897] The tautomeric state of the neutral imidazolyl group of a particular histidine in the active site of an enzyme can be established by nuclear magnetic resonance spectroscopy.[898] If it is in the range of rate constants for relaxation of excited states in nuclear magnetic resonance spectroscopy, the rate constant for the dissociation of a substrate or inhibitor from an active site can be estimated.[899] In the case of enzymes in which a substrate or intermediate must be bound in two different orientations at different steps in the enzymatic reaction, the observation of two distinct maxima of absorption in a nuclear magnetic resonance spectrum from the same nucleus originally in a substrate or inhibitor when the substrate or inhibitor is within the active site provides evidence for the existence of the two orientations. Such an observation has been made with the inhibitor 6-deoxy-6-fluoro-α-D-glucopyranosyl phosphate when it is bound in the active site of phosphoglucomutase from *O. cuniculus*,[900] an active site that must accommodate two orientations of the intermediate α-D-glucose 1,6-bisphosphate during the enzymatic reaction, just as the active site of phosphoglycerate mutase (Equation 3–421) must accommodate two orientations of the intermediate in its reaction.

Nuclear magnetic resonance spectroscopy can be used, just as crystallography is used, to obtain a **molecular model of the complex between an enzyme and a substrate or inhibitor**.[851,901] These nuclear magnetic molecular models are obtained by the usual procedures of assigning all the proton absorptions from the complex in two- and three-dimensional nuclear magnetic resonance spectra and then tabulating all nuclear Overhauser effects between them. The problem with such molecular models when active sites are examined is their low resolution. For example, in the molecular model of 19-nortestosterone (**3–120**) occupying the active site of steroid Δ-isomerase from *C. testosteroni* built from 1647 nuclear Overhauser effects (an average of 13.2 effects for each amino acid in the enzyme), it could not be determined unequivocally whether or not the carboxy group of Aspartate 99 and the hydroxy group of Tyrosine 14 form hydrogen bonds with the carbonyl oxygen of the inhibitor.[851] Crystallographic molecular models, however, because of their higher resolution,

unequivocally establish that they do, and they provide a measurement of the lengths of the hydrogen bonds.[852,853]

Originally, it was thought that molecular models derived from nuclear magnetic resonance spectra had the advantage that the molecules of enzyme were in solution, but this claim ignored the fact that molecules of enzyme in a crystal are still in solution. Molecular models from nuclear magnetic resonance spectroscopy, however, do have the advantage that different conformations of an enzyme in solution can be observed in equilibrium with each other rather than in separate crystals. There is also the advantage that a molecular model of a molecule of protein that has not yet been crystallized can be constructed from cross peaks in two-dimensional nuclear magnetic resonance spectra of that protein in solution, if the protein is small enough.

4-Chlorobenzoyl-CoA dehalogenase from *Pseudomonas* catalyzes the hydrolysis of 4-chlorobenzoyl-SCoA in a nucleophilic aromatic substitution



(3–434)

The stable complex between its active site and its substrate 4-hydroxybenzoyl-SCoA has been **examined by nuclear magnetic resonance spectroscopy, infrared spectroscopy, and ultraviolet spectroscopy**.[902] When the labeled substrate [^{13}C=O]4-hydroxybenzoyl-SCoA associates with the active site, the maximum of absorbance for the carbon-13 in the acyl group in a nuclear magnetic resonance spectrum shifts downfield +2.8 ppm, from 193.2 to 196.0 ppm. When the unlabeled substrate, 4-hydroxybenzoyl-SCoA, associates with the active site, the frequency of the maximum of absorbance for the stretching vibration of its acyl carbon–oxygen bond in the difference Raman infrared spectrum shifts −12 cm^{-1}, from 1609 to 1597 cm^{-1}, and the maximum of absorbance for its benzoyl group in the ultraviolet spectrum shifts to the red from 292 to 373 nm.

Both the deshielding of the carbon in the carbon–oxygen double bond and a vibrational Stark effect on the frequency of the maximum of absorbance for its stretching vibration are consistent with the existence of a significant component of an electric field, of negative sign, produced by the active site along the axis of the carbon–oxygen double bond of 4-hydroxybenzoyl-SCoA. In the crystallographic molecular model of the active site of the complex between the enzyme and 4-hydroxybenzoyl-SCoA, there is an oxyanion hole for the carbon–oxygen double bond that consists of two amido groups from the polypeptide, one normal to the plane of the benzoyl ring and the other near a tetrahedral location relative to the first.[699] This oxyanion hole should provide an electric field with a component along the axis of the carbon–oxygen double bond of negative sign. In the transition states leading to the tetrahedral intermediate in the nucleophilic aromatic substitution, in either direction, negative charge is greater on the oxygen than in the ground state because a negatively charged nucleophile has been added to carbon 4, and the acyl oxygen ends up with the majority of that negative charge in the pentadienyl intermediate of the nucleophilic aromatic substitution. This increase in negative charge, and hence the transition state, is stabilized by such an electric field.

The electric field detected by nuclear magnetic resonance spectroscopy and infrared absorption would cause a polarization of the highest occupied π molecular orbital system of the 4-hydroxybenzoyl group in 4-hydroxybenzoyl-SCoA, and the separation of charge produced by this polarization could be responsible in part for the red shift in the maximum absorption in the ultraviolet spectrum. The red shift observed, however, seems too large for such an effect to be responsible for it. In this instance, the change in relative permittivity between the solution and the active site should not be consequential, because the ultraviolet absorption spectrum of benzaldehyde actually displays a small blue shift upon transfer from water to cyclohexane.[903] It has been suggested that the red shift observed is in large part the result of a dehydronation of the 4-hydroxy group on 4-hydroxybenzoyl-SCoA by the carboxylato group of an aspartate that forms a hydrogen bond to it in the crystallographic molecular model.[699] In support of this possibility is the fact that the wavelength of the maximum of absorbance for 4-hydroxymethylbenzoyl-SCoA only shifts from 292 to 323 nm when it associates with the active site. The dehydronation of the oxygen following the initial addition of hydroxide to carbon 4 would provide push during the dissociation of the chloride.

Induced Fit

From crystallographic molecular models, it has become apparent that the active sites of enzymes display a spectrum of structural responses to the association of substrates. At one end of the spectrum are active sites the structures of which are affected very little when a substrate binds.[906] An example is ribonuclease T_1 from *Aspergillus oryzae*. The crystallographic molecular models of the polypeptide surrounding the active site of this enzyme display only a few reorientations of the side chains of amino acids surrounding and creating the active site upon association of an analogue for the substrate in the enzymatic reaction.[907-909] At the other end of the spectrum are active sites that close around the substrates as they bind so that the amino acids forming the active site and responsible for catalysis are assembled and properly oriented only after the substrates have associated. An example is hexokinase from *S. cerevisiae*.[910] When D-glucose associates with the enzyme, its structure changes so significantly that the unliganded enzyme and the liganded enzyme form crystals that are not isomorphous.[911] This difference in structure results from a rigid-body movement of 12° about an axis between two independently shifting domains within the same subunit. This movement closes the active site, which lies in the crevice between the domains, around the bound substrates (Figure 3–55).[910,912] Between the extremes represented by ribonuclease T_1 and hexokinase, examples of a variety of intermediate structural responses can be found.

B

Figure 3–55: Space-filling model of the two conformations of a subunit of hexokinase from *S. cerevisiae*: (**A**) the form in which the active site is open and (**B**) the form in which the active site is occupied by D-glucose and the protein has closed around the substrate.[912] The crystallographic molecular model of the open form was constructed from a map of electron density calculated from the reflections of a crystal of hexokinase with space group $P2_12_12_1$. The phases were determined by isomorphous replacement. The crystallographic molecular model of the closed form was obtained from crystals of the enzyme complexed with D-glucose. Although these crystals were, by chance, also of the space group $P2_12_12_1$, the dimensions of the unit cell and the packing of the protein were completely different. The phases of the reflections from this nonisomorphous crystal were also determined by multiple isomorphous replacement independently of the previous crystallographic study of the open form. The active site lies in the deep cleft between the two lobes of the open form (Panel A). When D-glucose is bound in this cleft, the lobes close around the active site to enclose the molecule of D-glucose (atoms highlighted with speckled pattern). Reorientations of the side chains of amino acids in the active site upon the association of substrates, such as those observed for phosphoserine phosphatase from *Methanococcus jannaschii* (Figure 3–56),[913] are probably universal. A particularly striking example is the rotation of –160° around the bond between the α carbon and β carbon of Tyrosine 248 in bovine carboxypeptidase, with no change in the position of these two carbon atoms, that brings the 4-hydroxy group of the side chain into a hydrogen bond with the carboxy-terminal carboxylato group of its substrate.[914,915]

Occasionally, a **prosthetic group shifts its position** rather dramatically during the association of a substrate. In a crystallographic molecular model of the active site of 4-hydroxybenzoate 3-monooxygenase

$$\text{4-hydroxybenzoate} + \text{NADPH} + \text{H}^+ + \text{O}_2 \rightleftharpoons \text{3,4-dihydroxybenzoate} + \text{NADP}^+ + \text{H}_2\text{O} \qquad (3\text{–}435)$$

from *P. aeruginosa*, in which the substrate 4-hydroxybenzoate is bound, the isoalloxazine of the prosthetic flavin in the enzyme sits between the bound 4-hydroxybenzoate and the solution. In a crystallographic molecular model of another conformation of the enzyme, however, the isoalloxazine has slid aside, providing unhindered access to the site with which the 4-hydroxybenzoate associates.[916] It was concluded that, following association of 4-hydroxybenzoate with this open version of the subsite, the isoalloxazine slides over it, isolating it from the solution. In crystallographic molecular models of the active site of the flavoenzyme L-ornithine N^5-monooxygenase [NAD(P)H] from *Neosartorya fumigata*, the adenylate and the phosphoribose to which the isoalloxazine of the prosthetic flavin adenine dinucleotide is attached are firmly anchored within the protein, but the isoalloxazine can swing into and out of the active site by pivoting on the stationary single bond between carbons 1′ and 2′ of the phosphoribosyl group. In the unoccupied active site, the flavin has swung out of the active site, but when the active site is occupied by either the substrate L-ornithine or the substrate NAD^+ or both of them, the flavin has swung in to leave room for them to bind.[917]

Another change in the conformation of an enzyme that is often observed when crystallographic molecular models of liganded and unliganded versions are compared is a **tightening of the structure** of the protein surrounding the active site. Segments of secondary structure around the active site often shift perceptibly in the direction of a bound inhibitor or substrate as if closing around it (Figure 3–57).[918-922] When crystallographic molecular models of unoccupied enzyme and enzyme occupied by substrates or inhibitors are compared, this tightening is also manifested as significant decreases in the crystallographic *B*-factors of segments of the polypeptide surrounding the active site[923] or increases in the order parameters for relaxation of the excitation of amido hydrons in the polypeptide backbone surrounding the active site in nuclear magnetic resonance spectra.[924,925] In small proteins with large substrates, this tightening often occurs over the entire structure of the protein.

In enzymes with two reactants, in which association of the reactants with the active site is ordered, association of the first reactant can cause **conformational changes that create the subsite for the second reactant**. For example, when aspartate carbamoyltransferase (Equation 3–220) from *E. coli* binds carbamoyl phosphate, which is the first reactant to associate with the enzyme (Figure 3–14), there are small but significant changes in the conformations of the side chains that surround the carbamoyl phosphate as well as shifts in the polypeptide backbone that together create the subsite for L-aspartate, the second reactant to bind to the active site.[926]

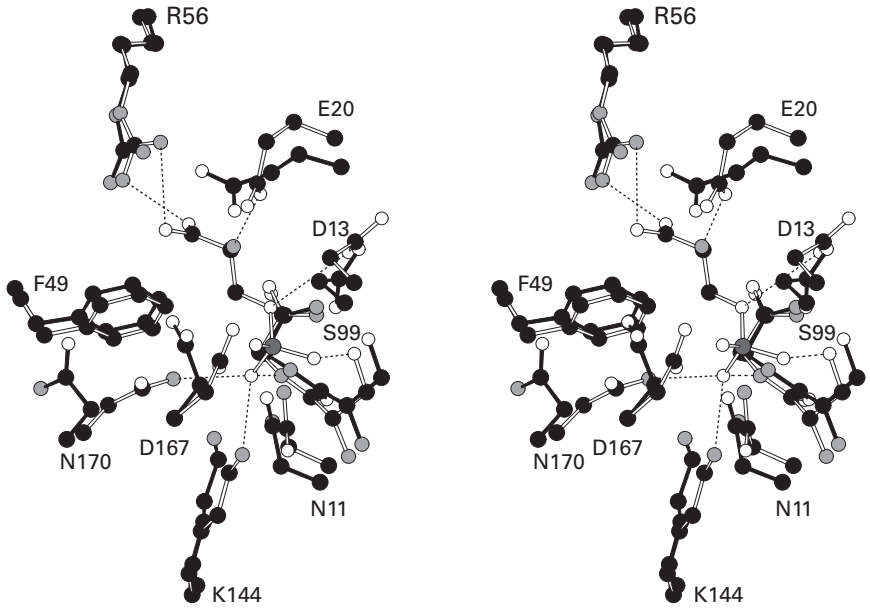

Figure 3–56: Superposed stereodrawings[576] showing the small shifts in side chains and a portion of the polypeptide backbone in the active site of phosphoserine phosphatase from *M. jannaschii* accompanying the association of the reactant *O*-phospho-L-serine.[913] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large dark gray atom is a phosphorus. An enzymatically inactive mutant of the enzyme in which Aspartate 11 had been mutated to an asparagine was crystallized in 5 mM $MgCl_2$ and a buffer at pH 7.4, either alone or in the presence of *O*-phospho-L-serine. The resulting crystallographic molecular models were superposed. The drawing is the superposition of the empty active site (black bonds) and the active site occupied by *O*-phospho-L-serine (white bonds). The side chains of several amino acids surrounding the active site are included in the drawing as well as a short segment of polypeptide. Hydrogen bonds (dashed lines) between donors and acceptors in the side chains or polypeptide and acceptors and donors in the *O*-phospho-L-serine are also drawn.

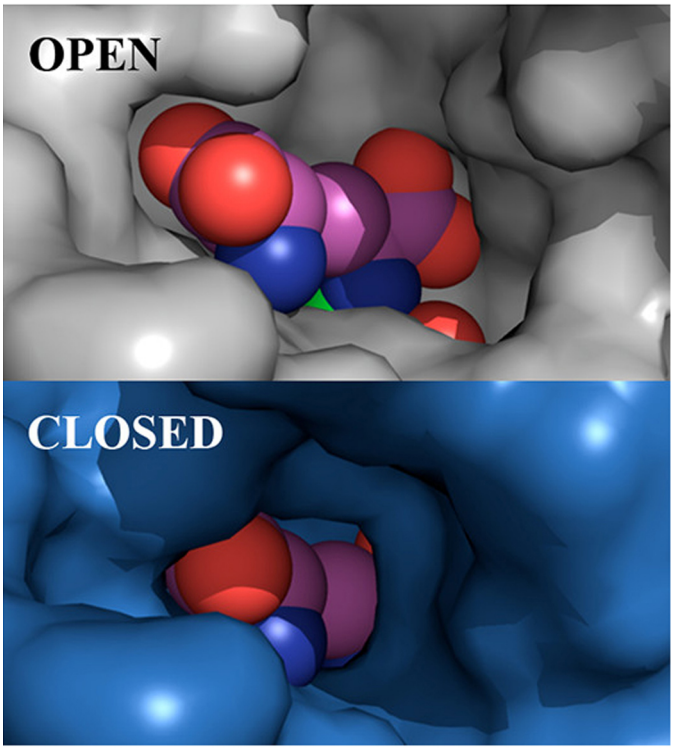

Figure 3–57: Tightening of the active site of cysteine synthase from *Fusobacterium nucleatum* around the external pyridoximine of L-lanthionine.[918] The central intermediate in the reaction catalyzed by cysteine synthase is the external pyridoximine of 2-aminoacrylate (Equation 2–13), which in the usual reaction is formed in one direction from *O*-acetyl-L-serine and formed in the other direction from L-cysteine. The enzyme, however, is promiscuous about the nucleophile that adds to the pyridoximine of 2-aminoacrylate. The sulfido group of L-cysteine is one of the nucleophiles that can add, and it gives L-lanthionine as the final product. The open active site is observed in the crystallographic molecular model of the internal pyridoximine in the otherwise unoccupied enzyme, and the closed active site is observed in the crystallographic molecular model of the external pyridoximine of L-lanthionine.[919] The molecular model of the L-lanthionine in the external pyridoximine from the latter model was inserted into the former model to provide a picture of the complex that forms between the open active site and the substrate L-lanthionine. Lavender atoms are carbons, red atoms are oxygens, and blue atoms are nitrogens The resulting superposition is presented as the OPEN conformation in space-filling format, and the crystallographic molecular model of the active site occupied by the external pyridoxime of L-lanthionine is presented as the CLOSED conformation. The view of the open conformation contains, from left to right, the α-carboxy group, the α-carbon, and the α-amino group from the L-cysteine that added to the pyridoximine of 2-aminoacrylate as well as carbon 3, the 2-amino group, and the carboxy group formerly in 2-amino-acrylate. Two segments of the polypeptide, each consisting of two amino acids, move toward each other to close over the occupied active site. Serine 224 in one of the segments provides both a donor, the amido oxygen of its peptide bond, and an acceptor, its hydroxy group, for hydrogen bonds to the α-carboxy group of L-lanthionine. The reorientation of side chains and prosthetic groups and the small shifts of secondary structures that close and tighten the structure of the protein around a substrate result in only **small changes in the relative positions of the α carbons** of the folded polypeptide that constitutes the enzyme. When crystallographic molecular models of the unliganded conformations and the respective liganded conformations in a large collection of crystallographic molecular models were compared, most of these enzymes (75–80%) showed only small changes (<0.1 nm) in the mean positions of their α carbons, consistent with only minor adjustments to a preexisting active site upon the association of substrates.[908,927] The minority (20–25%), however, show more significant conformational changes of the polypeptide upon the association of substrates and inhibitors.

