Preface

Over the past 70 years, our understanding of the strategies that are used by enzymes to catalyze their respective reactions has expanded so dramatically that, except for the explanations of every known enzyme, it could well be complete. At the moment, it seems unlikely that some new, as-yet-undescribed strategy will be discovered. It is the purpose of this text to present a comprehensive description of these strategies. It is not, however, intended to be a comprehensive, encyclopedic catalogue of the enzymes for which mechanisms are available, systematically presenting the mechanisms of each in its appropriate category, although this is sometimes done.

It is also the purpose of this book to describe the many techniques that are used to study enzymatic mechanisms. Each method provides information about a particular strategy and can be discussed as the respective strategy is discussed. The most informative observation about the mechanism of an enzyme is a crystallographic molecular model of that enzyme with its active site occupied by substrates in equilibrium with each other in which reactants and products are both observed or by an analogue of a high-energy intermediate in the normal reaction. The majority of our understanding of the mechanisms of enzymatic reactions, however, comes from chemical studies of these mechanisms. In fact, even the design of an analogue of a high-energy intermediate usually requires that a significant amount of chemical information has been gathered. Furthermore, even when a crystallographic molecular model of substrates at equilibrium or an analogue of a high-energy intermediate within an active site is available, its interpretation usually relies heavily on the available chemical information. At the moment, a comprehensive understanding of the methods that are used to study enzymatic mechanisms, as well as the limitations of these methods, is necessary, and for this reason these methods are discussed critically in this text.

Because an understanding of enzymatic mechanisms requires a firm knowledge of mechanistic organic chemistry and molecular association and and because an understanding of the techniques used to study these mechanisms requires a firm knowledge of kinetics, thermodynamics, synthetic organic chemistry, and analytical chemistry, the text places severe demands on the student. The concepts of mechanistic organic chemistry and molecular association are incorporated into structural drawings of individual molecules and chemical reactions. The kinetics and thermodynamics are represented in mathematical equations. The results of the particular techniques used to study enzymes are presented as graphs and tables from the original literature. The crystallographic molecular models are observed in stereo images. The student must have the background necessary to read each of these languages.

Before this book became so comprehensive, it was intended for a course in the mechanism of enzymatic reactions. Consequently, there are suggested readings in which the concepts discussed in each section are applied in an experimental setting. There are citations within the text that support the conclusions drawn but are also intended to direct the student to the research literature, and there are problems at the end of each section, based on actual experimental results, that are to be evaluated by the student. The original purpose of the book was to give the student the wherewithal to take charge of her own education by reading critically the experimental literature. To accomplish such a goal, she must be able to understand the experiments performed and be able to reach the same conclusions as did the authors or to realize that the authors were mistaken. It was my intention to develop in the student the ability to draw her own conclusions from only the experimental results.

The book, however, has expanded somewhat beyond its initial purposes and become a monograph covering the subject of the mechanism of enzymes. The advantage of publishing online is that the student can download the book, and a professor can choose to cover only particular portions of the book. The disadvantage is deciding which portion to choose.

Over the last year I have had the privilege to work with Heather Cammarn, an experienced chemical copyeditor going over the manuscript of this book. Her assistance has been invaluable. Heather was also the copyeditor for the first edition of this book. I have been impressed by the fact that each time she or I have read through a proof, one of us, usually Heather, has found errors I missed as I was

writing the text. I am certain that some still exist and would be grateful to any reader who draws them to my attention.

It is a pleasure to thank everyone who has helped me in the preparation of this book. My wife, Francey, beyond the call of duty, typed the first draft of the manuscript. Jack Kirsch read the entire manuscript of the first edition with remarkable care, understanding of the chemistry, and attention to detail. Individual sections of the manuscript for the first edition were reviewed critically by Charles Perrin, Tom Bruice, Bill Parson, Paul MacPherson, Ted Traylor, David Dolphin, Wallace Cleland, Jonathan Cohen, Howard Schachman, Paul Bartlett, David Matthews, Jeremy Knowles, Judy Klinman, Craig Townsend, Fred Hartman, Paul Saltman, Don Tilley, Bill Trogler, Marion O'Leary, Paul Boyer, and Bruce Kemp. Individual sections of the second edition were reviewed critcally by Tadhg Begley, Faruk Nome, Paul Cook, Harry Gray, Bob Blankenship, Judy Klinman, Neil Marsh, Dave Ballou, Dan Herschlag, Frank Jordan, Hazel Holden, Ivan Rayment, Bill Trogler, Michael Toney, Andrew Bennet, David Silverman, Russ Hille, Roberta Colman, Bob White, Elias Arner, Francesco Tarantelli, Doug Rees, Rick Debus, Johannes Messinger, Chris Murray, Paul Ortiz de Montellano, Janos Lanyi, Donald Hilvert, Ed Solomon, Sean Elliott, Nick Williams, Paul Fitzpatrick, Bob Gennis, Steven Boxer, and Stuart Edelstein. Each of them were kind enough to read the manuscript critically and provide many helpful comments.

Stereodrawings

Almost all the stereodrawings of crystallographic molecular models included in this book were produced by the program Molscript, created by Per J. Kraulis. To understand how the active sites of enzymes achieve their catalysis, anyone interested in understanding enzymatic mechanisms must learn to view these images in stereo. Although a few individuals can view them effortlessly by crossing their eyes, the rest of us need a stereo viewer. Stereo viewers of various qualities can be purchased at:

https://www.walmart.com/ip/American-Educational-Table-Top-Stereo-Glasses/115919914

https://www.forestry-suppliers.com/Search?stext=stereoviewer

https://www.navafresh.com/products/pocket-stereoscope?srsltid=AR5OiO18ZMCEmIJDRadipw54xy402jsC2rXc7pZiJG4fSX6LkabfFbnm_1c

It has been my experience that a student who has never viewed a stereodrawing before will usually complain that although everyone else can learn to use one of these viewers, he cannot. It is also my experience that everyone learns to use one. When I have put a question on an examination where one is asked to write down the sequence of the protein by examining a drawing of a crystallographic molecular model that none of the students has seen before, everyone in the class gets at least 90% of the sequence correct, which would have been impossible unless everyone was able to see the image in stereo. The stereodrawings in the text have been placed on separate pages with their legends so that each of these pages can be printed. Unless they are printed, you cannot view them properly in adequate detail, which is essential. In the text, the drawings are in black-and-white to accommodate a black-and-white printer. In the list of Equations, Structures, Figures, and Tables, the stereodrawings are presented in color. The colors are those of the CPK convention: carbon, black (coal); nitrogen, blue (sky); oxygen, red (fire); phosphorus, orange (an elemental allotrope); sulfur, yellow (elemental); and fluorine and chlorine, pale green (gas). Other colors used are alkali and alkaline earth metals, light gray (metallic); vanadium, pale yellow (VO^{3+}); manganese, purple (permanganate); iron, brown (rust); cobalt, blue (cobalt blue); nickel, dark green (hexaaquo Ni^{2+}); copper, green (cupric oxide); zinc, dark gray (metallic); and molybdenum, dark blue [Mo(V)]. These stereodrawings can be printed on a color printer if one is lucky enough to have access to one, and the printed copies can then be viewed in stereo.

IUBMB and IUPAC

The names of all enzymes are in the nomenclature of the IUBMB (https://www.enzyme-database.org). Unfortunately the committee sometimes changes the names, a practice which is somewhat exasperating. The names of all substrates for enzymes that are used in the reactions given in that database are used for these compounds. The names for all other biochemical compounds that have been assigned by the IUBMB have also been used (https://iubmb.qmul.ac.uk) The terms used in the discussion of enzyme kinetics are those used by the IUBMB (https://iubmb.qmul.ac.uk/kinetics/) All chemical compounds that have not been named by the IUBMB are given the names determined by the IUPAC nomenclature. A searchable copy of those rules can be downloaded (https://iupac.qmul.ac.uk/BlueBook/PDF/), and a list of substituent names is also available (https://www.acdlabs.com/iupac/nomenclature/79/r79_1036.htm). The definitions of many of the chemical and physical terms (albeit in rather awkward rhetoric), units of measure, physical quantities, and physical constants used in this book can be found in the IUPAC Gold Book (https://goldbook.iupac.org/terms). Values for pK_a noted in the text (http://www.fm.ehcc.kyoto-u.ac.jp/pKa_compilation_Williams_RipinEvans.pdf) can be found in the table compiled by William Jencks. The sequences of the amino acids for most, if not all, enzymes discussed can be found in Uniprot (https://www.uniprot.org/) as well as the names of all species from which those enzymes come (select Taxonomy).

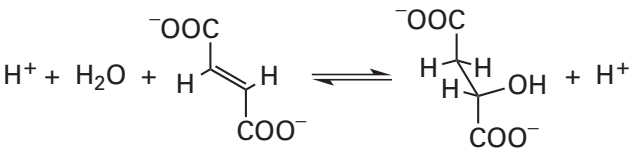
Protein Data Bank

The Protein Data Bank (https://www.rcsb.org/ search/advanced) contains the atomic coordinates of almost all crystallographic molecular models that have been constructed. At the moment there are 1,070,000 separate molecular models entered in the data bank. You should look at some of the lists of the full coordinates to get a feeling for what such a file contains. Enter the name of a protein for which there is a stereodrawing in the text of this book, click on the name of one of the molecular models that are then listed, choose “Download Files”, and then choose “PDB File”. The atoms are listed by the name of the amino acid, the position of that amino acid in the sequence of the protein, and their locations within that amino acid. The list tabulates the *x*, *y*, and *z* coordinates of each atom in angstroms (tenths of nanometers). Each file constitutes the raw data on which the Molscript program operates.

Chapter 1
Mechanisms for Reactions

Chemistry is the study of the behavior of electrons. Electrons in molecules behave in a certain, ultimately understandable way and the nuclei follow them passively. A chemical reaction is a sequence of rearrangements of electrons in the molecules involved that turns reactants into products. The rearrangements of the nuclei are automatic and are driven by the rearrangements of the electrons. The exercise of understanding the behavior of the electrons begins with a known chemical reaction for which the reactants, catalysts, and products have been defined by earlier observation. In order to understand that chemical reaction, one first has to account for each pair of electrons and know its location in the molecules that are the reactants and the molecules that are the products. Their locations in reactants and products usually provide insight into what happened to them in the transition states and intermediates in the reaction. A complete understanding, however, comes from learning enough about the behavior of electrons in general to figure out how they behave in a particular reaction as reactants are turned into intermediates and intermediates are turned into products.

Metabolism is the ensemble of the coordinated sequences of chemical reactions and physical processes that occur within all living cells to provide energy (catabolism) and to accomplish biosynthesis (anabolism). Each discrete step in any one of the sequences of reactions in the ensemble is catalyzed by a unique enzyme. An **enzyme** is a molecule of protein that catalyzes a particular chemical reaction. For example, the enzyme fumarate hydratase in the mitochondria from porcine heart is a molecule of protein composed of four identical subunits, each of which is a folded polypeptide 466 amino acids long. The enzyme catalyzes the interconversion of fumarate and (*S*)-malate



(1–1)

a reaction that is found in the sequence of reactions that comprise the citric acid cycle.* In most instances, the only role that a particular enzyme plays in a particular cell is to catalyze its particular chemical reaction and only its chemical reaction. During the catalysis of its reaction by an enzyme, the electrons in the reactants, the electrons in the catalytic groups on the enzyme that are involved in the reaction, the electrons in the intermediates in the reaction and its transition states, and the electrons in the products behave just as they always do. There is no magic to enzymatic catalysis. An enzymatically catalyzed reaction is a chemical reaction.

The sequences of chemical reactions that constitute the **metabolic pathways**—for example the citric acid cycle—can be written out in an organized scheme and committed to memory systematically. Each reaction in one of these sequences uses as its reactants the products of the reaction or reactions that precede it, and the products of each reaction are the reactants for the enzyme or enzymes that follow it on the chart. The diagrams of metabolic pathways leave the impression that metabolism is a highly organized and neatly ordered system. This organization, however, does not extend to the enzymes themselves, which, as the products of evolution by natural selection, are a motley collection. Within a particular metabolic sequence of reactions, each of the consecutive enzymes is usually a protein with a sequence of amino acids that is unrelated to the sequences of amino acids in the other enzymes; each is usually a protein with a stoichiometry of protomers unrelated to the stoichiometries of the protomers of the other enzymes; and each is usually a protein with a native molecular

*Fumarate and (*S*)-malate are both dianions. In the strictest sense, when referring to them, one should write fumarate ion and (*S*)-malate ion. The International Union of Biochemistry and Molecular Biology, however, in almost all cases omits the word ion, for example, simply using as the name fumarate or (*S*)-malate. In this book, that convention will be followed. When a name ends in –ate, for example phosphate, acetate, and so forth, it will be assumed that the reader understands that this name refers to an anion. When a name ends in –ium, for example ammonium, iminium, and so forth, it will be assumed that the reader understands that this name refers to a cation. Ambiguous names will be followed by the word ion.

structure unrelated to the native molecular structures of the other enzymes.

Consequently, when the enzymes themselves are discussed, they are not arranged in the order in which they occur in metabolic pathways. They can be presented as members of the various **families of proteins** that recapitulate their evolutionary relationships. This approach emphasizes structural homologies. Unfortunately, evolutionally related enzymes often catalyze chemically unrelated reactions. Enzymes can also be presented in categories reflecting the **types of chemical reactions** that they catalyze. Unfortunately, different enzymes sometimes catalyze homologous chemical reactions by different chemical mechanisms. Consequently, it is more effective to discuss the chemical strategies by which enzymes catalyze reactions and to use particular enzymes as examples of those strategies.

The **substrates** of an enzyme are the molecules that are interconverted by that enzyme as it catalyzes its own peculiar reaction. The substrates for the enzyme appear in the equation describing the equilibrium that it catalyzes—for example, water, fumarate, and malate are the substrates for fumarate hydratase. In the cytoplasm of the cell, all of the substrates of an enzymatic reaction are usually present simultaneously. In an experiment, the investigator decides which substrates will be the **reactants** and which will be the **products** of the reaction. This decision is made when a solution is prepared containing only the substrates on one side of the chemical equation—for example, a solution containing only malate—so that those substrates become the reactants, and the substrates produced during the reaction are the products.

An enzyme is a **catalyst**. As with any catalyst, an enzyme controls the reaction that it catalyzes by forming a molecular complex with the reactant or the reactants. The **active site** of an enzyme is the unique location on the surface or in the interior of one of its subunits where the reaction catalyzed by that enzyme takes place. The reactant or reactants must associate with the active site before the catalyzed reaction can occur. As a catalyst, an enzyme displays particular **abilities** and is constrained by particular **rules**.

When an enzyme (for example, fumarate hydratase) is added to a solution containing the reactants designated by the investigator (for example, an aqueous solution of malate), all of the products of the reaction that it catalyzes (for example, fumarate and water) are formed at a **greater rate** than they would have been in the absence of the enzyme. This increase in the rate of the reaction is directly proportional to the molar concentration of the enzyme but is almost never directly proportional to the molar concentration of reactant. At concentrations of reactants less than their dissociation constants from the active site of the enzyme, only a fraction of those active sites are occupied with reactants participating in the reaction at a given instant, but at saturating concentrations of reactants in excess of their respective dissociation constants, all of the active sites are occupied and busy catalyzing the reaction at a given instant. For enzymes that catalyze reactions in which there is only one reactant, the rates of those reactions when they are catalyzed in the respective active sites under these conditions of saturation are usually between 10 s^{-1} and 10^6 s^{-1}. These rates represent accelerations of the respective uncatalyzed rates[1-5] of 10^5 to 10^{21}, which are significant enhancements. On the active site of porcine fumarate hydratase,[6] the rate of the enzymatically catalyzed dehydration of malate at saturation is 700 s^{-1} at pH 6.8 and 37 °C, which represents an enhancement over the uncatalyzed rate[6-8] of between 10^{16} and 10^{17}.

Because of the problem of entropy of mixing, there is no agreement on which units should be used to compare the rate of an enzymatically catalyzed bimolecular or termolecular reaction with the rate of the respective uncatalyzed reaction. The rate of hydrolysis of alkyl sulfates, however, which is technically a bimolecular reaction, is accelerated by sulfatases by a factor of as much as 10^{26} relative to the monomolecular rate of the reaction in aqueous solution.[9] For a bimolecular reaction in which neither reactant is water, regardless of which units are chosen, the difference in rate between the enzymatically catalyzed reaction and the same uncatalyzed reaction is large.

An enzymatically catalyzed reaction is also **more specific** than the respective uncatalyzed reaction. For example, the enzyme fumarate hydratase produces only (*S*)-malate (Equation 1–1), while the uncatalyzed reaction[8] produces both (*S*)-malate and (*R*)-malate, as well as other side products such as maleate. The very **low yield of undesired side products**, which would normally appear in significant yield in an uncatalyzed reaction, is an essential requirement for each enzyme if the sequences of the reactions that comprise metabolism are to operate efficiently.

Under normal circumstances, tens to tens of thousands of molecules of substrate are interconverted during each second by one molecule of

enzyme. Therefore, little enzyme, in terms of its molar concentration relative to the molar concentrations of its substrates, must be added to produce a sufficient increase in the forward and reverse rates of the reaction. For this small amount of enzyme to be able to process these much larger amounts of substrates so efficiently, each molecule of enzyme, ready to process the next molecule of reactant, must be **regenerated in the same state** at the end of each turnover. This rule applies to any catalyst.

Because it is present in the solution in low molar concentration and because it must be regenerated after each transformation, an enzyme cannot be a stoichiometric participant in the chemical reaction. Therefore, an enzyme, under these normal circumstances, **cannot affect the equilibrium constant** and cannot affect the change in standard free energy of the reaction.* There are exceptions to this rule. These exceptions are the frequently encountered situations in which the molar concentration of an enzyme is artificially adjusted by an investigator in a particular experiment to within an order of magnitude of the molar concentrations of the substrates, as well as situations in which the concentration of an enzyme in the cell is actually greater than that of its substrates.[11]

Because an enzyme cannot change the equilibrium constant of a reaction as long as it is not itself a reactant or a product, it necessarily follows that, in spite of the amazement some investigators express at discovering this fact,[12] if the enzyme catalyzes the reaction in one direction, it must also catalyze the reaction in the other direction, even in situations in which the equilibrium constant for the reaction is very large.[13,14] The principle of **microscopic reversibility**, when applied to an enzymatically catalyzed reaction, is that the enzymatically catalyzed reaction must pass through the same transition states but in opposite order in the forward and reverse directions. The enzyme accelerates the reaction by lowering the relative free energy of one or more of the transition states in this sequence. Therefore, it must accelerate the reaction in both directions. For this reason, enzymatically catalyzed reactions are, as are all chemical reactions, **approaches to equilibrium**. It just happens to be the case that most biological reactions have changes in standard free energy between 40 and –40 kJ mol^{-1} and that an enzyme can rapidly bring its substrates to equilibrium, so the equilibria are more obvious. At pH 7 and 25 °C, the ratio between the concentration of fumarate and the concentration of (*S*)-malate is 0.22 at equilibrium.[15]

A **heterolytic reaction** is a reaction in the mechanism of which covalent bonds are always broken in such a way that both electrons in the bond being broken remain with only one of the two fragments between which the bond is broken. In addition, a heterolytic reaction is a reaction in the mechanism of which covalent bonds are formed in such a way that both electrons in a bond being formed arrive on the same reactant. The heterolytic reactions that occur on the active sites of enzymes proceed by mechanisms that often resemble closely the normal chemical mechanisms of similar organic reactions that proceed in solution without enzymatic catalysis. An enzyme usually accelerates a particular heterolytic reaction by controlling the steps that would normally occur even in its absence. It follows that the first step in any examination of the mechanism of a particular enzyme is to write out in exhausting detail one or more realistic chemical mechanisms for the reaction of interest as it would proceed in the absence of enzymatic catalysis and focus upon the specific features of those mechanisms that are vulnerable to manipulation by the enzyme. Therefore, a logical place to begin a discussion of enzymatic catalysis of heterolytic reactions is to examine the established chemical mechanisms of reactions similar to those that are catalyzed by such enzymes.

A **homolytic reaction** is a reaction in the mechanism of which covalent bonds are always broken in such a way that in a bond being broken, each of the molecular fragments between which the bond is broken retains one of the bonding electrons. In addition, a homolytic reaction is a reaction in the mechanism of which covalent bonds are always formed in such a way that in a bond being formed, each of the molecular fragments between which the bond is being formed provides one of the ultimate two bonding electrons. The homolytic breaking of a bond produces two radicals, and the homolytic formation of a bond, **colligation**, combines two radicals. A minority of the extant enzymes catalyze the reactions for which they are responsible homolytically. In the absence of the enzyme, these reactions usually do not occur, or if they do occur, they do not proceed homolytically. In order to catalyze a reaction homolytically, the enzyme must carefully direct the regioselectivity of each step in addition to enhancing its rate. Without an enzyme to direct

*Occasionally, there are publications that seem to indicate that the authors have forgotten the fact that an enzyme cannot alter the equilibrium constant for a reaction.[10]

its regioselectivity, a homolytic reaction usually proceeds along several different paths, one or none of which produces the product that the enzyme produces. Consequently, it is best to refrain from discussing homolytic reactions until the enzymes that catalyze them are discussed.

When a heterolytic reaction is studied as a model for the same reaction or a homologous reaction that is catalyzed by an enzyme, it is usually assumed that the most relevant model reaction is the one that proceeds in aqueous solution. Unless otherwise noted, all of the mechanisms discussed in this chapter will be for **nonenzymatic reactions occurring in water**.

*Transfer of a Hydron**

The molecules to be discussed, be they enzymes, substrates, or prosthetic groups, usually have several or many acidic hydrons and several or many basic lone pairs of electrons. Consequently, it is essential to make a distinction between, on the one hand, the various acidic hydrons and basic lone pairs of electrons in a molecule and, on the other hand, the molecule in which they are located. In other words, in biochemistry the molecules themselves are neither acids nor bases but frameworks on which acids and bases are distributed. For the sake of this discussion, **an acid is an acidic hydron and the atom to which it is attached. A base is a basic lone pair of electrons and the atom with which it is associated.**

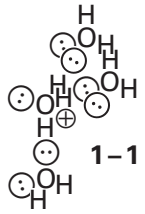
Historically, an acid was any molecule that, when added to water, decreased the pH of the water and a base was any molecule that, when added to water, increased the pH. It is also the case that, in the abstract, one can use the term "acidic molecule" to describe a molecule, such as sulfuric acid, in which there are only acidic hydrons. Similarly, one can use the term "basic molecule" to describe a molecule, such as trianionic phosphate, in which there are only basic lone pairs and no acidic hydrons. Such molecules, however, are seldom encountered in biochemistry. It is obvious that the historical definitions and habits are ambiguous when applied to most of the molecules to be discussed here. In fact, water is an excellent example of the ambiguity.

Water is both an acid and a base. When it is performing the role of an acid, water can provide a hydron in two ways: as its conjugate acid, the hydronium, or by itself. Water itself is an acid, albeit a weak one ($pK_a = 15.74$),* but its concentration (55.5 M) can overcome much of this deficit. Every basic lone pair of electrons on any molecule dissolved in an aqueous solution is adjacent to the hydrogen on a neighboring molecule of water and is usually already in a hydrogen bond with one of them, and that lone pair of electrons can immediately accept a hydron from that molecule of water. When it is performing the role of a base, water can remove a hydron in two ways: as its conjugate base, the hydroxide ion, or by itself. Water itself is a base. It is a weak base because its conjugate acid, a hydronium ion, is a strong acid ($pK_a = -1.74$). It is, however, a concentrated weak base (55.5 M). In aqueous solution, every acidic hydron on a dissolved molecule is adjacent to one of the lone pairs of a molecule of water and is usually already in a hydrogen bond with one of them, and that hydron can be immediately transferred to that molecule of water.

The **hydronium ion**, unavoidably present in aqueous solution, is composed of one hydron and some combination of either four molecules of water[16-20]

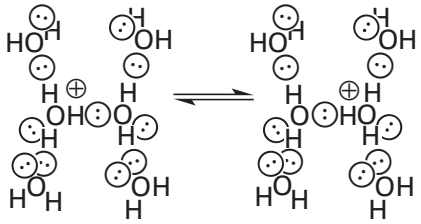
*According to the rules of the IUPAC, **hydron** is the general name for the cation H^+. Hydron is a general name to be used without regard to the nuclear mass of the hydrogen entity, either for hydrogen in its natural abundance or where it is not desired to distinguish between the isotopes. A **proton** is the nuclear particle of charge number +1 and rest mass of 1.007 276 470(12) unified atomic mass units. When discussing nuclear magnetic resonance spectroscopy, the proper term for the hydrogen nuclei being observed is protons since nuclear magnetic resonance, as it is commonly used, registers absorptions only from nuclei that consist of one proton and no neutrons.

*The only purpose of an acid dissociation constant is to compare acids and bases, one to the other. By the accepted convention, from which no acid is excepted, an acid dissociation constant is defined as the product of the molar concentration of hydronium ion and the molar concentration of the conjugate base of the acid divided by the molar concentration of the acid. Even though, by this convention, the concentration of the conjugate base of the hydronium ion is omitted from every acid dissociation constant, each of them is an equilibrium constant that must apply in any situation at standard temperature (25 °C) in an aqueous solution of any pH. In pure water at pH 7 and 25 °C, the concentration of hydronium ion is $10^{-7.00}$ M; the concentration of the conjugate base, hydroxide ion, is $10^{-7.00}$ M; and the concentration of water, the acid, is 55.5 M. Consequently, the pK_a of water is 15.74. Because, at any given instant, the hydron in a hydronium ion is on a single molecule of water, it is assumed that the conjugate base of a hydronium ion is water. In pure water, at pH 7.00 and 25 °C, the concentration of hydronium ion is $10^{-7.00}$ M; the concentration of water, the conjugate base, is 55.5 M; and the concentration of hydronium ion, the acid, is $10^{-7.00}$ M. Consequently, the pK_a of a hydronium ion is −1.74. At any pH, at standard pressure, and at 25 °C the concentration of hydronium ion times the concentration of hydroxide ion is $10^{-13.995}$ M. This is not an acid dissociation constant, it is the water constant.



1–1

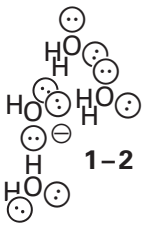
six molecules of water[17,18,21]



(1–2)

or 21 molecules of water.[22-25] The actual number of waters probably fluctuates, and its mean is unknown. At the periphery of the $H_9O_4^+$ ion (**1–1**), the $H_{13}O_6^+$ ion (Equation 1–2), or the $H_{43}O_{21}^+$ ion are 6, 8, or 10 hydrogen atoms, respectively. Each of these hydrogens is acidic and capable of being transferred within a hydrogen bond to a base in the solution. It is also capable of becoming the hydron of another hydronium simply by being transferred within a hydrogen bond to a neighboring molecule of water. Upon either of these transfers of a hydron, the original hydronium ion disappears. This arrangement makes each isolated hydron in an aqueous solution multivalent. It also enhances the rate of diffusion of the hydron, which appears to be limited not by transfer of hydrons among the waters but by rearrangement of the shells of hydration around the cation as it steps through the solvent.[18] For these reasons, in addition to its low pK_a (–1.74), the hydrated hydron, usually abbreviated H^+, is an efficient acid, a fact that can make up for its low concentration.

The **hydroxide ion**, also unavoidably present in aqueous solution, can be considered as a hydron hole. This hole is shared among the central oxygen and three or more of its nearest neighbors of water[26]



1–2

As with hydronium, this arrangement makes hydroxide a base that can diffuse more rapidly through the solution than any other base by extending its reach simultaneously to at least six lone pairs of electrons. Hydroxide is a strong base because its conjugate acid, a molecule of water, is a weak acid (pK_a = 15.74).

A reaction that occurs at the active site of an enzyme is usually compared to a reaction that occurs in aqueous solution. Because water is both an acid and a base, the mechanism of a reaction occurring in water is rarely hindered for want of hydrons that can be captured or for want of lone pairs of electrons onto which hydrons can be dumped, and these are taken for granted when the mechanism is written. The decision that the appropriate mechanism to use as a model for the one taking place within the active site of an enzyme is the mechanism occurring in aqueous solution implies that an additional assumption has been made about the nature of the active site of an enzyme; namely, that **the active site is at least as efficient a source of hydrons and lone pairs of electrons as an aqueous solution**. A corollary of this conclusion is that all of the removals and additions of hydrons, from and to the reactants, performed by water in the absence of the enzyme must be provided for within the active site of the enzyme by lone pairs of electrons and acidic hydrogens.

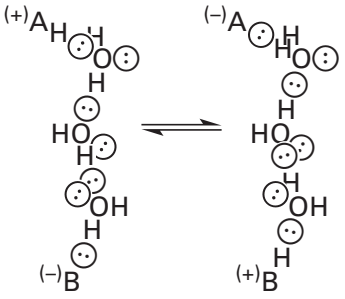
There are, however, differences between the transfer of a hydron that occurs in the active site of an enzyme and the transfer of a hydron that occurs in solution. The transfer of a hydron between any two lone pairs of electrons can proceed with the intermediate formation of a direct hydrogen bond[16,27] between acid and base

$$^{(+)}\mathrm{AH} + \odot\mathrm{B}^{(-)} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} {}^{(+)}\mathrm{AH}\odot\mathrm{B}^{(-)} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} {}^{(-)}\mathrm{A}\odot\mathrm{HB}^{(+)} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} {}^{(-)}\mathrm{A}\odot + \mathrm{HB}^{(+)} \qquad (1\text{–}3)$$

This sequence of steps is usually* what happens during the transfer of a hydron in an active site, where the distance and bond angles between a catalytic acid and the base it is to hydronate, or the distance and bond angles between a catalytic base

*There are exceptions in the active site of an enzyme. In those exceptional instances, a hydron is also relayed through a chain of hydrogen bonds, but even in those exceptions the relay is unique rather than promiscuous.

and the acid it is to dehydronate, are those of typical hydrogen bonds.[28] In solution, however, in some if not most instances in which a hydron is transferred from an acid to a base, the hydron is **relayed** from the acid to the base through two or three molecules of water[29]



(1–4)

Consequently, the transfer of the hydron in solution can be considered to be the result of the **collision of the layer of hydration around the molecule containing the acid with the layer of hydration around the molecule containing the base.** Each acid in a molecule is incorporated into the surrounding layer of hydration as a donor in a hydrogen bond to a molecule of water in the layer. Each base in a molecule is incorporated into the surrounding layer of hydration as an acceptor in a hydrogen bond to a molecule of water in the layer. It is easy to imagine that whenever the layer of hydration surrounding the molecule containing the acid collides with the layer of hydration surrounding the molecule containing the base, one or more chains of hydrogen-bonded molecules of water connecting the acid to the base form immediately and indiscriminately. The hydron is relayed through one of these chains. In this relay (Equation 1–4), the actual hydron that arrives at the encounter complex on the acid in the one molecule is not the hydron transferred to the base in the other. This relay is the same process that occurs in solution during the transfer of a hydron from hydronium (**1–1** or Equation 1–2) to a base or from an acid to hydroxide (**1–2**). Before the layers of hydration can be penetrated during the collision, the transfer of the hydron from acid to base has occurred within the fused layers of hydration. The hydronated base and the unhydronated acid then dissociate from each other, even though they may never have formed a hydrogen bond with each other.

Consequently, the **relevant equation* in solution** becomes

$$\begin{aligned} {}^{(+)}\mathrm{AH}\cdot(\mathrm{OH_2})_m + (\mathrm{OH_2})_n\cdot\odot\mathrm{B}^{(-)} &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \\ {}^{(+)}\mathrm{AH}\cdot(\mathrm{OH_2})_m\cdot(\mathrm{OH_2})_n\cdot\odot\mathrm{B}^{(-)} &\underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \\ {}^{(-)}\mathrm{A}\odot(\mathrm{H_2O})_o\cdot(\mathrm{H_2O})_p\cdot\mathrm{HB}^{(+)} &\underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \\ {}^{(-)}\mathrm{A}\odot(\mathrm{H_2O})_o + (\mathrm{H_2O})_p\cdot\mathrm{HB}^{(+)} & \end{aligned} \tag{1–5}$$

where $m + n = o + p$. This equation is a version of the overall acid–base reaction

$${}^{(+)}\mathrm{AH} + \odot\mathrm{B}^{(-)} \underset{k_\mathrm{R}}{\overset{k_\mathrm{F}}{\rightleftharpoons}} {}^{(-)}\mathrm{A}\odot + \mathrm{HB}^{(+)} \tag{1–6}$$

that has been expanded both in the identity of the participants and in the explicit steps involved. If the mechanism of either Equation 1–3 or Equation 1–5 pertains, k_F and k_R in Equation 1–6 are the composite rate constants[16]

$$k_\mathrm{F} = \frac{k_1 k_2 k_3}{\left(k_{-1} + k_2\right)k_3 + k_{-1}k_{-2}} \tag{1–7}$$

and

$$k_\mathrm{R} = \frac{k_{-1} k_{-2} k_{-3}}{\left(k_{-1} + k_2\right)k_3 + k_{-1}k_{-2}} \tag{1–8}$$

It follows that

$$K_{\mathrm{eq,AB}} = \frac{K_{\mathrm{a,HA}}}{K_{\mathrm{a,HB}}} = \frac{[\mathrm{A}]_{\mathrm{eq}}[\mathrm{HB}]_{\mathrm{eq}}}{[\mathrm{AH}]_{\mathrm{eq}}[\mathrm{B}]_{\mathrm{eq}}} = \frac{k_\mathrm{F}}{k_\mathrm{R}} = \frac{k_1 k_2 k_3}{k_{-1} k_{-2} k_{-3}} \tag{1–9}$$

*In spite of the fact that one woman's acid is another woman's base, the usual convention is to designate an acid with a simple capital A and a base with a simple capital B. Since these designations will be used later in the text for reactants, acids will always be designated as $^{(+)}$AH, $^{(+)}$BH, $^{(+)}$NH, $^{(+)}$OH, $^{(+)}$SH, or $^{(+)}$PH or as $\mathrm{HA}^{(+)}$, $\mathrm{HB}^{(+)}$, $\mathrm{HN}^{(+)}$, $\mathrm{HO}^{(+)}$, $\mathrm{HS}^{(+)}$, or $\mathrm{HP}^{(+)}$. Their conjugate bases will always be designated as $^{(-)}$A⊙, $^{(-)}$B⊙, $^{(-)}$N⊙, $^{(-)}$O⊙, $^{(-)}$S⊙, or $^{(-)}$P⊙ or ⊙$\mathrm{A}^{(-)}$, ⊙$\mathrm{B}^{(-)}$, ⊙$\mathrm{N}^{(-)}$, ⊙$\mathrm{O}^{(-)}$,⊙$\mathrm{S}^{(-)}$, or ⊙$\mathrm{P}^{(-)}$. The charges in parentheses indicate that a monoprotic acid can be neutral or can bear a net formal positive charge on the heteroatom, and the conjugate base of a monoprotic acid can be neutral or can bear a net formal negative charge on the heteroatom.

The observed rate constants, k_F and k_R, for the transfer of a hydron in solution (Figure 1–1)[16] provide insight into the differences in the abilities of various types of acids to provide hydrons and of various types of bases to remove hydrons.

The difference in the values of pK_a between an acid, $HA^{(+)}$, and the conjugate acid, $HB^{(+)}$, of a base, $\odot B^{(-)}$, can be defined by*†

$$\Delta pK_{a,AB} \equiv pK_{a,HB} - pK_{a,HA} = \log \frac{K_{a,HA}}{K_{a,HB}} \equiv \log K_{eq,AB} \quad (1\text{–}10)$$

Usually, when $\Delta pK_{a,AB}$ is positive and greater than 4, and the equilibrium constant for the transfer of the hydron is greater than 10^4, and the transfer of the hydron is significantly **exergonic**, the observed rate constant k_F for transfer of the hydron from the acid to the base falls between 10^9 and 10^{11} M^{-1} s^{-1} (right asymptotes in Figure 1–1). The particular value in a given situation is close to that calculated theoretically for the encounter-controlled bimolecular rate constant, which is the rate constant for simple collisions between the hydrated molecule of the acid, $HA^{(+)}$, and the hydrated molecule of the base, $\odot B^{(-)}$.[16]

The **encounter-controlled bimolecular rate constant** is the rate constant for a reaction in which every encounter between the two reactants results in product. It is referred to as encounter-controlled because the only factor that causes the reaction to be less than instantaneous is the requirement that molecules of the two reactants diffuse through the solution until they encounter and collide with their opposite numbers. If the two respective molecules that must collide in solution are both neutral and of the normal size of hydrated small molecules, the encounter-controlled bimolecular rate constant for the reaction should be between 10^9 and 10^{10} M^{-1} s^{-1} at 25 °C. In pure water, the particular value of the encounter-controlled rate constant is greater by a factor of about 6 if a molecule with at single positive elementary charge reacts with a molecule with a single negative elementary charge than if a neutral molecule reacts with either a neutral or a charged molecule because electrostatic attraction increases the rates of encounter in the former situation.[30]

Because the observed rates for significantly exergonic transfers of hydrons between small molecules are those expected for encounter-controlled reactions, it necessarily follows, in these circumstances, that each time the hydrated acid and the hydrated base collide in solution, a hydrated encounter complex forms and the **exergonic transfer of the hydron** within that complex ($k_2 >> k_{-2}$) occurs faster than the hydrated, hydronated base and the hydrated, unhydronated acid can dissociate.

In a situation where no encounter is required to occur—for example, **when the base is the solvent** and is already adjacent to the acid and forming a hydrogen bond with it—the transfer of the hydron becomes unimolecular. If the transfer of the hydron within the complex is, again, exergonic ($\Delta pK_{a,AB} > 4$), the observed first-order rate constant for the transfer[31] at 25 °C usually falls between 10^{10} and 10^{12} s^{-1}, which is the value calculated theoretically for the encounter-controlled dissociation of two preassociated molecules. This dissociation is governed by the unimolecular rate constant k_3 in Equation 1–3 or Equation 1–5.

All these results demonstrate that, **in an exergonic transfer of a hydron, the rate of the overall reaction is not limited by the rate of the actual transfer of the hydron** either within a direct hydrogen bond (Equation 1–3) or when the transfer of the hydron is relayed through a chain of water molecules (Equation 1–5).

Therefore, when the actual transfer of a hydron between acid and base, which is governed by the unimolecular rate constant k_2 in Equation 1–3 or Equation 1–5, is exergonic, it must be faster than 10^{10} s^{-1}. The value of the unimolecular rate constant for the transfer of a hydron, based on absolute rate theory, if no energy barrier existed, would be $k_B T h^{-1}$, or 6×10^{12} s^{-1} at 25 °C, where k_B is Boltzmann's constant and h is Planck's constant. This calculated value is consistent with an observed value of 10^{-13} s for the lifetime of the H_3O^+ ion at a particular position in ice, where the movement of this ion through the solid phase depends only on the transfer of hydrons in hydrogen bonds.[16]

*In chemical thermodynamics, the difference in a thermodynamic quantity describing a reaction is the value of that quantity for the products minus the value of that quantity for the reactants. For this reason—and for the reason that if this rule is followed, $\Delta pK_{a,AB}$ is equal to the logarithm of the equilibrium constant for the transfer of the hydron (Equation 1–8), which is a useful equality—it was decided that the pK_a of the acid should be subtracted from the pK_a of the conjugate acid of the base.

†The abbreviation for the common logarithm, which is the logarithm to the base 10, will be log, and the abbreviation for the natural logarithm, which is the logarithm to the base e, will be ln. This practice is the one designated by the American Chemical Society.

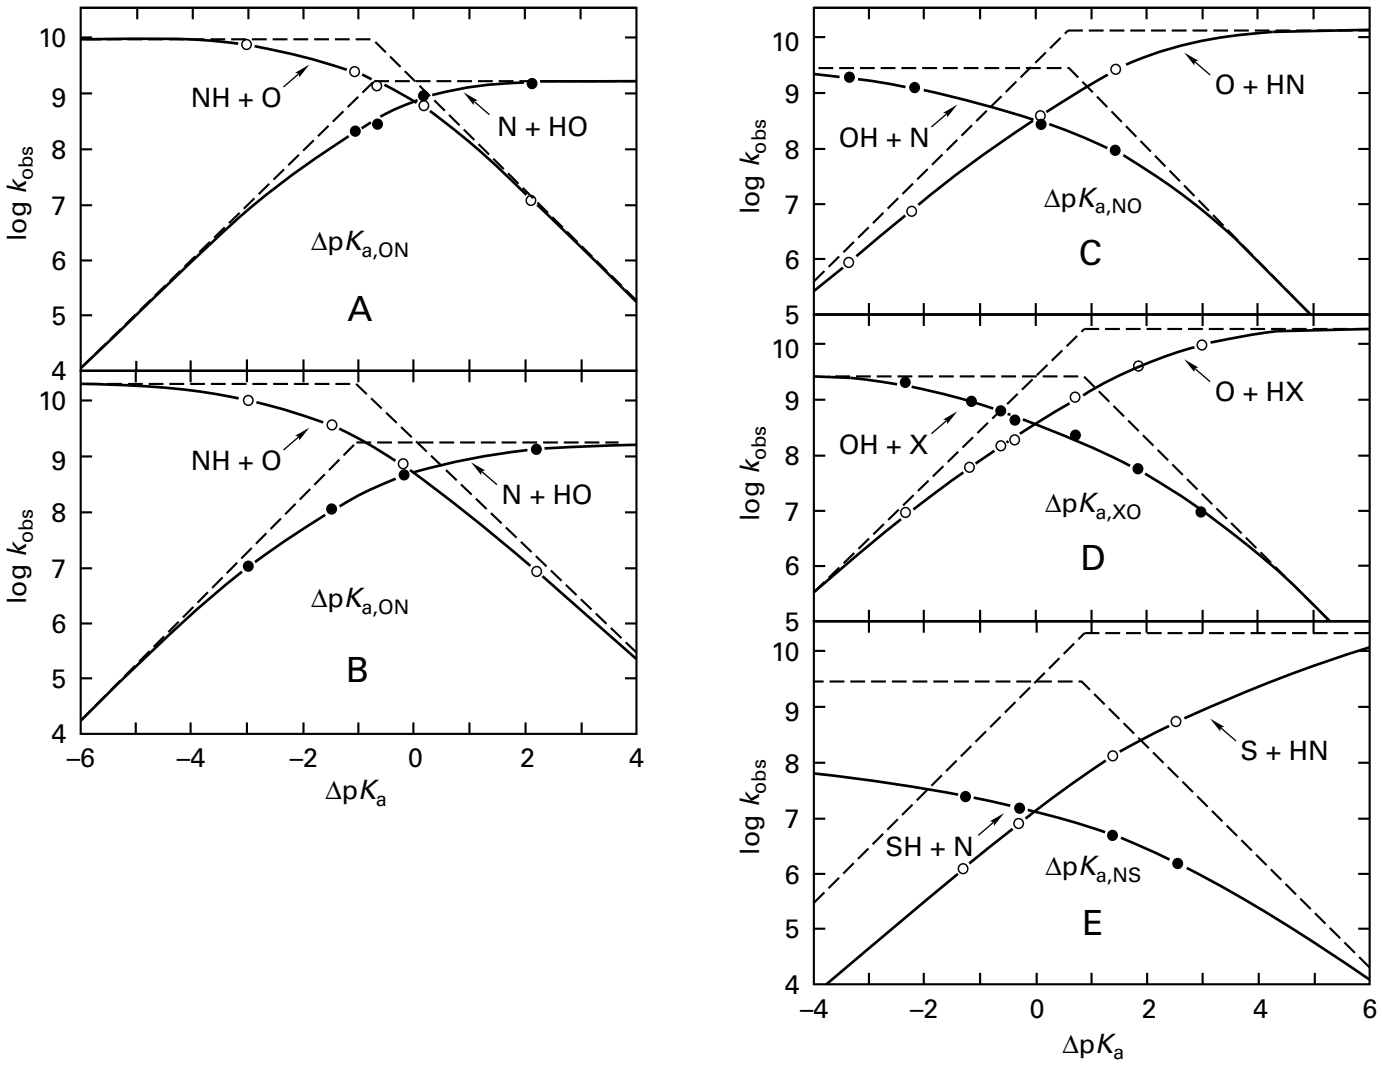


Figure 1–1: Bimolecular rate constants for transfer of a hydron between an acid and a base dissolved in aqueous solution.[16] In each panel, the common logarithms of the observed rate constants, k_{obs}, are presented for (●) the transfer of a hydron from a series of acids to the same common base and for (○) the transfer of a hydron from the conjugate acid of the same common base to the conjugate bases of the same series of acids. With the appropriate choice of reactants, these observed rate constants are the experimentally measured values of the rate constants k_F and k, respectively, of Equation 1–6. Each common logarithm of an observed rate constant is plotted as a function of the difference between the pK_a of the acid and the pK_a of the conjugate acid of the base (Equation 1–10) for that particular transfer of a hydron. **(A)** Common base (N), ammonia; common conjugate acid (NH), ammonium ion; acid series: (OH), D-glucose ($\Delta pK_a = -3$), bicarbonate ($\Delta pK_a = -1.1$), phenol ($\Delta pK_a = -0.7$), boric acid ($\Delta pK_a = +0.1$), and 4-nitrophenol ($\Delta pK_a = +2.1$); (●) transfer from the particular acid (OH) to the common base (N); (○) transfer from the common conjugate acid (NH) to the particular conjugate base (O). **(B)** Common base (N), imidazole; common conjugate acid (NH), imidazolium ion; acid series: (OH), phenol ($\Delta pK_a = -3$), hydrogen diphosphate trianion ($\Delta pK_a = -0.7$), 4-nitrophenol ($\Delta pK_a = -0.1$), and acetic acid ($\Delta pK_a = +2.3$); (●) transfer from the particular acid (OH) to the common base (N); (○) transfer from the common conjugate acid (NH) to the particular conjugate base (O). **(C)** Common base (O), acetate ion; common conjugate acid (OH), acetic acid; acid series: (NH), hydrazinium ion ($\Delta pK_a = -3.3$), imidazolium ion ($\Delta pK_a = -2.3$), anilinium ion ($\Delta pK_a = +0.1$), and 3-chloroanilinium ion ($\Delta pK_a = +1.4$); (●) transfer from the common conjugate acid (OH) to the particular conjugate base (N); (○) transfer from the particular acid (NH) to the common base (O). **(D)** Common base (O), phenolate ion; common conjugate acid (OH), phenol; acid series: (XH), hydrogen phosphate dianion ($\Delta pK_a = -2.4$), piperidinium ion ($\Delta pK_a = -1.3$), propylammonium ion ($\Delta pK_a = -0.6$), bicarbonate ion ($\Delta pK_a = -0.4$), ammonium ion ($\Delta pK_a = +0.7$), hydrazinium ion ($\Delta pK_a = +1.9$), and imidazolium ion ($\Delta pK_a = +2.9$); (●) transfer from the common conjugate acid (OH) to the particular conjugate base (X); (○) transfer from the particular acid (XH) to the common base (O). **(E)** Common base (S), thiolate ion of thioglycol; common conjugate acid (SH), thioglycol; acid series: (NH), dimethylammonium ion ($\Delta pK_a = -1.2$), trimethylammonium ion ($\Delta pK_a = +0.3$), hydrazinium ion ($\Delta pK_a = +1.4$), and imidazolium ion ($\Delta pK_a = +2.4$); (●) transfer from the common conjugate acid (SH) to the particular conjugate base (N); (○) transfer from the particular acid (NH) to the common base (S). The horizontal dashed lines are asymptotes based on the assumption that a sufficiently exergonic transfer of a hydron should have the theoretically calculated encounter-controlled bimolecular rate constant. The dashed lines with slope +1 or slope –1 are the endergonic asymptotes calculated by Equation 1–11.

For hydron transfers in solution that are not significantly exergonic, the behavior of the rate constants is a function of the encounter-controlled rate constant and of the difference in values of pK_a between the acid and the conjugate acid of the base. Within a particular class of hydron transfers—for example, all of the transfers of a hydron from a neutral oxygen to a neutral nitrogen to create an oxygen with a negative elementary charge and a nitrogen with a positive elementary charge—each transfer of a hydron from $^{(+)}$AH to ⊙B$^{(-)}$ in the exergonic direction ($\Delta pK_{a,AB} > 4$) is always encounter-controlled and therefore has the same value for its second-order rate constant k_F. Therefore, the rate of transfer of the same hydron in the reverse direction, or the endergonic direction ($\Delta pK_{a,BA} < -4$) from $^{(+)}$BH to ⊙A$^{(-)}$, must be governed only by $\Delta pK_{a,AB}$ because, from Equation 1–9, it follows that

$$\log k_R = \log k_F - \Delta pK_{a,AB} \qquad (1\text{–}11)$$

Because k_F is always the same in the exergonic direction, the rate constant for transfer of a hydron in the endergonic direction should decrease by a factor of 10 for every increase in $\Delta pK_{a,AB}$ of one common logarithmic unit. This expectation has been demonstrated experimentally. For example, Equation 1–11 defines the diagonal asymptotes in each panel of Figure 1–1. This behavior suggests that the probability the hydron will leave the encounter complex on the weaker base is governed only by the difference in pK_a between the conjugate acids of the two bases and reflects the distribution of the hydron between the lone pair on the conjugate base of the acid and the lone pair on the base in the complex. Consequently, the transfer of the hydron in the complex has reached equilibrium.

The behavior of the transfer of a hydron when the reaction is neither strongly exergonic nor strongly endergonic ($-4 < \Delta pK_{a,AB} < 4$) deviates smoothly from these limits. An example is the transfer of a hydron between a negative oxyanion as one base and a neutral amino nitrogen as the other base (Figure 1–1A)

$$R_1NH_3^+ + {}^-OR_2 \rightleftharpoons R_1NH_2 + HOR_2 \qquad (1\text{–}12)$$

When the transfer is from oxygen to nitrogen (the reverse of Equation 1–12) and exergonic, the encounter-controlled second-order rate constant is less than that for an exergonic transfer from nitrogen to oxygen (the direction of Equation 1–12) because of the asymmetry of charge (horizontal asymptotes in Figure 1–1A). In either direction, when the transfers of the hydrons have become strongly endergonic, the respective rate constants fall off as exponential functions of $\Delta pK_{a,ON}$. The horizontal asymptote, defined by the rate constant for the encounter-controlled exergonic transfer of a hydron from oxygen to nitrogen, intersects the diagonal asymptote, defined by the rate constant for the endergonic transfer from nitrogen to oxygen, when $\Delta pK_{a,ON} = 0$ as required by Equation 1–11. When $\Delta pK_{a,ON} = \Delta pK_{a,NO} = 0$, the actual rate constants for the transfer of the hydron in the two directions are equal, as required by Equation 1–9.

For transfer of a hydron in one direction, the distance at which the smooth curve defining the actual observed second-order rate constant of the transfer lies below the intersection of the two asymptotes, horizontal and diagonal, governing its class of hydron transfers (Figure 1–1) provides information about the **rate of transfer of the hydron within the encounter complex**. If the rate constant k_1 in Equation 1–3 or Equation 1–5 remains constant and encounter-controlled as $\Delta pK_{a,AB}$ is varied, and if k_2 and k_{-2} remain very fast, then k_F, the observed composite rate constant for transfer of the hydron, should have half its asymptotic, encounter-controlled value (horizontal asymptotes in Figure 1–1) at the $\Delta pK_{a,AB}$ at which the horizontal and diagonal asymptotes intersect. If this were the case, the common logarithm of the actual rate constant for the transfer of the hydron should lie a distance of $\log 2 = 0.30$ below the point of intersection. If, however, k_2 is less than k_{-1} because the transfer of the hydron within the encounter complex is not fast compared to diffusion of the reactants apart, then at the $\Delta pK_{a,AB}$ corresponding to the intersection of the two asymptotes, the smooth curve defining the common logarithm of the actual value for the composite rate constant k_F will lie below the intersection of the asymptotes by a distance greater than 0.30, and that distance will be approximately $\log (k_2/k_{-1})$. Consequently, the magnitude of that distance will be dictated by the rate constant k_2 for isoergonic transfer of the hydron within the hydrogen-bonded complex.

The observed rate constant for the transfer of a hydron between a particular acid and a particular base in solution provides a limit for the expected rate constant for the transfer of a hydron between the same acid and the same base during a chemical reaction in the active site of an enzyme. In the active site of the enzyme, there is usually a

direct hydrogen bond between a particular acid and a particular base. In solution, there is often, if not usually, a chain of water molecules connecting the acid and the base that relays the hydron to accomplish the transfer (Equation 1–4). Consequently, the rate constant k_2 for the actual transfer of the hydron in solution is probably a lower limit for the rate constant for transfer of a hydron in a direct hydrogen bond between acid and base. Because, however, most exergonic and even some **isoergonic** hydron transfers occur in solution with rate constants k_2 greater than or of equal magnitude to the rate constants k_3 for dissociations of the respective encounter complexes, the transfer of a hydron through such a relay system, once it is established, must be rapid in all situations in which the hydron transfer is indirect.

The rate constants for the isoergonic transfers of a hydron between various types of acids and bases in solution provide implications about the rate constants for the transfer of a hydron between the same types of acids and bases in the active site of an enzyme. The isoergonic transfer of a hydron to the primary amine or from the primary ammonium in the side chain of a **lysine** should be the most rapid (Figure 1–1A). Even in this case, however, the overall isoergonic reaction in solution is limited by the value of k_2 because the common logarithm of the actual rate constant k_F is more than 0.3 unit below the intersection of the asymptotes. The primary amine or ammonium of a lysine is followed in its efficiency of transfer by the imidazole or imidazolium of a **histidine** (Figure 1–1B), the carboxylate or carboxylic acid in the side chain of an **aspartate** or a **glutamate** (Figure 1–1C), and the phenolate or phenol of a **tyrosine** (Figure 1–1D). Nevertheless, even with carboxylic acids and phenols, which have the slowest transfers within the encounter complex, the distance below the intersection of the asymptotes is only about 1.2 common logarithmic units, and $k_2/k_{-1} \cong 0.06$. If the rate constant for separation of the products, k_{-1}, remains encounter-controlled at $>10^{10}$ s^{-1}, then the rate constant in solution for isoergonic transfer of the hydron, k_2, is still $>10^9$ s^{-1}. In the active site of an enzyme, the rate constant for the transfer of a hydron between any of these side chains and an amine, ammonium, imidazole, imidazolium, carboxylate, carboxylic acid, phenolate, or phenol on a substrate must be at least as rapid as the same type of transfer in solution. **Consequently, all these types of transfer must reach equilibrium in a few nanoseconds.**

If the transfer of a hydron within a hydrogen bond is endergonic, its rate constant, k_2, will be controlled by the equilibrium constant for the transfer of the hydron

$$K_{eq2} = \frac{k_2}{k_{-2}} \qquad (1–13)$$

Consequently, that rate constant should decrease by at most a factor of 10 for each decrease of ΔpK_a by one unit (Figure 1–1A–D). As the reverse reaction, however, becomes more and more exergonic because the forward reaction is becoming more and more endergonic, k_{-2} increases from its isoergonic value, so k_2 decreases by less than a factor of 10 for each change in ΔpK_a of one unit, and equilibrium within the hydrogen bond is nevertheless established rapidly. Consequently, the difference in the values of pK_a between acid and base in the endergonic transfer of a hydron within a hydrogen bond has to be fairly large before the transfer of a hydron between an oxygen and a nitrogen, between two nitrogens, or between two oxygens exerts any significant limitation on the rate of an enzymatic reaction. As long as the differences in the values of pK_a are not large, there is no need for an enzyme to accelerate such a transfer of a hydron.

Two other types of hydron transfer that often take place in enzymatic reactions, however, occur much more slowly in solution. First, the most inefficient heteroatomic acid–base participating in the transfer of a hydron in solution to or from nitrogen and oxygen is a thiol or thiolate (Figure 1–1E). Second, the transfer of a hydron to and from carbon is much slower than that between heteroatoms.

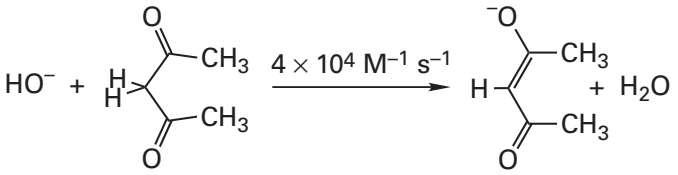
Part of the reason that the **transfer of a hydron from a thiol or to a thiolate** is anomalously slow in solution is that, because sulfur is an element in the third row of the periodic table, a thiol is a poor donor for a hydrogen bond and a thiolate is a poor acceptor for a hydrogen bond to nitrogen or oxygen. As a result, a thiol or thiolate may not be incorporated into the layer of hydration surrounding it by donating or accepting, respectively, a hydrogen bond to or from a molecule of water within the layer. If this is the case, when the hydrated molecule containing the thiol collides with the hydrated molecule containing a nitrogen or an oxygen to which the hydron is going to be transferred, or when the hydrated molecule

containing the thiolate collides with the hydrated molecule containing a hydronated nitrogen or a hydronated oxygen from which the hydron is going to be transferred, a chain of water molecules connecting the hydron of the thiol or a lone pair of the thiolate to that nitrogen or oxygen may not form. If this chain cannot form, it may be necessary for a collision to be energetic enough to penetrate the respective layers of hydration and actually juxtapose the thiol or thiolate with the nitrogen or oxygen that either accepts or donates the hydron before the encounter succeeds in transferring the hydron.

In the active site of an enzyme, however, the situation is different. When the **thiol of a cysteine** is to be used as an acid, it is forcibly juxtaposed immediately adjacent to the base on the molecule of substrate to which it is donating a hydron. Conversely, when the **thiolate of a cysteine** is to be used as a base, it is forcibly juxtaposed immediately adjacent to the acid on the molecule of substrate from which it is accepting a hydron. If, for the transfer of a hydron to or from sulfur in solution, there actually is a unique requirement for the intimate juxtaposition of the reactants, and if this requirement significantly decreases the rate of transfer of the hydron in solution, then the slow rates for these transfers observed in solution do not imply that the transfer of a hydron to or from the sulfur of a cysteine in an active site achieves equilibrium at a significantly slower rate than the transfer of a hydron to or from the heteroatomic bases and acids on the side chains of lysines, histidines, aspartates, glutamates, or tyrosines. In fact, the side chains of cysteines are frequently used as catalytic acids and bases in enzymatic reactions.

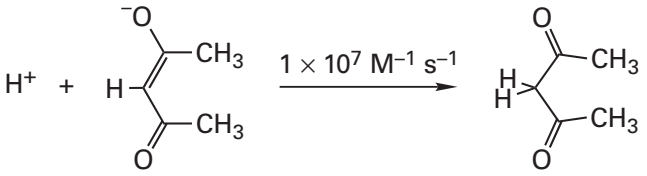
The rates for the transfers of hydrons to or from carbon atoms in solution are slow. Almost all of the transfers of hydrons to or from carbon that are relevant to enzymatic catalysis are to an enolate or from a carbon α to a carbonyl or an acyl group, and consequently most of the examples to be considered here are transfers of hydrons of this type. Such rate constants for the transfer of a hydron both to and from carbon exhibit large negative deviations from the asymptotic behavior exemplified by the transfers between heteroatoms displayed in Figure 1–1.

If the transfer of a hydron to or from carbon is severely **exergonic**, such as the transfer of a hydron from hydronium ($pK_a = -1.74$) to the enolate of acetone ($pK_a \cong 20$),[16] it proceeds at encounter-controlled rates,* but the significantly exergonic transfer of a hydron from the acidic carbon on acetylacetone to hydroxide ($\Delta pK_{a,AB} = +7$)



(1–14)

and the significantly exergonic transfer of a hydron from hydronium to the enolate of acetylacetone ($\Delta pK_{a,AB} = +11$)

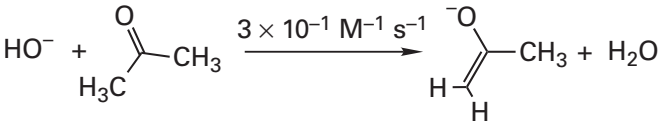


(1–15)

have second-order rate constants of 4×10^4 M^{-1} s^{-1} and 1×10^7 M^{-1} s^{-1}, respectively, which are considerably less than encounter-controlled rates. The rate constant[33] for the exergonic transfer of a hydron from the conjugate acid of 3-quinuclidinone to the enolate of acetone ($\Delta pK_{a,AB} \cong +12$) is 2×10^8 M^{-1} s^{-1} at 25 °C. The rate constants for the exergonic transfers of a hydron to diphenylmethyl anion from a set of acids with different values of pK_a in dimethylformamide at 22 °C[32] vary systematically from 2×10^5 M^{-1} s^{-1} to 2×10^9 M^{-1} s^{-1} within the range of $\Delta pK_{a,AB}$ from 0 to +10 before leveling out near the encounter-controlled limit, and the slope of the line defining log k_F as a function of $\Delta pK_{a,AB}$ is 0.6. If this correlation had been for exergonic transfer to a nitrogen or an oxygen, the rate constants would have reached the encounter-controlled limit at much smaller values of $\Delta pK_{a,AB}$ (Figure 1–1), and below the encounter-controlled limit, they would have been about 1000 times faster at the same respective values of $\Delta pK_{a,AB}$.

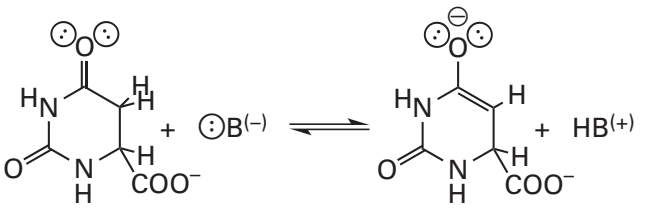
*If the transfer of the hydron to carbon becomes exergonic enough, the rate of its transfer from oxygen or nitrogen actually begins to decrease as the acid becomes stronger,[32] but this inverted region is probably well beyond the values of $\Delta pK_{a,AB}$ found in enzymatic reactions.

When the removal of a hydron from carbon is **endergonic**, where it necessarily should be less rapid than a encounter-controlled reaction, it is extraordinarily slow. For example, the rate constant for the removal of a hydron from acetone by hydroxide ($\Delta pK_{a,AB} \cong -5$)



(1–16)

is much less (3×10^{-1} M^{-1} s^{-1})[16] than the rate constant of about 10^5 M^{-1} s^{-1} expected for the rate of transfer of a hydron between two nitrogens or oxygens that differ this much in acid dissociation constants (Figure 1–1). The rate constants[33] for the removal of a hydron by 3-quinuclidinone from acetone ($\Delta pK_{a,AB} \cong -12$) and from ethyl thioacetate ($\Delta pK_{a,AB} \cong -13$) are 5×10^{-4} M^{-1} s^{-1} and 2×10^{-5} M^{-1} s^{-1}, respectively, at 25 °C. The rates of the endergonic transfer of a hydron at 37 °C from carbon 5 of dihydroorotate ($pK_a = 21$)



(1–17)

to the lone pairs of a set of bases vary systematically from 10^{-10} M^{-1} s^{-1} to 10 M^{-1} s^{-1} for bases the conjugate acids of which have values of pK_a from –1 to 16, and the slope of the line defining $\log k_F$ as a function of those values of pK_a is 0.8.[34] All these rate constants are more than 100-fold smaller than those expected for transfer of a hydron from oxygen or nitrogen at the same values of $\Delta pK_{a,AB}$ and temperature (Figures 1–1A–D).

The biggest problem in the transfer of a hydron from or to carbon is probably the **inability of a carbon–hydrogen bond or the carbon in an enolate to form a hydrogen bond** with molecules of water or other heteroatomic bases or heteroatomic acids, respectively. A carbon–hydrogen bond cannot act as the donor in a hydrogen bond because the electronegativities of carbon and hydrogen are so similar that a hydrogen–carbon bond has an insignificant electric dipole moment compared to that of a hydrogen–nitrogen bond or a hydrogen–oxygen bond.* The carbon in an enolate cannot act as an acceptor for a hydrogen bond because there is almost no free electron density on the carbon in an enolate. Another way of appreciating this latter problem is to realize that the carbon in an enolate does not have a lone pair of electrons that could act as an acceptor because the pair of electrons is delocalized in the π system and resides mainly on the oxygen. Consequently, as was the case with the thiol or thiolate , the acidic carbon–hydrogen bond or the carbon in an enolate cannot form a hydrogen bond with the molecules of water in the layer of hydration surrounding it. This inability to form a hydrogen bond with the molecules of water in the layer of hydration is even more extreme for carbon than for sulfur, and unlike the situation with a thiol or thiolate, this inability to form a hydrogen bond probably persists even in an encounter complex in which the carbon–hydrogen bond or the carbon in an enolate is immediately juxtaposed to the base that is to remove the hydron or the acid that is to donate the hydron, respectively.

The hydrogen bond that readily forms between a normal heteroatomic base and a normal Brønsted heteroatomic acid when both heteroatoms are from the second row of the periodic table also lowers the free energy of activation for the transfer of a hydron by bringing the reactants significantly closer together than the **van der Waals radii of their atoms** would normally permit. In the transfer of a hydron to or from carbon, advantage cannot be taken of this proximity. This missed opportunity causes the distance between the carbon and the heteroatom of the acid that hydronates the carbon or the base that removes a hydron from the carbon to be longer in the ground state for transfer of the hydron, and it causes the energy barrier for that transfer to be much more significant than the barriers for transfer of a hydron between two heteroatoms.[36]

In solution in both directions, large **changes in solvation** must occur upon transfer of a hydron between any acid and any base.[37] The change in solvation, however, is far more extensive in the removal of a hydron from carbon than in the removal of a hydron from a heteroatom because the resulting increase of one negative elementary charge in the conjugate base of an acidic carbon usually occurs several atoms away from the location within the base

*There are indications that, in the confines of the active site of an enzyme, hydrogen bonds between a carbon–hydrogen bond and a heteroatomic base can be sterically enforced.[35]

that gains the positive elementary charge. For an acidic carbon that has an enolate for its conjugate base, the negative elementary charge in the conjugate base appears primarily on the oxygen of the enolate, which is two atoms away from the atom of the base that gains the positive elementary charge upon hydronation.[38]

In addition, when a hydron is removed from a carbon α to a carbonyl or acyl group (Equations 1–14 and 1–17), **rehybridization** to form the enolate is required as the hydron is removed.

Because carbon does not form normal hydrogen bonds, the transfer of a hydron from and to carbon, a reaction occurring in many **enzymatic reactions**, is slow when it occurs in free solution between two independent solutes. To overcome this difficulty and increase the rate of removal of a hydron from carbon by a heteroatomic base, the lone pair of electrons on the base can be pushed by the enzyme into the hydrogen–carbon bond to enforce an arrangement similar to a hydrogen bond.[39] In the reverse direction, the rate of transfer of a hydron to an enolate can be increased if the excess π electron density on its anionic oxygen can be pushed onto the carbon causing the carbon to be more basic. In addition, in an enzymatic reaction, solvation of the ions is provided by the protein surrounding the location at which the transfer of the hydron occurs, and the surroundings can be tailored by natural selection to provide the necessary changes in solvation as efficiently as possible.

The intramolecular transfer of a hydron can be appreciated in the context of the intermolecular transfers that have been the subject so far. The ideal situation, for both the formation of an effective hydrogen bond and the efficient transfer of the hydron within that hydrogen bond, is that in which the hydrogen of the acid and the σ lone pair of electrons of the base both lie upon the line of centers connecting the nuclei of the two atoms between which the hydron is transferred. This requirement is accomplished in the direct intermolecular transfer of a hydron to and from heteroatoms by the formation of a properly aligned hydrogen bond between two independent, readily oriented molecules. In an ideal hydrogen bond within which the transfer of a hydron is occurring, the *s* atomic orbital of the hydron and the sp^3 or sp^2 orbitals from the two heavy atoms participating in the reaction overlap simultaneously to produce the transition state required for the transfer of the hydron

1–3

Although this transition state is not required to be precisely linear as drawn,[40] overlap of the three atomic orbitals creating it is an inescapable requirement.

In the intramolecular transfer of a hydron, the covalent connection between acid and base can **interfere with the proper alignment** of the orbitals to permit effective overlap. When the oxygen, nitrogen, or sulfur on which the hydron is situated is covalently attached to the same atom as the oxygen, nitrogen, or sulfur on which the lone pair is situated so that only this one atom separates them, the direct transfer of the hydron to the lone pair is impossible.

(1–18)

In such circumstances, a hydrogen bond cannot form because both the hydron and the lone pair lie too far off the line of centers and are held too far apart. In such a situation, if the acid loses a hydron and if the base gains a hydron, it does not result from the direct transfer of the hydron between them. There is always a separate base that removes the hydron from the acid, and the resulting conjugate acid of that base[41] or another acid then transfers a hydron to the lone pair of the base.[42]

When there are two atoms between the atoms on which the hydron and the lone pair are located, the intramolecular transfer of the hydron can occur, but the transfer is slow.[40] The hydrogen bond in which it proceeds, because it is not ideally aligned, is weak and easily disrupted by protic solvents, which consequently interfere with the direct transfer of the hydron.[43] When there are three or four atoms separating acid and base, the hydrogen bond between them is permitted to assume the proper geometry in the resulting five-membered or six-membered ring (not counting the hydron), the hydrogen bond is a strong one,[44] and transfer of the hydron is unimpeded.

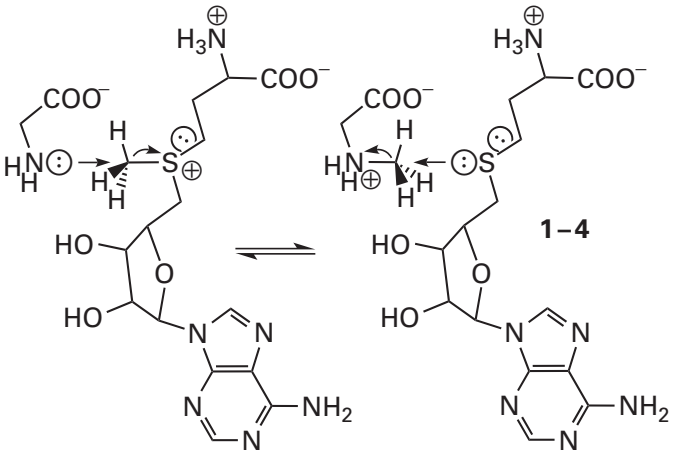
Nucleophilic Substitution

As is the transfer of a hydron, a nucleophilic substitution is the transfer of an electrophile between two lone pairs of electrons. Nucleophilic substitutions can occur at a saturated electrophilic carbon, at the electrophilic carbon in a carbonyl group, at the electrophilic carbon in an imine, at the electrophilic carbon in an acyl group, and at the electrophilic phosphorus in a phospho group.

The simplest reaction in organic chemistry, other than the transfer of a hydron, is a concerted nucleophilic substitution at a saturated carbon that proceeds without the formation of an intermediate. A **concerted nucleophilic substitution** is a nucleophilic substitution in which the bond between the leaving group and the electrophilic carbon is breaking as the bond between the nucleophile and the carbon is forming. An example of such a concerted nucleophilic substitution is the methylation of glycine by *S*-adenosyl-L-methionine to produce sarcosine



(1–19)

that is catalyzed by glycine *N*-methyltransferase from *Oryctolagus cuniculus*.[45] In this reaction, a bond between the carbon of the methyl group and the sulfur of *S*-adenosyl-L-homocysteine (**1–4**) has been substituted with a bond between the carbon of the methyl group and the amino nitrogen of the glycine. The electrophile, the methyl group, has been transferred from the lone pair of the sulfur of *S*-adenosyl-L-homocysteine to the lone pair of the nitrogen of glycine, as if it were a hydron.

The four electrons participating in a concerted nucleophilic substitution are confined initially in atomic and molecular orbitals of the reactants; they end up confined in atomic and molecular orbitals of the products; and at the apogee of the change in free energy during the reaction, they are confined in a **molecular orbital system of the transition state**. For these electronic transitions to occur, the atomic and molecular orbitals of the reactants that will mix to form the unique molecular orbital system in the transition state must be able to approach each other closely enough and in the proper orientation to **overlap**, and the atomic and molecular orbitals of the product must be such that they can be derived from a permitted unmixing of the molecular orbital system of the transition state.