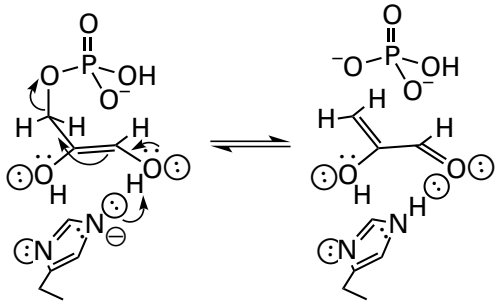
A common example of these more significant conformational changes is the **closing of a loop of polypeptide over the substrates** or inhibitors after they have associated. For example, after glycerone phosphate[1] or an analogue of the *cis*-enediol intermediate in the enzymatic reaction[928] associates with the active site of triose-phosphate isomerase (Equation 3–384), a short loop of polypeptide, comprising amino acids 165–175 in the enzyme from *S. cerevisiae*,[929] closes over the substrate or inhibitor to lock it in the active site (Figure 3–58).[928,930,931] The closing of this lid embeds the phospho group of the substrate within a mold of amino acids[932] that prevents it from moving during the reaction. Because the phospho group is held in the plane of the *cis*-enediol that is an intermediate in the reaction (Figure 3–58), orthogonal to its π system, and because it binds to the enzyme as the dianion,[2] the elimination of phosphate from the intermediate *cis*-enediol that would produce methyl glyoxal



(3–436)

an undesired side product, is prevented. This elimination requires that the phospho group be normal

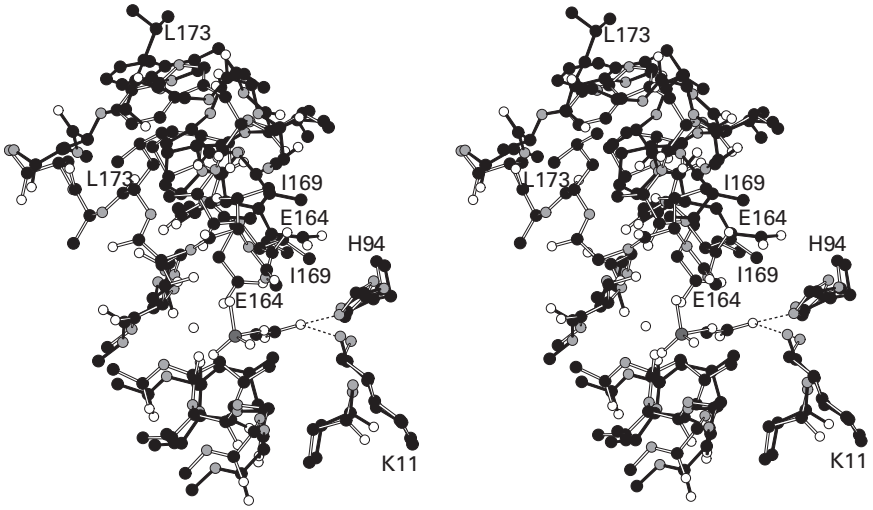


Figure 3–58: Superposed stereodrawings[576] showing the closing of the lid over the active site of triose-phosphate isomerase from *S. cerevisiae*.[930,931] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large dark gray atom is a phosphorus. The crystallographic molecular model of the enzyme with an empty active site (black filled bonds) was superposed onto the crystallographic molecular model of the enzyme with its active site occupied by phosphoglycerate (white open bonds), an analogue of the *cis*-enediol intermediate in the enzymatic reaction. The analogue of the intermediate occupies the active site and also causes the loop of polypeptide from Tryptophan 167 to Alanine 174 to drop over the active site, clamping down on the phospho group of phosphoglycerate. The movement can be appreciated by following the translation of Isoleucine 169 and Leucine 173 and the polypeptide between them. While Leucine 173 drops down with the lid, the side chain of Isoleucine 169, because it is at the edge of the lid, slides into place as the lid closes. The side chain of Glutamate 164 swings into the active site as the lid closes. The twisting of the polypeptide allowing this motion can be appreciated by observing the motion of Proline 165. The twist causes the side chain of Proline 165 to move up rather than down. The hydrogen bonds between the side chains of Histidine 94 (Figure 3–37) and Lysine 11 and the oxygen of the inhibitor that mimics the oxygens on carbons 2 of the substrates D-glyceraldehyde 3-phosphate and glycerone phosphate are drawn.

to the plane of the *cis*-enediol and that it be at least the monoanion. The unrelated enzyme methylglyoxal synthase from *E. coli*, the purpose of which is to produce methylglyoxal from glycerone phosphate, binds the glycerone phosphate so that its phospho group is normal to the plane of the *cis*-enediol, an orientation ideal for elimination.[393]

When the loop in triose-phosphate isomerase from *G. gallus* is shortened by four amino acids by site-directed mutation, the mutant enzyme, in addition to having a specificity constant for glyceraldehyde 3-phosphate that is 8×10^5 smaller than the wild type, produces significant quantities of methylglyoxal (as much as 95% of the product from glyceraldehyde 3-phosphate)[933] because the active site is still able to produce the *cis*-enediol intermediate but it dissociates and decomposes in solution,[934] presumably because the loop is not long enough to retain it until the isomerization has been completed. When only Valine 166 and Tryptophan 167 in one of the hinges for the loop, however, are mutated to proline and glutamate, respectively,[933] the specificity constant for glyceraldehyde 3-phosphate is still dramatically smaller (2×10^4) than that of the wild type, but the percentage of the product that is methylglyoxal decreases to 20%, presumably because the loop is long enough to prevent a larger fraction of the *cis*-enediol from escaping into the solution.

There is a loop that closes over the active site of ribulose-bisphosphate carboxylase (Equation 3–424) after the association of 2-carboxy-D-arabinitol 1,5-bisphosphate, an analogue for intermediate **3–119** in the enzymatic reaction (Figure 3–53). When the entire loop in the enzyme from *Rhodospirillum rubrum* was replaced by two glycines by site-directed mutation, the active site still catalyzed the enolization of D-ribulose 1,5-bisphosphate, which is the first step in the overall enzymatic mechanism, just as the active site of triose-phosphate isomerase was still able to catalyze the enolization of glyceraldehyde 3-phosphate. In the absence of the loop, however, the active site of ribulose-bisphosphate carboxylase was unable to carboxylate the enolate to complete the reaction.[935]

Loops that fold over the active site to enclose the substrates can be as short as four to six amino acids[936-938] or as long as 32 amino acids.[939]

So far, only the closing of a loop over the active site of enzymes with a single reactant have been considered. In an **enzyme with two reactants**, a loop of polypeptide can close over the active site once both of the reactants have associated to occlude them from the solution. There is a loop of polypeptide (53 aa) composed of three α helices on the surface of hydroxymethylglutaryl-CoA reductase from *S. pneumoniae* that swings as a rigid body in a rotation of 180° on a hinge of two strands of random meander* to close over the active site. In a crystallographic molecular model of the open conformation,[940] the loop adheres to the surface of the enzyme on one side of the hinge. In a crystallographic molecular model[941] of hydroxymethylglutaryl-CoA reductase from *Pseudomonas mevalonii* (40% identity; 0.4 gap percent) in the conformation in which the loop has enclosed the two oxidized substrates, 3-hydroxy-3-methylglutaryl-SCoA and NAD^+, the loop is adhering to the surface of the enzyme on the other side of the hinge and closing the active site. In the crystallographic molecular model[942] of hydroxymethylglutaryl-CoA reductase from *S. pneumoniae*, however, in which the active site is occupied by only one of the reactants, 3-hydroxy-3-methylglutaryl-SCoA, the loop has only partially closed, and the 3-hydroxy-3-methylglutaryl-SCoA has been enclosed; but the immediately adjacent subsite for the other reactant, NADPH, is still open to permit its association. In the enzymatic reaction, 3-hydroxy-3-methylglutaryl-SCoA is reduced by four electrons, so this partial closure permits the first molecule of NAD^+ to dissociate and the second molecule of NADH to associate while the partially reduced 3-hydroxy-3-methylglutaryl-SCoA remains enclosed.

Although the closing of a loop over an active site is often emphasized because it seems to have more catalytic advantages, **loops can also move over to open an active site** to its reactant and remain in this shifted conformation after the reactant associates. In a comparison of crystallographic molecular models of the unoccupied active site of cholesterol oxidase from *Brevibacterium sterolicum* and the active site occupied by the substrate dehydroisoandrosterone, it can be seen that a loop comprising amino acids 75–85 moves over, and this motion opens the active site rather than closing it.[943]

When a loop closes over an active site, **an amino acid participating in the catalysis is often brought into the active site by the closure of the loop**.[944-946] For example, Glutamate 140 in endoglucanase CelC

*A distinction is made between **random meander**, which is the fixed, randomly meandering path the polypeptide follows in the folded structure of a protein and which, aside from molecular vibration, does not change significantly with time, and a **random coil**, which is an expanded unfolded polypeptide in solution that is constantly changing its entire structure as a result of random rotations around its single bonds.

from *A. thermocellus*, which is the catalytic acid that hydronates the leaving group in the hydrolysis catalyzed by this enzyme, is brought into the active site when the loop containing amino acids 138–141 closes around the reactant.[936] In the active site of triose-phosphate isomerase (Equation 3–384) from *S. cerevisiae*, the catalytic carboxylato group of Glutamate 164 (Figure 3–37) enters the active site as the loop containing amino acids 164–175 closes over a reactant (Figure 3–58).

The loops that close over a substrate always assume a particular conformation in the crystallographic molecular model of the **closed conformation** of the active site, but they can have a particular conformation,[929,947] can have two conformations,[948] can be disordered and lack electron density,[949,950] or can be partially disordered[951] in the crystallographic molecular models of the **open conformation,** or the several open conformations, of the active site. Because the loop is often disordered or at least more exposed in the open conformation while it is ordered in the closed conformation, its availability to digestion by an endopeptidase when the enzyme is in solution can be used to determine when the active site is open and when it is closed.[952]

In some cases, the transition from the open to the closed conformation is accompanied by a **change in the secondary structure of a loop**. For example, the closing of a loop can cause a new α helix to form within it[953,954] or extend an already existing α helix.[955] In the case of purine-nucleoside phosphorylase from *E. coli*, an α helix of 14 amino acids that exists in the open conformation breaks in two, and one half shifts over to close the active site.[956] A loop in dihydrofolate reductase from *E. coli* has an irregular structure in the crystallographic molecular model of the open conformation, but when the loop is closed over the active site, it has become a hairpin of β structure.[957]

In contrast to these examples of changes in the secondary structure within a loop as it closes over the active site, the secondary structure of the loop, as was the case with hydroxymethylglutaryl-CoA reductase, can remain unchanged after it has closed. For example, the loop of fifteen amino acids that closes over the intermediate analogue ethyl *n*-hexylphosphonate, in crystallographic molecular models of the unoccupied and occupied conformations of triacylglycerol lipase from *Rhizomucor miehei* contains an α helix of seven amino acids that **moves as a rigid body** during the closure, which is accomplished by hinges at the two ends of the loop.[958]

In some cases, **two,**[959,960] **three**[949,961] **or as many as six**[962] **loops close over the active site**, almost as if they were short fingers closing as a fist over an object. Sometimes the **carboxy terminus**[963] or the **amino terminus**,[949] rather than an internal loop, closes over the substrates after they have associated with the active site. In one instance, however, the amino-terminal strand of the protein can block access to the active site in an unliganded conformation of the enzyme and must swing away to make the active site available to substrates.[964]

The ultimate solution to closing an active site around the substrate is to **bring together two independently shifting domains**, as does hexokinase from *S. cerevisiae* (Figure 3–55) or porcine citrate (*Si*)-synthase.[578] The motion of the two domains relative to each other can be described by comparing crystallographic molecular models of the enzyme in the open and closed conformations. In the transition from an open to a closed conformation, amino acids participating in catalysis and those recognizing substrates by noncovalent interactions are considerably reoriented to form a functional active site in the closed conformation where only a portion existed in the open conformation. In isocitrate dehydrogenase ($NADP^+$) from *Aeropyrum pernix* (Equation 3–345), one reactant, $NADP^+$, is bound to one domain in the crystallographic molecular model of the open conformation, and the other reactant, isocitrate, is bound to the other domain in the open conformation; and the closure of the two domains upon each other, in addition to creating the active site, moves the two substrates closer together by 0.5 nm so they can react with each other.[965] The two domains that close upon each other are usually domains in the same polypeptide, but the reorientation can also be between two heterologous subunits of the enzyme,[966] which in the future may become two domains of the same polypeptide as a result of gene fusion. Usually the reorientation of the domains occurs upon association of the reactants, but it can also occur between intermediate steps in the reaction.[967,968]

As was the case with the closing of the loop in hydroxymethylglutaryl-CoA reductase, in the closing of domains, there can be a **partially open conformation** in addition to the open and closed conformations. 4-Phytase from *Bifidobacterium longum* hydrolyzes the 4-phospho group from *myo*-inositol hexakisphosphate to give phosphate and 1D-*myo*-inositol 1,2,3,5,6-pentakisphosphate as products.

The open conformation is observed in the crystallographic molecular model of the unoccupied enzyme and the closed conformation in the crystallographic molecular model of the complex between the enzyme and *myo*-inositol hexakissulfate, an analogue of the reactant. When the active site, however, is occupied only by phosphate, one of the products, the site is partially open, with the angle between the two domains about half of the full angle through which the two independently shifting domains swing to fully close.[969]

As was the case with the closing of loops over the active site, but more so, **the closing of domains almost always gathers the functional groups on amino acids that participate in catalysis into the closed active site and orients them for catalysis**. This occlusion is often accomplished simply by the **closing of the jaws**. For example, when the two independently shifting domains of isocitrate dehydrogenase ($NADP^+$) from *E. coli* in the crystallographic molecular models of the open and closed forms are superposed, it can be seen that the amino acids responsible for catalysis on the two domains "move as rigid bodies during domain closure".[970] In other instances, there can be significant conformational changes that occur in the side chains of catalytic amino acids coordinated with the closing of the domains. For example, in the crystallographic molecular model of the open conformation of *β*-phosphoglucomutase from *L. lactis*, the carboxy group of Aspartic Acid 10 is swung out of the active site, forming a hydrogen bond with the amido group of Threonine 16 in the polypeptide backbone. In the crystallographic molecular model of the two domains closed around the substrate D-glucose 6-phosphate, however, the carboxy group has swung over to form a hydrogen bond with the oxygen on carbon 6 of D-glucose 6-phosphate, which is the leaving group in the phosphotransfer catalyzed by the enzyme.[971]

Often **closure of the domains causes the substrates to become completely surrounded by protein** and to be no longer in contact with the solution. Even substrates as large as NADH can be encased in protein in this way, as in the closed conformation of formate dehydrogenase from *Pseudomonas*.[972] Because the closure of the domains usually sequesters side chains of the amino acids as well as substrates from access to the solution, the rate of reaction for a side chain that is known to be sequestered with a reagent that modifies it, such as the reaction between a lysine and 2,4-dinitrophenyl acetate,[973] can be used to monitor the closure when the enzyme is in solution.

Other local changes in conformation often accompany the closure of the two domains. For example, during the closing of the two domains in adenosine kinase from *Toxoplasma gondii* around the substrate adenosine and the analogue $MgAMPPCP^{2-}$ (**3–5**), the *α*-helical segment composed of amino acids 312–316 in the open conformation becomes a random coil that creates an oxyanion hole, and the segment of random coil composed of amino acids 307–310 in the open conformation becomes a 3_{10} helix.[611] Often, segments of polypeptide that are disordered and lack electron density in models of the open conformation of the enzyme become ordered and display well-defined electron density when the domains close around a substrate.[974]

As might be expected, the closure of domains around the substrates decreases the number of amido hydrogens in the polypeptide backbone that can exchange with hydrons in the solution. As the domains close, the **amido nitrogen–hydrogen bonds become buried** and inaccessible. For example, there is a large cleft between two independently shifting domains in phosphoglycerate kinase (Equation 3–375) in the absence of substrates. From the crystallographic molecular model[975] of the ternary complex between phosphoglycerate kinase from *T. brucei* and the reactant 3-phospho-D-glycerate and the product $MgADP^-$, as well as measurements of the scattering of X-radiation[976] from solutions of the ternary complex between phosphoglycerate kinase from *S. cerevisiae* (44% identity; 1.9 gap percent) and 3-phospho-D-glycerate and $MgADP^-$, it has been concluded that these two domains have closed around the ligands. When the rates of exchange for the amido hydrons in the polypeptide backbone of phosphoglycerate kinase from *G. stearothermophilus* (45% identity; 1.2 gap percent) were measured, it was observed that the number of amido groups that had rates of exchange 10^8 times slower than those they would have in the unfolded polypeptide increased from 17 to 40 when either 3-phospho-D-glycerate or $MgADP^-$ was bound in the active site. The number then further increased to 59 when 3-phospho-D-glycerate, AlF_4^-, and $MgADP^-$ were all bound in the active site.[977] The latter combination forms within the active site either an analogue of the transition state or an analogue of the intermediate monomeric metaphosphate in the phosphotransfer catalyzed by the enzyme. These

increases in the slowly exchanging amido hydrons monitor their exclusion from the solution as the domains close.

A closure of domains that sequesters both substrates and side chains of amino acids from the solution also involves **changes in the hydration of the protein**. The water hydrating the two surfaces in the open conformation is mostly gone in the closed conformation after they have closed upon each other. Consequently, the closed conformation is dehydrated relative to the open conformation, causing dissociation constants for substrates[978] and enzymatic rate constants[979] to become functions of the concentration of water. For example, from changes in the dissociation constant for D-glucose from hexokinase from *S. cerevisiae* as a function of the concentration of water, it has been estimated[978] that about 60 molecules of water of hydration are lost upon closure of the active site (Figure 3–55).

Usually the two domains that close upon each other are about the same size, but sometimes one is considerably smaller than the other.[973,980,981] In most cases, as with hexokinase (Figure 3–55), the **two domains move as rigid bodies** because they are large enough to retain their stable tertiary structures during the conformational change. In some instances, however, usually when one of the domains is small, there can be changes in the tertiary structure of the smaller domain during the closure,[982] or one of the domains in the open conformation can be disordered in the crystal.[941] When one of the domains is small enough, it is simply a more or less structured loop that closes over the active site.[947]

The closure of the domains[983] can be a simple **hinged bending** as in hexokinase (Figure 3–55), a twisting motion that slides one domain over the surface of the other,[984] or a ball-and-socket motion that rotates one domain within a shallow cup on the surface of the other.[968,980] When the motion closing the domains is a hinged bending, two to as many as seven strands of polypeptide form the hinge upon which the two domains swing.[983] These strands are usually random meander and hence flexible enough to bend by the necessary angle. The two domains in aspartate transaminase from *G. gallus* are joined by two strands of polypeptide. One strand is a random meander in both the open and closed conformations, but the other strand in the open conformation is a long continuous rod of α helix, half in one domain and half in the other, that kinks in its center by 12° in the closed conformation to accommodate the closing of the domains.[985,986] In one instance where the closure results from a twisting motion, there are only two flexible strands connecting the two domains on either side of the axis of the twist.[984] In the case of 5′-nucleotidase from *E. coli*, in which a ball-and-socket motion closes the active site, the rotation of the ball unwinds a turn of α helix in the lone segment polypeptide connecting the two domains.[987]

Sometimes a screw axis, which is an operation capable of describing any reorientation of two rigid bodies, must be used to describe the motion.[912] Usually, however, **the motion of the two domains as rigid bodies can be described as a relative motion about a rotational axis** (Table 3–8).

Enzymes that have **nucleic acids** as their substrates usually have the most dramatic induced fits as they associate with their respective reactants because nucleic acids are also macromolecules, and they are of a size equal to the enzymes themselves. For example, it has already been noted that human DNA ligase (ATP) completely surrounds nine of the base pairs in the nicked double-stranded DNA that is its reactant.[760] The induced fit required to accomplish this enclosure has been described in crystallographic molecular models of DNA ligase (NAD^+) from *E. coli* both in the absence of DNA[995] and after it has surrounded a segment of DNA.[996] In the crystallographic molecular model of the unliganded conformation, the enzyme contains four independently shifting domains that form an arc of roughly 160° that is open on its concave side. As the DNA is surrounded during formation of the complex, the arc contracts into an almost complete circle. During this contraction, the four domains twist and flip with respect to each other as they contact the surface of the DNA so that surfaces on three of them that were not on the concave side of the arc end up on the concave surface of the final structure.

Type II site-specific deoxyribonuclease from *B. subtilis* hydrolyzes foreign, double-stranded DNA at restriction sites that have not been modified by the bacterium. The enzyme is a homodimer of two subunits (233 aa) that is rotationally symmetric in the crystallographic molecular models of both the free enzyme[997] and the complex with double-helical DNA.[998] The sequence of nucleotides in the double-stranded DNA is palindromic, and in the complex the rotational axis of symmetry of the protein coincides with the rotational axis of symmetry of the palindrome. During the transition from the unliganded to the liganded conformation, the two

Table 3-8: Rotations of Domains about an Axis during Closure of Active Sites

enzyme	rotation
formate dehydrogenase from *Pseudomonas*[972]	7.5°
2*S* epimer (D-mannose) from *S. cerevisiae*[912]	12°
orotidine-5′-phosphate decarboxylase from *E. coli*[988]	12°
3-dehydroquinate synthase from *Aspergillus nidulans*[972,989]	12°
glycogen synthase from *E. coli*[990]	15°
thermolysin from *B. thermoproteolyticus*[991]	16°
porcine citrate (*Si*)-synthase[578]	18°
isocitrate dehydrogenase ($NADP^+$) from *A. pernix*[965]	19°
phospho*enol*pyruvate carboxykinase (ATP) from *E. coli*[992]	20°
pyruvate kinase from *O. cuniculus*[993]	41°
human lactotransferrin[994]	53°
periplasmic dipeptide transport protein from *E. coli*[993]	55°

dimers pivot with respect to each other by 100° about an axis that passes through the interface between the two subunits and that intersects and is normal to the rotational axis of symmetry, just as the two blades of a scissors, which are related to each other by a rotational axis of symmetry, pivot around the pin that holds them together and that is perpendicular to that rotational axis of symmetry. Within the interface, the two faces rotate relative to each other about this axis so that the noncovalent interactions creating the interface are almost completely different in the complex than what they were in the unliganded conformation, even though there is still a rotational axis of symmetry running through the interface. This pivot allows the two subunits to close around the DNA and surround a 250° sector of the cylinder of DNA. The enclosure is completed by two loops of polypeptide from each subunit that were disordered in the unliganded conformation but become ordered as they embrace the DNA.

Unlike DNA ligase and type II site-specific deoxyribonuclease, which must find a specific nick or a specific sequence of nucleic acids in the long DNA of the chromosome, DNA-directed DNA polymerase is responsible for elongating any segment of DNA of any sequence. On one side of the active site in its substrate, there is a double-stranded DNA duplex in which one strand ends at the catalytic site with a 3′-hydroxy group. On the other side of the active site, the other strand of the DNA is a continuous single strand forming the template on which the elongation is to occur. On the surface of a large (604 aa) truncated version of DNA-directed DNA polymerase I from *E. coli*, in the crystallographic of molecular model of the unliganded conformation,[999] there is a deep groove, the width of double-stranded DNA, on one side of the active site. On the other side of the active site, there is a narrower groove on the surface of the protein at an angle of 130° to the wider groove. In the crystallographic molecular model of the liganded conformation,[1000] associatied with a molecule of DNA that is a complex between a single strand representing the template and a primer the 3′ end of which represents the point of elongation, the double-stranded portion of the DNA is sitting in the wide groove and the short single-stranded portion of the DNA is sitting at the entrance to the narrow groove, presumably representing the single strand of a much longer template on its way into the active site. An independently shifting domain of the protein (100 aa), known as the "thumb", has closed over the catalytic portion of the active site in an induced fit that isolates it from the solution. Presumably, the wide groove has no preference for the sequence of nucleotides in the double-stranded DNA, and likewise, the narrow groove has no preference for the sequence of nucleotides in the single-stranded DNA.

The open form of DNA-directed DNA polymerase I from *E. coli* with the thumb swung away from the catalytic site is susceptible to digestion by trypsin while the closed form is not. Using susceptibility of the intact polypeptide to tryptic digestion, as well as using selective templates in which a short single strand of DNA is annealed to a longer strand so that the identity of the next nucleotide to be added to the elongating strand is known, it could be shown that the thumb closes over the catalytic site only when the nucleoside triphosphate of the correct, complementary base has associated with the active site and presumably the template.[1001,1002] The subsequent opening of the active site following the catalytic step permits release of the diphosphate that is the product of elongation of the primer by one nucleotide and permits association of the next, correct nucleoside triphosphate. The active site then closes around that correct nucleotide and the DNA. Consequently, both the opening and the closing must happen at each step in elongation. For the structurally related DNA-directed DNA polymerase from Escherichia phage T7,[1003] both the rate constant at which the active site opens to release the diphosphate as a product ($1.2\ ms^{-1}$) and the rate constant at which the active site closes over the DNA and the correct magnesium deoxyribonucleoside triphosphate in the next step of the elongation ($0.3\ ms^{-1}$) have been measured.[1004] These rate constants are fast enough to accomplish the opening and closing of the active site at each step in the elongation, just as the active site of hexokinase opens and closes during each turnover.

In the much shorter (335 aa), but nevertheless structurally related[1005] DNA-directed DNA polymerase β from *R. norvegicus*, the grooves are missing and only the portion the enzyme containing the active site remains. In the crystallographic molecular model of the unliganded enzyme,[1005] the active site is wide open to a molecule the size of a molecule of DNA that is a duplex up to the 3′-hydroxy group and a single strand beyond the point of elongation. In the crystallographic molecular model of the closed conformation,[1006] a rather long rodlike, independently shifting domain (80 aa), composed of six short α helices, has closed over the single-stranded and double-stranded DNA by an almost rigid-body motion through an angle of 80° about a hinge composed of two short α helices. The movement of this domain again isolates the active site from the solution and creates the catalytic center.

Tightening of the protein around the substrates, closure of a loop or several loops over the substrates, or enclosure of the substrates brought about by the reorientation of domains are **not exclusive possibilities**. Tightening of the active site can accompany closure of a loop,[1007,1008] and closure of two domains can be accompanied by closure of one or more loops.[947,986,1009,1010] When aspartate—tRNA ligase associates with its substrate $tRNA^{Asp}$, two of its three independently shifting domains rotate with respect to the third, each about its own axis, to form contact with $tRNA^{Asp}$, which is a large substrate. In the single sites on each domain that make contact, as well as in the catalytic site that associates with L-aspartyl acyl adenylate and $tRNA^{Asp}$, the only conformational changes from the respective unliganded conformations are rotations of side chains to adjust to the substrates.[1011] The sum of all the structural changes characteristic of a particular enzyme defines the difference between open and closed conformations.

In a certain sense, many of the rotations, pivots, reorientations, and closings of hinges observed in the respective pairs of crystallographic molecular models may be illusory. Although the closed conformation is most likely the conformation the protein assumes in solution upon association of the substrate or substrates, the particular open conformation observed in a crystallographic molecular model may be more a result of the crystallization than any inherent structure. **In solution, the two domains in the open conformation may be constantly reorienting** relative to each other rather that being rigidly held at some particular angle. In several crystallographic studies, more than one structure has been observed for the open conformation of an enzyme.[1012,1013] In other instances, the angle between the two domains in the open conformation fluctuates widely.[1014,1015] In the case of triose-phosphate isomerase, calculations suggest that the loop in the open conformation is in fact highly flexible and samples many different conformations,[1016] so the picture of a rigid-body motion (Figure 3–58), although educational, is probably incorrect.

There are other observations, however, suggesting that **the structures observed in static crystallographic molecular models of the unoccupied, open conformations are often realistic**. For example, in five different, nonisomorphous crystalline forms, aspartate transaminase from *G. gallus* exists in only two conformations, either open or closed.[1017] There are spectroscopic observations with a modified form of the enzyme in which a fluorescent functional group has been incorporated that are consistent with only two conformations of the enzyme existing

in solution.[985] The conclusion that there are only two conformations in this instance seems reasonable since the open conformation has a long, rigid α helix spanning the two domains.

When arginine kinase from *L. polyphemus* is in solution in the absence of substrates or inhibitors, nuclear magnetic resonance spectra are consistent with an equilibrium existing between open and closed conformations that are observed crystallographically and that differ from each other by the opening and closing of two independently shifting domains.[1018] These observations correlate the motions in solution to the conformational change defined in these static structures.

The behavior of the absorbances of 27 amido nitrogens-15 and their amido hydrogens in a two-dimensional (^{1}H–^{15}N) correlated nuclear magnetic resonance spectrum of adenylate kinase from *E. coli*, which shift in concert under perturbation, are also consistent with only two conformations, open and closed, being present in the solution.[962]

Any change in the conformation of an enzyme that is thermodynamically linked to the association of its substrates is an induced fit. That such alterations in the structure of a protein could occur in response to the binding of a reactant or reactants was proposed before any such changes were observed crystallographically.[1019] Assume for the moment that the sequence of amino acids for the polypeptide that folds to form the native structure for a protomer of the enzyme contains the information necessary to specify two distinct native structures, which are **two distinct conformations** of the enzyme. These two conformations could be, for example, the open conformation (E_o) and the closed conformation (E_c) observed in crystallographic molecular models. Assume also that, in the absence of reactant A, the open conformation is more stable than the closed, but that when reactant A is bound, the closed conformation is more stable than the open. The equilibria describing this situation are

$$\begin{array}{ccc} E_o + A & \underset{\Delta G_4^\circ}{\rightleftharpoons} & E_o{\cdot}A \\ \Big\Updownarrow \Delta G_2^\circ & & \Big\Updownarrow \Delta G_3^\circ \\ E_c + A & \underset{\Delta G_1^\circ}{\rightleftharpoons} & E_c{\cdot}A \end{array} \qquad (3\text{–}437)$$

The standard free energy changes for binding of reactant A to the two conformations of the enzyme are for the directions of dissociation, from right to left, and those for the conformational changes are for the directions from closed to open, upward. The free energies for all four limbs of such a **linkage relation** have been measured for the association of nucleotides with tryptophan—tRNA ligase from *G. stearothermophilus*,[1020]

Because free energy is a state function and independent of path

$$\Delta G_1^\circ + \Delta G_2^\circ = \Delta G_3^\circ + \Delta G_4^\circ \qquad (3\text{–}438)$$

Because the enzyme is open in the absence of reactants and closed in the presence of reactant A, $\Delta G^\circ_2 < 0$, and $\Delta G^\circ_3 > 0$, from which it follows that

$$\Delta G_1^\circ >> \Delta G_4^\circ \qquad (3\text{–}439)$$

These linkage relations state that if and only if reactant A binds more tightly to the closed conformation than the open conformation, as is reasonable, will the binding of reactant A be able to invert the equilibrium between the open and closed conformations of the enzyme. This difference in the standard free energies of dissociation tips the balance and closes the active site around the reactant.

The linkage relation of Equation 3–437, for the sake of simplicity, assumes that the enzyme can exist in only two conformations, open and closed. When domains or loops in the open conformation fluctuate among many different orientations, which may be the more common situation, the ensemble of the conformations can be treated thermodynamically as the single open conformation in Equation 3–437 by assigning to the ensemble a mean standard free energy.

Although a thermodynamic distinction between the two is irrelevant, a kinetic distinction can be made between the two directions around the linkage square (Equation 3–437). The path on which the ligand associates before the conformational change occurs, designated as **induced fit**,[1019] can be distinguished kinetically from a path on which the conformational change occurs before the ligand can associate with the active site, designated as **conformational selection**.[1021,1022] The difference is between a thermodynamic statement that free energy is independent of path and a kinetic mechanism describing the actual events of the association. In the former instance, a site with which a reactant can associate must exist in the open conformation. Certainly, in the instances in which the active site

closes around that substrate and its cosubstrates, occluding them from the solution, it must be the case that a site exists on the open conformation since there is no access of any ligand to the active site in the closed conformation. In the latter kinetic mechanism, the actual association of the reactant or reactants is preceded by a pre-equilibrium that does not involve the reactants. That many kinetic mechanisms not involving enzymes proceed through preequilibria is well-known and uncontroversial. There is no reason to doubt that there may be instances in which an active site is both open to the solution in the closed conformation and unable to associate with the reactants in the open conformation. Although such a situation may be involved in the control of enzymatic activity, if such control is not occurring, the main consequence of such a kinetic mechanism is to decrease the concentration of active enzyme in the solution and decrease the efficiency of catalysis, an outcome that seems contrary to natural selection.

The original proposal for the existence of induced fit was provided as an **explanation for the specificity that certain enzymes displayed toward certain reactants**. For example, bovine 5′-nucleotidase catalyzes the hydrolysis of the phosphate ester of adenosine 5′-phosphate 100-fold more rapidly than it does that of ribose 5-phosphate.[1019] One explanation for this kinetic preference was that the larger reactant causes an induced fit to occur more effectively.* If the active site is able to catalyze the reaction only in the closed conformation, then any reactant that is more effective at inducing closure of the active site will be more effectively transformed by the enzyme. Consequently, in this explanation, induced fit is a strategy to enhance the specificity of the enzyme for its reactant relative to portions of its reactant or other related reactants if only the proper reactant is able to elicit the induced fit, which in turn brings the catalytic groups into proper locations and orientations for catalysis.

Induced fit can be used to improve the specificity of an enzyme only at the expense of its catalytic efficiency.[1023] This conclusion follows from the fact that a portion of the negative change in free energy accompanying the association of the reactant must be expended to shift the equilibrium between the inactive, open conformation and the active, closed conformation of the enzyme rather than being used to hasten the reaction. If almost all the unoccupied enzyme is in the open conformation to begin with, the total change in standard free energy for dissociation of reactant A from the catalytically active complex, E_c·A, is either $\Delta G^\circ_1 + \Delta G^\circ_2$ or $\Delta G^\circ_3 + \Delta G^\circ_4$, but either sum is always more negative than ΔG°_1, the standard free energy of dissociation of reactant A from the closed form. Therefore, reactant A binds less tightly to the enzyme than it would if only the closed conformation were present from the beginning. Therefore, tight binding is sacrificed to perform the conformational change.

Because the active site assembles only after the proper reactant or all the proper reactants are present, and therefore catalysis can proceed only after the active site closes, the enzyme avoids catalyzing a reaction for which it was not intended. It has been shown, for example, that the open active site of 5′-nucleotidase from *E. coli* is unable to catalyze the enzymatic reaction.[1024] If the enzyme were always present in the closed conformation and reactant A were able to bind to the closed conformation, reactant A would bind more tightly, and the enzyme could be a better catalyst. Nothing, however, would prevent molecules that contained only a portion of reactant A from binding and participating in the normal reaction mechanism. For example, the specificity constant for oxaloacetate, which is 3-carboxylatopyruvate, in the reaction catalyzed by porcine malate dehydrogenase, which normally reduces oxaloacetate to (*S*)-malate with NADH, is 10^6 times greater than the specificity constant for the reduction of pyruvate to lactate in the same active site. This discrimination in favor of 3-carboxylatopyruvate and against pyruvate can be explained by the fact that there is an induced fit upon the binding of 3-carboxylatopyruvate, which has been demonstrated crystallographically.[392] This conformational change, which assembles the catalytic groups, seems to require the presence of the 3-carboxylato group on oxaloacetate.

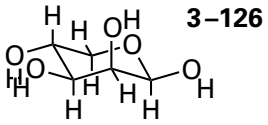
The **smaller molecule of most concern is water,** and the reaction catalyzed by hexokinase from *S. cerevisiae* (Figure 3–55) illustrates this problem most graphically. Hexokinase transfers the γ-phospho group from $MgATP^{2-}$ to the primary alcohol on carbon 6 of D-glucose. Water is also a primary alcohol and occupies the same location in the active site occupied by the primary alcohol of D-glucose in its absence. If the active site in hexokinase were properly configured for catalysis in the absence of D-glucose, $MgATP^{2-}$ could bind, water would be

*The conformational change accompanying the induced fit linked to the association of a nucleotide accomplished by 5′-nucleotidase from *E. coli* was subsequently shown to exist.[980]

present at the site for the primary alcohol, and the γ-phospho group would be transferred to water. In this instance, hexokinase would catalyze the hydrolysis of $MgATP^{2-}$, an unfortunate outcome.

Hexokinase from *S. cerevisiae* does catalyze the hydrolysis of $MgATP^{2-}$ in the absence of D-glucose, but the Michaelis constant for $MgATP^{2-}$ (4 mM) and the catalytic constant ($4\ s^{-1}$) are higher and lower, respectively, than the Michaelis constant for $MgATP^{2-}$ (0.2 mM) and the catalytic constant ($140\ s^{-1}$) for the transfer of phosphate to the primary 6-hydroxy group of D-glucose. From what is known about the conformational changes in which hexokinase from *S. cerevisiae* engages (Figure 3–55), one explanation for this counterproductive hydrolytic activity would be that occasionally the active site closes when $MgATP^{2-}$ is bound but D-glucose is not bound. Because water is occupying the location in the active site at which the primary hydroxy group at carbon 6 of D-glucose would normally be located, the hydrolysis of $MgATP^{2-}$ would result as soon as the proper active site was assembled.

If this is the explanation for the observed hydrolysis of $MgATP^{2-}$, it should be possible to amplify the error by including a **ligand missing a portion of the normal substrate**. D-Mannose is also a substrate for hexokinase. When D-lyxose



3–126

which is the five-carbon analogue missing carbon 6 of D-mannose, is added at a concentration of 0.1 M ($K_{m,lyx}$ = 5 mM), the hydrolysis of $MgATP^{2-}$ is remarkably accelerated to levels approaching the normal levels of hexokinase activity [$K_{m,ATP}$ = 0.1 mM and $k_0 = 60\ s^{-1}$].[1025] D-Xylose, the five-carbon analogue for D-glucose, also accelerates the hydrolysis of $MgATP^{2-}$. Because both D-mannose and D-glucose are excellent substrates for hexokinase (Table 3–5) these results suggest that D-lyxose or D-xylose, instead of D-mannose or D-glucose, respectively, induces the closing of the active site when $MgATP^{2-}$ is also bound but that a molecule of water is trapped at the position usually occupied by the hydroxymethyl group on the respective hexose and acts as the acceptor.

In a similar set of experiments, it could be shown that 3-phosphoshikimate 1-carboxyvinyltransferase (Equation 3–262) from *E. coli* would catalyze hydrogen exchange at carbon 3 of phospho*enol*pyruvate only when 4,5-dideoxyshikimate 3-phosphate was present.[1026] This analogue is missing the 5-hydroxy group to which the enzyme normally transfers the carboxyvinyl group of phospho*enol*pyruvate, but its ability to activate the catalysis of one of the partial reactions catalyzed by the enzyme indicates that it can nevertheless induce the active site to close.

Under certain circumstances, the process of induced fit would **not be able to accomplish the increase in specificity** that has just been described. Consider the closed conformation of an enzyme (E_c in Equation 3–437). Suppose that both the proper reactant, for example, D-glucose in the case of hexokinase, and an improper reactant, for example, water in the case of hexokinase, could equilibrate so rapidly with the active site in its closed conformation that the association and dissociation of each reactant with and from the closed conformation were all faster than the turnover of the enzyme and the rate at which the active site could open. If this were the case, adding the ability of the enzyme to open and close would not change the ratio of the rates for participation of the two reactants in the enzymatic reaction. As soon as the enzyme closed, these two competing reactants would equilibrate on the active site, and the fact that the enzyme had just closed would be irrelevant unless the opening of the enzyme when the improper reactant is bound were much faster than the catalytic constant of the closed enzyme to which the improper reactant was bound. Therefore, if the proper and improper reactant were able to enter and leave the closed conformation of the enzyme rapidly, induced fit would not improve the specificity of the enzyme. Induced fit can increase the specificity of an enzyme only if the active site closes so tightly on the proper reactant that it cannot dissociate or be displaced by an improper reactant before turnover occurs. This secure enclosure seems to be the case with hexokinase (Figure 3–55). It is unlikely that a molecule of D-glucose upon which the enzyme has closed would be able to dissociate from the closed conformation. This consideration suggests that induced fit will usually involve the closing of the active site around a reactant, as it does in hexokinase and triose-phosphate isomerase (Figure 3–58), and that seldom will the unoccupied active site in the closed conformation be able to associate with its substrate.

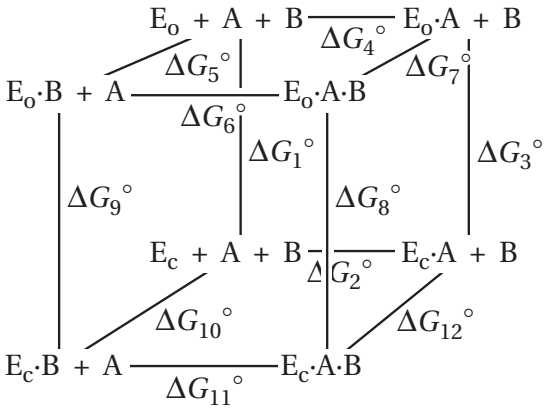
The foregoing considerations suggest that, in most cases in which the association of substrates induces the enzyme to close, the loops of polypeptide or the clefts between the two hinged domains should close sufficiently that entry and exit of substrates from the closed conformation should be

very difficult if not impossible. If so, the closed conformation cannot by itself be a more efficient enzyme. Even though, in theory, substrates bind more tightly to the closed form, their entry into it and exit from it should be kinetically too slow for it to be an effective catalyst. Consequently, **induced fit can be viewed as a way to create an active site that surrounds the substrates on all sides but that can nevertheless bind and release reactants and products rapidly**. The ability to surround substrates completely seems to be a reasonable advantage for catalysis.