In the case of the concerted nucleophilic substitution described in Equation 1–19, the sp^3 atomic orbital on the nucleophilic nitrogen occupied by its lone pair of electrons mixes with the molecular orbital system of the σ bond between the carbon and the sulfur to produce the unique molecular orbital system of the transition state (Figure 1–2). This process can be viewed as a smooth transition in which the occupied sp^3 atomic orbital on nitrogen overlaps with the unoccupied σ^* anti-bonding molecular orbital of the σ bond between carbon and

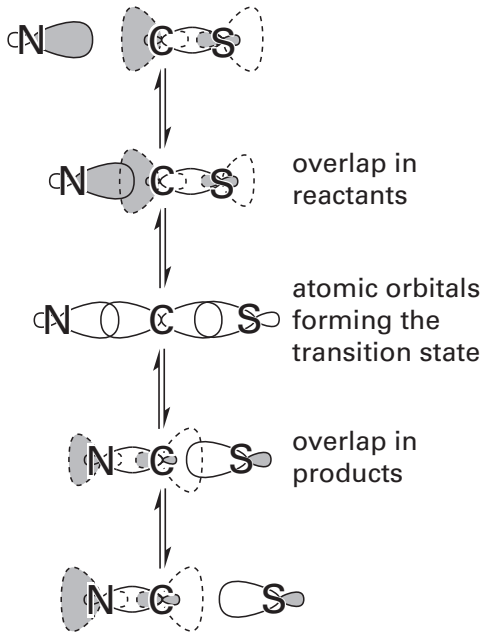


Figure 1–2: Progress of a concerted nucleophilic substitution. An atomic orbital on the nucleophile, occupied by a lone pair of electrons (drawn with solid outline), overlaps the antibonding molecular orbital (drawn with dashed outline) of the carbon–sulfur bond. The overlap proceeds to a transition state formed from a combination of three atomic orbitals, one from each of the three atoms: nitrogen, carbon, and sulfur. The transition state decomposes through an overlap between an atomic orbital on sulfur (drawn with solid outline), which will contain a lone pair of electrons in one product, and the antibonding molecular orbital (drawn with dashed outline) of the carbon–nitrogen bond in the other product. The phases within the molecular and atomic orbitals are indicated with gray shading.

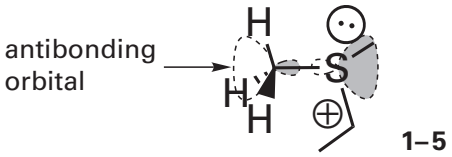
sulfur. This initial overlap leads to a molecular orbital system in the transition state composed of an atomic orbital from the attacking nitrogen, a *p* atomic orbital from the carbon of the methyl group, and an atomic orbital from the sulfur. Therefore, the unique molecular orbital system in the transition state has three molecular orbitals formed from the three atomic orbitals shown in Figure 1–2, and its two molecular orbitals of lowest energy are occupied by the four electrons that are being rearranged. These electrons are the two originally in the lone pair on the nitrogen and the two originally in the σ bond between carbon and sulfur.

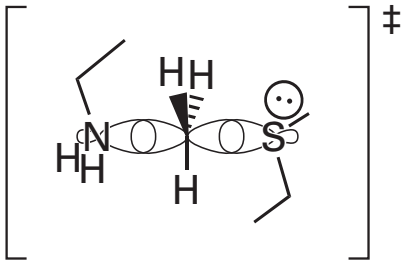
When the structure of the methyl group on *S*-adenosyl-L-methionine is examined, one aspect of the **energy barrier** encountered by the lone pair of electrons on the nucleophilic nitrogen can be appreciated. The vacant antibonding orbital on the carbon*



1–5

is in a depression formed from the three σ bonds between the three hydrogens and the electrophilic carbon of the methyl group, and the six electrons in these three σ bonds repel the two electrons in the lone pair on the nitrogen. This **electron repulsion** also results from orbital overlap, but in this case the overlap occurs between filled orbitals rather than between a filled and a vacant orbital. Along the trajectory of the reaction, as the atomic orbital containing the lone pair of electrons on the nitrogen overlaps the occupied bonding molecular orbitals of these three σ bonds between the carbon and the three hydrogens, electron repulsion occurs. This unfavorable overlap is a major contributor to the instability of the transition state relative to the ground state.

The three σ bonds form a repulsive funnel confining the trajectory of the nucleophile and dictating the **stereochemistry** of the reaction. These three σ bonds are pushed forward by the electron repulsion of the lone pair of electrons on the nucleophile as the reaction progresses. As they are pushed forward, they flatten into a plane perpendicular to the σ bond between the carbon and the dissociating sulfur



1–6

This reorientation does lead to a decrease in the mutual repulsion of the three σ bonds. Nevertheless, the transition state involves too much electron repulsion to be stable, not to mention a pentavalent carbon, and it breaks down to yield the products. The reaction proceeds with **inversion of configuration** of the methyl group being transferred.

To effect the reaction, the lone pair of electrons on nitrogen must approach a location on the electrophilic carbon opposite the carbon–sulfur bond of *S*-adenosyl-L-methionine with sufficient kinetic energy or, just as effectively, be forced against the carbon with sufficient potential energy to overcome the electron repulsion inherent in the transition state. In solution, the kinetic energy of the reactants, which are freely diffusing prior to the encounter, and the kinetic energy of collisions of molecules of water from the solution with the encounter complex, after the encounter has been effected, provide the kinetic energy to overcome the repulsion in the transition state. Only encounters between two molecules that have kinetic energy greater than the free energy of activation and are correctly aligned can be productive. In the active site of the enzyme, once the reactants are properly aligned, normal thermal fluctuations in the positions of the atoms promote the reaction, but the lone pair of electrons on the nitrogen can also be compressed against the electrophilic face of the methyl group.

There is also an energy barrier to the reaction in solution, resulting from the requirement to **desolvate** the amine. As the nitrogen of the lone pair approaches the carbon, there must be sufficient kinetic energy to peel away the layer of hydration around the lone pair in addition to overcoming the electron repulsion. In the case of the enzymatic reaction catalyzed by glycine *N*-methyltransferase (Equation 1–19), the layer of hydration is stripped

*Because biochemical molecules are often complex and only portions of them are usually shown in chemical drawings, the convention used in this book is to represent a bond to the rest of the molecule as an open line rather than using the convention $-R_n$ as is done in organic chemistry. Instead of using an open line to represent a methyl group, as is commonly done in organic chemistry, a methyl group will always be written explicitly as $-CH_3$.

from the amine as it associates with the active site. This **stripping of layers of hydration** during the association of substrates with an active site is a major contributor to the catalysis performed by enzymes.

A leaving group is the atom or group of atoms that dissociates from the rest of the electrophile during a nucleophilic substitution. The rest of the electrophile contains the electrophilic atom of the reactant, and the leaving group contains the dissociating atom that was originally bound to that electrophilic atom. The leaving group in all of the methylations performed by *S*-adenosyl-L-methionine (Equation 1–19) is the dialkylated sulfur of *S*-adenosyl-L-homocysteine (**1–4**), a sulfide, and the rest of the electrophile is the methyl group. Because the leaving group is an uncharged sulfide, the sulfur in *S*-adenosyl-L-methionine bears the formal single positive charge number of a sulfonium ion, a fact that is responsible for the electrophilicity of its methyl group. This positive elementary charge cannot be delocalized. The other carbons attached to the positively charged sulfur are also electrophilic. For example, the 3-aminopropyl group, rather than the methyl group, in *S*-adenosyl-3-(methylthio)propylamine, the decarboxylated version of *S*-adenosyl-L-methionine, is transferred to butane-1,4-diamine by spermidine synthase from *Escherichia coli* in a concerted nucleophilic substitution that proceeds with inversion of configuration at carbon 1 of the 3-aminopropyl group.[46-48] Likewise, *S*-alkylsulfonium ions are competent alkylating agents[49] in free solution in the absence of enzymatic catalysis.

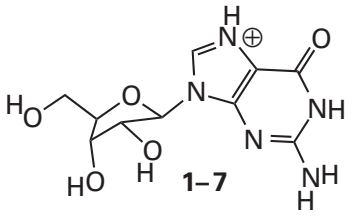
The leaving group in a nucleophilic substitution can be **improved by making its conjugate acid more acidic**. Because the leaving group dissociates with a lone pair of electrons (Equation 1–19), its dissociation from the electrophilic carbon resembles in its character the dissociation of the same constellation of atoms from a hydron during the acid dissociation of the conjugate acid of the leaving group. For example, the acid dissociation of the conjugate acid of *S*-adenosyl-L-homocysteine, the leaving group in a methylation performed by *S*-adenosyl-L-methionine (Equation 1–19), is

(1–20)

Any alteration in the leaving group that decreases the pK_a of its conjugate acid improves its capacity for dissociation. For example, *S*-adenosyl-L-homocysteine (Equation 1–19) is a better leaving group from *S*-adenosyl-L-methionine than L-homocysteinyl anion, $^{-}SCH_2CH_2CH(NH_3^{+})CO_2^{-}$, is from L-methionine because the cationic conjugate acid of *S*-adenosyl-L-homocysteine (**1–4**; p$K_a \cong -10$) is a stronger acid than is L-homocysteine (p$K_a = 8.9$), the conjugate acid of L-homocysteinyl anion. Consequently, by adenosylating the L-methionine, the leaving group has become the sulfide rather than the thiolate, and *S*-adenosyl-L-methionyl ion is a significantly more effective methylating agent than L-methionine.

Almost all examples of improvements to the ability of the leaving group involve the **addition of electrophiles**. When the oxygen of a hydroxy group in an alcohol has been hydronated, it becomes a better leaving group because it dissociates as water rather than hydroxide ion. The conjugate acid of water, HOH_2^{+} (p$K_a = -1.74$), is a stronger acid than the conjugate acid of hydroxide, HOH (p$K_a = 15.74$). If a phospho group is added to the hydroxy group in an alcohol so that the leaving group is $-OPO_3H^{-}$ rather than –OH, then the bonded oxygen becomes a better leaving group because the conjugate acid of the $^{-}OPO_3H^{-}$ that dissociates, $HOPO_3H^{-}$ (p$K_a = 7.2$), is a stronger acid than the conjugate acid of the ^{-}OH that would have dissociated (p$K_a = 15.74$). If a sulfo group is added to the hydroxy group in an alcohol so that the leaving group is $-OSO_3^{-}$, then the bonded oxygen becomes a better leaving group because the conjugate acid of the $^{-}OSO_3^{-}$ that dissociates, $HOSO_3^{-}$ (p$K_a = 2.0$), is a stronger acid than the conjugate acid, HOH (p$K_a = 15.74$).[50] The hydronation of a monobasic phosphate on another of its oxygens produces an even better leaving group, $^{-}OPO_3H_2$, because the corresponding conjugate acid, $HOPO_3H_2$ (p$K_a = 2.1$), is even more acidic. When the oxygen of a hydroxy group on an alcohol has been acylated with an electrophilic functional group, such as an acetyl group, so that the leaving group becomes $-OC(O)CH_3$, it is a better leaving group because the conjugate acid of the $^{-}OC(O)CH_3$ that dissociates, $HOC(O)CH_3$ (p$K_a = 4.7$), is a stronger acid than the conjugate acid HOH (p$K_a = 15.74$). The hydronation of the sulfur of L-methionine (Equation 1–20), causing it to resemble a sulfonium ion, makes its methyl group more electrophilic.

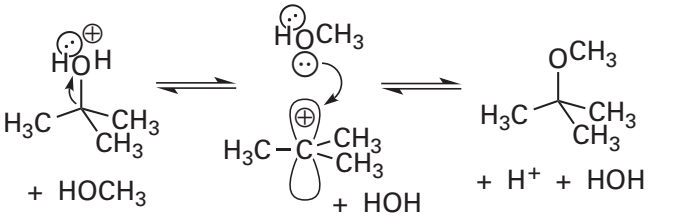
The hydronation of nitrogen 7 in guanosine



1–7

causes the guanine to become a better leaving group because the cationic conjugate acid of guanine ($pK_a = 3.3$) is a stronger acid than guanine itself ($pK_a = 9.2$). When guanosine is hydronated on the oxygen on carbon 6, when inosine[51] is hydronated on the oxygen on carbon 6, when adenosine[51] is hydronated on nitrogen 1, or when adenosine[52] is hydronated on nitrogen 7, each of the respective nitrogenous bases becomes a better leaving group.

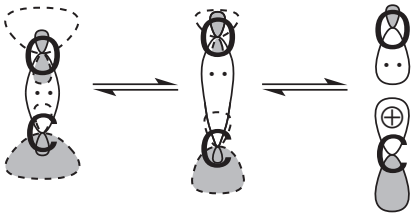
If the leaving group in a nucleophilic substitution at carbon is improved sufficiently that it leaves from the electrophilic carbon before any nucleophile collides with the carbon, it leaves behind a carbenium ion as an intermediate in a dissociative nucleophilic substitution



(1–21)

A **dissociative nucleophilic substitution** at carbon is a nucleophilic substitution in which the bond between the leaving group and the electrophilic carbon breaks completely before the bond between the carbon and the nucleophile begins to form. If the resulting carbenium ion then reacts with a nucleophile other than the nucleophile of the leaving group itself, the addition of that nucleophile completes the dissociative nucleophilic substitution. For example (Equation 1–21), the hydronated hydroxy group dissociates and leaves behind a carbenium ion before methanol, the nucleophile, adds. The improvement of the leaving hydroxy group by its hydronation is essential to the formation of the carbenium ion, but the most consequential distinction between the dissociative nucleophilic substitution of Equation 1–21, which is initiated by the formation of the carbenium ion, and the concerted nucleophilic substitution of Equation 1–19, which proceeds through a single transition state with no intermediate, is not so much the enhancement of the leaving group as the fact that the methyl group of the former has a primary carbon as the electrophile while the *tert*-butyl group of the latter has a tertiary carbon as the electrophile. The **hyperconjugation** of the three methyl groups surrounding the carbenium ion is the key to its stability.

During the formation of a carbenium ion by dissociation of the leaving group, the two **molecular orbitals** of the σ bond, bonding (filled) and antibonding (vacant), have been smoothly turned into the filled atomic orbital containing the lone pair of electrons on the leaving group and the vacant *p* orbital of the carbenium ion



(1–22)

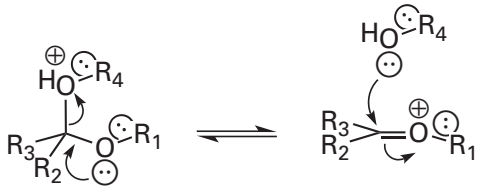
At the same time, the three substituents around the carbon have entered the plane perpendicular to the axis of the *p* orbital (Equation 1–21).

Carbenium ions have the **hybridization** *p*, sp^2, sp^2, sp^2 because of electron repulsion among the three occupied molecular orbitals of the three σ bonds to the substituents, which are no longer repelled by a fourth σ bond and want to be as far apart as possible, and because of the decrease in energy produced by bringing the six electrons in these three σ bonds closer to the nucleus in the more compact sp^2 orbitals. Nevertheless, the reaction is endergonic because a covalent bond—in the example of Equation 1–21, that between carbon and oxygen—is broken with no recompense other than these changes and changes in solvation. The heterolytic cleavage of this bond is the energy barrier to the reaction. In the reverse direction, however, no significant energy barrier exists and the combinations of nucleophiles with carbenium ions are usually encounter-controlled reactions.

Aliphatic carbenium ions are not widely used in **biochemical reactions**. Natural selection presumably has avoided them for the same reasons they are avoided in organic synthesis: the problems of elimination and rearrangement. There is, however, a broad class of enzymatically catalyzed reactions involved in the biosynthesis of carotenoids, steroids, and terpenoids. In each of these reactions, a carbe-

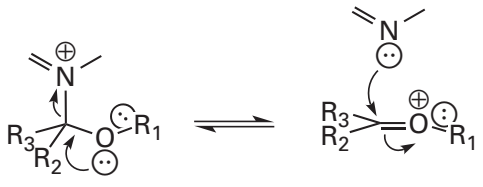
nium ion is generated from the substrate when it is in the active site expressly because it can engage in rearrangement and elimination. The rearrangements and eliminations are carefully controlled sterically by these enzymes and are used to produce dramatic alterations in the structure of their substrates. In each of these reactions, the carbenium ion is generated from a diphosphorylated alcohol ($-OPO_3PO_3^{2-}$) or from a hydronated oxirane, both of which have good leaving groups.

An oxocarbenium ion is a distinct type of carbenium ion. One substituent on the carbon atom in an oxocarbenium ion is an oxygen atom so that the positive charge is delocalized between the carbon and the oxygen. Following the required hydronation of the leaving oxygen, an oxocarbenium ion is formed by the dissociation of that hydronated oxygen from a **hemiacetal**



(1–23)

(R_2 = H; R_4 = H; R_1 and R_3 are substituents attached through carbon), a **hemiketal** (R_4 = H; R_1, R_2, and R_3 are substituents attached through carbon), an **acetal** (R_2 = H; R_1, R_3, and R_4 are substituents attached through carbon), or a **ketal** (R_1, R_2, R_3, and R_4 are substituents attached through carbon). When a formally positive nitrogen leaves from a **hemiaminal ether**



(1–24)

(R_1, R_2, and R_3 are substituents attached through carbon), an oxocarbenium ion is also formed.

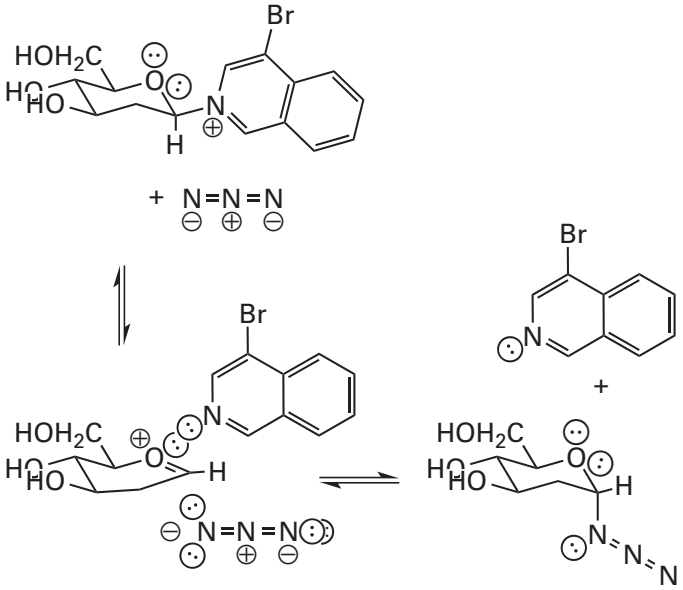
When an acetal is formed, almost always from a hemiacetal, the hydroxy group of that hemiacetal, after it has been hydronated, leaves as a molecule of water (forward direction of Equation 1–23, R_4 = H), and the oxygen of an alcohol other than water adds to the resulting oxocarbenium ion (reverse direction of Equation 1–23, $R_4 \neq$ H). When a ketal is formed, almost always from a hemiketal, the hydronated hydroxy group of the hemiketal leaves as a molecule of water and the oxygen of an alcohol adds to the resulting oxocarbenium ion. The replacement of the hydroxy group with an alkoxy group in each of these instances turns a hemiacetal or a hemiketal, which readily reverts to the aldehyde or ketone, into an acetal or a ketal, which, in the absence of enzymatic catalysis, only reverts to the aldehyde or ketone in strong acid.

The **π molecular orbital system of an oxocarbenium ion** contains two electrons, which leaves the system with a net positive formal elementary charge. This formal charge can be represented by **resonance**

1–8

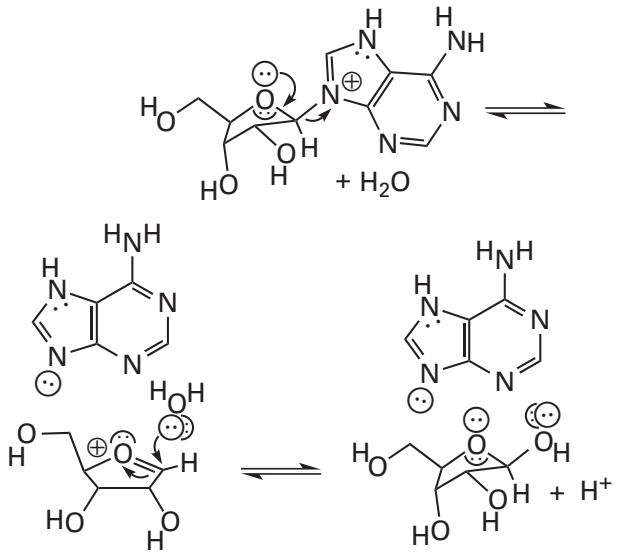
The resonance form drawn to the right in Equations 1–23 and 1–24 and **1–8** for the oxocarbenium ion is the form in which all atoms have octets, but oxygen, the more electronegative element, is required to bear a positive formal elementary charge. In this resonance form, there is a π bond between carbon and oxygen, which is why the oxocarbenium ion is more stable than a simple carbenium ion. An oxocarbenium ion is not so prone to rearrangement and elimination as a carbenium ion because the conjugated oxygen both confines the location of the formal positive elementary charge and moderates its reactivity.

Specific examples of dissociative nucleophilic substitutions involving an oxocarbenium ion as an intermediate would be the nucleophilic substitution of 3-bromoisoquinoline by azide[53]



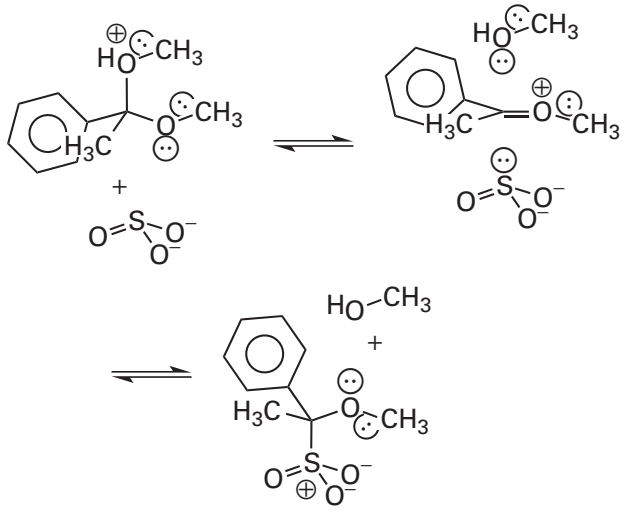
(1–25)

and the acid-catalyzed hydrolysis of adenosine[54] hydronated at nitrogen 7



(1–26)

The oxocarbenium ion formed during the acid-catalyzed hydrolysis of acetophenone dimethyl ketal has been identified by trapping it with sulfite[55]



(1–27)

In the latter two reactions, the formation of the oxocarbenium ion requires that the leaving group be hydronated, and in all three reactions, the atom that is leaving bears a formal positive elementary charge in the reactant, as is the case with the leaving oxygen atom in the hydrolysis of any acetal or ketal (see Equation 1–23).[56]

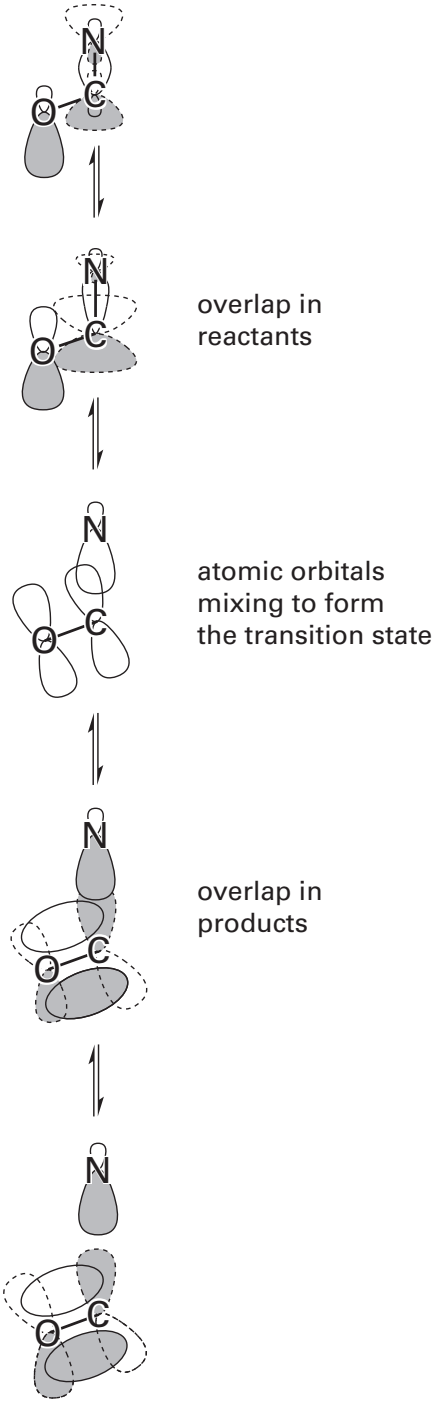


Figure 1–3: Dissociation of a hemiaminal ether to produce an oxocarbenium ion (Equations 1–24 and 1–25). The atomic orbital on oxygen bearing the lone pair of electrons (drawn with solid outline) overlaps the unoccupied antibonding molecular orbital (drawn with dashed outline) of the carbon–nitrogen σ bond to produce the transition state formed from the overlap of three atomic orbitals, one from each of the three atoms, oxygen, carbon, and nitrogen. The transition state decomposes through an arrangement in which the unoccupied antibonding π molecular orbital (drawn with dashed outline) of the oxocarbenium ion in the one product overlaps the atomic orbital on nitrogen (drawn with solid outline) occupied by the lone pair of electrons present in the other product.

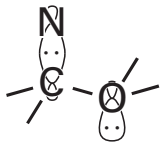
The **molecular orbital system of the transition state** in a dissociation that produces an oxocarbenium ion is formed from three atomic orbitals. For example, the orbitals of the reactant that mix to form the molecular orbital system of the transition state lying between the hemiaminal ether and the oxocarbenium ion and the leaving 3-bromoisoquinoline in Equation 1–25 are a *p* atomic orbital on the adjacent oxygen, a *p* atomic orbital on the carbon, and an sp^2 atomic orbital on the nitrogen (Figure 1–3). The unique molecular orbital system of the transition state created from mixing these three atomic orbitals has three molecular orbitals, and the two with lowest energy are occupied by the four electrons participating in the reaction.

Dissociative nucleophilic substitutions that have oxocarbenium ions as intermediates are **accelerated by the push of an adjacent lone pair of electrons on the oxygen**. For example, in the forward direction of the reaction in Equation 1–26, the dissociation to form the oxocarbenium ion can be considered as expulsion of the nitrogen of the leaving group accelerated by the push of a lone pair of electrons on the oxygen.[57] This lone pair of electrons in the reactant is located in an sp^3 atomic orbital on the oxygen. In the approach to the transition state, this occupied sp^3 atomic orbital overlaps with the unoccupied σ^* antibonding molecular orbital of the carbon–nitrogen σ bond (Figure 1–3). This σ^* antibonding orbital is to become the *p* orbital on the carbon (see Equation 1–22). In the absence of the oxygen, it would normally be a simple vacant *p* orbital of a carbenium ion, but in the presence of the oxygen, it will participate in the π molecular orbital system of the oxocarbenium ion. The overlap of the occupied sp^3 orbital of the oxygen with the unoccupied σ^* antibonding orbital of the carbon–nitrogen bond lowers the energy of the transition state relative to the situation in which there is no adjacent heteroatom. There is little doubt that a push is operating in displacements of this type because they are always more rapid than the same reaction in which the oxygen, or a nitrogen (Equation 1–24), is replaced by carbon.

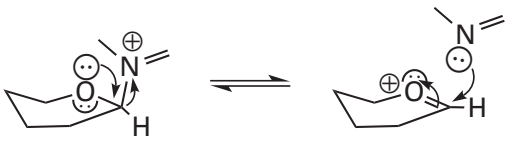
The **direction from which the push is applied** is an issue. The atomic orbital holding the lone pair of electrons on oxygen, which will provide the push during the formation of an oxocarbenium ion, has been shown in Figure 1–3 and Equations 1–23 and 1–24 assuming an antiperiplanar orientation to the dissociating nitrogen



1–9

In **1–9** the nitrogen atom, the σ bond between nitrogen and carbon, the carbon atom itself, the σ bond between carbon and oxygen, the oxygen atom, and the lone pair of electrons on the oxygen atom are all in the same plane so that the lone pair of electrons and the carbon–nitrogen σ bond are periplanar. This **periplanarity** is always necessary for the proper overlaps to occur. In the **antiperiplanar conformation** drawn, when viewed along the carbon–oxygen bond, the lone pair of electrons on the oxygen is oriented at a dihedral angle of 180° from the pair of electrons in the σ bond between carbon and nitrogen. In a **synperiplanar conformation**, which would result from a 180° rotation of the carbon–oxygen bond, the lone pair of electrons is oriented at a dihedral angle of 0° from the σ bond between carbon and nitrogen. There is a proposal, described by the author as **stereoelectronic control**,[58,59] that an antiperiplanar orientation is a necessity of the reaction because the push must be provided through the antibonding orbital (Figure 1–3), from the opposite side of the carbon from which the nitrogen is leaving. In this orientation, the overlap between the atomic orbital containing the lone pair of electrons and the antibonding orbital of the molecular orbital system of the σ bond is at its maximum.

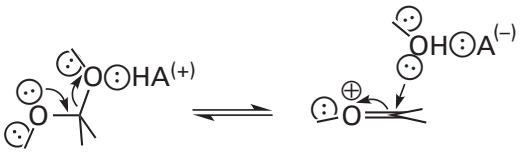
It has been documented in studies of the hydrolysis of cyclic ortho esters[60] that **antiperiplanar push** is stronger than **synperiplanar push**. Even in this situation, however, in which two oxygens rather than one are providing the push, the push from the antiperiplanar side was less than 10 kJ mol^{-1} stronger than the push from the synperiplanar side.[60,61] In other reactions, such as nucleophilic substitution at the anomeric carbon of the pyranose in Equation 1–25, a reaction of the type most common in enzymatic catalysis, there is experimental evidence that the conformation of the pyranose required to effect antiperiplanar push is so sterically disfavored that, in such instances, synperiplanar push dominates.[62-64] For example, in the reaction shown in Equation 1–25, synperiplanar push would be expressed as



(1–28)

Consequently, the decision as to whether synperiplanar push or antiperiplanar push dominates in a particular reaction is probably more often a steric one than an electronic one because, if there is any electronic advantage to antiperiplanar push, it is a small one. Nevertheless, if there is even a small advantage in a situation in which steric effects do not dominate, that advantage may have been exploited by natural selection.

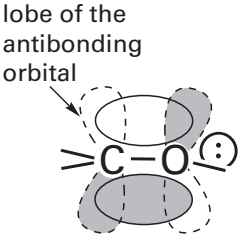
Periplanar pull may be exerted in the formation of an oxocarbenium ion from an acetal (Equation 1–27) by hydronating a lone pair of electrons on the leaving group that is periplanar rather than orthogonal to the developing π bond of the oxocarbenium ion



(1–29)

Whether or not periplanar pull can be exerted is of interest for reactions occurring in the active sites of enzymes where the stereochemistry of the acid relative to the acetal can be dictated.[65]

The **addition of a nucleophile to an oxocarbenium ion**, which leads to the product in the second step of a dissociative nucleophilic substitution, is the reverse of the dissociation that produces an oxocarbenium ion (Figure 1–3). Addition of the nucleophile to the oxocarbenium ion can be viewed as being initiated by overlap between the sp^2 atomic orbital on the nucleophile occupied by its σ lone pair of electrons and the vacant π^* antibonding molecular orbital of the molecular orbital system of the double bond between carbon and oxygen in the oxocarbenium ion



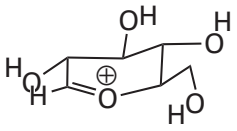
1–10

The resulting transition state separates to produce the two molecular orbitals of the σ bond between carbon and the heteroatom of the nucleophile and the sp^3 atomic orbital on oxygen containing the lone pair of electrons.

During the addition of a nucleophile to the electrophilic carbon in an oxocarbenium ion, a significant portion of the energy barrier is again due to **electron repulsion**. This electron repulsion affects both addition of the leaving group, in the reverse direction, and addition of the original nucleophile, in the forward direction (Equations 1–25 to 1–27) of the dissociative nucleophilic substitution. The lone pair of electrons of the nucleophile on a trajectory toward the **unoccupied antibonding molecular orbital** of the π bond between the carbon and the electropositive oxygen finds itself surrounded by the two pairs of electrons in the two σ bonds between the carbon and its two other substituents and by the pair of electrons in the **occupied bonding molecular orbital** of the π bond between carbon and oxygen. The two electrons in the π bond are delocalized and more concentrated over oxygen because of its electronegativity, so the electron repulsion is not so great as that experienced by a nucleophile in a concerted nucleophilic substitution at a fully saturated carbon. Nevertheless, either the kinetic energy of the nucleophile as it collides or the potential energy of squeezing the nucleophile against the carbon, or a combination of these forces, is required to overcome the energy barrier. As the nucleophile moves in, the two σ bonds are pushed downward and the delocalized electrons in the occupied bonding molecular orbital of the π bond are pushed over onto the oxygen (Equations 1–23 and 1–24).

The lifetime of an oxocarbenium ion measures its electrophilicity. Lifetimes of oxocarbenium ions in water have been estimated by measuring the competition between azide ion and water for trapping them. Because the nucleophilic addition of water extinguishes the oxocarbenium ions, these measurements use water as a reference nucleophile to probe the relative electrophilicities of the oxocarbenium ions. The estimated lifetimes varied from 2×10^{-8} s for methylphenylmethoxocarbenium ion to 5×10^{-11} s for ethylethoxocarbenium ion.[66] As one might expect from the electrophilicities of alkyl carbenium ions, substituents decrease the electrophilicity of an oxocarbenium ion in the order phenyl > alkyl > alkoxymethyl > hydrogen. From these short lifetimes, it follows that an oxocarbenium ion is significantly electrophilic. In fact, it is electrophilic enough to participate in intramolecular electrophilic aromatic substitution.[67]

Various estimates of the lifetime of the D-glucopyranosylium ion

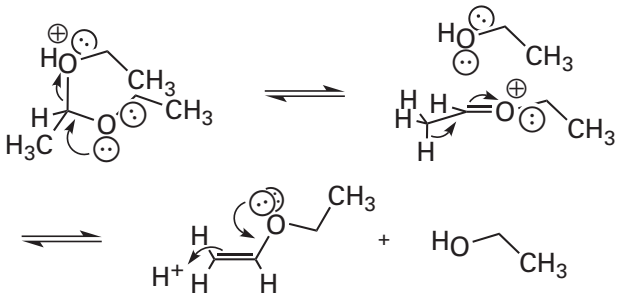


1–11

which is the oxocarbenium ion formed by the dissociation of a leaving group from a D-glucopyranoside, are on the order of 10^{-11} to 10^{-12} s in water at 25 °C.[53,66] These lifetimes are for a situation in which water, a weak nucleophile but nevertheless a nucleophile, surrounds the oxocarbenium ion and solvates it by directing its nucleophilic lone pairs of electrons towards the cation, an orientation in which they are aligned to add to it. The lifetime of the D-glucosyloxocarbenium ion is so short because the two substituents on the electrophilic carbon are a 1-hydroxyalkyl group and a hydrogen. The hydroxy in the the 1-hydroxyalkyl group withdraws electron density, and the hydrogen cannot provide hyperconjugation. Although D-glucopyranosylium ion has never been observed in solution because of its lability, tetramethyl-D-glucopyranosylium ion has been produced in the gas phase and lives long enough for its infrared spectrum to be gathered.[68] In the active site of an enzyme, unlike in solution where nucleophilic molecules of water are immediately adjacent to it, the lifetime of a D-glucopyranosylium ion will depend, as it does in the gas phase, critically on the access of nucleophiles to its two faces. Consequently, the lifetime of the ion in aqueous solution cannot be used as an argument that it is too evanescent to exist as an intermediate in an active site.[69]

"The kinetic equation of a multistep reaction will contain the rate constants of some or all of the successive reaction steps. The last step in this series, the rate constant for which appears in the kinetic equation, is rate-limiting."[70] By this definition, all of the steps that follow the **rate-limiting step**, although they are real, unavoidable steps, must be so fast that they occur immediately relative to the passage through the rate-limiting step, and therefore they have no effect on the observed rate of the reaction. In the hydrolyses of acetals and ketals (Equation 1–27 with H_2O in place of SO_3^{2-}), although hydronation of the oxygen of the leaving group is always required, either the dissociation of the carbon–oxygen bond[71] or the addition of water or hydroxide to the oxocarbenium ion can be the rate-limiting step, depending on the pH of the solution.[72,73]

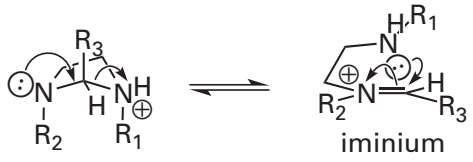
Although in most cases an oxocarbenium ion is less prone to elimination than a carbenium ion, an oxocarbenium ion is an intermediate in the formation of vinyl ethers by elimination. For example, in an acidic solution, the diethyl acetal of ethanal gives ethyl vinyl ether



(1–30)

This reaction is analogous to the elimination from a carbenium ion that would be a side product during a simple dissociative nucleophilic substitution. Such an elimination would be an undesired side reaction in a desired nucleophilic substitution at a carbon atom immediately adjacent to an oxygen. Because the loss of the hydron (the second step) is the rate-limiting step in this elimination,[71] such an **undesired elimination** can be prevented from occurring on an enzymatic active site by denying the hydron a base and capturing the oxocarbenium ion by the intended nucleophile before it can eliminate the hydron. In solution, however, for most dissociative nucleophilic substitutions involving oxocarbenium ions as intermediates, the transition state for substitution is of lower energy than the transition state for elimination. The reverse of this type of elimination (Equation 1–30), in which the enol ether is first hydronated at the β carbon to give the oxocarbenium ion, produces the hemiacetal when the nucleophile is water rather than ethanol and leads to the hydrolysis of the vinyl ether.[74] For example, the hydrolysis of ethyl vinyl ether produces ethanal and ethanol.

Tertiary iminiums are the nitrogen equivalents of oxocarbenium ions. During the opening of imidazolines



(1–31)

the less basic nitrogen, which is determined by the identity of R_1 and R_2, is the leaving group, but only after it is hydronated.[75] Equation 1–31 serves as an

example of a nitrogen rather than an oxygen providing the lone pair of electrons stabilizing the carbocation by forming an iminium rather than an oxocarbenium ion. Both the fact that the more basic, more electron-releasing nitrogen is better able to stabilize the carbocation while forming an iminium and the fact that the less basic nitrogen, once it is hydronated, is a better leaving group explain the regiochemistry of the reaction. Because a nitrogen is less electronegative than an oxygen, the carbon of an iminium is less electropositive and **significantly less reactive** than the carbon of an oxocarbenium ion. Because it is less electronegative, the nitrogen with a positive elementary charge in a tertiary iminium exerts a weaker electron withdrawal than oxygen with a positive elementary charge in an oxocarbenium ion, and the nitrogen stabilizes the positive elementary charge of the cation more effectively.

A concerted nucleophilic substitution proceeding through a single concerted transition state and a dissociative nucleophilic substitution proceeding through an unassociated, fully intermediate carbenium ion or oxocarbenium ion are two extremes of a continuous spectrum of mechanism.[76] Making a firm distinction between concerted mechanisms and dissociative mechanisms, as well as any other attempts to define boundaries within this continuous spectrum of mechanism, are at best counterproductive.

One way to visualize this continuous spectrum of mechanism is to represent the energetics of a particular nucleophilic substitution on a **three-dimensional surface of potential energy** (Figure 1–4A,B).[77,78] One coordinate for this surface is the distance between the carbon at which the substitution is taking place and the atom (Y) that is leaving the electrophile. Another coordinate is the distance between that same carbon and the nucleophilic atom (X) that is adding to it. These two coordinates define a continuous two-dimensional field.

For every point on this two-dimensional field, there is a potential energy associated with the two distances that are the coordinates of that point. The potential energy is the third coordinate, and these three coordinates together produce the three-dimensional surface of potential energy. This surface of potential energy can be represented topographically with contours of equal potential energy. On this undulating surface of potential energy there will always be a path from reactant to product, the **reaction coordinate** (dashed arrow), through a point of lowest potential energy, a **col**.* The **transition state** of the reaction, which is at the maximum of potential energy experienced between reactant and product, is at this col.

For a **dissociative nucleophilic substitution**, in which the bond to the leaving group is completely broken before the bond to the nucleophile begins to form, there is a carbenium ion or oxocarbenium ion as an intermediate (Figure 1–4A). Before the dissociation begins, there is a minimum of potential energy (lower right corner) at the bond length between the atom of the leaving group and the electrophilic carbon representing the ground state, and the nucleophile is far enough away to have no effect on the potential energy of the electrophile. Following the dissociation, there is a minimum of potential energy (upper right corner) when both the leaving group and the nucleophile are far enough away to have no effect on the potential energy of the carbenium ion or the oxocarbenium ion. After the product has formed, there is a minimum of potential energy (upper left corner) when the leaving group is far enough away to have no effect on the potential energy of the reaction. The reaction proceeds through the first transition state (‡) along a reaction coordinate over a col to produce the carbenium ion or the oxocarbenium ion (vertical dashed arrow) and through the second transition state along a reaction coordinate over a col to give the product (horizontal dashed arrow).

For a **concerted nucleophilic substitution** (Figure 1–4B), in which the bond to the leaving group is being broken while the bond to the nucleophile is being formed, the reaction passes through only one transition state (‡) at a col in the potential energy. In this transition state, the nucleophilic atom and the atom of the leaving group are both closer to the carbon as the bonds are being simultaneously broken and formed than they are when a carbenium ion or oxocarbenium ion is the intermediate. The respective lengths of the bond to the nucleophile and the bond to the leaving group in the transition state of a concerted nucleophilic substitution are determined by the position of the col on the surface of potential energy. For example, it has been estimated from various kinetic isotope effects on the rate of the reaction at pH 6.0 and 50 °C

*A col is a pass in a range of mountains. The term historically applied to this point on a three-dimensional surface of potential energy was a saddle point. Saddle is a term in mountaineering that is more commonly used in certain regions for a col.

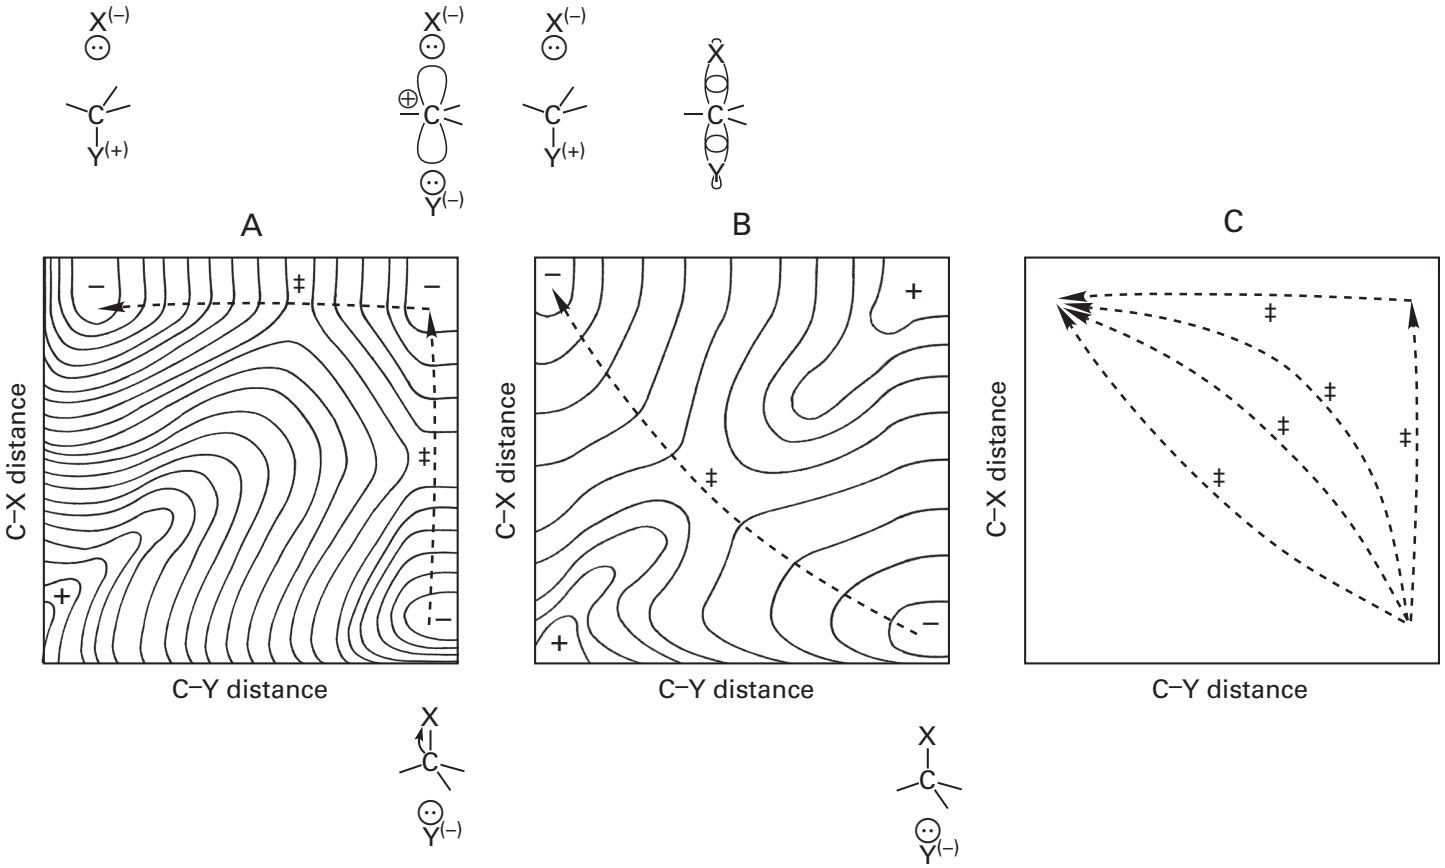


Figure 1–4: Hypothetical three-dimensional representations of surfaces of potential energy[77,78] for a nucleophilic substitution at a saturated carbon. The ordinate of the plot is the distance between the electrophilic carbon and the atom X that is leaving during the substitution. The abscissa of the plot is the distance between the electrophilic carbon and the nucleophilic atom Y that is forming the new bond with the electrophilic carbon. The intersection of these two axes, for the sake of brevity, is not the point at which each has a value of zero, which would be a singularity of potential energy. The point of their intersection has coordinates or distances close to the values for the lengths of the respective covalent bonds, one between the electrophilic carbon and the atom leaving and one between the electrophilic carbon and the nucleophilic atom in the product. The third dimension is the potential energy associated with each value for these two distances. The third dimension is represented topographically by contour lines of equal potential. These contour lines represent a sinuous surface of potential energy. The two topographic maps of potential energy are entirely hypothetical, do not represent the surface of potential energy for any reaction, and are intended only for demonstration. The positive signs identify peaks of potential energy, and the negative signs identify wells of potential energy. The usual sign (‡) for a transition state designates a minimum of potential energy between reactants and products at the col through which the reaction proceeds. The dashed, curved arrows indicate the path of the reaction coordinate along which the reaction proceeds. In all instances of nucleophilic substitution at carbon, the contours nearest the origin of the plot represent a pentavalent carbon, which has such a high potential energy that it has never been observed. The species involved as reactants, intermediates, transition states, or products are represented outside the plots below (reactants) or above (intermediate carbocation, associated intermediate, or products) the location of their respective potential energies. **(A)** Hypothetical surface of potential energy for a dissociative nucleophilic substitution. The atom X, which is the leaving group, dissociates completely (vertical dashed, curved arrow) before the nucleophile Y associates (horizontal dashed, curved arrow) with the resulting carbocation. The carbocation is at a minimum of potential energy as are the reactants and the products. There is a transition state between the reactant and the carbocation and another transition state between the carbocation and the products. **(B)** Hypothetical surface of potential energy for a concerted nucleophilic substitution. The atom X that is leaving dissociates as the bond to the nucleophilic atom Y is forming. Consequently, there is only one col between reactants and products and only one transition state. The position at which a carbocation would be formed is a maximum of potential energy in this instance because the carbocation is unstable. **(C)** Several possible reaction coordinates between reactants and products that represent, in descending order, a more and more unstable carbocation and a more and more associative nucleophilic substitution. Adapted with permission from reference 77. Copyright 1972 American Chemical Society. https://doi.org/10.1021/cr60280a004

that in the transition state for the substitution of a fluoro group on α-D-glucopyranosyl fluoride by an azido group (see Equation 1–25 and **1–14**), the distance from the electrophilic carbon to the fluoride that is leaving is 0.27 nm and the distance from the electrophilic carbon to the nucleophilic nitrogen of the azide is 0.19 nm.[79]

The potential energy is always very large for the situation in which the length of the bond between the nucleophile and the electrophilic carbon is the same as its length in the product at the same time that the bond between the leaving group and the electrophilic carbon is the same length as it is in the reactant (lower left corner) because this would be the situation for a pentavalent carbon, which is so unstable that it has never been observed in solution.* Consequently, there is always a mountain of potential in the lower left corner of the surface of potential energy in both dissociative and concerted nucleophilic substitutions at a saturated carbon.

One way to think about the continuous progression from a dissociative nucleophilic substitution to a concerted nucleophilic substitution is to concentrate on the **stability of the carbenium ion or oxocarbenium ion**, represented by the well of potential energy in the upper right corner of the surface of potential energy for the dissociative substitution (Figure 1–4A). As the carbenium ion or oxocarbenium ion becomes more and more unstable, the well of potential energy becomes a plain and then a hill of potential and then a mountain of potential energy (Figure 1–4B). This increase in the potential energy of the carbenium ion or oxocarbenium ion first creates a col immediately adjacent to the upper right corner and then pushes the col more and more in a lower left direction (Figure 1–4C) until it is a col between two substantial mountains of potential energy (Figure 1–4B). These mountains are the unstable carbenium ion or oxocarbenium ion (upper left corner) and a pentavalent carbon (lower right corner).

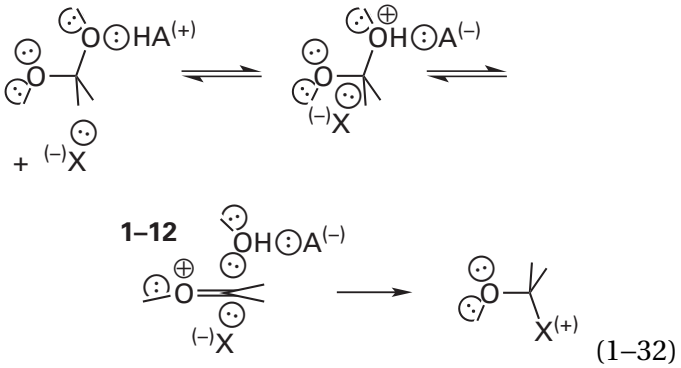
This spectrum of mechanism can be considered for the particular case of a reaction involving an electrophilic carbon attached to an alkoxy group for which an oxocarbenium ion is a possible intermediate (Equations 1–25 to 1–30). In a mechanism with a fully developed intermediate oxocarbenium ion, the bond between leaving group and carbon breaks completely before the bond between nucleophile and oxocarbenium ion begins to form (Equation 1–25). Two steps can be distinguished—namely the dissociation of the leaving group followed by the association of the nucleophile—and the reaction has two transition states—one for the first step that produces the oxocarbenium ion and one for the second step that produces the products. This disjunction is the reason for the existence of the oxocarbenium ion as an intermediate. In the single transition state of a concerted nucleophilic substitution proceeding without an intermediate, however, the bond between the leaving group and the electrophilic carbon is breaking in concert with the formation of the new bond to the nucleophile. If the two are fully coordinated, the carbon remains uncharged.

The difference in these two extremes can be also thought of as a matter of **timing**, and the spectrum between these two extremes covers mechanisms in which the formation of the bond to the nucleophile lags behind by a certain degree or precedes by a certain degree the disintegration of the bond to the leaving group. Within this spectrum, an oxocarbenium ion is more or less realized. In the case of nucleophilic substitution at a fully saturated carbon next to an alkoxy oxygen, the formation of the bond between the electrophilic carbon and the nucleophile cannot precede the disintegration of the bond to the leaving group by too much of an interval or the carbon would become pentavalent, but it definitely can lag behind by any interval. The more it lags behind, the more the electrophilic carbon in the transition state resembles an oxocarbenium ion.

One of the traditional distinctions between the two extremes of mechanism for nucleophilic substitution is the molecularity of the observed rate. A concerted nucleophilic substitution proceeding in free solution through a single transition state without the formation of an intermediate (Equation 1–19) is a bimolecular reaction, and its observed rate constant is second-order (S_N2). The rate of the reaction is first-order in electrophile and first-order in nucleophile. The first step of a dissociative nucleophilic substitution, however, which proceeds through an unassociated, intermediate carbenium ion or oxocarbenium ion, is the unimolecular formation of that carbenium ion or oxocarbenium ion (Equations 1–21 and 1–25). Because the second step is almost always more rapid, the first step is the rate-limiting step, and the observed rate for such a dissociative nucleophilic substitution is first-order (S_N1).

*There is a hexacoordinated carbon atom in the center of a metallic cluster in the enzyme nitrogenase.

Consider the following three conditions. First, the nucleophile must be immediately adjacent to the electrophilic carbon within its shell of solvation before the bond to the leaving group can begin to break. Second, after the bond to the leaving group and the electrophilic carbon has completely broken, the new bond to the adjacent nucleophile has not yet begun to form and a full oxocarbenium ion exists. Third, the adjacent nucleophile, while still in the solvent shell, then forms the new bond without having the time to exchange with another nucleophile in the solution because the lifetime of the oxocarbenium ion is so short



(1–32)

If all three conditions are met, then the reaction is bimolecular, so its rate is first-order in the concentration of the electrophile and first-order in the concentration of the nucleophile, and it proceeds with inversion of configuration at the electrophilic carbon. The reaction, however, also proceeds in two steps with a fully formed, intermediate oxocarbenium ion (**1–12** in Equation 1–32). Such **a mechanism, containing prominent features of the two extremes in the spectrum**, is possible because it has been shown that, in order for an oxocarbenium ion to form, it usually must be solvated above and below the plane of its bonds by lone pairs of electrons from at least the solvent if not the nucleophile.[80] The nucleophile can provide a lone pair of electrons to solvate the oxocarbenium ion on one face, and the leaving group can provide a lone pair of electrons on the other face (**1–12**). Before the solvation by the nucleophile is provided or if the nucleophile dissociates too soon from the shell of sovation, the oxocarbenium ion cannot form.

Nucleophilic substitutions that occur in solution at the electrophilic carbon of a ketal usually have first-order rate constants, and the concentration of nucleophile has no effect on the rate of the reaction. This lack of an effect is presumably because, in a ketal, the oxocarbenium ion that is an intermediate in the nucleophilic substitution is a secondary oxocarbenium ion and the two alkyl substituents on the electrophilic carbon stabilize the carbocation by hyperconjugation, just as a tertiary carbenium ion is stabilized by hyperconjugation.

Most of the **nucleophilic substitutions that occur in solution at the electrophilic carbon of an acetal** (for example Equation 1–27), for which an oxocarbenium ion is a possible intermediate, have second-order rate constants, and the rates of the reactions are first-order in the concentration of the nucleophile. This molecularity is established experimentally by measuring the rate of the nucleophilic substitution as a function of the concentration of the nucleophile and demonstrating that the two are linearly related.[81] From the slope of the line, a second-order rate constant is calculated.

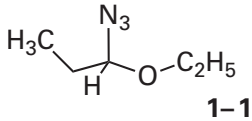
If the reaction takes place in water, one of these nucleophilic substitutions by a particular nucleophile usually proceeds in concert with hydrolysis of the acetal that occurs even in the absence of that nucleophile. For example, as azide ion is added to the solution, the rate of release of 4-bromoisoquinoline from 2-deoxy-β-D-glucopyranosyl-4′-bromoisoquinolinium ion (Equation 1–25) increases. From this increase in rate, an observed second-order rate constant of 1.2×10^{-4} M^{-1} s^{-1} at 65 °C can be calculated for the nucleophilic substitution of 4-bromoisoquinoline by azide ion,[53] which is in addition to the background rate of hydrolysis of the deoxy-D-glucosylisoquinolinium ion that has an observed first-order rate constant of 1.5×10^{-4} s^{-1}. If a particular nucleophilic substitution has a second-order rate constant, the question then becomes how far along is the formation of the bond with the nucleophile and how far along is the breaking of the bond with the leaving group in the transition state responsible for its observed second-order rate constant.

A determination of the degree to which the bond between the carbon and the nucleophile has been formed and the degree to which the bond between the carbon and the leaving group has been broken in the transition state for a nucleophilic substitution can be made from linear free energy relationships.

The **dependence of the observed second-order rate constant for a nucleophilic substitution on the nucleophilicity of the nucleophile** provides an indication of the extent to which the bond is formed between the nucleophile and the electrophilic carbon in the transition state governing the rate constant for the reaction relative to the degree

to which it is formed in the transition state for a purely concerted nucleophilic substitution. The second-order rate constants for several series of nucleophilic substitutions at the same electrophilic carbon by a series of different nucleophiles are measured. The common logarithms of these observed second-order rate constants are plotted in a **Swain–Scott correlation** (Figure 1–5)[81-84] as a function of a set of parameters, known as nucleophilicities, that are related to the common logarithms of the rate constants for the nucleophilic substitutions between the respective nucleophile and methyl iodide. Methyl iodide is used as the reference electrophile because nucleophilic substitutions at methyl iodide are always concerted nucleophilic substitutions that involve a single transition state with no intermediate carbenium ion and there are almost no steric problems associated with this nucleophilic substitution. In the case of the reaction in Equation 1–25, there is little if any dependence (slope of the Swain–Scott correlation is 0.03 ± 0.05) of the observed second-order rate constants on the respective nucleophilicities of the noted set of nucleophiles. This fact indicates that there is little if any bond formed between the nucleophile and the electrophilic carbon in the transition state governing the observed second-order rate constant even though the nucleophile must be present in this transition state to explain the bimolecularity of the reaction.

The greater the dependence of the rate constant for a nucleophilic substitution on the strength of the nucleophile, the more fully developed is the **bond between the nucleophile and the electrophilic carbon** in the transition state governing the observed second-order rate constant. For the nucleophilic substitutions of the azido group in 1-azido-1-ethoxypropane



1–13

involving each of a set of nucleophiles, the correlation between the common logarithms of the observed second-order rate constants for the respective nucleophilic substitutions and the respective nucleophilicities of those nucleophiles (Figure 1–5)[81] has a slope of 0.18. This fact indicates that, with this electrophile, the bond between the nucleophile and the electrophilic carbon is only partly developed in the transition state governing this rate constant. When azidomethoxyphenylmethane is used as the electrophile, the slope of the Swain–Scott correlation is 0.4, indicating that with this electrophile the bond between the nucleophile and the electrophilic carbon is further advanced in the transition state than it is with 1-azido-1-ethoxypropane.

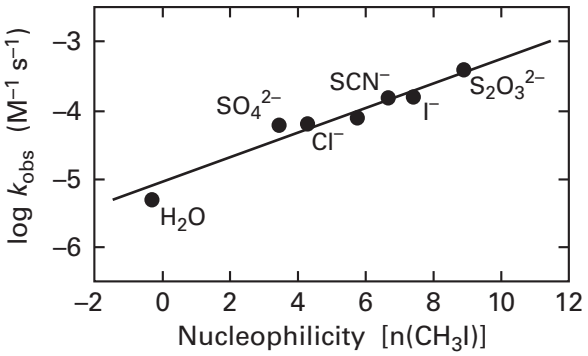


Figure 1–5: Correlation between the rate constants for a common nucleophilic substitution by each of a series of nucleophiles and their respective nucleophilicities.[81] The rate constants for the hydrolysis of 1-azido-1-ethoxypropane (**1–13**) at 25 °C and an ionic strength of 1.0 M were measured by following the production of propanal. Various concentrations of the nucleophilic ions SO_4^{2-}, Cl^-, Br^-, SCN^-, I^-, and $S_2O_3^{2-}$ were added to the solution, and the second-order rate constants for the acceleration of the hydrolysis that they produced were determined from the slopes of plots of observed rate constants against their concentrations. The common logarithms of these observed second-order rate constants, k_{obs} (molar^{-1} second^{-1}), are plotted[82] against parameters [n(CH_3I)] derived from the common logarithms of the respective rate constants of the reaction of these same nucleophiles with methyl iodide in methanol.[83] The line drawn through the points has a slope of 0.18. The observed second-order rate constant of the uncatalyzed hydrolysis is the point[84] labeled H_2O.

The **dependence of the observed rate constant of a nucleophilic substitution on the acidity of the conjugate acid of the leaving group** provides information about the degree to which the bond between the electrophilic carbon and the leaving group is broken in the transition state governing that rate constant. A series of electrophiles, identical except for the leaving group, is synthesized, and the rate of the nucleophilic substitution of each of these electrophiles by the same nucleophile is measured. The common logarithms of the observed rate constants for these nucleophilic substitutions are plotted as a function of the respective values of pK_a for the conjugate acids of the leaving groups (Figure 1–6).[85-88]

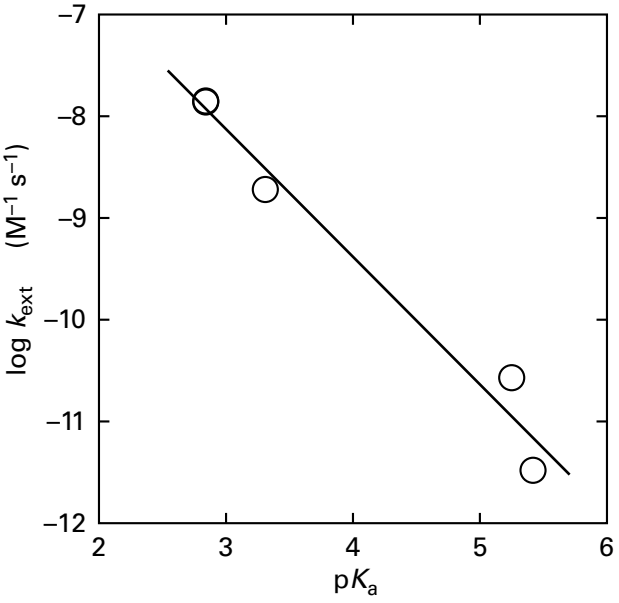

Figure 1–6: Brønsted correlation between the rate constants for the hydrolyses of a series of β-D-galactopyridinium ions and the acid dissociation constants of the conjugate acids of the respective pyridine that is the leaving group.[85] The hydrolyses of 3-chloro-1-(β-D-galactopyranosyl)pyridinium ion, with 3-chloropyridine as the leaving group (pK_a = 2.84); 3-bromo-1-(β-D-galactopyranosyl)pyridinium ion, with 3-bromopyridine as the leaving group (pK_a = 2.84); 4-bromo-1-(β-D-galactopyranosyl)isoquinolinium ion, with 4-bromoisoquinoline as the leaving group (pK_a = 3.31); 1-(β-D-galactopyranosyl)pyridinium ion, with pyridine as the leaving group (pK_a = 5.25); and 1-(β-D-galactopyranosyl)isoquinolinium ion, with isoquinoline as the leaving group (pK_a = 5.42) were measured at pH 6.0 and various temperatures between 48 and 138 °C by following the change in ultraviolet absorption that occurs when the respective pyridine or isoquinoline is released into the solution. Each reaction was monitored at the wavelength at which the change in absorbance is the greatest (276, 290, 350, 260, and 340 nm, respectively). For each D-galactosylpyridinium ion, the rate constant measured for its hydrolysis was extrapolated to a temperature of 25 °C. The common logarithm of each extrapolated first-order rate constant (k_{ext}; seconds^{-1}) is plotted against the respective pK_a for the conjugate acid of the leaving group. The slope of the line, β_{lg}, fit to the data by least-squares numerical analysis is 1.26 ± 0.12. This slope is the Brønsted coefficient for the leaving groups.

A **Brønsted correlation** is any correlation between the common logarithms of a set of rate constants or equilibrium constants for the members of a set of interchangeable participants in a particular reaction—be they reactants, products, or catalysts—and the values of pK_a for the respective participants or for their conjugate acids corrected for the number of acidic hydrons and basic lone pairs of electrons on the participating atom. The distinction between a Swain–Scott correlation and a Brønsted correlation is the use of nucleophilicities in the former and values of pK_a in the latter. The use of a Brønsted correlation is far broader than the use of a Swain–Scott correlation because values of pK_a for a wide variety functional groups are known and variation of the values of pK_a for any of the participants in the reaction produces a Brønsted correlation.

It is usually the case that the common logarithms of equilibrium constants or of rate constants, respectively, are linearly correlated with the common logarithms of the relevant acid dissociation constants. These correlations suggest that what is actually being correlated are changes in the standard free energy or the standard free energy of activation for the reaction, respectively, with changes in the standard free energy of the acid dissociation. Consequently, a Brønsted correlation is an example of the more general class of **free energy correlations**.

A **Brønsted plot** is a graph of the common logarithms of the rate constants or equilibrium constants plotted against the respective values of pK_a for the chosen participant or its conjugate acid. If the data show a linear correlation over a particular range of rate constant and pK_a, the slope of that line is the **Brønsted coefficient**, designated as β. The **Brønsted coefficient for the leaving groups, β_{lg}**, in a series of homologous nucleophilic substitutions, which is the slope of the line on a Brønsted plot (Figure 1–6), is a measure of the degree to which the transition state governing the observed rate constant resembles the fully dissociated conjugate acid. Brønsted plots can also be made for the ability of a leaving group in an enzymatic reaction.[89]

For the hydrolysis of a set of D-galactosylpyridinium ions (similar to Equation 1–25, with D-galactose as the monosaccharide instead of 2-deoxy-D-glucose, water as the nucleophile instead of azide ion, and a set of pyridines as the leaving groups instead of isoquinoline), the value of β_{lg} is –1.26 ± 0.12 (Figure 1–6).[85] This fact indicates that there is a somewhat larger change in the charge of a particular pyridine between the reactant and the transition state controlling the observed rate constant for the hydrolysis of the electrophile than there is upon dissociation of the same pyridine from a hydron.* Consequently, the bond between nitrogen and carbon is fully broken at the transition state.

The value of β_{lg}[53] for the rates of hydrolysis of three different (2-deoxy-β-D-glucopyranosyl)isoquinolinium ions (Equation 1–25) is –1.0 ± 0.1. This fact, and

*That the difference in the case of hydrolysis is greater than 1 is probably because the charge on the nitrogen of the pyridinium ion (the reference for the comparison) is actually less than the charge on the pyridino group in the electrophiles.

the fact that there is only a small effect of the nucleophilicity of nucleophiles other than azide ion (0.03 ± 0.05) on the rate constant for the nucleophilic substitution, together indicate that in this reaction, as shown in Equation 1–25, in the transition state governing the observed rate constant for this reaction, the oxocarbenium ion is fully developed even though the reaction is second-order.

An additional observation indicating that an oxocarbenium ion is formed in the nucleophilic substitutions of D-glucopyranosylpyridiniums[85] as well as phenyl D-glucopyranosides,[90] is that, when the hydrogen on carbon 2 of the D-glucose is replaced by a deuterium, the rates of these reactions decrease by about 10%, a large secondary deuterium kinetic isotope effect. This decrease in rate suggests that this hydrogen participates in hyperconjugation with a double bond between carbon and oxygen in an intermediate oxocarbenium ion.

The **properties of the electrophilic carbon**, by determining the stability of a potential carbocationic intermediate, also affect the timing of formation of the bond to the nucleophile and breaking of the bond to the leaving group. In all of the nucleophilic substitutions at carbon that have been discussed so far, there have been three players: the nucleophile, the leaving group, and the electrophilic carbon. So far, the emphasis of the discussion has been on the properties of the nucleophile and the leaving group that determine the timing of formation of the new bond to the nucleophile and disintegration of the old bond to the leaving group, and hence the type of intermediate that occurs. Substituents on the electrophilic carbon determine its potential to support positive charge and its ability to sustain the vacant *p* orbital that produces this positive elementary charge (Equation 1–21). The substituents of biochemical importance and the order in which they stabilize an adjacent-carbocation with a vacant *p* orbital are $-NH(CH_2-)$ > $-NH_2$ > $-N(CH=)-$ > $-N(CO-$ > $-OCH_2-$ > $-OH$ > $-OPO_3H_2$ > $-OC(O)-$ > =O > $-CH(CH_2-)-$ > $-CH_2-$ > $-CH_3$ > $-CH(NH_2)-$ > $-CH(OH)-$ > $-H$ > $-CONH-$ > $-COOH$. If a hydron is added to any of these substituents, the carbocation is destabilized; if a hydron is removed from any one, the carbocation is stabilized. If the substituents on the electrophilic carbon are ones that increase the stability of a carbocation, then the bond to the leaving group breaks more readily, the bond to the nucleophile forms less readily, and the transition state expands.

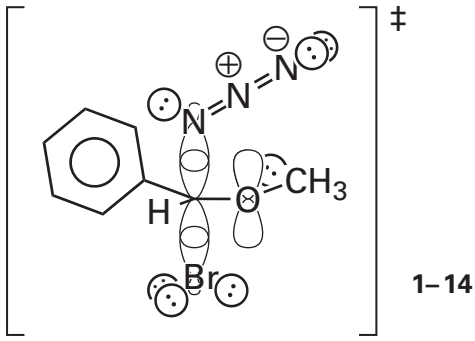
Another of the traditional distinctions between the two extremes of mechanism for nucleophilic substitution is the stereochemistry of the reaction. If a concerted nucleophilic substitution proceeds without the formation of a carbenium ion or oxocarbenium ion, complete **inversion of configuration** at the electrophilic carbon (**1–6**) is observed, and the nucleophilic substitution is usually judged to be concerted. If a carbenium ion exists long enough for the leaving group to diffuse away, and if the nucleophile is free to attack either side of the resulting unencumbered carbenium ion with equal facility, the products of **both inversion and retention of configuration** result, in equal concentration, and the nucleophilic substitution is usually judged to be dissociative.

In the **dissociative nucleophilic substitution** of Equation 1–25, however, most of the product (90%) is the α-D-2-deoxyglucosyl azide formed from inversion of configuration. The fact that little retention of configuration (10%) occurs suggests that although the oxocarbenium ion is fully formed in this reaction, it retains contact with the isoquinoline at the one face, blocking entry to that face, long enough that most of the substitution proceeds with inversion of configuration as indicated in Equation 1–25. That some retention of configuration (10%) is observed, however, suggests that the association of the oxocarbenium ion with the isoquinoline is weak enough that the isoquinoline sometimes dissociates from the oxocarbenium ion before the azide ion associates with the oxocarbenium ion at the opposite face, leaving the oxocarbenium ion free in solution to be attacked by the nucleophile from either face.

In the solvolysis of a series of different D-glucopyranosides in mixtures of ethanol and trifluoroethanol,[91] the various nucleophilic substitutions yield products in which retention of configuration varies from 8% to 90% depending on the leaving group.* These results suggest that the oxocarbenium ions produced in some of these reactions have lifetimes long enough for the leaving group to diffuse completely away before the nucleophile ever enters the reaction.

*That the concentration of product resulting from retention of configuration exceeds 50% is due to the fact that the glucopyranosyl oxocarbenium ion in this case is diasteriomeric. Nucleophilic attack at its α face is preferred over nucleophilic attack at its β face. This preference is thought to result from the formation of a hydrogen bond between the oxygen atom of the 2-hydroxy group and the hydroxy group of the approaching alcohol.