When the closing of the active site sequesters the reactants so effectively from the solution that they are unable to enter the closed conformation, it must necessarily follow that the reactants are able to associate with the open conformation rapidly and with a large enough free energy of dissociation so that most of the time, when reactants are present at saturating concentrations, they are occupying the active site when it closes.[1027]

So far it has been assumed that the enzyme is active only in the closed conformation, but this assumption is not necessary for induced fit to be beneficial. When equine alcohol dehydrogenase is locked artificially in the open conformation, its catalytic constant is actually somewhat greater than when it can assume both open and closed conformations as it does naturally. The Michaelis constant for an alcohol, however, decreases by a factor of 100–1000 when the enzyme is able to close around it.[1028] Consequently, the enzyme can catalyze the reaction more effectively at low concentrations of reactant, when the induced fit is functioning, but not when the reactant is present at high enough concentrations to saturate the active site in the open conformation.

When the **two reactants of a bimolecular reaction** catalyzed by an enzyme together induce the closing of the active site around themselves, each individual dissociation constant is affected by the presence of the other reactant.[1029] The reason for this interaction is most easily understood by examining the **linkage cube** for this reaction



(3–440)

In this representation, the changes in standard free energies ΔG°_2, ΔG°_4, ΔG°_5, ΔG°_6 ΔG°_7, ΔG°_{10} ΔG°_{11}, and ΔG°_{12} are standard free energies of dissociation and ΔG°_1, ΔG°_3, ΔG°_8, and ΔG°_9 are standard free energies of isomerization in the direction from closed to open, as in Equation 3–437. Double arrows are replaced with lines for simplicity. If it is assumed, to simplify matters, that each of the two reactants, A and B, binds with the same affinity to the open conformation of the enzyme whether the other is bound or not, then $\Delta G^\circ_5 = \Delta G^\circ_7$ and $\Delta G^\circ_4 = \Delta G^\circ_6$. If it is assumed that the enzyme does not close until both reactants are present, then $\Delta G^\circ_1 < 0$, $\Delta G^\circ_3 < 0$, and $\Delta G^\circ_9 < 0$. When both reactants are bound, the conformational change takes place, and therefore $\Delta G^\circ_8 > 0$. When reactant A binds to the enzyme in the absence of reactant B to form E_o·A, the standard free energy of dissociation is ΔG°_4. When reactant A binds to the enzyme after reactant B has been bound to form E_c·A·B, the standard free energy of dissociation is $\Delta G^\circ_6 + \Delta G^\circ_8$ or $\Delta G^\circ_9 + \Delta G^\circ_{11}$, both of which must be more positive than ΔG°_4. When reactant B binds to the enzyme in the absence of reactant A to form E_o·B, the standard free energy of dissociation is ΔG°_5. When reactant B binds to the enzyme after reactant A has been bound to form E_c·A·B, the standard free energy of dissociation is $\Delta G^\circ_7 + \Delta G^\circ_8$ or $\Delta G^\circ_3 + \Delta G^\circ_{12}$, both of which must be more positive than ΔG°_5. Therefore, each reactant will bind more tightly when the other is already bound.

This linkage can be observed in the binding of reactants to hexokinase from *S. cerevisiae*. The dissociation constant for the binding of $MgATP^{2-}$ in the absence of monosaccharide to the empty, open active site is 4 mM. When D-lyxose binds along with $MgATP^{2-}$, the Michaelis constant for $MgATP^{2-}$ is 0.1 mM, and when D-mannose binds along with

$MgATP^{2-}$, the Michaelis constant for $MgATP^{2-}$ is 28 μM.[1029]

The linkage box and the linkage cube (Equations 3–437 and 3–440) imply that, in the absence of substrate, **open and closed conformations of the unoccupied enzyme are both present** and that, when substrates occupy the active site, closed and open conformations of the enzyme are also both present. Both open and closed conformations of the loop in triose-phosphate isomerase from *O. cuniculus* have been observed in the absence of ligands;[1030] both open and closed conformations of the loop in triose-phosphate isomerase from *P. falciparum* have been observed when the active site of the enzyme is occupied by phosphoglycolate, an analogue of the *cis*-enediol intermediate in the reaction;[1031] and both open and closed conformations of the loop in triose-phosphate isomerase from *S. cerevisiae* have been observed in the unoccupied enzyme, the enzyme occupied by substrates, and the enzyme occupied by phosphoglycolate.[1032]

The loop that closes over the substrates when they associate with the active site of human phosphoribosylglycinamide formyltransferase also closes over the empty active site when the pH of the solution for crystallization is 4, and this closure blocks access of the substrates. When the pH of the solution for crystallization is 8, however, the loop is in the open conformation with the active site ready for association.[1033] At intermediate values of pH, both the open and closed forms must be in equilibrium with each other because the catalytic constant of the enzyme declines smoothly as the pH is lowered as a consequence of the shift in the equilibrium between the open accessible active site and the closed inaccessible active site.

When arginine kinase from *L. polyphemus* is in solution in the absence of substrates or inhibitors, nuclear magnetic resonance spectra are consistent with an equilibrium existing between the open and closed conformations that are observed crystallographically.[1018]

In solution, nuclear magnetic resonance spectra of adenylate kinase from *E. coli* to which $MgATP^{2-}$ has bound are consistent with the existence of an equilibrium mixture in which its two domains are in closed and open conformations.[1034] When the equilibrium for the unoccupied enzyme is shifted toward the open conformation by mutation, the catalytic constant of the enzyme increases, and when the equilibrium is shifted in favor of the closed conformation by decreasing the concentration of water in the solution, the catalytic constant decreases,[962] as expected if the substrates can associate only with the open conformation of the enzyme.

It is the case, however, that the linkage box and the linkage cube (Equations 3–437 and 3–440) only imply that, in the absence of substrate, open and closed conformations of the unoccupied enzyme are both present, not that they are required to be. It has already been noted that even if the open conformation observed in crystallographic molecular models is only one member of an array of states, the entire ensemble can be assigned a standard free energy. Even if the closed conformation does exist only in vanishingly small concentration in the absence of substrate or substrates, nevertheless it would have a standard free energy.

In solution, the closing of a loop of polypeptide or the closing of domains over an active site is a dynamic process, and particular rate constants govern these conformational changes. In triose-phosphate isomerase from *S. cerevisiae*, the rate constant at 25 °C for closing the loop over either the unoccupied or the occupied active site is 40 ms^{-1}, and the rate constant at which it swings open is 3 ms^{-1}.[1032,1035] These rates are in the same range as the catalytic constant of the enzyme (3–10 ms^{-1}), and this fact suggests that either the closing or the opening of the loop is the rate-limiting step in catalysis or at least a significant rate-affecting step.

In the crystallographic molecular model of the complex between arginine kinase from *L. polyphemus* and L-arginine, $MgADP^{-}$, and nitrate (Figure 3–41), in addition to the two domains that have closed around the substrates, there is a loop of polypeptide from Isoleucine 182 to Glycine 209 that has folded over the substrates and the nitrate. Arginine 309, Threonine 311, and Glutamate 314 in this loop form hydrogen bonds to the substrates.[630] In the crystallographic molecular model of the unliganded enzyme, this loop has swung away from the active site, and the portion of the loop from Threonine 311 to Glutamate 319 is disordered and lacks electron density in the map.[1018] Transverse relaxation optimized spectra of nitrogen-15 nuclei in this loop in arginine kinase can be used to estimate the rate at which this loop closes over the active site. The rate of its closure in the unoccupied enzyme (40 s^{-1}) is slower than the catalytic constant (110 s^{-1}), but the activation energy for its closure (35 ± 10 kJ mol^{-1}) is the same as that for the catalytic constant.[1036] These measurements suggest that the rate-limiting step in

the nucleophilic substitution at phosphorus catalyzed by arginine kinase is the closure of this loop.

The dynamic opening and closing of the cleft between the domains in unoccupied phosphoglycerate kinase[1037] also seems to correlate with the turnover of the enzyme,[1038] and the rate constant for a global conformation change in unoccupied bovine pancreatic ribonuclease ($1.7\ ms^{-1}$) agrees closely with the catalytic constant of the enzyme ($1.9\ ms^{-1}$) under the same conditions.[1039,1040] All these results suggest that, in at least some enzymes, the rates of the conformational changes required for the active site to close around the reactants or for the active site to open to release products are rate-limiting steps in the rate of the reaction catalyzed by the enzyme.

In the case of dihydrofolate reductase from *E. coli*, however, conformational fluctuations associated with catalysis are observed after substrates have associated with the active site, it has already closed around them, and catalysis is taking place.[1041] Intrinsic fluctuations in the closed, occupied active site of the same enzyme that are detected by nuclear magnetic resonance spectroscopy are dramatically reduced in two different mutants of the enzyme, and in active sites of these rigid mutants, the rate of hydride transfer is 20-fold less than in the wild type.[1042] These results suggest that conformational fluctuations in an active site can continue to play a role in catalysis even after that active site has closed around the reactants.

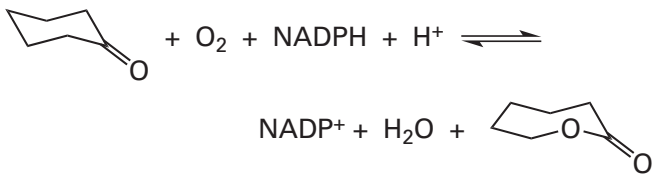
Association of Reactants and Dissociation of Products

Both associations of the reactants with the active site and usually their respective dissociations from the active site as reactants, as well as dissociations of the products of the enzymatic reaction, are inescapable steps in the kinetic mechanism of an enzymatic reaction, and they can be rate-affecting or even rate-limiting. Although most active sites are open to the solution and immediately accessible to their reactants or open and accessible before they close around their assembled reactants by an induced fit, there are a number of **molecular and structural aspects** that influence the events involved in this association in addition to its rate. For example, in a crystallographic molecular model of the ternary complex of $NADP^+$, cyclohexanone, and the flavoenzyme cyclohexanone monooxygenase



(3–441)

from *Rhodococcus*, the cyclohexanone occupies the same position as the nicotinamide ring does in the binary complex between the enzyme and $NADP^+$. This observation suggests that the nicotinamide ring in the ternary complex has swung out of its position in the binary complex. It was concluded that the oxidized nicotinamide ring, after it has reduced the flavin, has to swing away from the flavin before the cyclohexanone can associate.[1043]

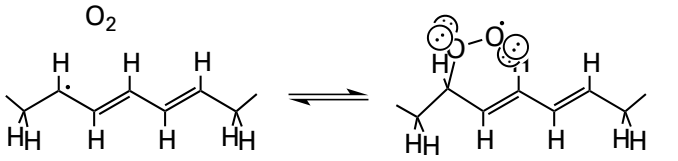
When a reactant associates with an active site, it must always displace molecules of water that occupy the active site in its absence. It has been pointed out that, because the active site has been designed by natural selection to associate with its reactants and not those molecules of water, the molecules of water that will be displaced by the reactant are poorly coordinated relative to their coordination in the bulk solution. As a result, they are more easily displaced during the association.[1044] The rate at which they are displaced may have been enhanced by natural selection.

The **reactant in one direction of an enzymatically catalyzed reaction is a product in the other direction**. Consequently, the molecular aspects of the process of association of a particular reactant apply in reverse to its dissociation as a product and

vice versa. For example, the steps in the dissociation of CO_2 as a product from the active site of human carbonic anhydrase and its replacement by two fixed molecules of water can be followed crystallographically,[1045] and these steps must apply in reverse to its association as a reactant.

Often **access to an active site can be a compromise** mediated by natural selection. In the active site of myohemerythrin from *Phascolopsis gouldii*, a carrier of molecular oxygen, there is an invariant leucine. Mutating the leucine to a phenylalanine decreases the rate of association of oxygen with the iron ions by a factor of more than 100 because of steric hindrance by the larger side chain, but mutating it to valine, which has a smaller side chain, increased 3-fold the rate of autoxidation of the heme, an unfortunate side reaction.[1046] Mutating Alanine 68 in myoglobin from *Physeter catodon* to large amino acids also decreased the rate of association of oxygen with the heme.[1047]

In other instances, access of a reactant to the active site has been altered by natural selection to create new opportunities. In the common mechanism of a set of closely related lipoxygenases, each with different regiochemistry or stereochemistry, a molecule of oxygen adds to a pentadienyl radical



(3–442)

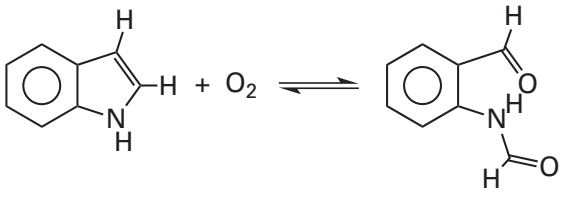
formed during the enzymatic reaction within the respective polyunsaturated fatty acid that is a reactant for the enzyme. The presence of a glycine at a particular location in the active site of two enzymes in this family permits the oxygen to associate and react at a carbon of the pentadienyl radical immediately adjacent to the glycine to produce the products specific to these enzymes. The presence of an alanine, however, at the same location in the active sites of two other members of the family prevents access to this carbon, and the oxygen adds instead to the other end of the pentadienyl radical to produce the products specific to these other enzymes.[1048]

It has already been noted that association of a nucleic acid with an enzyme is challenging because of its size. In the case of aspartate—tRNA ligase from *S. cerevisiae*, the initial nucleophilic substitution at the γ-phospho group of $MgATP^{2-}$ and the subsequent nucleophilic substitution at the α-carboxy group of L-aspartate catalyzed by the active site occurs at the 3′-hydroxy group of the ribose at the 3′ end of the $tRNA^{Asp}$; the four nucleotides at the 3′ end are not paired in the acceptor stem of the $tRNA^{Asp}$ and are freely moiling in solution;[1049] and the active site at which the nucleophilic substitutions occur is a shallow depression on the surface of enzyme with which only the cytidine and the adenine at the very 3′ end have any contact.[1050] Consequently, one might think that there would be no problem with the association of the reactant $tRNA^{Asp}$ with the active site of the enzyme. Aspartate—tRNA ligase, however, must recognize the transfer RNA as $tRNA^{Asp}$ unerringly. If it were to esterify L-aspartate to any other transfer RNA, a mutation would occur in the elongating protein to which L-aspartate is subsequently added. Aspartate—tRNA ligase from *S. cerevisiae* is a rigid homodimer (2×556 aa) of the same dimensions as $tRNA^{Asp}$ from *S. cerevisiae*, and following the association of $tRNA^{Asp}$ with the enzyme, an interface has formed along the whole length of the enzyme and the whole length of the $tRNA^{Asp}$ that brings them into intimate contact.[1050,1051] At one end of the interface, the cytidine and adenine at the 3′ end of the $tRNA^{Asp}$ have entered the active site of aspartate—tRNA ligase. Seven nanometers from the active site at the other end of the interface, which is at the other end of $tRNA^{Asp}$ at the tip of the anticodon arm, the guanosine, uridine, and cytidine of the anticodon associate intimately with a binding site on the surface of aspartate—tRNA ligase. In this instance, recognition of the actual anticodon ensures that the correct transfer RNA with the correct anticodon has been selected. In contrast, in the complex between $tRNA^{Leu}$ and leucine—tRNA ligase from *T. thermophilus*, although the anticodon stem is held firmly by the homologous domain on the ligase, the anticodon loop itself does not contact the ligase.[1052] In the middle of the interface, between the active site and the anticodon in aspartate—tRNA ligase from *S. cerevisiae*, there is another binding site on the surface of the protein into which the D loop of $tRNA^{Asp}$ inserts to provide further insurance. During the association of $tRNA^{Asp}$ with aspartate—tRNA ligase, there are various loops of polypeptide that reorient in induced fits, but these reorientations, although they may perform other purposes, are not so consequential to the correct association of the enzyme with its reactant.

Provocative descriptions of the **intermediate steps in the association or dissociation** of a substrate can be provided by calculations, and those descriptions can then be assessed experimentally.[1053]

Occasionally, as was the case with carbonic anhydrase, intermediates in the association and dissociation of a substrate can be observed crystallographically. For example, in a crystallographic molecular model of the active site of aspartate carbamoyltransferase (Equation 3–220) from *E. coli*, crystallized in the presence of the substrate phosphate, there are two phosphate ions occupying the site, one at the location occupied by the phospho group of the substrate carbamoyl phosphate in the crystallographic molecular model of its complex with the active site, and the other in an adjacent location.[1054] It has been proposed that the second phosphate is occupying a way station for a phosphate on its way out of or into the active site.

Separate crystals of human indoleamine 2,3-dioxygenase (previously Equation 2–248)



(3–443)

that had been soaked for different times in a solution of the inhibitor *N*-(4-chlorophenyl)-4-(6-fluoro-4-quinolyl)-α-methyl-*cis*-(αR)-cyclohexaneacetamide could be selected. In three different crystallographic molecular models obtained from these selected crystals, the inhibitor occupied three different locations in the tunnel leading to the active site. In each model, only one inhibitor was in the tunnel, in each case in its unique location. It was proposed that these three different locations represented intermediate way stations in the passage of inhibitor to its final location as a ligand to the iron ion in the heme at the end of the tunnel.[1055]

As with indoleamine 2,3-dioxygenase, there are a number of enzymes in which the active site is deeply buried in the protein, and access for substrates is afforded by a tunnel passing into the protein from the solution. For example, the iron ion of the heme in catalase from *Bos taurus* or *S. cerevisiae* is at the blind end of a straight tunnel 3 nm long and 1.5 nm wide at its opening to the solution on the surface of the protein. The tunnel gradually narrows to a width of 0.6–0.9 nm just above the iron ion and is lined by nonpolar side chains (Figure 3–59).[1056-1058] The substrates H_2O_2, H_2O, and O_2 pass through this tunnel while associating with and dissociating from the iron. When they are not occupied by substrates, locations along one of these tunnels in a catalase are occupied by molecules of water except at its narrow, innermost end. The tunnel for substrates into the imino carbon of the internal pyridoximine in the active site of diaminopropionate ammonia-lyase from *E. coli* is 1.2 nm long. It narrows slightly as the imino carbon is approached and the intruder has to be identified as one of the substrates: 2,3-diaminopropanoate, pyruvate, or ammonia.[1059]

The tunnel into the heme in the active site of bovine cholesterol monooxygenase (side-chain-cleaving) is also a long one. When 22*R*-hydroxycholesterol, an intermediate in the reaction, is in position to be oxidized, it fills two-thirds of the tunnel because it is so large.[1060] This situation is in contrast to the tunnel to the heme in catalase and the tunnel to the pyridoximine in diaminopropionate ammonia-lyase, which are both enzymes with small substrates. In cholesterol monooxygenase, the tunnel not only serves as access to the heme but probably has a role in specifically selecting the cholesterol that is the substrate for the reaction.

There is a long convoluted tunnel from the surface of the protein into the diiron cluster (see Figure 2–57I) in the active site of methane monooxygenase (soluble) from *Methylosinus trichosporium* that is remarkably uniform in width. It is wide enough to allow the passage of the substrates O_2 and CH_4 from the solution into the active site but narrow enough to hinder the access of larger hydrocarbons, a fact that would explain the preference of the enzyme for methane. The enzyme is activated by a smaller protein, the association of which with the enzyme increases the bimolecular rate of association of O_2 with the cluster by a factor of more than 1000. In the absence of this activator, the tunnel is almost completely constricted about halfway along its length; the conformational change of the enzyme produced by the activator eliminates the constriction and opens the channel.[1061] Site-directed mutation of Valine 41 at the opening of the tunnel on the surface of the protein, which is well removed from the active site, to an arginine decreases the rate of association of O_2 with the cluster in the center of the protein by a factor greater than 25,000.

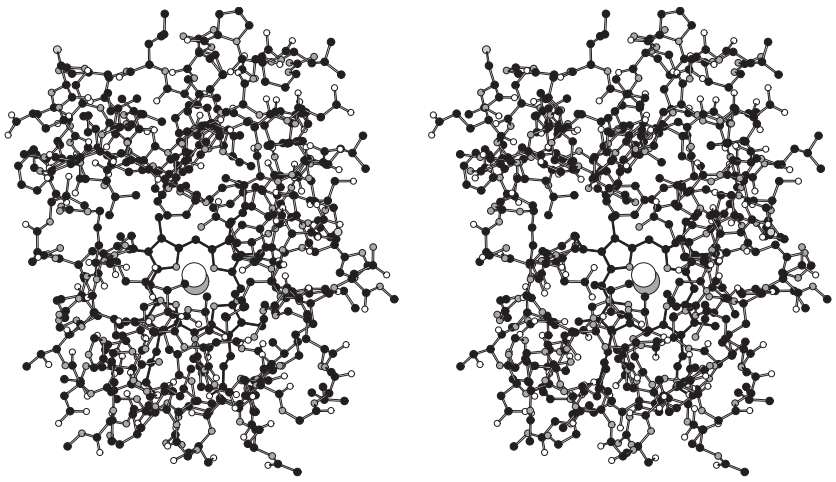


Figure 3–59: Stereodrawing[576] of the tunnel into the active site in the crystallographic molecular model of bovine catalase.[1058] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. Bovine catalase was purchased and further purified by size-exclusion chromatography. To the pooled and concentrated solution of catalase, NH_4OH was added to adjust the pH, and an equal volume of 50 mM magnesium formate was then added. The protein was then crystallized in this solution. The crystals were suspended and mixed with 1-(*N*,*N*-diethylamino)diazen-1-ium-1,2-diolate, which releases nitric oxide when dissolved in water, and the nitric oxide generated was then bound as a ligand to the iron in the heme. The crystals diffracted X-rays to Bragg spacing of 0.188 nm. A map of electron density was calculated by molecular replacement using the known structure of bovine catalase,[1056] and the molecular model was submitted to refinement. The drawing is of six segments of polypeptide in the molecular model that line the tunnel into the active site. The heme (black bonds) can be seen at the end of the tunnel. The nitric oxide on the iron ion in the center of the heme, which is hidden by the nitric oxide, is drawn in space-filling representation to illustrate the sizes of molecular oxygen, hydrogen peroxide, and water, which are the substrates for the enzyme and each must pass through the tunnel to and away from the heme.

One of the longest tunnels (16 nm) that has been found to date is the tunnel into the active site of the exosome from *S. cerevisiae*, a large enzyme (4000 aa) responsible for the hydrolysis of single-stranded RNA. This tunnel accommodates about 25 nucleotides of single-stranded RNA.[1062] The enzyme is composed of 11 different subunits, some structurally related and others structurally unrelated to each other, and the tunnel passes through the center of the protein among and within the subunits. The active site at the end of the long tunnel is an exoribonuclease II, catalyzing the hydrolysis of 5′-nucleotides from the unphosphorylated 3′ end of the single-stranded RNA threading through the tunnel. As each 5′-nucleotide is disconnected from the RNA by hydrolysis, it dissociates from the active site into the solution.

An acyl-SCoA is a long molecule. At one end of the molecule is a 3′-phosphoadenosyl group, and between its 5′-oxygen and the sulfur of the coenzyme A, there is a linear chain of 15 atoms, none of which is excessively substituted. Attached to the sulfur of the coenzyme A is an acyl group, which in the case of the reaction catalyzed by acyl-CoA:acyl-CoA alkyltransferase from *Xanthomonas campestris* is at least 14 carbons long, which makes the entire linear portion of the molecule at least 31 atoms long. There is a tunnel from the surface of the enzyme into the active site, which is in the center of the protein (338 aa). The linear portion of an acyl-SCoA that is a reactant for the enzyme threads through the tunnel, with the fatty acyl group in the lead, and it continues threading beyond the catalytic subsite into a blind tunnel lined with nonpolar side chains while the linear portion of coenzyme A ends up filling the tunnel with the adenylyl group sitting on the outside end of the tunnel acting as a stop to the threading. When the threading is halted by this stop, the thioester of the acyl-SCoA ends up adjacent to the catalytic subsite. When the thioester arrives at the catalytic subsite, its acyl group is transferred to the sulfanyl group of a cysteine to form a thioester of the cysteine. Then, the first product of the overall reaction, the coenzyme A that was a portion of the first acyl-SCoA, dissociates from the tunnel, leaving behind the thioester of the acyl group. A second acyl-SCoA threads into the tunnel. Its acyl group threads into a second blind tunnel leading away from the catalytic subsite in the opposite direction to the first. The enolate of the second acyl-SCoA then adds in a Claisen condensation to the thioester of the initial acyl group on the sulfanyl group of the cysteine to form the ketone containing both alkyl chains that is the product of the enzymatic reaction.[1063]

The active site of cellulose synthase (UDP-forming) adds D-glucosyl groups from UDP-glucose to an elongating polymer of cellulose, $[(\beta 1,4)$-D-glucosyl$]_n$.* In the crystallographic molecular model of the enzyme from *Cereibacter sphaeroides*, the active site at which the glucosyl groups are added to the elongating polymer could be identified by the UDP-glucose with which it is occupied. The active site is located in the cytoplasmic domain of the enzyme, which spans the plasma membrane of the cell. UDP-Glucose enters the active site from the cytoplasmic solution in which it is made, but the elongating polymer emerges from the enzyme across the membrane into the extracytoplasmic solution. In the crystallographic molecular model, there is a polymer of cellulose, 18 $(\beta 1,4)$-D-glucosyl groups long, located in a tunnel 0.8 nm wide and 6 nm long that leads out of the active site across the membrane into the extracytoplasmic solution.[1064] As each $(\beta 1,4)$-D-glucosyl group is added to the elongating chain of cellulose, it slides along the tunnel. In theory, an infinitely long polymer of cellulose could be continuously secreted into the extracytoplasmic solution by the enzyme. The distantly related (according to alignment of amino acids in the active site) cellulose synthase from *Populus tremula* is a rotationally symmetric trimer, rather than being a monomer, with a threefold rotational axis of symmetry normal to the plane of the membrane. The three tunnels in its membrane-spanning portion converge on a common point of exit on the threefold rotational axis of symmetry. The product that emerges from this common point of exit is a protofibril of cellulose, which is a trimeric strand of cellulose monomers.[1065]

Tunnels that connect a buried active site with the solution are often not so straight and direct as they are in catalase, diaminopropionate ammonia-lyase, cellulose synthase (UDP-forming), superoxide dismutase from *E. coli*,[1066] and ascorbate oxidase from *Cucurbita pepo*.[1067] Tunnels can be **tortuous** and of irregular width[1068] and contain **abrupt changes of direction**.[1069] They sometimes bifurcate and have **two openings** to the solution.[1070] The tunnel into the active site in 3-hydroxybenzoate 4-monooxygenase from *C. testosteroni* has two openings to the solution, one hydrophilic and the

*Amylose, which is the primary source of energy for humans, is $[(\alpha 1,4)$-D-glucosyl$]_n$, which is readily digested. Cellulose, $[(\beta 1,4)$-D-glucosyl$]_n$, unfortunately, cannot be digested by humans.

other hydrophobic, that provide access to a large internal chamber adjacent to the prosthetic flavin.[1071] In some instances, as was the case with the tunnel into the active site in the unactivated form of methane monooxygenase (soluble), the tunnels seem to be interrupted by side chains that act as gates along the way, swinging into the tunnel or out of it.[1072]

As was the case for association of the inhibitor with indoleamine 2,3-dioxygenase, as reactants move into and products move out of the active site through these tunnels, there are **way stations along the course** with which substrates have been observed to associate in crystallographic molecular models.[1071,1073] These way stations may assist in the selection of the correct reactant and thereby increase the rate of the enzymatic reaction at low concentrations of reactant, but the association of a reactant with one of these way stations may cause reactant inhibition by blocking the dissociation of product at high concentrations of reactant.[1074]

Tunnels into active sites are usually identified by applying algorithms that calculate the surface of the anhydrous crystallographic molecular model to molecules of water and then search for **regions of continuous empty space** wide enough to permit passage of small molecules.[1075,1076] Tunnels can also be recognized in a crystallographic molecular model by the continuous distribution of actual, fixed molecules of water that usually occupy them.[1044] Those tunnels that are lined with hydrophobic amino acids can be traced in a crystallographic molecular model by filling them with xenon (van der Waals radius = 0.21 nm), an electron-dense (54 electrons atom^{-1}), hydrophobic noble gas applied to the crystal at high pressure while the data are collected.[1068,1070,1077,1078]

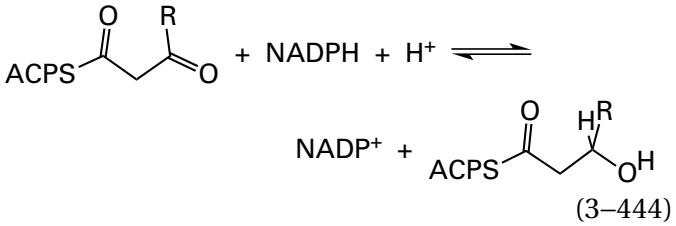
Aside from permitting sensitive prosthetic groups such as hemes, internal pyridoximines, flavins, and clusters of metallic ions to be **isolated within the protection provided by the protein** and yet still gain access to the substrates they must transform, tunnels into the active site can accomplish other purposes. The mouth of the hydrophobic tunnel in ovine prostaglandin-endoperoxide synthase is placed against the surface of a lipid bilayer when the enzyme is bound at a cellular membrane, and the arachidonic acid that is its reactant can slither up the tunnel out of the membrane into the active site.[1079] The narrow tunnel along the sevenfold rotational axis of symmetry of the eicosaoctamer into the large central cavity of the proteosome, in which the active sites for its endopeptidases are located[1080] and which is ungated in the prokaryotic enzymes but gated in the eukaryotic enzymes,[1081] is narrow enough to ensure that the protein to be digested by the proteosome enters as the unfolded polypeptide,[1082] which threads through the tunnel on its way to its hydrolysis.[1083]

When there are several tunnels from the solution to the active site, the question arises as to **which tunnel or tunnels are used by the substrates.** The cluster of four manganese ions, five μ-oxo ions, and a Ca^{2+} (Figure 2–59) in the crystallographic molecular model of photosystem II from *Thermosynechococcus vulcanus* is responsible for the oxidation of two molecules of water to a molecule of oxygen. This cluster is well buried within the protein. There are three tunnels from the solution to the cluster that are occupied by fixed molecules of water, and each is a candidate for the tunnel through which the molecules of water that are substrates for the enzyme could queue.[1076] Only one of the three tunnels leads from the solution to a molecule of water that is a ligand to the Ca^{2+} in the cluster. Results from Fourier transform infrared spectroscopy identify this molecule of water as contributing one of the oxygen atoms in the molecule of oxygen produced by the cluster.[1084] The μ-oxo ion that contributes the other oxygen atom is also a ligand to the Ca^{2+}, as well as to three manganese ions. In the coordination sphere of the Ca^{2+}, that μ-oxo ion is immediately adjacent to the molecule of water at the end of the tunnel. As the cluster produces molecules of oxygen, molecules of water destined to become oxygen move along the tunnel from the solution to the cluster.

In each crystallographic molecular model from three different species, five tunnels from the solution to various locations around the [Mo–7Fe–9S–C] cluster buried in dinitrogenase can be identified.[1085] In this instance, since it is still unclear with what position in the cluster molecular nitrogen associates, the tunnel or tunnels through which it usually approaches the active site cannot yet be assigned.

Pharmaceutical agents can exert their effects by **blocking a tunnel**. Aspirin, 2-acetyloxybenzoic acid, achieves its anti-inflammatory effect by acetylating a serine lining the tunnel[1079] into the active site of ovine prostaglandin-endoperoxide synthase and blocking the slither of the arachidonic acid from a membrane into the active site.[1086] Ibuprofen, 2-[4-(2-methylpropyl)phenyl]propanoic acid, blocks the same tunnel by binding tightly within it.[1079]

Because there is no such thing as a bare hydron in solution, for enzymes that have a hydron as one of their stoichiometric reactants or products, there must be one or several lone pairs of electrons responsible for shuttling a hydron into or out of the active site. When a hydron is a reactant, that hydron could occupy a lone pair of electrons on another reactant as it enters the active site, but then the active site would have to associate with the conjugate acid of that reactant, which may be present at lower concentration in the solution than the conjugate base. When a hydron is a product, that hydron could leave the active site on a lone pair of electrons on another product, but there may be no basic lone pair of electrons on that other product that is accessible to the hydron when the other product and the hydron are produced in the active site. For example, a hydron is a reactant in the reaction catalyzed by 3-oxoacyl-[acyl-carrier-protein] reductase



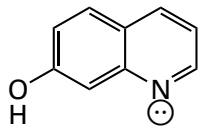
(3–444)

where ACPSH is acyl-carrier protein. This hydron does not enter the active site on its ultimate receptacle, the 3-oxo oxygen of the 3-oxoacyl-[acyl-carrier-protein], because this oxygen is not basic ($pK_a < -7$).

In many instances, an active site is exposed sufficiently to the bulk solvent to permit the delivery of a hydronium, or there is a water-filled channel connecting it to the bulk solvent that would permit a hydronium to enter it. In the crystallographic molecular model of the complex between 3-oxoacyl-[acyl-carrier-protein] reductase from *E. coli* and $NADP^+$, however, a tyrosine, which forms a hydrogen bond with the carbonyl oxygens of the respective substrates in crystallographic molecular models of the complexes of homologous enzymes with their substrates and which hydronates each of these oxygens during those reactions, is not in direct contact with the solution but is connected to it by a network of hydrogen bonds (Figure 3–60)[1087,1088] that can act as a hydron wire during the association of the hydron that is a stoichiometric reactant.

A **hydron wire** is a chain of hydrogen bonds into one end of which a hydron enters and out of the other end of which a hydron emerges[1089] or out of one end of which a hydron is removed and into the other end of which a hydron enters.[1090] The distinction between these two processes is that, as the hydrons are transferred between donors and acceptors for hydrogen bonds within the wire, either a sequence of conjugate acids or a sequence of conjugate bases, respectively, is the intermediate. In one case a hydron on sequential hydroniums is transported, and in the other case a basic lone pair of electrons on sequential hydroxides is transported. The distinction is a kinetic one based on whether the acid at one end initiates the transfer by adding a hydron to the hydron wire or the base at the other end initiates the transfer by removing a hydron from the hydron wire. In the case of 3-oxo-acyl-[acyl-carrier-protein] reductase from *E. coli*, the two processes would be distinguished as a hydronium at one end of the hydron wire that adds a hydron to the wire and a hydron emerging from the wire onto the oxygen of the carbonyl of 3-oxoacyl-[acyl-carrier-protein] (Figure 3–60) or the oxygen of the carbonyl oxygen that removes a hydron from the wire and a molecule of water at the other end that adds a hydron to the wire and becomes a hydroxide. Considering the pK_a of the carbonyl group ($pK_a < -7$) the overwhelmingly most likely sequence of events is the former.

When 7-hydroxyquinoline, which is the neutral tautomer in solution at pH 7



3–127

absorbs a photon, the pK_a of the hydroxy group in the resulting excited state becomes 0.4 and the pK_a of the conjugate acid of the quinolyl nitrogen becomes 11.1 while the values of pK_a are 8.7 and 5.6, respectively, for these functional groups in the ground state. Consequently, in water or methanol, a hydron dissociates from the hydroxy group and a hydron is added to the nitrogen when neutral 7-hydroxyquinoline enters the excited state. In this instance, the removal of a hydron from a molecule of water or methanol by the quinolyl nitrogen initiates the transfer, rather than the addition of a hydron from the hydroxy group to a molecule of water or methanol, and, contrary to the probable situation in 3-oxoacyl-[acyl-carrier-protein] reductase, the transfer through a hydron wire of water molecules between the two functional groups is hydroxide or methoxide transfer.[1090]

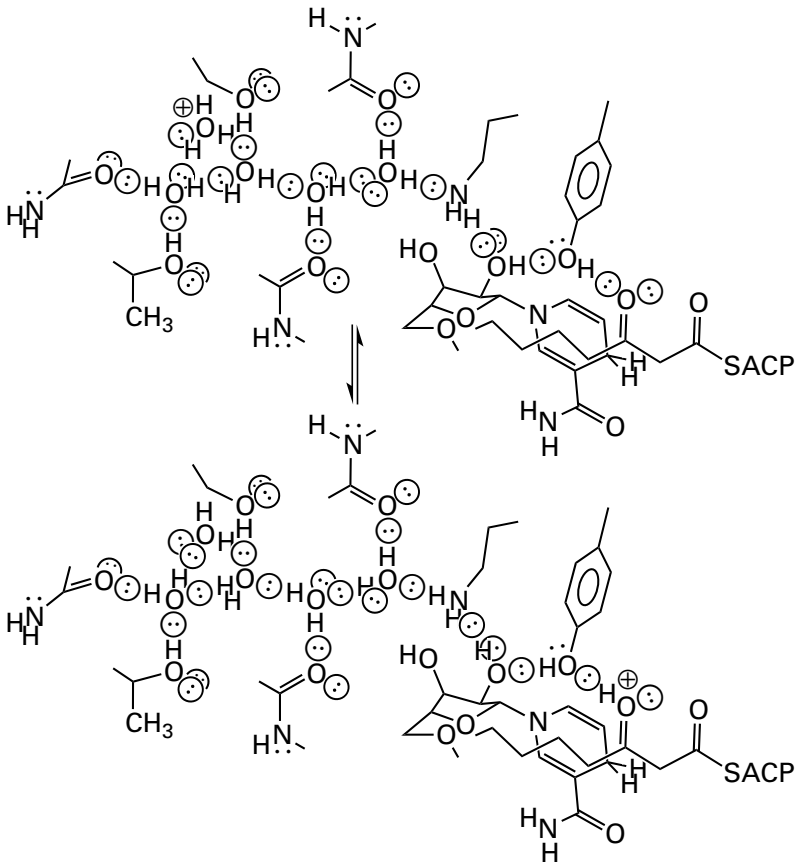


Figure 3–60: The hydron wire in the crystallographic molecular model of 3-oxoacyl-[acyl-carrier-protein] reductase from *E. coli*. The hydron wire does not form until the coenzyme $NADP^+$ or NADPH associates with the active site and induces a conformational change. The crystallographic molecular models on which the drawing is based are those of the binary complexes of the enzyme with either $NADP^+$ or NADPH. The hydrogen bond between the tyrosine and the carbonyl oxygen is inferred from crystallographic molecular models of complexes between substrates and inhibitors or other homologous short-chain dehydrogenases and reductases that reduce β-oxoacids in which the homologous tyrosine forms a hydrogen bond with the carbonyl carbon of the substrate. In the hydron wire illustrated here, a string of four molecules of water is held in fixed location by hydrogen bonds to the side chains of asparagine, threonine, and serine and the acyl oxygens of two amido groups of the polypeptide backbone. The wire then runs through the side chain of lysine, the 2-hydroxy group of NADPH, and the side chain of tyrosine before ending on the carbonyl oxygen of 3-oxoacyl-[acyl-carrier-protein]. Acyl-carrier protein is abbreviated ACPSH. A hydronium is shown donating a hydron to the first water in the wire.

In enzymatic reactions, although it can be decided with some certainty in cases such as 3-oxoacyl-[acyl-carrier-protein], it is usually unknown whether the transfer of a hydron through a hydron wire is the result of the transport of a hydron on sequential hydroniums or the transport of a lone pair of electrons on sequential hydroxides. From here on, for the sake of simplicity, it will be assumed that transport of a hydron is occurring.