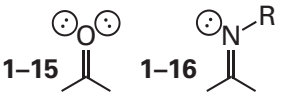
When a **concerted nucleophilic substitution** that has only one transition state and in which an oxocarbenium ion is not formed occurs adjacent to an alkoxy group complete inversion of configuration should occur, as in the substitution of azide by bromide in azidomethoxymethylbenzene[81]



1–14

The dependence of the observed rate constant of the reaction on the nucleophilicity of the nucleophile and the acidity of the conjugate acid of the leaving group should indicate that formation of the bond to the nucleophile occurs in concert with disintegration of the bond to the leaving group. To the extent, however, that the electrophilic carbon in the transition state of a concerted nucleophilic substitution resembles a carbenium ion, the adjacent oxygen should improve its stability by electron donation. In the transition state **1–14**, there are six electrons in the four designated atomic orbitals that mix to form the four molecular orbitals of its unique molecular orbital system. The three of lowest energy are occupied by the three pairs of electrons.

In reactions involving the addition of a nucleophile to an oxocarbenium ion, the oxygen atom has a substituent attached to it in addition to the electrophilic carbon. This substituent fixes a **positive formal elementary charge** on the oxygen and thereby increases its electronegativity and draws the two electrons in the π bond more strongly over it (**1–8**). In a tertiary iminium, such as the one in that is the product of the opening of an imidazoline (Equation 1–31), the nitrogen atom has two substituents attached to it in addition to the electrophilic carbon. These two substituents fix the positive formal elementary charge on the nitrogen, also increasing its electronegativity. If the substituent on the oxygen is replaced by a lone pair of electrons, the oxocarbenium ion becomes a **carbonyl group** (**1–15**),* and if one of the substituents on the nitrogen is replaced by a lone pair of electrons, the tertiary iminium (Equation 1–31) becomes an **imino group** (**1–16**)



1–15 **1–16**

Although it is far more stable than an oxocarbenium ion because the electronegative oxygen is no longer required to bear a formal positive charge, a carbonyl group is nevertheless susceptible to nucleophilic addition, just as an oxocarbenium ion is. An imino group is also susceptible to nucleophilic addition. The energy barrier experienced by the nucleophile, however, is greater for addition to a carbonyl group or an imino group than to an oxocarbenium ion or a tertiary iminium, respectively, because of the greater electron density over carbon in the bonding molecular orbital of the respective π molecular orbital system. If, however, the carbonyl group or the imino group is hydronated on one

*The hybridization of the two lone pairs of electrons of the oxygen in a carbonyl group or acyl group seems to be conditional on the circumstances. In a liquid of a pure compound containing a carbonyl group or in the gas phase of the pure compound, there are several physical measurements demonstrating that the hybridization of the oxygen is *sp* with one *sp* orbital contributing to the σ bond, one *sp* orbital coaxial with the σ bond and occupied by one of the lone pairs of electrons, one *p* orbital contributing to the π bond, and the other *p* orbital, orthogonal to the π system, occupied by the other lone pair of electrons.[92] In crystallographic molecular models of small molecules, however, in which either one N–H forms a single hydrogen bond with a carbonyl oxygen or acyl oxygen or two N–H form two hydrogen bonds with a carbonyl oxygen or acyl oxygen,[93] the distribution of the angles at which the N–H is oriented is that expected if the carbonyl oxygen or the acyl oxygen is hybridized sp^2, with one sp^2 orbital contributing to the σ bond, the lone *p* orbital contributing to the π system, and the other two sp^2 orbitals in the plane of the carbonyl group. Both when there is one hydrogen bond and when there are two hydrogen bonds, the lines of centers between the oxygen and each nitrogen form angles distributed around a maximum at 120°. In extremely high resolution maps of electron density from X-ray crystallography, valence electron density can be observed. In these maps,[94] the total valence electron density, as opposed to the distribution of electron density in each atomic orbital, is seen to be distributed so that there are maxima of density at the oxygen in the plane of the carbonyl group and quite near the locations occupied by the symbols for lone pairs of electrons in drawing **1–15**. Because all of protein chemistry occurs in surroundings that maximize hydrogen bonding, the hybridization in drawing **1–15** has been chosen for all of the drawings of the oxygen in a carbonyl group or acyl oxygen, but no decision as to the actual hybridization of the particular oxygen is implied.

of its lone pairs, it becomes homologous with an oxocarbenium ion or a tertiary iminium, respectively, and becomes just as electrophilic.

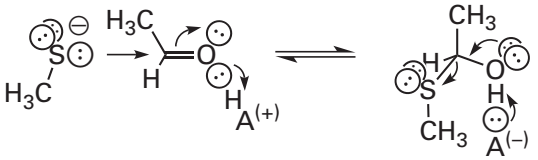
Nucleophilic Addition and Nucleophilic Substitution at a Carbonyl Carbon

The compounds that can be formed by a nucleophilic addition at a carbonyl carbon or the carbon of an imine are hemiacetals, hemiketals, acetals, ketals, thiohemiacetals, thiohemiketals, and hemiaminals (Table 1–1).

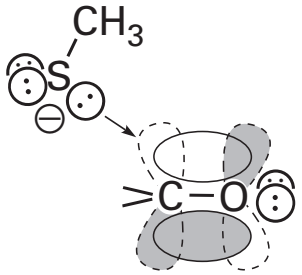
A paradigm of these several reactions is the nucleophilic addition of a thiolate to an aldehyde[96] or a ketone[97] to produce a thiohemiacetal or thiohemiketal, such as the addition of methanethiolate to acetaldehyde



(1–33)

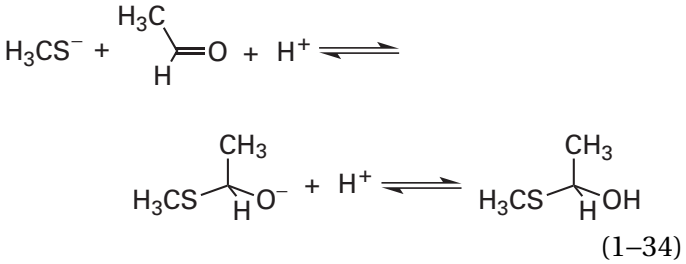
In this reaction, the initial contact between the reactants is the **overlap** between one of the atomic orbitals on sulfur occupied by a lone pair of electrons and the unoccupied antibonding orbital of the π molecular orbital system of the carbonyl group (reverse of the reaction in Figure 1–3 with nitrogen replaced by sulfur). In the process, electron density builds on oxygen at the expense of the nucleophile as the molecular orbital system of the transition state, produced from the three overlapping atomic orbitals, is formed. As the transition state decomposes to the product, the new σ bond is formed by the mixing of an atomic orbital from sulfur and an atomic orbital from carbon as an atomic orbital bearing the lone pair of electrons withdraws onto the oxygen.

As the reaction progresses, **electron repulsion** develops from overlap between the nucleophilic lone pair of electrons on sulfur in the one reactant and the occupied bonding molecular orbital of the π molecular orbital system and two of the three occupied σ bonds to the carbon in the other. Therefore, productive encounters occur only when the trajectory of the lone pair of electrons on sulfur is from above or below the plane of the carbonyl group and from a direction distal to the oxygen



1–17

In the formation of a thiohemiacetal or thiohemiketal, two steps can be formally recognized: formation of the carbon–sulfur bond and **hydronation of the oxygen**. At values of pH greater than 3, the behavior of the reaction as a function of pH is consistent with a mechanism in which the formation of the carbon–sulfur bond precedes the hydronation of the oxygen[98]



(1–34)

The intermediate anion is unstable and reverts rapidly to reactants unless it is trapped by addition of a hydron from water or other acids in the solution.[99]

Table 1–1: Derivatives of Acetaldehyde or Acetone as Examples of Carbonyl Compounds[a]

derivatives of acetaldehyde[b]		derivatives of acetone[b]	
hemiacetal		hemiketal	acetal		ketal	thiohemiacetal		thiohemiketal	hemiaminal		hemiaminal ether	thiohemiaminal		aminal	
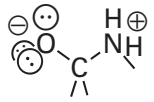
R, R_1, and R_2 can each be either H or CH_3

[a]Derivatives formed from methanol, methanethiol, or methylamine are presented for the sake of simplicity. [b]Only one enantiomer of each derivative is presented.

Consequently, the rate-limiting step in the addition is the hydronation of the oxygen, and the rate of the reaction is determined by the rate at which the anion is hydronated.

A **hemiaminal** (Table 1–1 and **1–18** in Figure 1–7) is formed by the addition of an amine to a carbonyl group.[86-88] This addition initially produces a zwitterion



1–19

which is then subject to **tautomerization**. The tautomerization of the initial zwitterion (Figure 1–7) is formally equivalent to the hydronation of the oxyanion that is the second step in addition of the thiolate to a carbonyl group. The tautomerization proceeds by transfer of a hydron from the ammonium to a base in the solution and addition of a different hydron to the oxyanion from the same acid or a different acid in the solution. It cannot occur by intramolecular transfer of the hydron (Equation 1–18) because the acidic ammonium ion is only two atoms away from the basic oxyanion.

Tautomerizations involving the removal of a hydron from an ammonium ion and the addition of a hydron to an alkoxide ion two atoms away or the reverse are encountered frequently in biochemical mechanisms. **Bifunctional acid–bases**, such as phosphate and bicarbonate, catalyze reactions in which

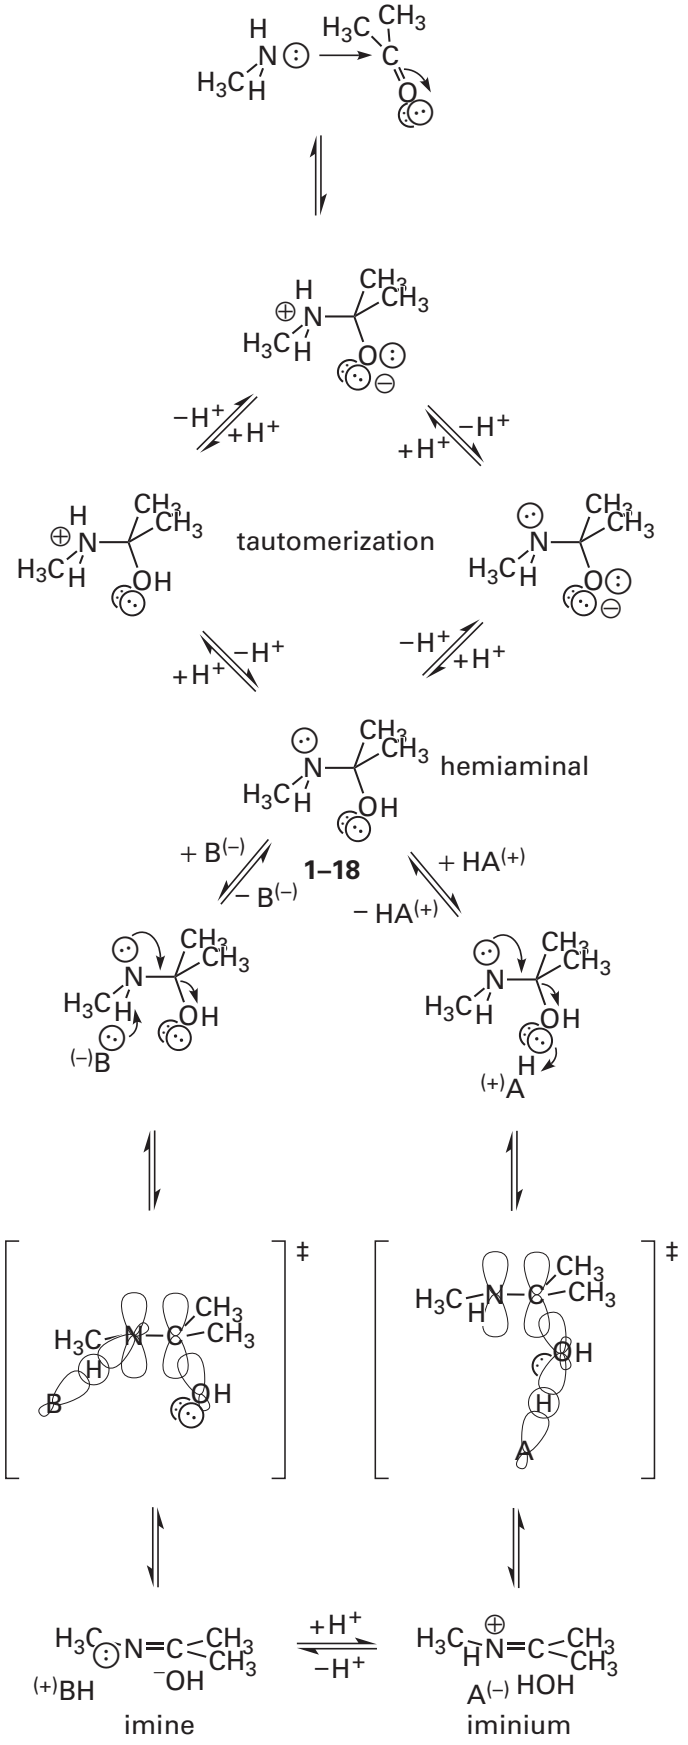


Figure 1–7: Addition of an amine to a carbonyl compound. The conjugate base of the amine adds to the carbonyl group to produce the zwitterion. A base in the solvent removes a hydron from the ammonium ion and an acid in the solvent adds a hydron to the oxyanion to produce the hemiaminal (**1–18**). The hemiaminal is susceptible to elimination in a reaction catalyzed by a general base[87] or a general acid.[86,88] In the reaction catalyzed by a general base, a hydron is removed from the nitrogen at the same time that an orthogonal lone pair of electrons on the same nitrogen pushes out the leaving group, a hydroxide ion. In the reaction catalyzed by a general acid, a hydron is added to a lone pair of electrons on the dissociating oxygen at the same time that the lone pair of electrons on nitrogen is pushing out the orthogonal σ bond to the same oxygen. In both the transition state for the reaction catalyzed by the general base and the transition state for the reaction catalyzed by the general acid, six atomic orbitals mix to form the respective transition states.

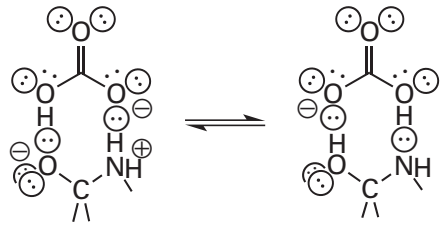
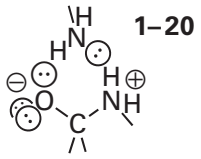
the mechanisms require such tautomerizations two to three orders of magnitude more effectively than monofunctional acids or bases with similar values of pK_a. This efficiency has been presented as evidence for the participation of such acid–bases in a cyclic, simultaneous transfer of the two hydrons[100]



(1–35)

A similar **cyclic intermediate** has been invoked to explain the much less remarkable catalysis of such tautomerizations by primary amines[101,102]

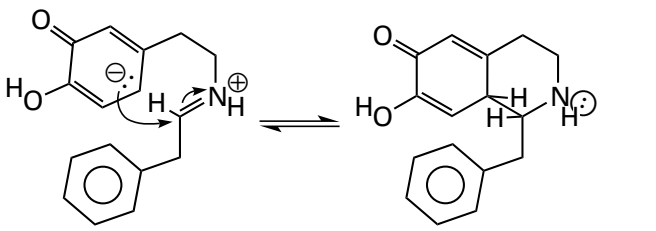


1–20

The hemiaminal (**1–18** in Figure 1–7) that results from the tautomerization is a pseudosymmetric intermediate. There are lone pairs of electrons on oxygen able to **push** away nitrogen to return to the ketone or aldehyde, and there is a lone pair of electrons on nitrogen able to push away oxygen to produce an imine. This abundance of push is another way of looking at the fact that the lone pairs on the heteroatoms in a hemiaminal or any adduct of a carbonyl group produce significant electron repul-

sion. This electron repulsion causes these adducts to be **significantly unstable in solution** relative to the aldehyde or the ketone or the imine. It is possible, however, to form a **stable intramolecular hemiaminal** by using a large synthetic octaphenyl cup to juxtapose sterically an aniline and an anthracene-2-carbaldehyde,[103] just as they can be stabilized on the active site of an enzyme by juxtaposition.

Iminiums are the conjugate acids of imines (Figure 1–7). The carbon of an iminium is electrophilic and **susceptible to addition**, just as a carbonyl group is susceptible to addition. In fact, the electrophilic carbon in an iminium is about 10^{10} times more electrophilic than the electrophilic carbon in the homologous aldehyde or ketone.[104] They are electrophilic enough to participate in the intramolecular electrophilic aromatic substitution of the Pictet–Spengler reaction.[105,106] An enzymatic example of an intramolecular nucleophilic addition to an iminium, which is similar to the Pictet–Spengler reaction, occurs in one of the steps of the reaction catalyzed by (*S*)-norcoclaurine synthase from *Thalictrum flavum*[107]



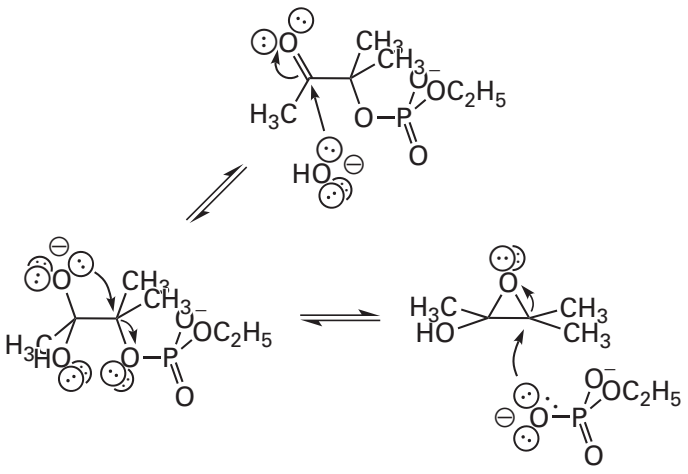
(1–36)

The product of nucleophilic addition of a thiolate to an iminium, the analogue of the addition of a thiolate to a carbonyl group (Equation 1–33 with oxygen replaced by a hydronated, cationic nitrogen), is a **thiohemiaminal** (Table 1–1).

The thiohemiacetals, thiohemiketals, hemiacetals, hemiketals, and hemiaminals formed in all these reactions represent a class of products that can be considered to be the ultimate products of the addition of one nucleophile or two nucleophiles in succession to a carbonyl group. Many biochemical metabolites such as D-glucopyranose (reactant in Equation 1–38) contain such products. In each of these products, the carbon that was the initial **carbonyl carbon** is bonded directly to two heteroatoms and either to two other carbons, to one carbon and one hydrogen, or to two hydrogens (Table 1–1). There is no oxidation or reduction involved in such additions so the carbon is still at the carbonyl oxidation state and can be considered a carbonyl carbon *in maschera*.

Nucleophilic additions to carbonyl groups are susceptible to catalysis by acids and bases. For example, during the nucleophilic addition of an alcohol to a carbonyl group under **catalysis by a base** (Figure 1–8A),[99,108,109] two different reactions occur simultaneously: the formation of the oxygen–carbon bond and the transfer of a hydron from the nucleophilic hydroxy group to the base. A hydroxy group that is already participating at its oxygen in a hydrogen bond with the catalytic base is the nucleophile, and the hydron in this hydrogen bond between the base and the hydroxy group is transferred from the hydroxy group to the base in concert with the formation of the σ bond between its oxygen and the electrophilic carbon of the carbonyl group. The σ lone pair of electrons on the nucleophilic oxygen that is attacking is mixing with the antibonding orbital of the π molecular orbital system of the carbonyl group (reverse of reaction in Figure 1–3, with nitrogen replaced by oxygen). The hydron that is being transferred to the catalytic base from this nucleophilic oxygen during the approach to the transition state is removed from a **different lone pair of electrons** from the pair adding to the electrophilic carbon of the carbonyl group.

During the addition of a nucleophile to a carbonyl group under basic conditions, the carbonyl oxygen becomes an initially unhydronated **oxyanion** (Figure 1–8A). This oxyanion is itself a nucleophile that can participate in a nucleophilic substitution, for example[110]



(1–37)

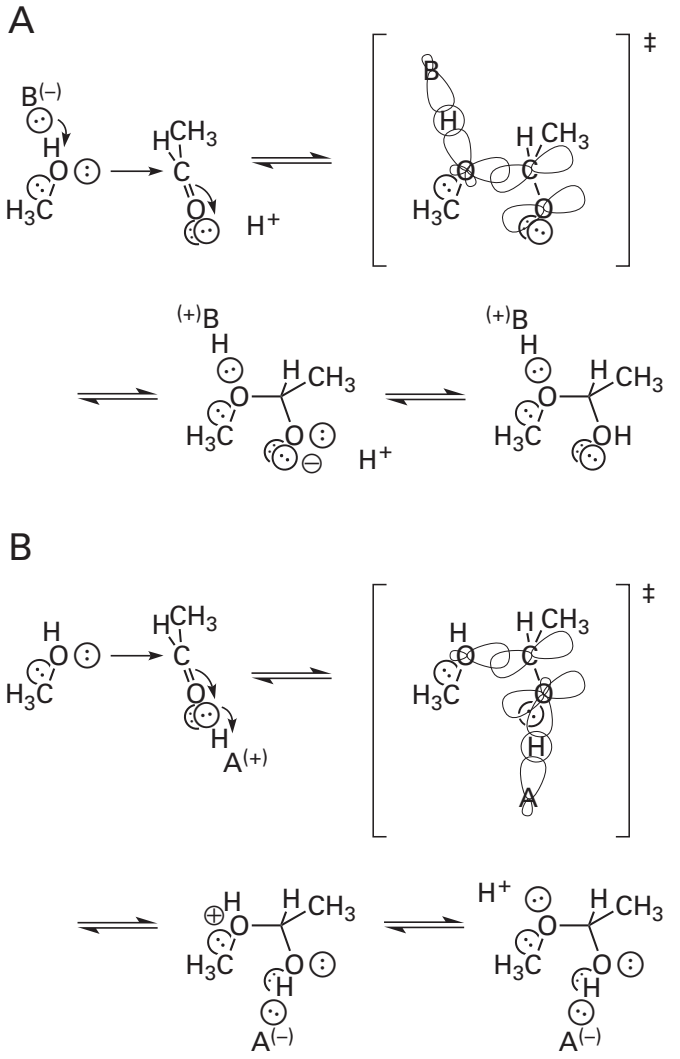


Figure 1–8: Catalysis of the formation of a hemiacetal by a general base or a general acid.[108] **(A)** In catalysis by a general base, the base B⊖, forming a hydrogen bond with the alcohol, removes the hydron from the oxygen at the same time another lone pair of electrons on the same oxygen adds to the carbonyl carbon. The two reactions are orthogonal to each other. The atomic orbitals mixing in the transition state (‡) are an atomic orbital of the base, the 1*s* orbital of hydrogen, two sp^3 orbitals of one oxygen, a *p* orbital of the carbon, and a *p* orbital of the other oxygen. The second step in the reaction is hydronation of the oxyanion to form the hemiacetal. **(B)** In catalysis by a general acid, the acid $HA^{(+)}$, forming a hydrogen bond with the carbonyl oxygen, adds a hydron to this oxygen at the same time that the oxygen of the alcohol adds to the carbonyl carbon. Again, the two reactions are orthogonal to each other. The atomic orbitals mixing to form the transition state (‡) are an atomic orbital of the acid, the 1*s* orbital of the hydron, an sp^2 orbital of one oxygen, a *p* orbital of the same oxygen, a *p* orbital of carbon, and an sp^3 orbital of the other oxygen. The second step in the reaction is dissociation of the hydron from the oxygen of the ether.

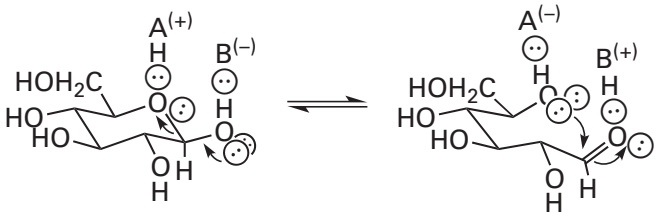
During the nucleophilic addition of an alcohol to a carbonyl group under **catalysis by an acid** (Figure 1–8B),[99,108,109] two different reactions again occur simultaneously: formation of the oxygen–carbon bond and transfer of a hydron. A carbonyl group that is already participating at its carbonyl oxygen in a hydrogen bond with the catalytic acid is the electrophile, and the hydron in this hydrogen bond between the acid and the carbonyl group is transferred from the acid to the oxygen of the carbonyl group in concert with formation of the σ bond between the oxygen of the alcohol and the electrophilic carbon. The hydron is transferred from the catalytic acid to a lone pair of electrons already on the carbonyl oxygen that is distinct from and orthogonal to the pair arising from the retraction of the π molecular orbital system of the carbonyl group onto that oxygen.

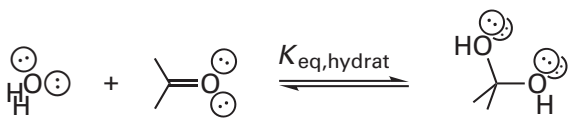
Catalysis by a base, however, is much more effective than catalysis by an acid because it is easier for a base to remove a hydron from a hydroxy group ($pK_a = 16$) than it is for an acid to add a hydron to a carbonyl group ($pK_a = -10$). This difference is in contradistinction to the absolute requirement for hydronation of the leaving oxygen in the next step in the formation of an acetal or ketal.

A biochemical example in which catalysis either by an acid or by a base or by both of them simultaneously can occur during the dissociation or the formation of a hemiacetal is the reversible **formation of D-glucopyranose**



(1–38)

The susceptibility of a particular carbonyl group to addition can be evaluated by referring to its standard free energy of hydration (Table 1–2). The formal reaction defining the hydration of a carbonyl group is



(1–39)

Table 1–2: Standard Free Energies of Hydration of Selected Aldehydes and Ketones at 25 °C[a]

carbonyl compound[b]	ΔG°_{hydrat} (kJ mol^{-1})	carbonyl compound[b]	ΔG°_{hydrat} (kJ mol^{-1})
1–21 	–19	**1–30** 	–1
1–22 	+15	**1–31** 	–9
1–23 	+1	**1–32** 	–6
1–24 	+10	**1–33** 	–5

1–26 	–1	**1–35** 	0
1–27 	+6	**1–36** 	–17
1–28 	–8	**1–37** 	–14
1–29 	–8	**1–38** 	+11

[a]Standard free energy of hydration[96,97,111] based on a standard state of the infinitely dilute solutions and the omission of the concentration of water from the equilibria. [b]The table is arranged intentionally to permit various comparisons in both the horizontal and the vertical directions.

where water is a reference nucleophile. The equilibrium constant for hydration is defined as

$$K_{\text{eq,hydrat}} = \frac{[R_1R_2C(OH)_2]}{X_{H_2O}[R_1R_2C{=}O]} \qquad (1\text{–}40)$$

where the standard state is an infinitely dilute solution of carbonyl compound and its hydrate and X_{H_2O} is the mole fraction of water, which can be less than 1.00 if mixed solvents are used. The standard free energy of hydration

$$\Delta G^\circ_{\text{hydrat}} = -RT \ln K_{\text{eq,hydrat}} \qquad (1\text{–}41)$$

The use of water as a reference for addition to a carbonyl group resembles the use of hydronium as the reference acid and water as the reference base in the definition of the acid dissociation constant.

Values for the standard free energy of hydration* of a large number of aldehydes and ketones are available (Table 1–2).[96,97,111] The more negative the value of $\Delta G^\circ_{\text{hydrat}}$, the more susceptible is the carbonyl carbon to addition.

The **effects of substituents on the value of $\Delta G^\circ_{\text{hydrat}}$** result from their ability to stabilize or destabilize, respectively, the electron-deficient carbonyl carbon in the π system of the unhydrated carbonyl group relative to the saturated *gem*-diol of the hydrated carbonyl group by either donating electron density to the carbonyl carbon or withdrawing electron density from the carbonyl carbon. **Electron-donating substituents**, especially those capable of conjugation or hyperconjugation, decrease the susceptibility of the carbonyl group to addition [compare formaldehyde (**1–21**), acetaldehyde (**1–30**), and acetone (**1–22**)]. **Electron-withdrawing substituents** increase its susceptibility [compare acetaldehyde (**1–30**) to chloroacetaldehyde (**1–31**) or acetone (**1–22**) to chloroacetone (**1–22**) and 1,3-dichloroacetone (**1–32**)]. A hydroxy group or methoxy group is less electron-withdrawing than a carboxy group or esterified carboxy group [compare methoxyacetone (**1–24**) with methyl pyruvate (**1–25**)]. Neighboring negative elementary charge increases electron density at the carbonyl carbon [compare pyruvate anion (**1–27**) with methyl pyruvate (**1–25**)], and neighboring positive elementary charge decreases electron density [compare ammonioacetaldehyde (**1–36**) with acetaldehyde (**1–30**)]. A phosphate in its uncharged acidic form is strongly electron-withdrawing, but it becomes less so as it is titrated [compare glyceraldehyde (**1–28**) with glyceraldehyde 3-phosphate monoanion (**1–37**) and glyceraldehyde 3-phosphate dianion (**1–29**)]. Therefore, lowering the pH will increase the extent of hydration of a carbonyl group near a phosphate in the same molecule because hydration itself neither consumes nor produces hydrons (Equation 1–39) and cannot be affected by pH directly. The second

*The purpose of these standard free energies of hydration is to compare the hydration of the various carbonyl groups, just as the purpose of the acid dissociation constant is to compare the acidity of the various acids. Unlike the situation with the acid dissociation constant, however, where water itself appears in only one of the expressions for the equilibrium constant as an acid and only one of the expressions for the equilibrium constant as a base, by definition in each of these hydrations of a carbonyl group, water appears as a reactant. Consequently, one is free to omit the concentration of water, and all of the comparisons remain valid. In this instance, it was decided that the concentration of water would be omitted. The activities of the particular carbonyl group and its hydrate are expressed as molar concentrations at equilibrium and at infinite dilution. The latter stipulation is to avoid activity coefficients. In practice, the measurements are made at finite concentrations and the activity coefficients are assumed to be negligible. The advantage of omitting the concentration of water is that the tabulated standard free energy of hydration is for the reaction in an aqueous solution. Furthermore, the relative values of the actual free energies of hydration should remain the same for any aqueous solution, such as cytoplasm, in which the concentraation of water remains the same as the comparisons are made. It should be stressed that this is simply a convention, which is a decision agreed to by everyone who measures these values. Both the equilibrium constants and the standard free energies tabulated are not the equilibrium constants and standard free energies that are based on units of molarity, which would require that molarity be used for the concentrations of all reactants and products, as is the case with the acid dissociation constant. The same convention cannot be used for the acid dissociation constant because water appears as a participant only in the acid dissociation constants for hydronium ion and water and none of the others, so the molar concentration of water must be used in these two quotients because in every other quotient the molar concentrations of the conjugate base and the acid are used. It is also the case that by omitting the concentration of water from the equilibrium constant and expressing the concentrations of carbonyl group and hydrate in units of molarity at infinite dilution, the standard free energy of hydration is identical to the standard free energy of hydration if mole fraction had been chosen for the units of concentration. There are convincing arguments that mole fraction is the more defensible choice of units for all standard free energies for participants in any solution. Even if one accepts these arguments and decides that it would be more rigorous to express the concentrations for the acid dissociation constant in mole fractions, this choice would have no effect on the relative values for pK_a. You should convince yourself that if units of mole fraction had been chosen for pK_a rather than molarity, the values of every pK_a, including those for hydronium ion and for water itself, would simply increase by 1.745.

methyl group on an α carbon both donates electrons to the carbonyl carbon and exerts a steric effect, and these two opposite tendencies cancel each other [compare 2-oxobutyrate (**1–26**) to 3-methyl-2-oxobutyrate (**1–35**)].

In aqueous solution aldehydes and ketones are **in equilibrium with their hydrates**. Because the concentration of water is expressed in mole fraction in Equation 1–40, any carbonyl compound with a standard free energy of hydration less than 0 will be present mostly as the hydrate in aqueous solution and any carbonyl compound with a standard free energy of hydration greater than 0 will be present mostly as the unhydrated carbonyl group in aqueous solution. Recall that 5.7 kJ mol^{-1} is equivalent to a factor of 10 in equilibrium constant at 25 °C. In all cases, hydration has the effect of decreasing the concentration of unhydrated carbonyl group, which is the reactive species in any desired addition competing with hydration.

The standard free energies for the addition of thiols to carbonyl groups are linearly correlated to the standard free energies of hydration.[96,97] This correlation is not surprising since the formation of a thiohemiacetal (Equation 1–33) is homologous to the formation of the hydrate (Equation 1–39). Therefore, the relative susceptibility of different carbonyl groups to addition by a thiol can be estimated from the corresponding standard free energies of hydration.

Nucleophilic substitutions at a carbonyl carbon are reactions in which the oxygen of a carbonyl group, the nitrogen of an imine, or the sulfur of a thiocarbonyl group is replaced by the oxygen, nitrogen, or sulfur of a nucleophile. A nucleophilic substitution proceeds through the nucleophilic adduct that is the product of nucleophilic addition of the nucleophile that will replace the oxygen, nitrogen, or sulfur of the leaving group. For example, if the hydroxy group (the leaving group), which began as the oxygen of a carbonyl group, dissociates from the hemiaminal that results from the addition of an amine (the nucleophile) to a carbonyl carbon, then an imine, the product of a nucleophilic substitution, is formed (Figure 1–7). A ketimine is the nitrogen analogue of a ketone, and an aldimine is the nitrogen analogue of an aldehyde. An imine is the product of a nucleophilic substitution of water by an amine at a carbonyl group. A thioketone or thioaldehyde is formally the product of the nucleophilic substitution of water by hydrogen sulfide at a carbonyl group. Nucleophilic substitution at a carbonyl carbon usually involves a discrete, reasonably stable intermediate that is formed by addition of the nucleophile to the carbonyl group (Table 1–1).

The dissociation of oxygen from a hemiaminal (lower half of Figure 1–7) during nucleophilic substitution of the oxygen of a carbonyl group by the nitrogen of an amine can occur under either catalysis by an acid or catalysis by a base. Under **catalysis by an acid** (Figure 1–7), breaking of the bond between carbon and oxygen, assisted by the push of the lone pair of electrons on nitrogen, occurs simultaneously[88] with hydronation[86] of one of the available lone pairs of electrons on the oxygen of the leaving group. This lone pair of electrons that is hydronated by the acid is different from the pair created during the dissociation of the carbon–oxygen bond. Addition of the hydron to the oxygen decreases its electron density and attenuates the σ bond between carbon and oxygen by pulling its electrons toward the oxygen so that the σ bond is weak enough to be broken by the relatively feeble push of a lone pair of electrons on a neutral nitrogen. Under **catalysis by a base**, breaking of the bond between carbon and oxygen, assisted by the push of the lone pair of electrons on nitrogen (Figure 1–7), occurs simultaneously[87] with removal of a hydron by the base from a different lone pair of electrons on nitrogen. Removal of the hydron from the other lone pair of electrons on nitrogen during formation of the transition state increases the electron density on nitrogen and amplifies the push of the initially present lone pair of electrons by electron repulsion so that it is strong enough to push out the poor leaving group, hydroxide ion. Removal of the hydron from nitrogen must occur during formation of the transition state. A hydron cannot be removed from the nitrogen in a pre-equilibrium because of its poor acidity ($pK_a \cong 40$). Usually catalysis by an acid is considerably more effective than catalysis by a base because it is easier to hydronate a hydroxy group ($pK_a = -2$) than it is to remove a hydron from an amino nitrogen.

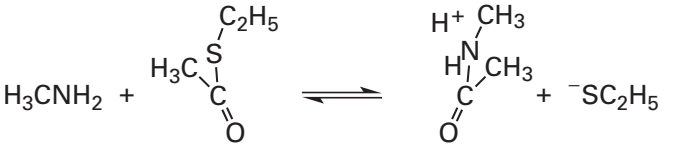
Nucleophilic Substitution at an Acyl Group

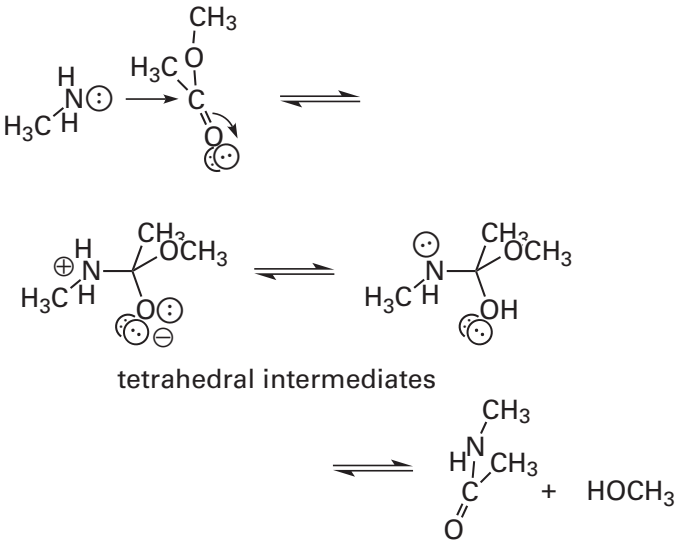
A nucleophilic substitution at an acyl group is a special case of a nucleophilic substitution at a carbonyl group. An example would be the aminolysis of a thioester[112]



(1–42)

in which a methylamino group is substituted for an ethylsulfanyl group to produce an **amide**.

Most nucleophilic substitutions at acyl groups proceed through a tetrahedral intermediate. The tetrahedral intermediate in a nucleophilic substitution at an acyl group results from nucleophilic addition of the nucleophile to the acyl derivative.[112-114] For example, during the aminolysis of an ester

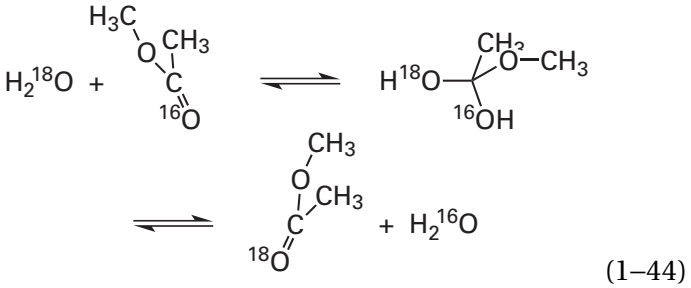


(1–43)

several tautomeric tetrahedral intermediates and their conjugate acids and bases are formed. They resemble the conjugate acids, conjugate bases, and tautomers of the hemiaminal that results from the nucleophilic addition of an amine to an aldehyde or ketone (Figure 1–7).* A nucleophilic substitution at an acyl carbon that proceeds through a tetrahedral intermediate is an example of an associative nucleophilic substitution.

An **associative nucleophilic substitution** is a nucleophilic substitution that proceeds through a tetrahedral intermediate in which a covalent bond is formed between the nucleophile and the electrophilic carbon before the covalent bond between the leaving group and the electrophilic carbon begins to break. The resulting tetrahedral intermediate is a molecule in its own right, albeit an unstable one. It is distinct from the transition state in a concerted nucleophilic substitution at a saturated, electrophilic carbon because that transition state does not have covalent bonds between the carbon and either the nucleophile or the leaving group.

The existence of an intermediate in a nucleophilic substitution at an acyl group is indicated by a **change in the rate-limiting step** from the formation of the intermediate to its breakdown as the pH is lowered.[113] That the intermediate detected in such pH–rate behavior is the proposed tetrahedral intermediate is indicated by the fact that **oxygen exchange** into the initial reactant occurs during the reaction. An example of such isotopic exchange is that observed during the hydrolysis of methyl acetate[115]



(1–44)

Oxygen exchanges into the initial reactants occur during the hydrolysis of esters, thioesters,[116] anilides,[117] and amides[118] under both strongly acidic[115-117] and strongly basic[115,118] conditions.

*By definition, the various named adducts of a carbonyl group are also tetrahedral intermediates in addition to the tetrahedral intermediates in nucleophilic substitutions at acyl carbons and carbonato carbons.

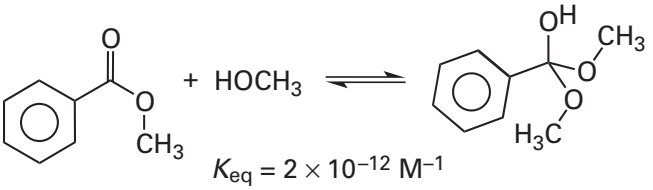
That a tetrahedral intermediate exists in a nucleophilic substitution at an acyl group is also consistent with observed **secondary kinetic isotope effects**. When the two hydrogens on a carbon immediately adjacent to the carbon in the acyl group are replaced with deuteriums, the rates of the hydrolyses of esters[119-122] increase by about 5%. This significant inverse kinetic isotope effect, an increase in rate rather than a decrease upon substituting hydrogen with deuterium, indicates that the hyperconjugation between these two adjacent hydrogens and the π bond between carbon and oxygen in the acyl group is decreased considerably or lost completely in the transition state of the rate-limiting step or during a pre-equilibrium preceding the rate-limiting step. The hyperconjugation is weaker when the hydrogen is a deuterium, so the deuterated ground state is less stable relative to the transition state than the hydronated ground state. This result is consistent with the formation of a tetrahedral intermediate,* which has no π bond with which hyperconjugation can occur.[123] The effects on the rate constants for aminolysis of methyl formate that result from replacement of the hydrogen on the acyl carbon with deuterium, the acyl oxygen-16 with oxygen-18, the amino nitrogen-14 with nitrogen-15, the ester oxygen-16 with oxygen-18, and the acyl carbon-12 with carbon-13 are all consistent with changes expected for the formation of a tetrahedral intermediate during this reaction.[124]

The molecular details of the formation and dissociation of a tetrahedral intermediate are homologous to those for the formation and dissociation of an adduct to a carbonyl group. All of the considerations—structure of the transition state, electron repulsion on the approach to it, stereochemistry of the attack, energy barriers to the formation of the transition state, push of the adjacent heteroatoms during its dissociation, and the involvement of the atomic and molecular orbitals in the dissociation—that are pertinent to nucleophilic addition to a carbonyl group apply to the formation and dissociation of the tetrahedral intermediate in the associative nucleophilic substitution at an acyl group. Addition of the nucleophile to the acyl group (Equation 1–43) proceeds through overlap of the atomic orbital bearing the lone pair of electrons on the nucleophile with the antibonding π molecular orbital of the carbon–oxygen (**1–17**), carbon–nitrogen, or carbon–sulfur double bond of the acyl group. Expulsion of the leaving group from the tetrahedral intermediate (Equation 1–43) proceeds through overlap of the atomic orbital containing a lone pair of electrons on the oxygen or the nitrogen providing push with the antibonding orbital of the σ bond between carbon and the leaving group (Figure 1–3). For example, in the aminolysis of an ester (Equation 1–43), the lone pairs of electrons providing push in the forward direction and the reverse direction is a lone pair on the hydroxy group that was the oxygen in the carbon–oxygen double bond of the ester, but the lone pair of electrons on the other oxygen also provides push in the reverse direction, and the lone pair of electrons on the nitrogen provides push in the forward direction.

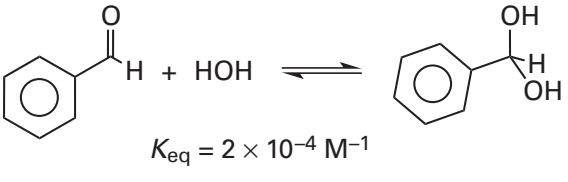
The **difference between an acyl group and a carbonyl group** is that there is a second heteroatom in the former, and the difference between the tetrahedral intermediate in a substitution at an acyl group and the product of addition to a carbonyl group is that there is a third heteroatom attached to carbon in the former. On the one hand, the second heteroatom in the acyl group makes it more stable than a carbonyl group because the lone pairs of electrons on this heteroatom can conjugate with the electropositive acyl carbon. On the other hand, the third heteroatom makes a tetrahedral intermediate much less stable than the product of a nucleophilic addition to a carbonyl group because the lone pair or lone pairs of electrons on the third heteroatom will increase electron repulsion in the tetrahedral intermediate. The net result of these two effects, the one lowering the energy of the reactant and the other raising the energy of the transition state, is that the tetrahedral intermediate in an associative nucleophilic substitution at an acyl group (Equation 1–45) is much less stable than the tetrahedral intermediate in an associative nucleophilic substitution at a simple carbonyl group (Equation 1–46). This instability can be demonstrated by a comparison[96,125] of equilibrium constants*

*These kinetic isotope effects are also consistent with a single transition state for the substitution, in which the bond between the nucleophile and the acyl carbon is forming as the bond to the leaving group is breaking, and the double bond of the carbonyl group is significantly but only partially broken.

*Because the addition of methanol is being compared to the addition of water, these equilibrium constants are for the reactions as written using the molar concentrations of methanol (24.7 M) and water (55.5 M) rather than the mole fractions of methanol and water as was done in Equation 1–40.

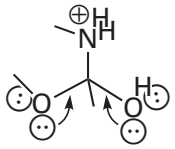


(1–45)



(1–46)

The additional heteroatom also creates a situation in which two lone pairs of electrons can be simultaneously periplanar to the leaving group and provide **greater push**



1–39

In every tetrahedral intermediate this double push is possible. It has already been noted that during the hydrolyses of ortho esters (acyl derivatives in which the two lone pairs of electrons providing the push are on two oxygens) antiperiplanar push is stronger than synperiplanar push[60] but by less than 10 kJ mol^{-1}. During the hydrolysis of amidiniums[126] and guanidiniums,[127] acyl derivatives in which the two lone pairs of electrons providing the push in the tetrahedral intermediate are on a nitrogen and an oxygen respectively, antiperiplanar push is also stronger than synperiplanar push but by less than 5 kJ mol^{-1}. To be effective, however, the push must always be **periplanar** for maximum overlap to occur.[60]

Often the tetrahedral intermediate must be formed and **revert to reactants** many times before the expulsion producing a product of associative nucleophilic substitution occurs. If the nucleophile that produces the tetrahedral intermediate in the first place is the most likely leaving group from that tetrahedral intermediate, then the yield of product for every encounter that produces a tetrahedral intermediate will be low because most of the time the initial nucleophile will be expelled from the tetrahedral intermediate to regenerate the reactant. For example, in the esterification of *N*-acetylimidazole by trifluoroethoxide (Figure 1–9)[128] at high pH, the tetrahedral intermediate dissociates to form the reactants about 200 times more rapidly than it dissociates to form the products imidazole and trifluoroethyl acetate.

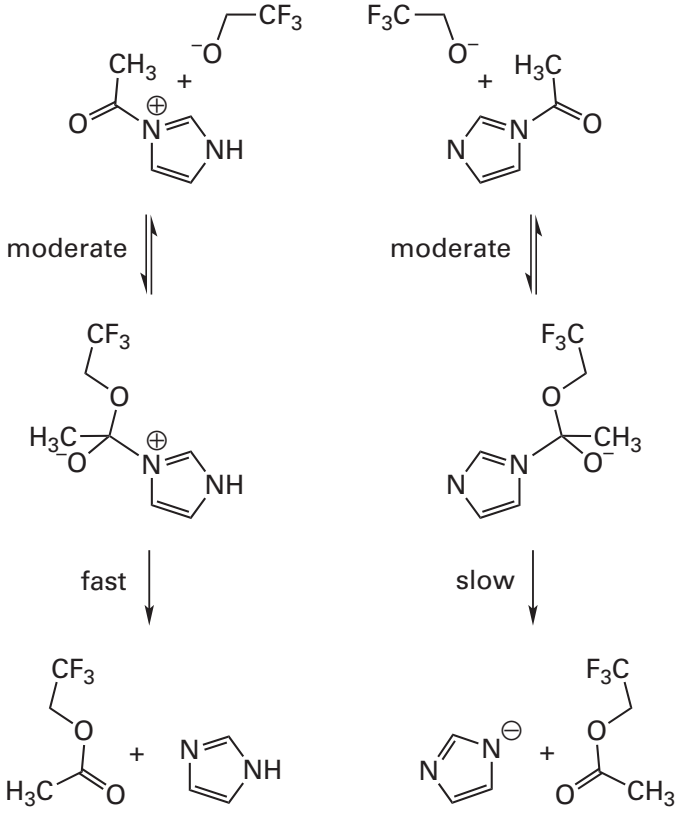


Figure 1–9: Effect of hydronation of the leaving group on the partition in a tetrahedral intermediate.[128] Addition of 2,2,2-trifluoroethoxide ion to *N*-acetylimidazole, in either its hydronated or unhydronated form, produces a tetrahedral intermediate from which either the trifluoroethoxide ion or the imidazole is a potential leaving group. (**Left side**) At low pH, when the imidazole in the tetrahedral intermediate is hydronated, it is the preferred leaving group because its conjugate acid (pK_a = 7.05) is more acidic than the conjugate acid of the trifluoroethoxide ion (pK_a = 12.4). Consequently, imidazole dissociates rapidly from the tetrahedral intermediate relative to the trifluoroethoxide ion (fast against moderate). (**Right side**) At high pH, when the imidazole in the tetrahedral intermediate is unhydronated and must leave as the imidazolate anion, the trifluoroethoxide ion is the preferred leaving group because its conjugate acid (pK_a = 12.4) is more acidic than the conjugate acid of the imidazolate anion (pK_a = 14.5), and the loss of imidazole becomes slower than the loss of trifluoroethoxide from the tetrahedral intermediate (slow against moderate). Because the major change in acidity has been to the imidazole, the major change in rate occurs in its dissociation from the tetrahedral intermediate.

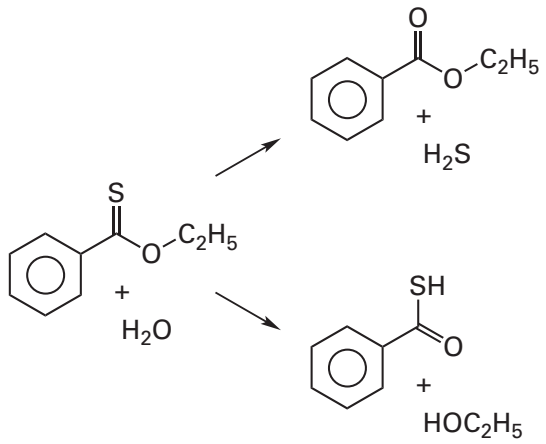
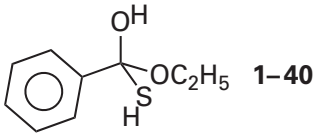
Because there are three heteroatoms in a tetrahedral intermediate and any one of the three can dissociate, there are always **two possible products** that can form in addition to the one formed by the dissociation regenerating the reactants. Consequently, the ratio of the products formed from the tetrahedral intermediate depends on a partition. For example, when ethyl thionobenzoate is hydrolyzed, two products in addition to the reactant form



(1–47)

The identity of the leaving group from a tetrahedral intermediate, and hence the acyl derivative that is the product, is usually determined both by hydronation of the leaving group and by the magnitude of the push provided by the different heteroatoms.

The hydrolysis of *O*-ethyl benzenecarbothioate (Equation 1–47) provides an example of the effect of **hydronation** on the identity of the product. During the hydrolysis, ethyl benzoate predominates under weakly acidic conditions, but the fraction of benzenecarbothioic acid increases significantly as the pH is lowered below 1.0.[129] This change in the ratio of the products is due to a shift in the preference for expulsion within the tetrahedral intermediate

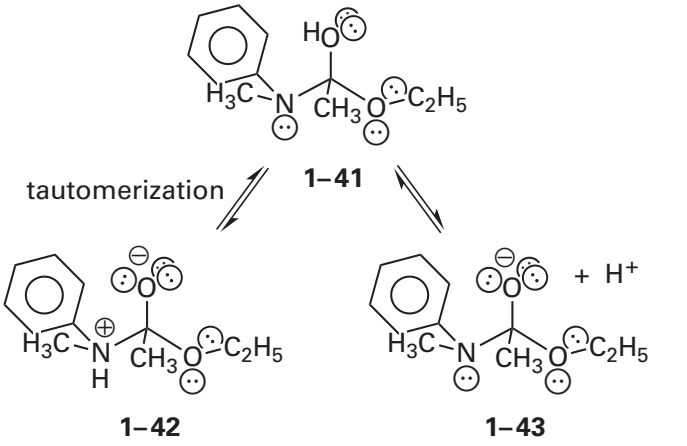


1–40

This conclusion was validated by generating an analogous tetrahedral intermediate through a completely different route involving the decomposition of an ortho ester. The same increase in the yield of thiobenzoate relative to benzoate was observed as the pH was lowered.[130] A reasonable explanation for the shift in the ratio of products is the increased rate for hydronation of the ethoxy oxygen or an increased concentration of the hydronated form of the ethoxy oxygen within tetrahedral intermediate **1–40** at the lower values of pH.* Either of these effects, or both together, will cause the ethoxy oxygen to become a better leaving group than the sulfanyl group, although given the rates at which acid–base reactions reach equilibrium, the latter explanation seems more reasonable.

Another example of the importance of hydronation in determining the identity of the leaving group from a tetrahedral intermediate occurs in the associative nucleophilic substitution of imidazole by trifluoroethoxide in acetylimidazole (Figure 1–9).[128] If the imidazole group is unhydronated (right column), expulsion of trifluoroethoxide from the tetrahedral intermediate predominates; if the imidazole is hydronated (left column), its expulsion predominates. This shift in predominance explains why both the *N*-hydronated and the *N*-methylated acetylimidazolium ions produce the trifluoroethyl ester 200 times more rapidly than unhydronated acetylimidazole.

Hydrolysis of ethyl *N*-methyl-*N*-phenyl-acetimidate ion[131] proceeds by the addition of hydroxide or water to the cationic imidate ester in a slow, rate-limiting step to produce the initial tetrahedral intermediate **1–41**



1–41 **1–42** **1–43**

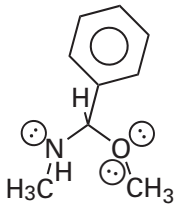
(1–48)

This intermediate can tautomerize to tetrahedral intermediate **1–42** and expel *N*-methylaniline or lose a hydron to produce tetrahedral intermediate **1–43** and expel the ethoxide. The partition between these

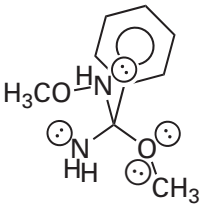
*Hydronation of a sulfide ($pK_a \cong -8$) occurs at much lower pH than hydronation of an ether ($pK_a \cong -3.5$).

two outcomes is influenced secondarily by other acids and bases in the solution, but expulsion of the aniline always increases as the pH of the solution is lowered and hydronation of the nitrogen increases.

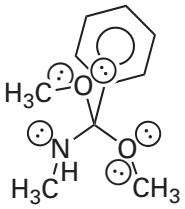
The magnitude of the **push** available in the tetrahedral intermediate also has a significant influence on the choice of the leaving group. This influence can be appreciated by examining the products formed from the collapse of each of the following hemiaminals and tetrahedral intermediates under catalysis by a general acid[57]



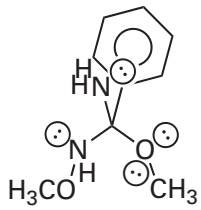
1–44



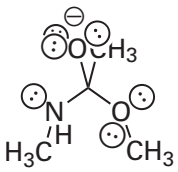
1–45



1–46



1–47



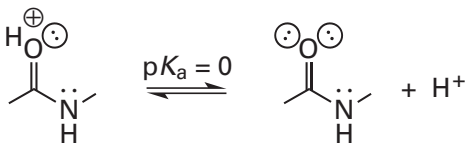
1–48

In the drawings of each of these compounds,* the two potential leaving groups have been placed to the right and left sides of the central carbon, respectively. In each case, the lone pair of electrons on the oxygen to the right is less basic than the lone pair of electrons on the nitrogen to the left, usually by about 14 units of pK_a. Under catalysis by a general acid, the nitrogen will always be hydronated more readily and should be the better leaving group.

The fact that the lone pair of electrons on nitrogen is the more basic, however, also means that it can provide more push. In the hemiaminal **1–44**, nothing other than one of the two potential leaving groups can provide push, so push becomes more important than hydronation, and hemiaminals preferentially expel the alcohol under catalysis by an acid. In either the methoxyamino tetrahedral intermediate **1–45** or the methoxy tetrahedral intermediate **1–46**, the third heteroatom is able to provide only a weak push (pK_a = 5 and pK_a = –3, respectively) but it is enough to enhance the expulsion of nitrogen sufficiently so that its rate of disdissociation becomes equivalent to that of the oxygen under catalysis by an acid. In the amino tetrahedral intermediate **1–47**, the push of the more basic lone pair of electrons on the amino nitrogen (pK_a = 10) predominates over that of the lone pair of electrons on the leaving nitrogen in the methoxyamino group, and the dissociation of the methoxylamine, the more readily hydronated leaving group under catalysis by an acid, is several hundred times more rapid than that of methanol. Finally, in the alkoxy tetrahedral intermediate **1–48**, the push from the lone pair of electrons on nitrogen becomes irrelevant in comparison to the push of the more basic lone pair of electrons of the oxyanion. In the presence of such an abundance, which is able to be directed at either leaving group promiscuously, hydronation of the nitrogen, which is the more basic leaving group, dictates the preference, and alkoxy tetrahedral intermediate **1–48** decomposes almost exclusively through expulsion of amine.

Nucleophilic substitutions at acyl groups can be catalyzed either by acids or by bases. An example relevant to enzymatic catalysis is the **hydrolysis of amides**, which takes place at elevated temperatures in the presence of strong acid or strong base.

In **strong acid** (Figure 1–10A), the acyl oxygen is hydronated[132] in a regular acid–base dissociation



(1–49)

This hydronation causes the acyl carbon to be electrophilic enough to react with water to form a tetrahedral intermediate, but because water is a poor nucleophile, this remains the slowest step in the reaction. Before the tetrahedral intermediate is formed, the lone pair of electrons on nitrogen is unavailable for hydronation (pK_a = –7),[132] but after the tetrahedral intermediate has formed, the nitrogen has become the nitrogen of an amine rather than the nitrogen of an amide. In the case of hydrolysis of primary and secondary amides, the amino nitrogen (p$K_a \cong 9$) in the tetrahedral intermediate initially formed by the addition of water to the hydronated acyl group is immediately and irreversibly hydronated (pH < 0). Because of this immediate hydronation, which makes the amine

*Although **1–45** and **1–47** are enantiomers of each other and both of them would be formed at random in the same nucleophilic substitution, these facts are irrelevant to the present argument. Each is presented as a tetrahedral intermediate that produces a particular product, and each product is different from the other.

the preferred leaving group, insignificant oxygen exchange (see Equation 1–44) is observed during the hydrolysis of amides catalyzed by strong acid. Following its expulsion as the leaving group, the amine is hydronated under acidic conditions, and this hydronation precludes the reverse reaction and provides the free energy necessary to make the hydrolysis favorable.[133]

In **strong base** (Figure 1–10B), hydroxide is the nucleophile during the hydrolysis of an amide. From measurements of the rates of amide hydrolysis in mixtures of ^1H_2O and ^2H_2O, it has been concluded that the hydrated form of hydroxide (**1–2**) is the nucleophile, [134] but whether the actual nucleophile is the lone pair of electrons on the central hydroxide itself or one of the lone pairs of electrons on one of the three surrounding molecules of water[135,136] is unsettled. The hydroxide readily adds to the acyl carbon in a rapid reaction.[133] This addition of the nucleophile creates the oxyanion, ready to push out the leaving group. The amino nitrogen created during this first step is only slowly hydronated because the concentration of hydrons is so low and the transfer of a hydron from water is endergonic. As a result, the transfer of a hydron to the nitrogen is the slow step under basic conditions.[133] Consequently, isotopic exchange (see Equation 1–44) is readily observed during the hydrolysis of amides in strong base, except in the case of tertiary amides.[137] When the nitrogen is hydronated, it leaves in preference to oxygen because the tetrahedral intermediate resembles tetrahedral intermediate **1–48** under acidic conditions. The carboxylic acid produced loses its hydron under the basic conditions, and this ionization precludes the back reaction and provides the free energy necessary to make the reaction favorable.[133]

At **neutral pH**, although transfer of a hydron to the amino nitrogen in the tetrahedral intermediate occurs readily, the acyl oxygen cannot be significantly hydronated so the reaction of water as a nucleophile at the acyl carbon is extremely slow, and the concentration of hydroxide is so low that nucleophilic attack of hydroxide is also slow.[133] Both of these problems luckily cause the hydrolysis of an amide to take years at pH 7 and 25 °C in the absence of catalysis.[1] At neutral pH, both the amine and the carboxylic acid are ionized following the hydrolysis, and both of these ionizations together provide sufficient favorable free energy to cause the

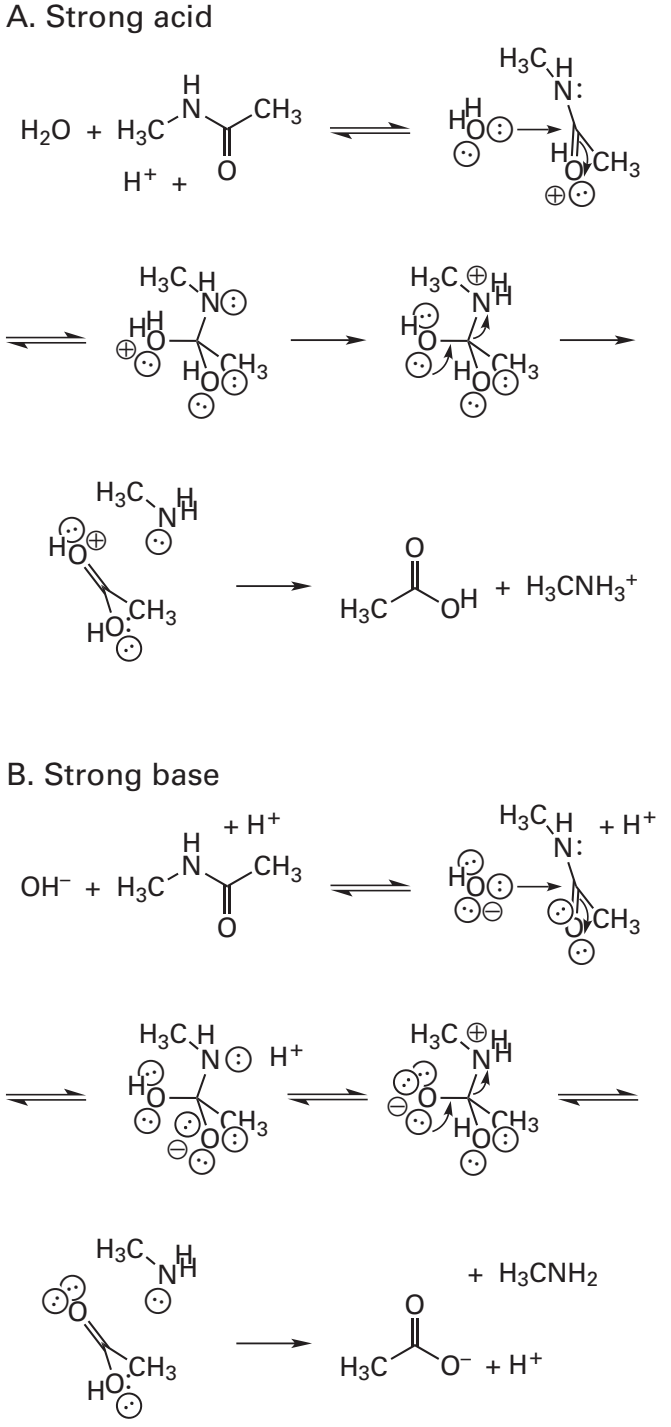


Figure 1–10: Mechanisms of hydrolysis of an amide under specific acid catalysis or specific base catalysis. (**A**) In strong acid, under catalysis by a hydron, a molecule of water adds to the amide, which is hydronated on oxygen, to produce the tetrahedral intermediate. (**B**) In strong base, under specific catalysis, a hydroxide ion adds to the neutral amide to produce the tetrahedral intermediate. In each case, the nitrogen in the tetrahedral intermediate must be hydronated, regardless of whether the pH of the solution in low or high, before it can leave.

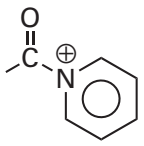
hydrolysis, although slow in the absence of catalysis, to be isoergonic rather than endergonic.[133] The equilibrium constant for the hydrolysis of an amide is at a minimum in the midrange of pH and increases at both low pH and high pH.[138]

When the **hydrolysis of an ester** is catalyzed by a base other than hydroxide, and probably by hydroxide as well, a molecule of water, already forming a hydrogen bond with the base, is the nucleophile, just as it is in the addition of an alcohol to a carbonyl group catalyzed by a base (Figure 1–8).[120] During the addition of the molecule of water to the acyl carbon, the hydron in the hydrogen bond is simultaneously transferred to the base.

In addition to catalysis by acids and bases, certain nucleophilic substitutions at acyl groups are susceptible to **catalysis by desolvation**. For example, the rates of nucleophilic substitutions in which the nucleophile is phosphate dianion, which is a common nucleophile in biochemical reactions, are increased by a factor as large as 10^5 when water is replaced by dimethyl sulfoxide, but all anionic nucleophiles exhibit enhancement upon decreases in the concentration of water.[139] This effect is thought to result from the fact that the nucleophilic oxygens of phosphate dianion in particular, but most nucleophilic atoms with a negative elementary charge, usually are masked by a strongly held layer of water molecules solvating the respective ions and the fact that their intrinsic nucleophilicity is revealed upon desolvation. When phosphate or another nucleophilic anion reacts in the **active site of an enzyme**, it has usually been desolvated in the process of associating with the site, and this desolvation should increase its nucleophilicity significantly.

Nucleophilic substitutions at an acyl group are also susceptible to **nucleophilic catalysis**. For example, pyridine is a nucleophilic catalyst for acyl derivatives with good leaving groups. The acceleration of the reaction that occurs in the presence of pyridine results from the fact that pyridine enters and leaves tetrahedral intermediates readily, yet acylpyridinium ions are fairly unstable because the unavoidable positive formal elementary charge on the nitrogen activates the acyl carbon for nucleophilic attack. Therefore, pyridine reacts rapidly with the initial acyl derivative to produce the acylpyridinium ion

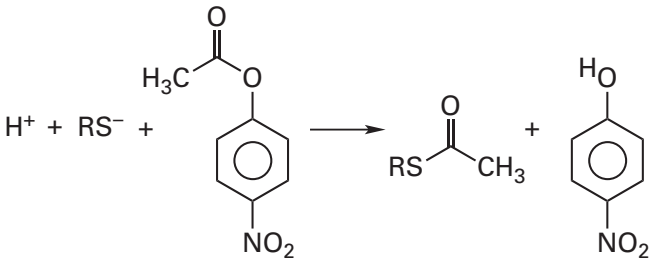


1–49

which then reacts rapidly with the nucleophile to produce the product of the particular reaction and regenerate the catalyst.[140] Many enzymes catalyze substitution at an acyl group nucleophilically, using one or the other of the heteroatoms in the side chains of their amino acids.

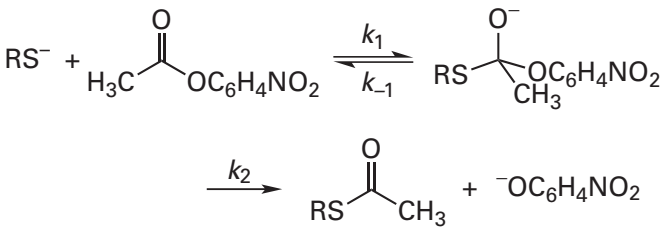
In a nucleophilic substitution at an acyl group that passes through a tetrahedral intermediate, there are always at least two steps: combination of the acyl derivative and the nucleophile to create the tetrahedral intermediate and expulsion of the leaving group to create the products. Either of these steps can be the rate-limiting step of the reaction. Usually, as the identity of the nucleophile,[141] the identity of the acyl derivative, the pH, or the identity of the catalyst[142] is changed within a given series of such associative nucleophilic substitutions, the major effect of each of these changes will be on only one step in the mechanism. It often happens that as these parameters are changed systematically, at some point the step that was rate-limiting becomes faster than either a step preceding it or a step following it, and the new slower step then becomes the rate-limiting step. It has already been mentioned that one of the facts consistent with the existence of an intermediate in most nucleophilic substitutions at an acyl group is the observation of such **a change in the rate-limiting step**.

A change in rate-limiting step occurs in a series of nucleophilic substitutions between 4-nitrophenyl acetate and a set of thiolate ions[141]



(1–50)

A kinetic mechanism, incorporating a tetrahedral intermediate, can be written for this reaction



(1–51)

When the rate constant k_{-1} in Equation 1–51 is smaller than the rate constant k_2, the 4-nitrophenolate leaves the tetrahedral intermediate more rapidly than the thiolate, and most of the tetrahedral intermediates formed proceed to molecules of product. If the rate constant k_{-1} is much smaller than the rate constant k_2, almost none of the tetrahedral intermediates can revert to reactants before they proceed on to products. Because a tetrahedral intermediate is always unstable relative to reactants and products and almost none is present in solution at a given instant, the step governed by the rate constant k_1 is rate-limiting because the rate of the reaction depends entirely on the rate at which the tetrahedral intermediate is formed. The observed rate constant for the reaction is simply the rate constant k_1, and the transition state governing the observed rate constant is that of the first step.

When the rate constant k_{-1} is larger than the rate constant k_2, the thiolate leaves in preference to the 4-nitrophenolate, a **pre-equilibrium** establishes an equilibrium concentration of tetrahedral intermediate, and the rate of the reaction is affected by the rate at which this tetrahedral intermediate breaks down to product through the step governed by k_2, now the rate-limiting step. Under these circumstances, however, the rate constants for all three steps—those governed by k_1, k_{-1}, and k_2—determine the rate of the associative nucleophilic substitution because a change of any of these rate constants will affect the observed rate of the reaction, even though only the step governed by k_2 is the rate-limiting step. In this situation, the observed rate constant for the reaction is $K_{eq1}k_2$, where K_{eq1} is the equilibrium constant for the first step, the pre-equilibrium determined by the rate constants k_1 and k_{-1}, and k_2 is the rate constant for the second step.