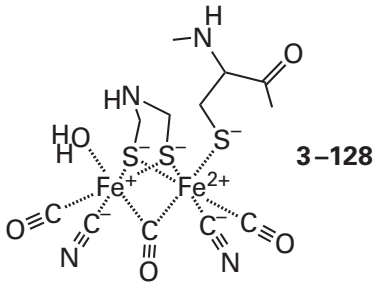
In at least one set of enzymes, the carbonic anhydrases

$$CO_2 + H_2O \rightleftharpoons HCO_3^- + H^+ \qquad (3–445)$$

it has been shown that, in the hydrations catalyzed by these enzymes, the **rate-limiting step is the transit of the hydron** that is the stoichiometric product through a hydron wire consisting of the imidazolyl group of a histidine and a chain of two fixed molecules of water.[1091] One of the hydrons on a molecule of water on the Zn^{2+} in the active site enters the hydron wire connecting the active site with the solution. This hydron is transferred through the hydron wire to a general base or a molecule of water in the solution.[1092-1096] The distribution of hydrons in this hydron wire can be defined by **neutron diffraction**.[1097] The molecule of water that will accept the hydron is neutral and is the acceptor in a hydrogen bond to the molecule of water on

the Zn^{2+} from which the hydron is to be removed. One of its hydrogens is the donor in a hydrogen bond to the next molecule of water, and one of the hydrons on this molecule of water is a donor to the lone pair of electrons on the nitrogen of the imidazolyl group from which a hydron is to depart into the solution.*

Changes in the hydronation state within a hydron wire resulting from changes in the active site can be assessed by examining difference spectra from **Fourier transform infrared spectroscopy**. The wire for the two hydrons that are substrates for ferredoxin hydrogenase from *Chlamydomonas reinhardtii* runs from the solution through the guanidinio group of an arginine, the carboxy group of a glutamate, the hydroxy group of a serine, the carboxy group of a glutamate, a fixed molecule of water, and the sulfanyl group of a cysteine to the secondary amino group in a diiron cluster (previously **2–137**)

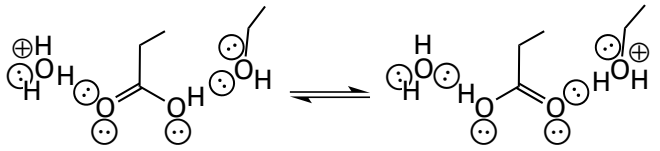


3–128

in the active site.[1098] The same hydron wire is also conserved in the related ferredoxin hydrogenase from *Clostridium pasteurianum* (37% identity; 1.6 gap percent)[1099] The cluster can be photoreduced, and differences in peaks of absorbance in Fourier transform infrared spectra between the oxidized state and the photoreduced state are observed upon photoreduction. These differences could be assigned by successive site-directed mutation to changes in the absorption of side chains of the amino acids in the hydron wire resulting from changes in their state of hydronation upon photoreduction.[1100]

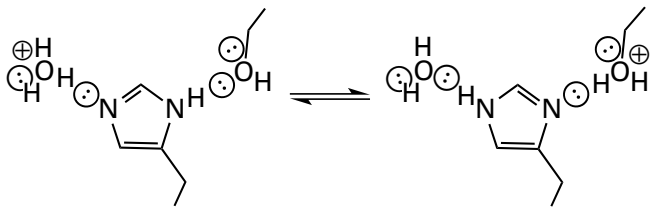
A hydron wire can be as short as a molecule of water and the hydroxy group of a threonine,[1101] but in the hydron wire in 3-oxoacyl-[acyl-carrier-protein] reductase (Figure 3–60), there are four fixed molecules of water at one end, then an unhydronated lysine, the 2′-hydroxy group of the NADPH, and the tyrosine, with the carbonyl oxygen of the bound reactant at the other end. The hydron wire in thymidylate kinase from *M. tuberculosis* runs from the solution through the carboxy group of a glutamic acid, the hydroxy group of a serine, the guanidinio group of an arginine, and the carboxy group of an aspartic acid to the phospho group that is transferred by the enzyme.[1102] The hydron wire that connects the oxygen of sorbose that must be hydronated during the reaction catalyzed by sorbose reductase from *Gluconobacter frateurii* runs from the solution through two fixed molecules of water, the 6-amino group of a lysine, the 2′-hydroxy group of the nicotinamide ribose in NADPH, and the 4-hydroxyphenyl group of a tyrosine.[1103] The hydron wire out of the active site of betaine-aldehyde dehydrogenase from *P. aeruginosa* runs through two carboxy groups of two glutamates into the solution.[1104] The hydron wire in nitrite reductase (NO-forming) from *Alcaligenes xylosoxidans* runs from the solution through the imidazolyl group of a histidine, two fixed molecules of water, and the carboxy group of an aspartic acid to the nitrite being reduced by the enzyme. [1105]

While one of their oxygens alone can function as if it were a simple hydroxy group, albeit with a far more negative pK_a, **carboxy groups**, such as the two in the hydron wire of betaine-aldehyde dehydrogenase, are able to span a greater distance



(3–446)

than a molecule of water, a hydroxy group, or an amino group. The two nitrogens in a stationary **imidazolyl group** are able to span the same distance as the two oxygens in a carboxyl group



(3–447)

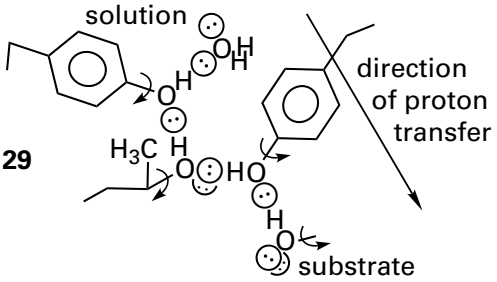
but in the hydron wire in human carbonic anhydrase 2,[1092] the imidazolyl group on Histidine 64 covers an even greater distance by swinging 0.35 nm about the pivot of the bond between its α and β carbons. It assumes two different conformations

*In this instance, it seems more likely that a hydroxide ion in the solution removes a hydron from the imidazolyl group to initiate the transfer of the hydron.

while shuttling the hydron, one in contact with the solution and the other in contact with a fixed molecule of water in the hydron wire leading from the active site.[1091]

For many hydron wires, only the hydron that is a stoichiometric reactant or product has to be transferred into or out of the active site, respectively, for each turnover, and the arrangement of hydrogen bonds in the wire can be **reset between turnovers**. In the case of the hydron wire in 4-hydroxy-tetrahydrodipicolinate synthase from *E. coli*, however, three hydrons are passed along it into the active site during a single turnover.[1106]

To accomplish the **transfer of more than one hydron**, which is always required for multiple turnovers of an enzyme that has only one hydron as a stoichiometric substrate, each participant in a hydron wire has to rotate after the first hydron has been moved to reestablish the initial distribution of hydrons in the wire. For example, the distribution of hydrons in the wire in 4-hydroxy-tetrahydrodipicolinate synthase[1106] after the transfer of the first hydron



3–129

can be converted to the distribution required for the second transfer by rotations of the hydroxy groups on tyrosine, threonine, tyrosine, and the substrate of 180°, 120°, 180°, and 120°, respectively. A rotation of 180° in a carboxyl group (Equation 3–446) reestablishes the initial distribution, but an imidazolyl group (Equation 3–447) cannot rotate to reestablish the initial distribution because its two nitrogens are not symmetrically disposed. Consequently, as in carbonic anhydrase and nitrite reductase (NO-forming), the imidazolyl groups in a hydron wire are usually at the interface with the solution where a symmetric rotation is not required.

Bacteriorhodopsin from *Halobacterium salinarium* is an enzyme that catalyzes the reaction[1107]

$$2\ h\nu_{575} + H_i^+ \rightleftharpoons H_o^+ \qquad (3\text{–}448)$$

where H_i^+ is a hydron inside the cell and H_o^+ is a hydron outside the cell. The absorption of a photon produces a photoisomerization of the retinal that is a prosthetic group in the active site, and for every two photons absorbed, the photoisomerization succeeds in moving one hydron in the proper direction. The hydron wire from the solution on one side of the membrane into the active site and the hydron wire from the active site into the solution on the other side of the membrane together **have to transfer hydrons over a considerable distance** (3.5–4.0 nm).[1108,1109]

The hydron wire from the cytoplasmic solution into the active site is composed of a carboxy group from an aspartic acid and four molecules of water, and it is reconstructed from different molecules of water from the solution during each turnover so that no rotation of its participants is required between turnovers.[1110] Mutation of the aspartic acid in this hydron wire to asparagine slows the uptake of hydrons by the enzyme by 20-fold.[1111,1112]

The hydron wire out of the active site into the extracytoplasmic solution is composed of a molecule of water, the oxygen of a carboxyl group, a molecule of water, and the guanidinio group of an arginine.[1113,1114] The guanidinio group changes its position during each turnover from one in which it is forming a hydrogen bond to the interior molecule of water in the hydron wire to one in which it can form hydrogen bonds with molecules of water in the solution.[1115] Mutation of the aspartate in this hydron wire decreases the quantum yield of hydron transport 20-fold without affecting hydron uptake,[1112] and mutation of the arginine eliminates rapid hydron release into the extracytoplasmic solution.[1116]

Many hydron wires in enzymes contain two or more fixed molecules of water. The hydron wire into the active site in bacteriorhodopsin is composed in part of four **fixed molecules of water in a chain of hydrogen bonds**. In liquid water, such evanescent chains of molecules of water, through which the net of one hydron can be rapidly transferred, are thought to be responsible for the anomalously high mobility of hydrons in this solvent. In this explanation, a hydron would associate with a molecule of water at one end of the chain, and then there would be an almost instantaneous, concerted shift of hydrons within the hydrogen bonds of the chain that results in the molecule of water at the other end of the chain becoming a hydronium.* The net result would be the formal transfer of a hydron from one end of the chain to the other.[1089] Such hydron jumping probably

*The description of this process is usually attributed to Theodor Grotthus.[1117]

occurs in a hydron wire in enzymes where there are molecules of water in a chain of hydrogen bonds and hydroxy groups.[1118] There are also a number of synthetic materials that incorporate continuous, isolated chains of water molecules,[1119,1120] and there are calculations leading to the conclusion that hydron transfer through such single-file chains of water molecules can be as much as 40 times faster than hydron transfer in bulk water.[1121,1122]

As was the case with bacteriorhodopsin, a decrease in the rate of an enzymatic reaction resulting from the **mutation of an amino acid** participating in a chain of hydrogen bonds that is a candidate for a hydron wire is often used as evidence for the participation of that hydron wire in transferring hydrons into or out of the active site.[1101,1123] For example, mutation of two histidines on the way from the solution into the active site of the reaction center from *C. sphaeroides* decreases the rate of the first hydron transfer into the active site by a factor of 10 and the second hydron transfer by a factor of 4.[1124] Mutation of a histidine on the way from the active site of aryl-alcohol dehydrogenase from *P. putida* into the solution[1028] to glutamine decreases the specificity constant of the enzymatic reaction for benzyl alcohol by a factor of 125, and the effects of amines added to the solution are consistent with this decrease in rate arising from a decrease in the rate of transfer of the stoichiometric hydron in the overall reaction out of the active site.[1125] The fact that the participants in a hydron wire are conserved in a large number of species in which the enzyme is found is another indication of their importance to the enzymatic reaction.[1099]

While in some instances the rate constant of association of a reactant is so fast that it is equal to that expected for encounter control,[1126] the second-order rate constants for associations of reactants with the active site of an enzyme usually have values that are less than the rate constant predicted for an encounter-controlled reaction between a small molecule and a macromolecule by 1–3 orders of magnitude. At 25 °C, the rate of a encounter-controlled reaction is about $10^9\ M^{-1}\ s^{-1}$, depending on the diffusion constant for the substrate.[284,1127,1128] The concentrations of most substrates in the cytoplasm, however, are usually less than 1 mM, which means that the pseudo-first-order rate constants of association between reactants and most enzymes at physiologically relevant concentrations are usually significantly less than $10^5\ s^{-1}$. With this in mind, it should come as no surprise that some enzymes have catalytic constants that are equal to or greater than the pseudo-first-order rate constants with which the reactants, when present at physiological concentrations rather than at saturation, associate with the active site. Consequently, it is possible for the association of the reactants with the active site, rather than the subsequent turnover of the bound reactants, to be the rate-limiting step in an enzymatic reaction when those reactants are at their physiological concentrations.

The association of the reactants when they are present at physiological concentrations can be rate-limiting, however, only if those reactants are sticky.[1129] A **sticky reactant** is a reactant that is converted to products free in solution faster than it can dissociate from the active site once it has associated with it. For example, in the simple kinetic mechanism

$$\mathrm{E} + \mathrm{A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}A} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{E{\cdot}Z} \xrightarrow{k_3} \mathrm{E} + \mathrm{Z} \qquad (3\text{–}449)$$

if k_2 and k_3 are much greater than k_{-1}, then reactant A is converted to product Z free in solution much faster than it can dissociate back into the solution, and reactant A is a sticky reactant. If a reactant is sticky, almost every molecule of that sticky reactant that associates with the enzyme is converted to a molecule of product free in the solution.

If the reactants are not sticky and dissociate from the active site faster than they can be converted into products that have dissociated from the enzyme—for example if k_{-1} in Equation 3–449 is much greater than either k_2 or k_3—then a rapid pre-equilibrium is established between the enzyme and the reactants, and either chemical turnover or the release of the products must be the rate-limiting step, not association of the reactant.[1129] Pyruvate is a sticky reactant in the reaction catalyzed by acetolactate synthase from *E. coli*

$$2\ \text{pyruvate} + \mathrm{H^+} \rightleftharpoons \mathrm{CO_2} + \text{2-acetolactate} \qquad (3\text{–}450)$$

The enzyme associates in a kinetically irreversible step with the first pyruvate, the sticky reactant, and the second pyruvate then associates with the enzyme in a reversible pre-equilibrium preceding the chemical conversion and the release of acetolactate.[1130]

If a reactant in a particular enzymatic reaction is sticky, then two situations can be distinguished.

If the concentrations of the reactants in the enzymatic reaction are all at saturation, then as each active site releases products, it is immediately filled with reactants, and the rate-limiting step of the reaction must be a step that does not involve association of reactants, usually turnover of the bound reactants or the dissociation of the products. If the concentration of one reactant is so low that the rate of its association with the active site becomes less than the rates of turnover, dissociation of the products, and any other step affecting the overall rate of the reaction; if that reactant is sticky so that almost every molecule is converted to product free in solution once it associates with the active site; and if the concentrations of the other reactants remain at saturation, then the rate-limiting step in the reaction will become the association of that sticky reactant with the active site. It follows that **when one of the reactants in an enzymatically catalyzed reaction is sticky, a change in rate-limiting step must occur when the concentration of that reactant is decreased below a certain level**.

Coincident with this change in rate-limiting step for the sticky reactant is a **change in reaction order**. At high concentrations of the sticky reactant that is being varied, its turnover, the dissociation of products, or some other first-order process not involving its association is rate-limiting; at low concentrations of the reactant, its association, a second-order process, is rate-limiting. As a result, the behavior observed is an increase in the initial rate of the enzymatic reaction that is proportional to the concentration of reactant at low concentrations, followed by an approach to a horizontal asymptote at higher concentrations of reactant as the rate-limiting step changes from association to turnover. This change in rate-limiting step is observed as apparent saturation. This **apparent saturation**, however, is not caused by saturation of the active site but by the change in rate-limiting step. This behavior will be indistinguishable by steady-state kinetics from the behavior of an enzyme that does not have sticky reactants. In each instance, the initial rate of the enzymatic reaction is a rectangularly hyperbolic function of the concentration of reactant.

These general conclusions, however, have significant consequences for natural selection. To understand these consequences, consider the simplest kinetic mechanism

$$\mathrm{E} + \mathrm{A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}A} \xrightarrow{k_2} \mathrm{E} + \mathrm{Z} \qquad (3\text{–}451)$$

In all cases, at concentrations of reactants that saturate an enzyme, none of the pseudo-first-order rate constants for association between an enzyme and its reactants can be rate-limiting because the concentrations of reactants—and consequently their pseudo-first-order rate constants of association, which can be increased until no more reactant will dissolve in the solution—have been purposely increased by the investigator to a level at which no further increases in the rate of the enzymatic reaction are observed. When saturation is reached, the first-order rates at which bound reactant is converted to product and product dissociates from the enzyme limit any further increase in the initial rate of the reaction.

If, on the one hand, $k_{-1} << k_2$ so that the reactant is sticky, then Equation 3–62 becomes

$$v_0 = \frac{k_2[\mathrm{E}]_t k_1[\mathrm{E}]_t[\mathrm{A}]_0}{k_2[\mathrm{E}]_t + k_1[\mathrm{E}]_t[\mathrm{A}]_0} \qquad (3\text{–}452)$$

the specificity constant $k_A = k_1$, and the catalytic constant $k_0 = k_2$. At low concentration of reactant

$$v_0 \cong k_1[\mathrm{E}]_t[\mathrm{A}]_0 \qquad (3\text{–}453)$$

and the enzymatic reaction is limited by the rate of the second-order association of enzyme with reactant. At high concentration of reactant

$$v_0 \cong k_2[\mathrm{E}]_t \qquad (3\text{–}454)$$

and the rate of the reaction is limited by the rate of the first-order conversion of reactant to product and dissociation of the product. In this situation the Michaelis constant K_{mA} for the reaction is $k_2\, k_1^{-1}$, which is not even remotely connected to the dissociation constant K_{dA} for reactant A from the active site.

If, on the other hand, $k_{-1} >> k_2$ so that the reactant is not at all sticky, then Equation 3–62 becomes

$$v_0 = \frac{k_2[\mathrm{E}]_t[\mathrm{A}]_0}{\left(\frac{k_{-1}}{k_1}\right) + [\mathrm{A}]_0} \qquad (3\text{–}455)$$

At high saturating concentrations of reactant A, Equation 3–454 still applies, $k_0 = k_2$, and the rate of the reaction is limited by the rate of the first-order conversion of reactant to product and dissociation

of the product, but the Michaelis constant is equal to the dissociation constant for reactant A from the active site

$$K_{mA} = \frac{k_{-1}}{k_1} = K_{dA} \tag{3–456}$$

The consequential aspect of this situation is that, at concentrations of reactant A significantly less than the Michaelis constant

$$v_0 = \frac{k_2[E]_t[A]_0}{K_{dA}} \tag{3–457}$$

the rate of the reaction is not limited by the rate of association of reactant with the enzyme. At this low concentration of the reactant, the rate of the reaction should increase as the dissociation constant for reactant A decreases. If the physiological concentration of reactant A is less than the Michaelis constant and reactant A is not sticky, natural selection can increase the rate of the enzymatic reaction, and hence its efficiency, by selecting for decreases in the dissociation constant of reactant A.

If, however, reactant A is sticky and its physiological concentration is less than the Michaelis constant for the enzyme, then the rate of diffusion of sticky reactant A to the active site is rate-limiting at its physiological concentrations; the initial rate for the enzymatic reaction at the physiological concentration of reactant A will be proportional to its concentration; and the constant of that proportionality, by definition the observed specificity constant k_A for reactant A, will be equal to the second-order rate constant for its association with the enzyme, k_1. If the catalytic constant of an enzyme is so fast that the rate of association of one or more sticky reactants, when they are at their physiological concentrations, is the rate-limiting step in the reaction, then the enzyme will have evolved to a state where an increase in its catalytic constant cannot increase the rate of the enzymatic reaction as it occurs in the cytoplasm, and natural selection can no longer operate upon the catalytic constant. At this stage, if it is not possible to increase the rate of diffusion of that reactant or those reactants to the active site, short of increasing their cellular concentrations, the enzyme will have become a **perfect catalyst.**[284,1131] Natural selection, however, might still select for an increase in the rate at which the reactant associates with the active site once it has collided with the enzyme.

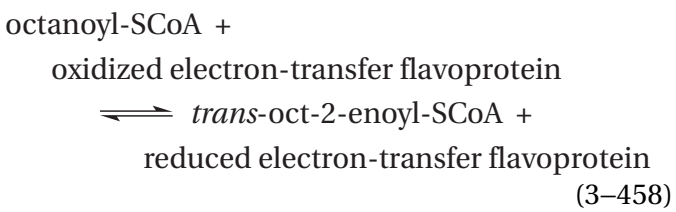
As most substrates for enzymes bear a net charge at physiological pH, the possibility that rates of association can be increased by providing elementary charges around the active site that are opposite to the charge of the reactant has been rather enthusiastically considered as one way in which natural selection could increase the rate of association. For example, the rate of association of NADH, which has a charge number of –1 above pH 7, decreases by a factor of 10 as the net elementary charge on equine liver alcohol dehydrogenase is changed from +16 to –24 by increasing the pH, but only when the ionic strength of the solution is 0.01 M.[1132] As with most such purely electric effects, enhancements in the rate of association observed when the vicinity of the active site is oppositely charged from its substrate decrease dramatically, in the case of alcohol dehydrogenase to less than a factor of 2, at physiological levels of ionic strength. In the case of acetylcholine receptor, mutation of an aspartate or glutamate in the region surrounding its channel for the transport of potassium ions to a neutral amino acid decreases its conductance by a factor of around 2 at an ionic strength of 0.10 M, a change thought to result from an electric effect on the rate of association of K^+ with the channel in the enzyme,[1133] a rather small effect. Although there are other reasons for the fact that all cytoplasm has this level of ionic strength, one reason may be to minimize electric effects between charged reactants and charged proteins.