For the nucleophilic substitution between a series of thiolate ions and 4-nitrophenyl acetate (Equation 1–51), there is a **change in the slope of a Brønsted plot** (Figure 1–11; third curve from the top),[141] in which the common logarithms of the rate constants for the nucleophilic substitutions are plotted as a function of the values of pK_a for the thiols that are the conjugate acids of the respective thiolate ions. The slope of a line on such a plot is the **Brønsted coefficient for the nucleophiles, β_{nuc}.** On moving from right to left on the plot, it can be seen that when the thiolate used in the reaction described in Equation 1–51 becomes sufficiently acidic (pK_a < 6 for the nucleophilic substitutions of

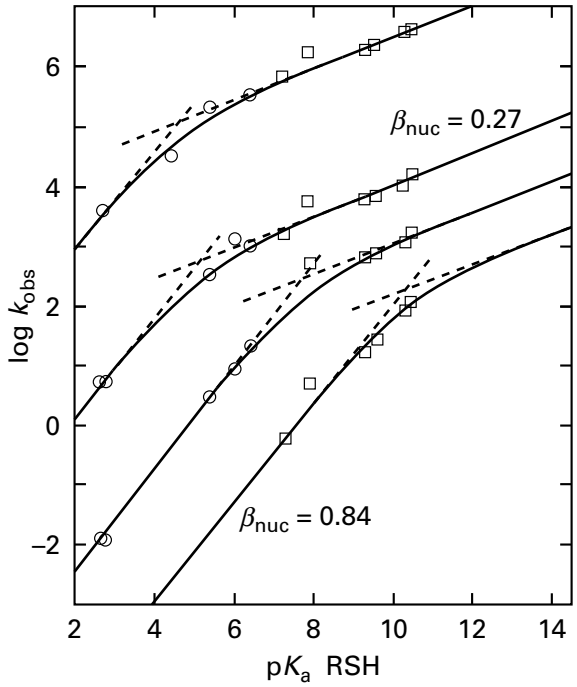


Figure 1–11: Brønsted correlations between the rate constants for nucleophilic substitutions at four different acetate esters by a series of nucleophilic aryl thiolate ions (○) and alkyl thiolate ions (□), the conjugate acids of which have different acid dissociation constants.[141] The rates for each nucleophilic substitution (Equation 1–50) were followed at two or more values of pH at an ionic strength of 1.0 M and at 25 °C. The values of pH chosen in each case were those appropriate to the pK_a of the particular thiol the thiolate ion of which was used as the nucleophile. The pH at which each rate was measured was used to determine the actual concentration of thiolate ion in the solution. For each of the 36 combinations of electrophile and thiolate ion, represented by the 36 points on the graph, the rate constants calculated, based on the actual concentration of thiolate ion, were the same for all values of pH. The common logarithms of the observed rate constants are plotted as a function of the values of the pK_a for the thiol. The thiols chosen, in order of increasing pK_a, were pentafluorobenzenethiol (pK_a = 2.68), 2,3,5,6-tetrafluorobenzenethiol (pK_a = 2.75), 4-nitrobenzenethiol (pK_a = 4.5), 3,4-dichlorobenzenethiol (pK_a = 5.48), 4-acetamidobenzenethiol (pK_a = 6.08), benzenethiol (pK_a = 6.43), 2,2,2-trifluoro-1-sulfanylethane (pK_a = 7.30), methyl 2-sulfanylacetate (pK_a = 7.91), methyl 3-sulfanylpropionate (pK_a = 9.33), 2-sulfanylethanol (pK_a = 9.61), sulfanylethane (pK_a = 10.35), and 1-sulfanylpropane (pK_a = 10.53). Each of the four curves in the figure is for the nucleophilic substitutions of a particular acetate ester. The four acetate esters used as electrophiles, in descending order on the field of the graph, were 1-acetoxy-4-methoxypyridinium ion, 2,4-dinitrophenyl acetate, 4-nitrophenyl acetate, and phenyl acetate. The products produced by the leaving groups were 4-methoxypyridine 1-oxide, 2,4-dinitrophenolate ion, 4-nitrophenolate ion, and phenolate ion, respectively. The curves drawn through the data each have linear asymptotes of the same slope to the left and of the same slope to the right of the respective inflections. The slopes of the linear asymptotes, the values of β_{nuc}, are 0.84 to the left and 0.27 to the right. There is a gradual change in slope in the middle of each curve.

4-nitrophenyl acetate), there is a change in slope (β_{nuc}) from 0.27 to 0.84.

This **change in slope** can be explained as the result of a change in rate-limiting step. The dissociation of 4-nitrophenyl acetate from the sulfur in the tetrahedral intermediate (step governed by k_{-1} in Equation 1–51) is analogous to the dissociation of a hydron from the respective thiol. When the conjugate acid of the thiolate becomes acidic enough, the dissociation of 4-nitrophenyl acetate from the sulfur in the tetrahedral intermediate becomes faster than the expulsion of 4-nitrophenolate from the tetrahedral intermediate. The kinetic mechanism of the reaction changes from one in which the first step, formation of the tetrahedral intermediate, is the rate-limiting step governing the observed rate constant to one in which the second step, expulsion of nitrophenolate, is the rate-limiting step.

For the more basic thiols, before the change in rate-limiting step has occurred, the observed rate constant is governed only by the first step. The **Brønsted coefficient for the nucleophile**, β_{nuc}, is small (0.27) and indicates that, in the transition state for addition of the thiolate to the acyl carbon of the 4-nitrophenyl acetate, the bond between sulfur and carbon is only partially formed.

For the more acidic thiols, after the change in rate-limiting step has occurred, the observed rate constant is governed by both the pre-equilibrium and the second step, expulsion of the leaving group, which is now the rate-limiting step. The Brønsted coefficient for the nucleophile, β_{nuc}, is now large (0.84). If only the rate constant k_{-1}, that for dissociation of 4-nitrophenyl acetate from the sulfur in the tetrahedral intermediate, were affected by the increasing acidity of the thiol, and if dissociation of 4-nitrophenyl acetate from the thiolate when the tetrahedral intermediate dissociates were equivalent to the dissociation of a hydron, then the Brønsted coefficient would have been 1.

Three other acetates were also used in these experiments (Figure 1–11).[141] 1-Acetoxy-4-methoxypyridinium gives the product 4-methoxypyridine 1-oxide (top curve), 2,4-dinitrophenyl acetate gives the product 2,4-dinitrophenolate ion (second curve from the top), and phenyl acetate gives the product phenolate ion (bottom curve). For each of these acetates there also seems to be a similar change in rate-limiting step. These results reinforce the conclusion that a change in rate-limiting step is occurring.

There are nucleophilic substitutions at acyl groups, however, that do not seem to have a tetrahedral intermediate in their mechanism. Evidence for the lack of a tetrahedral intermediate also comes from Brønsted correlations.

In fully associative nucleophilic substitutions in which **both the nucleophile and the leaving group are of the same class of molecules**, at the point that the nucleophile and the leaving group are identical, there should be a change in rate-limiting step as the acidity of the nucleophile is decreased further. In any associative nucleophilic substitution at an acyl group that proceeds through a tetrahedral intermediate, as the acidity of the nucleophile is increased, the rate constant k_{-1} (Equation 1–51) increases. When k_{-1} becomes greater than the rate constant k_2, the rate-limiting step changes from formation of the tetrahedral intermediate to its breakdown. If the leaving group and the nucleophile are both of the same class of compounds—for example, both phenolate ions[143,144] or both pyridines[145]—then the following must be true: As the basicity of the nucleophile is decreased while the leaving group remains unchanged until nucleophile and leaving group are the same molecule, the rate constants k_{-1} and k_2 must become identical because expulsion of the initial nucleophile from the tetrahedral intermediate is chemically identical to expulsion of the initial leaving group. Because the formation of the tetrahedral intermediate and its breakdown are electronically quite different, the rate constant k_1, that for the rate-limiting step when the nucleophile is *more* basic than the leaving group, should have a different dependence on the pK_a of the conjugate acid of the nucleophile than does the rate constant k_2, that for the rate-limiting step when the nucleophile is *less* basic than the leaving group. Consequently, the effect of changing the basicity of the nucleophile on the overall rate of the reaction should be different for nucleophiles of the same class more basic than the leaving group than it is for nucleophiles of the same class less basic than the leaving group.

The rates of nucleophilic substitution of the 4-nitrophenyl group in 4-nitrophenyl acetate by each of a series of phenolate ions were measured. Phenols with values of pK_a both greater than and less than 4-nitrophenol were chosen. The common logarithms of the rate constants for nucleophilic substitutions were plotted as a function of the values of pK_a for phenols that were the conjugate acids of the phenolate ions used as nucleophiles (Figure 1–12).[143]

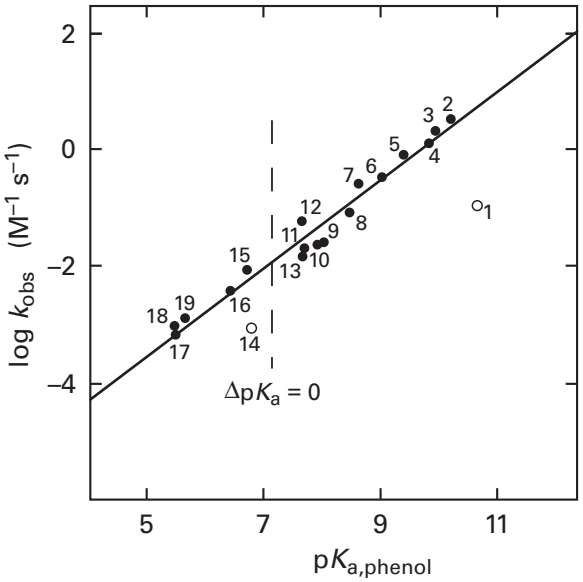

Figure 1–12: Brønsted correlation between rate constants for nucleophilic substitutions of the 4-nitrophenolate ion in 4-nitrophenyl acetate by a series of other phenolate ions.[143] The rate of release of the 4-nitrophenolate ion from 4-nitrophenyl acetate was monitored in water at 25 °C and an ionic strength of 0.1 M by following the increase in absorbance at 400 nm resulting from its production. A buffer strong enough to maintain the pH within 0.02 unit was used in each reaction. The pH chosen was appropriate to the pK_a of the particular phenol being used as the nucleophile. The phenols chosen were (1) 2,6-dimethylphenol; (2) 4-methylphenol; (3) 4-fluorophenol; (4) phenol; (5) 4-chlorophenol; (6) 3-chlorophenol; (7) 3,4-dichlorophenol; (8) 2-chlorophenol; (9) 4-acetylphenol; (10) 4-cyanophenol; (11) 2,3-dichlorophenol; (12) 3,4,5-trichlorophenol; (13) 4-formylphenol; (14) 2,6-dichlorophenol; (15) 2,4,5-trichlorophenol; (16) 2,3,5-trichlorophenol; (17) pentafluorophenol; (18) 2,3,5,6-tetrafluorophenol; and (19) 2,3,4,5-tetrachlorophenol. After the rate of release of 4-nitrophenolate ion resulting from the background hydrolysis of the 4-nitrophenyl acetate was monitored, the nucleophilic phenol was added to the solution to initiate the substitution. The increase in the rate of release of 4-nitrophenolate ion was then measured. It was assumed that the increase in the rate was due to the nucleophilic substitution of 4-nitrophenol by the phenol that had been added to the solution and that the nucleophile responsible for this nucleophilic substitution was the phenolate ion of the phenol that had been added. The phenol was added at a concentration sufficiently in excess of the concentration of 4-nitrophenyl acetate to ensure that its concentration would change insignificantly as the reaction progressed. From the increase in the rate of release of 4-nitrophenolate ion, the concentration of phenol added, and the pH of the solution, a pseudo-first-order rate constant (second^{-1}) could be calculated for the nucleophilic substitution of 4-nitrophenolate ion by the phenolate ion added as the nucleophile. Several different initial concentrations of each phenol were used. From the slope of the line relating the observed pseudo-first-order rate constant to the molar concentration of the nucleophilic phenolate ion, an observed second-order rate constant (k_{obs}; molar^{-1} second^{-1}) for the nucleophilic substitution of 4-nitrophenolate ion by that particular phenolate ion could be calculated. The common logarithm of each second-order rate constant (log k_{obs}) is plotted as a function of the values of the pK_a for the phenol. The slope of the line drawn through the points, β_{nuc}, determined by least-squares numerical analysis, was 0.75. The two points designated with open circles were not included in the analysis. This slope is the Brønsted coefficient for the conjugate acids of the nucleophiles. The vertical dashed line is located at the pK_a of 4-nitrophenol to indicate that the same correlation holds for phenols both more acidic and less acidic than the conjugate acid of the leaving group.

The Brønsted coefficient for the conjugate acids of the nucleophiles, β_{nuc}, which is the slope of the line in Figure 1–12, has a value of 0.75. There is, however, **no change in the slope of the line** as the values of pK_a for the conjugate acids of the phenolate ions used as nucleophiles pass through the point at which they are equal to the pK_a of 4-nitrophenol (pK_a = 7.15). Because there is no evidence for the existence of a tetrahedral intermediate, it was concluded that the nucleophilic substitution of one phenol for another in phenyl acetates proceeds by a concerted nucleophilic substitution with the simultaneous formation of a bond to the nucleophile and disintegration of the bond to the leaving group through a **single transition state**.[143]

Further evidence for this conclusion is that the Brønsted coefficient for the nucleophiles β_{nuc} increases as the pK_a of the leaving group increases and the Brønsted coefficient for the leaving groups, β_{lg}, decreases as the pK_a of the nucleophile increases. These observations imply that the bond to the nucleophile is forming while the bond to the leaving group is breaking in the transition state for the rate-limiting step in the reaction. There is also no change in the Brønsted coefficient for the conjugate acids of the nucleophiles, β_{nuc}, for pyridines reacting with *N*-methoxycarbonylisoquinolium ion[145] as well as for phenols reacting with several phenyl formates,[144] acyl derivatives that should form even more stable tetrahedral intermediates.

Because it was the pronounced break in the plot of the rate constants as a function of the pK_a of the nucleophile for associative nucleophilic substitutions of the 4-nitrophenyl group in 4-nitrophenyl acetate by a series of thiolate ions (Equation 1–50) that indicated the existence of two transition states and a tetrahedral intermediate in each of these reactions (Figure 1–11), the failure to observe the effect of a change in rate-limiting step suggests that, **in these nucleophilic substitutions at an acyl group, no tetrahedral intermediate is formed**.

Kinetic isotope effects also indicate that the bond to the leaving group in this class of nucleophilic substitutions is breaking in the transition

state. In 4-nitrophenyl acetate, the rate of nucleophilic substitution should decrease when the nitrogen-14 atom of the nitro group is replaced by nitrogen-15 if the bond between the 4-nitrophenol and the acyl carbon is breaking in the transition state. That the rate does decrease (by 0.1% ± 0.02%) when phenolate is the nucleophile but does not decrease significantly (0.02% ± 0.01%) when hydroxide is the nucleophile is evidence that a tetrahedral intermediate exists in the latter reaction but not in the former.[146]

The foregoing considerations provide an introduction into **a more comprehensive use of free energy correlations to examine the structures of transition states**. Consider the following coefficients. A Brønsted coefficient for a correlation of any set of rate constants

$$\beta_{rc} = -\frac{d \ln k}{d \ln K_a} \qquad (1\text{–}52)$$

A Brønsted coefficient for a correlation of any set of equilibrium constants

$$\beta_{eq} = -\frac{d \ln K_{eq}}{d \ln K_a} \qquad (1\text{–}53)$$

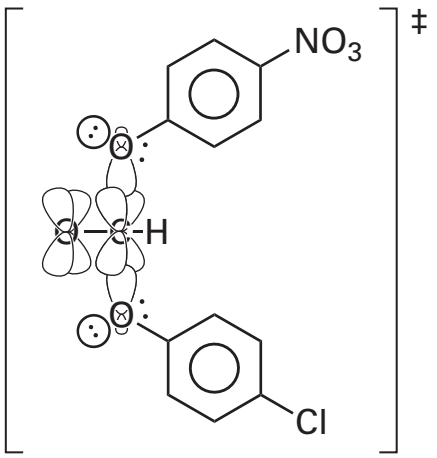
A Leffler coefficient

$$\alpha \equiv \frac{d \ln k}{d \ln K_{eq}} = \frac{\beta_{rc}}{\beta_{eq}} \qquad (1\text{–}54)$$

A **Leffler coefficient** correlates changes in the standard free energy of activation of a reaction with changes in the standard free energy of the reaction itself.[147] It differs from a Brønsted coefficient in that the reference reaction is not the acid dissociation of a participant but the reaction being monitored itself. As such, a Leffler coefficient is considered to be a more reliable measure of the fraction that the bond to the nucleophile has formed in the transition state when the values of K_a in the two Brønsted correlations (Equations 1–52 and 1–53) are for the conjugate acids of the nucleophiles. A Leffler coefficient is also considered to be a more reliable measure of the fraction that the bond to the leaving group has broken in the transition state when the values of K_a in the two Brønsted correlations are for the conjugate acids of the leaving groups. There is, however, some ambiguity when the Leffler coefficient is equated with the degree to which a bond is broken in the transition state because the Leffler coefficient actually measures the degree to which negative charge has accumulated on the heteroatom of the leaving group in the transition state or the degree to which the negative charge of the nucleophile has diminished on the heteroatom of the nucleophile in the transition state.[148]

For nucleophilic substitution of the 4-nitrophenyl group in 4-nitrophenyl acetate by the series of phenols shown in Figure 1–12, the Brønsted coefficient for the correlation between values of K_a for the conjugate acid of the nucleophile and equilibrium constants[143,149] for the nucleophilic substitutions, $\beta_{eq,nuc}$, is 1.7; and the Brønsted coefficient for the correlation between the values of K_a for the conjugate acids of the nucleophiles and the observed rate constants for the nucleophilic substitutions, β_{nuc}, is 0.75. Consequently the Leffler coefficient for the series of nucleophiles, α_{nuc}, is 0.44. This Leffler coefficient implies that the bond to the nucleophile is only about one-half formed in the transition state, if the reaction actually is a concerted nucleophilic substitution at the acyl group.

For the nucleophilic substitution of one phenol for another at a formyl group, a Brønsted coefficient β_{nuc} of 0.4 to 0.6 and a Brønsted coefficient β_{lg} of –0.3 to –0.5 suggest that formation of the bond to the nucleophile and disintegration of the bond to the leaving group proceed in parallel. These values also suggest that, in the transition state, the oxygen of the entering nucleophile and the oxygen of the leaving group form roughly equivalent partial bonds with the formyl carbon.[144]



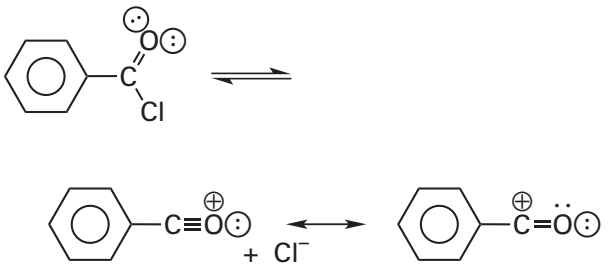
1–50

In the **molecular orbital system of the transition state**, formed from one atomic orbital from each of the two phenolate oxygens, two *p* orbitals from the electrophilic carbon, and two *p* orbitals from the

acyl oxygen, there are six molecular orbitals and eight electrons.

As in any nucleophilic substitution, in the nucleophilic substitution at an acyl group, the σ bond to the leaving group is broken and a σ bond to the nucleophile is formed. Again, it is a matter of timing. If the σ bond to the nucleophile is formed completely before the σ bond to the leaving group begins to break, a tetrahedral intermediate, the homologue of the various products of addition to a carbonyl group (Table 1–1), is produced. This formation of a tetrahedral intermediate is what happens in most nucleophilic substitutions at an acyl group, such as the associative nucleophilic substitution of a 4-nitrophenyl group by a thiolate (Equation 1–50 and Figure 1–11). If the σ bond to the leaving group is breaking in concert with formation of the σ bond to the nucleophile, the nucleophilic substitution is concerted and proceeds through a single transition state with no intermediate just as the concerted nucleophilic substitution at the methyl group of *S*-adenosyl-L-methionine does (Equation 1–19). The concerted formation of the bonds is what happens in the substitution of a phenyl group by another phenyl group in phenyl formates (**1–50**). If the bond to the leaving group breaks before the bond to nucleophile begins to form, an intermediate homologous to a carbenium ion (Equation 1–21) or oxocarbenium ion (**1–8**) forms.

It is when the conjugate acid of the leaving group has a low pK_a that this last possibility is realized. Nucleophilic substitutions at acyl triflates,[150] acyl halides,[151-154] and hindered acyl groups, such as in 2,4,6-trimethylbenzoates,[155] can proceed through **acylium ions as intermediates in dissociative nucleophilic substitutions**



(1–55)

As with any other type of nucleophilic substitution, each nucleophilic substitution at an acyl group falls at a particular point in a continuous spectrum of mechanism. As with a nucleophilic substitution at a tetrahedral, saturated carbon, this spectrum of mechanism can be appreciated by examining a **three-dimensional surface of potential energy** (Figure 1–4). Again, the first coordinate is the distance between the atom of the leaving group and the electrophilic carbon, the second coordinate is the distance between the nucleophilic atom and the electrophilic carbon, and the third coordinate is the potential energy of the system for the point defined by the first and second coordinates.

In the case of a nucleophilic substitution at an acyl group, however, unlike the situation in a simple nucleophilic substitution at a tetrahedral carbon, there is a significant well of potential energy in the **lower left corner**, rather than a mountain of potential energy as in Figure 1–4, because this is the position of the tetrahedral intermediate, in which the carbon is tetravalent, rather than the forbidden pentavalent carbon. The intermediate in a nucleophilic substitution at an acyl group can be tetravalent because the initial electrophile is only trivalent. If the tetrahedral intermediate is the most stable of all the possibilities, there will be two cols of potential energy: one between the reactants and the tetrahedral intermediate and the other between the tetrahedral intermediate and the products.

The **upper right corner** in the three-dimensional surface of potential energy for the nucleophilic substitution at an acyl carbon is the location of the acylium ion, homologous to a carbenium ion or oxocarbenium ion that occupies the upper right corner in a simple nucleophilic substitution. If the acylium ion is the most stable of all the possibilities, as in the organic reactions just discussed that have an acylium ion as an intermediate, there will again be two cols of potential energy: one between the reactants and the acylium ion and the other between the acylium ion and the products, just as is the case when there is a carbenium ion or oxocarbenium ion as an intermediate (Figure 1–4A).

There is, however, always the possibility in a nucleophilic substitution at an acyl group that there is a col of potential energy that occurs when the bond between the nucleophile and the electrophilic carbon is partially formed while the bond between the electrophilic carbon and the leaving group is partially broken and that there is no tetrahedral intermediate nor the creation of a full positive elementary charge on the acyl group in the single transition state.[76] Such nucleophilic substitutions at an acyl group are **concerted nucleophilic substitutions**, just as is the case in a concerted nucleophilic substitution at a saturated carbon (Figure 1–4B).

The properties that determine the position of the transition state or the transition states for a particular nucleophilic substitution at an acyl group on the surface of potential energy are most readily appreciated by considering the **nucleophilic substitutions in which nucleophile and leaving group are identical**:[76] for example, both the same phenol or both the same alcohol. In addition to emphasizing the fact that the leaving group and the nucleophile interchange roles in the reverse reaction, such an identity reaction permits one to focus on only one pK_a, which is the same for the conjugate acid of both the nucleophile and the leaving group.

The effect of the pK_a of nucleophile and leaving group on the rates of such identity reactions with phenyl acetates suggests that when the leaving group and the nucleophile have a pK_a of 7, formation of the bond to nucleophile and disintegration of the bond to leaving group are fully coupled. In this instance, **the poor nucleophile and the poor leaving group** favor a concerted substitution with no intermediate and a single transition state. As the leaving group and nucleophile together become more basic, **the nucleophile becomes stronger and the leaving group becomes poorer**, and formation of the bond to the nucleophile precedes more and more the disintegration of the bond to the leaving group until it precedes it completely and the nucleophilic substitution is associative and proceeds through a tetrahedral intermediate. The combination of a strong nucleophile and a poor leaving group favors a tetrahedral intermediate. As the conjugate acids of the leaving group and the nucleophile in an identity reaction become more acidic, **the nucleophile becomes weaker and the leaving group becomes more able**, and formation of the bond to the nucleophile lags more and more behind the disintegration of the bond to the leaving group until it lags behind it completely and the reaction proceeds through an acylium ion. A weak nucleophile and good leaving group favor an acylium ion as an intermediate.

The same considerations apply to any nucleophilic substitution. The existence of an intermediate carbenium ion, oxocarbenium ion, or acylium ion in a dissociative nucleophilic substitution is more likely when the conjugate acid of the leaving group has a low pK_a and the conjugate acid of the nucleophile also has a low pK_a. The existence of a concerted nucleophilic substitution with a single transition state is more likely when the conjugate acid of the leaving group has an intermediate pK_a and the conjugate acid of the nucleophile also has an intermediate pK_a. When the conjugate acid of the leaving group has a high pK_a and the conjugate acid of the nucleophile also has a high pK_a, a nucleophilic substitution at an acyl group will proceed through a tetrahedral intermediate, but a nucleophilic substitution at a saturated carbon cannot proceed through a pentavalent intermediate and must still proceed through a concerted nucleophilic substitution. There is, however, one other consideration.

In solution, in cases of catalysis resulting from the hydronation of leaving groups, hydronating the acyl oxygen, or dehydronating nucleophiles, the catalytic acid and the catalytic base or the several catalytic acids and catalytic bases have to be supplied simultaneously to the single transition state for a concerted nucleophilic substitution at an acyl group. These participations of catalytic acids and catalytic bases, however, can be divided between the two transition states of an associative nucleophilic substitution with a tetrahedral intermediate. Catalysis increasing the nucleophilicity of the nucleophile and the electrophilicity of the acyl carbon can be supplied during the formation of the tetrahedral intermediate, and catalysis increasing the ability of the leaving group can be supplied during the dissociation of the tetrahedral intermediate. This division of labor is one of the reasons that a nucleophilic substitution at an acyl group under acid–base catalysis usually proceeds through a tetrahedral intermediate in solution. This division of requirements between two transition states, however, is unnecessary **in the active site of an enzyme** because the catalytic acids and bases are assembled and positioned in their proper places before the chemistry begins. In the active site of an enzyme, where catalytic acids and bases are pre-positioned to improve dramatically the ability of the leaving group and the nucleophilicity of the nucleophile, a reaction coordinate for a concerted nucleophilic substitution at an acyl group with a single transition state that passes somewhere on the surface of potential energy between a tetrahedral intermediate and an acylium ion is a reasonable possibility.

In none of the nucleophilic substitutions at acyl groups catalyzed by enzymes, however, is there yet any evidence for such a concerted mechanism, and even in the absence of any evidence, a nucleophilic substitution at an acyl group on an

Table 1–3: Standard Free Energies of Hydrolysis of Selected Acyl Derivatives at 25 °C[a]

acyl derivative[b]	ΔG°_{hydro} (kJ mol^{-1})	pK_a of conjugate acid of the leaving group

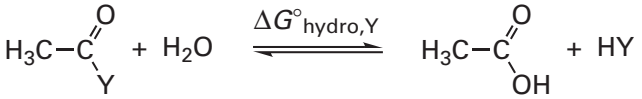
[b]Based on a pK_a of inorganic phosphate of 7.2 and of an acyl phosphate of 6.2. Value for the monoanions of acetyl phosphate and phosphate. [c]Value for the dianions of acetyl phosphate and phosphate.

enzymatic active site is usually assumed to be associative and to pass through a tetrahedral intermediate. If the pK_a of the conjugate acid of the leaving group is high and that of the conjugate acid of the nucleophile is high, the reaction will certainly proceed through a tetrahedral intermediate. When, however, the biochemical leaving group and the biochemical nucleophile each have a conjugate acid with a low pK_a, the possibility of a concerted mechanism, or even an intermediate acylium ion, should be considered for the enzymatic reaction.

Biochemically relevant acyl derivatives can be arranged in order of their standard free energies of hydrolysis, ΔG°_{hydro} (Table 1–3).[156] These are the changes in standard free energy* for the reaction



(1–56)

Water acts as a reference nucleophile, permitting the various acyl derivatives to be placed on the same scale of stability.

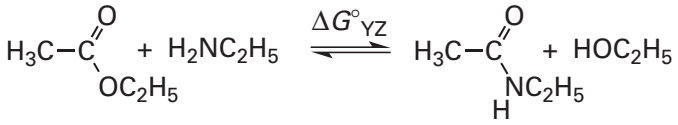
The **change in standard free energy of any particular nucleophilic substitution** at an acyl group

(1–57)

can be estimated by taking differences between the two values for the two relevant standard free energies of hydrolysis

$$\Delta G^\circ_{YZ} = \Delta G^\circ_{hydro,Y} - \Delta G^\circ_{hydro,Z} \qquad (1–58)$$

For example, the change in standard free energy for the aminolysis of an ester



(1–59)

a reaction resembling the formation of a peptide bond during protein synthesis,† should be –41 kJ mol^{-1}.

*See footnote to Table 1–2 on the decision to omit the concentration of water.

†The standard free energy for the dehydronation of ethylamine has to be included when the aminolysis of the ester occurs at a pH less than 11.

When the nucleophilic substitutions of imidates are being considered

(1–60)

the same scale of standard free energies of hydrolysis can be used to estimate roughly the standard change in free energy for the reaction. Consistent with Equation 1–58, the nucleophilic substitutions commonly observed are those that convert an acyl derivative with a more negative standard free energy of hydrolysis into one with a less negative standard free energy of hydrolysis.

The heteroatomic nucleophiles and leaving groups in biochemical nucleophilic substitutions at acyl groups are usually amines, pyridines, phosphates, phenolate ions, alcohols, thiolate ions, enolates, and enamines. For these nucleophiles and leaving groups, **as the leaving groups become stronger bases and their conjugate acids become weaker acids, the standard free energies of hydrolysis increase** (Table 1–3). The acidity of the parent acid of the acyl derivative, however, has much less of an effect, if any.[157]

The dissociation of the leaving group from an acyl carbon resembles its dissociation from a hydron. The equation for the hydrolysis used as the reference (Equation 1–56), however, formally involves the subsequent hydronation of the leaving group. Therefore, the tabulated standard free energies of hydrolysis are actually correlated to the standard free energy for transfer of the leaving group from an acyl carbon to a hydron. If a hydron and an acyl carbon were electrophilically equivalent to each other, there would be no dependence of the standard free energy of hydrolysis on the values of pK_a for the conjugate acids of the leaving groups, and yet there is. For example, within a series of oxygen esters, the equilibrium constant for Equation 1–56, $K_{eq,hydro}$, is correlated to the respective acid dissociation constants of the alcohols that leave (Figure 1–13)[149] by the equation

$$\log K_{eq,hydro} = A + \beta_{eq,lg}\, pK_a \qquad (1–61)$$

where the Brønsted coefficient $\beta_{eq,lg}$ is –0.70.[149] For thioesters, $\beta_{eq,lg}$ is –0.38,[141] and for amides, it is –0.51.[157]

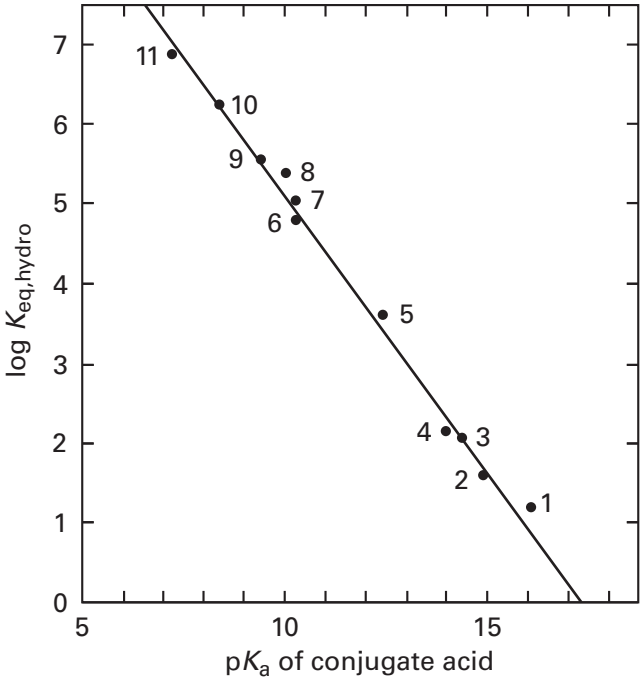


Figure 1–13: Brønsted correlation of the equilibrium constants, $K_{eq,hydro}$, for the hydrolysis of the respective acetate esters of a series of alcohols and phenols with the pK_a of the alcohol or phenol.[149] The esters were (1) ethyl acetate; (2) 2-methoxyethyl acetate; (3) chloroethyl acetate; (4) acetylcholine; (5) trifluoroethyl acetate; (6) 4-methoxyphenyl acetate; (7) 4-methylphenyl acetate; (8) phenyl acetate; (9) 4-chlorophenyl acetate; (10) 3-nitrophenyl acetate; and (11) 4-nitrophenyl acetate. The values for the equilibrium constants were for uncharged reactants, ester and water, and uncharged products, carboxylic acid and alcohol (Equation 1–56). The concentration of water was omitted from the equilibrium constants. The equilibrium constants are plotted as a function of the values for pK_a. The slope of the line drawn through the points (Equation 1–61), which is the Brønsted coefficient for the conjugate acids of the leaving groups, $\beta_{eq,lg}$, is –0.70.

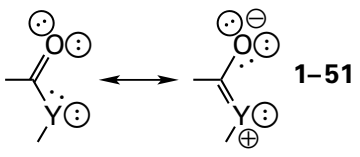
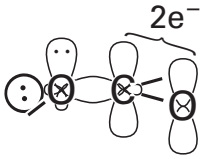
These negative values mean that as the pK_a increases and the conjugate acid of the leaving group becomes less acidic so that the leaving group becomes more basic, the equilibrium constant for hydrolysis of the respective acyl derivative becomes smaller and the standard free energy of hydrolysis becomes more positive. If this is the case, as the leaving group becomes more basic, and more electron-releasing, the acyl derivative of the leaving group becomes more stable, relative to the conjugate acid of the leaving group. This increased stability is almost certainly due to the increasing **ability of the leaving group to conjugate with the carbonyl**



1–51

an ability that increases the stability of the acyl group. This opportunity for conjugation is not available in its conjugate acid, where the leaving group is attached only to a hydron.

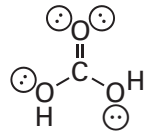
Consider an ester, in which the atom bound to the acyl carbon is the oxygen of the leaving group. As the leaving group, RO–, becomes more basic, the electron density in the σ bond between the acyl carbon and the oxygen of the leaving group increases, just as the electron density in the oxygen–hydrogen bond of the alcohol increases, but so does the electron density in the two lone pairs of electrons on the oxygen of the leaving group



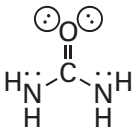
1–52

Either one of these lone pairs of electrons can **overlap with the π molecular orbital system between the acyl carbon and the acyl oxygen**, and this overlap also increases the strength of the bond between the acyl carbon and the acyl oxygen.[158] Such overlap, however, is not possible with a hydron. This presence or absence of overlap explains why the free energies of hydrolysis for oxygen esters increase more rapidly than do the free energies for acid dissociation of their leaving groups, and it also explains why the Brønsted coefficient $\beta_{eq,lg}$ for the hydrolysis of oxygen esters is more negative than that for thioesters. A σ lone pair of electrons on a sulfur overlaps poorly with a *p* orbital on a carbon.

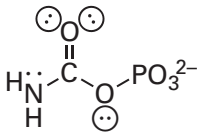
When all four of the bonds to a carbon, single bonds or double bonds, are to heteroatoms, that carbon is in a derivative of carbonic acid (1–53).



1–53

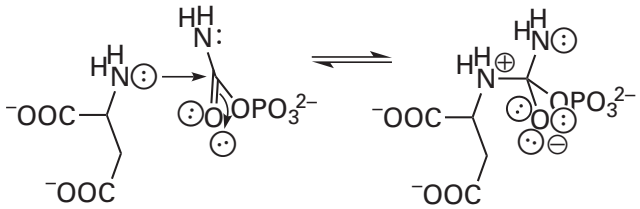


1–54

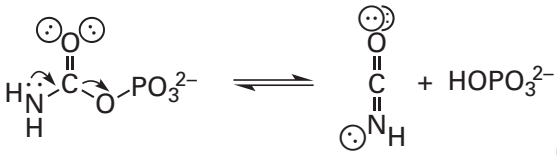


1–55

Examples of such carbons that are of biochemical importance are those in urea (**1–54**), carbamoyl phosphate (**1–55**), and an *N*-alkylguanidinium ion. In the nucleophilic substitutions of derivatives of carbonic acid, the same considerations apply as for nucleophilic substitutions at an acyl group. For example, in nucleophilic substitution at carbamoyl phosphate, either a tetrahedral intermediate or the equivalent of an acylium ion is possible[159]



(1–62)



(1–63)

as well as a concerted nucleophilic substitution.

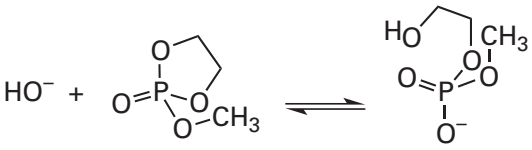
Nucleophilic Substitution at Phosphorus

Derivatives of phosphoric acid are susceptible to nucleophilic substitution at phosphorus[160] just as derivatives of carboxylic acids are susceptible to nucleophilic substitution at carbon. An example of such a nucleophilic substitution at phosphorus would be



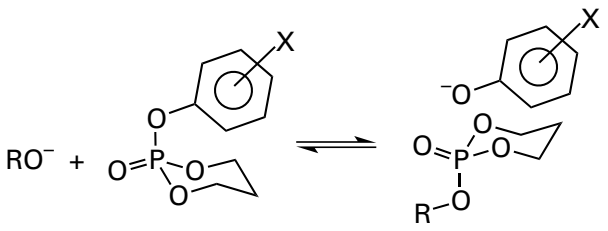
(1–64)

in which the oxygen of hydroxide , the nucleophile, has substituted for one of the two oxygens of the 2-hydroxyethoxy group, the leaving group. The reactant in this reaction is a **phosphotriester**, in which the phosphoric acid has been esterified with

three alcohols. In **phosphodiesters**, such as dinucleotides, the phosphoric acid has been esterified with two alcohols, and in **phosphomonoesters**, such as D-glucose 6-phosphate, the phosphoric acid has been esterified with only one alcohol.

As does nucleophilic substitution at the carbon of an acyl group, nucleophilic substitution at phosphorus includes a continuous **spectrum of mechanism** in which the two dimensions again are the integrity of the bond to the leaving group and the integrity of the bond to the nucleophile. As with nucleophilic substitutions at an acyl group, the two extremes of this spectrum are an **associative nucleophilic substitution,** in which the bond between the nucleophile and the phosphorus has formed completely before the bond to the leaving group begins to break, and a **dissociative nucleophilic substitution,** in which the bond to the leaving group has broken completely before the bond to the nucleophile has begun to form. The former extreme produces a pentavalent intermediate, a pentaoxyphosphorane, while the latter produces a trivalent intermediate, a monomeric metaphosphate. Unlike pentavalent carbon, pentavalent phosphorus can exist both in an intermediate and even in a stable molecule.

The reaction of Equation 1–64 is a nucleophilic substitution at a triester of phosphoric acid. When a series of triesters of phosphoric acid were synthesized with different aryloxy leaving groups and submitted to nucleophilic substitutions with an array of nucleophiles (RO^-)



(1–65)

where X indicates the various substitutions at the phenyl group, a plot of the Brønsted coefficient for the leaving groups against the values of pK_a for the nucleophiles shows a pronounced break at a pK_a of 11.[161] The existence of this break in the secondary Brønsted plot, as well as other characteristics of the reaction, suggests that each of the nucleophilic substitutions of these triesters proceeds through at least two steps with at least one intermediate. The fact that oxygen-18 exchanges into the phospho group of the reactant as a nucleophilic substitution in a triester progresses[162] suggests that the intermediate* in such reactions, in analogy to the tetrahedral intermediate in nucleophilic substitution at an acyl group, is a pentaoxyphosphorane and that these reactions are associative nucleophilic substitutions.[163]

Associative nucleophilic substitutions at phosphorus are reactions that proceed through intermediate pentaoxyphosphoranes. Phosphoranes are compounds in which a central phosphorus atom has five substituents. There are pentaoxyphosphoranes that can exist as stable compounds. Simple acyclic examples of stable pentaoxyphosphoranes would be pentaphenoxyphosphorane[164] and pentacyclohexyloxyphosphorane (Figure 1–14A).[165,166] These two molecules are stable, just as an ortho ester of a carboxylic acid is stable, because none of the oxygens can become anionic, increasing the electron repulsion around the phosphorus and, in turn, pushing out one of the phenols or one of the cyclohexanols. The structure of a pentaoxyphosphorane is a **trigonal bipyramid** (Figure 1–14A). Even though all five of the substituents are identical, they are not distributed in such a way that all the angles between the bonds are the same, as they are in a tetrahedral carbon like an ortho ester; this fact indicates that the hybridization of the atomic orbitals on phosphorus controls the structure. In a trigonal bipyramid, three of the substituents lie in a plane containing the central atom at ideally 120° angles to each other (the three horizontal oxygens in Figure 1–14A). These substituents are designated **equatorial**. Two of the substituents are located above and below the plane, respectively, on a line (vertical in Figure 1–14A) passing through the phosphorus and perpendicular to the plane. These substituents are designated **apical**. The angles between each of the equatorial oxygens and each of the apical oxygens are all ideally 90°. The ideal equatorial and apical angles are altered somewhat by steric effects in an actual pentaoxyphosphorane.

The **hybridization of the atomic orbitals** that overlap to form the bonds in a pentaoxyphosphorane can be inferred from its bond angles. The bond angles between the equatorial oxygens are those expected if the central phosphorus in a pentaoxyphosphorane has sp^2 hybridization and each of its sp^2 orbitals participates in a σ bond to one of the three equatorial oxygens.

*Strictly speaking, the intermediate that is responsible for the isotopic exchange could be in a side reaction that is not on the reaction pathway for the hydrolysis.

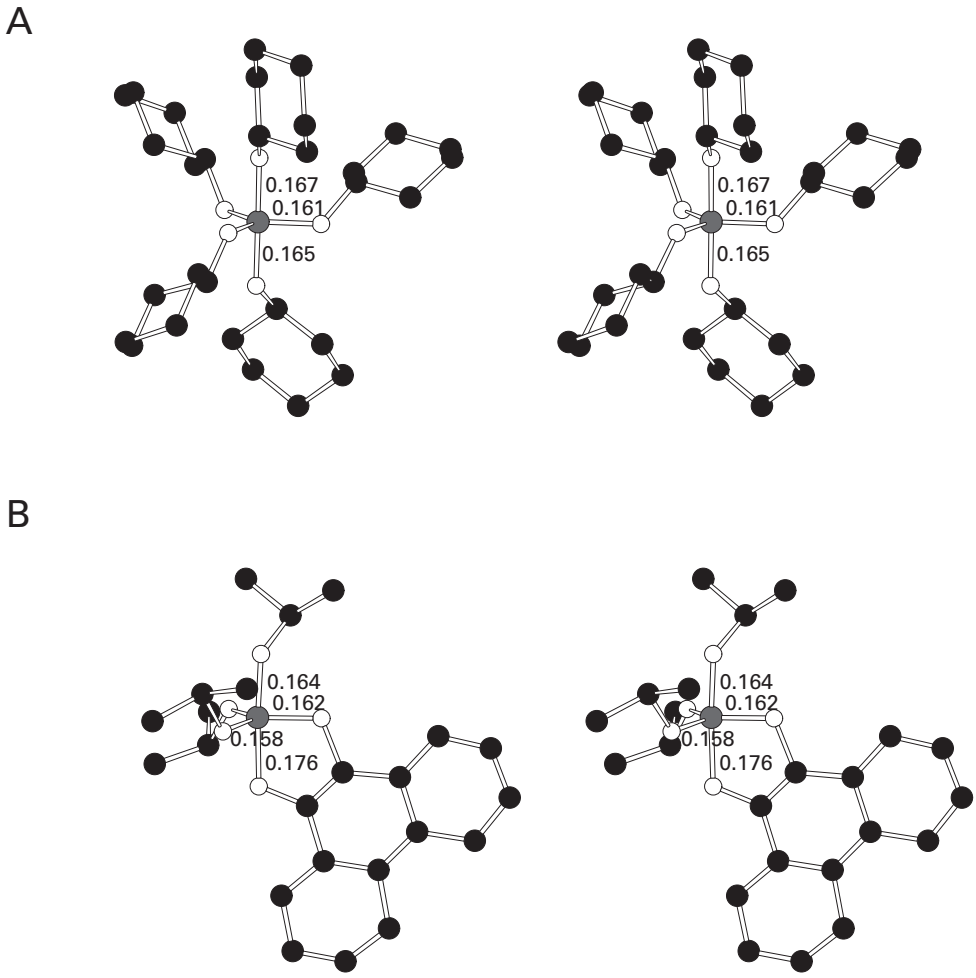


Figure 1–14: Stereodrawings[166] of the arrangement of the five oxygen atoms and the substituents attached to them around the pentavalent phosphorus in crystallographic molecular models of two pentaoxyphosphoranes. Black atoms are carbons, white atoms are oxygens, and the large gray atom is a phosphorus. **(A)** Crystallographic molecular model of pentacyclohexyloxyphosphorane.[165] Pentacyclohexyloxyphosphorane was synthesized by mixing tricyclohexyl phosphite and cyclohexyl benzenesulfenate in pentane at –78 °C. In the crystallographic molecular model, the phosphorus atom lies at the intersection of the five bonds between it and the five oxygen atoms of the cyclohexyloxy groups. Three of the oxygens are in the same plane at the equatorial positions, and the other two oxygens are on a line of centers with the phosphorus at the apical positions. The angles between the equatorial oxygens are almost ideal (120°, 124°, and 116°) and the angles between each equatorial oxygen and the two apical oxygens are also almost ideal (88°, 89°, 92°, 90°, 93°, and 88°). Deviations from the ideal result from the steric effects of the bulky cyclohexyl groups. The bond lengths between the phosphorus and the equatorial oxygens are 0.161, 0.161, and 0.160 nm. The bond lengths between the apical oxygens and the phosphorus are indicated in the drawing (in nanometers). That the apical bonds are longer suggests that they are weaker than the bonds to the equatorial oxygens. The bond angles at the oxygens between carbon 1 of a cyclohexyl group and the phosphorus are 124°,127°, 128°, 128°, and 130°; these angles suggest that the oxygens are all hybridized sp^2. **(B)** Crystallographic molecular model of (9,10-phenanthroquinolyl)triisopropylpentaoxyphosphorane, the adduct that forms between triisopropyl phosphite and 9,10-phenanthroquinone.[174] The phosphorus atom lies at the intersection of the five bonds between it and the five oxygen atoms at the center of a "near [sic] perfect trigonal bipyramid". The angles between the equatorial oxygens are almost ideal (118°, 120°, and 121°) and the angles between each equatorial oxygen and the two apical oxygens are also almost ideal (97°, 85°, 92°, 91°, 87°, and 89°). Within the five-membered ring, the two oxygens from the 9,10-phenanthroquinolyl group occupy one equatorial and one apical position of the trigonal bipyramid, respectively, as expected when there is a five-membered ring, and the other three positions are occupied by the oxygens of the isopropoxy groups. The bond angles at the oxygens between the two carbons of the 9,10-phenanthroquinolyl group and the phosphorus are 113° and 112°, and the angle at the phosphorus between the two oxygens of the 9,10-phenanthroquinolyl group is 89°, so the five-membered ring is distorted to ensure an angle of almost exactly 90° at phosphorus. Four of the bond lengths (in nanometers) are noted in the drawing, and the bond length of the other equatorial phosphorus–oxygen bond is 0.161 nm. The bond angles at the three oxygens of the isopropoxy groups between the carbons and the phosphorus are 126°, 132°, and 127°, these angles again suggest that these oxygens are all hybridized sp^2.

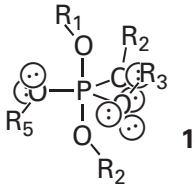
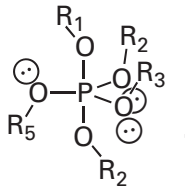
The hybridization of these equatorial oxygens, however, is not so simple. On the one hand, in a calculated structure of pentahydroxyphosphorane,[167] a molecule that for obvious reasons has never been observed, the bond angle at each equatorial oxygen between the phosphorus and the hydrogen is about 110° and the dihedral angle for the hydrogen along a bond between the phosphorus and an equatorial oxygen is around 30°. These angles suggest that, in a normal, unhindered pentaoxyphosphorane,* the three equatorial oxygens have sp^3 hybridization with the usual σ lone pairs and covalent bonds to peripheral substituents



1–56

where the peripheral substituents (R_1–R_5) are either alkyl groups or hydrogens. A dihedral angle of 30°, because it places the two sp^3 lone pairs and the σ bond to the substituent at an equatorial oxygen as far away from the electrons in the two apical bonds as possible, engenders the least electron repulsion. On the other hand, in pentacyclohexyloxyphosphorane the bond angle at each equatorial oxygen between the phosphorus and the cyclohexyl carbon is about 120° (Figure 1–14A).[165] This angle suggests that, in a normal, unhindered pentaoxyphosphorane, the three equatorial oxygens could have sp^2 hybridization with the usual σ lone pairs and covalent bonds to peripheral substituents

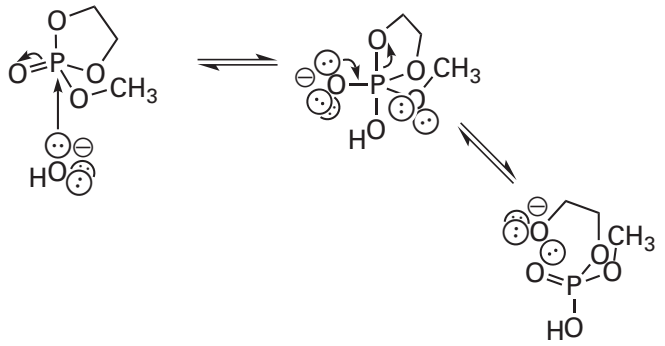


1–57

The bond angles in pentacyclohexyloxyphosphorane, however, could result from steric effects rather than electronic effects. The pK_a of an equatorial hydroxy group in a pentaoxyphosphorane[165] has been estimated to be about 9, which would also be consistent with the equatorial oxygens being hybridized sp^2 because sp^2 hydroxy groups are always more acidic than sp^3 hydroxy groups.

The bonding of the two apical oxygens has not been explained unequivocally, and it probably does not involve simple two-center covalent bonds.[168-172] The *p* orbital on the phosphorus and one sp^3 orbital[167] or one sp^2 orbital[165] from each of the two apical oxygens mix together, by themselves or perhaps with *d* orbitals from the phosphorus and another orbital from each oxygen, to produce the bonding that connects those apical oxygens to phosphorus. The pK_a of an apical hydroxy group[165] has been estimated to be 14, perhaps coincidentally about the same as a normal hydroxy group on carbon.

In an associative nucleophilic substitution at phosphorus that proceeds through a pentaoxyphosphorane, the five oxygens are not equivalent as they are in pentacyclohexyloxyphosphorane or pentaphenoxyphosphorane. The intermediate pentaoxyphosphorane is formed by attack of the nucleophile on the electrophilic phosphorus atom. That attack pushes electron density onto the unsubstituted oxygen or the unsubstituted oxygens of the phospho group



(1–66)

as the addition of a nucleophile to an acyl group pushes electron density onto the former acyl oxygen. Each unalkylated oxygen in the resulting pentaoxyphosphorane is either hydronated and is a hydroxy group or is unhydronated, bears a net negative elementary charge, and is an oxyanion. At neutral pH, each unalkylated equatorial hydroxy group (p$K_a \cong 9$) would be hydronated and only one will be transiently unhydronated and negatively charged at a time. An unhydronated, equatorial oxygen with a negative elementary charge in a pentaoxyphosphorane has a lone pair of electrons, in either an sp^3 orbital or an sp^2 orbital, that can provide **periplanar push to assist in the dissociation of a leaving group** from the phosphorus in the second step of

*If pentacyclohexyloxyphosphorane represents the actual structure of a pentaoxyphosphorane when it is unhindered by the cyclohexyl groups, then the sp^2 lone pair of electrons on each equatorial oxygen would be held by the bonding in the molecule in a periplanar orientation (Figure 1–14A).

the nucleophilic substitution (Equation 1–66). This push, which is essentially inescapable because of the relatively low pK_a of an equatorial oxygen, explains the kinetic instability of a pentaoxyphosphorane that is not completely alkylated.

In associative nucleophilic substitutions at phosphorus involving a pentaoxyphosphorane as an intermediate, the **rule of apical entry and apical exit** provides the best explanation of the observed reactivity.[173] The nucleophile must enter the phospho group at a location that becomes an apical position of the pentaoxyphosphorane, and the leaving group must leave from an apical position of the pentaoxyphosphorane (Equation 1–66). The reason for apical entry is that, to avoid electron repulsion, the lone pair of electrons of the nucleophile must approach the phosphorus atom of the phospho group in one of the four cavities below the faces of the tetrahedron each of which is formed by three of its σ bonds, just as, again to avoid electron repulsion, the nucleophile approaches the electrophilic carbon from the cavity formed by three of the σ bonds in a concerted nucleophilic substitution (Equation 1–19 and **1–5**). Because of the electron repulsion of these three σ bonds between phosphorus and oxygen, the nucleophile has to approach on a trajectory bisecting the three σ bond angles and in line with the fourth σ bond to phosphorus in the tetrahedral phospho group. In the resulting pentaoxyphosphorane, the three substituents pushed forward by the nucleophile end up in the three equatorial positions, the nucleophile ends up at one apical position, and the fourth substituent, the one in line with the nucleophile, ends up at the other apical position (Equation 1–66). That apical entry dictates apical exit follows from microscopic reversibility.

A **second rule**[165,173,174] is that in a five-membered cyclic phosphorane, such as the one in Equation 1–66, **one oxygen in the ring must be equatorial and the other oxygen must be apical** (Figure 1–14B).* This rule follows from the fact that a transition state that would lead to both of the oxygens in the ring being at equatorial positions is more sterically unstable than a transition state that leads to one of the oxygens of the ring being equatorial and the other being apical. The reason this is so is that the interior angles in a regular pentagon are all 72°, which is closer to 90° than 120°. Consequently, in the production of such an intermediate pentaoxyphorane from a five-membered cyclic phosphodiester or phosphotriester, the nucleophile adds to the phosphorus from a direction opposite to one of the oxygens in the ring so that that oxygen ends up in the other apical position, as shown in Equation 1–66.

The crystallographic molecular models of the phosphoranes in Figure 1–14 are for the more biochemically relevant case of phosphorus surrounded by five oxygens, but the most commonly encountered pentavalent compounds of phosphorus are its fluoride and its chloride. Phosphorus pentafluoride has the infrared spectrum of a trigonal bipyramid[177] but the fluorines all have equivalent absorptions in nuclear magnetic resonance spectra. It has been proposed that the five fluorines remain apical and equatorial, respectively, on the time scale of infrared spectroscopy but equilibrate among the apical and equatorial positions of the trigonal bipyramid over the much longer time scale of nuclear magnetic resonance.[178]

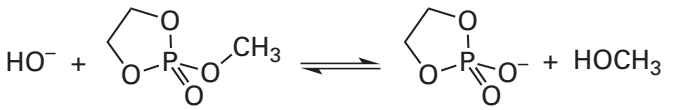
The motion in a trigonal bipyramid that accomplishes this equilibration between apical and equatorial positions most efficiently is a **pseudorotation**.[178] One of the pseudorotations available to the trigonal bipyramid of Figure 1–14B would move the equatorial oxygen on the left front backward horizontally into the plane of the page to fall in line with the equatorial oxygen to the right so that these two oxygens become the new apical oxygens while moving the two apical oxygens forward and moving the equatorial oxygen on the back left horizontally back and to the right to form a new plane of three equatorial oxygens.

In instances where **pseudorotation is slower than the entry and exit of nucleophile** and leaving group, the nucleophile in an associative nucleophilic substitution at a phospho group enters the pentaoxyphosphorane at an apical position, and the leaving group is determined only by the direction from which the nucleophile attacked the phosphorus because the leaving group is required to be the substituent that occupies the other apical position, opposite to the point of entry of the nucleophile. There would be three ways to **control the identity of the leaving group**. First, if the nucleophile is forced to enter at only one of the four available points of entry on phosphorus, the leaving group will always be the substituent opposite that point of entry. Such

*The hydrolysis of 2-methoxy-1,3,2-dioxaphospholane 2-oxide (Equation 1–66) is much more rapid (by a factor of 5×10^5) than the hydrolysis of trimethyl phosphate. It was concluded from enthalpies of activation that this increase in rate was due in part to the steric strain destabilizing the cyclic reactant relative to the acyclic reactant but also due to less steric hindrance in the transition state for the formation of the cyclic phosphorane relative to the acyclic phosphorane because the ring ties back the two methylene groups in the cyclic transition state.[175]

stereochemical control is possible in the active site of an enzyme. Second, if only one of the three substituents surrounding the phosphorus in the reactant is a better leaving group than the nucleophile itself, then each intermediate pentaoxyphosphorane in which that substituent is not apical would decompose to regenerate reactants. Third, if all three substituents surrounding the phosphorus in the phosphoester are poorer leaving groups than the nucleophile, the ability of a substituent to leave the intermediate pentaoxyphosphorane can be controlled, as in the situation of nucleophilic substitution at an acyl group (Equation 1–47), by hydronations or dehydronations.

When **pseudorotation in an intermediate pentaoxyphosphorane is fast** enough, however, it can become a third step in the mechanism, between the entry of the nucleophile and the dissociation of the leaving group.[179,180] The products from the reaction of Equation 1–64 are both the one shown, which arises from cleavage of the ring, and the products of exocyclic cleavage

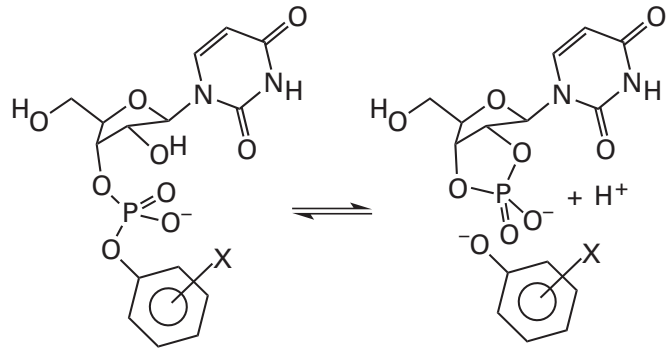


(1–67)

The ratio between these two products varies with pH. If the intermediate is a trigonal bipyramid, and if both the rule of apical entry and apical exit and the rule requiring an apical position of one of the oxygens in a five-membered ring apply, then this variation in the ratio of products can be explained only if pseudorotation occurs in the intermediate pentaoxyphosphorane for this reaction.[181] This additional step and the fact that, as the pH is varied, hydronation of the potential leaving groups varies would permit two or more changes in the rate-limiting steps of the mechanism. Together all these factors can provide an explanation for the rather complex changes with pH in the ratio between the two products (Equations 1–64 and 1–67).

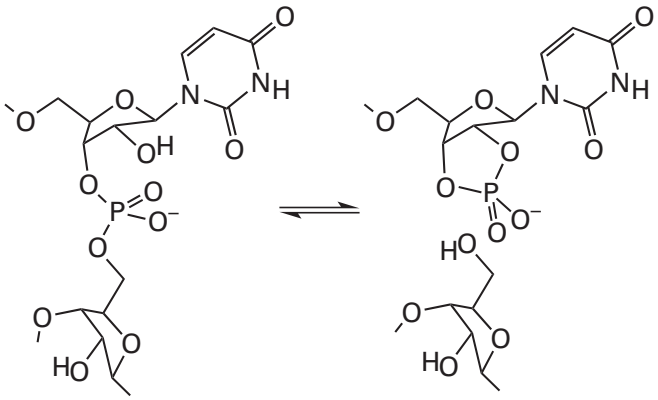
The cyclic phosphotriester that is the reactant in Equation 1–64 is a particularly reactive phosphotriester that has larger than normal rate constants for hydrolysis. In nucleophilic substitutions of less reactive phosphotriesters and phosphodiesters with smaller rate constants for nucleophilic substitution, pseudorotation could easily be so rapid that it would have little or no effect on the overall rate of the reaction. In the particular nucleophilic substitution of Equation 1–64, however, it may be that the saturated five-membered ring in the pentaoxyphosphorane increases the rate of pseudorotation dramatically. If this is so, then in most nucleophilic substitutions at phosphorus pseudorotation is slow relative to entry and exit. These considerations suggest that pseudorotation may or may not be a common feature of nucleophilic substitutions at acyclic phosphoesters.

Just as is the case for nucleophilic substitution at an acyl group (Figure 1–11), observations consistent with the existence of a **change in rate-limiting step** in a nucleophilic substitution at a phospho group is evidence for the existence of an intermediate in the reaction. The intramolecular nucleophilic substitutions of a series of phenolate ions by the 2′-hydroxy group of the uridinyl group in a series of phosphodiesters in solution under catalysis by base[182]



(1–68)

is a model for the cleavage of ribonucleic acid catalyzed by the enzyme ribonuclease



(1–69)

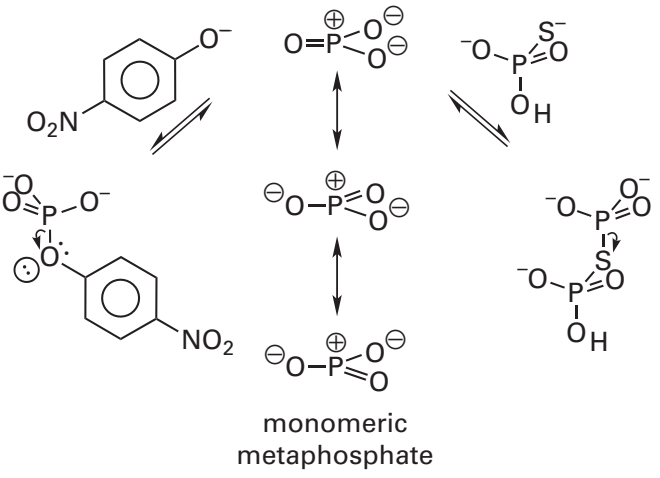
Because there is a pronounced **break in the Brønsted plot** in which the common logarithms of the rate constants for the nucleophilic substitution (Equation 1–68) are plotted against the values of pK_a for the conjugate acids of the phenolates that are the

leaving groups, it was concluded that each of these nucleophilic substitutions at a phosphodiester has an intermediate, presumably the respective pentaoxyphosphorane.[183]

Nucleophilic substitutions at phosphorus in adenosine 3′-phosphate diesters, adenosine 2′-phosphate diesters,[184] and uridine 3′-phosphate diesters under catalysis by acid[185,186] and base,[187] also pass through two transition states[180] with a pentaoxyphosphorane as an intermediate.[179] One piece of evidence for a pentaoxyphosphorane as an intermediate in such nucleophilic substitutions, in which an alcohol is the leaving group rather than phenol, is the effects of the replacement of each of several oxygens-16 with oxygen-18 on the rate of the reaction. Isotopic effects, however, are also consistent with the existence of only a single transition state with significant disintegration of the bond to the leaving group, as in the nucleophilic substitution of 4-nitrophenol by hydroxide in thymidine 5′-(4-nitrophenyl)phosphate.[188]

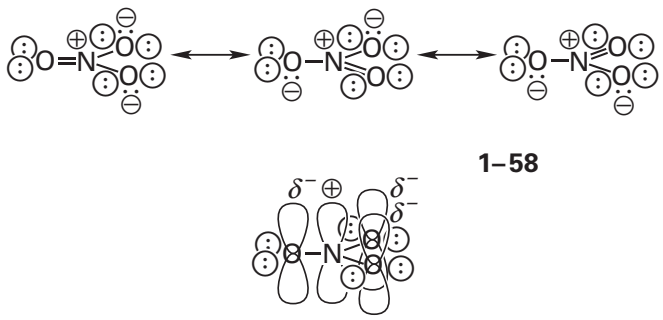
One side product of an associative nucleophilic substitution at phosphorus, homologous to the reaction in Equation 1–69 in which the leaving group is also an alcohol, is the direct transfer of the phospho group from the 3′-hydroxy group to the 2′-hydroxy group in a nucleoside monophosphate.[184-186,189] Because the two oxygens of a five-membered ring in a pentaoxyphosphorane must be apical and equatorial, respectively (Figure 1–14), and because the 2′-hydroxy group must enter the pentaoxyphosphorane at an apical position and the 3′-hydroxy group must leave from an apical position, pseudorotation must occur in this nucleophilic substitution of the 3′-hydroxy group by the 2′-hydroxy group.[179,187]

Dissociative nucleophilic substitutions at phosphorus proceed through intermediate monomeric metaphosphates. The associative nucleophilic substitutions of phosphotriesters, such as that of Equation 1–64, and of phosphodiesters with poor leaving groups, such as that of Equation 1–69, proceed through intermediate pentaoxyphosphoranes. Nucleophilic substitutions, however, of **phosphomonoesters with good leaving groups by poor nucleophiles**, such as the substitution of the 4-nitrophenoxy group in the *O*-phosphomonoester of 4-nitrophenol by the hydroxy group of 2-methylpropan-2-ol[190] or the substitution of the thiophospho group in the *S*-phosphomonoester of thiophosphate by the hydroxy group of water,[191] proceed under appropriate conditions by the initial release of monomeric metaphosphate from *O*-phospho-4-nitrophenol or μ-thiodiphosphate, respectively



(1–70)

Monomeric metaphosphate is a planar molecule in which phosphorus is trivalent and hybridized sp^2 and forms σ bonds to each of the three oxygens (Equation 1–70). The nitrogen homologue of monomeric metaphosphate is nitrate [192]



1–58

In nitrate, a *p* orbital from each of the oxygens and a *p* orbital from the central nitrogen comprise its π molecular orbital system. The four *p* orbitals mix to produce four π molecular orbitals in a trimethylenemethane configuration. Three of these four molecular orbitals are occupied by three pairs of electrons, and one is unoccupied. In monomeric metaphosphate there is a similar **π molecular orbital system** containing three pairs of electrons. The only unoccupied π molecular orbital of monomeric metaphosphate, the π^* molecular orbital, is localized almost exclusively on the phosphorus atom.[193] This unoccupied π molecular orbital overlaps with the atomic orbital occupied by the lone pair of electrons on the nucleophile during addition of the nucleophile to monomeric metaphosphate, just as the electrophilic, unoccupied *p* orbital on the carbon in a carbenium ion overlaps with the occupied orbital

on the nucleophile during the second step in a dissociative nucleophilic substitution at a saturated carbon. By microscopic reversibility, when the leaving group dissociates from the phosphoester, the antibonding molecular orbital of the phosphorus–oxygen bond becomes the unoccupied π^* orbital of the monomeric monophosphate, and the bonding molecular orbital and the two electrons in the phosphorus–oxygen bond become the atomic orbital and the two electrons of the lone pair of electrons of the leaving group.

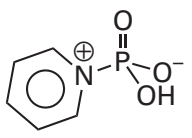
Unlike nitrate , however, which is quite stable, monomeric metaphosphate is so **unstable** that it has never been isolated. Monomeric metaphosphate differs from nitrate because the phosphorus atom in monomeric metaphosphate has *d* orbitals that can overlap with *p* orbitals on the peripheral oxygens. This ***dpπ* overlap** delocalizes pairs of electrons on the oxygens. The pK_a of nitric acid, the conjugate acid of nitrate , is –1.3. The pK_a of the conjugate acid of monomeric metaphosphate should be lower than this because the delocalization of electron density from the oxygens in the monomeric metaphosphate should make them less basic. The pK_a of monomeric metaphosphate in solution has never been measured, but it has been calculated[167] to be around –11.

This calculated pK_a suggests that the neutral, hydronated form of monomeric metaphosphate is even more unstable than the anion. If monomeric metaphosphate had to be anionic to stabilize the electropositive phosphorus, only nucleophilic substitutions at phosphomonoesters could have monomeric metaphosphate as an intermediate. The fact, however, that methyl nitrate is a stable molecule suggests that O-alkylated monomeric metaphosphate might be stable enough to exist. Observations that are consistent with the existence of *O*-methyl monomeric metaphosphate as an intermediate in the solvolysis of a series of α-oxyiminobenzylphosphonate monomethyl esters have been reported.[194] Both of these considerations suggest that ***O*-alkyl monomeric metaphosphate could perhaps be an intermediate in nucleophilic substitutions at phosphodiesters**. An *O,O*-dialkylmetaphosphate, however, is probably so unstable that it is never an intermediate in a nucleophilic substitution at phosphorus. Transition states that resemble an *O,O*-dialkylmetaphosphate are probably also unstable relative to the respective pentaoxyphosphorane. This instability is probably one of the reasons that nucleophilic substitution at the phospho group of a triester usually proceeds through a pentaoxyphosphorane.

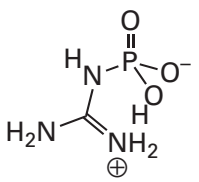
That monomeric metaphosphate exists, and that it is of biochemical relevance, follows from the fact that it has been observed in crystallographic molecular models: one from a crystal of porcine fructose-bisphosphatase that had been soaked in a solution of fructose 6-phosphate and phosphate,[195] as well as one of human fructose-bisphosphatase[196] and one of chloride peroxidase from *Curvularia inaequalis* that also catalyzes the hydrolysis of phosphate monoesters.[197] In the case of porcine fructose-bisphosphatase, the monomeric metaphosphate in the complex crystallized at pH 7 has the oxygen of a molecule of water 0.24 nm from the phosphorus, and in the case of chloride peroxidase, the monomeric metaphosphate has the nitrogen of the imidazole of a histidine 0.21 nm from the phosphorus. The van der Waals radii of phosphorus, nitrogen, and oxygen are 0.18, 0.16, and 0.15 nm, so these nucleophilic atoms are well within these radii. The length, however, of a phosphorus–oxygen bond is 0.16 nm, and the length of a phosphorus–nitrogen bond is 0.17 nm. It seems that in each case these nucleophiles are close enough to stabilize the monomeric metaphosphate by orbital overlap, but they are held by the active site too far from the respective phosphorus atoms to form covalent bonds.

Evidence for the production of monomeric metaphosphate during the solvolysis of 4-nitrophenyl phosphate in *tert*-butanol (Equation 1–70) is the **stereochemistry** of the product, *tert*-butylphosphate. To study the stereochemistry of a nucleophilic substitution at a phospho group in a simple monoester, its three oxygens can be labeled respectively with the three isotopes of oxygen: oxygen-16, oxygen-17, and oxygen-18. A single stereoisomer of the reactant can be synthesized, and the absolute stereochemistry of reactant and product can be determined.[198,199] Solvolysis of the dianion of 4-nitrophenyl phosphate in *tert*-butanol proceeds with complete **racemization** as expected for the production of free monomeric metaphosphate as an intermediate.[190]

Other examples of phosphomonoesters with good leaving groups are *N*-phosphopyridine (**1–59**) and *N*-phosphoguanidine (**1–60**)



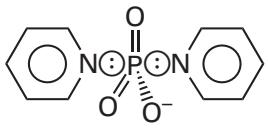
1–59



1–60

There are several features[200] of nucleophilic substitutions involving these types of leaving groups that were at one time explained[201] to be the result of the production of monomeric metaphosphate as an intermediate.[202-204] It has been demonstrated, however, that nucleophilic substitutions at phosphorus with these leaving groups nevertheless proceed with **inversion of configuration**.[200] Such nucleophilic substitutions at other monoesters of phosphoric acid with good leaving groups that proceed with inversion of configuration also seem to pass through a single transition state.[205]

Although these results rule out the existence of monomeric metaphosphate completely free of leaving group and nucleophile as an intermediate in these latter nucleophilic substitutions, they do not rule out the existence of monomeric monophosphate that is captured by the nucleophile before the leaving group has the time to diffuse away from the face from which it has dissociated. Such a situation would be analogous to the example of the intermediate complex between the leaving 4-bromoisoquinoline and the oxocarbenium ion of 2-deoxy-D-glucose in the nucleophilic substitution at 2-deoxy-β-D-glucopyranosyl-4′-bromoisoquinolinium (Equation 1–25). In nucleophilic substitutions of pyridylphosphates (**1–59**) either by other pyridines[205,206] or by oxyanions,[207] the transition state governing the observed rate constant seems to be one in which most of the bond (80%) between leaving group and phosphorus has been broken at the same time that only a small fraction (10%–20%) of the bond between nucleophile and phosphorus has been formed. As such, the transition state resembles monomeric metaphosphate sandwiched between the lone pairs of electrons of the two pyridines



1–61

or of a pyridine and an oxyanion.

Between the two extremes of formation of an intermediate pentaoxyphosphorane and release of free unassociated monomeric metaphosphate are mechanisms in which the formation of the bond to the nucleophile and the disintegration of the bond to the leaving group are concerted, as in the nucleophilic substitutions of pyridylphosphates. The timing within such concerted processes can cause the disintegration of the bond to the leaving group to precede or to follow in some degree the formation of the bond to the nucleophile.

The result of such **differences in timing** is either a steady net decrease or a steady net increase, respectively, in the bond order of the phosphorus atom as the transition state is approached. As a result, the reaction may pass through a single transition state that is partly dissociative or partly associative in character, respectively. For example, for the nucleophilic substitutions of the phenols in a set of phenyl methyl diesters of phosphoric acid with pyridines and amines as nucleophiles,[208] the Brønsted coefficient for the leaving groups, β_{lg}, is –1.0 and the Brønsted coefficient for the nucleophile, β_{nuc}, is 0.35. These Brønsted coefficients suggest that disintegration of the bond to the leaving group is more advanced than formation of the bond to the nucleophile in the transition state, and that the central phospho group in the single, partly dissociative transition state resembles somewhat monomeric metaphosphate. If, however, breaking of the bond to the leaving group is synchronous with formation of the bond to the nucleophile, then the bond order to the phosphorus atom does not change during the process, the bond changes are balanced, and the transition state is neither dissociative nor associative.

Such an analysis can be performed on enzymatic nucleophilic substitutions at phosphorus. The Brønsted coefficient, β_{lg}, for nucleophilic substitution of the diphosphate of the appropriate nucleoside triphosphate by the hydroxy group on the 3′-hydroxy group at the 3′ end of an elongating single strand of DNA catalyzed by human DNA-directed DNA polymerase β could be determined. A series of analogues of the nucleoside triphosphate that adds to the 3′ end of the elongating single strand was synthesized in which the oxygen bridging the β and γ-phospho groups of the nucleotide is replaced with a series of methylenes substituted with fluoro, chloro, bromo, and methyl groups. These various substitutions alter the pK_a of the leaving bisphosphonate which replaces the diphosphate that is the usual leaving group during each step in the elongation. The Brønsted coefficient for the leaving groups, β_{lg}, assessed with these analogues is 0.77 when the nucleoside triphosphate has as its base a thymine, recognizing an adenine on the template.[209] This Brønsted coefficient suggests that the bond to the leaving group is mostly gone in the transition state.

As with nucleophilic substitution at an acyl group, the degree to which the bond to the nucleophile is formed and the degree to which the bond to the leaving group is broken in the transition state governing the observed rate constant for a nucleophilic substitution at phosphorus can be judged by the **Leffler coefficients**, α_{nuc} and α_{lg}, respectively (Equation 1–54). For example, for the transfer of a phospho group from a phosphotyrosine in a peptide, a **monoester**, to $MgADP^-$ catalyzed by non-specific protein-tyrosine kinase Csk, for which peptides with various aryl-substituted phosphotyrosines were synthesized as reactants, the Brønsted coefficient for the leaving groups, β_{lg}, for the rate constants of the enzymatic reaction[210] is –0.33. The Brønsted coefficient for the equilibrium constants for the transfer of a dianionic phospho group between two oxyanions[211] when the values of pK_a for the conjugate acids of the leaving groups are changed, $\beta_{eq,lg}$, is –1.36; that for the transfer of a monoanionic phospho group is –1.74; and that for the transfer of a neutral uncharged phospho group is –1.85. Consequently, the Leffler coefficient, α_{lg}, of around 0.2 was estimated from the Brønsted coefficient for the rates of the enzymatic reactions and the Brønsted coefficients for the equilibrium constants for phosphotransfer.

The Leffler coefficient for this nucleophilic substitution at phosphorus catalyzed by non-specific protein-tyrosine kinase Csk suggests that, in the transition state of the reaction catalyzed by the enzyme, the bond to the leaving group has dissociated by about 20%. The Leffler coefficient for the leaving group, however, is actually a measure of the degree to which a negative charge has accumulated on the leaving group in the transition state as the bond between the leaving group and the phosphorus dissociates. It has been shown that the enzyme is in the process of hydronating the leaving group as the bond is breaking.[212] Consequently, a Leffler coefficient of 0.2 would also be consistent with an almost complete dissociation of the bond between the leaving group and the phosphorus because this concerted hydronation could be neutralizing any accumulation of charge on the oxygen of the leaving group in the transition state.

For the nonenzymatic hydrolysis of **diaryl phosphate ions**,[213] the Brønsted coefficient, β_{lg}, is –1.0, and since the Brønsted coefficient for the equilibrium constant for the transfer of a monoanionic phospho group between two oxyanions, which is analogous to the transfer of an *O*-aryl-phospho group, is –1.74, it can be concluded that the bond to the leaving group in these latter nucleophilic substitutions has dissociated by about 60% in the transition state.

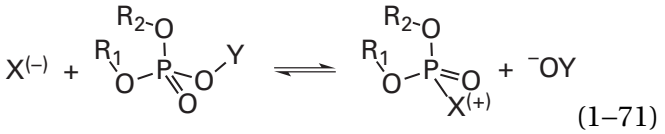
For the nonenzymatic nucleophilic substitutions of a series of aryloxy groups from a series of **aryl diethyl phosphates** by phenoxide anion,[214] the Brønsted coefficient, β_{lg}, is –0.5, and since the Brønsted coefficient for the equilibrium constant for the transfer of a neutral, nonanionic phospho group between two oxyanions, which is analogous to the transfer of an *O,O′*-diethylphospho group, is –1.85, it can be concluded that the bond to the leaving group in these latter nucleophilic substitutions has dissociated by about 30% in the transition state.

The three nucleophilic substitutions just discussed occur at a phosphomonoester, a phosphodiester, and a phosphotriester. In each case, the Leffler coefficients suggested that there was significant, but not complete, disintegration of the bond between phosphorus and oxygen of the leaving group in the transition state. Consequently, it can be concluded that each of these nucleophilic substitutions is concerted and that concerted mechanisms are possible for phosphotriesters as well as phosphodiesters and phosphomonoesters. Presumably this is also the case in nucleophilic substitutions at phosphorus in enzymatically catalyzed reactions. In a concerted reaction, the leaving group is always the oxygen on the opposite side of the phosphorus in line with the nucleophile, and pseudorotation is not an issue. Consequently, the leaving group is determined only by the alignment of nucleophile and phospho group.

The same **considerations that explain the relative timing** for formation of the bond to the nucleophile and for disintegration of the bond to the leaving group in nucleophilic substitutions at an acyl group apply for nucleophilic substitution at phosphorus. The more acidic the conjugate acid of the leaving group and the less nucleophilic the nucleophile, the more likely it is that formation of the bond to the nucleophile will lag behind disintegration of the bond to the leaving group in the transition state and the more likely it is that the phospho group will resemble monomeric metaphosphate in the transition state, until it becomes monomeric metaphosphate. The poor nucleophilicity of *tert*-butanol and the acidity of 4-nitrophenol ensured the production

of monomeric metaphosphate in the nucleophilic substitution of the former by the latter (Equation 1–70). The less acidic the conjugate acid of the leaving group and the more nucleophilic the nucleophile, the more likely it is that formation of the bond to the nucleophile will precede disintegration of the bond to the leaving group in the transition state and the more likely it is that the phospho group will resemble a pentaoxyphosphorane in the transition state, until it becomes a pentaoxyphosphorane. The use of hydroxide as a nucleophile and an alkoxy group as a leaving group in the nucleophilic substitution of 2-methoxy-1,3,2-dioxaphospholane 2-oxide in one case (Equation 1–66), and the use of the 2′-hydroxy group, the nucleophilicity of which is enhanced by approximation, as the nucleophile and an alkoxy group as a leaving group in the nucleophilic substitution of the monophenyl esters of 3′-uridylic acid in another case (Equation 1–68), ensured the production of a pentaoxyphosphorane.

In all the nucleophilic substitutions at phosphorus that have been discussed so far, there are three players: the nucleophile, the leaving group, and the electrophilic phosphorus. So far, the emphasis of the discussion has been on the properties of the nucleophile and the leaving group that determine the timing of formation of the new bond to the nucleophile and disintegration of the old bond to the leaving group. The **substituents on the other oxygens on the phosphorus** that are not the leaving group in a particular situation also affect the nucleophilic substitution. For example, in the nucleophilic substitutions at various triesters of phosphoric acid with several nucleophiles X



(1–71)

where YO^- is the leaving group, linear Brønsted plots demonstrate that the less basic are the alkoxide ions of the two uninvolved substituents, R_1O^- and R_2O^-, the larger is the rate constant for the nucleophilic substitution.[215] The basicity of an alkoxide ion is a reflection of the ability of the substituent on its oxyanion to stabilize its negative elementary charge; the less basic the alkoxide ion is, the more able the substituent is to stabilize its negative elementary charge. Consequently, the fact that the less basic alkoxy groups have faster rates demonstrates that the ability of the groups that do not leave, R_1O^- and R_2O^-, to stabilize the negative charge developing in the transition state is responsible for these increases in rate. In the active site of an enzyme, anything that makes a substituted oxygen on the phospho group that is not involved in the nucleophilic substitution better able to stabilize adjacent negative charge should increase the rate of the enzymatic reaction.

In situations in which the leaving groups are the same and the nucleophiles are the same, phosphomonoesters are more likely to produce monomeric metaphosphate because they yield its anionic conjugate base and in the ground state they have one or two oxyanions, depending on the pH, to push out the leaving group, and phosphotriesters are more likely to produce an intermediate pentaoxyphosphorane because they cannot give a monomeric metaphosphate as an intermediate and, in the ground state, they have fewer lone pairs of electrons on the uninvolved oxygens to push and they can never have an oxyanion to push.

As with any other type of nucleophilic substitution, the reaction coordinate and the transition state of each nucleophilic substitution at phosphorus fall at a particular point in a continuous spectrum of mechanism. As with a nucleophilic substitution at a tetrahedral, saturated carbon (Figure 1–4) or at an acyl group, this spectrum of mechanism can be appreciated by examining a **three-dimensional surface of potential energy** (Figure 1–15).[77,78] Again, one of the coordinates is the distance between the atom of the leaving group and the electrophilic phosphorus atom, and the other coordinate is the distance between the nucleophilic atom and the electrophilic phosphorus atom. The third coordinate is the potential energy of the system for each pair of coordinates.

In the case of a nucleophilic substitution at phosphorus, as was the case in a nucleophilic substitution at an acyl group, there is a significant well of potential energy in the **lower left corner** of the diagram because this is the position of the respective pentaoxyphosphorane, the pentavalent analogue of the tetrahedral intermediate. If the pentaoxyphosphorane is the most stable of all the possibilities, there will be two cols of potential energy: one between the reactants and the pentaoxyphosphorane, and the other between the pentaoxyphosphorane and the products.

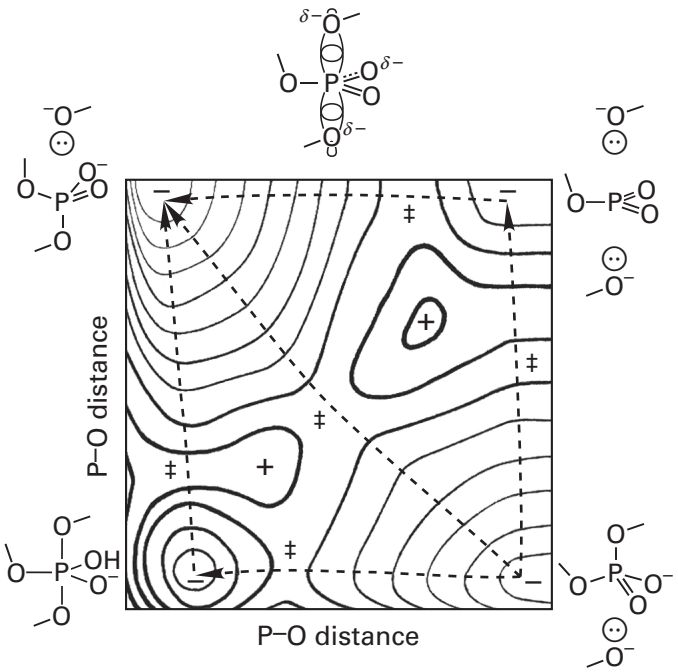


Figure 1–15: Hypothetical three-dimensional representation of a surface of potential energy[77,78] for nucleophilic substitution at phosphorus. The ordinate of the plot is the distance between phosphorus and the oxygen that is leaving during the substitution. The abscissa of the plot is the distance between phosphorus and the nucleophilic oxygen that is forming the new bond. The intersection of these two axes, for the sake of brevity, is not the point at which each has a value of zero, which would be a singularity of potential energy. The point of their intersection has coordinates or distances close to the values of the lengths of the respective covalent bonds: the bond between phosphorus and the oxygen that is leaving in the reactant and the bond between phosphorus and the nucleophilic oxygen that has formed the new bond in the product. The third dimension is the potential energy associated with each value for these two distances. The third dimension is represented topographically by contour lines of equal potential. These contour lines represent a sinuous surface of potential energy. The two topographic maps of potential energy are entirely hypothetical, do not represent the surface of potential energy for any reaction, and are intended only for demonstration. The positive signs identify peaks of potential energy, and the negative signs identify wells of potential energy. The usual sign (‡) for a transition state designates a minimum of potential energy between reactants and products at the col through which the reaction proceeds. The dashed, curved arrows indicate paths on which the reaction coordinate could pass as the reaction proceeds. In this case, three possible paths on which the reaction could proceed were arbitrarily given cols of about the same potential energy to illustrate the three possibilities. In the case of nucleophilic substitution at phosphorus, a pentavalent phosphorane is a possible stable intermediate, as opposed to a pentavalent carbon, so there is a well of potential energy when both distances are short (lower left corner). The species involved as reactants, intermediates, transition states, or products are represented outside the plots to the right (reactants or intermediate monomeric metaphosphate), to the left (intermediate phosphorane or products), or above (associative intermediate) the location of their respective potential energies. The three reaction coordinates are, in descending order of presentation, that for a reaction with monomeric metaphosphate as an intermediate, that for a concerted reaction in which the bond to phosphorus in the product is forming as the bond to phosphorus in the reactant is breaking, and that for a reaction with a phosphorane as an intermediate. Adapted with permission from reference 77. Copyright 1972 American Chemical Society. https://doi.org/10.1021/cr60280a004

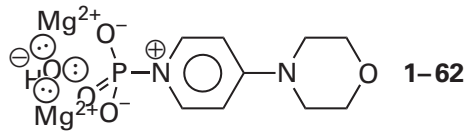
The **upper right corner** in the three-dimensional surface of potential energy for the nucleophilic substitution at phosphorus is the location of a monomeric metaphosphate, the trivalent analogue of an acylium ion that occupies the upper right corner in a nucleophilic substitution at an acyl group or a carbenium ion or oxocarbenium ion that occupies the upper right corner in a nucleophilic substitution at a saturated carbon. If a monomeric metaphosphate is the most stable of all the possibilities, there will again be two cols of potential energy: one between the reactants and the monomeric metaphosphate, and the other between the monomeric metaphosphate and the products.

There is, however, always the possibility in a nucleophilic substitution at phosphorus that the lowest col in the surface of potential energy occurs when the bond between the nucleophile and the electrophilic phosphorus is partially formed while the bond between the electrophilic phosphorus and the leaving group is partially broken and that there is neither a pentaoxyphosphorane nor a monomeric metaphosphate as an intermediate. Such nucleophilic substitutions at phosphorus are **concerted nucleophilic substitutions**. The reaction coordinate in all these cases passes through only one col somewhere outside of the corners and has only **one transition state at this one col**.

Metallic cations can accelerate nucleophilic substitutions at phosphorus in solution. In solution, the rate of hydrolysis of thymidine 5′-(4-nitrophenyl)phosphate, an electrophilic phosphodiester, is linearly related to the concentration of the nucleophilic ion $Mg(H_2O)_5(OH)^+$.[216] The second-order rate constant for the reaction of this electrophile with this nucleophile is 5 times the second-order rate constant of the same electrophile with hydroxide even though the pK_a of its conjugate acid, $Mg(H_2O)_6^{2+}$ is only 11.4 rather than 15.74. The substitution of $H_2{}^{16}O$ with $H_2{}^{18}O$ in the solvent decreased the rate of this nucleophilic substitution at phosphorus by 3%, but this was less than the 6% decrease observed for the same nucleophilic substitution when the nucleophile was uncomplexed hydroxide. This latter result suggests that in the

presence of the complexed **Mg^{2+}**, the transition state has become more like a pentaoxyphosphorane.[179]

The rate constant for the hydrolysis of the complex between Mg^{2+} and 4-(4-morpholinyl)-1-phosphonopyridinium by $Mg(H_2O)_5(OH)^+$ is about 100 times greater than that expected from the basicity of the $Mg(H_2O)_5(OH)^+$.[217,218] It was proposed that in the case of this phosphoramide, the nucleophile is either a hydroxide held by one Mg^{2+}, coordinated by both of the anionic oxygens on the phospho group, or a hydroxide held between two Mg^{2+}, each coordinated by one of the two anionic oxygens of the phospho group



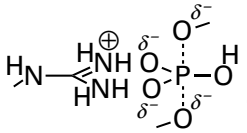
1–62

This proposal assumes that one or two four-membered rings in the transition state (each formed from the phosphorus, two oxygens, and a Mg^{2+}) are effective at positioning the hydroxide. In favor of this possibility, each bond angle at a Mg^{2+} between two coordinated oxygens is required by the octahedral coordination of Mg^{2+} to be 90°, the interior angle of a square.

Magnesium ion, although it is almost always involved in enzymatic nucleophilic substitutions at phosphorus, is not the sole metallic ion that can accelerate such nucleophilic substitutions. Metallic ions of transition metals can also do so.[219] A large organic chelating agent that simultaneously coordinates two **Zn^{2+}** accelerates[220] the hydrolysis of a series of alkyl esters of 3′-uridylic acid by a factor of 10^6, perhaps by a complex resembling that in **1–62**. The association of the phosphodiester, methyl 4-nitrophenyl phosphate, through its two phospho oxygens with a complex of two **Co^{2+}** accelerates[221] the nucleophilic substitution of its 4-nitrophenol by hydroxide by a factor of 10^{11}. The mechanism of the reaction, when it is catalyzed by this complex, is also different from the mechanism of the same reaction in the absence of the complex. The complex causes the reaction to pass through a pentaoxyphosphorane as an intermediate, while the same reaction in solution in the absence of the complex is concerted.[222] This same complex of two Co^{2+} also changes the mechanism of the hydrolysis of the phosphomonoester, 4-nitrophenyl phosphate, from one that passes through an almost dissociative nucleophilic substitution to a concerted nucleophilic substitution with significant bonding to both leaving group and nucleophile in the transition state,[223] which perhaps is stabilized by multidentate coordination of the two Co^{2+}. By associating with the anionic oxygens on a phospho group and decreasing their push, the two Co^{2+} may also shift the mechanisms of these nucleophilic substitutions in the direction of an intermediate pentaoxyphosphorane.

Nucleophilic substitutions at phosphorus catalyzed by the active sites of enzymes have the same spectrum of mechanism: those with intermediate pentaoxyphosphoranes,[179,180,224,225] those with intermediate monomeric metaphosphates,[195,226] and those with concerted mechanisms with no intermediate and a single transition state.[227] For example, the hydrolysis of ribonucleic acid (Equation 1–69) catalyzed by bovine ribonuclease, a reaction in which the nucleophile is enhanced by approximation and the leaving group is poor, passes through a pentaoxyphosphorane intermediate,[224] while the phosphorylation of tyrosines in proteins catalyzed by nonspecific protein-tyrosine kinase Csk, a reaction in which nucleophiles are poor and leaving groups are good, has monomeric metaphosphate as an intermediate.[210]

Regardless of whether the mechanism of a nucleophilic substitution at phosphorus proceeds through a phosphorane or monomeric metaphosphate or is concerted, in the intermediates and the transition state, respectively, the phosphorus and the three oxygens uninvolved in the substitution are all in the same plane and the bond angles between the three phosphorus–oxygen bonds are 120°. It has been pointed out that arginine side chains are often present in the active sites of enzymes catalyzing nucleophilic substitutions at phosphorus, and in many instances these side chains seem to form a cyclic structure with two of these uninvolved oxygens



1–63

Presumably this cyclic structure stabilizes the intermediate or the transition state for that reaction.[228]

In at least two instances, it seems that the mechanism of a particular nucleophilic substitution at phosphorus is the same in solution as in the active site of an enzyme.[179,180,224,225,227,229] This result suggests, at least in these instances, that the enzyme does not change the relative timing of formation of the bond to the nucleophile and disintegration of the bond to the leaving group[195] while accelerating[1,2,4] both by factors as large as 10^{20}. There are enzymatic nucleophilic substitutions at phosphorus, however, that appear to employ different mechanisms than those for the same reactions in solution.[230] It seems also to be the case that in enzymatic active sites using metallic caions, usually Mg^{2+}, for the catalysis of nucleophilic substitutions at phosphorus, which is quite a common strategy, the mechanism could also be quite different from the same reaction in solution in the absence of metallic ions.[220] The metallic ion can enter the active site either alone or in complex with one or more of the phospho groups of the substrate.

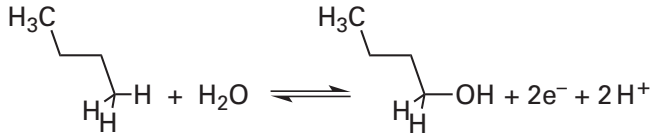
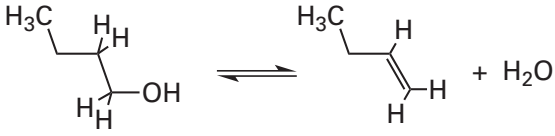
Formal Hydride Transfer

Each carbon in a metabolite serves as a representative of one of the five oxidation states of carbon. When a carbon is bonded only to other carbons and hydrogens and not participating in any π bonds, it is **fully reduced** and fully saturated at the **oxidation state of an alkane**. If one of the hydrogens on the carbon is replaced by a hydroxy group, an oxidation of that carbon has occurred. For example, the half-reaction for the oxidation of carbon 1 of butane catalyzed by butane monooxygenase (soluble) is*



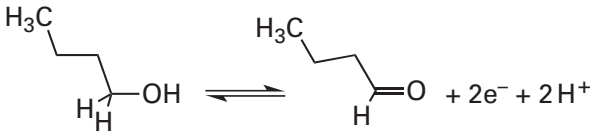
(1–72)

The carbon has undergone a **two-electron oxidation–reduction**. Carbon 1 of the resulting butan-1-ol is at the **oxidation state of an alcohol**. Alcohols can be turned into ethers, amines, thiols, and sulfides by nucleophilic substitution without any net oxidation or reduction. A carbon at the oxidation state of an alcohol can be identified in a molecule by the fact that it has one σ bond to a heteroatom and three other σ bonds to either carbon or hydrogen. If one of the carbons immediately adjacent to a carbon at the oxidation state of an alcohol bears a hydrogen, the two carbons can be converted into an alkene without any net oxidation or reduction



(1–73)

An alcohol can be oxidized to a ketone or an aldehyde, and in reverse, a ketone or an aldehyde can be reduced to an alcohol

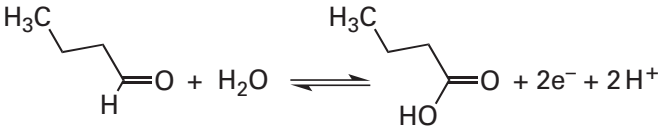


(1–74)

*Formally, Equation 1–72, although it is a balanced chemical equation, is the **half-reaction** of a complete oxidation–reduction. Just as hydrons are never free in solution as cations, electrons are free in solution as solvated electrons only under extraordinary circumstances unrelated to biochemical situations. Just as hydrons, when they are hydronium ions, are always associated with one or more molecules of water, each electron shown in a half-reaction is always associated with another molecule, which appears in the other half-reaction or one of the other half-reactions of the complete oxidation–reduction. In biochemical situations, it is almost always useful to present oxidation–reduction as two or more half-reactions because in this way it is clear where the electrons arose and where they have gone, and it distinguishes the particular molecules that are oxidized or reduced from the general carriers of electrons that receive or provide electrons as the other half of most of the oxidation–reductions in metabolism.

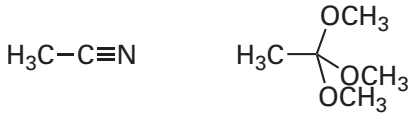
The carbon has undergone a two-electron oxidation–reduction. The carbon in a ketone or an aldehyde is at the carbonyl oxidation state and can be converted by nucleophilic addition or nucleophilic substitution into a hemiacetal, a hemiketal, an acetal, a ketal, a hemiaminal, a *gem*-diamine, an imine, a thiohemiacetal, a thiohemiketal, a thioketone, or a thioaldehyde (Table 1–1). These transformations do not involve any net oxidation or reduction. A carbon at the **carbonyl oxidation state** can be identified in a molecule by the fact that it has two σ bonds to either carbon or hydrogen and either two single σ bonds or a σ bond and a π bond, the two components of a double bond, to the heteroatoms oxygen, nitrogen, or sulfur.

An aldehyde or the derivative of an aldehyde can be oxidized to a carboxylic acid or an acyl derivative of a carboxylic acid, and in reverse, a carboxylic acid or an acyl derivative can be reduced to an aldehyde or the derivative of an aldehyde



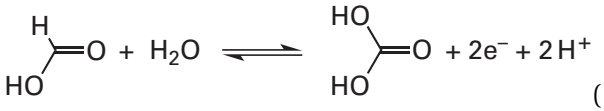
(1–75)

The carbon has again undergone a two-electron oxidation–reduction. Any carbon at the acyl oxidation state can be converted by nucleophilic substitution into an ester, an amide, an imidoester, an amidine, a thioester, a thiocarboxylic acid, or a thionoester, and none of these nucleophilic substitutions involves net oxidation or reduction. A carbon at the **acyl oxidation state** can be identified in a molecule as a carbon that has three bonds, either σ bonds or a mixture of σ bonds and π bonds, to heteroatoms and only one σ bond to carbon or hydrogen. Extreme examples of acyl carbons are the carbon in a nitrile (**1–64**) and the carbon in an ortho ester (**1–65**)



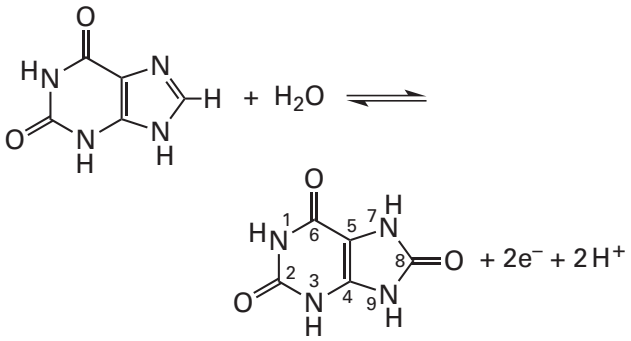
1–64 **1–65**

Formic acid or a derivative of formic acid can be oxidized to carbonic acid or a derivative of carbonic acid, and in reverse, carbonic acid or a derivative of carbonic acid can be reduced to formic acid or a derivative of formic acid



(1–76)

The carbon has again undergone a two-electron oxidation–reduction. For example



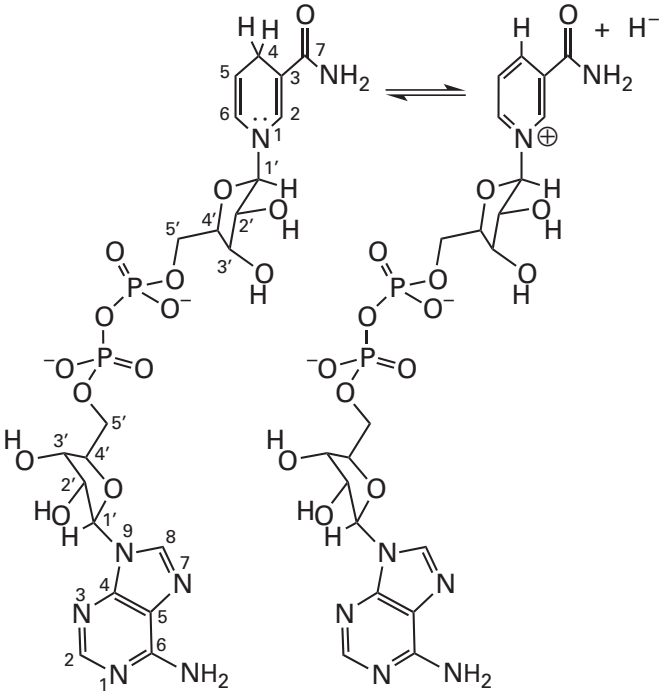
(1–77)

which is the half-reaction catalyzed by xanthine dehydrogenase. Any carbon at the carbonato oxidation state can be converted by nucleophilic substitution, nucleophilic addition, or elimination into carbon dioxide, a carbonato ester, a carbamate, a urea, a guanidine, a thiocarbonate, a thiocarbamate, or a thiourea, and none of these nucleophilic substitutions involves net oxidation or reduction. A carbon at the **carbonato oxidation state** can be identified in a molecule as a carbon that is entirely bonded to heteroatoms, as is carbon 8 of urate (Equation 1–77).

Most of the reactions that occur in metabolism can be placed into this scheme. There are **five oxidation states of carbon**. Within any one of these oxidation states, substrates are transformed by nucleophilic substitution, nucleophilic addition, and elimination. The transitions between any two of these oxidation states are oxidations and reductions that have their own distinct chemistry, which is represented by half-reactions indicating the removal or addition of electrons to the substrates.

In enzymatic reactions that change oxidation states, the oxidation–reductions connecting the oxidation state of an alcohol with the carbonyl oxidation state (Equation 1–74) and the carbonyl oxidation state with the acyl oxidation state (Equation 1–75) often involve the formal transfer of a hydride. A hydride is usually transferred from the nicotinamide ring in reduced **nicotinamide-adenine dinucleotide** (NADH) or reduced nicotinamide-adenine dinucleotide phosphate (NADPH) in one direction and transferred to the nicotinamide ring of oxidized nicotinamide-adenine dinucleotide

(NAD^+) or oxidized nicotinamide-adenine dinucleotide phosphate ($NADP^+$), in the other direction



(1–78)

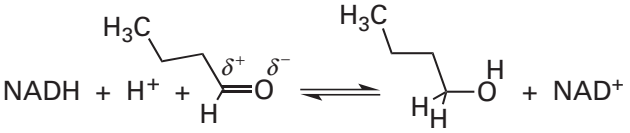
Nicotinamide-adenine dinucleotide phosphate (Figure 1–16),[166,231] which differs by only a 2′-phospho group on the adenosine, which is distant from the nicotinamide ring, performs chemistry that is identical to that performed by NADH, but each enzyme will have its own particular preference for one or the other of these hydride carriers.

A hydride never exists as a free hydride ion, just as a hydron never exists as a free hydron. Equation 1–78 can be written as a half-reaction

(1–79)

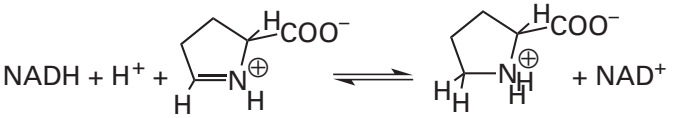
which indicates that the hydride that is transferred by NADH is equivalent to a hydron and two electrons, the latter of which also do not exist as free species in solution. Consequently, the half-reaction emphasizes the formality of the hydride transfer.

Just as a hydron, which is formally an electrophile, is transferred from one basic lone pair of electrons to another basic lone pair of electrons, a hydride, which is formally a nucleophile, is transferred from one electrophilic carbon (for example, carbon 4 of NAD^+ in Equation 1–78) to another electrophilic carbon (for example, the carbon on the substrate that is to be reduced). In the direction of reduction, the nucleophilic hydride is usually transferred to an electrophilic carbonyl carbon



(1–80)

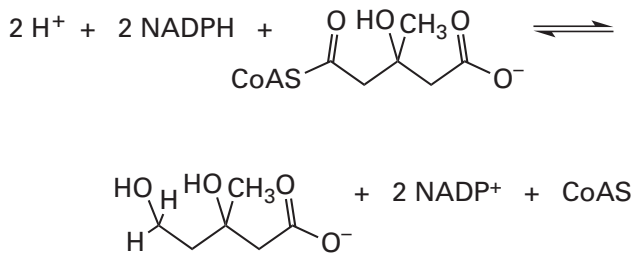
an electrophilic acyl carbon, or an electrophilic carbonato carbon in the substrate, so the reduction is formally a **nucleophilic addition to a carbonyl group, an acyl group, or the derivative of a carbonate.** Formation of the covalent bond between a hydride and the carbon reduces the carbon to the next lower oxidation state. In order for this to occur, the carbon is usually in a double bond to a heteroatom. In the reverse direction, the hydride is transferred from the carbon in the substrate that is to be oxidized to NAD^+, and that carbon is oxidized to the next higher oxidation state. There are also enzymes that use NADH to reduce an imine, such as pyrroline-5-carboxylate reductase



(1–81)

and enzymes that use NADH to reduce alkenes to alkanes.[232]

Usually an enzyme will catalyze the transfer of one hydride from one NADH to a carbonyl carbon, an acyl carbon, or a carbonato carbon to reduce it to a carbon at the oxidation state of an alcohol, a carbonyl carbon, or an acyl carbon, respectively, and vice versa. Hydroxymethyl-glutaryl-CoA reductase (NADPH), however, catalyzes an oxidation–reduction in which two hydrides are transferred consecutively from two molecules of NADPH to the same carbon, converting it from the acyl oxidation state down two levels to the oxidation state of an alcohol



(1–82)

as can be done, much less specifically and only in the direction written, with lithium aluminum hydride.

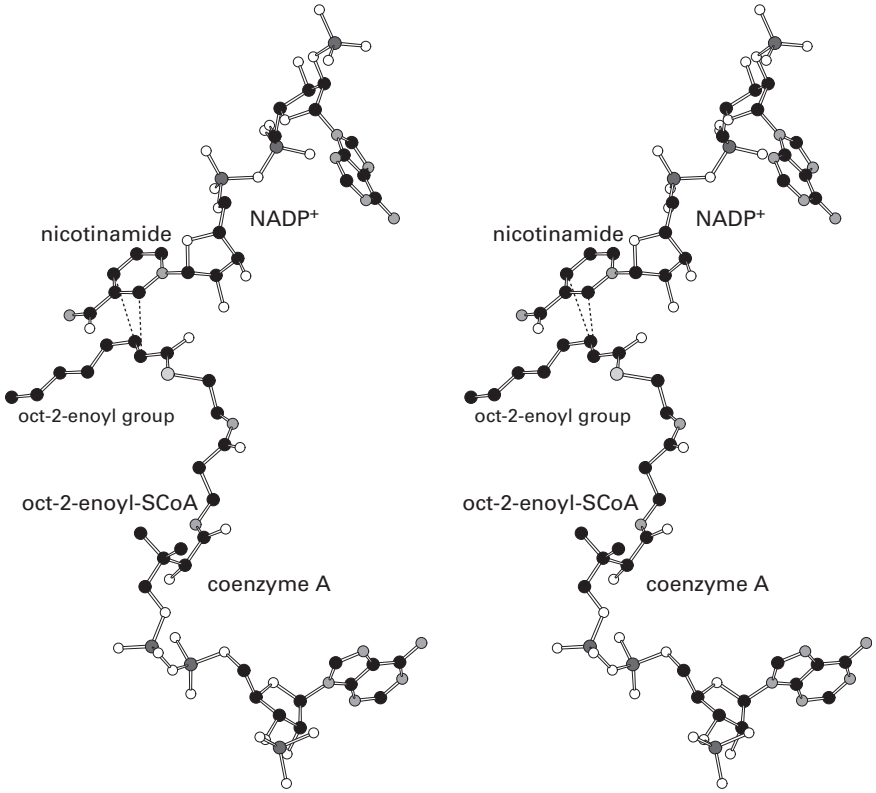


Figure 1-16: Stereodrawing[166] of the stacking of the π molecular orbital system of (*E*)-oct-2-enoyl-SCoA against the π molecular orbital system of $NADP^+$ in the crystallographic molecular model[231] of the active site of octenoyl-CoA reductase/carboxylase from *S. cinnabarigriseus*. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, the large light gray atom is a sulfur, and the large dark gray atoms are atoms of phosphorus. The gene for octenoyl-CoA reductase/carboxylase from *S. cinnabarigriseus* was expressed in *E. coli* by using a plasmid that adds six histidines to its amino terminus. The protein was purified by the use of an adsorbent to which Ni^{2+} ions are coordinated and with which the histidines associate. After removal of the six histidines, the protein was submitted to molecular exclusion chromatography. A concentrated solution of the protein was crystallized in a buffer containing 10 mM $NADP^+$, 10 mM (*E*)-oct-2-enoyl-SCoA, and 50 mM $NaHCO_3$ at pH 8. A map of electron density was produced from the data set by molecular replacement. In the map of electron density, features were observed into which molecular models of $NADP^+$ and (*E*)-oct-2-enoyl-SCoA, respectively, could be inserted. These features identified the active site. After insertion of the molecular models, the crystallographic molecular model of the resulting complex between enzyme, $NADP^+$, and (*E*)-oct-2-enoyl-SCoA was refined against the data set. Only the molecular models of $NADP^+$ and (*E*)-oct-2-enoyl-SCoA as they are oriented by the active site are drawn. The nicotinamide of the $NADP^+$ and the oct-2-enoyl group and the coenzyme A portion of the (*E*)-oct-2-enoyl-SCoA are labeled. The π molecular orbital system of the oct-2-enoyl group consists of the oxygen, the acyl carbon, and the α and β carbons. The dashed lines connect the α carbon to carbon 2 of the nicotinamide and the β carbon to carbon 4 of the nicotinamide, respectively.

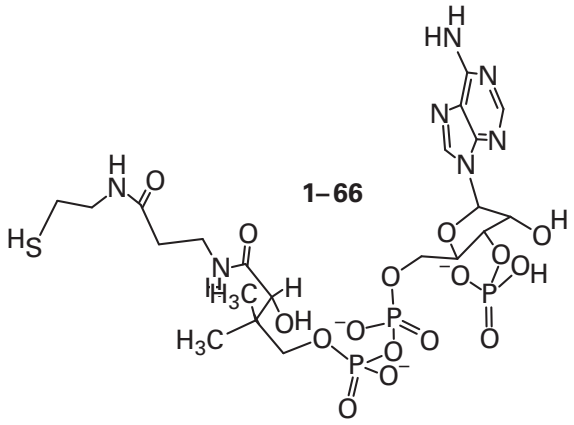
In these oxidation–reductions, **the NADH or the NADPH acts simply as the carrier of a hydride**, much as a catalytic acid acts as a carrier of a hydron. The hydride being carried exists as a lone hydrogen in a large molecule that seems unnecessarily elaborate to an organic chemist (Equation 1–78), but its large size permits it to be bound tightly and to be easily recognized by an enzyme. The extensive interactions between the enzyme and the elaborate substituent attached to the hydrogen atom can also provide free energy that can be used to decrease the free energy of activation of the enzymatic reaction. In its role as the carrier of a hydride, nicotinamide-adenine dinucleotide is a representative of a class of molecules known as coenzymes.

There are several terms that classify molecules, other than substrates, associating with an enzyme. These terms are relevant to oxidation–reductions catalyzed by enzymes, so they should be clarified here.

A **cofactor** is any ion, usually a metallic ion, or any organic molecule that is required by an enzyme for its function. A cofactor can be either a coenzyme, a functional group in a coenzyme, or a prosthetic group.

A **coenzyme** is a small molecule, relative to the enzyme itself, that associates and dissociates from the active site of an enzyme just as a substrate does and that transfers chemical groups, hydrogens, or electrons among active sites. In the case of NADH, the chemical group that is transferred is a hydride in the form of a hydrogen. In the case of *S*-adenosyl-L-methionine (Equation 1–19), another elaborate coenzyme, it is a methyl group, the one on the sulfur. A coenzyme is distinguished from the substrate or the substrates of an enzyme by its promiscuity. The same coenzyme serves the same role in a number of enzymatic reactions, each of which has different unrelated substrates. A coenzyme readily associates with and dissociates from the active site of an enzyme, just as rapidly as the other substrates, and it transfers chemical groups, hydrogens, or electrons within the active site to and from a substrate for that enzyme. A coenzyme enters the active site; donates or accepts the electron, the electrons, a hydrogen, or the chemical group; and then leaves the active site during a single turnover. In most of the enzymatic reactions in which they are involved, NAD^+, $NADP^+$, NADH, and NADPH are coenzymes, acting indistinguishably, except by formal definition, from the other substrates for the enzyme (Equation 1–80). Kinetically, they are the same as a substrate for the enzyme. Because every coenzyme, by definition, is required by at least one enzyme for its function, all coenzymes are cofactors.

Coenzyme A

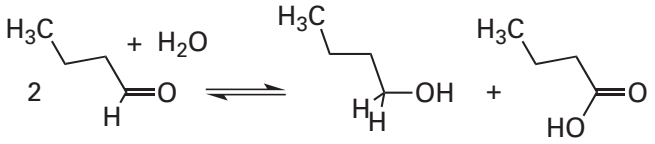


is another elaborate coenzyme. The chemical groups that **coenzyme A** is responsible for carrying between active sites are carboxylic acids. These carboxylic acids are thioesters at the lone sulfanyl group in coenzyme A.* An example of an ester of coenzyme A would be oct-2-enoyl-SCoA (Figure 1–16).[231] In addition to making it easier for an enzyme to recognize the particular thioester of coenzyme A that is its substrate and increasing the free energy of association between the active site and the thioester of coenzyme A, coenzyme A, because it is quite hydrophilic, also increases the solubility of the carboxylic acids that it carries, which are often quite hydrophobic. For example, coenzyme A carries fatty acids of fairly long chain lengths between active sites.

A **prosthetic group** is any group that is neither a protein nor a peptide that is either covalently or tightly attached to a protein and remains tightly bound to the protein for an extended period of time. When it is within the active site of an enzyme, a prosthetic group that is a cofactor for that particular enzyme remains fixed there through many turnovers. The prosthetic group either provides a catalytic group that is chemically unchanged during the enzymatic reaction, or it accepts or donates one or two electrons, a hydrogen, or a chemical group and then donates or accepts, respectively, one or two electrons, a hydrogen, or the chemical group

*Although the rule in IUBMB nomenclature for a thioester of coenzyme A is to append "-CoA" to the name of the acyl group, for example, oct-2-enoyl-CoA, in the current text, the "CoA" is replaced by "SCoA" to remind the reader that the compound discussed is a thioester of coenzyme A, for example, oct-2-enoyl-SCoA.

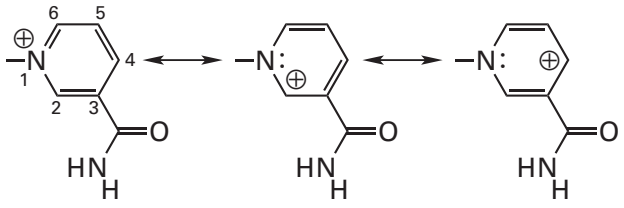
during a single turnover. At the end of that turnover, a prosthetic group that is a cofactor for the enzyme is chemically identical to its state at the beginning of that turnover. For example, NADH is a prosthetic group in a set of enzymes that catalyze the dismutation of aldehydes[233-236]



(1–83)

The reduced form of the enzyme, with NADH bound tightly in its active site as a prosthetic group, reduces the first aldehyde to the alcohol. The resulting oxidized form of the enzyme, now with NAD^+ in its active site, then oxidizes the second aldehyde to the carboxylic acid, regenerating the reduced form of the enzyme at the end of the complete turnover. There are prosthetic groups, such as lipids and oligosaccharides, that are attached covalently, or tightly but noncovalently, to a protein but that are not required by any enzymatic activity displayed by that protein. Consequently, unlike coenzymes, some prosthetic groups are not cofactors.

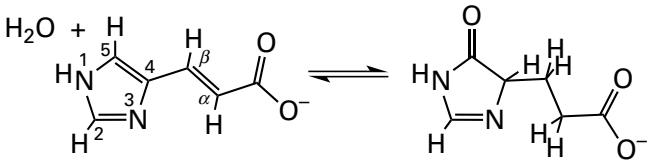
The positive formal elementary charge on the nitrogen of the nicotinamide ring in NAD^+ causes the 2, 4, and 6 positions on the ring to be electrophilic. This effect can be demonstrated by drawing resonance structures



1–67

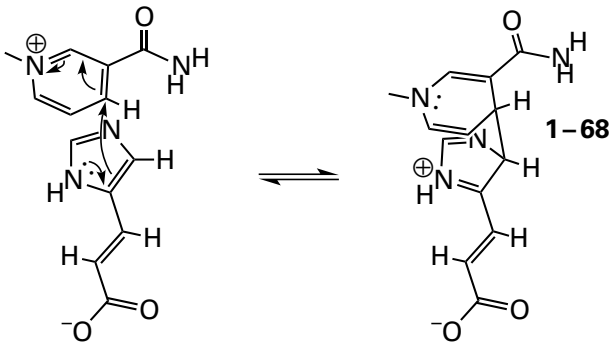
This enhanced electrophilicity permits carbon 4 in NAD^+ to be an effective acceptor of a formal, nucleophilic hydride.

This electrophilicity is also reflected in the tendency of carbon 4 of NAD^+ to **participate as an electrophile in nucleophilic additions** with carbon nucleophiles. Most of the reactions producing nucleophilic adducts of NAD^+ at carbon 4 are adventitious and counterproductive.[237,238] As part of its mechanism, however, the active site of urocanate hydratase, which catalyzes the hydration of urocanate



(1–84)

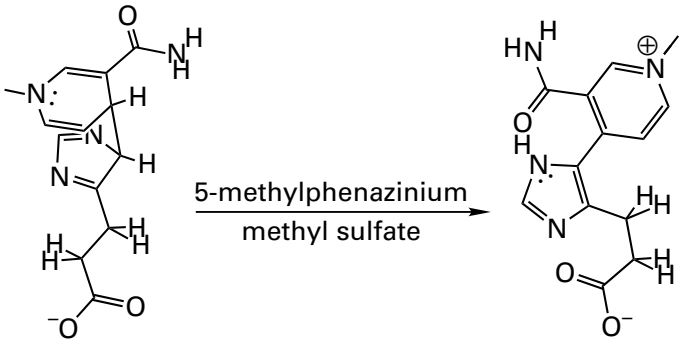
forms adduct **1–68** [239]



(1–85)

by an electrophilic aromatic addition between carbon 4 of NAD^+, which is the electrophile, and carbon 5 on urocanate, which is within an aromatic ring and hence nucleophilic. Because the NAD^+ in urocanate hydratase is a prosthetic group that never leaves the active site of the enzyme, the adduct must form and unform within the active site during each turnover of the enzyme.

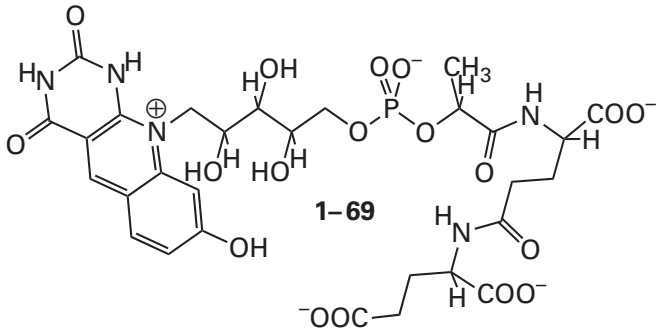
Evidence for the existence of this **covalent intermediate** in the normal enzymatic reaction is the fact that the saturated analogue of urocanate, 3-imidazolylpropionate, forms an analogous electrophilic adduct in the active site of urocanate hydratase from *Pseudomonas putida* that cannot proceed further in the enzymatic reaction because of the lack of a double bond between the α carbon and the β carbon and can be trapped by oxidation with 5-methylphenazinium methyl sulfate



(1–86)

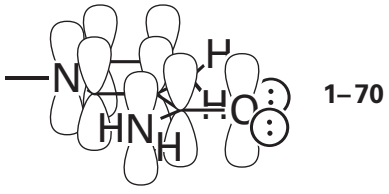
The stable oxidized product could be isolated[240,241] and its identity was verified by nuclear magnetic resonance spectroscopy.[242]

The electrophilicity of carbon 4 of NAD^+ is at its greatest when the **carbamoyl group on the nicotinamide** is in the conformation in which its acyl oxygen is syn to carbon 4 (the conformation shown in Equation 1–78 and **1–67**), and even though the syn conformation is the less stable, the carbamoyl group is usually held within ±30° of the planar syn conformation within the active sites[243,244] of enzymes having NAD^+ as a coenzyme (Figure 1-16). Coenzyme F_{420}



a formal hydride carrier from methanogenic bacteria,[245,246] contains an elaboration of nicotinamide that has a two-electron reduction potential (–0.36 V) similar to that of NAD^+ (–0.33 V) and a structure that locks the acyl oxygen of the analogue of the carbamoyl group of NAD^+ in the conformation in which it is syn to and in the plane of the carbon that is the analogue of carbon 4 of NAD^+.

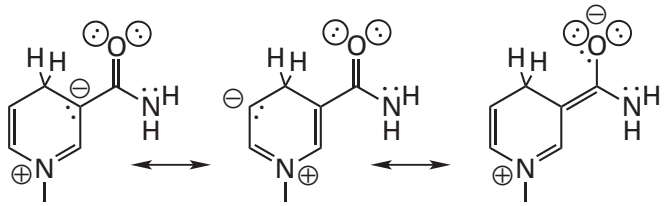
Upon the reduction of NAD^+ by addition of a hydride to carbon 4, the aromatic π molecular orbital system is broken. Carbon 4 becomes saturated and can no longer support a *p* orbital. A partial compensation for the loss of aromaticity during the reaction is the formation of an extended π molecular orbital system that includes the exocyclic carbamoyl group, the two carbon–carbon double bonds, and the nitrogen within the ring



This π molecular orbital system provides an unbroken, acyclic, terminally bifurcated set of 8 *p* orbitals that mix to form a π molecular orbital system containing 10 *p* electrons. This π molecular orbital system explains the fact that the six atoms in the ring, the three atoms in the amide, and the carbon of the functional group attached to the nitrogen in the ring are in the same plane in NADH.[247-249] This extended π molecular orbital system is responsible for the absorbance displayed by NADH or by its phospho derivative, NADPH, at 339 nm.[250]

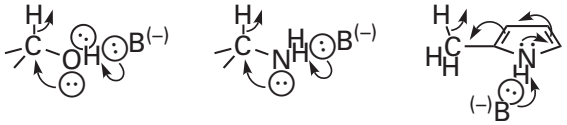
Oxidized nicotinamide in NAD^+ is aromatic, so all its bonds are of equal length.[251] The **bond lengths** in NADH, however, reflect the uneven distribution of **bond order** over the seven bonds in its molecular orbital system. If the lengths of the bonds in reduced nicotinamide are compared to the lengths of the same bonds in oxidized nicotinamide, the bonds between carbons 2 and 3 and between carbons 5 and 6 each shorten by 0.007 nm to a length equal to the bond length of a normal carbon–carbon double bond,[248] while the bonds between nitrogen 1 and carbon 2 and between nitrogen 1 and carbon 6 each lengthen by 0.007 nm.[248,249] These changes demonstrate that the carbon–carbon bonds gain bond order while the carbon–nitrogen bonds lose bond order upon reduction of nicotinamide (see Equation 1–78). The increase in bond order explains the fact that the double bond between carbons 5 and 6 in NADH is susceptible to hydration[252] as well as an oxidation that converts it to the diol.[253]

The observed bond lengths and bond orders in NADH can be understood by drawing **resonance structures**. Those resonance structures containing double bonds between carbon and nitrogen within the ring are unfavorable relative to the usually drawn resonance structure for NADH (Equation 1–78) because of separation of charge and cross-conjugation



The substrate from which a hydride is to be removed by NAD^+ almost always has at least one lone pair of electrons on an oxygen or a nitrogen that can provide push to the leaving hydride.[254]

This lone pair of electrons can be on an oxygen or a nitrogen that is either attached directly to the carbon to be oxidized or conjugated to that carbon by one or more π bonds

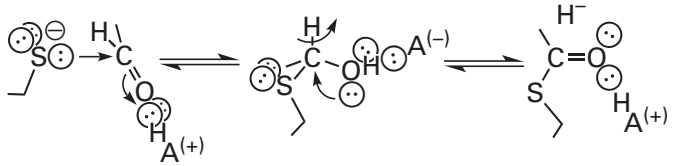


1–72 **1–73** **1–74**

It must be a lone pair of electrons that can be positioned periplanar to the σ bond between the carbon and the hydrogen. This push causes the hydrogen that is to be removed to be more electron-rich and more nucleophilic.

It is also important to have a **hydron on this heteroatom providing the push** before the oxidation takes place rather than an alkyl group so that, as the hydride leaves, that hydron can be simultaneously removed to increase further the nucleophilicity of the lone pair of electrons that is providing the push. The hydron is removed from a lone pair of electrons orthogonal to the pair providing the push. For example, in the active site of ovine phosphogluconate dehydrogenase ($NADP^+$-dependent, decarboxylating), Lysine 183 is responsible for removing the hydron from the 3-hydroxy group of 6-phospho-D-gluconate while the hydrogen on carbon 3 of 6-phospho-D-gluconate is removed by $NADP^+$. The 6-amino group of Lysine 183 is aligned so that it participates in a linear hydrogen bond only when the hydroxy group is in a rotational conformation that places one of its two lone pairs antiperiplanar to the hydride that is being transferred (Figure 1–17).[166,255] When Lysine 183 is mutated to any other amino acid, even to arginine, the rate of the enzymatic reaction decreases by a factor of 1000 or more.[256] In the active site of glucose-6-phosphate dehydrogenase ($NADP^+$) from *Leuconostoc mesenteroides*, Histidine 240 is responsible for removing the hydron from the hydroxy group on carbon 1 of the hemiacetal of D-glucose 6-phosphate while the $NADP^+$ removes the hydrogen from carbon 1. When Histidine 240 is mutated to an asparagine, the rate of the enzymatic reaction decreases by a factor of 50,000.[257] In alcohol dehydrogenase from *Saccharomyces cerevisiae*, however, the hydroxy group of the alcohol is a ligand to a Zn^{2+} ion. This Zn^{2+} lowers the pK_a of the hydroxy group sufficiently so that it has already lost its hydron to form the zinc alkoxide by the time the NAD^+ removes the hydrogen from the adjacent carbon. The Zn^{2+} is placed in the active site in such a way that a lone pair of electrons on the oxyanion, other than the one coordinating the Zn^{2+}, ends up antiperiplanar to the hydrogen that is being removed.[258]

In **aldehydes**, a similar arrangement of hydrogen, carbon, heteroatom, lone pair of electrons, and orthogonal hydron is achieved by forming a hemiacetal, an aminal, a hemiaminal, or a thiohemiacetal



(1–87)

In the **reverse reaction**, the substrate to which a hydride is to be added by NADH or NADPH almost always contains a carbonyl group, an imino group, or an acyl group. This group in the substrate either itself contains the sp^2 carbon to be reduced or is conjugated to that sp^2 carbon by one or more π bonds. Because the sp^2 carbon to be reduced is either in or conjugated to a carbonyl, imino, or acyl group, it is already electrophilic, but its electrophilicity is usually increased by hydronating the oxygen or the nitrogen of the carbonyl, imino, or acyl group as the hydride is being transferred to it (reverse of Equation 1–87). Again, the lone pair of electrons that is being hydronated is in the σ plane of the carbonyl, imino, or acyl group, orthogonal to its π system.

For a reduction accomplished by NADH of an isolated, unconjugated carbonyl group or acyl group in one direction, or for an oxidation accomplished by NAD^+ of an isolated, unconjugated alcohol or hemiacetal in the other direction, the transition state is formed by mixing all nine *p* atomic orbitals of the nicotinamide ring, the *s* atomic orbital of the hydrogen, and the *p* atomic orbitals of the carbonyl or acyl group that is either the reactant in the reduction or the product in the oxidation.

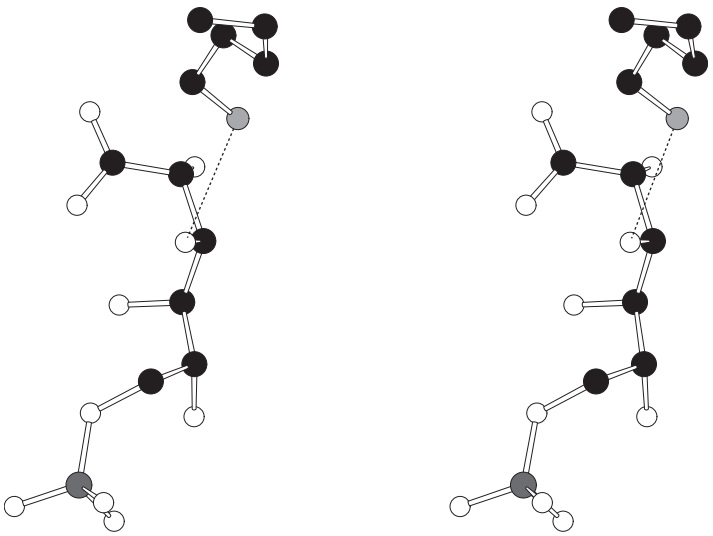


Figure 1–17: Stereodrawing[166] of the orientation of the hydrogen bond between the 3-hydroxy group of the substrate 6-phospho-D-gluconate and Lysine 183 in a crystallographic molecular model of the active site of ovine phosphogluconate dehydrogenase ($NADP^+$-dependent, decarboxylating).[255] Black atoms are carbons, white atoms are oxygens, the small gray atom is a nitrogen, and the large dark gray atom is a phosphorus. The purified enzyme was crystallized from a solution containing 30 mM 6-phospho-D-gluconate. The drawing is of the 6-phospho-D-gluconate bound in the active site of the crystallographic molecular model and the side chain of Lysine 183. In the orientation drawn, the carbon–hydrogen bond on carbon 3 of the 6-phospho-D-gluconate is horizontal and in the plane of the page. Because it is hybridized sp^3, the 3-hydroxy group is held by the hydrogen bond to the 6-amino group of the lysine in a conformation in which one of its lone pairs of electrons is antiperiplanar to the hydrogen on carbon 3 that is to be removed.

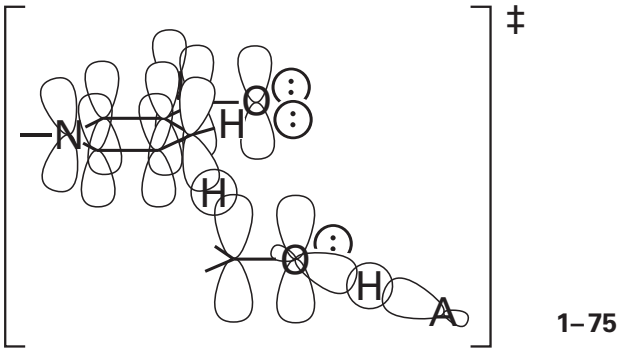
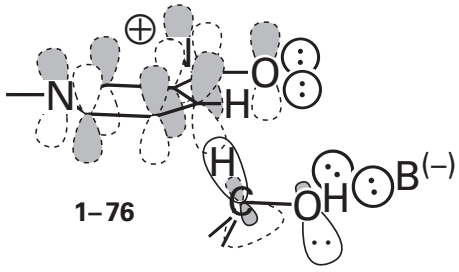
In the case of a simple, unconjugated carbonyl group, 12 atomic orbitals are mixing



1–75

to produce the 12 molecular orbitals of the transition state, and the 14 electrons fill the seven molecular orbitals of lowest energy. A hydron is usually being removed from or added to, respectively, the oxygen at one of its lone pairs of electrons, which is orthogonal to the molecular orbital system of the rest of the transition state.

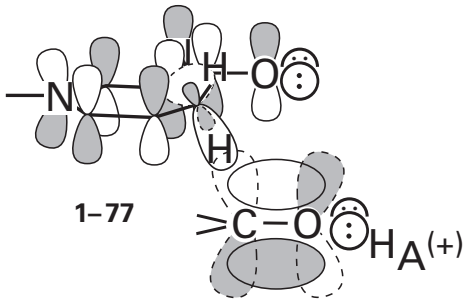
At the beginning of the reaction between NAD^+ and a substrate from which a hydride is to be removed, there are two **initial overlaps of molecular orbitals**.[259] One is between the lowest unoccupied molecular orbital of the cation of the nicotinamide and the occupied bonding molecular orbital of the hydrogen–carbon σ bond of the substrate. The other is between the unoccupied antibonding orbital of the carbon–hydrogen bond and the sp^3 atomic orbital on the oxygen occupied by a lone pair of electrons



1–76

where gray shading indicates phase within the molecular orbitals and dashed outline indicates antibonding molecular orbitals. The overlap of the unoccupied antibonding molecular orbital of the carbon–hydrogen bond with the occupied atomic orbital of the lone pair of electrons provides the push.

In the reverse direction, at the beginning of the reaction between NADH and a substrate to which a hydride is to be added, there are also two **initial overlaps of molecular orbitals**.[260] One is between the highest occupied molecular orbital of the linear, bifurcated π molecular orbital system of the reduced nicotinamide ring (**1–70**) and the unoccupied antibonding orbital of the σ bond between carbon 4 of the nicotinamide and the hydrogen that will be transferred. This antibonding orbital accepts electron density from the π molecular orbital system of the NADH and will become a p orbital on that carbon in the eventual aromatic system of the NAD^+. The other is between the occupied bonding molecular orbital of the σ bond between carbon 4 of the nicotinamide and its hydrogen and the unoccupied antibonding molecular orbital of the π bond between the carbon and the oxygen of the carbonyl group



1–77

as is the case with any nucleophile (**1–17**).

Consistent with these assignments, the **favored stereochemistry in the transition state** (**1-75**) for the transfer of a hydride between two electrophilic carbons is one in which the hydrogen being transferred is on a line of centers between the two carbons. This line of centers makes 115° angles with the two σ planes of the respective electrophilic carbons: the plane of the nicotinamide ring and the plane of the carbonyl group. In the transition state, the two carbons are 0.26 nm apart.[261,262]

This favored stereochemistry has been **observed in crystallographic molecular models** of active sites occupied by a substrate and NADH or NAD^+. UDP-Glucose 4-epimerase from *E. coli* catalyzes the epimerization of carbon 4 in the D-glucosyl group in UDP-D-glucose

$$\text{UDP-glucose} \rightleftharpoons \text{UDP-galactose} \qquad (1\text{–}88)$$

In this enzymatic reaction a hydride is removed from carbon 4 of the UDP-D-glucose or UDP-D-galactose by the prosthetic NAD^+ in the active site of the enzyme and then added back to the 4-oxo group of the resulting UDP-4-dehydro-D-glucose with the epimeric stereochemistry, after it has flipped over, to produce the product.[263] In the crystallographic molecular model of the inactive complex between

UDP-glucose 4-epimerase, NADH, and UDP-D-glucose,[264] in which **reduced substrate is paired with reduced coenzyme**, the angle between the carbon–oxygen bond at carbon 4 of D-glucose and the line of centers between carbon 4 of the nicotinamide and carbon 4 of D-glucose is 125° (Figure 1–18).[166,264] In this complex, the distance between the two carbons (0.37 nm) cannot be 0.26 nm because each carbon has a hydrogen on it and they butt up against each other rather than one hydrogen passing between the carbons. The plane of the nicotinamide ring of the NAD^+ makes an angle of 145° with the line of centers rather than the ideal 115°, perhaps because the abutting hydrogens shift the nicotinamide ring from its ideal position. A similar orientation and distance between the carbon from which the hydride is removed and carbon 4 of the nicotinamide is observed in the crystallographic molecular model between shikimate, NADPH, and shikimate dehydrogenase ($NADP^+$) from *Thermus thermophilus*[265] and in the crystallographic molecular model[266] between GDP-D-glycero-α-D-*manno*-heptose, NADH, and GDP-D-glycero-α-D-*manno*-heptose 4-dehydrogenase[267] from *Campylobacter jejuni*. Again, these are complexes between reductant and reductant.

Reduced coenzyme F_{420} (**1–69**) is used by methylenetetrahydromethanopterin dehydrogenase to reduce 5,10-methenyltetrahydromethanopterin at its methenyl carbon. In a crystallographic molecular model of the active site of this dehydrogenase from *Methanopyrus kandleri* occupied by 5,10-methylenetetrahydromethanopterin, the reduced substrate, and reduced coenzyme F_{420}, the hydride on the reduced coenzyme F_{420} points directly at the methylene carbon of 5,10-methylenetetrahydromethanopterin.[268] In this orientation it would be poised for the direct transfer of a hydride to the methenyl carbon if the active site were occupied by 5,10-methenyltetrahydromethanopterin, the oxidized reactant, instead of 5,10-methylenetetrahydromethanopterin.

Dihydroflavonol 4-reductase from *Vitis vinifera* uses NADH to reduce the carbonyl group in (+)-dihydroquercetin. In the crystallographic molecular model of the inactive ternary complex between (+)-dihydroquercetin, NAD^+, and the enzyme, in which **oxidized substrate is paired with oxidized coenzyme**, the line of centers between carbon 4 of the nicotinamide ring of NAD^+ and the carbon of the carbonyl group makes an angle of 105° with the plane of the nicotinamide ring and an angle of 90° with the σ plane of the carbonyl group of (+)-dihydroquercetin. The dihedral angle between the plane of the nicotinamide ring and the plane formed by the carbon of the carbonyl group, nitrogen 4 of the nicotinamide, and carbon 1 of the nicotinamide is 81°, instead of 90° as in **1–75**, and the distance between the two carbons is 0.30 nm.[269] This latter distance is determined by the fact that the π electrons in the carbonyl group of (+)-dihydroquercetin and the π electrons in the aromatic nicotinamide ring of NAD^+ cannot approach any closer because of electron repulsion in the ground state. A similar orientation of the carbon from which a hydride is normally removed and carbon 4 of the nicotinamide can be found in a molecular model for the complex between the active site of L-glutamate γ-semialdehyde dehydrogenase from *T. thermophilus*; NAD^+, the oxidized coenzyme; and the thioester between the substrate L-glutamate and a cysteine, the oxidized intermediate in the enzymatic reaction.[270]

When oxidant is mixed with reductant, however, to form the active complex between NADH and oxidized substrate or between NAD^+ and reduced substrate, the pucker of the reduced nicotinamide at carbon 4 in the former complex or the sp^3 hybridization of the α carbon of the alcohol in the latter complex should shorten the distance between these two carbons.[271] A superposition of NADPH, in the crystallographic molecular model of its complex with dihydrofolate reductase from *E. coli*

$$\text{NADPH} + \text{7,8-dihydrofolate} + H^+ \rightleftharpoons \text{5,6,7,8-tetrahydrofolate} + NADP^+ \quad (1\text{–}89)$$

and folate (an alternative substrate for the enzyme), in the crystallographic molecular model of its complex with dihydrofolate reductase, suggests that in the productive complex between this enzyme, folate and NADPH, carbon 4 of the nicotinamide ends up 0.28 nm away from carbon 6 of the folate,[272] almost the ideal distance for the transfer of a hydride. This juxtaposition, in part, explains why the transfer of the hydride from NADPH to 7,8-dihydrofolate has a rate constant[273] of 940 s^{-1}.

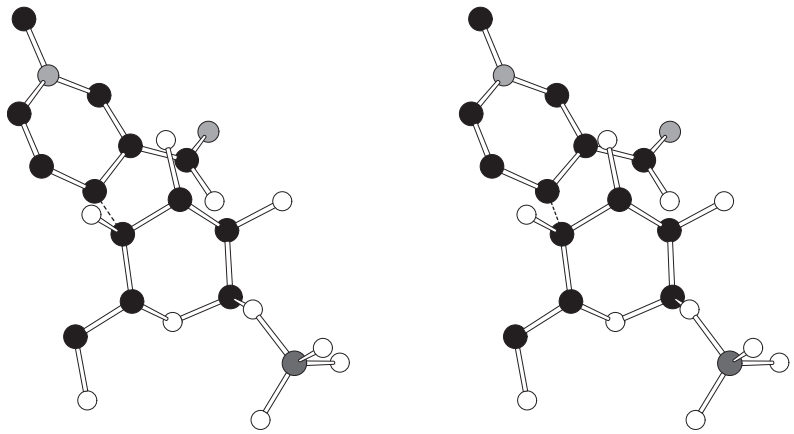


Figure 1–18: Stereodrawing[166] of the in-line transfer of a hydride between carbon 4 of a D-glucosyl group and carbon 4 of the nicotinamide of NADH.[264] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large dark gray atom is a phosphorus. UDP-Glucose epimerase, purified from *E. coli* with tightly bound NAD^+ at its active site, was mixed with the complex of dimethylamine and borane to reduce the NAD^+ to NADH. UDP-D-Glucose was then added to form a complex at the active site containing both NADH and UDP-D-glucose, reductant and reductant. This complex between the enzyme, NADH, and UDP-D-glucose was crystallized, and a crystallographic map of electron density was calculated. In the active site, a segment of electron density, into which could be inserted a molecular model of UDP-D-glucose, was situated adjacent to the electron density previously assigned to the nicotinamide group of NAD^+. The D-glucose 1-phosphate from UDP-D-glucose and the nicotinamide from NADH (Equation 1–78) in the resulting refined crystallographic molecular model are presented, with NADH to the upper left and the D-glucose 1-phosphate to the lower right. A dotted line is drawn between carbon 4 of the D-glucose 1-phosphate and carbon 4 of the nicotinamide.

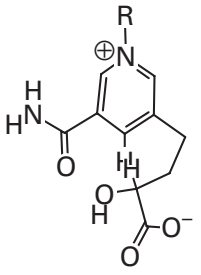
Perhaps the most dramatic demonstration of the stereochemistry of hydride transfer is that occurring intramolecularly within (3*S*)-5-(3-carboxy-3-hydroxypropyl)nicotinamide-adenine dinucleotide



1–78

R ≡ 5′-[(*β*-adenosyl)diphospho]ribosyl

which is a substrate for the enzyme L-lactate dehydrogenase[274]

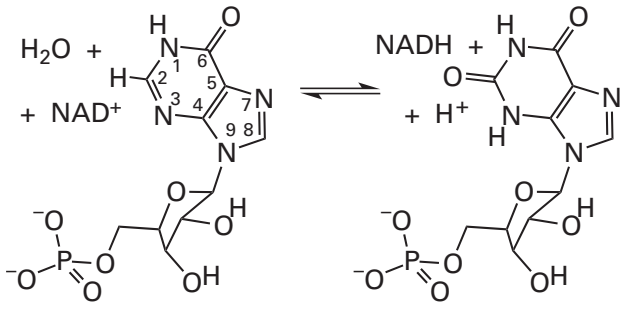
$$NAD^+ + \text{L-lactate} \rightleftharpoons NADH + H^+ + \text{pyruvate} \qquad (1\text{–}90)$$

When **1–78** is the reactant, the transfer of the hydride occurs intramolecularly. This molecule, in which substrate and coenzyme are fused, fits snugly into the active site of the crystallographic molecular model of the porcine enzyme with the hydrogen that is transferred during the enzymatic reaction immediately adjacent to carbon 4 of the nicotinamide ring in the conformation drawn above for **1–78**.[275] When **1–78** is held by the enzyme in this conformation competent for hydride transfer, the distance between the exocyclic carbon of the alcohol that is to be oxidized and carbon 4 of the oxidized nicotinamide is 0.23 nm. The angle between the line of centers connecting these two atoms and the carbon–oxygen bond of the exocyclic carbonyl group is 105°, but the angle between the line of centers and the plane of the nicotinamide is again about 145°. In the crystal, the hydride is being transferred back and forth between the two carbons continuously.

When the electrophilic carbon in the oxidized form of a substrate is located in a conjugated portion of the substrate for a particular enzyme, the planar *π* molecular orbital system of that substrate often forms a parallel stack with the *π* molecular orbital system of the nicotinamide ring when it is bound in the active site of the enzyme responsible for the oxidation–reduction. A simple example would be that found in the crystallographic molecular model of the active site of octenoyl-CoA reductase/carboxylase from *Streptomyces cinnabarigriseus* when it is occupied by $NADP^+$ and oct-2-enoyl-SCoA (Figure 1–16).[231] In this case, oxidized coenzyme is paired with oxidized substrate. The *π* molecular orbital system, consisting of the first four atoms of the *α*,*β*-unsaturated thioester (the acyl oxygen, the acyl carbon, and the double bond of the oct-2-enoyl group), is found stacked against the aromatic *π* molecular orbital system of the oxidized nicotinamide. The space between the two planes is about 0.34 nm, the usual distance between stacked *π* molecular orbital systems such as those in the stack of nucleotide bases in DNA.