Electric effects on rates of association at physiological levels of ionic strength appear to be significant in cases in which a small protein acting as a carrier of an electron associates with an enzyme.[1134,1135] In this instance the net elementary charges on the participants can be large. For example, at physiological pH, the net charge number on equine ferricytochrome *c* is +7 and that on a tryptic fragment of cytochrome b_5 is –9, and it seems that the large difference in the elementary charge on these two proteins increases the rates at which they associate by a factor of around 20 at physiological ionic strength.[1136] In these cases, natural selection would be able to operate successfully on electric effects.

The rate of dissociation of a product from the active site is often slow enough to be the rate-limiting step in an enzymatically catalyzed reaction. Because the dissociation constants of substrates from enzymes are often in the range of 10^{-6} M and

the respective second-order rate constants for their association are usually less than $10^8\ M^{-1}\ s^{-1}$, it follows that rates of dissociation of the substrates, and hence the products, of an enzymatic reaction can be less than $100\ s^{-1}$. Many enzymatic reactions in which the dissociations of the products are rate-limiting have been identified. Therefore, the rate of release of products from the active site can be an important factor in the overall rate of the enzymatic reaction.

A **sticky product** is a product that dissociates slowly from the active site relative to the rate of either the back reaction to bound reactant or the forward reaction from bound reactant to bound product. In other words, for the simple kinetic mechanism of Equation 3–449, a sticky product would be the product in the enzymatic reaction for which $k_3 << k_{-2}$ or $k_3 << k_2$ or both of these inequalities occur, regardless of whether k_3, k_2, or k_{-2} themselves are microscopic or composite rate constants. Under these circumstances, the dissociation of a sticky product (k_3), not the chemical transformation of reactant and product (k_2), determines the catalytic constant of the enzymatic reaction. For example, the rate at which acyl-CoA dehydrogenase



(3–458)

from *E. coli* oxidizes octanoyl-SCoA on its active site at 25 °C is $400\ s^{-1}$, but the rate at which the resulting large, sticky *trans*-oct-2-enoyl-SCoA dissociates from the enzyme is only $13\ s^{-1}$, which determines the catalytic constant for the enzyme of $15\ s^{-1}$. When the enzyme is mutated so that oxidation of octanoyl-SCoA decreases from $400\ s^{-1}$ to $0.5\ s^{-1}$, this rate of $0.5\ s^{-1}$ determines the catalytic constant of $0.7\ s^{-1}$, not the dissociation of the no longer sticky product, which is $8\ s^{-1}$ in the mutant.[1137] The catalytic constant of equine alcohol dehydrogenase is equal to the rate constant at which the large, sticky product NADH dissociates from the enzyme, and a mutation that increases this rate of dissociation by a factor of 7 increases the catalytic constant of the enzyme by a factor of 6.[1138]

Even the smallest substrate, a hydron, however, can be a sticky product. For example, the dissociation of the hydron that is a product of the dehydration catalyzed by fumarate hydratase (Equation 3–1) from *E. coli* is slower than both the dehydration itself and the dissociation of fumarate.[1139]

In the case of nucleophilic aromatic substitution of the sulfanyl group of glutathione for the chloro group in 1-chloro-2,4-dinitrobenzene catalyzed by isoenzyme M1-1 of glutathione transferase from *R. norvegicus*, the dissociation of the product is 60-fold slower than the actual nucleophilic substitution because a conformational change in the enzyme must precede the dissociation.[1140,1141] The dissociation of the product nitric oxide from nitric-oxide synthase (flavodoxin) from *G. stearothermophilus*, however, is slow not because of a conformational change but because an isoleucine and a histidine on the way out of the active site sterically hinder its release into the solution.[1142]

In an enzymatic reaction in which **both product and reactant are sticky**, the chemical transformation converting reactant and product has time to reach equilibrium while the reactant and product remain on the enzyme.

The effects of microviscosity of the solution on the observed steady-state catalytic constant k_0 and the specificity constant k_A for reactant A can be used to distinguish microscopic rate constants for the association and dissociation of reactant A and for the dissociation of product Z in the underlying kinetic mechanism from those rate constants for the chemical transformations that occur within the active site.[1143] If the rate constant for the association of substrate A with the active site of enzyme E[1143] and the rate constant for the dissociation of substrate A from the active site of enzyme E[1144] are each directly proportional to the sum of the diffusion coefficient of substrate A, D_A, and the diffusion coefficient of enzyme E, D_E, in the solution, then

$$k_i = \xi_i (D_A + D_E) = \xi_i \frac{k_B T}{6\pi\eta}\left(\frac{1}{r_A} + \frac{1}{r_E}\right) \qquad (3–459)$$

where k_i is a rate constant for either association or dissociation, ξ_i is a constant of proportionality unique to that rate constant, k_B is the Boltzmann constant, T is the temperature, η is the microviscosity of the solution, and r_A and r_E are the Stokes radii of substrate A and enzyme E, respectively. It follows that

$$\frac{k_i}{k_{i\eta}} = \frac{\eta}{\eta_0} = \eta_{rel} \qquad (3–460)$$

where k_i is the rate constant in a reference solution of microviscosity η_0, usually chosen to be the aqueous solution containing the enzyme at the pH and ionic strength at which the initial rates of its reaction have been studied, and $k_{i\eta}$ is the rate constant in the reference solution to which a microviscogen such as glycerol, sucrose, or trehalose has been added to produce a microviscosity η,* which is greater than η_0.

Suppose the enzyme has one reactant A and one product Z. If the dissociation of product Z is explicitly included, the kinetic mechanism of the reaction is that of Equation 3–449 and the rate equation (see Equation 3–89) for this kinetic mechanism is

$$v_0 = \frac{\left(\frac{k_2k_3[\mathrm{E}]_t}{k_{-2}+k_2+k_3}\right)\left(\frac{k_1k_2k_3[\mathrm{E}]_t}{k_{-1}k_{-2}+k_{-1}k_3+k_2k_3}\right)[\mathrm{A}]_0}{\left(\frac{k_2k_3[\mathrm{E}]_t}{k_{-2}+k_2+k_3}\right)+\left(\frac{k_1k_2k_3[\mathrm{E}]_t}{k_{-1}k_{-2}+k_{-1}k_3+k_2k_3}\right)[\mathrm{A}]_0} \tag{3–461}$$

from which it follows that

$$k_0 = \frac{k_2k_3}{k_{-2}+k_2+k_3} \tag{3–462}$$

and

$$k_\mathrm{A} = \frac{k_1k_2k_3}{k_{-1}k_{-2}+k_{-1}k_3+k_2k_3} \tag{3–463}$$

If only the rate constants governing association and dissociation of substrates with and from the active site are affected by the microviscosity of the solution and k_1, k_{-1}, and k_3 behave according to Equation 3–460, it follows that the ratio

$$\frac{k_0}{k_{0\eta}} = \frac{(k_{-2}+k_2)\eta_\mathrm{rel}+k_3}{k_{-2}+k_2+k_3} \tag{3–464}$$

where k_0 and $k_{0\eta}$ are the catalytic constants observed in the absence and presence of microviscogen, respectively. It also follows that the ratio

$$\frac{k_\mathrm{A}}{k_{\mathrm{A}\eta}} = \frac{(k_{-1}k_{-6}+k_6k_7)\eta_\mathrm{rel}+k_{-1}k_7}{k_{-1}k_{-6}+k_6k_7+k_{-1}k_7} \tag{3–465}$$

The ratio $k_0\,k_{0\eta}^{-1}$ as a function of η_rel defines a line with a slope

$$\mathrm{slope}_{0\eta} = \frac{k_{-2}+k_2}{k_{-2}+k_2+k_3} \tag{3–466}$$

and a value of 1 when $\eta_\mathrm{rel} = 1$. The ratio $k_\mathrm{A}\,k_{\mathrm{A}\eta}^{-1}$ as a function of η_rel defines a line with a slope

$$\mathrm{slope}_{\mathrm{A}\eta} = \frac{k_{-1}k_{-2}+k_2k_3}{k_{-1}k_{-2}+k_2k_3+k_{-1}k_3} \tag{3–467}$$

and a value of 1 when $\eta_\mathrm{rel} = 1$. Consequently, the slopes of these plots provide information in addition to the only observed rate constants, k_0 and k_A, obtained from steady-state kinetics.[1143]

Consider first the situation in which the slope of the line for the ratio $k_0\,k_{0\eta}^{-1}$ as a function of η_rel (Equation 3–464) is indistinguishable from 0 and the slope of the line for the ratio $k_\mathrm{A}\,k_{\mathrm{A}\eta}^{-1}$ as a function of η_rel (Equation 3–465) is indistinguishable from 1, as is the case for bovine adenosine deaminase (Figure 3–61A)[283,455] and bovine alkaline phosphatase at pH 6.[1144] From the former observation it follows that $k_3 >> k_2$ and $k_3 >> k_{-2}$, and from the latter observation it follows that $k_{-1} << k_2$. Therefore, if the kinetic mechanism of Equation 3–85 describes the reaction, reactant A—for example, adenosine in the case of adenosine deaminase or a phosphate monoester in the case of alkaline phosphatase—is a sticky reactant, the respective product is not sticky, the specificity constant k_A for reactant A (Equation 3–463) is equal to the bimolecular rate constant k_1 for association of reactant A with the enzyme,[1144] the Michaelis constant K_mA is unrelated to the dissociation constant for reactant A from the active site, and the observed catalytic constant k_0 is equal to k_2.

*The **microviscosity** of the solution, the viscosity experienced by a molecule, is distinguished from the **macroviscosity** of the solution, the viscosity measured by a viscometer. Small viscogens such as glycerol, sucrose, or trehalose affect both the microviscosity and the macroviscosity equivalently. In these instances, the microviscosity is the viscosity measured by a viscometer. Macromolecular viscogens such as long, flexible, hydrophilic polymers can affect the macroviscosity more than they do the microviscosity.[1145] The lack of an effect of a macromolecular viscogen on the rate constants for an enzymatic reaction demonstrates that it is actually the microviscosity that is affecting those rates.[1146]

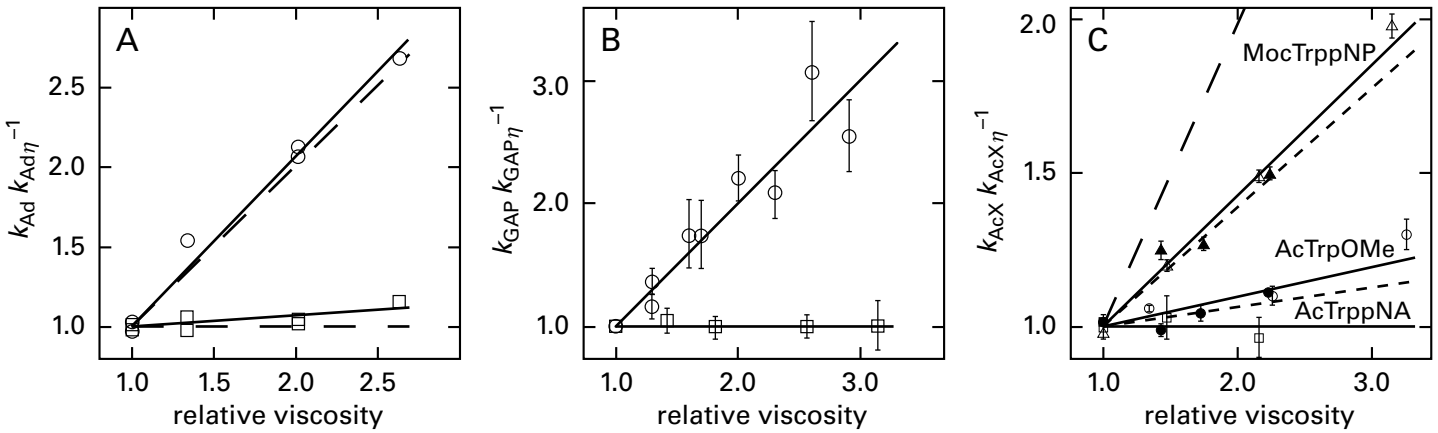


Figure 3–61: Effect of microviscosity of the solution on rate constants for the reactions catalyzed by bovine adenosine deaminase,[455] triose-phosphate isomerase from *G. gallus*,[284] and bovine chymotrypsin.[1143] **(A)** Steady-state catalytic constant k_0 and specificity constant k_{Ad} for adenosine for the conversion of adenosine (Ad) to inosine catalyzed by adenosine deaminase were determined by fitting full time courses for approaches to equilibrium (see Figure 3–1A) at an ionic strength of 0.15 M, pH 7.0, and 20 °C, and in solutions containing various concentrations of sucrose to increase the microviscosity. The ratios of the steady-state rate constants $k_{Ad}\ k_{Ad\eta}^{-1}$ (○) and $k_0\ k_{0\eta}^{-1}$ (□), where k_{Ad} and k_0 refer to values for the rate constants in the absence of microviscogen and $k_{Ad\eta}$ and $k_{0\eta}$ refer to values for the rate constants at a particular relative microviscosity, are plotted as a function of relative microviscosity η_{rel}, which is the microviscosity of the particular solution, η, divided by the microviscosity of the same solution in the absence of sucrose, η_0. The solid lines are linear, least-squares fits to the data, and the dashed lines are lines of slope 1 and slope 0, respectively. **(B)** Initial rates of conversion of D-glyceraldehyde 3-phosphate to glycerone phosphate, catalyzed by wild-type triose-phosphate isomerase (○) or a mutant in which Glutamate 164 had been changed to aspartate (□), were measured at pH 7.6 and 30 °C in solutions containing various concentrations of D-glyceraldehyde 3-phosphate (GAP) and various concentrations of glycerol to increase the microviscosity. The initial rates were used to determine the specificity constant k_{GAP} for D-glyceraldehyde 3-phosphate in the absence of glycerol and the specificity constants $k_{GAP\eta}$ at particular relative viscosities, and the data are presented as in Panel A. The solid lines are lines of slope 1 and slope 0. **(C)** Initial rates of hydrolysis catalyzed by chymotrypsin were measured for various concentrations of several acyl derivatives (AcX) that are reactants for the enzyme—the 4-nitroanilide (□, AcTrppNA) and the methyl ester (○, ●, AcTrpOMe) of *N*-acetyl-L-tryptophan and the 4-nitrophenyl ester of *N*-(methoxycarbonyl)-L-tryptophan (△, ▲, MocTrppNP)—at an ionic strength of 0.5 M, pH 8.0, and 25 °C. Initial rates were also measured in solutions containing various concentrations of sucrose (□, ○, △) to increase the microviscosity or Ficoll (●, ▲) to increase the macroviscosity. The initial rates were used to determine the specificity constant k_{AcX} for the various reactants in the absence of microviscogen and the specificity constants $k_{AcX\eta}$ at particular relative viscosities for each of the reactants, and the data are presented as in Panel A. The solid lines are fits to the data for sucrose as microviscogen, and the lines with shorter dashes are fits to the data for Ficoll as the macroviscogen. The line with longer dashes is a line of slope 1.

The only reason the initial rate of the reaction decreases below V as the concentration of adenosineis decreased is that a change in rate-limiting step occurs from turnover, at high concentrations, to the unidirectional association of adenosine, at low concentrations.

That these conclusions are reasonable in a particular instance is strengthened by the observation that when turnover of the reactant is decreased significantly—either by site-directed mutation (Figure 3–61B),[284,840,1147,1148] by using a reactant that is turned over more slowly,[1143] or by changing the pH[1145]—the slope of the line for $k_A\ k_{A\eta}^{-1}$ as a function of η_{rel} goes to 0 because the reactant is no longer sticky.

If the slope of the line for $k_A\ k_{A\eta}^{-1}$ as a function of η_{rel} is 0, as is the case for cytidine deaminase from *E. coli* with no alterations,[283] then $k_2 << k_{-1}$ and the reactant is not at all sticky; a pre-equilibrium between reactant A, the enzyme, and a complex of reactant A with the enzyme precedes the chemical step transforming reactant to product within the active site; and in the simplest case, the Michaelis constant is the dissociation constant for reactant A from the active site (Equation 3–455).

Consider the situation in which the slope of the line for the ratio $k_0\ k_{0\eta}^{-1}$ as a function of η_{rel} (Equation 3–464) is indistinguishable from 1 and the slope of the line for the ratio $k_A\ k_{A\eta}^{-1}$ as a function of η_{rel} (Equation 3–465) is indistinguishable from 0. It follows from both of these observations together that $k_{-2} << k_3$, $k_3 << k_2$, and $k_2 << k_{-1}$. Therefore, if the kinetic mechanism of Equation 3–449 describes the reaction, the product is sticky, all steps before the release of product reach equilibrium, and the rate-limiting step of the reaction is

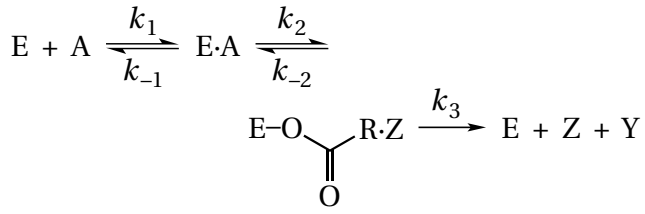
the release of product Z. For example, in the case of murine cyclic-AMP-dependent non-specific serine/threonine protein kinase, the slope of the line for $k_0\ k_{0\eta}^{-1}$ as a function of η_{rel} is indistinguishable from 1 and the slope of the line for $k_{pep}\ k_{pep\eta}^{-1}$ as a function of η_{rel} is close to 0 for the peptide LRRASLG as a reactant. It could be concluded that the rate-limiting step in the reaction is the dissociation of the product; that k_3, the rate constant for dissociation of product, is equal to the observed catalytic constant k_0 (22 s^{-1});[1149] and that the association of the peptide with the active site is at equilibrium. Even though the association of the reactant is at equilibrium, because

$$K_{mA} = \frac{k_0}{k_A} = \frac{k_{-1}k_{-2} + k_{-1}k_3 + k_2k_3}{k_1k_{-2} + k_1k_2 + k_1k_3} \cong \frac{k_{-1}k_3}{k_1k_2} \qquad (3\text{–}468)$$

the Michaelis constant is not equal to the dissociation constant for the reactant. If it is the case for this enzyme, as seems reasonable, that $k_{-2} << k_2$ because the chemical step is the transfer of a phospho group from a phosphoric anhydride to an aliphatic hydroxy group, it can concluded that product piles up on the active site waiting to dissociate.

If the slope of either the line for behavior of the ratio $k_0\ k_{0\eta}^{-1}$ as a function of η_{rel} (Equation 3–464) or the line for behavior of the ratio $k_A\ k_{A\eta}^{-1}$ as a function of η_{rel} (Equation 3–465) is significantly different from either 1 or 0, then the rate of association of reactant A at low concentration cannot be rate-limiting. Nevertheless, the rate of association for the reactant must be affecting the overall rate of the reaction, and in such circumstances, the slope of one or the other of these lines can be used to obtain **estimates of the values for underlying rate constants in the kinetic mechanism** of Equation 3–449.[1143,1150]

For example, the lines describing the effect of relative microviscosity of the solution on the ratio of the specificity constants, $k_{ester}\ k_{ester,\eta}^{-1}$, for hydrolysis of *N*-(methoxycarbonyl)-L-tryptophan 4-nitrophenyl ester and *N*-acetyl-L-tryptophan methyl ester by bovine chymotrypsin (Figure 3–61C)[1143] have slopes of 0.4 ± 0.1 and 0.1, respectively. Over the same ranges, the respective values for the catalytic constants k_0 actually increased by about 10% rather than decreasing as the microviscosity of the solution was increased. Consequently, the rate constant k_3 in the kinetic mechanism for chymotrypsin



(3–469)

for both reactants cannot be affected by the rate constant for the dissociation of either product. It is also known that, for the two reactants used in these experiments, the second step in the kinetic mechanism is irreversible because the respective product Z, 4-nitrophenol or methanol, dissociates rapidly and immediately after the acyl enzyme is formed, so the value of the rate constant k_{-2} is formally 0. It follows (Equation 3–467) that

$$\text{slope}_{ester,\eta} = \frac{k_2}{k_{-1} + k_2} \qquad (3\text{–}470)$$

From the slopes of the lines for *N*-(methoxycarbonyl)-L-tryptophan 4-nitrophenyl ester and *N*-acetyl-L-tryptophan methyl ester, values for the ratio $k_{-1}\ k_2^{-1}$ of 1.5 and 11, respectively, could be calculated (Equation 3–470). Since the values for k_{ester} in the absence of microviscogen are 35 and 0.81 $\mu M^{-1}\ s^{-1}$, respectively, the values estimated for k_1 are 90 and 10 $\mu M^{-1}\ s^{-1}$.