In the crystallographic molecular model of the inactive complex between D-2-hydroxyacid dehydrogenase (NAD^+) from *Lactobacillus casei*, NAD^+, and 2-oxoisocaproate,[276] which is inactive because oxidant is paired with oxidant, the distance between the two electrophilic carbons (0.36 nm) again is not 0.26 nm because, in this instance, the *π* molecular orbital system of the unconjugated oxo group in 2-oxoisocaproate also stacks upon the *π* system of the NAD^+, forcing the carbon–oxygen double bond to sit 0.34 nm above the plane of the ring.

If the substrate has a planar unsaturated ring, its planar *π* molecular orbital system usually tends to form a stack with the nicotinamide of the NADH or the NAD^+ when they are associated with the active site of an enzyme responsible for its oxidation–reduction. A paradigm of this type of arrangement for a cyclic substrate is observed in the crystallographic molecular model of the complex between IMP dehydrogenase from *Tritrichomonas foetus* and its substrates. Inosine monophosphate dehydrogenase catalyzes the reaction



(1–91)

in which a derivative of formic acid is oxidized to a derivative of carbonic acid. In the crystallographic molecular model of the inactive complex between the enzyme, NAD^+, and xanthosine monophosphate, in which again oxidant is paired with oxidant and electrophile with electrophile, xanthine is stacked

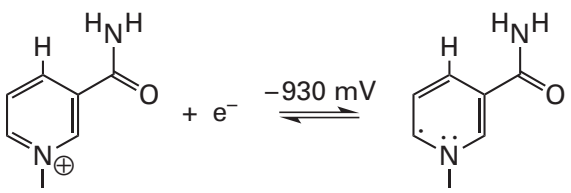
flat against the nicotinamide (Figure 1–19).[166,277] The distance between the planes of the two rings is again 0.34 nm. As before, this distance is enforced by the van der Waals widths of the π molecular orbital system of the two rings.

There are **several problems** with all these arrangements in which the π molecular orbital systems stack upon each other. First, the carbons between which the equivalent of a hydride is transferred, carbon 4 of nicotinamide and carbon 2 of xanthine, necessarily end up 0.34 nm apart, and because of **the van der Waals surfaces of the rings**, there seems to be no way they can approach within the necessary 0.26 nm. Second, carbon 2 of the xanthine in xanthosine monophosphate ends up in the complex directly below carbon 4 of nicotinamide in the NAD^+ (Figure 1–19) so that the **angles between the line of centers** and the respective planes of the two rings are both within 10° of 90°. Finally, the most crucial violation is that the hydride is not on the line of centers between the two atoms between which it is to be transferred.

In these stacked complexes—those in which the ring of NAD^+ stacks upon the π molecular orbital system of a extended linear conjugated arrangement, those in which the ring of NAD^+ stacks upon a carbonyl group or an acyl group, and those in which the ring of NAD^+ stacks upon an unsaturated ring—it seems that there should be a **different mechanism operating** for the transfer of the equivalent of a hydride.

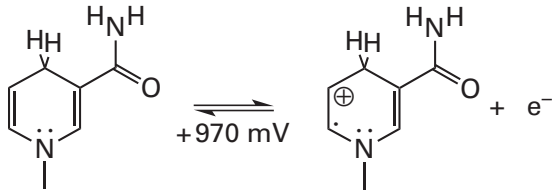
It is possible for the reduction of NAD^+ or the oxidation of NADH to occur in **two consecutive one-electron steps**. In organic solvents,[278] mixtures of water and organic solvents,[279,280] and aqueous solution,[281] NADH participates in one-electron oxidations[279-281] and NAD^+ participates in one-electron reductions,[278,282,283] either at the surface of an electrode[278] or with one-electron oxidants or reductants such as ferricyanide,[279] ferrocenium ion,[280] *N,N,N′,N′*-tetramethyl-4-phenylenediamine radical cation,[281] or hydrated electrons.[282,283]

The reduction potential for the one-electron reduction of NAD^+ to form the neutral radical



(1–92)

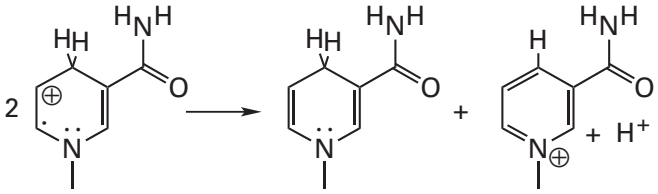
is –930 mV,[280,282,283] and the reduction potential for one-electron reduction of the radical cation of NADH to form NADH is –970 mV.[280,284] This reduction potential means that the potential for the oxidation of NADH by the removal of one electron to form the radical cation



(1–93)

is +970 mV. The neutral radical formed from NAD^+ (Equation 1–92) and the radical cation formed from NADH (Equation 1–93) differ from each other by a hydron and are interconverted by the association or dissociation of a hydron.

The reduction potential for the reduction of NAD^+ is quite negative (Equation 1–92), and the reduction potential for the oxidation of NADH is quite positive (Equation 1–93). These facts state that **both the neutral radical and the radical cation of nicotinamide are unstable species** relative to NAD^+ and NADH, respectively. The radical cation[285] has been observed transiently during the pulsed photooxidation of NADH,[286] but it disproportionates rapidly and completely



(1–94)

because of its instability relative to NAD^+ and NADH. From the one-electron reduction potentials of NADH and NAD^+ and the two-electron reduction potential of NAD^+, the pK_a of the radical cation (Equation 1–93) can be estimated to be about –5, an estimate indicating that it is a strong acid.[281,287]

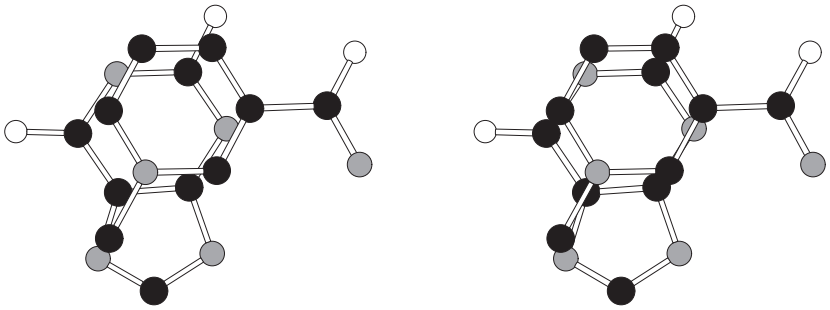


Figure 1–19: Stereodrawing[166] of the π stacking between the nicotinamide of NAD^+ and the xanthine in xanthosine monophosphate in a crystallographic molecular model of IMP dehydrogenase from *T. foetus*.[277] Black atoms are carbons, white atoms are oxygens, and small gray atoms are nitrogens. Inosine monophosphate dehydrogenase from *T. foetus* was mixed with xanthosine monophosphate and then crystallized. The crystals were soaked in a solution of NAD^+ to introduce it into the active site of the enzyme, which was already occupied by xanthosine monophosphate, to form a complex of oxidant and oxidant. In difference maps of electron density, features into which molecular models of xanthosine monophosphate and NAD^+ respectively could be inserted were observed. After insertion of these molecular models, the crystallographic molecular model of the resulting complex between enzyme, xanthosine monophosphate, and NAD^+ was refined against the data set. The xanthine of the xanthosine monophosphate and the nicotinamide of the NAD^+ in the final crystallographic molecular model are drawn: the nicotinamide is shown above and the xanthine is shown below.

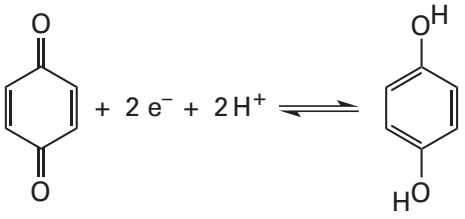
The dissociation of the hydron, albeit a significantly exergonic reaction at pH 7, is required before an electron can be removed from the intermediate radical.[279] Consequently, the consecutive steps in the homolytic oxidation of NADH are removal of an electron, dissociation of a hydron, and removal of the second electron. It follows that in the homolytic reduction of NAD^+, which is the reverse reaction of the homolytic oxidation of NADH, a hydron must be added to the neutral radical formed by the addition of a single electron to NAD^+ (Equation 1–92) before the second electron can be added, and the addition of this hydron to this weak base is a significantly unfavorable step.

The significant instabilities of both the radical cation of NADH and the neutral radical of NAD^+ mitigate against the involvement of nicotinamide in one-electron reactions, particularly with two-electron reactants such as alcohols, carbonyl and acyl groups, and derivatives of carbonic acid. Certainly, the stereochemistry of such oxidation–reductions at the active sites of enzymes responsible for their catalysis (Figure 1–18 and **1–78**) suggests that direct two-electron hydride transfer from NADH or NADPH, which proceeds with a reduction potential for the half-reaction (reverse of Equation 1–79) of –330 mV at pH 7, is the favored path if the orientations required by the transition state can be achieved.

A two-electron reduction that may also have a mechanism involving the transfer of an electron, transfers of hydrons, and then the transfer of a second electron is the **reduction by 1,4-dihydropyridines related to NADH** of 1,4-benzoquinone or its derivatives



(1–95)

If these reductions do proceed in two one-electron steps, each involves an intermediate charge-transfer complex in which the radical cation of the dihydropyridine is stacked upon the radical anion of the benzoquinone,[288] an arrangement reminiscent of the nicotinamide stacked upon the xanthine in the crystallographic molecular model of IMP dehydrogenase (Figure 1–19). Evidence in favor of a mechanism for this reduction involving the consecutive transfer of one electron after the other[288] and evidence in favor of a mechanism involving only direct hydride transfer[289-291] for these reactions have been presented.

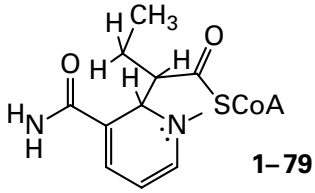
As for enzymatically catalyzed reactions, it has been demonstrated that within the active site of peroxidase from *Armoracia rusticana* (horseradish peroxidase), NADH can be oxidized in a one-electron transfer to the oxoiron(IV) porphyrin$^{\bullet+}$ that is formed at the heme in the enzyme by hydrogen peroxide.[292] This one-electron transfer produces $NADH^{\bullet+}$. A homologous electron transfer also occurs in solution when non-heme oxoiron(IV) complexes oxidize homologues of NADH.[293] Both on the enzymatic active site and in solution, however, the oxidants are strong and also ones that normally engage in one-electron transfers, and for both of these reasons, they are quite different from most of the weak two-electron oxidants that NADH is required to reduce in other enzymatic reactions.

Because of the reduction potentials involved, however, it seems unlikely that an active site, even by stacking the nicotinamide of the coenzyme and the π system of the substrate to facilitate the formation of a charge-transfer complex and by positioning an acid–base for the transfer of the hydron or the hydrons required, could perform a hydride transfer in a process involving the transfer of an electron, the transfer of a hydron, and the transfer of an electron.

There is, however, a more reasonable mechanistic explanation for the common observation of the stacking by an active site of a nicotinamide upon the π molecular orbital system of an extended linear, conjugated system within the substrate or upon a carbonyl group, an acyl group, or an unsaturated ring within the substrate. An intermediate formed during the reduction of (*E*)-but-2-enoyl-SCoA by NADPH in the active site of crotonyl-CoA carboxylase/reductase

$$\text{NADPH} + (E)\text{-but-2-enoyl-SCoA} + CO_2 \rightleftharpoons \text{NADP}^+ + (2S)\text{-ethylmalonyl-SCoA} \quad (1\text{–}96)$$

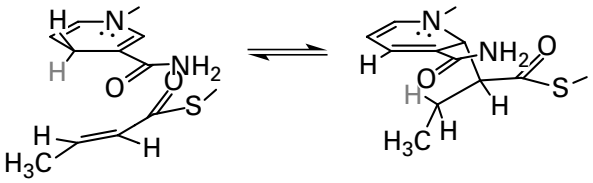
from *Methylorubrum extorquens* has been isolated, and its structure



1–79

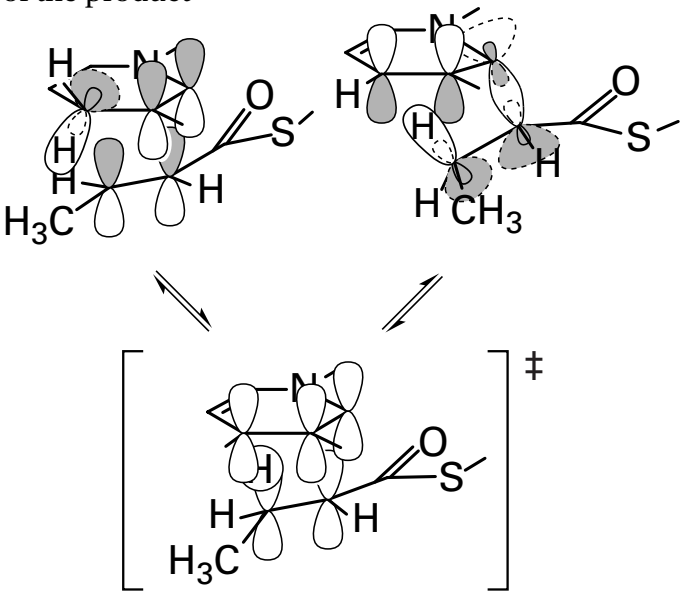
confirmed by high-resolution mass spectrometry and two-dimensional nuclear magnetic resonance spectroscopy. It is a covalent adduct between NADPH and (*E*)-but-2-enoyl-SCoA. When added to a solution containing crotonyl-CoA carboxylase/reductase, $NaHCO_3$, and carbonic anhydrase, an enzyme that converts $NaHCO_3$ into CO_2, but no (*E*)-but-2-enoyl-SCoA or NADPH, the isolated, purified intermediate is converted rapidly by the crotonyl-CoA carboxylase/reductase into (2*S*)-ethylmalonyl-SCoA and $NADP^+$, the usual products of the reduction.[294] Consequently, the intermediate seems to be on the main path of the enzymatic mechanism. Crotonyl-CoA carboxylase/reductase from *M. extorquens* is a homologue (34% identity; 1.6 gap percent)* of octenoyl-CoA reductase/ carboxylase from *S. cinnabarigriseus*, in the active site of which (Figure 1–16) the substrate (*E*)-but-2-enoyl-SCoA is stacked against $NADP^+$, so it seems to be the case that intermediate **1–79** is the result of an analogous stacking of substrate against coenzyme in the active site of crotonyl-CoA carboxylase/ reductase.

Intermediate **1–79** is **proposed to be the product of an ene reaction**, which is a pericyclic reaction. A **pericyclic reaction** is a concerted reaction that passes through a single transition state formed from a continuous ring of overlapping atomic orbitals creating a π molecular orbital system containing the magic aromatic numbers of electrons, 6 or 10, that make it aromatic. An ene reaction that forms intermediate **1–79** in the reduction of (*E*)-but-2-enoyl-SCoA by NADPH in the active site of crotonyl-CoA carboxylase/reductase



(1–97)

has a transition state arising from remixing of the molecular orbitals of the reactant to form an aromatic transition state and from remixing of the atomic orbitals forming the π molecular orbital system of the transition state to form the molecular orbitals of the product



(1–98)

Carbon 4 of the nicotinamide on which the hydrogen transferred is located is only 0.34 nm from carbon 3 of the (*E*)-but-2-enoyl-SCoA to which it is to be transferred, and carbon 2 of the nicotinamide is only 0.36 nm from carbon 2 of the (*E*)-but-2-enoyl-SCoA with which it is to form a σ bond (dashed line in Figure 1–16).

The octanoyl homologue of intermediate **1–79**, in which the methyl group is an *n*-pentyl group, has been isolated from a reaction mixture in which a mutant of enoyl-[acyl-carrier-protein] reductase (NADH) from *Mycobacterium tuberculosis* is reducing (*E*)-oct-2-enoyl-SCoA* to octanoyl-SCoA[295] while oxidizing NADH to NAD^+. In a crystallographic molecular model of the active site of this enzyme,[296] the π molecular orbital system of (*E*)-oct-2-enoyl-SCoA forms a stack with NAD^+. In this instance, however, the enolate of octanoyl-SCoA that dissociates from the intermediate homologous to **1–79** during the normal enzymatic reaction is hydronated at the α carbon instead of being carboxylated because the product of the reaction is to be octanoyl-SCoA. The

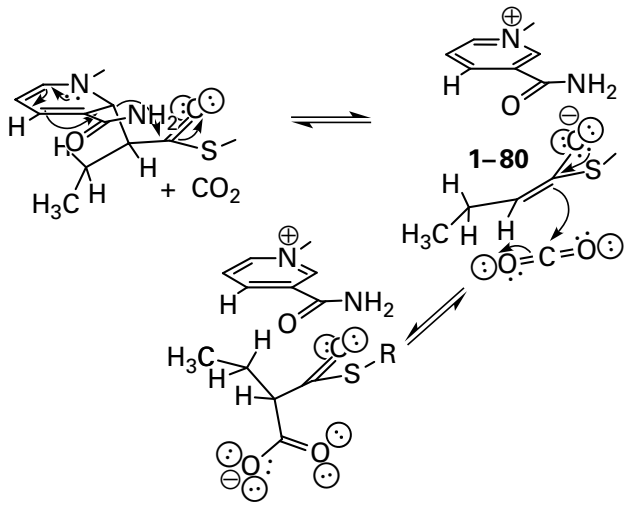
*Acyl-carrier protein is a small protein that carries thioesters among the enzymes involved in the biosynthesis of fatty acids. The portion of acyl-carrier protein closest to the thioester is identical to the distal portion of coenzyme A so the two can usually be interchanged in the reaction of an enzyme that normally would have the thioester of acyl-carrier protein as a substrate such as enoyl-[acyl-carrier-protein] reductase (NADH).

*__Percent identity__ is the percent of positions in the two optimally aligned sequences that have identical amino acids. __Gap percent__ is the number of gaps for every 100 amino acids required to obtain the greatest percent identity. A percent identity in excess of 20% is usually a strong indication that the two protein molecules have superposable structures and that the catalytic groups in the active sites, their roles, and the orientation of the substrates when they are associated with the active site are quite similar.

absence of a catalytic acid in the appropriate location in the active site of crotonyl-CoA carboxylase/reductase precludes the hydronation of the enolate in its enzymatic reaction. Enoyl-[acyl-carrier-protein] reductase (NADH) is a much more widely distributed enzyme than crotonyl-CoA carboxylase/reductase because it is essential for the biosynthesis of fatty acids.

There are calculations based on the crystallographic molecular model of the active site of the unrelated[297] enoyl-[acyl-carrier-protein] reductase (NADPH) from *Candida tropicalis*, in the active site[298] of which (*E*)-but-2-enoyl-SCoA also forms a stack with $NADP^+$. These calculations indicate that the direct transfer of the hydride to (*E*)-but-2-enoyl-SCoA in a Michael addition should be more energetically favorable than an ene reaction.[299] The transition state, however, for the transfer of the hydride that is pictured in the report of these calculations does not involve any reorientation of the (*E*)-but-2-enoyl-SCoA to assume the orientation for an in-line transfer, which other calculations indicate is a requirement for the transition state of hydride transfer.[261,262] Following the transfer of the hydride, the carbon–carbon bond holding the two halves of intermediate **1–79** would form through a separate transition state. No explanation, however, is given as to why intermediate **1–79** would be necessary if the hydride has already been transferred.

Intermediate adduct **1–79** between (*E*)-but-2-enoyl-SCoA and NADPH dissociates into $NADP^+$ and the enolate of butanoyl-SCoA (**1–80**)



(1–99)

The aromatization of $NADP^+$ drives the dissociation, which would otherwise involve the loss of a σ bond and the formation of a weaker π bond. The enolate of butanoyl-SCoA is nucleophilic at its α carbon. In the active site of crotonyl-CoA carboxylase/reductase, the nucleophilic carbon of the enolate adds to a molecule of carbon dioxide, an electrophile, held by the active site adjacent to the enolate, to give the product (2*S*)-ethylmalonyl-SCoA.

These observations suggest that there may well be a common mechanism for the transfer of the hydrogen from NADH to an electrophilic atom in the enzymes in which the substrate forms a stack with the nicotinamide. This mechanism proceeds with **a pericyclic addition followed by the dissociation of the adduct to form an enolate or the homologue of an enolate, which is then either hydronated or carboxylated**.

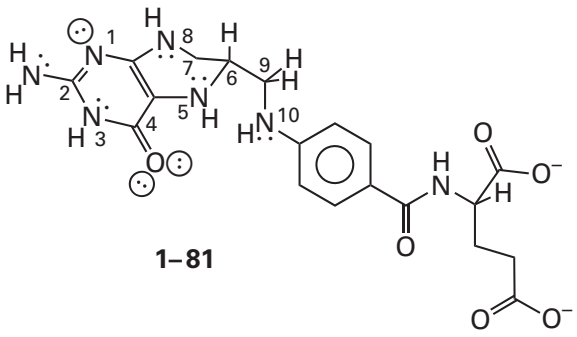
One-Carbon Chemistry

Formaldehyde and formic acid are one-carbon compounds widely involved in metabolism. These molecules, however, are rarely found free in the cytoplasm but are, like a hydride, a fatty acyl group, or a methyl group, associated with a coenzyme. **The coenzyme that carries the single carbons equivalent to formaldehyde and formic acid is tetrahydrofolate**



1–81

The formaldehyde or the formic acid is carried on nitrogen 5 or nitrogen 10 of the tetrahydrofolate or on both of them simultaneously. These nitrogens are three atoms apart, so the transfer of the equivalent of formaldehyde or formic acid between them, which involves either a *gem*-diamine or a tetrahedral intermediate, respectively, can occur through an intermediate five-membered ring.

Again, the coenzyme seems far more elaborate than the role of carrying formaldehyde and formic acid should require. In addition, the form of the coenzyme present in the cell is even more elaborate. In a cell, several additional L-glutamates, each linked by its α-amino group to the γ-glutamyl group of the one previously added, are attached to the γ-carboxyl group of the L-glutamate in tetrahydrofolate to form a regular, linear polymer of L-glutamates,[300] and enzymes using tetrahydrofolate associate preferentially with one or the other of the **polyglutamylated forms**.[301]

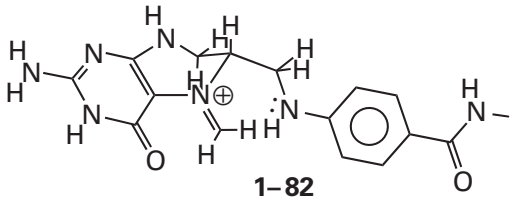
Other portions of the coenzyme act to adjust the **basicities of nitrogen 5 and nitrogen 10**. The planar pyrimidinyl group of tetrahydrofolate (the ring containing atoms 1–4) is analogous to a heterocyclic pyrimidinyl base in nucleic acid; and, as with the base of a nucleic acid, the three nitrogens exocyclic to the pyrimidinyl group, those attached to carbon 2 and at positions 5 and 8, are planar nitrogens[302] with conjugated π lone pairs of electrons. The exocyclic amino group at carbon 2 of the pyrimidinyl group and nitrogen 8 of the tetrahydrofolate are both directly conjugated to the acyl oxygen at position 4. The lone pairs of electrons on these nitrogens are presumably as weakly basic as the lone pair of electrons on the nitrogen of *N*-methylacetamide, the conjugate acid of which is quite strong ($pK_a = -6$). These two nitrogens will rarely if ever be dihydronated and cationic.

The **values of pK_a for nitrogen 5 and nitrogen 10**, however, are the more relevant to the chemistry of tetrahydrofolate. Nitrogen 5 of tetrahydrofolate (exocyclic to the pyrimidinyl group) is only poorly conjugated to the acyl oxygen at position 4 in the pyrimidinyl group, and the pK_a of its conjugate acid (4.82)[303] is close to that of the conjugate acid of aniline (4.63). If this is also true for the second pK_a of nitrogen 5, that for the neutral secondary amino group, then this second pK_a should be about the same as that for the neutral amino group in aniline ($pK_a \cong 30$). The nitrogen at position 10 is analogous to the nitrogen in 4-carbamoylaniline (estimated $pK_a = 2–3$).* Its conjugate acid, however, has a pK_a of –1.25, which reflects both the electron withdrawal of the carbamoyl group para to the amino group and the fact that at the pH at which the hydron dissociates from the 10-ammonio group, both nitrogen 1 and nitrogen 5 are hydronated and cationic. Consistent with these values of pK_a, the **equilibrium constant between 10-formyltetrahydrofolate and 5-formyltetrahydrofolate** is about 10^7 in favor of the latter.[304-306]

The difference in the values of pK_a between the conjugate acids of nitrogen 5 and nitrogen 10, however, does not seem to be necessary for the role that tetrahydrofolate plays in one-carbon chemistry. Tetrahydromethanopterin is a folate used in one-carbon chemistry in many archaebacteria.[307] The substituent para to nitrogen 10 in 5,6,7,8-tetrahydromethanopterin, unlike that in 5,6,7,8-tetrahydrofolate, is a fully saturated carbon so the pK_a of the conjugate acid of nitrogen 10 should be close to that of aniline and no different from the pK_a of the conjugate acid of carbon 5, and yet tetrahydromethanopterin functions effectively in its role in these bacteria. The two folates, tetrahydrofolate and tetrahydromethanopterin, however, are not interchangeable.[308]

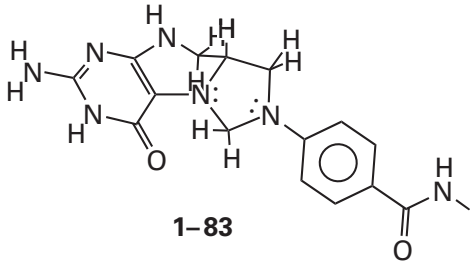
*This estimate is based on the fact that pK_a of 4-ethoxycarbonylaniline is 2.38 and the observation that a carbamoyl group and and ethoxycarbonyl group have about the same ability to withdraw electron density.

An equivalent of formaldehyde is carried as the iminium on nitrogen 5 of tetrahydrofolate



1–82

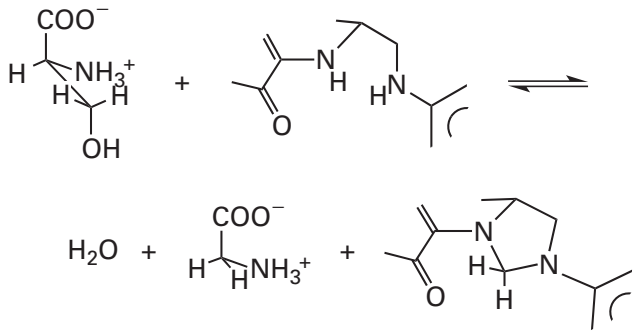
or, more stably,[309] as the *gem*-diamine in N^5,N^{10}-methylenetetrahydrofolate



1–83

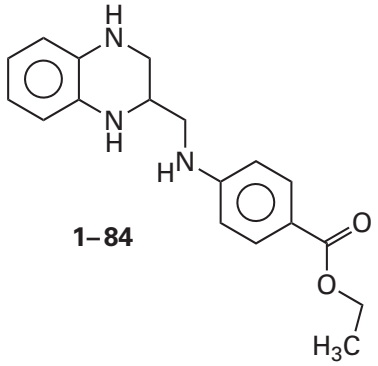
It is rarely carried on nitrogen 10 alone. In the *gem*-diamine, the two nitrogens remain conjugated to the adjacent π molecular orbital systems of the respective rings. Because of its stability and the fact that it is chemically unreactive, N^5,N^{10}-methylenetetrahydrofolate is the exclusive adduct of formaldehyde found in free solution in the cytoplasm of organisms that use tetrahydrofolate as a carrier of formaldehyde. **N^5-Methylenetetrahydrofolate** (**1–82**), however, is the electrophilic intermediate that usually reacts with a nucleophilic substrate in the nucleophilic substitutions at the methylene carbon in the active sites of enzymes that use N^5,N^{10}-methylenetetrahydrofolate as a donor of the equivalent of formaldehyde.[84]

Because of their toxicity, neither the hydrate of formaldehyde nor the small amount of unhydrated formaldehyde in equilibrium with the hydrate (Table 1–2) usually exists in the cytoplasm. Their toxicity arises from the fact that formaldehyde free in solution reacts with proteins and nucleic acids to modify them and to crosslink them in complex and as yet poorly understood reactions. Its direct, nonenzymatic reaction with tetrahydrofolate to form N^5,N^{10}-methylenetetrahydrofolate may occur under certain circumstances;[310] but most, if not all, of the N^5,N^{10}-methylenetetrahydrofolate in the cell is **made from L-serine** by the enzyme glycine hydroxymethyltransferase



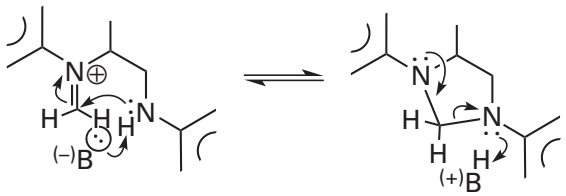
(1–100)

In the reaction between formaldehyde and a model compound for tetrahydrofolate[309]



1–84

the iminium of one of the two nitrogens homologous to nitrogen 5 and nitrogen 10 is formed in a rapid equilibrium by a reaction involving a hemiaminal that dehydrates under catalysis by an acid (Figure 1–7). The homologue of this reaction occurs rarely in living organisms, but the iminium that is the product of this nucleophilic addition is homologous to the intermediate in the reaction catalyzed by glycine hydroxymethyltransferase that immediately precedes the formation of the N^5,N^{10}-methylenetetrahydrofolate (**1–83**) that is the final product of the enzymatic reaction. In the model reaction in solution, the ***gem*-diamine is formed from the iminium by nucleophilic addition**

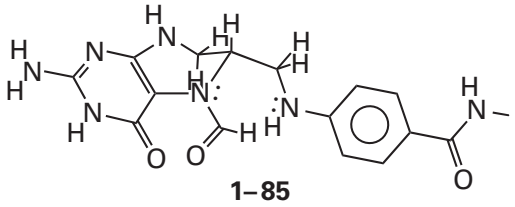


(1–101)

Because the nucleophile in this nucleophilic addition is a weakly basic anilino nitrogen ($pK_a = 2.9$), this step must be catalyzed by a base, which removes the hydron from that nitrogen during its addition

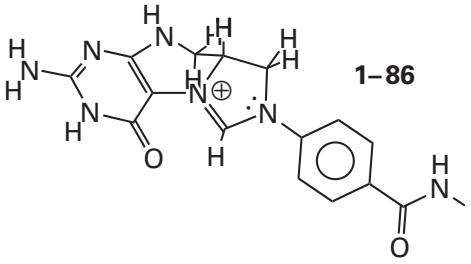
to make it more nucleophilic.[309] The hydron cannot be removed prior to the nucleophilic addition because of its high pK_a.

An equivalent of **formic acid is also carried** at one or both of the two anilino nitrogens, either on nitrogen 5



1–85

as the more stable ***N*⁵-formyltetrahydrofolate** (**1–85**), or at nitrogen 10 as the less stable *N*¹⁰-formyltetrahydrofolate, or as the formamidinium between the two nitrogens, as in ***N*⁵,*N*¹⁰-methenyltetrahydrofolate**



1–86

In its various guises, the formic acid has, as it must, three bonds to heteroatoms. The hydrogen on the methenyl group in *N*⁵,*N*¹⁰-methenyltetrahydrofolate is acidic because the conjugate base is an ylide.[311]

*N*⁵,*N*¹⁰-Methenyltetrahydrofolate (**1–86**) is formed from *N*⁵-formyltetrahydrofolate by a nucleophilic substitution (Figure 1–20). Nitrogen 10 is a poor nucleophile (pK_a = –1.25). Consequently, while nitrogen 10 adds to the formyl group of **1–85** to form this tetrahedral intermediate, a base must simultaneously remove its hydron to make it a better nucleophile, as is the case in the model compound.[312] The reaction proceeds through a tetrahedral intermediate from which the oxygen is the leaving group.

In *N*⁵,*N*¹⁰-methenyltetrahydrofolate (**1–86**) both the 4-*N*-acylaminophenyl ring attached to nitrogen 10 and the pyrimidinyl ring attached to nitrogen 5 are twisted out of the plane of the formamidine by steric effects (Figure 1–21),[302] but the twist is not sufficient to break an extended π system that includes the entire pyrimidinyl group, nitrogen 5, the formyl carbon, nitrogen 10, and the 4-*N*-acylaminophenyl group.

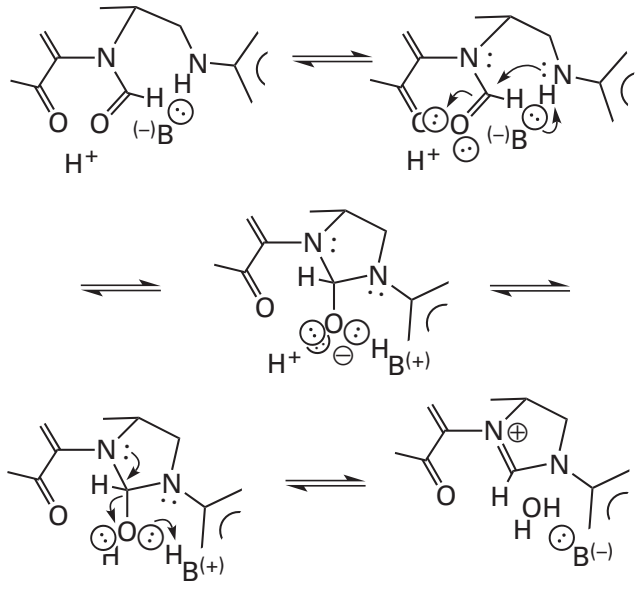


Figure 1–20: Transformation of *N*⁵-formyltetrahydrofolate to *N*⁵,*N*¹⁰-methenyltetrahydrofolate. Formation of the tetrahedral intermediate occurs with catalysis by a general base, and the oxygen of the tetrahedral intermediate must be hydronated before it can leave to yield the amidinium ion.

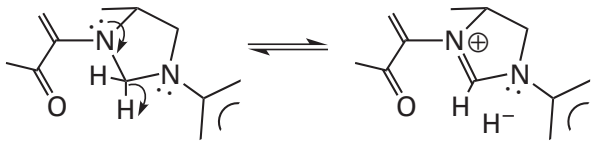
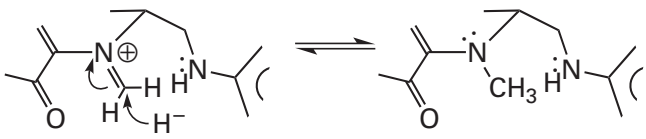
When they are adducts of tetrahydrofolate, the equivalents of formaldehyde and formic acid are interconverted by an oxidation–reduction involving hydride transfer



(1–102)

This hydride transfer is catalyzed by the enzyme methylenetetrahydrofolate dehydrogenase, which uses as a source of the hydride either nicotinamide-adenine dinucleotide, nicotinamide-adenine dinucleotide phosphate,[313] or coenzyme F_{420} (**1–69**),[314] depending on the species from which the enzyme is purified.

The reduction of *N*⁵-methylenetetrahydrofolate



(1–103)

produces ***N*⁵-methyltetrahydrofolate**. This reaction

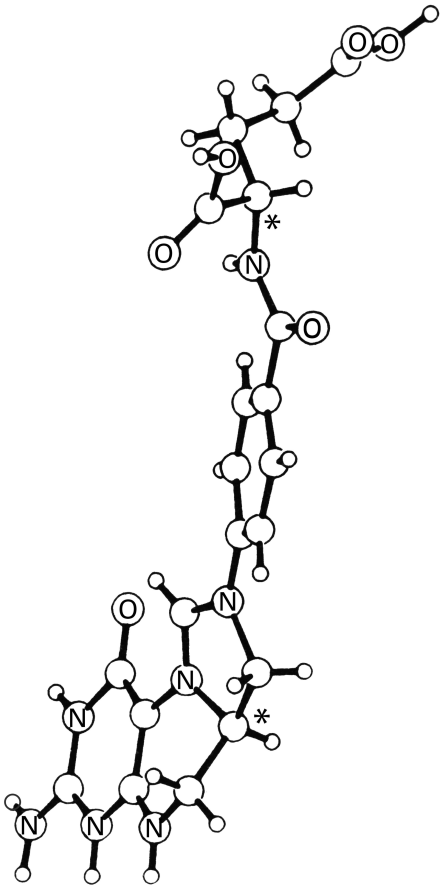


Figure 1–21: Crystallographic molecular model of the conjugate acid of N^5,N^{10}-methenyltetrahydrofolate.[302] White atoms are carbons unless otherwise indicated and the small white atoms are hydrogens. The dication of N^5,N^{10}-methenyltetrahydrofolate was produced from N^5-formyltetrahydrofolate in hydrochloric acid and crystallized as the bromide salt from 50% hydrobromic acid. A map of electron density was derived from X-ray diffraction of these crystals. The asterisks denote the two chiral carbons in this, the naturally occurring diastereomer. The absolute configuration at these carbons was verified with anomalous dispersion. The two formal positive elementary charges of the dication are located in the planar guanidino group in the lower left of the molecule and the amidinium of the methenyl group. Reprinted with permission from reference 302. Copyright 1979 American Chemical Society. https://doi.org/10.1021/ja00514a041

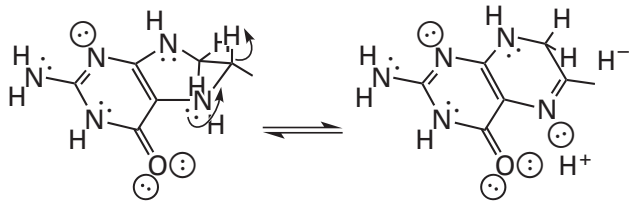
is catalyzed by the enzyme methylenetetrahydrofolate reductase, which also uses either NADH or NADPH. N^5-Methyltetrahydrofolate can act as a simple **methylating agent** (Equation 1–19) in a concerted nucleophilic substitution with strong nucleophiles such as thiolate ion.[315] For example, the archaebacterial analogue of N^5-methyltetrahydrofolate, 5-methyl-5,6,7,8-tetrahydromethanopterin, is the source of the methyl group of *S*-methyl coenzyme M (*S*-methyl-2-sulfanylethanesulfonate). It is this methyl group that is, in turn, the source of the methane produced by these bacteria.[245]

Methionine synthase transfers the methyl group from N^5-methyltetrahydrofolate to L-homocysteine to produce L-methionine. The thiolate of L-homocysteine is the nucleophile, and nitrogen 5 of N^5-methyltetrahydrofolate is the leaving group in a simple concerted nucleophilic substitution. The problem faced by the enzyme is that nitrogen 5 is an anilino nitrogen. Because the pK_a of the conjugate acid of nitrogen 5 in N^5-methyltetrahydrofolate is 5, it is unhydronated at neutral pH, and because the pK_a of the neutral 5-alkylamino group of 5,6,7,8-tetrahydrofolate is around 30, the unhydronated nitrogen is a poor leaving group. The enzyme from *Candida albicans* solves this problem by providing an acid that hydronates the nitrogen before the nucleophilic substitution commences to make it a better leaving group.[316] The hydron on a histidinium side chain is relayed to nitrogen 5 by a molecule of water.[317]

Tetrahydrofolate itself is oxidized and 7,8-dihydrofolate is reduced by hydride transfer in a reaction catalyzed by dihydrofolate reductase



(1–104)

This reaction regenerates tetrahydrofolate by reduction from the 7,8-dihydrofolate produced during the synthesis of thymidine by thymidylate synthase

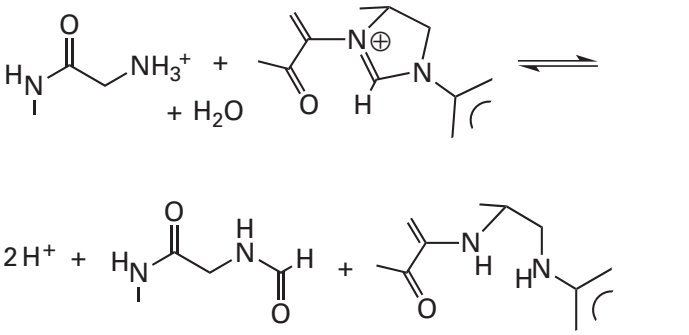
5,10-methylenetetrahydrofolate + dUMP
$\rightleftharpoons$ 7,8-dihydrofolate + dTMP

(1–105)

and it also participates in the production of tetrahydrofolate from the vitamin folate.

The enzymatically catalyzed reactions involving adducts of tetrahydrofolate with the equivalent of either formic acid or formaldehyde have mechanisms that avoid the formation of free formic acid or free formaldehyde.

The **transfer of a formyl group** from N^5,N^{10}-methenyltetrahydrofolate (**1–86**) is often to a third amine, as in the reaction catalyzed by phosphoribosylglycinamide formyltransferase 1



(1–106)

The first step in a reaction of this type is addition of the amine of the acceptor to the formyl carbon in N^5,N^{10}-methenyltetrahydrofolate (Figure 1–22),[318,319] which is an amidine and as a result a strongly electrophilic acyl derivative. After it has been dehydronated, the resulting neutral form of the resulting tetrahedral intermediate has three possible leaving groups, each an amine. The hydronation of one or the other of the two π lone pairs of electrons on the nitrogens of the tetrahydrofolate to make that nitrogen a reasonable leaving group is far more difficult than the hydronation of the aliphatic amine that just associated. If, however, the aliphatic amine is hydronated and leaves, this only regenerates the reactants. In order for the reaction to proceed, one of the anilino nitrogens of the tetrahydrofolate must be hydronated to make it a leaving group. Usually it is nitrogen 5 that is hydronated because it is the more basic nitrogen.[319]

After nitrogen 5 of the tetrahydrofolate leaves, the product of the first nucleophilic substitution is a mixed amidine between nitrogen 10 of tetrahydrofolate and the nitrogen of the amine. To complete the transfer of the formyl group, either hydroxide or water from which a hydron is being removed attacks this mixed amidine to form a second tetrahedral intermediate. At this point a difficulty arises. In free solution the leaving group from this tetrahedral intermediate is always the aliphatic amine rather than the anilino nitrogen,[318] because the aliphatic nitrogen is definitely more basic, and hence more readily hydronated, than the anilino nitrogen. Presumably, in the enzymatic reaction there is a catalytic acid adjacent to nitrogen 10 to hydronate the anilino nitrogen and complete the transfer of the formyl group to the aliphatic amine. If the aliphatic amine were to leave, then the products of the second nucleophilic substitution would be 10-formyltetrahydrofolate and the amine that was the original reactant.

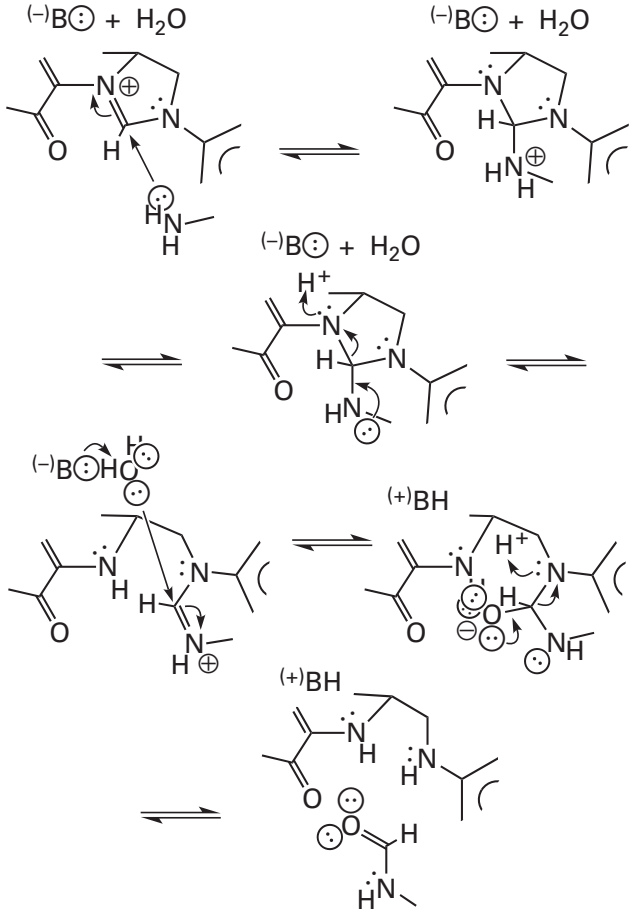


Figure 1–22: Transfer of the formyl group from N^5,N^{10}-methenyltetrahydrofolate to the primary amine on phosphoribosylglycinamide.[318,319] The reaction involves two consecutive nucleophilic substitutions at the formyl carbon: in the first, the amine from the glycinamide enters and an anilino nitrogen of tetrahydrofolate leaves, and in the second, the oxygen of a molecule of water under base catalysis or a hydroxide ion enters and the other anilino nitrogen of tetrahydrofolate leaves.

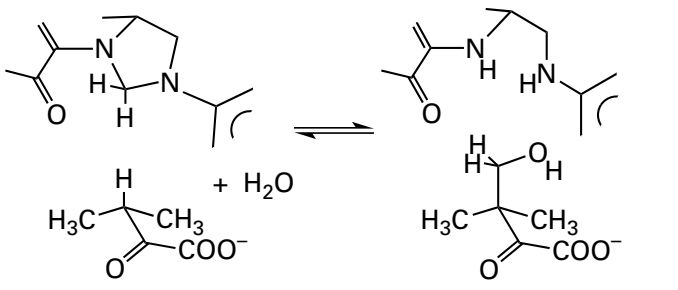
The **transfer of the equivalent of formaldehyde** from N^5,N^{10}-methylenetetrahydrofolate (**1–83**) to a nucleophile usually proceeds through the electrophilic iminium of N^5-methylenetetrahydrofolate (**1–82**), which can transfer the single carbon to a nucleophile directly. The necessary N^5-methylenetetrahydrofolate is formed in the reverse of the reaction in Equation 1–101. For example, in the reaction catalyzed by 3-methyl-2-oxobutanoate hydroxymethyltransferase



(1–107)

the single electrophilic imino carbon on nitrogen 5 of N^5-methylenetetrahydrofolate is transferred in a nucleophilic substitution (see reverse of the reaction in Figure 1–7) in which the nucleophilic carbon in the enolate of 3-methyl-2-oxobutanoate replaces the anilino nitrogen of tetrahydrofolate. The leaving group in this nucleophilic substitution at the methylene carbon is nitrogen 5 of tetrahydrofolate ($pK_a \cong 30$). Consequently, it is again necessary to provide an acid to hydronate nitrogen 5 during the nucleophilic substitution, or it will not leave.

When **the equivalent of either formaldehyde or formic acid is transferred to nitrogen 5** in tetrahydrofolate from an electrophile, nitrogen 5 is required to act as a nucleophile. It is, however, a poor nucleophile because its conjugate acid is fairly strong ($pK_a = 4.82$). Its **nucleophilicity can be enhanced**, however, by removing the hydron from nitrogen 3 ($pK_a = 10.5$).[303] Although this enhancement cannot be demonstrated by resonance, the negative formal elementary charge resulting from this dehydronation at nitrogen 3, which is shared by nitrogen 3 and oxygen 4, decreases inductively the delocalization of the lone pair of electrons on nitrogen 5 into the pyrimidinyl ring and increases its nucleophilicity. For example, in the active sites of aminomethyltransferase from *Thermotoga maritima*[320] and thymidylate synthase from *E. coli*, [321] both enzymes in which nitrogen 5 of tetrahydrofolate must be nucleophilic in the normal forward direction, the nitrogen–hydrogen bond of nitrogen 3 of the tetrahydrofolate forms a hydrogen bond to a glutamate and an aspartate, respectively, which are significant bases capable of increasing the nucleophilicity of nitrogen 5. There are exceptions to this assistance. In glycine hydroxymethyltransferase from *Geobacillus stearothermophilus*, nitrogen 3 is forming a hydrogen bond with an amido oxygen from the polypeptide backbone,[322] which is not a significant base.

In the reaction catalyzed by 3-methyl-2-oxobutanoate hydroxymethyltransferase (Equation 1–107), the electrophilic methenyl group is transferred from nitrogen 5 of N^5,N^{10}-methylenetetrahydrofolate to carbon 3 of 3-methyl-2-oxobutanoate. The nucleophile in this transfer is the enolate that is the conjugate base of 3-methyl-2-oxobutanoate. This enolate is formed by the dissociation of a hydron from the saturated but acidic carbon 3 of 3-methyl-2-oxobutanoate. This carbon is acidic because it is immediately adjacent to an acyl group.

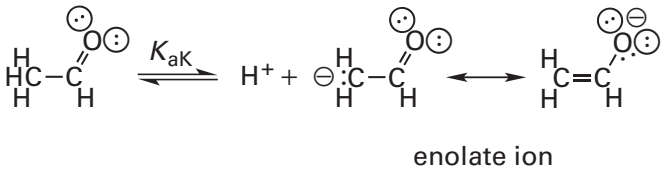
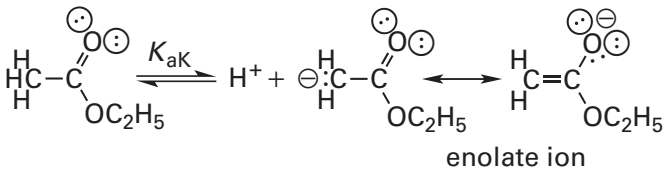
Enolates, Enols, and Enamines

The hydrogen on a carbon immediately adjacent to a carbonyl group or an acyl group is acidic (Figure 1–23)[33,34,38,323-335] because the electronegative oxygen two atoms away from that carbon can support the excess electron density of the conjugate base. The simplest examples of this acidity are that of acetaldehyde, the pK_{aK}* of which is 16.7



(1–108)

and ethyl acetate ($pK_{aK} = 25.6$)



(1–109)

*The subscript K indicates that the pK_a is that for the keto tautomer of the carbonyl compound or the keto form of the acyl derivative. The subscript E indicates that the pK_a is that for the enol tautomer.

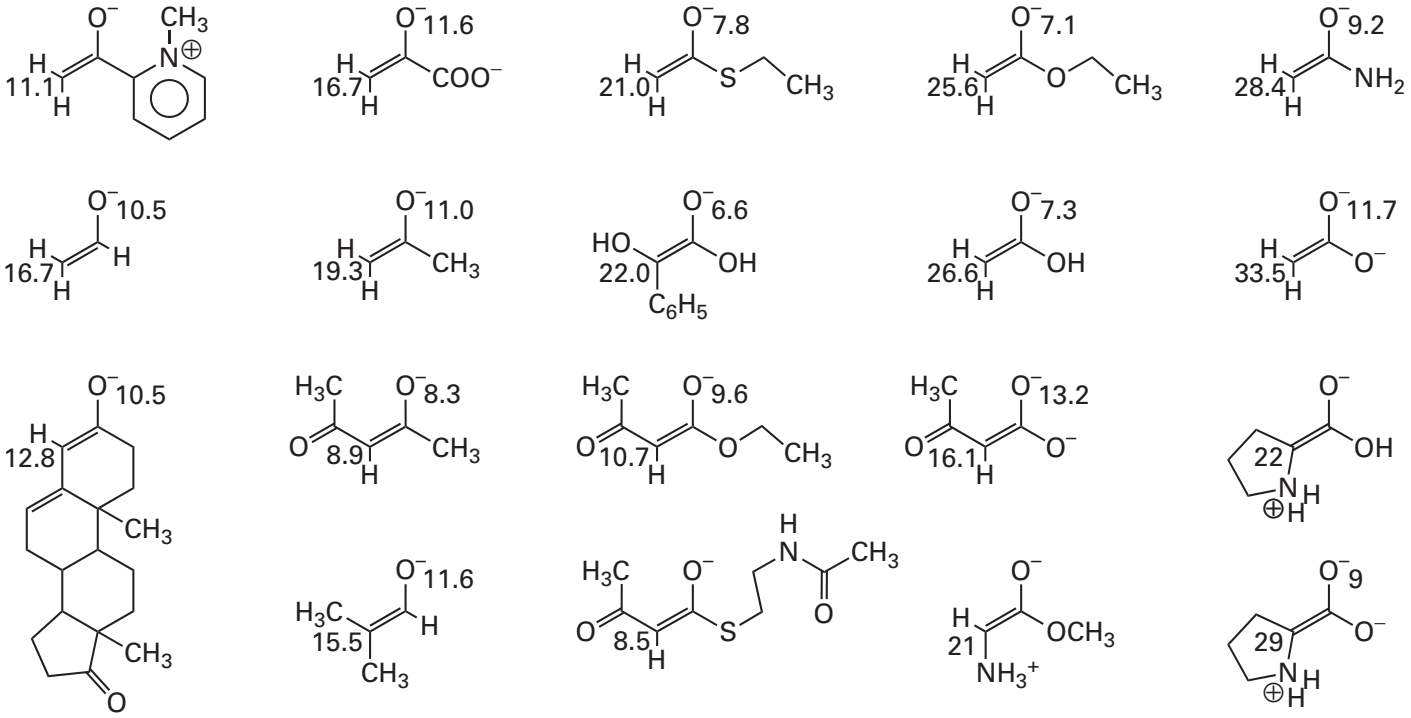


Figure 1–23: Values of pK_a for the acid dissociations of a series of keto tautomers and their enol tautomers.[33,34,38,323-335] The enolate ion of each compound is drawn. The number next to the α carbon of the enolate ion is the pK_a of the keto tautomer of its conjugate acid (pK_{aK}, Equation 1–110); the number next to the oxygen of the enolate ion is the pK_a of the enol tautomer of its conjugate acid (pK_{aE}, Equation 1–110). The value of the respective pK_E (Equation 1–110) is the difference between the two numbers (Equation 1–111). The values of pK_a for the different tautomers of glycine and L-proline containing ammonio groups are estimates from various thermodynamic cycles.[332,334]

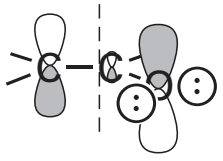
The two respective resonance structures demonstrate the conjugation of the neighboring oxygen in the enolate. This conjugation, which shifts negative charge from the carbon onto the more electronegative oxygen to stabilize the enolate, causes the acid dissociation constant of acetaldehyde to be much less than that of propane (p$K_a \cong 50$), in which a methyl group takes the place of the oxygen, and it causes the acid dissociation constant of ethyl acetate to be much less than that of ethyl isopropyl ether (p$K_a \cong 49$).

Because hydroxide can remove a hydron from acetaldehyde many orders of magnitude more rapidly than it can from propane, the neighboring π molecular orbital system must be involved in the **transition state for the dissociation of a hydron on the carbon adjacent to a carbonyl or acyl group** (Figure 1–24). The two electrons in the occupied bonding molecular orbital of the original carbon–hydrogen σ bond remain behind in the π molecular orbital system of the enolate. As the transition state is approached, this occupied σ molecular orbital of the carbon–hydrogen bond overlaps the unoccupied antibonding π^* molecular orbital of the π molecular orbital system between carbon and oxygen. This overlap will create the occupied nonbonding π molecular orbital of the enolate once the hydron has been removed. Also during the approach to the transition state, the occupied atomic orbital of the lone pair of electrons on the base that removes the hydron overlaps the unoccupied antibonding molecular orbital of the carbon–hydrogen bond to gain access to the hydron. In the transition state, the atomic orbital of the base, the 1*s* orbital of the hydrogen, two *p* orbitals, one on each of the two carbons, and a *p* orbital on the oxygen mix, and three of the five resulting molecular orbitals of the transition state are occupied by the six electrons participating in the reaction. The transition state decomposes into the hydronated base and the π molecular orbital system of the enolate through an overlap between the unoccupied antibonding molecular orbital of the σ bond between the base and the hydron and the **nonbonding π molecular orbital of the resulting enolate**



1–87

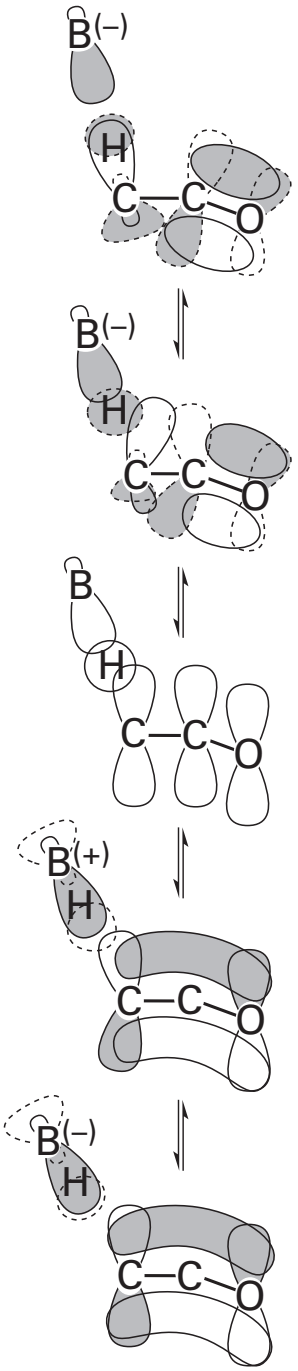


Figure 1–24: Removal of a hydron by a base, B, from a carbon adjacent to a carbonyl group. As the atomic orbital occupied by the lone pair of electrons on the base (solid outline) overlaps the unoccupied antibonding molecular orbital of the carbon–hydrogen bond (dashed outline), the occupied bonding molecular orbital of the carbon–hydrogen bond (solid outline) overlaps the unoccupied antibonding molecular orbital of the π bond between carbon and oxygen (dashed outline). The five atomic orbitals that mix in the transition state are the atomic orbital of the base, the *s* orbital of the hydrogen, and three *p* orbitals on the two carbons and the oxygen. The transition state decomposes through a form in which the unoccupied antibonding molecular orbital of the σ bond between the base and the hydron (dashed outline) overlaps the occupied nonbonding π molecular orbital (composed from the two peripheral *p* orbitals) of the enolate. These overlaps occur in each direction of the reaction.

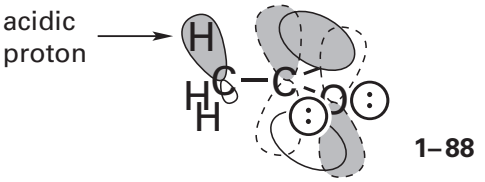
which is its highest occupied molecular orbital.

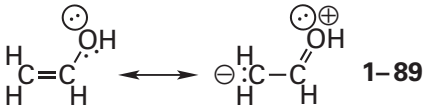
For the acid–base reaction to occur in this way, the hydron removed from carbon must be in a **σ bond parallel to the π molecular orbital** system to permit the necessary overlaps and mixing in the transition state



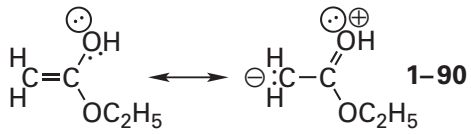
It has already been explained in the section describing the transfer of a hydron why this removal of a hydron from the carbon α to a carbonyl or acyl group by a base, even when the reaction is significantly exergonic, is a slow process.

The highest occupied nonbonding π molecular orbital of the enolate (**1–87**) is **nucleophilic** because it bears the pair of electrons that constitute the excess electron density of the enolate and are responsible for its negative elementary charge. The fact that an enolate can be stabilized by donors for hydrogen bonds directed parallel to this nonbonding π molecular orbital[336] is consistent with the fact that it contains the excess electron density and the nucleophilicity. This nonbonding π molecular orbital accounts for the resonance structures (Equation 1–108) that assign negative charge only to the two end atoms of the three atoms participating in the enolate. The formalism of resonance structures is a reflection of the fact that the highest occupied molecular orbital (**1–87**) has a node close to the central carbon and significant lobes over only the peripheral carbon and the oxygen.

The enolate of a carbonyl compound or acyl compound can be hydronated on oxygen to form the enol tautomer. Examples of enol tautomers would be the enolate of acetaldehyde (Equation 1–108) that has been hydronated on its oxygen



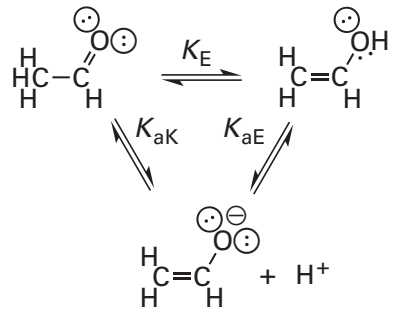
and the enolate of ethyl acetate (Equation 1–109) that has been hydronated on its oxygen



1–90

The enol tautomer of acetaldehyde is acidic at its hydroxy group and is a much stronger acid ($pK_{aE} = 10.5$) than acetaldehyde itself, and the enol tautomer of ethyl acetate is acidic at its hydroxy group and is a much stronger acid ($pK_{aE} = 7.1$) than ethyl acetate itself (Figure 1–23). During the dehydronation of an enol tautomer, the hydron that is removed and that leaves behind a σ lone pair of electrons is in a σ bond to oxygen that is in the σ plane of the enol orthogonal to and uninvolved in the π molecular orbital system of the enol tautomer (see **1–87**). Removal of the hydron from the oxygen of the enol tautomer of acetaldehyde ($\Delta pK_a = 5.2$) or the oxygen of the enol tautomer of ethyl acetate ($\Delta pK_a = 8.6$) by a strong base such as hydroxide is a encounter-controlled reaction.[16] This behavior is consistent with an uncomplicated removal of a hydron from a σ lone pair of electrons on oxygen.

In solution, an enol tautomer is in equilibrium with both its enolate and its **keto tautomer**. An example of these equilibria is shown for acetaldehyde



(1–110)

The equilibrium between the keto form and the enol, with the equilibrium constant K_E, is a **keto–enol tautomerization**. Because the three reactions are linked

$$-\log K_E = pK_E = pK_{aK} - pK_{aE} \qquad (1–111)$$

For compounds such as acetaldehyde ($pK_E = 6.2$)[324] and other aldehydes; for acetoacetic acid ($pK_E = 2.2$),[337] other β-oxo acids, and β-oxo esters;[325] and for enol tautomers conjugated to carbon–carbon double bonds,[333] the value for K_E is large enough that measurable amounts of the enol tautomer are present in solution at equilibrium with the dominant keto tautomer. In most other cases, the equilibrium constant for the keto–enol tautomerization, K_E, is so small that the concentration of enol tautomer is undetectable. A **solution of the pure enol tautomer**, however, can be prepared by rapidly mixing a metallic salt of the enolate, dissolved in organic solvent, with water. The enolate is immediately hydronated on the oxygen to produce the enol tautomer[338] before the enol tautomer slowly converts to the keto tautomer because the hydronation of a σ lone pair of electrons on a heteroatom, even though it is less basic, is much faster than the hydronation of a carbon atom in a π molecular orbital system. A solution of the enol tautomer can also be prepared even more rapidly by photolysis of an appropriate precursor.[339] From the kinetics of the subsequent approach to equilibrium between the keto and enol tautomers, the equilibrium constants of Equation 1–110 can be measured.[324] The values of pK_{aK} and pK_{aE} for a series of enol tautomers and their keto tautomers have been measured by these methods and also estimated from the rates[33] at which the hydrons on α carbons adjacent to carbonyl or acyl groups exchange in the presence of base (Equation 1–110).

The acidity of a hydron on the α carbon adjacent to a carbonyl or acyl group in the keto tautomer varies as the substituents attached to the carbonyl or acyl carbon, or to the α carbon itself, are changed (Figure 1–23). These effects are relevant because there are many enzymatic reactions in which a hydron is removed from a carbon α to a carbonyl or acyl group by a catalytic base in the active site. In each of these enzymatic reactions, the pK_a of that particular carbon determines the ease with which it can be transferred to the base in the active site.

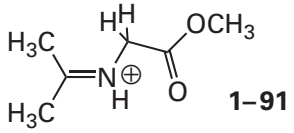
When the hydrogen on the carbonyl carbon of acetaldehyde [pK_{aK} (acetaldehyde) = 16.7] is changed to a methyl group, the pK_a of the α hydron increases [pK_{aK}(acetone) = 19.3]. This increase in pK_a reflects the **hyperconjugation** of the carbon–hydrogen σ bonds of the methyl group. In the enolate, the pairs of electrons in these σ bonds push into the π system and destabilize the anion relative to the neutral conjugate acid, and in the neutral conjugate acid, this hyperconjugation releases electron density to the electron-deficient carbon of the carbonyl group to stabilize it.

When the hydrogen on the carbonyl carbon of acetaldehyde is replaced with an ethoxy group or a hydroxy group, the pK_a of the α hydron increases even more [pK_{aK}(ethyl acetate) = 25.6; pK_{aK}(acetic acid) = 26.6] because the **lone pairs of electrons** on the oxygen that has been added push electron density even more strongly into the π molecular orbital system of both the enolate and the keto tautomer than does the methyl group. When the hydrogen on the carbonyl carbon of acetaldehyde is replaced with a carbamoyl group, the pK_a of the α hydron [pK_{aK}(acetamide) = 28.4] increases further because the electrons in the lone pair on the neutral nitrogen are more basic than those on a neutral oxygen. When the hydrogen on acetaldehyde is replaced by an oxyanion, the pK_a of the α hydron [pK_{aK}(acetate ion) = 33.5] increases even further because of the even stronger basicity of lone pairs of electrons on the anionic oxygen. Because the electrons affecting the acidity in these instances are lone pairs of electrons rather than σ bonds as in the case of hyperconjugation, **resonance structures** can be written for each of these electron donations.

When the hydrogen on the carbonyl carbon of acetaldehyde is replaced by an ethylsulfanyl group, however, the pK_a of the α hydron [pK_{aK}(ethyl thioacetate) = 21.0] does not increase so much as when it is replaced by an ethoxy group because the **lone pairs of electrons on a sulfur** do not overlap effectively with the π system of the enolate or the carbonyl group. Consequently, they do not destabilize the enolate and stabilize the carbonyl group as much as do the lone pairs of electrons on an oxygen.[340] This failure of lone pairs of electrons on sulfur, an element in the third row of the periodic table, to overlap effectively with a π system of atoms from the second row[341] results from a mismatch in the size of the respective *p* orbitals. This fact explains why, when a hydron has to be removed by an enzyme from the carbon α to an acyl group, the acyl group will usually be a thioester of coenzyme A, a thioester of a cysteine on the enzyme itself, or a thioester of a pantetheine attached to the enzyme as a posttranslational modification.

When the hydrogen of acetaldehyde is replaced by a carboxy group, the pK_a of the α hydron does not change at all [pK_{aK}(pyruvate ion) = 16.7] because the withdrawal of electron density from the enolate or the carbonyl carbon by the electropositive carbon of the carboxylato group through the σ system is cancelled by the donation of electron density into the π system of the enolate and the carbonyl group from the π system of the carboxylato group. If, however, the hydrogen on acetaldehyde is replaced by an *N*-methylpyridinio group, the pK_a of the α hydron decreases significantly [pK_{aK}(2-acetyl-*N*-methylpyridinium ion) = 11.1] because the withdrawal of electron density through the σ system by the nitrogen bearing a positive elementary charge outweighs the donation of electron density through the π system from the aromatic pyridinyl group.

The acidity of the α carbon in the keto tautomer of a carbonyl or acyl compound is also affected by **substitutions at the acidic α carbon** itself. In particular, when a carbon in an α position is adjacent to **a double bond between the atoms in the β and γ positions**, the π molecular orbital system of that double bond becomes conjugated to the enolate in a π molecular orbital system encompassing five atoms upon removal of the hydron from the α carbon. The pK_a of the α carbon decreases relative to an analogous α carbon that is adjacent to a fully saturated carbon [pK_{aK}(4-andro-stene-3,17-dione) = 12.8; pK_{aK}(acetone) = 19.3] because the loss of the hydron permits extended conjugation to occur. The rate at which the hydron can be removed by a base also increases dramatically in such a situation,[7] a fact suggesting that the π system of the adjacent double bond overlaps the carbon–hydrogen σ bond in the transition state for hydron transfer, lowering its energy. Another example of the effect of a double bond between the atoms in the β and γ positions on the acidity of an α hydron in a keto tautomer is manifest in the iminium

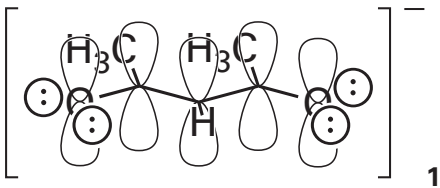


1–91

The removal of the hydron α to the methyl ester creates an sp^2 carbon with a *p* orbital that conjugates the carbon–nitrogen double bond to the resulting enolate. This conjugation again produces a π molecular orbital system spread over five atoms. As a result, the pK_{aK} (14)* of iminium **1–91** is 7 units lower than the pK_{aK} (21) of the cationic conjugate acid of methyl glycinate.[342]

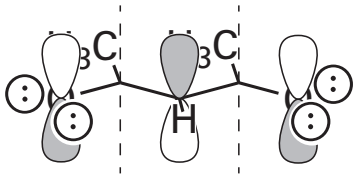
*Again, the pK_a of the iminium cation was estimated indirectly from other acid dissociation constants and rate constants for dehydronation.

When **a second carbonyl or acyl group** is substituted for one of the hydrogens on the carbon α to a carbonyl group or acyl group, the hydron between the two carbonyl groups is much more acidic. For example, acetylacetone ($pK_{aK} = 8.9$) is more acidic than acetone ($pK_{aK} = 19.3$). This increase in acidity reflects the stabilization brought about by delocalization of the negative elementary charge through a π molecular orbital system spread over five atoms in the enolate



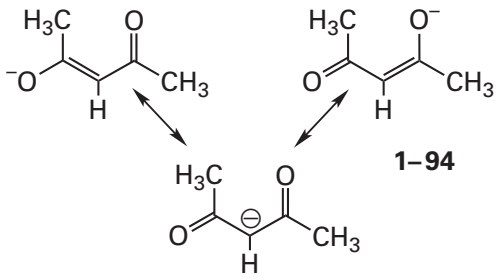
1–92

In this π molecular orbital system, the highest occupied molecular orbital, the orbital containing the excess electron density and the negative elementary charge, has nodes at the two carbons adjacent to the central carbon



1–93

and lobes over the two oxygens and the central carbon. The highest occupied molecular orbital explains why the negative elementary charge is shared by only the two oxygens and the central carbon in the resonance structures

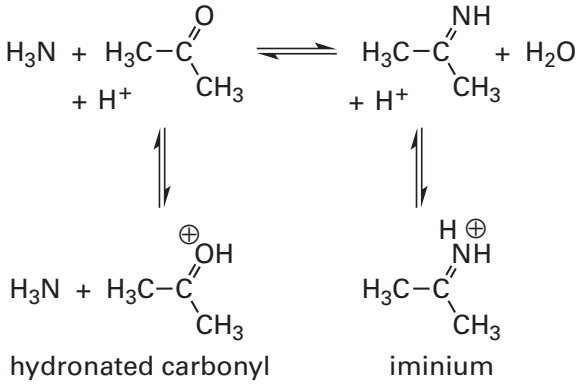


1–94

The fact that the negative elementary charge is shared by two electronegative oxygens instead of one explains the dramatic decrease in the pK_{aK}.

When one of the methyl groups of acetylacetone ($pK_{aK} = 8.9$) is replaced with an ethoxy group, the acidity decreases [pK_{aK}(ethyl acetylacetate) = 10.7], and when the other is replaced by an ethoxy as well, there is a further decrease [pK_{aK}(diethyl malonate) = 13.3]. These decreases in acidity reflect the stronger π electron donation of the lone pairs of electrons on oxygen than the hyperconjugation of the pairs of electrons in the carbon–hydrogen σ bonds of a methyl group. When one of the methyl groups of acetylacetone ($pK_{aK} = 8.9$), however, is replaced by an alkylsulfanyl group, the acidity of the carbon α to the resulting thioester remains essentially unchanged {pK_{aK}[*S*-(2-acetamido)ethylthioacetylacetate] = 8.5}, again because of the ineffective overlap of an atomic orbital on sulfur containing a lone pair of electrons with the π system of the enolate.

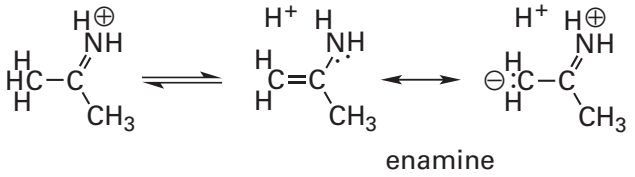
It is possible to acidify a hydron on a carbon adjacent to a carbonyl group further by converting the carbonyl group into an iminium[343]



(1–112)

The pK_a of a hydron on acetone is decreased by around 11 units, from $pK_{aK} = 19$ to $pK_{aK} \cong 8$, by this substitution.[343] It has also been observed that, depending on the strength of the base, the rate of hydron removal from the α carbon increases by a factor of 10^5–10^8 in the iminium compared to the parent carbonyl compound.[343,344] Nevertheless, the rates of hydron removal from the α carbon of an iminium are a factor of 10^3 slower than the rates of hydron removal from the respective cationic carbonyl compound hydronated on its oxygen (Equation 1–112), but hydronating an imine, the conjugate acid of which has a $pK_a \cong 8$, is much easier than hydronating a carbonyl oxygen, the conjugate acid of which has a $pK_a \cong -7$.

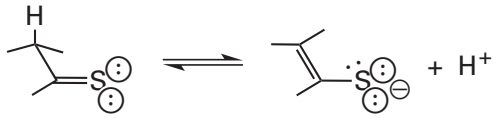
An **enamine** is the vinylic amine that is the conjugate base resulting from the removal of a hydron from the carbon atom of an iminium



(1–113)

An enamine is more nucleophilic at the carbon than the corresponding enol tautomer (**1–89**) because the electronegativity of nitrogen is less than that of oxygen. All these considerations illustrate the advantages of an enamine relative to an enol at neutral pH in the absence of strong bases and acids.

A hydron α to a **thiocarbonyl** is also acidic.[345] The conjugate base is an **enethiolate,** a vinylic thiolate

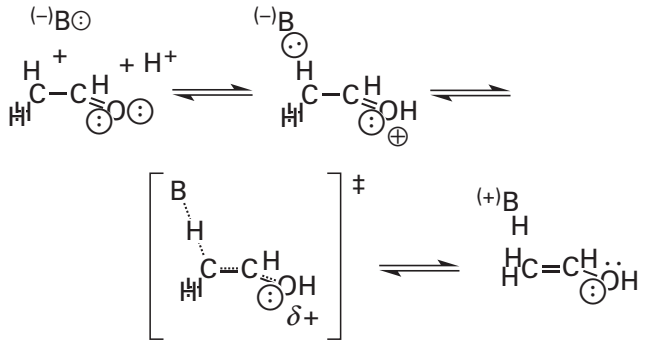


(1–114)

The **acid dissociation constants of the hydroxy groups of enol tautomers** (K_{aE} in Equation 1–110) are affected much less than those of the respective keto tautomers by substitutions at the α carbon or the carbonyl or acyl carbon (Figure 1–23), and often in the opposite direction. The values of pK_{aE} for the hydroxy groups of the enol tautomers usually fall within the range between 7 and 13, a range that makes one of these hydroxy groups a compatible partner with a base on the side chain of an amino acid in an enzyme such as a histidine ($pK_{a1} = 6.6$; $pK_{a2} = 14$), a tyrosine ($pK_a = 9.8$), a lysine ($pK_a = 10.5$), an arginine ($pK_a = 13$), or even an aspartate or a glutamate the pK_a of which has been elevated by its surroundings. Consequently, the transfer of a hydron between the hydroxy group of an enol tautomer and one of these bases will be rapid and uncomplicated. It is simply the removal of a hydron from an otherwise undistinguished heteroatom.

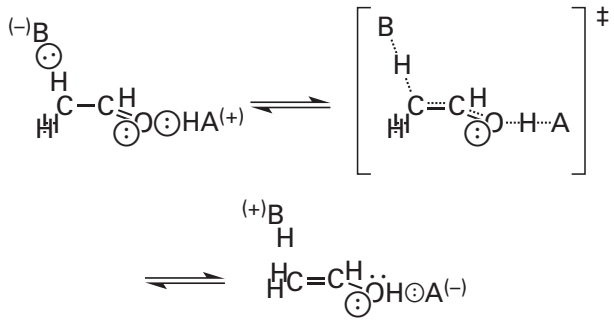
An enol tautomer is less nucleophilic than its conjugate enolate. One way to see this is to examine the effect of hydronation of the enolate oxygen on the distribution of electron density in the nonbonding π molecular orbital of the enolate (**1–87**). When one of the σ lone pairs of electrons on the oxygen of the enolate is hydronated, the oxygen loses the negative charge that was pushing electron density onto the α carbon, and the underlying electronegativity of its oxygen increases the π electron density on that oxygen at the expense of the electron density on carbon. Nevertheless, the carbon in an enol tautomer does retain excess electron density, as illustrated in the right-hand resonance form of **1–89**. On paper, this is an unlikely resonance form because of separation of charge, but it does indicate that the carbon shares the π electron density in the highest occupied molecular orbital and remains nucleophilic. When the enol tautomer is paired with a functional group on a side chain that has similar pK_a in the active site of an enzyme, significant amounts of the more nucleophilic enolate are usually present in rapid equilibrium with the enol. Consequently, once the enolate is formed, it is an effective nucleophile.

The enol tautomer can be produced from the keto tautomer of an aldehyde or a ketone in an acid-catalyzed reaction or base-catalyzed reaction in which either hydronation at oxygen precedes dehydronation at carbon



(1–115)

or hydronation at oxygen occurs simultaneously with dehydronation at carbon[346-348]

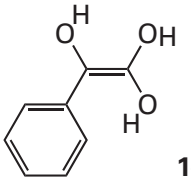


(1–116)

In either case, as indicated in Equations 1–115 and 1–116, the hydron is added to a lone pair of electrons on oxygen orthogonal to the developing π molecular orbital system of the enol tautomer, a hydronation that both increases the electronegativity of oxygen and increases its ability to withdraw electron density from the carbon–hydrogen σ bond.

The **simultaneous hydronation of the oxygen of the carbonyl or acyl group** by a general acid (Equation 1–116) makes it much easier to remove a hydron from the α carbon.[349] In the active site of an enzyme, there will usually be a Brønsted acid acting as the donor in a hydrogen bond to one of the lone pairs of electrons on the oxygen of a carbonyl or acyl group or two Brønsted acids acting as donors to both of the lone pairs. One of these donors will provide the necessary hydron. A dicationic, metallic Lewis acid coordinated to one of the lone pairs will also acidify the α hydron, an acidification making it easier to remove the hydron. Nevertheless, even when it is immediately adjacent to a carbonyl or acyl group, the oxygen of which has been hydronated or is the ligand to a metallic ion, the removal of a hydron from carbon is always slow.

The problem of removing an α hydron is encountered in the extreme in the **removal of the hydron α to a carboxylate** [pK_{aK}(acetate ion) = 33.5; Figure 1–23]. Mandelate racemase from *P. putida* removes a hydron from the α carbon of mandelate (2-phenyl-2-hydroxyacetate ion). In the active site of this enzyme, one of the carboxylate oxygens of mandelate forms a hydrogen bond with the side chain of Glutamate 317, and the other forms a hydrogen bond with the side chain of Lysine 164 and is also a ligand to a Mg^{2+} ion.[350] If the former oxygen in this complex is equivalent to the hydronated oxygen of mandelic acid, then the pK_{aK} of the hydron on the α carbon would be lowered to 22. It has been pointed out that hydronation of the second oxygen would lower the pK_{aK} of the α carbon to 7.4,[351] but the pK_a of the second oxygen should be around –8, which would make it difficult to hydronate. The postulated dihydronated intermediate would be the *gem*-enediol of mandelic acid*

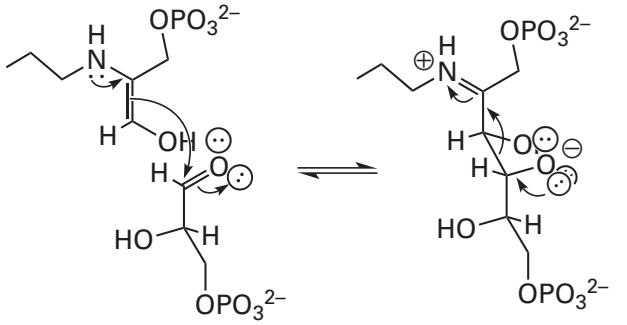


1–95

Although a particularly stable *gem*-enediol has been synthesized,[352] such compounds are usually so unstable that they cannot be observed. In addition, the fact that Mg^{2+} is bound at one of the two carboxylate oxygens when mandelic acid is bound to the active site of the enzyme also would dramatically inhibit its hydronation. The nonenzymatic dehydronation of the α carbon of mandelic acid, however, is accelerated by Mg^{2+} acting as a Lewis acid.[3] It seems to be the case that when mandelate forms a hydrogen bond at one of its carboxylate oxygens with a carboxylic acid and forms a hydrogen bond with an ammonium ion and a complex with Mg^{2+} at the other, the pK_{aK} of the hydron α to that carboxylate is decreased significantly to make its dehydronation relatively rapid.

So far, the nucleophilic substitution of one heteroatom for another at a saturated carbon, a carbonyl carbon, an acyl carbon, or phosphorus; the nucleophilic addition of a heteroatom to a carbonyl group; and the oxidation or reduction of carbon by the transfer of a hydride have been discussed. These several classes of organic reactions account for most of metabolism. They do not, however, involve the making or breaking of carbon–carbon bonds, which is essential to biosynthesis as well as catabolism.

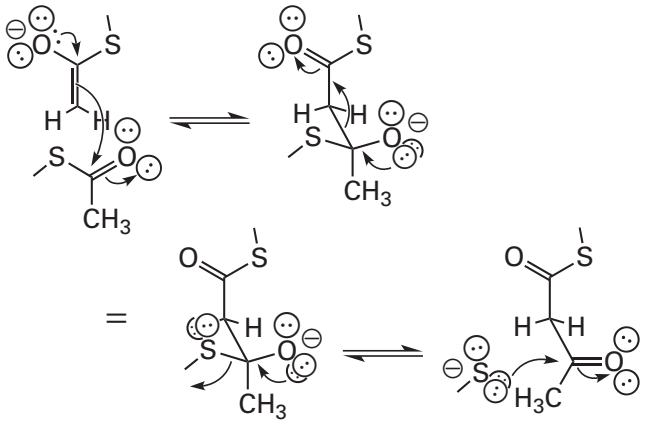
Carbon–carbon bonds are usually made or broken biochemically by the nucleophilic addition of an enolate or an enamine to a carbonyl group or by the nucleophilic substitution of a heteroatom at an acyl group by an enolate or an enamine. An enzymatic example of the nucleophilic addition of an enamine to a carbonyl group is the **aldol condensation** catalyzed by fructose-bisphosphate aldolase



(1–117)

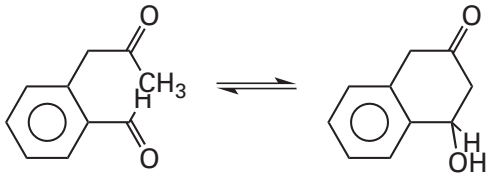
An enzymatic example of the substitution of an enolate for the thiol of a thioester is the **Claisen condensation** catalyzed by the active site for 3-oxoacyl-[acyl-carrier-protein] synthase in fatty acid synthase

*Enetriol **1–95** is a *gem*-enediol that happens to have a hydoxy group at carbon 2. It is the *gem*-enediol, the two hydroxy groups on carbon 1, that would make the intermediate dramatically unstable were it free in solution rather than bound in an active site.



(1–118)

In an aldol condensation in which the enolate is held immediately adjacent to the carbonyl group with which it is to condense, as in the base-catalyzed reaction

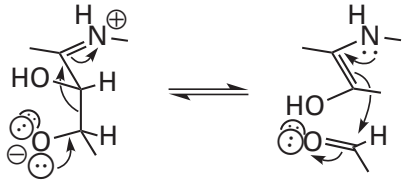


(1–119)

the rate-limiting step of the nucleophilic addition is the removal of the hydron from the α carbon to form the enolate[353] because the rehydronation of the enolate on carbon is much slower[324] than its condensation with the carbonyl or acyl group. Presumably, in the active site of an enzyme, where the enolate or enamine and the carbonyl or acyl group are held even more rigidly, the rate-limiting step of the reaction will usually be the removal of the hydron from carbon.

In enzymatic aldol condensations and Claisen condensations, there is usually a catalytic acid that is the donor for a hydrogen bond to the carbonyl or acyl oxygen on the electrophile: for example, the aldehyde to which the enolate adds in the reaction catalyzed by fructose-bisphosphate aldolase (Equation 1–117) or the thioester to which the enolate adds in the reaction catalyzed by 3-oxoacyl-[acyl-carrier-protein] synthase (Equation 1–118). This hydrogen bond with the acid polarizes the carbon–oxygen double bond and increases its electrophilicity significantly,[349] in addition to providing the hydron required in the formation of the hydroxy group.

In the **reverse reactions** of Equation 1–117 and the first step in Equation 1–118, one of the lone pairs of electrons on the incipient carbonyl or acyl oxygen, respectively, participates in the breaking of the carbon–carbon bond by providing **push**. For example, in the reverse of Equation 1–117



(1–120)

the orbitals that mix to form the transition state, and that also must be able to overlap as the transition state is approached, are the atomic orbital bearing the lone pair of electrons on the oxyanion, the σ molecular orbital system of the carbon–carbon σ bond that is broken, and the π molecular orbital system of the carbon–nitrogen double bond (Figure 1–25). A hydroxy group in a hydrogen bond also provides push, but it is weaker.

In the direction of forming the carbon–carbon bond in Equation 1–117, the orbitals that mix to produce the transition state are the π molecular orbital system of the enamine and the π molecular orbital system of the carbonyl group. For the transition state to be accessible, these atomic orbitals and all the composite atomic orbitals of these molecular orbitals must be parallel to each other, as indicated in Equation 1–120 and Figure 1–25. By microscopic reversibility, if the sp^3 atomic orbital on the oxygen providing the push enters the reaction parallel to the σ bond being broken, it must emerge from the transition state in the reverse reaction parallel to the newly formed σ bond.

Enolates, enols, enamines, and enethiols[345] are intermediates in carboxylations and decarboxylations. The most consequential examples of such reactions are the carboxylation of ribulose 1,5-bisphosphate, which is responsible for the fixation of carbon dioxide during photosynthesis and hence ultimately all the carbon in living organisms, and the decarboxylation of oxalosuccinate, which is responsible for a significant fraction of the expired carbon dioxide in living organisms.

Carbon dioxide

1–96

can be considered to be a dicarbonyl compound*

*Because of the two perpendicular π systems in carbon dioxide that each include all three of the atoms, the oxygens in carbon dioxide are hybridized *sp* and resemble the oxygens in a carbonyl compound in the gas phase or an aprotic solvent.

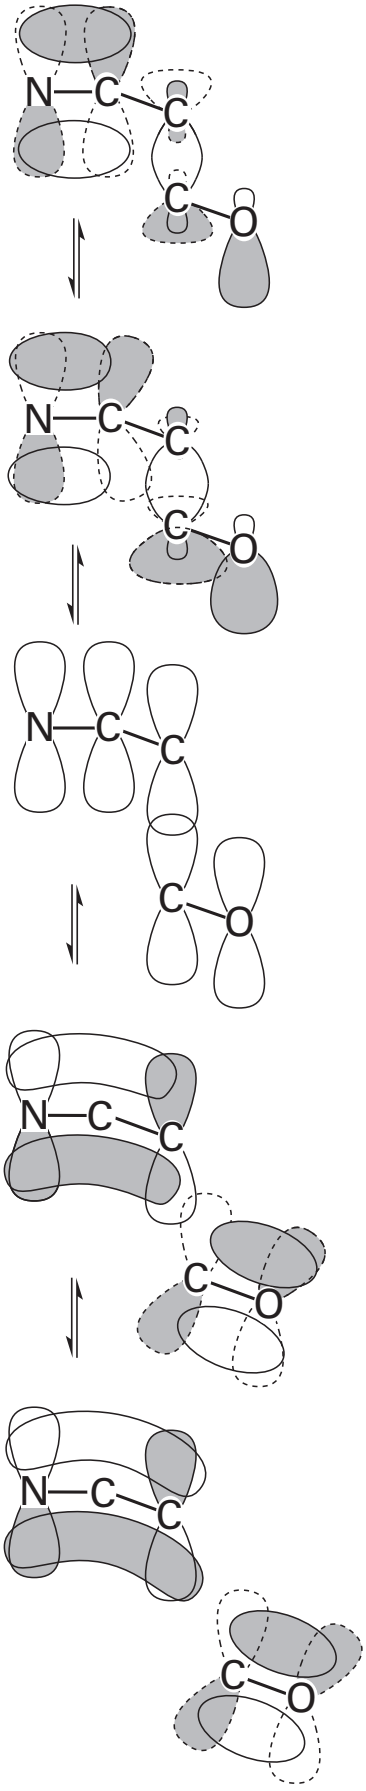


Figure 1–25: Breaking or forming of a carbon–carbon bond adjacent to an imine (Equation 1–117). The reaction breaking the carbon–carbon bond is initiated by overlap of the atomic orbital occupied by the lone pair of electrons on oxygen (solid outline) and the unoccupied antibonding σ molecular orbital of the carbon–carbon bond (dashed outline) and by overlap of the occupied bonding σ molecular orbital of the carbon–carbon bond (solid outline) and the unoccupied antibonding π molecular orbital of the carbon–nitrogen π bond (dashed outline). In the transition state, five p orbitals, one from each of the five atoms, overlap. The transition state decomposes through overlap of the occupied nonbonding π molecular orbital of the enamine (composed from the two peripheral p orbitals of the enamine) and the unoccupied antibonding π molecular orbital (dashed outline) of the carbon–oxygen π bond. The formation of the carbon–carbon bond is the reverse direction.

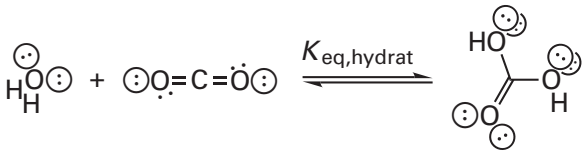
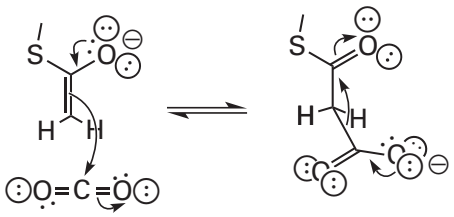
in which the central carbon is electrophilic and hence a Lewis acid, as is a hydron. In fact, it is educational to consider carbon dioxide and a hydron to be interchangeable, as was the case when the final steps in the respective mechanisms of crotonyl-CoA carboxylase/reductase (Equation 1–99) and enoyl-[acyl-carrier-protein] reductase (NADH) were equated. As a Lewis acid, the central carbon in carbon dioxide associates with a nucleophilic lone pair of electrons during a **carboxylation**. Again, the simplest example of such a nucleophilic addition is **hydration**



(1–121)

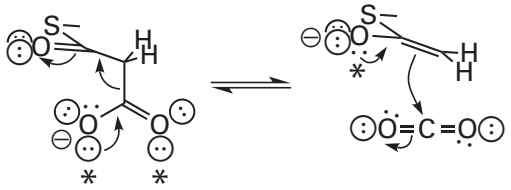
The mechanism of the hydration of carbon dioxide involves removal of a hydron from water and addition of a hydron to one of the carbonyl oxygens during the nucleophilic addition to form the bicarbonate, which is then hydronated as a simple base. As a carbonyl compound, carbon dioxide can also participate in nucleophilic additions to its dicarbonyl group by enolates



(1–122)

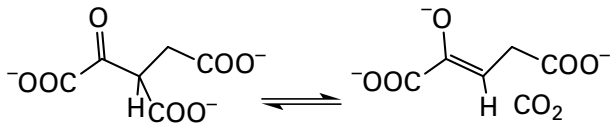
When carbon dioxide dissociates from an acidic carbon during a **decarboxylation**, its dissociation is analogous to that of a hydron from the same acidic carbon. Evidence for this conclusion is that the common logarithms of the rate constants for a series of decarboxylations are linearly related to the values of pK_a for dissociation of a hydron from the respective positions in the respective carbon acids, with a Brønsted slope, β, of –0.7.[354]

Decarboxylations, because they are the reverse of additions of the dicarbonyl group of carbon dioxide to an enolate, are assisted by **push from the lone pairs of electrons on the carboxylate**



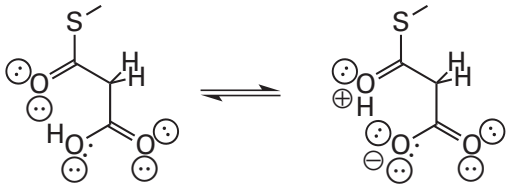
(1–123)

In this equation the negative elementary charge is moved among the three oxygens the lone pairs of electrons of which are indicated by asterisks. The lone pairs of electrons providing the push are parallel to the carbon–carbon bond that is cleaved during the decarboxylation, and that σ bond must also be parallel to the π system of the carbon–oxygen double bond of the adjacent carbonyl or acyl group (reverse of Equation 1–123). This alignment is enforced, for example, by the enzyme isocitrate dehydrogenase ($NADP^+$) from *E. coli* in its complex with the oxalosuccinate that it decarboxylates[355]



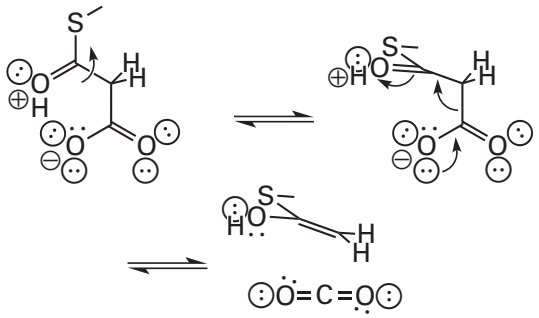
(1–124)

In free solution, **decarboxylations of β-oxo acids** occur more rapidly when the carboxy group is hydronated than when it is unhydronated and anionic, a fact that seems counterintuitive. This increase in rate is usually explained, however, as the result of an **intramolecular transfer of the hydron** between a hydronated lone pair of electrons on the oxygen of the carboxylic acid and the lone pair of electrons on the oxygen of the carbonyl or acyl group



(1–125)

This stereochemically efficient transfer of a hydron from one oxygen to another oxygen that is four atoms away enhances the ability of the acyl or carbonyl group to which the hydron is transferred to withdraw electrons from the carbon–carbon bond to be broken. The transfer of the hydron also increases the push of the lone pairs of electrons on the oxygens of the carboxy group from which the hydron is transferred. Because it is between two lone pairs of electrons, both orthogonal to the orbitals mixing in the transition state for decarboxylation, and because it is sterically impossible while the atomic orbitals of the transition state for decarboxylation are aligned, the transfer of the hydron must precede and must be independent from the decarboxylation itself. The transfer of the hydron and the decarboxylation itself are separated from each other by a rotation around a carbon–carbon bond

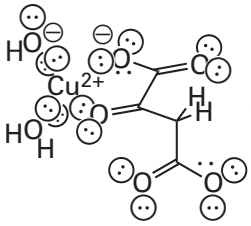


(1–126)

Although it is stereochemically allowed, the transfer of a hydron from a carboxy group to a carbonyl oxygen or acyl oxygen ($\Delta pK_a = +11$) is still thermodynamically unfavorable. In the nonenzymatic decarboxylation of β-oxo acids, this transfer of the hydron from the carboxylic acid to the carbonyl or acyl oxygen permits the enol tautomer to be the immediate product of the decarboxylation (Equation 1–126). Such decarboxylations are also further enhanced by forming the imine at the carbonyl carbon.[356]

Because the transfer of the hydron must precede the dissociation of the carbon–carbon bond and because a rotation is required between transfer of the hydron and dissociation of the carbon–carbon bond, such an intramolecular transfer of the hydron probably cannot occur within the active site of an enzyme, in which substrates are usually held rigidly and seldom permitted to rotate internally, unless required by the reaction. In such a situation, the hydron must be supplied by some other acid, such as the side chain of an amino acid, and the carboxylate must be unhydronated, as it usually is when it enters the active site.

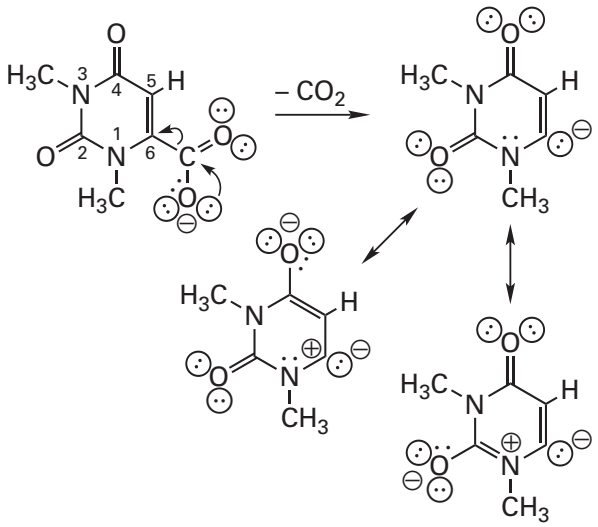
Metallic ions, such as cupric ion, can catalyze the decarboxylation of β-oxodicarboxylic acids, presumably by forming a complex involving the carbonyl oxygen of the β-oxo group and the uninvolved carboxylate in the enolate that will be the leaving group from carbon dioxide



1–97

The metallic ion neutralizes the negative charge forming on the carbonyl oxygen during the reaction.[357] A lone pair of electrons on the uninvolved carboxylate of the dicarboxylic acid provides an additional point of attachment for the copper, the main function of which is to act as a Lewis acid at the oxygen of the incipient enolate and stabilize it as if the metallic ion were a hydron.

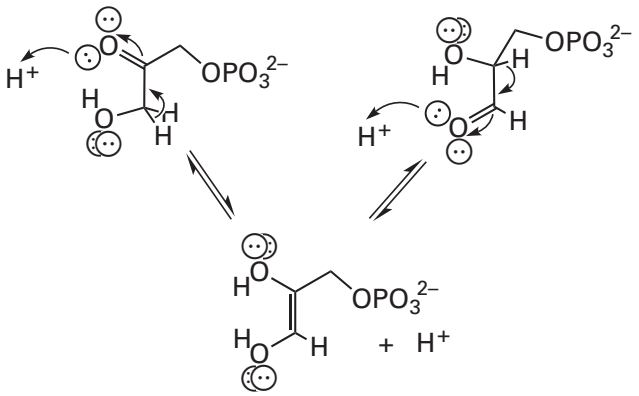
The **decarboxylation of 1,3-dimethylorotic acid**, which is an analogue of the reaction catalyzed by orotidine-5′-phosphate decarboxylase, is quite peculiar because it proceeds through a carbanion that, unlike those discussed so far, cannot be stabilized by an adjacent carbonyl or acyl group because it is orthogonal to any that are available. It is believed that the carbanion is stabilized as a **partial ylide** with the electron-deficient nitrogen immediately adjacent to it.[358]



(1–127)

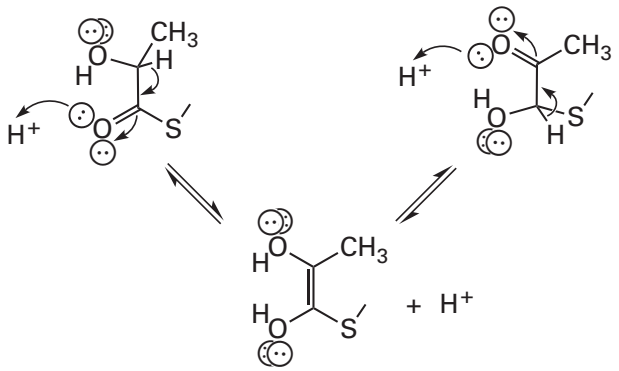
The decarboxylation of 1,3-dimethylorotic acid (Equation 1–127) is enhanced when one of the exocyclic oxygens is hydronated, which would further increase the positive charge on nitrogen 1. In addition, carbon 6 in 1,3-dimethylorotic acid and carbon 6 in uridine are both electropositive because they are each the β carbon in an α,β-unsaturated amide. The exchange of the hydron at carbon 6 of uridine for a deuteron in the solution, which is catalyzed by hydroxide, increases 5000-fold when the hydrogen on carbon 5 of the uridine is replaced by a fluorine.[359] This observation is consistent with a carbanionic partial ylide homologous to the one in Equation 1–127 performing the role of an intermediate in this exchange because electron withdrawal by the adjacent fluorine should stabilize the anion. For reasons that are not obvious because if anything the negative elementary charge is less delocalized in the product and hence in the transition state, the rate constant at 25 °C for the decarboxylation of 1-cyclohexylorotic acid is greater by a factor of 1000 in nonpolar solvents such as dioxane and tetrahydrofuran than it is in water. This observation suggests that the removal of orotidine 5′-phosphate from water as it enters the active site of orotidine-5′-phosphate decarboxylase by itself is responsible for a portion of the catalysis achieved by the enzyme.[360]

Enol tautomers are also intermediates in the isomerizations of α-hydroxy ketones or α-hydroxy aldehydes.[361] An example of such an enzymatic reaction is that catalyzed by triose-phosphate isomerase



(1–128)

in which the carbonyl group moves between two adjacent carbons. A similar isomerization can interconvert a carbonyl group and an acyl group by the same mechanism[362,363] as in the reaction catalyzed by lactoylglutathione lyase



(1–129)

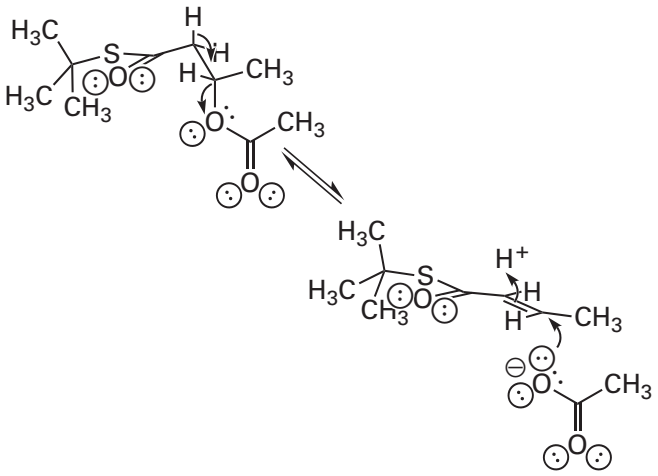
Elimination–Addition

In an elimination–addition, an acid or electrophile and a base or nucleophile are removed from two adjacent carbons or two carbons separated by one or more double bonds to produce a double bond or an additional double bond or an acid or electrophile and a base or nucleophile are added to a carbon–carbon double bond or the two ends of a conjugated set of double bonds.* For example, during the elimination[364]



(1–130)

a hydron is removed from one carbon and acetate leaves the adjacent carbon to produce the carbon–carbon double bond. In the addition, which is the reverse reaction, a hydron is added to one carbon and acetate adds to the other carbon in a carbon–carbon double bond. The thioester adjacent to the hydron that is removed facilitates the reaction by acidifying that hydron.

Some elimination–additions proceed through an intermediate carbenium ion and others proceed through an intermediate carbanion but the majority are probably somewhere on a spectrum between these extremes. Two examples of **elimination–additions that proceed through a carbenium ion** are the hydration–dehydration of simple aliphatic olefins such as propene in solutions of strong acids[365] and the more complex elimination of trifluoroacetate and a hydron from 2-(dimethyl-amino)-1-methyl-1-phenyl-2-thioxoethyl 2,2,2-trifluoroacetate[366]

*Most acids are electrophiles and most bases are nucleophiles and vice versa, but each person has a term she prefers for each particular example of an electrophile or an acid and for each particular example of a nucleophile or a base.

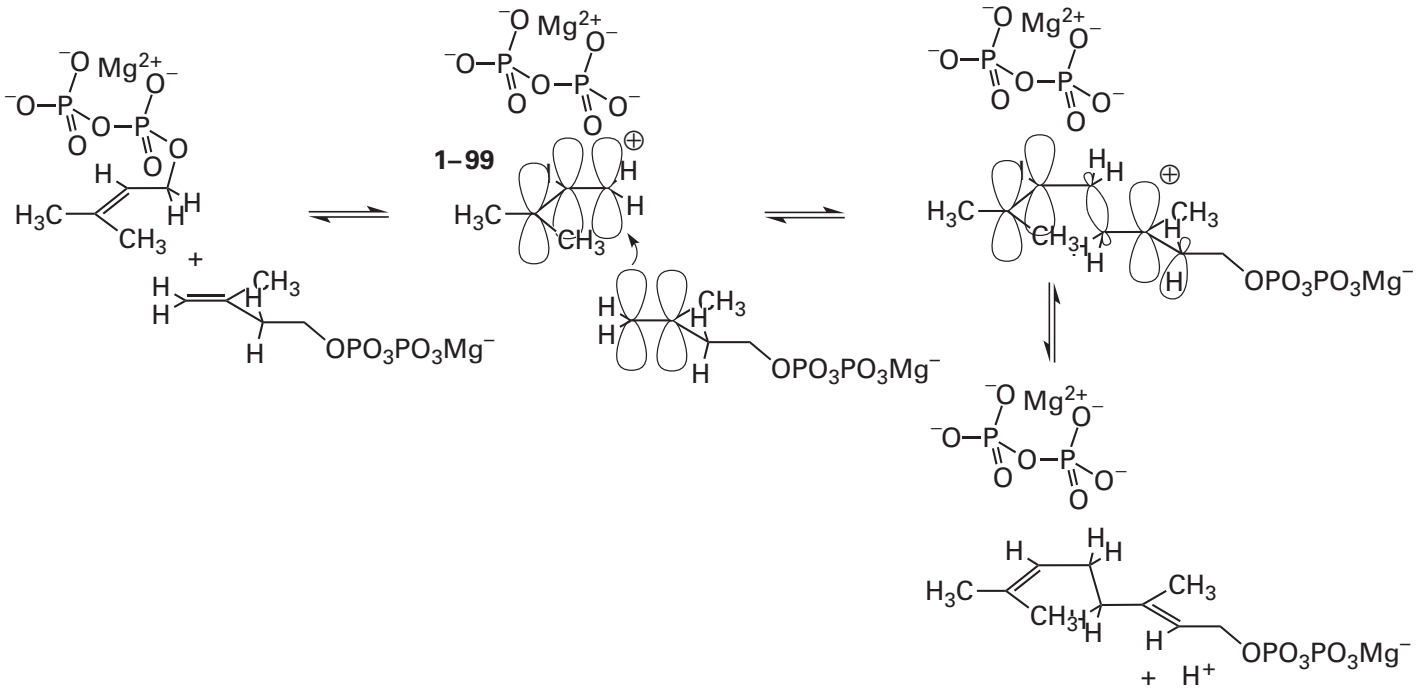


Figure 1–26: Addition of the 3,3-dimethylallyl carbenium ion to isopentenyl diphosphate. The 3,3-dimethylallyl carbenium ion is formed by elimination of diphosphate from 3,3-dimethylallyl diphosphate. The carbon–carbon double bond of isopentenyl diphosphate adds to this allyl carbenium ion to form a new carbon–carbon σ bond in a carbenium ionic adduct. The carbenium ionic adduct loses a hydron in an acid dissociation to produce geranyl diphosphate.

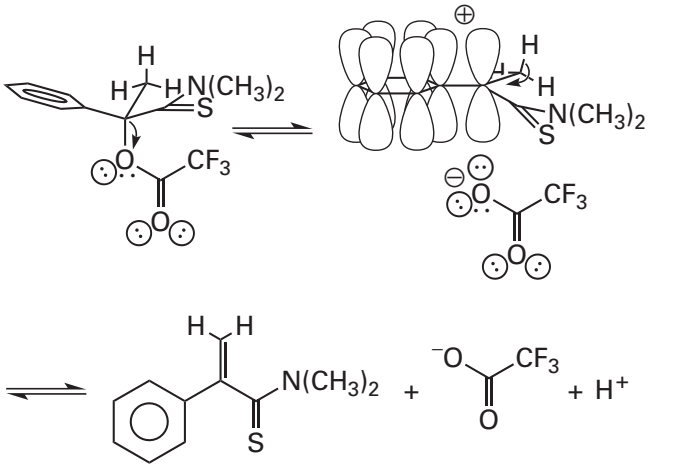
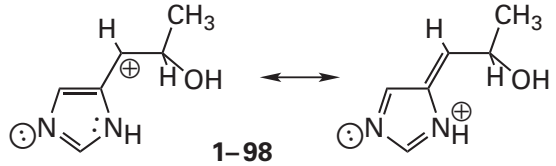


(1–131)

In this latter instance, the intermediate carbenium ion is stabilized by the adjacent phenyl group. In the dehydration–hydration catalyzed by imidazole-glycerol-phosphate dehydratase from *E. coli*,[367] the intermediate carbenium ion is stabilized by an adjacent neutral imidazolyl group

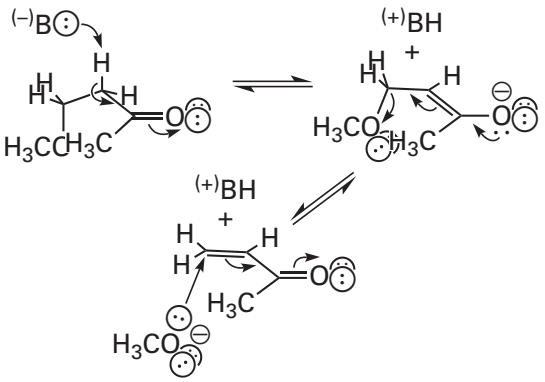


1–98

In this instance, because they are two atoms apart, if either nitrogen is hydronated, the same resonance structures stabilize the carbenium ion: regardless of which nitrogen is hydronated, the formal positive elementary charge ends up on it in the same resonance structure. The resonance structures define the electron donation from the π molecular orbital system of the imidazolyl group to the carbenium ion.

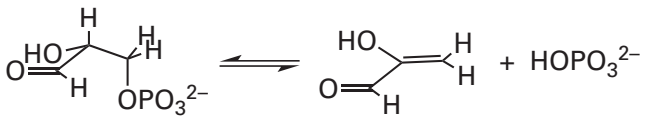
An example of an addition that proceeds through a carbenium ion but involves the initial addition of an **electrophile other than a hydron** occurs in terpene biosynthesis in the reaction catalyzed by dimethylallyl*trans*transferase (Figure 1–26). Carbenium ion **1–99** formed from 3,3-dimethylallyl diphosphate adds to isopentenyl diphosphate, but instead of then reacting with a nucleophile, which is a possibility that the enzyme guards against, the resulting carbenium ion eliminates a hydron to yield the desired product, geranyl diphosphate. The first step in the reaction is the formation of the allylic 3,3-dimethylallyl carbenium ion **1–99**, which consists of three parallel *p* orbitals creating an allyl π molecular orbital system with only two π electrons. It is a Lewis acid, and it adds as would a hydron to the carbon–carbon double bond in isopentenyl diphosphate.

Examples of **elimination–additions that proceed through an enolate** are the elimination of methoxide and a hydron from 4-methoxybutan-2-one under basic conditions to give the respective α,β-unsaturated carbonyl compound[368]



(1–132)

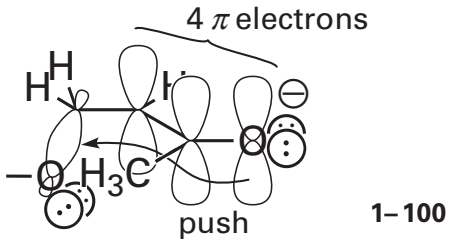
and elimination of the phosphate and a hydron when glyceraldehyde 3-phosphate is exposed to base[361]



(1–133)

In both of these instances, removal of the hydron on a carbon adjacent to a carbonyl group initiates the elimination rather than dissociation of the leaving group.

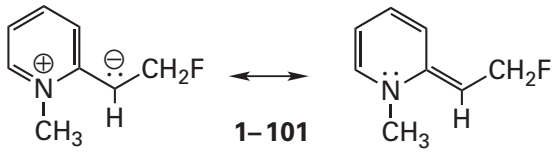
The dissociation of the respective leaving group in the second steps of Equations 1–132 and 1–133 is effected by the **push of the enolate**. To experience the push, the σ bond between the oxygen on the leaving group and the carbon from which it is leaving must be aligned parallel to the π system of the enolate before elimination can proceed



1–100

Electron density in the highest occupied molecular orbital of the enolate (**1–87**) enters the unoccupied antibonding molecular orbital of the carbon–oxygen σ bond on the β carbon and pushes away the two σ electrons of the leaving group that originally were in the bonding σ molecular orbital of the carbon–oxygen bond.

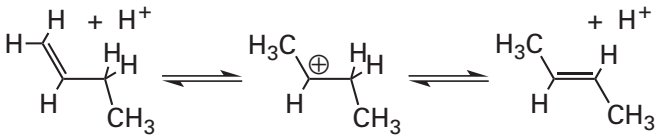
As in Equations 1–132 and 1–133, in most elimination–additions that proceed through a carbanionic intermediate, the intermediate is an enolate. There are, however, other ways to stabilize a carbanion. In the elimination of hydrogen fluoride from 2-(2-fluoroethyl)-1-methylpyridinium in strongly basic aqueous solution, the intermediate carbanion produced by the dissociation of a hydron[369] is stabilized by the adjacent pyridinium group



1–101

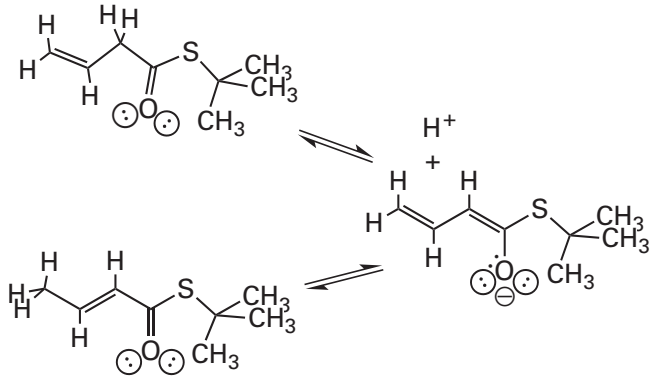
much as the electron excess in the pentadienyl molecular orbital system of reduced nicotinamide is stabilized by the nitrogen in the ring (Equation 1–78). In effect, however, this stabilization is achieved by the equivalent of an iminium conjugated to the carbanion through two double bonds.

The isomerization of olefins can proceed through either an intermediate carbenium ion or an intermediate carbanion. For example, the isomerization of simple aliphatic olefins under acidic conditions proceeds through a carbenium ion



(1–134)

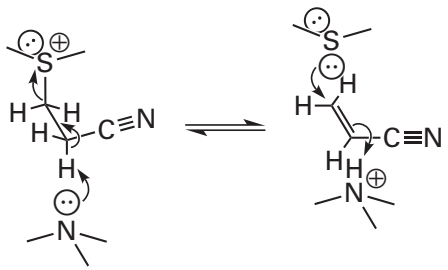
Isomerization of carbon–carbon double bonds α to carbonyl or acyl groups, however, can occur under basic conditions by proceeding through an enolate, which is the conjugate base common to the different isomers. For example, the isomerization of *S*-(1,1-dimethylethyl) but-3-enethioate to *S*-(1,1-dimethylethyl) but-2-enethioate[370] proceeds through the enolate



(1–135)

As has already been discussed, the excess negative elementary charge is delocalized over five atoms in the enolate, four carbons and one oxygen. The cis and trans isomers of a carbon–carbon double bond can be equilibrated in the same way.

A **concerted elimination–addition** is one in which there is no carbanionic or carbocationic intermediate because the bond between the one carbon and the base or the nucleophile that is the leaving group is breaking or forming in concert with the breaking or forming of the bond between the other carbon and the electrophile or hydron. The degree to which the bond between the leaving group and its carbon is broken in the transition state of a concerted elimination is assessed by **Brønsted correlations** between the pK_a of the conjugate acid of the leaving group and the rate of the reaction, and the degree to which the bond between the electrophile or the hydron and its carbon is broken is assessed by Brønsted correlations between the pK_a of the conjugate acid of the base that removes the hydron and the rate of the reaction. For example, in the concerted elimination of the respective sulfides from a series of 2-cyanoethyl-sulfonium ions catalyzed by a series of amines

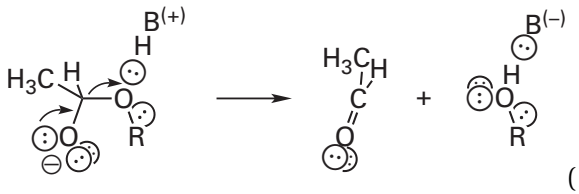


(1–136)

the Brønsted slopes for the catalytic amines ($\beta = 0.62$–0.75) and for the leaving groups ($\beta_{lg} = -0.24$ to -0.38) indicate that, in the transition state for this reaction, the bond between one carbon and the hydron and the bond between the other carbon and the sulfur are both dissociating in concert.[371]

Because the removal of the hydron from the one carbon and dissociation of the leaving group from the other carbon are both proceeding as the transition state is reached, the rate constant of a concerted elimination increases as the strength of the base that removes the hydron increases and as the acidity of the conjugate acid of the leaving group increases.[372] It follows that the rate of a concerted elimination will also increase when **the ability of the leaving group to dissociate** is improved by hydronating it or adding another electrophile to it before it leaves.

In many nucleophilic substitutions, nucleophilic additions, and elimination–additions catalyzed by an acid or a base, the making or breaking of a bond is concerted with the transfer of a hydron (Equations 1–29, 1–33, 1–38, 1–116, and 1–136 and Figures 1–7 and 1–8). In such concerted reactions, a correlation is often observed between the rate of the reaction and changes in both the strength of the acid or the base catalyzing the reaction and the strength of the bond between the two heavy atoms being made or broken brought about by the effect of adjacent substituents. For example, in the acid-catalyzed dissociation of an alcohol from the anionic conjugate base of its hemiacetal with acetaldehyde



(1–137)

as the alcohol becomes a better leaving group, the effect of acidity of the acid on the rate of the reaction decreases.[373] This interaction suggests that transfer of the hydron and the breaking of the bond to the leaving group occur in the same transition state and are thus concerted. Likewise, in the elimination of sulfides from β-cyanoethylsulfonium salts (Equation 1–136), as the strength of the base that removes the hydron from carbon increases, the effect of acidity of the leaving group on the rate of the reaction, as reflected in the Brønsted coefficient β_{lg}, decreases. This **interaction coefficient** ($\partial\beta_{lg}/\partial pK_{a,BH} = 0.026$) was presented as evidence for the conclusion that the breaking of the bond between the leaving group and one carbon is simultaneous with the transfer of the hydron from the other carbon to the base and that the elimination is concerted.[371]

An elimination–addition passing through an intermediate carbocation and an elimination–addition passing through an intermediate carbanion are two extremes of a spectrum of mechanism, and each concerted elimination–addition occupies a position in this spectrum between these two extremes. The two determinants of this spectrum of mechanism[369] are the degree to which the bond between the acid or the electrophile and the one carbon is broken or formed and the degree to which the bond between the base or the nucleophile and the other carbon is broken or formed in the transition state.[371] As with a nucleophilic substitution at a tetrahedral, saturated carbon (Figure 1–4) or a nucleophilic substitution at phosphorus (Figure 1–15), this spectrum of mechanism can be appreciated by examining a **three-dimensional surface of potential energy** for an elimination–addition (Figure 1–27). In the case of elimination–addition,[78] one coordinate is the distance between the atom of the base or nucleophile that is leaving and the carbon from which it is leaving, and the other coordinate is the distance between the atom of the acid or electrophile and the carbon from which it is being removed. The third coordinate is the potential energy of the system for each pair of coordinates.

For an elimination–addition with an intermediate enolate (Figure 1–27A) or some other carbanionic intermediate, there is a well of potential energy in the **upper left corner** of the diagram because this is the position at which the acid or the electrophile has been removed far enough from its carbon that it no longer affects the potential energy of the system, but the bond between the leaving group and the other carbon has remained intact. If the reaction proceeds through an enolate or another carbanionic intermediate because it is the most stable of all the possibilities, there will be two cols of potential energy: one between the reactants and the carbanionic intermediate and the other between the carbanionic intermediate and the products.

For an elimination–addition with an intermediate carbenium ion (Figure 1–27B), there is a well of potential energy in the **lower right corner** of the diagram because this is the position at which the leaving group has been removed far enough from its carbon that it no longer affects the potential energy of the system, but the bond between electrophile and the other carbon is still intact. If the reaction proceeds through an intermediate carbenium ion because it is the most stable of all the possibilities, there will again be two cols of potential energy: one between the reactants and the intermediate carbenium ion and the other between the carbenium ion and the products.

There is, however, always the possibility in an elimination–addition that there is a col of potential energy, lower than any other col, at a point where the bond between the base or nucleophile and the carbon from which it is dissociating is partially broken while the bond between the acid or electrophile and the carbon from which it is being removed is partially broken. In this case, there would be neither an intermediate carbenium ion nor a carbanionic intermediate (Figure 1–27B). Such elimination–additions are concerted. Each of the reaction coordinates for these concerted elimination–additions passes through only one col **somewhere outside the corners** and has only one transition state at this one col.

The position of the col defining the transition state in an elimination–addition on the surface of potential energy is determined, in part, by the **ability of the leaving group**. In addition to changing the rate of an elimination, changing the leaving group can change the nature of the transition state. The elimination of HF from 1-methyl-2-(2-fluoroethyl)-pyridinium passes through zwitterionic intermediate **1–101**, which is formed by the initial removal of a hydron because fluorine is such a poor leaving group ($pK_{aHF} = 3.2$). When the fluorine is replaced by the better leaving group chlorine ($pK_{aHCl} = -7$) and then by the even better leaving group bromine ($pK_{aHBr} = -9$), rather than passing through the homologous zwitterionic intermediates, the reactions pass through concerted transition states in which dissociation of the bond between the halogen and its carbon becomes greater and greater, and dissociation of the bond between the hydron and the carbon adjacent to the pyridinium becomes lesser and lesser as the halogen becomes a better and better leaving group.[369]

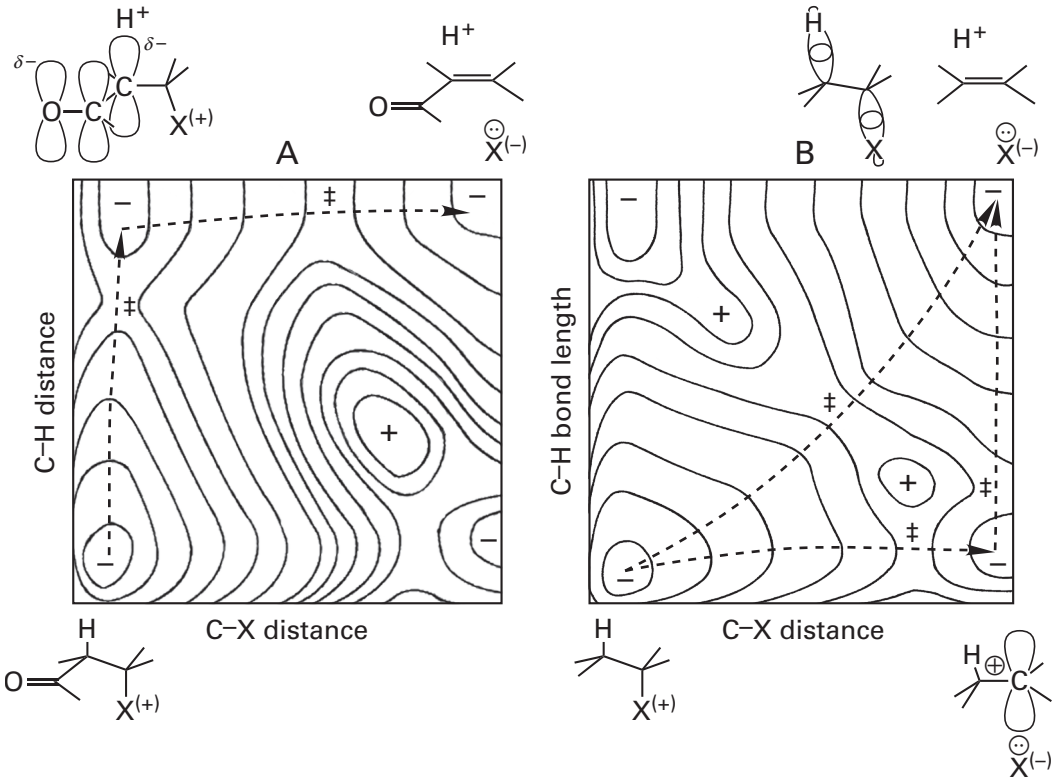


Figure 1–27: Hypothetical three-dimensional representations of surfaces of potential energy[77,78] for elimination–addition. The ordinate of the plot is the distance between the hydron that is being removed during an elimination and its carbon. The abscissa of the plot is the distance between the atom X that is leaving during an elimination and its carbon. The intersection of these two axes, for the sake of brevity, is not the point at which each has a value of zero, which would be a singularity of potential energy. The point of their intersection has coordinates or distances close to the values of the lengths of the respective covalent bonds, that between the hydrogen atom and its carbon and that between the leaving group X and its carbon. The third dimension is the potential energy associated with each value for these two distances. The third dimension is represented topographically by contour lines of equal potential. These contour lines represent a sinuous surface of potential energy. The two topographic maps of potential energy are entirely hypothetical, do not represent the surface of potential energy for any reaction, and are intended only for demonstration. The positive signs identify peaks of potential energy, and the negative signs identify wells of potential energy. The usual sign (‡) for a transition state designates a minimum of potential energy between reactants and products at the col through which the reaction proceeds. Dashed, curved arrows indicate the path of the reaction coordinate along which the reaction proceeds. The species involved as reactants, intermediates, transition states, or products are represented outside the plots, below (reactants or intermediate carbocation) or above (intermediate enolate, associated intermediate, or products) the locations of their respective potential energies. The corresponding addition proceeds along the same reaction coordinate through the same col or cols inthe reverse direction of the elimination. **(A)** Hypothetical surface of potential energy for an elimination with an enolate as an intermediate. The hydron is removed completely (vertical arrow) from its carbon before the leaving group dissociates (horizontal arrow) from the resulting enolate. The enolate is in a well of potential energy, as are the reactants and the products. There is a transition state between the reactant and the enolate and a transition state between the enolate and the products. **(B)** Hypothetical surface of potential energy for an elimination that could proceeds through a carbocationic intermediate or a concerted elimination in which the hydron is removed at the same time that the leaving group is dissociating. In this case, two possible paths on which the reaction could proceed were arbitrarily given cols of the same potential energy to illustrate the two possibilities. In the elimination proceeding through a carbocation as an intermediate, the atom X that is leaving dissociates completely from its carbon before the hydron is removed from its carbon. These two consecutive reactions follow the reaction coordinates represented by the horizontal and vertical arrows, respectively. In the concerted elimination (represented by the diagonal arrow), the atom X that is leaving dissociates from its carbon as the hydron is being removed from its carbon. Consequently, there is only one col between reactants and products and only one transition state. In any particular elimination–addition, the col for the reaction can be located at any point on the surface of potential energy between the coordinates for an intermediate enolate (upper left) or the coordinates for an intermediate carbocation (lower right). The position of the col defining the transition state for a concerted elimination–addition on the surface of potential energy is also determined, in part, by the **substituents on the substrate** from which the acid and base dissociate. In the transition state of a concerted elimination–addition, the bond to the hydron is breaking or forming at the same time that the bond to the leaving group or nucleophile is breaking or forming, and negative charge is accumulating on the former carbon while positive charge is accumulating on the latter. Any alteration in the substrate itself that stabilizes positive charge on the carbon from which the leaving group dissociates, or with which the nucleophile or the base associates, will shift the col in the direction of a carbenium ion as an intermediate. Any alteration in the substrate that stabilizes negative charge on the carbon from which the hydron or the electrophile is removed or added will shift the col in the direction of a carbanion as an intermediate. If one or the other of these accumulations of charge is stabilized sufficiently, the breaking or forming of the bond creating that charge precedes completely the breaking or forming of the other bond, and the reaction passes through an intermediate carbanion or carbocation.

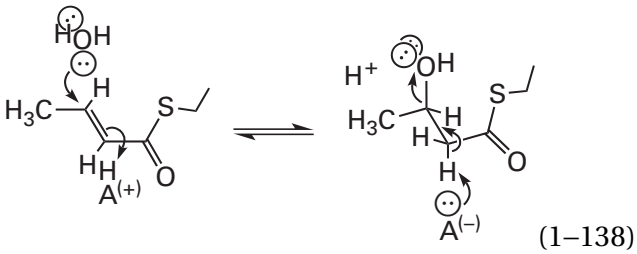
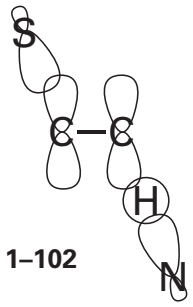
Because negative charge is accumulating on one carbon while positive charge is accumulating on the other, any alteration that stabilizes either of these accumulations of charge will also increase the **rate of a concerted elimination–addition**.[340,372,374] For example, the elimination of HBr from ethyl bromide catalyzed by ethoxide in ethanol is 5 times slower than its elimination from isopropyl bromide, which is 4 times slower than its elimination from 1-phenylethylbromide[372] because these alterations stabilize the partial positive elementary charge that has developed on the carbon from which the bromide is leaving. In the enzymatically catalyzed hydration of *trans*-crotonyl-SCoA



(1–138)

changing the sulfur of the thioester to an oxygen[340] destabilizes the accumulation of negative charge on the α carbon and decreases the acidity of that carbon (Figure 1–23), and the rate of the reaction decreases by a factor of 300.

In a concerted elimination–addition, the pair of electrons in the σ bond between the carbon and either the hydron or the electrophile, which are shifted onto that carbon by dissociation of the hydron or the electrophile and which create the negative charge accumulating on that carbon, provide **push to expel the leaving group**. For example, in Equation 1–136, the atomic orbitals that mix in the transition state of the concerted elimination–addition



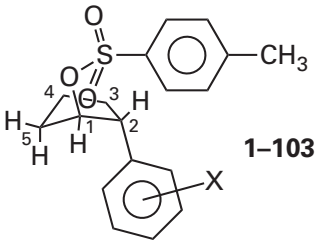
1–102

are the atomic orbital of the amine containing the basic lone pair of electrons that removes the hydron, the *s* atomic orbital of the hydrogen, the two respective *p* atomic orbitals on the two adjacent carbons, and the atomic orbital on the leaving sulfur. All must be parallel to each other. During the approach to the transition state, electrons in the bonding molecular orbital of the σ bond between carbon and the hydrogen that is dissociating are entering the *p* orbitals that are forming on the two carbons, which will become the π molecular orbital system of the carbon–carbon double bond. Through these *p* orbitals they are also entering the antibonding orbital of the σ bond of the carbon–sulfur bond and pushing away the leaving group.

The stereochemistry of a concerted elimination–addition is determined mainly by steric effects. Concerted eliminations are usually anti eliminations as shown in Equation 1–136. An **anti elimination** is an elimination in which the leaving group and the hydron or electrophile dissociate on opposite sides of a plane containing the carbons in a carbon–carbon bond to which they are attached. The orbitals taking part in the elimination, however, are all required to be periplanar. A **syn elimination** is an elimination in which the leaving group and the hydron or electrophile dissociate on the same side of a plane containing the carbons in a carbon–carbon bond to which they are attached. The orbitals are

still periplanar, but the transition state is so crowded as to be sterically disfavored. This crowding, however, is not severe. For example, under basic conditions, the elimination in Equation 1–130, in which the two hydrons, syn and anti, although diastereotopic, have almost the same acidity, proceeds with 15% syn elimination.[364]

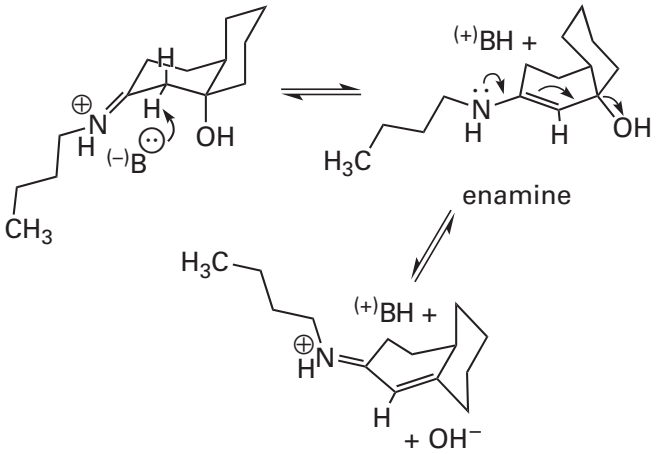
When elimination of 4-toluenesulfonic acid from a series of *trans*-2-arylcyclopentyl tosylates



1–103

is catalyzed by *tert*-butoxide in *tert*-butanol, the choice between syn elimination of the hydron at carbon 2 to produce 1-arylcyclopentene and anti elimination of the hydron at carbon 5 to produce 3-arylcyclopentene varies depending on the ability of the phenyl substituent at carbon 2 to stabilize the anionic character that develops at that carbon in the transition state for syn elimination.[375] The yield of the product of syn elimination relative to that for the sum of the products for both syn and anti elimination varies from 10% for *trans*-2-(4-meth-oxyphenyl)cyclopentyl tosylate to 94% for *trans*-2-(3-chlorophenyl)cyclopentyl tosylate.[374] This result is also another example illustrating the increase in the rate of a concerted elimination that occurs when the structure of the substrate is altered to stabilize the negative charge developing on the acidic carbon because it is only the increase in the rate of the syn elimination that leads to the increase in the yield of 1-arylcyclopentene.

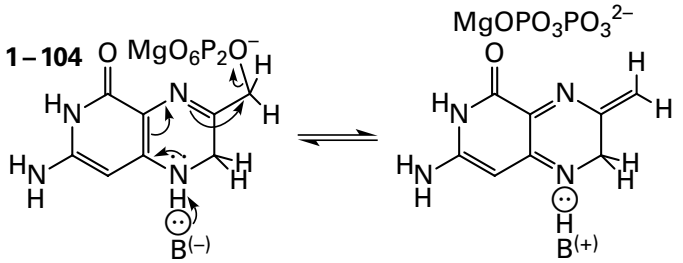
The rate of an elimination that occurs adjacent to the carbonyl group of a ketone or aldehyde, and that proceeds through an intermediate enolate under catalysis by a base, can be enhanced by conversion of the ketone or aldehyde to an imine. An example of this enhancement is the dehydration of 4a-hydroxy-*N*-propyl-*cis*-decahydronaphthalen-3-iminium[376]



(1–139)

under alkaline conditions. The slow step in the forward direction is the second one: dissociation of the leaving group. The π lone pair of electrons on the intermediate enamine provides the push required to expel the hydroxide, a poor leaving group (arrows in Equation 1–139). The highest occupied π molecular orbital of the enamine must be parallel to the σ bond between the carbon and the oxygen of the leaving group to exert the necessary push (see **1–100**) before the elimination can proceed.

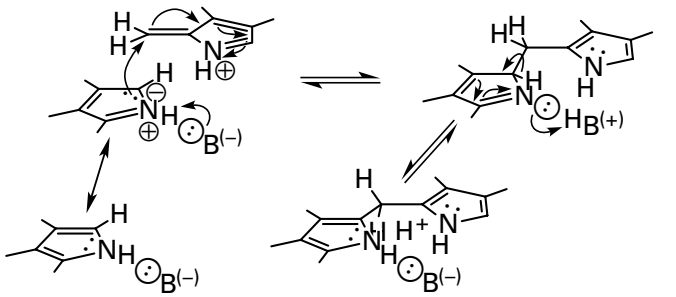
Usually an acyclic enamine, such as the one in Equation 1–139, is unstable relative to the ketone or aldehyde from which it is formed or the unsaturated ketone or aldehyde that is the product of an elimination in which it is an intermediate. The cyclic enamine (7,8-dihydropterin-6-yl)methyl diphosphate (**1–104**), however, is a stable metabolite. The first step in its enzymatic conversion to 7,8-dihydropteroate is the elimination of diphosphate to form the imine[377]



(1–140)

in a reaction that is the vinylogous analogue of the elimination in Equation 1–139 with diphosphate as the leaving group rather than hydroxide.

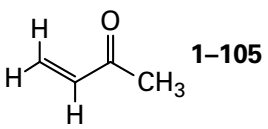
An addition to a carbon–carbon double bond conjugated to a carbonyl, imino, or acyl group in which a nucleophile adds to the carbon in the double bond peripheral to and a hydron or electrophile adds to the carbon distal to the carbonyl, imino, or acyl group is a commonly encountered reaction. It is common enough to warrant a name, the **Michael addition**. The reverse reactions of Equations 1–132 and 1–133 are Michael additions. If the nucleophile is itself an enolate or another carbanion, the Michael addition is another way, in addition to an aldol condensation or a Claisen condensation, to produce a carbon–carbon bond. An example would be the Michael addition performed by hydroxymethylbilane synthase



(1–141)

In this instance, the nucleophile is a pyrrolyl group that, under base catalysis, adds to the peripheral, electrophilic carbon in a carbon–carbon bond that is conjugated to an iminium nitrogen rather than being immediately adjacent to it. Instead of a hydron being added to the other carbon originally in the carbon–carbon bond, as in the reverse reactions of Equations 1–132 and 1–133, a hydron dissociates from the intermediate to restore the aromaticity of the pyrrolyl group.

By measuring the rate constants for the Michael additions of a set of eight carbanionic nucleophiles to a set of 15 α,β-unsaturated ketones and acyl derivatives, a scale for the electrophilicity of the respective carbon–carbon double bonds in these electrophiles to addition of a nucleophile can be constructed.[378] The simplest electrophile examined was but-3-en-2-one



1–105

When the methyl group on the carbonyl in but-3-en-2-one is replaced by an ethoxy group to give the ester, ethyl prop-2-enoate, the electrophilicity of the carbon–carbon bond decreases, and when it is replaced by a dimethylamino group to give the amide, *N,N*-dimethylprop-2-enamide, it decreases further as increasing electron density on the oxygen of the ester and the nitrogen of the carbamoyl group is donated into the π molecular orbital system containing the carbon–carbon double bond. When either the hydrogen on the α carbon or a hydrogen on the β carbon in ethyl prop-2-enoate is replaced by a methyl group to give ethyl 2-methylprop-2-enoate or ethyl but-2-enoate, respectively, the electrophilicity decreases further as a result of sacrificial hyperconjugation donating electron density to the π molecular orbital system of the α,β-unsaturated carbonyl. When the β methyl group on ethyl but-2-enoate is replaced by a phenyl group, the electrophilicity of the carbon–carbon bond decreases even further because the phenyl group donates electron density by resonance rather than hyperconjugation. When the methyl group on the carbonyl of but-3-en-2-one, however, is replaced by a phenyl group, the electrophilicity of the carbon–carbon bond increases, presumably because the phenyl group in this location is not so effective as the methyl group in donating electron density.

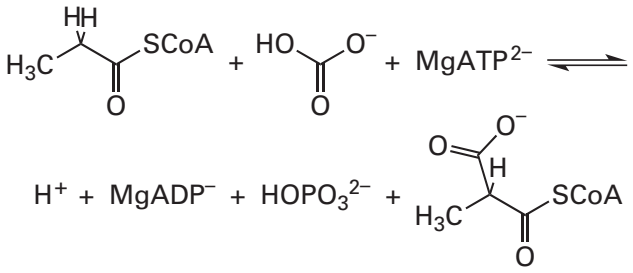
Biotin

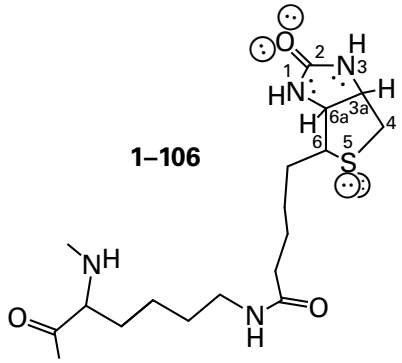
Biotin participates in carboxylations. For example, the reaction catalyzed by propionyl-CoA carboxylase



(1–142)

is a carboxylation requiring biotin. In such reactions, an acidic hydrogen on carbon is removed as a hydron and is replaced by the electrophilic acyl carbon of bicarbonate.[379]

Biotin* is a prosthetic group covalently attached to **biotin carboxyl-carrier protein** by an amide between the carboxylate of the biotin and a lysine from the protein[380-382]



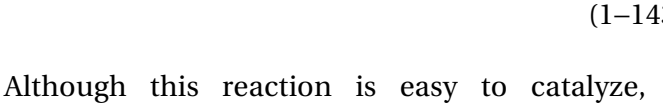
1–106

Biotin carboxyl-carrier protein is either a separate subunit or a domain in a much larger protein.

At one end of the two fused rings in biotin is an ***N,N′*-dialkylurea**. The bond length between the carbonato carbon and the oxygen and those between the carbonato carbon and the two nitrogens are very close to the bond lengths in urea itself .[383] This coincidence suggests that the incorporation of this functional group into the one ring is electronically inconsequential except for the hyperconjugation of the two alkyl groups, which should make the *N,N′*-dialkylurea less acidic. The ring containing the *N,N′*-dialkylurea is absolutely flat (Figure 1–28),[166,383] consistent with a planar structure enforced by the π molecular orbitals of the ureido group. These facts suggest that biotin is simply a complex functional group that is used to hold on to urea.

Because the two bridgehead carbons are tetrahedral, the two rings are tilted with respect to each other at an angle of 122° as if they were the wings of a butterfly. The **cyclic sulfide** is fully saturated, and fully saturated five-membered rings are usually puckered. In biotin, the sulfur occupies the **puckered** position. It is puckered toward the carbonato carbon of the urea rather than away from it. This configuration allows the alkyl group of the side chain of biotin to occupy an equatorial position, and presumably this steric effect explains the direction of the pucker. This configuration also moves the sulfur closer to the urea, perhaps to assist in reactions at this location by a transannular effect,[384] but the sulfur is too far from the carbonate carbon of the urea for significant overlap to occur.[383] The sulfur, however, may be responsible in part for the planarity of the ureido ring because in dethiobiotin the ureido ring is puckered instead of flat.[385]

Decarboxylations are **always significantly exergonic**. An example would be the decarboxylation of oxaloacetate[386]



(1–143)

Although this reaction is easy to catalyze, it involves a large waste of free energy, and it is almost never catalyzed in living organisms. In one rare exception, natural selection has discovered the gift, and the oxaloacetate decarboxylase of bacteria such as *Klebsiella aerogenes* stores the free energy of this reaction in the form of an electrochemical gradient of sodium ions.[387]

*The numbering of biotin seems to vary. In this text, the numbering of the IUPAC name will be used.