The slope of the line for the effect of microviscosity on the catalytic constant for the decarboxylation of orotidine 5′-phosphate by orotidine-5′-phosphate decarboxylase (Equation 3–366) from *M. thermautotrophicus* is 0.02 ± 0.03, so dissociation of the product, uridine monophosphate, cannot be the rate-limiting step in the enzymatic reaction. The slope of the line for the effect of microviscosity on the specificity constant for the reactant,[1146] orotidine 5′-phosphate, however, is 0.6 ± 0.1, so the association of orotidine 5′-phosphate must be a rate-affecting step. From the value of the slope, it could be calculated that the rate constant k_1 for its association is 4 $\mu M^{-1}\ s^{-1}$.

In theory, if the slopes of both the line for $k_0\ k_{0\eta}^{-1}$ and the line for $k_A\ k_{A\eta}^{-1}$ as a function of the relative microviscosity are between 0 and 1, and one of the rate constants in the mechanism of Equation 3–449 has been assigned a value by some other observation, the remaining four underlying rate constants can be estimated from these slopes and from the observed values of the specificity constant k_A for reactant A and the catalytic constant k_0. In practice,

however, the rate constants k_{-1}, k_2, and k_3 are seldom, if ever, close enough to each other in numerical value that both slopes fall between and are significantly different from 1 and 0.

In the preceding discussion, it has been assumed that the only effects of relative microviscosity on the observed rate constants for the enzymatic reaction are on the rates of association and dissociation of substrates with the enzyme. There are, however, several situations in which it has been concluded that the **observed effects of the relative microviscosity result from changes in the rates of conformational changes**, such as an induced fit (Figure 3–55) that the enzyme undergoes during catalysis.[1151-1153] These observations suggest that the effects of relative viscosity on observed kinetic constants may be more ambiguous than they are often assumed to be and that effects of microviscosity on conformational changes must be ruled out before the assumption that the effects of microviscosity are only on rates of association and dissociation is made. The observation that an increase in relative microviscosity affects only the observed specificity constant k_A for reactant A and not the observed catalytic constant k_0 is the least ambiguous result and usually means that the effect of microviscosity is only on association and dissociation of reactant A. For example, the 10% increase in the catalytic constant for chymotrypsin observed at high concentrations of microviscogens was used as an argument that the only effect of microviscogens was on the association of reactant with the enzyme.[1143]

Now that you are familiar with the molecular details of noncovalent interactions between substrates and active sites, it becomes possible for you to imagine the steps in the dissociation of a product. Because almost every substrate is held in the active site of an enzyme by many localized interactions and because covalent bonds about which free rotation can occur are located between these individual points of contact within most substrates, the release of a product can be viewed as the culmination of a series of steps taken in a random order.[1154] A molecule of a given product can be divided into segments connected by one or more covalent bonds about which free rotation can occur. Even though the configurational flexibility of a bound or partially bound product is likely to be much less than what it displays in solution, it is possible to imagine each segment independently detaching from the active site momentarily as the subset of noncovalent interactions holding that segment in the active site breaks and rotation, albeit hindered, occurs around the covalent bonds connecting that segment to the rest of the substrate. Just as quickly, however, that segment reestablishes its connection with the active site before the neighboring segments can break theirs. These local dissociations and reassociations from subsites of the active site occur randomly over the molecule of product. Eventually, at some instant, all the local contacts are broken at the same time, and the molecule of product departs. For example, a mutant of streptavidin from *Streptomyces avidinii* in which Aspartate 128 has been changed to alanine is unable to form the usual hydrogen bond between one of the ureido nitrogen–hydrogens of the biotin that is the normal ligand of the protein because the acyl oxygen in the carboxy group of the aspartate is no longer there. In a crystallographic molecular model of the complex between biotin and the mutant, the rigid, bicyclic 2-oxohexahydro-1*H*-thieno-[3,4*d*]imidazol-4-yl group of the biotin has pulled away from its normal position into a configuration believed to represent one of the **individual detachments** leading to the eventual dissociation of biotin from streptavidin.[1155]

Another example of such a process may occur within the active site of phosphoglycerate kinase (Equation 3–375) from *S. cerevisiae*.[1154] At high concentrations, sulfate is a competitive inhibitor with respect to $MgATP^{2-}$ in the forward reaction and with respect to 3-phospho-D-glyceroyl phosphate, but not with respect to $MgADP^{-}$, in the reverse reaction.[1154] These results suggest that sulfate can bind to the same location as the phospho group that is transferred from the phosphoanhydride of $MgATP^{2-}$ to the carboxylato group of 3-phospho-D-glyceroyl phosphate. At low concentrations, however, sulfate and several other polyanions activate the enzymatic reaction (Figure 3–62).[1156]

One explanation for both **the activation and the competitive inhibition observed in the respective ranges of concentration** is that, during the instant that the 1-phosphate group on the carboxy carbon of the product 3-phospho-D-glyceroyl phosphate has momentarily detached from its cup of both donors for hydrogen bonds and the Mg^{2+} and rotated away and before it can reattach, sulfate can associate with the cup that the phospho group normally occupies (Figure 3–63).[644,1156-1159] The sulfate prevents reassociation of the 1-phospho group, and 3-phospho-D-glyceroyl phosphate is forced to depart as soon as the 3-phospho group breaks away from its

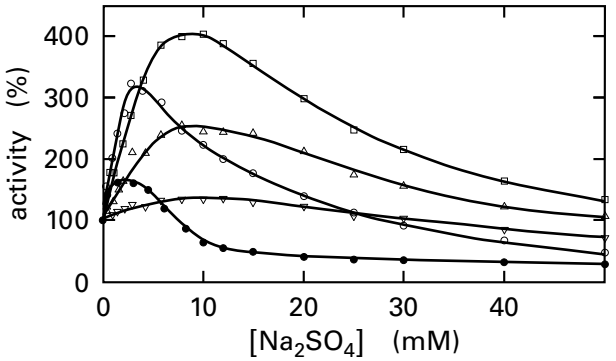


Figure 3–62: Effect of sulfate on the enzymatic activity of yeast phosphoglycerate kinase.[1156] Samples were prepared that contained phosphoglycerate kinase in 5 μM (●), 50 μM (○), 0.5 mM (□), 1.5 mM (△), or 5.0 mM (▽) $MgATP^{2-}$ and 1.0 mM free Mg^{2+}, 50 mM 3-phosphoglycerate, and various concentrations of Na_2SO_4. The initial rate of production of 1,3-bisphosphoglycerate was monitored by the decrease in concentration of NADH in a coupled assay involving glyceraldehyde-3-phosphate dehydrogenase, creatine kinase, creatine phosphate, and triose-phosphate isomerase. Initial rates of decrease in the fluorescence of NADH were measured continuously for each sample. The activity of the enzyme (percent of the initial rate in the absence of phosphate) is presented as a function of the concentration of Na_2SO_4 (millimolar).

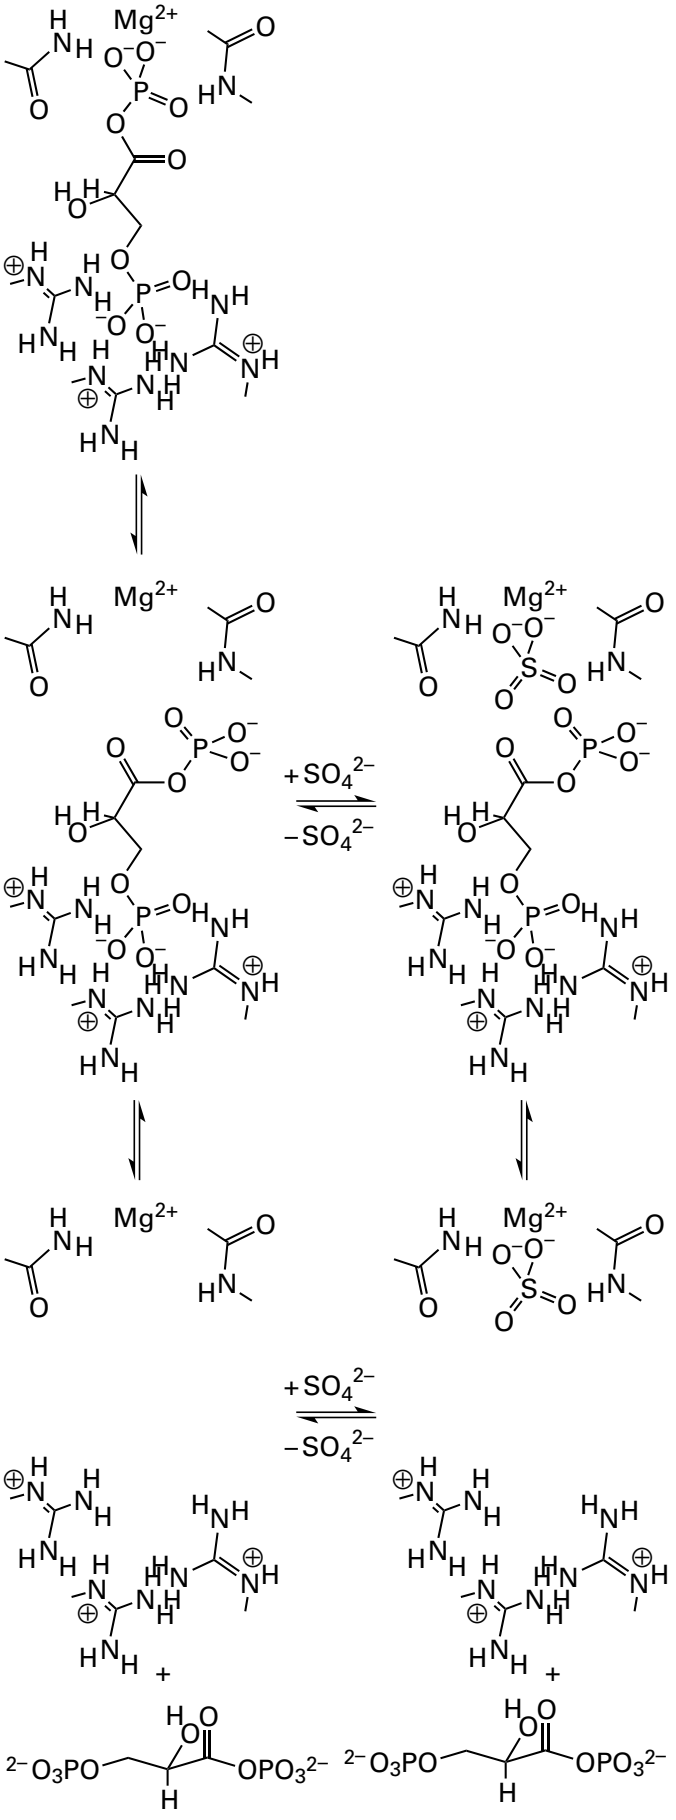

Figure 3–63: Schematic representation of the possibility that sulfate may accelerate the dissociation of 3-phospho-D-glyceroyl phosphate from the active site of phosphoglycerate kinase from *S. cerevisiae* by associating with one of the two subsites that bind its phospho groups.[644,1156-1158] Dissociation of 3-phospho-D-glyceroyl phosphate from the active site can be considered to occur in at least two steps: release of the 1-phospho group and release of the 3-phospho group (left side of drawing). These dissociations can occur in either order, but either dissociation probably coincides with an induced widening of the active site.[1159] In the drawing, the 1-phospho group is the first to dissociate. During its dissociation, the bond between carbons 1 and 2 has rotated to remove the 3-phospho group from the vicinity of its subsite. It is possible that sulfate occupies the subsite for either the 1-phospho group, as is drawn, or the 3-phospho group (right side of drawing), preventing its reassociation and the reclosing of the active site and hastening the dissociation of the complete molecule of 3-phospho-D-glyceroyl phosphate. The sulfate is drawn as occupying the subsite for the 1-phospho group because sulfate appears to compete with $MgATP^{2-}$ for its association with the enzyme (Figure 3–62), perhaps because it occupies the same subsite occupied by both the 1-phospho group of 3-phospho-D-glyceroyl phosphate and the γ-phospho group of $MgATP^{2-}$.

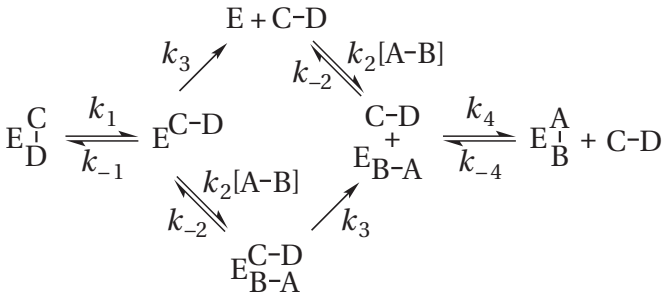
cup of donors for hydrogen bonds. In this view of the process of dissociation, the 3-phospho group in the absence of sulfate would usually break away from its cup after the 1-phosphate group had already reassociated with its cup, and the 3-phospho group would have to detach many times before it happened to detach at the same time that the 1-phosphate group was also unattached. The sulfate, however, at concentrations high enough to occupy the active site effectively but not high enough to occupy the active site continuously and block the association of the γ-phospho group of $MgATP^{2-}$, would block the reassociation of the 1-phosphate group, and activation rather than inhibition would result. For this explanation to be the correct one, dissociation of the product must be a rate-limiting step in the enzymatic reaction.

Phosphoglycerate kinase serves as an example not only of stepwise dissociation of a product but also of a mechanism by which **reactants or other ligands could accelerate the dissociation of a product** from the active site. The individual sites of noncovalent interaction distributed over the reactants in an enzymatic reaction are usually found distributed over the products, albeit in a different order. For example, the γ-phospho group of $MgATP^{2-}$ is the 1-phospho group of 3-phospho-D-glyceroyl phosphate in the reaction catalyzed by phosphoglycerate kinase, but the 3-phospho group of 3-phosphoglycerate is the 3-phospho group of 3-phospho-D-glyceroyl phosphate. It follows that reactants usually have substituents that can occupy the regions of the active site occupied by the respective substituents on products. In this view, a molecule of reactant that contains a functional group that ends up in a product should always have the potential to hasten dissociation of the molecule of that product that immediately precedes association of that reactant with the active site. In the particular case of phosphoglycerate kinase, the γ-phospho group of $MgATP^{2-}$ is an anion that can bind at the site for the 1-phospho group of 3-phospho-D-glyceroyl phosphate and should be able to accelerate the dissociation of 3-phospho-D-glyceroyl phosphate just as sulfate was able to do. As it turns out, $MgATP^{2-}$ does display reactant activation,[1156] consistent with an ability to perform this acceleration of the reaction by displacement of the product 3-phospho-D-glyceroyl phosphate.

Reactant activation in steady-state kinetics is the acceleration of an enzymatic reaction by a reactant as its concentration is increased, beyond the usual increase in rate resulting only from its association with the active site. One way in which reactant activation can occur is the **acceleration of dissociation of the product from the active site** by association of the reactant with the active site.

Consider an enzyme the product of which, C–D, is bound at the active site by separate subsets of noncovalent interactions to segments C and D, respectively. Assume that these separate subsites are beyond the immediate vicinity of the chemical transformation and that the reactant, A–B, is bound by the same subsets of noncovalent interactions to segments A and B, which are identical to segments C and D, respectively. Under conditions of initial rate, in which the concentration of product C–D is 0, the replacement of product C–D by reactant A–B during the kinetic mechanism could occur in the following sequence



(3–471)

In this scheme, the binding of segment B of the reactant blocks the rebinding of segment D of the product. The rate of dissociation of product C–D from the complex between enzyme and product is

$$\frac{d[\text{C-D}]}{dt} = k_3\left(\left[\text{E}^{\text{C-D}}\right] + \left[\text{E}^{\text{C-D}}_{\text{B-A}}\right]\right) \tag{3–472}$$

where [C–D] is the concentration of fully dissociated C–D. From the various steady-state relations it follows that

$$\frac{d[\text{C-D}]}{dt} = k_{1,\text{app}}\left[\text{E}^{\text{C}}_{\text{D}}\right] \tag{3–473}$$

where the apparent rate of dissociation of the product C–D

$$k_{1,\text{app}} = k_1\frac{k_3(k_{-2}+k_3) + k_2k_3[\text{A-B}]}{(k_{-1}+k_3)(k_{-2}+k_3) + k_2k_3[\text{A-B}]} \tag{3–474}$$

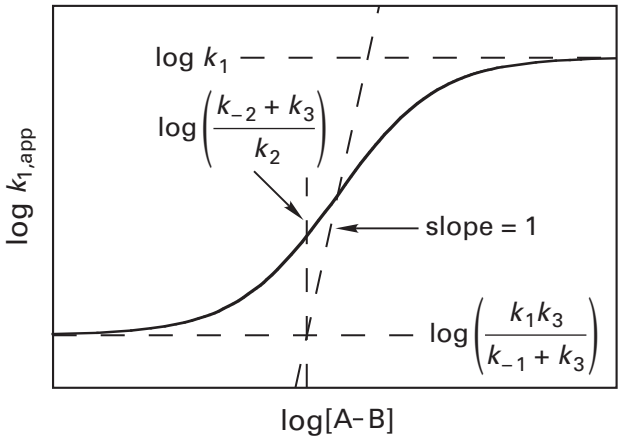


Figure 3–64: Graphical representation of the common logarithm of the function defined by Equation 3–474. The horizontal asymptotes of the curve are fixed by the values for log $[k_1k_3(k_{-1}+k_3)^{-1}]$ and log k_1, and the intersection of a line of slope 1 passing through the midpoint of the curve and the lower horizontal asymptote is fixed at a value of log[A–B] equal to log $[(k_{-2}+k_3)\ k_2^{-1}]$. These are the points that position the curve on the axes.

The common logarithm of the apparent first-order dissociation rate constant $k_{1,app}$ can be plotted as a function of the common logarithm of the concentration of reactant, [A–B] (Figure 3–64). Because $k_1k_3\ (k_3+k_{-1})^{-1}$ is always less than k_1, the addition of reactant A–B will always accelerate the dissociation of product C–D.

Equation 3–471 is for a **branched mechanism** and contains two paths from the fully intact complex between the enzyme and product C–D to the fully intact complex between the enzyme and reactant A–B, and the fluxes on the two paths shift in relative magnitude as the concentration of A–B is increased. Such a branched mechanism is known to produce reactant activation.[1160]

Many instances of reactant activation might result from the process of reactants displacing products. For example, in the steady-state kinetics of human dihydrofolate reductase (Equation 3–428), NADPH displays reactant activation.[1161] This activation results from the fact that the product tetrahydrofolate dissociates from the enzyme 5 times more rapidly when the site for nicotinamide-adenine dinucleotide is occupied by the reactant NADPH than when it is occupied by the product $NADP^+$. A reasonable explanation of this fact is that the hydride on carbon 4 of NADPH, after the hydronicotinamide ring slips into its subsite following the momentary departure of the 2-amino-4-oxo-5,6,7,8-tetrahydro-1*H*-pteridinyl group from its subsite, blocks the reattachment of the pteridinyl group. This block permits the 4-aminobenzoyl group and the L-glutamyl group, which comprise the remainder of tetrahydrofolate, to dissociate without the complication of the pteridinyl group reassociating.