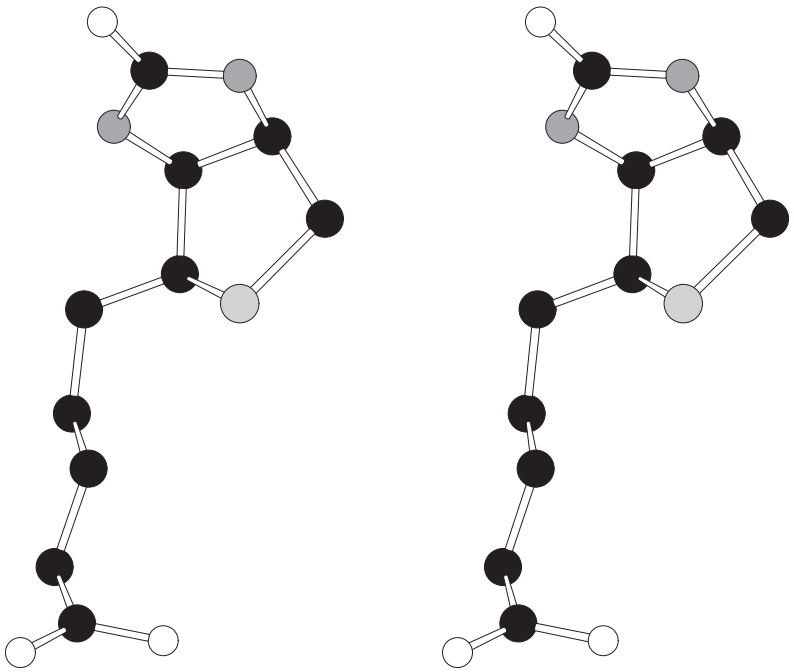


Figure 1–28: Stereodrawing[166] of the crystallographic molecular model of D-(+)-biotin. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large light gray atom is a sulfur. Crystals were obtained from an aqueous solution of the free acid of D-(+)-biotin by cooling a saturated solution from 95 °C. The two fused rings in the molecule are inclined at 122° with the *N,N′*-dialkylurea at the top.[383]

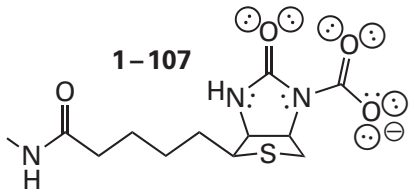
If it is not to be disadvantageously endergonic, **a carboxylation must be coupled to a reaction that yields energy**. In the case of carboxylations under catalysis by biotin, this energy-yielding reaction is the hydrolysis of $MgATP^{2-}$ to $MgADP^{-}$ and phosphate.* Each time a molecule of carboxylated product is produced, a molecule of $MgATP^{2-}$ is hydrolyzed. An example is the reaction catalyzed by pyruvate carboxylase

$$\text{pyruvate} + HOCO_2^- + MgATP^{2-} \rightleftharpoons HOPO_3^{2-} + MgADP^- + H^+ + \text{oxaloacetate} \qquad (1\text{–}144)$$

with the participation of biotin.

The *N,N′*-dialkylurea is the catalytic center of biotin, and the central intermediate in all reactions involving biotin is *N*³-carboxybiotin[389,390]



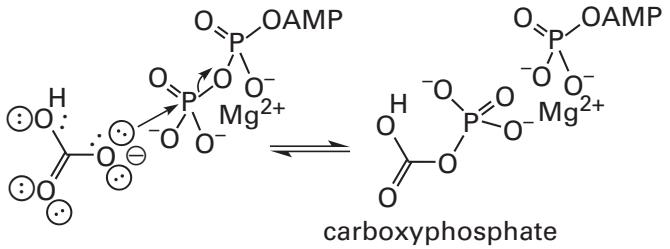
N^3-Carboxybiotin is produced in the active site of biotin carboxylase

$$\text{[biotin carboxyl-carrier protein]-biotin} + HOCO_2^- + MgATP^{2-} \rightleftharpoons HOPO_3^{2-} + MgADP^- + H^+ + \text{[biotin carboxyl-carrier protein]-}N^3\text{-carboxybiotin} \qquad (1\text{–}145)$$

In N^3-carboxybiotin, one of the oxygens on the bicarbonate has been replaced by one of the ureido nitrogens of the biotin in a formal nucleophilic substitution at a carbonato carbon. As a result, N^3-carboxybiotin is the derivative of two carbonic acids: one forms the ureido group and the other forms the carbamate.

The function of biotin carboxyl-carrier protein is to insert the biotin in turn into one or the other of two active sites either in two other subunits or in two other domains of the larger protein. In most instances, these are the active site for biotin carboxylase in which N^3-carboxybiotin is produced from biotin, $MgATP^{2-}$, and bicarbonate and the active site that then transfers the carboxy group on N^3-carboxybiotin to a particular reactant that is to be carboxylated. In methylmalonyl-CoA carboxytransferase, however, biotin is the carrier that transfers a carboxy group between pyruvate and propanoyl-SCoA. Because its role is to transfer a carboxy group between active sites, biotin carboxyl-carrier protein is formally a **coenzyme**, even though the active sites are within the same protein.

The intermediate that precedes the formation of N^3-carboxybiotin in the active site of biotin carboxylase is **carboxyphosphate.**[391] Carboxyphosphate is the product of a nucleophilic substitution at phosphorus



(1–146)

in which bicarbonate is the nucleophile and $MgADP^-$ is the leaving group. It is the carboxyphosphate that accomplishes the coupling of carboxylation to hydrolysis of the $MgATP^{2-}$.

During the overall reaction catalyzed by biotin carboxylase (Equation 1–145), one of the three oxygens-18 of [$^{18}O_3$]bicarbonate is incorporated into the phosphate, and the other two end up in the N^3-carboxylato group (Figure 1–29).[392] This fact, and the fact that the enzymatically catalyzed carboxylation of biotin proceeds with inversion of configuration[393] at the terminal phosphate of $MgATP^{2-}$, are together consistent with nitrogen 3 of the biotin

*At 25 °C, pH 7.0, and a free concentration of Mg^{2+} of 1.0 mM, nominal conditions for cytoplasm but values that vary significantly from organism to organism, $MgATP^{2-}$ (the tridentate complex between ATP^{4-} and Mg^{2+}) accounts for more than 80% of the total ATP in the solution.[388] Under the same conditions, $MgADP^-$ and ADP^{3-} each account for about 45% of the total ADP in the solution. Because the free concentration of Mg^{2+} used in most experiments in which ATP and ADP are substrates usually exceeds 1 mM, and therefore the fraction of nucleotides present as the complexes increases; because $MgADP^-$ is often, if not usually, the actual substrate used by an enzyme; and because the reader should be reminded that Mg^{2+} almost always plays a role in reactions involving ATP and ADP and that the complexes between Mg^{2+} and the respective nucleotide almost always are negatively charged, $MgATP^{2-}$ and $MgADP^-$ will be used from now on to designate ATP and ADP, respectively.

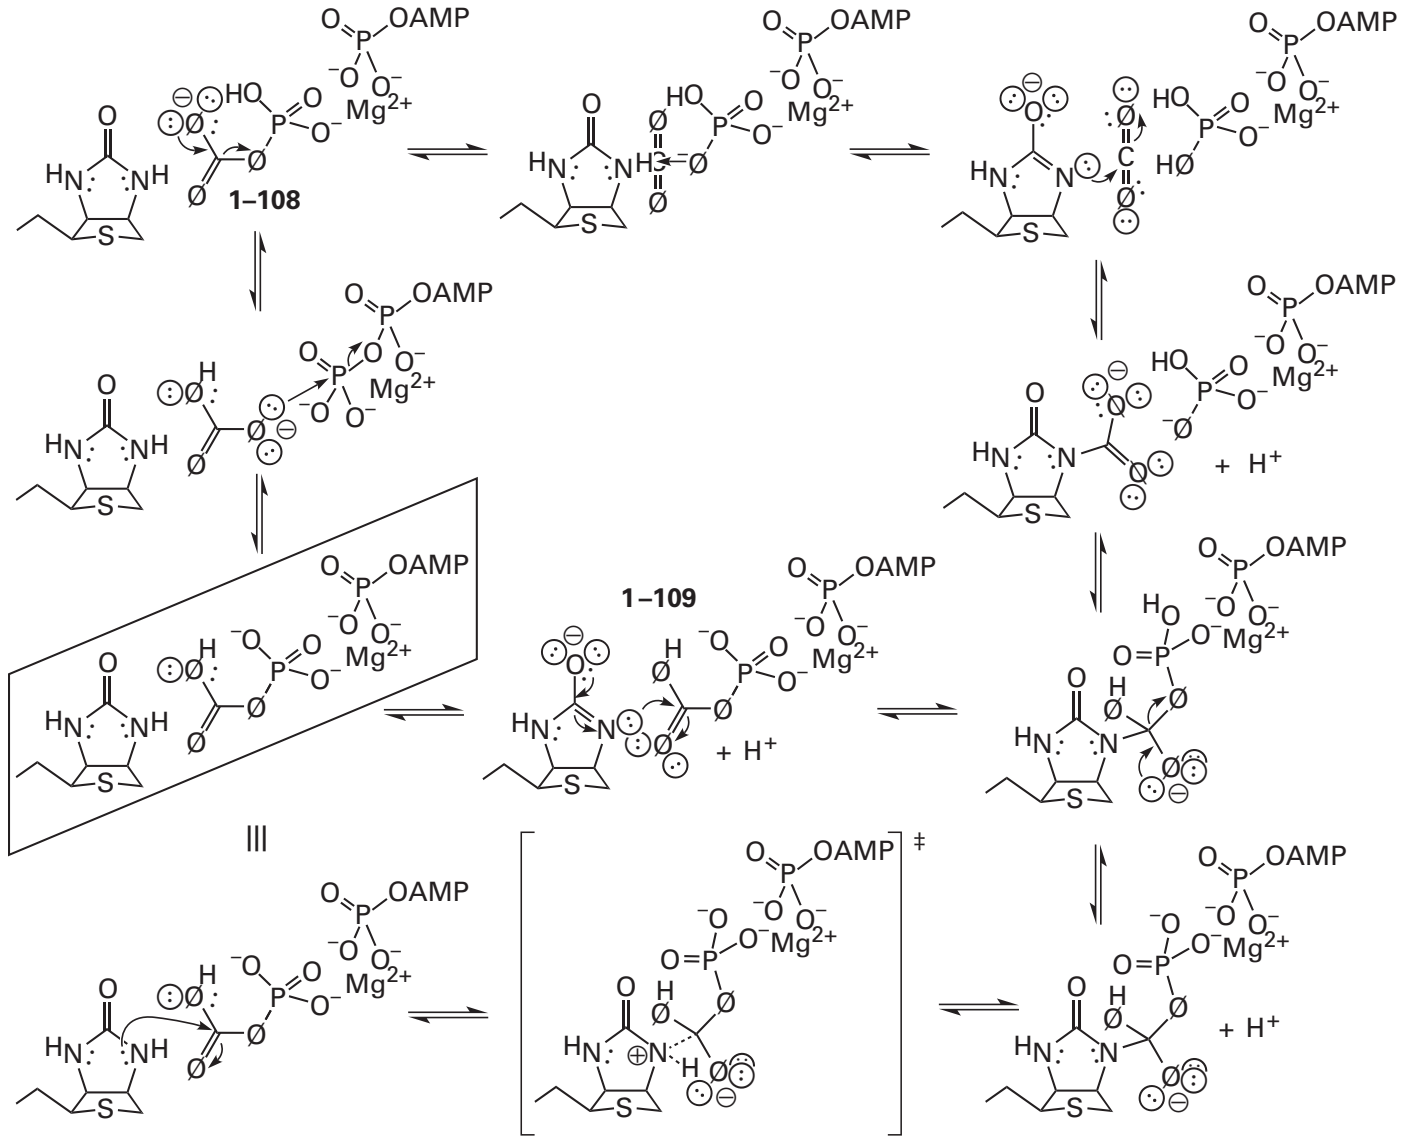


Figure 1–29: Formation of N^3-carboxybiotin coupled to the hydrolysis of $MgATP^{2-}$. There are three presently accepted possibilities for the mechanism. All three begin with biotin, HCO_3^-, and $MgATP^{2-}$ (within the box to the left). (**Upper path**) Carbon dioxide as an intermediate.[391,395] Bicarbonate substitutes nucleophilically at the γ-phospho group of $MgATP^{2-}$ in a direct in-line transfer of the phospho group, with inversion of configuration at phosphorus to produce carboxyphosphate (**1–108**). The leaving group is $MgADP^-$. The intermediate carboxyphosphate then dissociates to carbon dioxide and phosphate. The phosphate, as a catalytic base, removes the hydron from nitrogen 3 of the biotin, and the resulting ureido anion, which is the conjugate base of biotin, adds nucleophilically to the carbon dioxide to produce N^3-carboxybiotin. (**Middle path**) Nucleophilic substitution at carboxyphosphate.[391] Carboxyphosphate (**1–109**) is formed as before by nucleophilic substitution at the γ-phospho group of $MgATP^{2-}$. The ureido anion then adds nucleophilically to the carboxyphosphate to form a tetrahedral intermediate that dissociates to N^3-carboxybiotin and phosphate ion. The carboxy group of the carboxyphosphate is hydronated to improve the electrophilicity of its carbon; and, to improve its capacity as a leaving group, the phospho group of the carboxyphosphate is still coordinated by the Mg^{2+} that coordinated it in the $MgATP^{2-}$. The resulting tetrahedral intermediate decomposes with loss of phosphate to produce N^3-carboxybiotin. (**Lower path**) Neutral biotin as the nucleophile.[397] The π lone pair of electrons on nitrogen 3 of the biotin, which is more nucleophilic than a fully delocalized pair of electrons because of cross-conjugation, is the nucleophile in a nucleophilic substitution that can occur either at the carbonato carbon of the carboxyphosphate (as shown) or at the carbonato carbon of the carbon dioxide that has dissociated from carboxyphosphate (see upper path). In either case, the electrophilic carbon of the carboxyphosphate or carbon dioxide would be adding to the π lone pair of electrons of nitrogen 5, either directly or as the phosphate ion, or another catalytic base was removing the hydron from nitrogen 3. In all three mechanisms, one of the three oxygens of bicarbonate, which are distinguished by the letter Ø, ends up in the phosphate, as required by the observation that the phosphate produced during carboxylation of biotin with $[^{18}O]HOCO_2^-$ bears an equivalent of oxygen-18.

engaging in a nucleophilic substitution at the carbonate carbon of carboxyphosphate with phosphate as the leaving group. The transfer of ^{18}O from [^{18}O]bicarbonate to the phosphate is also observed[394] in the slow, wasteful bicarbonate-dependent ATPase reaction

$$H^{18}OC^{18}O_2^- + MgATP^{2-} + H_2{}^{16}O \rightleftharpoons MgADP^- + H^+ + H^{18}OPO_3^{2-} + H^{16}OC^{18}O_2^- \quad (1\text{–}147)$$

catalyzed by the active site of biotin carboxylase in the absence of biotin in which water slowly hydrolyzes the carboxyphosphate by a nucleophilic substitution at the carbonato carbon with $H^{18}OPO_3^{2-}$ as the leaving group. All these results are consistent with a mechanism involving the intermediate formation of carboxyphosphate.

There are **three current contenders for the mechanism of transfer of the carboxy group** from the carboxyphosphate to nitrogen 3 of the biotin. In the first, the carboxyphosphate dissociates to carbon dioxide and phosphate and the anionic conjugate base resulting from the dehydronation of nitrogen 3 of the ureido group of biotin adds nucleophilically to the electrophilic carbon of the carbon dioxide. In the second, the anionic conjugate base of the ureido group engages in a concerted nucleophilic substitution at the electrophilic carboxy carbon of the carboxyphosphate. In the third, the neutral ureido group is the nucleophile in the nucleophilic substitution, which could be either dissociative or concerted.

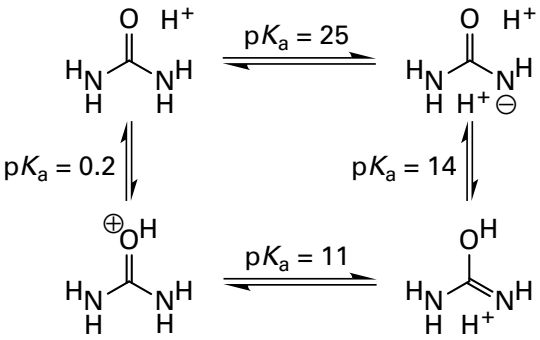
In the first proposal, the transfer of the carboxy group is a **dissociative nucleophilic substitution at the carbonato carbon with carbon dioxide as an intermediate** (Figure 1–29, upper path). The equilibrium constant for dissociation of the dianion of carboxyphosphate (**1–108**) to form carbon dioxide and phosphate has been estimated to be 10 M, and the rate of its dissociation has been estimated to be 10 s^{-1}. At the same time, it was demonstrated that carbon dioxide is much more electrophilic than carboxyphosphate.[395] Estimates of the rate of decomposition and the dissociation constant suggest that, once formed on an active site, carboxyphosphate requires little catalysis to dissociate rapidly enough and completely enough for its dissociation to be a step in the overall mechanism for an enzyme that uses biotin as a coenzyme. A molecule of CO_2 would fully dissociate from the carboxyphosphate, and that molecule of CO_2 would be the electrophile to which the anionic conjugate base of biotin would add.[391] If this is the actual mechanism, $MgATP^{2-}$ is not responsible for enhancing the electrophilicity of the bicarbonate by forming carboxyphosphate. Instead, it performs the function of dehydrating the bicarbonate exergonically by converting it into carbon dioxide.

There is **crystallographic evidence** consistent with the participation of CO_2 as an intermediate in the carboxylation of biotin. In a crystallographic molecular model of the active site of biotin carboxylase from *E. coli*, when it is occupied by bicarbonate and $MgADP^-$, one of the oxygens of the bicarbonate is only 0.27 nm from nitrogen 3 of the coenzymatic biotin.[396] The same oxygen of the bicarbonate is also only 0.4 nm from the β phosphorus atom of $MgADP^-$. It is the closest oxygen of the bicarbonate to the β phosphorus atom and should be the oxygen of the bicarbonate that is phosphorylated by $MgATP^{2-}$ during formation of the carboxyphosphate. Consequently, it is destined to be one of the oxygens of the phosphate that is the final product, the one that has gained the oxygen-18 in an isotopic transfer from the bicarbonate (Equation 1–147). If the carboxyphosphate does dissociate to CO_2 and phosphate and that oxygen, which is now on a phosphate ion, remains in the same position, it would be in the perfect location to remove a hydron from nitrogen 3 of the biotin to create the anionic, nucleophilic conjugate base (Figure 1–29, upper path). The carbon dioxide would then move a slight distance to place its carbon immediately adjacent to the now anionic nitrogen 3 for the nucleophilic addition.

In the second proposal, transfer of the carboxy group to biotin is an **associative nucleophilic substitution at the carbonato carbon with a tetrahedral intermediate** (Figure 1–29, middle path). Phosphorylation of the oxygen of the bicarbonate by $MgATP^{2-}$ has turned a poor leaving group (HO^-) into a good leaving group (HO_3PO^{2-}). The electrophile is the carboxyphosphate, with a hydron on the carboxy group to increase its electrophilicity and the Mg^{2+} from $MgATP^{2-}$ still on one of the oxygens of the phospho group to increase its ability to leave. In this proposal, the nucleophile is also the σ lone pair of electrons on the anionic conjugate base of the ureido group.

In both the first and the second proposals, the nucleophile is the anionic conjugate base of the ureido group. A model reaction that is consistent with the anionic conjugate base of the ureido group

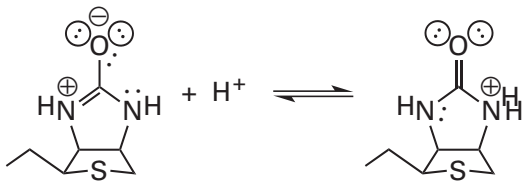
being the nucleophile is the rapid (15 s^{-1} at pH 7.4), base-catalyzed exchange of the hydrons on nitrogen 3 of the ureido group in biotin,[384,397] which suggests that these hydrons can be readily removed to form the conjugate base. The problem with this nucleophile is the acid dissociation constants of the ureido group. The difficulty can be understood by examining the acid dissociation constants of urea itself



(1–148)

The pK_a for urea[398,399] is 25, so even though the hydron on nitrogen 3 of biotin is susceptible to base-catalyzed exchange and even if the base that removes the hydron from nitrogen 3 were the conjugate base of an arginine (pK_a = 13), only 10^{-12} of the ureido group would be the conjugate base at any instant. If the base that removes the hydron (Figure 1–29, upper path) is the dianion of phosphate (pK_a = 6.8), only 10^{-18} would be the conjugate base. In crystallographic molecular models of the active sites of biotin carboxylase from *E. coli*[396,400] and the almost identical biotin carboxylase (82% identity; 0 gap percent) from *Haemophilus influenzae*[401] when they are occupied by biotin, there are two arginines. One of them forms a hydrogen bond with the carbonato 2-oxo group of the biotin, but neither of them is properly situated to be a catalytic base that removes the hydron from the ureido group of the biotin. There is also a lysine in the active site, the amino group of which might be able to stretch to the hydron,[401] but if it is the catalytic base (pK_a = 10.5), only 10^{-15} of the ureido group would be the conjugate base. The situation would be improved if the carbonato oxygen of the ureido group could be hydronated. This hydronation would lower the pK_a of the hydron on nitrogen 3 to 11, but the pK_a of this oxygen is 0.2. In the active site of biotin carboxylase, the carbonato oxygen is, as noted above, usually in a hydrogen bond with the cationic guanidinio group of an arginine, an unusually weak acid. The fact, however, that the guanidinio group bears a positive elementary charge should at least lower the pK_a of the ureido group.

In the third proposal (Figure 1–29, lower path), the transfer of the carboxy group to biotin would be coincident with the concerted removal of the hydron on that same nitrogen by a base participating in the reaction.[397,401] The observation prompting this proposal is the fact that acid-catalyzed hydron exchange of biotin[397,402] proceeds by hydronation of the π lone pair of one of the ureido nitrogens, which is somewhat more basic than the nitrogen of an amide because of cross-conjugation, to produce the ureido cation (**1–110**)



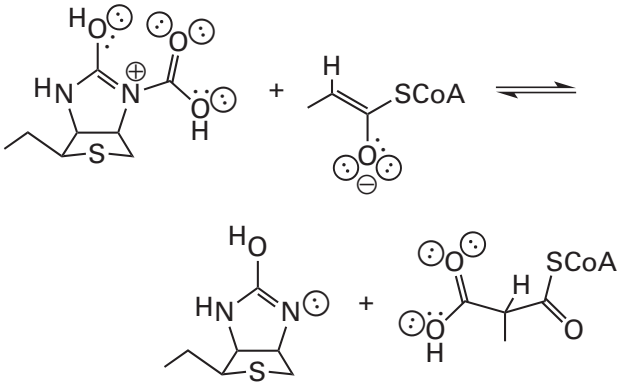
1–110

(1–149)

In this latter acid–base reaction, the π lone pair of the nitrogen has participated as a nucleophile, the reaction of which with an electrophile, the hydron, has preceded removal of the other hydron. In the carboxylation catalyzed by biotin carboxylase, the electrophile would be either carbon dioxide (Figure 1–29, upper path) or carboxyphosphate (Figure 1–29, middle and lower paths) rather than a hydron.

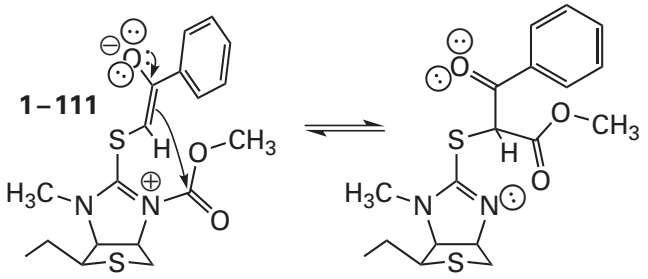
At the moment, in spite of many attempts to do so,[391] there is no unambiguous observation that can establish one or the other of these mechanisms for transferring the carboxy group from bicarbonate to biotin,[400] so all three are possible explanations.

In an active site catalyzing the transfer of the carboxy group from N^3-carboxybiotin to an acceptor, the carboxy group is transferred to an enol or enolate



(1–150)

This transfer is usually considered to be a concerted nucleophilic substitution at the carbonato carbon of the N^3-carboxybiotin. If this is the mechanism, because of its acid dissociation constants (Equation 1–148), either hydronation of the biotin on the exocyclic oxygen (as shown in Equation 1–150) or formation of strong hydrogen bonds to it is probably a necessary step in enabling it to be the leaving group. A similar, intramolecular nucleophilic substitution occurs in the intramolecular model reaction[403]

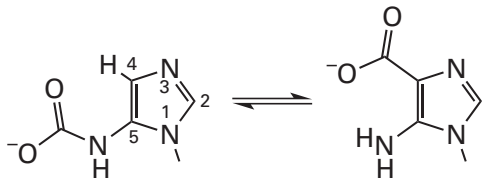


(1–151)

but only if the other nitrogen of the ureido group is methylated to prevent it from losing its hydron. The *N*-methyl-*O*-methyl-*S*-alkenyl model compound **1–111** is the sulfur homologue of the biotinyl cation in Equation 1–150.

Under the proper circumstances, the biotin should be a reasonably good leaving group in a concerted nucleophilic substitution, as illustrated by the fact that the free energy of hydrolysis of N^3-carboxybiotin is –20. kJ mol^{-1} at pH 7 and 0 °C.[386] Because the electrophile has a poor leaving group and the nucleophile, an enolate, is a strong one, an **associative nucleophilic substitution with a tetrahedral intermediate** should be the mechanism.

Another intramolecular reaction that is chemically homologous to Equation 1–150 is catalyzed by 5-(carboxyamino)imidazole ribonucleotide mutase



(1–152)

It has been shown that the carboxy group is transferred during this reaction from nitrogen 5 to carbon 4 on the same molecule of substrate.[404] Because a direct, concerted nucleophilic substitution in which carbon 4, as a nucleophile, adds to the carbonato carbon before or while nitrogen 5 leaves is sterically forbidden, it has been proposed that the carboxy group dissociates completely from nitrogen 5 as CO_2, which is then attacked by carbon 4 of the resulting unhydronated enamine. It is possible that the analogous two steps, between which CO_2 would be present as an intermediate, occur in the reaction of Equation 1–150. This disconnection would make it a **dissociative nucleophilic substitution rather than an associative nucleophilic substitution**. The CO_2 would fully dissociate from the N^3-carboxybiotin before the enolate adds to it nucleophilically.[391]

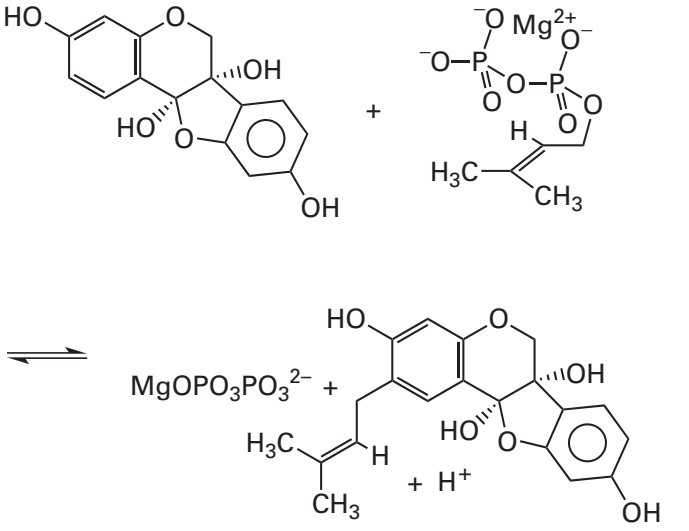
Electrophilic Aromatic Substitution

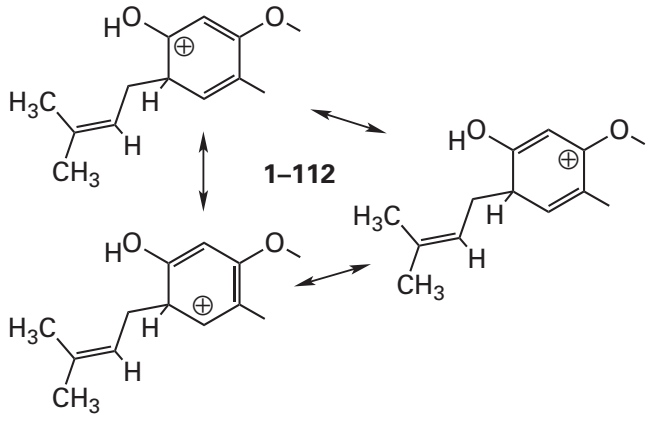
There are a number of electrophilic aromatic substitutions catalyzed by enzymes. An example of an **electrophilic aromatic substitution on a phenyl ring** that is encountered in a metabolic pathway is the one catalyzed by trihydroxypterocarpan dimethylallyltransferase



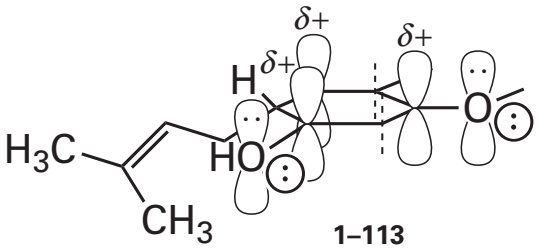
(1–153)

from *Glycine max*.[405] This enzyme participates in the biosynthetic pathway for glyceollin.

The electrophile in the reaction is 3,3-dimethylallyl carbenium ion **1–99** formed by the dissociation of diphosphate from 3,3-dimethylallyl diphosphate (Figure 1–26). The electrophilic allyl carbenium ion adds to the nucleophilic π molecular orbital system of the phenyl ring at a position ortho to the hydroxy group and para to the ether oxygen, both of which increase the nucleophilicity of the ortho position, to produce a pentadienyl carbenium ion as an intermediate. This pentadienyl carbenium ion can be represented by resonance



or by its **lowest unoccupied π molecular orbital**



1–113

which contains the electron deficiency of the carbenium ion.

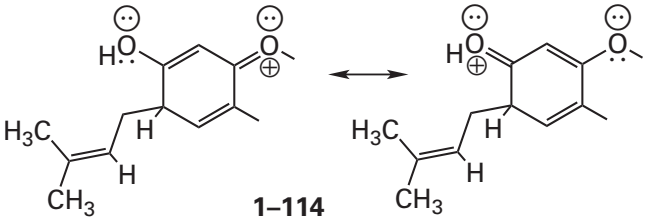
The intermediate in a generic electrophilic aromatic substitution on a phenyl group is a **pentadienyl carbenium ion**. In the particular instance of trihydroxypterocarpan dimethylallyltransferase, the pentadienyl carbenium is defined by the three resonance structures of **1–112** and is formed by mixing the five *p* atomic orbitals in the ring remaining after the electrophilic addition.

In almost all electrophilic aromatic substitutions, with the exception of those on benzene, there are **substituents on the ring** that either withdraw or donate electron density and determine the regioselectivity of the substitution. These substituents withdraw or donate electron density by resonance through the π molecular orbital system of the pentadienyl carbenium ion or by induction through the σ bonds of the system orthogonal to the π molecular orbital system. A withdrawal or donation by resonance, as opposed to one by induction, is represented by aligning the orbital or orbitals on the substituent responsible for it with the π molecular orbital of the pentadienyl carbenium ion as in **1–113**. In the present circumstance, the hydroxy group and the alkoxy group **donate electron density by resonance**, and an orbital on each oxygen containing one of its lone pairs of electrons is aligned with the π molecular orbital system. Each lone pair of electrons is located in a *p* atomic orbital because that permits the greatest overlap and also explains the coplanarity of the alkoxy group. A carbonyl group would be an example of a substituent that **withdraws electrons by resonance**, and in this instance its carbon–oxygen double bond, which is responsible for the withdrawal, would be drawn so that its π molecular orbital system is parallel to the π molecular orbital system of the pentadienyl carbenium ion.

The pentadienyl carbenium ion **1–112** has a π molecular orbital system composed from five consecutive *p* orbitals situated on the five unsaturated carbons around the ring. The two bonding

π molecular orbitals of the pentadienyl carbenium ion, those of lowest energy, are each occupied by a pair of electrons. The lowest unoccupied π molecular **1–113** has lobes at three of the carbons and nodes at the other two. The lobes of this π molecular orbital of the pentadienyl carbenium ion define its electron-deficient positions, and these positions are the same locations at which a carbenium ion is found in each of the three respective resonance structures of **1–112**.

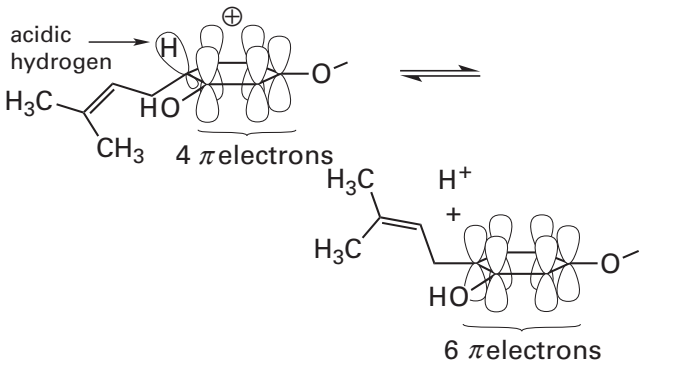
The oxygens attached at two of these three locations stabilize the respective π electron deficiency in these lobes by electron donation from their respective *p* orbitals, each occupied by a pair of electrons. This stabilization is responsible for the regioselectivity of the reaction because it also occurs, but to a lesser extent, in the transition state for the addition. The π electron donation can be represented by two resonance structures in addition to those in **1–112**



1–114

These resonance structures suggest that the actual π molecular orbital system of this particular pentadienyl carbenium ion includes the two *p* orbitals, one from each of the oxygens. In this case, the π molecular orbital system would be the result of mixing seven *p* orbitals to create seven π molecular orbitals occupied pairwise by eight electrons. The lowest unoccupied molecular orbital of the set would contain the electron deficiency and will have lobes over the atoms identified by the full set of resonance structures.

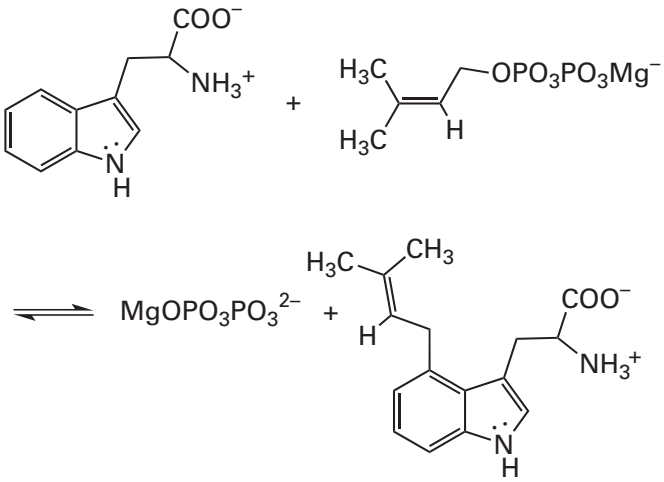
Addition of the dimethylallyl carbenium ion to the phenyl ring destroys the aromatic π molecular orbital system by introducing a saturated carbon at the one tetravalent position, the position at which both a hydrogen and the dimethylallyl group are attached. The aromatic π molecular orbital system can be regained only by loss of the original electrophile, which yields the reactants, or by loss of the hydron from that saturated carbon. **Loss of the hydron** leaves behind the two electrons formerly in the carbon–hydrogen σ bond and also permits that carbon to rehybridize sp^2, sp^2, sp^2, *p*. The *p* orbital of this carbon, the two electrons, and the pentadienyl carbenium ion together then coalesce to form the aromatic π molecular orbital system of the product



(1–154)

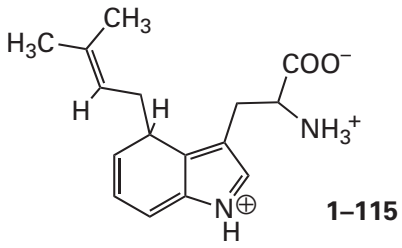
The reason that the carbon from which the hydron dissociates is acidic is that the pair of electrons in the carbon–hydrogen bond are withdrawn into the pentadienyl carbenium ion to complete the aromatic sextet.

Electrophilic aromatic substitutions on indoles are also common. An example of such a substitution, again by dimethylallyl carbenium ion **1–99** formed from dimethylallyl diphosphate (Figure 1–26), is that catalyzed by 4-dimethylallyltryptophan synthase[406]



(1–155)

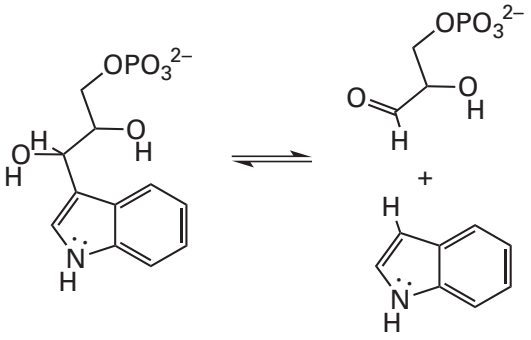
In this reaction, the intermediate carbenium ion is stabilized by the π lone pair of electrons on the nitrogen of the indole ring



1–115

In this intermediate, an **octatetraenyl π molecular orbital system** encompasses all seven of the unsaturated carbons and the nitrogen in the two rings.

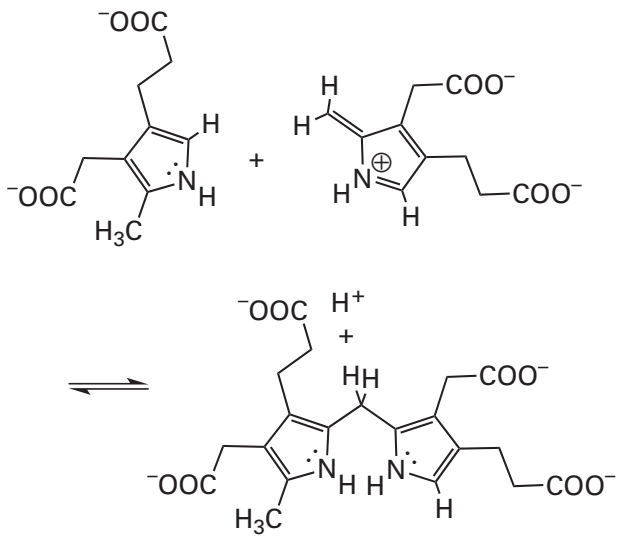
The lone pair of electrons on the nitrogen of indole also stabilizes the intermediate cation in the electrophilic aromatic substitution catalyzed by tryptophan synthase[407,408]



(1–156)

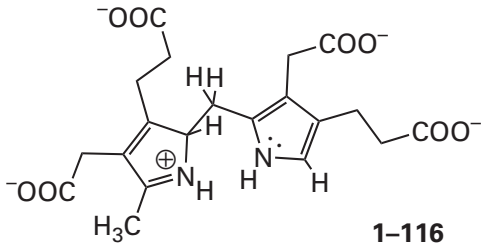
In this electrophilic aromatic substitution on the pyrrolyl ring of the indolyl group, an aldehyde, which is an electrophile, is replaced by a hydron, another electrophile, and the tetravalent carbon in the cationic intermediate is at carbon 3 of the indole rather than at carbon 4 as it is in **1–115**.

Simple pyrroles that are not further conjugated as the one is in indole are also aromatic heterocycles, and as such, they are subject to electrophilic aromatic substitution. In the discussion of the Michael addition catalyzed by hydroxymethylbilane synthase (Equation 1–141), the focus was on nucleophilic addition of the pyrrole to the electrophilic, vinylogous α,β-unsaturated iminium. Here the focus is on the electrophilic aromatic substitution that proceeds at the pyrrole



(1–157)

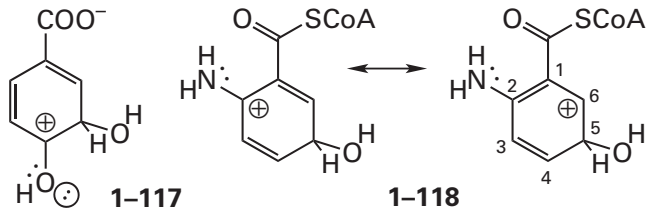
the other substrate in the reaction.[409] In this electrophilic aromatic substitution the cationic intermediate



1–116

has a butadienyl π molecular orbital system with four π electrons in which the nitrogen, if hydronated, bears the positive charge. In the next step of the reaction, the hydron on the carbon atom to which the electrophile added dissociates to rearomatize the pyrrole.

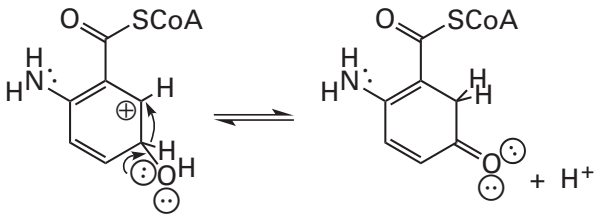
There are **electrophilic forms of atomic oxygen** generated enzymatically by flavin that add to phenyl rings in an electrophilic aromatic addition to produce intermediate pentadienyl carbenium ions



1–117 **1–118**

stabilized by exocyclic oxygens or nitrogens.[410-412]

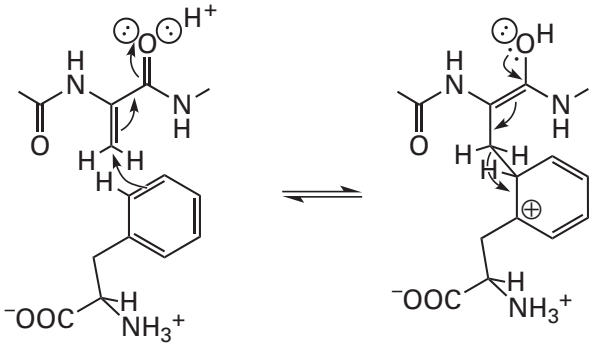
In the former instance, in which there is a hydroxy group stabilizing the pentadienyl carbenium ion, the usual dissociation of the hydron from **1–117** completes the electrophilic aromatic substitution to give the catechol, the reaction catalyzed by 4-hydroxybenzoate 3-monooxygenase. In the latter instance, in which there is an amino group stabilizing the pentadienyl carbenium ion, the hydrogen at the tetravalent carbon 5 in intermediate **1–118** migrates to cationic carbon 6 as a hydride[412,413]



(1–158)

to produce the intermediate ketone in the reaction catalyzed by anthraniloyl-CoA monooxygenase.

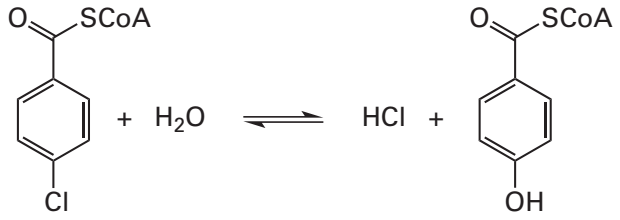
One of the more unusual electrophilic aromatic additions is that forming the pentadienyl carbenium ion



(1–159)

that is an intermediate covalently bonded to the folded polypeptide of phenylalanine ammonia-lyase from *Petroselinum crispum*.[414] This intermediate is formed by Michael addition of the nucleophilic phenyl ring to the **electrophilic dehydroalanine** in the polypeptide of the enzyme, which is an α,β-unsaturated acyl derivative. The purpose of this electrophilic aromatic addition is to acidify one of the β hydrons of L-phenylalanine so that it and ammonia can be eliminated. Once the elimination has occurred, the dehydroalanine rather than a hydron leaves the intermediate to regenerate the phenyl ring. The enzyme must avoid loss of the hydron on the saturated carbon of the pentadienyl intermediate. If the hydron were to dissociate instead of the dehydroalanine, the enzyme would be covalently inactivated.

Nucleophilic aromatic substitutions are rarely encountered in enzymatically catalyzed reactions.[415] One of the few is that catalyzed by 4-chlorobenzoyl-CoA dehalogenase



(1–160)

in which the acyl-SCoA substituent stabilizes the intermediate pentadienyl carbanion.

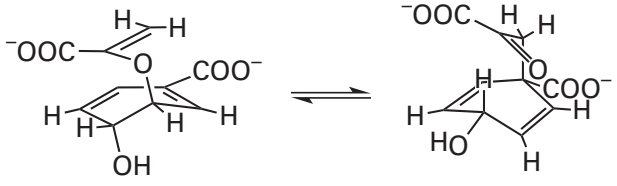
Pericyclic Reactions

A pericyclic reaction is a rearrangement of covalent bonds that proceeds in a concerted manner through one transition state. The sigmatropic rearrangement catalyzed by chorismate mutase

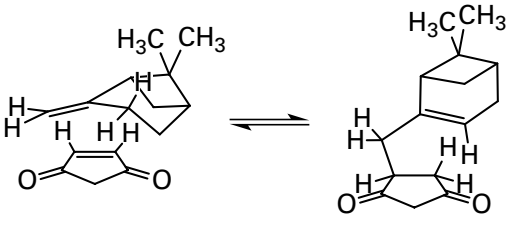


chorismate prephenate

(1–161)

is an example of a pericyclic reaction. It proceeds in one step through a single transition state in which the ether in chorismate is almost fully cleaved heterolytically while only a small fraction of the new carbon–carbon bond has formed.[416-421] As a result, the oxygen of the ether that is leaving bears a partial negative elementary charge; and the pentadienyl group that it leaves, a partial positive elementary charge. These conclusions about the enzymatic mechanism place this rearrangement just within the borderline between a concerted reaction and a stepwise reaction. The same reaction between chorismate and prephenate occurs in free solution in the absence of the enzyme. In this nonenzymatic conversion of chorismate to prephenate, little if any dissociation of the chorismate to *enol*-pyruvate and 4-hydroxy-benzoate occurs,[419] an observation consistent with the reaction proceeding in a concerted mechanism through a single transition state. Were the carbon–oxygen bond to dissociate fully before the carbon–carbon bond had begun to form, the upper and lower fragments of the molecule—the enolate of *enol*-pyruvate and the pentadienyl carbenium ion—would no longer be bonded together and should diffuse apart. This pericyclic reaction is a **sigmatropic rearrangement** because a σ bond allylic to a π bond is broken, a new σ bond allylic to a π bond is formed, and two π bonds migrate to adjacent positions.

Another example of a pericyclic reaction is the ene reaction. The formation of intermediate **1–79** that occurs during the reduction of (*E*)-but-2-enoyl-SCoA by NADPH (Equations 1–97 and 1–98) is presumed to be a concerted pericyclic ene reaction,[294] on the basis of the identity of the reactants and the products, although it has already been mentioned that this conclusion has been challenged.[299] A less controversial example of an ene reaction is the nonenzymatic coupling of 6,6-dimethyl-3-methylidenebicyclo[3.1.1]heptane and maleic anhydride



(1–162)

In this reaction, an allylic hydrogen in the 6,6-dimethyl-3-methylidenebicyclo[3.1.1]heptane is transferred to one of the carbons in the double bond of the maleic anhydride while the distal carbon of the methylene group forms a σ bond with the other carbon in the double bond. In an **ene reaction**, the distal atom in the double bond adjacent to an allylic hydrogen adds to an atom in a second double bond unconjugated to the first, either in another molecule or within the same molecule, to form a new σ bond while the allylic hydrogen is transferred to the other atom in the second double bond.

A pericyclic reaction is a concerted reorganization of bonding that takes place through an aromatic transition state that is a cyclic array of overlapping atomic orbitals. The bonding around the ring in the transition state, however, does not need to be a continuous circle of σ bonds. In fact, in most pericyclic reactions one or two of the bonds connecting the atoms in the ring of the transition state are solely π bonds with no σ bond connecting them. To be a true pericyclic reaction, however, the bonds being broken and those being formed must be broken and formed during the passage through a single transition state. Sigmatropic rearrangements, ene reactions, cycloadditions, and electrocyclic reactions are examples of pericyclic reactions.

A pericyclic reaction has an aromatic transition state. The aromatic transition state for the sigmatropic rearrangement catalyzed by chorismate mutase, and the aromatic transition state for the coupling of 6,6-dimethyl-3-methylidenebicyclo-[3.1.1]heptane and maleic anhydride, are both transition states in which there is a continuous ring of six parallel atomic orbitals, each of which overlaps in sequence around the ring with its two nearest neighbors so that they can together form a complete cyclic π molecular orbital system, and the π molecular orbital system in each of these transition states is occupied by six electrons. To satisfy the requirement for an aromatic transition state, there can be atomic orbitals, either *s* orbitals or *p* orbitals, from any number of atoms, as long as they are sterically permitted to overlap and form a continuous, conjugated cyclic transition state, and provided that six or ten electrons (or another aromatic number) participate in the resulting molecular orbital system. Most of the pericyclic reactions catalyzed by enzymes have cyclic transition states of five or six atoms in which only six electrons are rearranged.

In the transition state for the sigmatropic rearrangement catalyzed by chorismate mutase, all six of the atoms involved are hybridized sp^2, and the ring is composed of the six *p* orbitals (Figure 1–30).

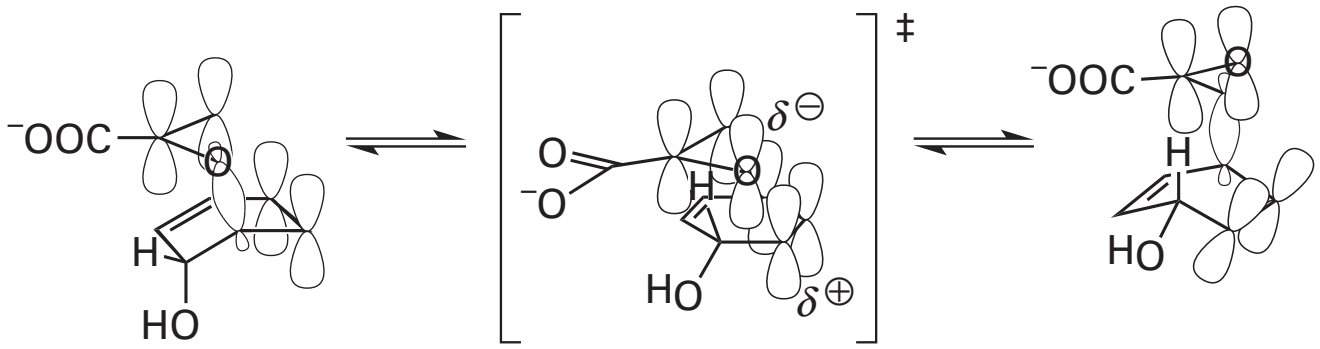


Figure 1–30: Reactant, transition state, and product of the reaction catalyzed by chorismate mutase. The reactant, chorismate, has a σ bond between oxygen and carbon flanked by two carbon–carbon double bonds. In the transition state (‡), the carbon–oxygen σ bond has broken to produce two additional p orbitals, and these new p orbitals and the four p orbitals already in the reactant now form an unbroken ring of six p orbitals. The π molecular orbital system is occupied by six electrons. This aromatic π system holds together the two fragments that are no longer connected by a σ bond. When a σ bond forms between two p orbitals on the opposite side of the ring, the product prephenate (upper right) is produced. It also has a σ bond flanked by two double bonds.

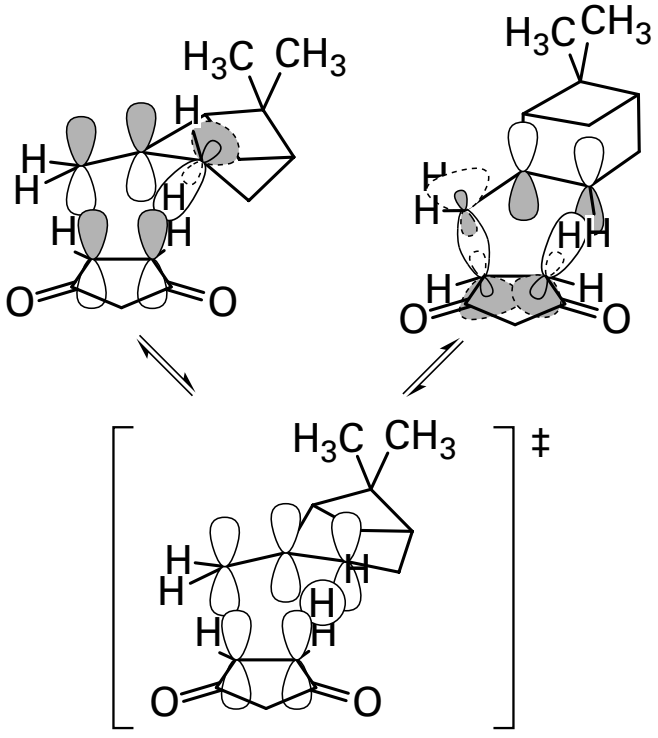
These six p atomic orbitals that mix in the transition state were the two molecular orbitals, bonding and antibonding, that form the σ bond between the carbon and the oxygen and the four π molecular orbitals, bonding and antibonding, that form the two π molecular orbital systems in the two double bonds of the reactant. They will become the four π molecular orbitals that form the π molecular orbital systems in the two double bonds of the product and the two molecular orbitals, bonding and antibonding, that form the molecular orbital system in the new carbon–carbon σ bond in the product. The π molecular orbital system of the transition state (Equation 1–161 and Figure 1–30) is formed from six p orbitals from five carbons and one oxygen. These six π electrons are delocalized and mobile, so it is not surprising that significant negative charge builds up on the more electronegative oxygen in the transition state at the expense of electron density on the five carbons, which become electron-deficient.[421] Because of this imbalance of electron density, the transition state is more polar than the ground state, and the nonenzymatic reaction is more rapid in polar solvents than nonpolar solvents.[419]

The transition state for the ene reaction of 6,6-dimethyl-3-methylidenebicyclo[3.1.1]heptane and maleic anhydride



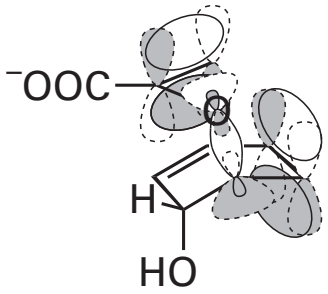
(1–163)

is formed from p orbitals from the five carbons involved and the s orbital of the hydrogen that is transferred from one of the carbons to another. These six atomic orbitals that mix in the transition state were the two molecular orbitals, bonding and

antibonding, that form the σ bond between the carbon and the allylic hydrogen and the four π molecular orbitals, bonding and antibonding, that form the two π molecular orbital systems in the two double bonds of the reactant. They will become the two π molecular orbitals, bonding and antibonding, that form the π molecular orbital system in the double bond of the product and the four molecular orbitals, bonding and antibonding, that form the two molecular orbital systems in the two σ bonds, carbon–carbon and carbon–hydrogen, in the product.

Although aromatic, the transition states in the sigmatropic rearrangement catalyzed by chorismate mutase and in the ene reaction of 6,6-dimethyl-3-methylidenebicyclo[3.1.1]heptane and maleic anhydride are **unstable with respect to reactant and product** because in the reactants and products one or two of the π bonds in the transition state have become σ bonds in the reactant or product. σ Bonds are more stable than π bonds. Each transition state therefore readily decomposes to the reactant or product, either of which is more stable than the transition state. In each case, if the π molecular orbital system of the transition state is examined closely, it can be seen that there are only two ways that it can decompose to form three covalent bonds. In the case of chorismate mutase, the transition state must either form prephenate, in which it has disassembled into two carbon–carbon π bonds and a carbon–carbon σ bond, or form chorismate, in which the transition state has disassembled into two carbon–carbon π bonds and a carbon–oxygen σ bond. In the case of the ene reaction of 6,6-dimethyl-3-methylidenebicyclo[3.1.1]-heptane and maleic anhydride, the transition state must either form 6,6-dimethyl-3-methylidenebicyclo-[3.1.1]heptane and maleic anhydride, in which it has disassembled into two carbon–carbon π bonds and a carbon–hydrogen σ bond, or form the adduct, in which the transition state has disassembled into a carbon–carbon π bond, a carbon–carbon σ bond, and a carbon–hydrogen σ bond.

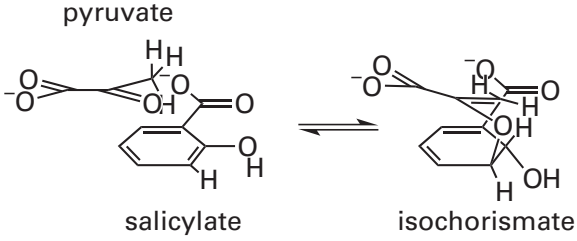
In pericyclic reactions, the transition state is approached by **overlaps of atomic and molecular orbitals in the reactant or in the product.** The active site of the enzyme catalyzing a pericyclic reaction ensures that a conformation of the two molecules is enforced in which these overlaps are permitted. For example, in the pericyclic, sigmatropic rearrangement catalyzed by chorismate mutase (Equation 1–161)



1–120

the following interactions are occurring. First, the lower lobe of the unoccupied antibonding molecular orbital of the carbon–oxygen σ bond overlaps the lower lobe of the occupied bonding π molecular orbital of the lower right double bond. Second, the upper lobe of the unoccupied antibonding π molecular orbital of the lower right double bond overlaps the lower lobe of the occupied bonding π molecular orbital of the upper left double bond. Third, the lower lobe of the unoccupied antibonding π molecular orbital of the upper left double bond overlaps with the occupied bonding molecular orbital of the carbon–oxygen σ bond. Fourth, the occupied bonding molecular orbital of the carbon–oxygen σ bond overlaps with the upper lobe of the unoccupied antibonding π molecular orbital of the lower right double bond. Fifth, the upper lobe of the occupied bonding π molecular orbital of the lower right double bond overlaps with the lower lobe of the unoccupied antibonding π molecular orbital of the upper left double bond. Sixth, the upper lobe of the occupied bonding π molecular orbital of the upper left double bond overlaps with the upper lobe of the unoccupied antibonding molecular orbital of the carbon–oxygen σ bond.

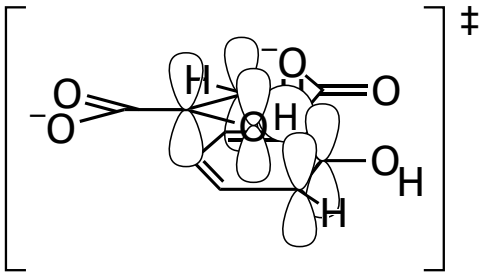
There are other instances of enzymatically catalyzed pericyclic reactions. For example, an enzymatically catalyzed pericyclic ene reaction is that catalyzed by isochorismate lyase from *Pseudomonas aeruginosa*[422]



(1–164)

The reaction proceeds through a single aromatic transition state formed from the *s* orbital of the

hydrogen that is migrating and five *p* orbitals from the five heavy atoms, four carbons and an oxygen



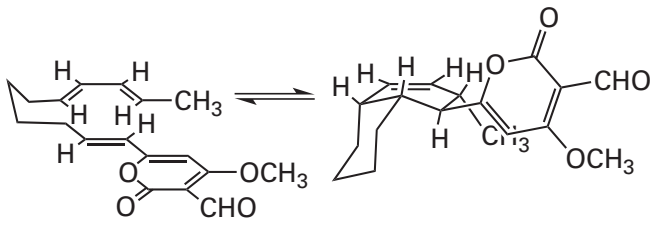
1–121

In the transition state, the σ bond between carbon and hydrogen and the σ bond between carbon and oxygen in the reactant do not exist because their constituent atomic orbitals have been transformed into participants in the π molecular orbital system, but the transition state is held together by that continuous π molecular orbital system. In this ene reaction in the direction of salicylate formation, kinetic isotope effects indicate that dissociation of the carbon–oxygen bond precedes dissociation of the carbon–hydrogen bond but that the reaction is nevertheless concerted and pericyclic.

The proposal that an ene reaction forms intermediate **1–79** during the reduction of (*E*)-but-2-enoyl-SCoA by NADPH was invoked to explain the fact that the π molecular orbital system of the (*E*)-but-2-enoyl-SCoA is stacked against and parallel to the π molecular orbital system of the NADPH. In the case of the ene reaction that is catalyzed by isochorismate lyase the **π molecular orbital systems of the reactants and the products must be parallel** to and stacked against each other. Consequently, the plane of the π molecular orbital system of the pyruvyl moiety must be parallel to the plane of the π molecular orbital system of the salicyl moiety. When the active site of the enzyme is occupied by pyruvate and salicylate, the π molecular orbital system of the pyruvate is parallel to and stacked upon the π molecular orbital system of the salicylate, and the two products are positioned in the orientation they should assume in the transition state (**1–121**).[423]

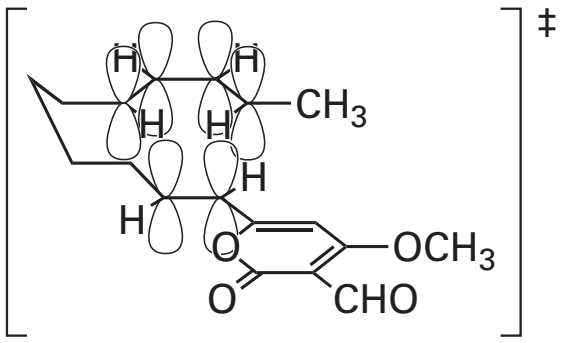
If the π molecular orbital system of transition state **1–121** is examined closely, it can be seen that there are only two ways that it can decompose to form three covalent bonds. It must either form isochorismate, in which the transition state has decomposed into a carbon–carbon π bond, a carbon–hydrogen σ bond, and a carbon–oxygen σ bond, or form salicylate and pyruvate, in which the transition state has decomposed into a carbon–carbon π bond, a carbon–oxygen π bond, and a carbon–hydrogen σ bond. Although the isochorismate has one more σ bond and one fewer π bond than pyruvate and salicylate, the fact that the salicylate is aromatic while isochorismate is not evens up the reaction.

A **cycloaddition** is a pericyclic reaction in which a total of $(2n + 1)$ double bonds from two unsaturated molecules, or two parts of the same unsaturated molecule, participate and during which a cyclic adduct is produced in which the number of π bonds has decreased by two and the number of σ bonds has increased by two, namely, the two σ bonds creating the cyclic adduct. A **Diels–Alder reaction** is a (4+2) cycloaddition in which four atoms in two adjacent, conjugated double bonds, the diene, form a cyclohexene by combining with a double bond, the dienophile, elsewhere in the same molecule or in another molecule. A Diels–Alder reaction has a single, aromatic transition state formed from a ring of six parallel *p* orbitals through which a cyclohexene is formed or a cyclohexene dissociates. An enzymatically catalyzed example of such a Diels–Alder reaction[424-426] is that catalyzed by prosolanapyrone-III cycloisomerase from *Alternaria solani*, which produces solanapyrone A



(1–165)

Six parallel *p* orbitals

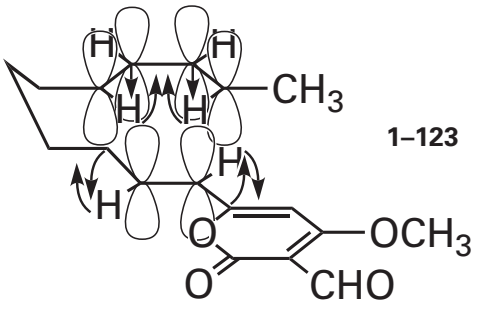


1–122

and six π electrons in the reactant mix to produce the aromatic π molecular orbital system of the transition state. An enzyme catalyzing a similar synthesis of a cyclohexene through a Diels–Alder reaction is involved in the pathway for the biosynthesis of versipelostatin.[427]

A cycloaddition, such as the reaction that produces solanapyrone A, proceeds with an enforced **stereochemistry**, and the product observed in an enzymatically catalyzed reaction, because enzymatic reactions are always stereospecific, is only one of four stereochemical outcomes that can result from this reaction. In the reaction catalyzed by prosolanapyrone-III cycloisomerase, the two possible exo products would be those resulting from the dienophile, with its pyran-2-one pointed away from the diene, approaching the diene either from the bottom as in the drawing or from the top. The two possible endo products would be those resulting from the dienophile, with its pyran-2-one nestled under or above the two double bonds of the diene, approaching the diene either from the bottom or from the top.

In the enzymatically catalyzed reaction, the dienophile approaches from below the diene with its pyran-2-one in the exo orientation as drawn in **1–122**. The dienophile pushes the two central hydrogens of the diene up while the hydrogen and the alkyl group on the dienophile in the center are pushed down by the diene. In response to these steric drives in the center, the carbon–carbon double bond on the periphery of the diene moves downward, and the hydrogen and the pyran-2-one on the periphery of the dienophile twist upward as the two new σ bonds are formed

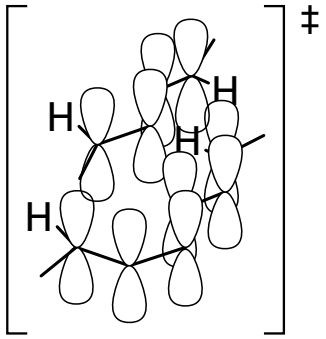


1–123

These drives give the observed stereochemistry of the product (Equation 1–165). The unique feature of this stereochemical enforcement is that the four paired substituents, each of which begins on one of the two sides of the diene or one of the two sides of the dienophile, respectively, remain paired so that each pair ends up only on one side or the other of the cyclohexene. If the stereochemistry of the cyclohexene in the product of an enzymatic reaction that is proposed to proceed by a Diels–Alder reaction satisfies these requirements and furthermore if only one of the four possibilities is observed, then this stereochemistry and the **exclusivity of the product** can be used as an argument for the enzyme catalyzing a concerted, pericyclic cycloaddition passing through a single transition state.

A Diels–Alder reaction is a (4+2) cycloaddition because four *p* orbitals from one fragment combine with two *p* orbitals from the other fragment. In a **(6+4) cycloaddition**, six *p* orbitals from one fragment combine with four *p* orbitals from the other fragment in an aromatic transition state with ten electrons in a decacyclic π molecular orbital system formed from mixing these ten atomic orbitals.

An example of a (6+4) cycloaddition is the reaction catalyzed by the enzyme encoded by the *ngnD* gene in *Nocardia argentinensis* (Figure 1–31).[428] In the first step, a ten-membered ring with three π bonds is formed within a much larger 18-membered ring. During the cycloaddition, five carbon–carbon π bonds are converted into two carbon–carbon σ bonds and three carbon–carbon double bonds through the aromatic transition state*



1–124

The product of the cycloaddition is then converted by a sigmatropic ring contraction into a cyclohexene with a ten-membered ring on one side and a six-membered ring on the other side. The stereochemistry† of the hydrogens in the ultimate product is that expected for a (6+4) cycloaddition followed by a sigmatropic rearrangement. An almost identical (6+4) cycloaddition followed by a sigmatropic ring contraction to yield a cyclohexene is catalyzed by an unrelated[428,429] enzyme encoded by the *spnF* gene in *Saccharopolyspora spinosa.*[430-432]

*In order to produce a comprehensible drawing, the structure of the reactant in Figure 1–31 was flipped over so that the fragment with two carbon–carbon bonds approaches the transition state from above rather than from below.

†Professor Hui Ming Ge has written: "The CAS drawing in ChemAbstract's SciFinder is the enantiomer, which we think is not correct based on single crystal X-ray analysis."

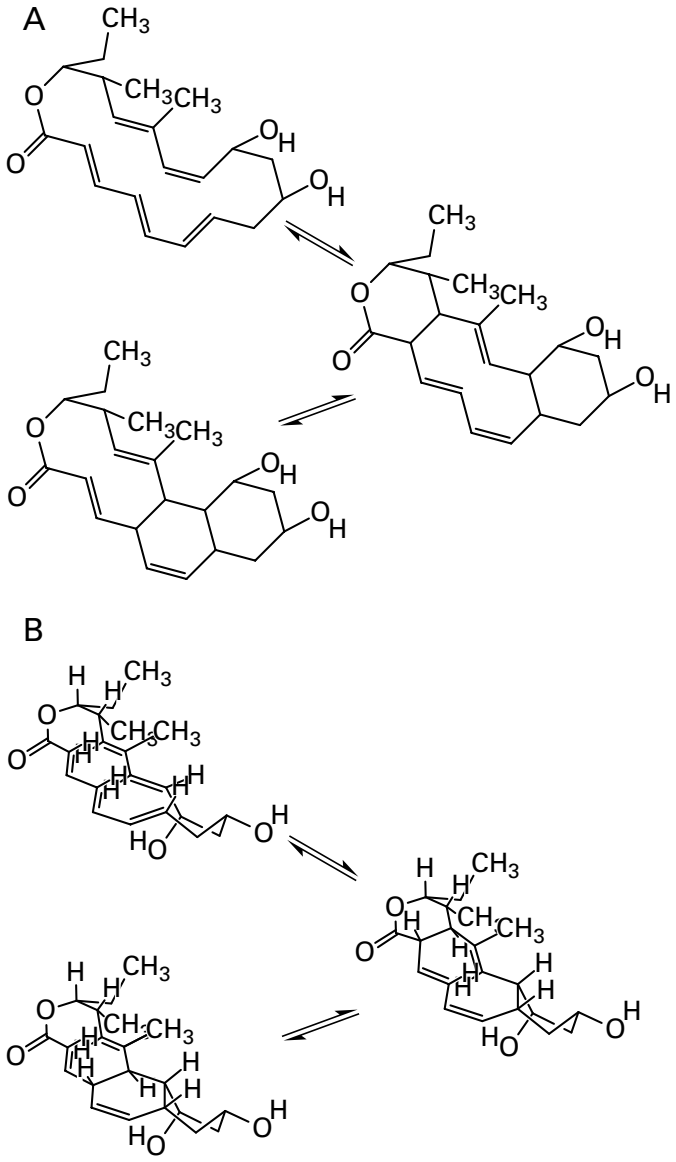


Figure 1–31: The (6+4) cycloaddition and sigmatropic rearrangement catalyzed by the enzyme encoded by the *ngnD* gene in *N. argentinensis*.[428] **(A)** Schematic drawing of the reaction, displaying the (6+4) cycloaddition that converts the octadecacycle into the fused hexacycle, decacycle, and hexacycle and the subsequent sigmatropic rearrangement that produces the fused decacycle, hexacycle, and hexacycle. The initial reactant is the lactone of the linear carboxylic acid (2*E*,4*E*,6*E*,12*E*,14*E*)-9,11,17-trihydroxy-14,16-dimethylnonadeca-2,4,6,8,12,14-pentaenoic acid. **(B)** Stereochemical drawing of the same two reactions. During the (6+4) cycloaddition, the lower left-hand side of the octadecacycle is situated above the upper right-hand side. When the central decacycle forms, the hydrogens and the carbon–carbon bonds attached to the ends of the π bonds rearranging to form the two new σ bonds swing in such a way that those groups in the center on the top and bottom move up and down, respectively, and those pointed away from the center on the top and bottom move down and up, respectively, as in **1–123**. During the sigmatropic rearrangement, the lower left-hand side of the central decacycle is still situated above the upper right-hand side. When the central decacycle contracts, the hydrogens and the carbon–carbon bonds attached to the ends of the π bonds forming the new σ bond swing in such a way that those groups in the center on the top and bottom move up and down, respectively, and those pointed away from the center on the top and bottom move down and up, respectively. As the former σ bond on the upper left dissociates, the two hydrogens swing into the center and the lower left-hand hydrogen ends up above the upper right-hand hydrogen.

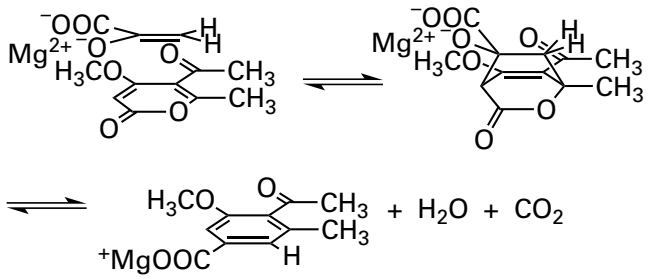
An **electrocyclic reaction** is a pericyclic reaction in which a σ bond is formed between the termini of a fully conjugated linear π molecular orbital system containing three (or $2n+3$) π bonds among six (or $4n+6$) atoms that become a ring with two (or $2n+2$) π bonds and the σ bond connecting the former termini. The number of π bonds has decreased by one and the number of σ bonds has increased by one. The transition state is formed from a ring of the six (or $4n+6$) p atomic orbitals of the six (or $4n+6$) atoms participating in the rearrangement. There are many conversions involved in the synthesis of natural products that can be explained as the result of electrocyclic reactions.[433] There is, however, little evidence as yet that they are catalyzed by enzymes. Nevertheless, the fact that such electrocyclic reactions are quite slow at ambient temperatures and should require catalysis, as well as the fact that it is often the case that the biosynthetic products are chiral even though the precursors are achiral, together strongly suggest that enzymatic catalysis is involved.

The assignment of a pericyclic reaction as the mechanism of an enzyme in the absence of direct evidence of such an involvement results from its irresistibility, but in many cases, this may be wishful thinking.[425] For example, prosolanapyrone-III cycloisomerase (Equation 1–165), the enzyme that is involved in the biosynthesis of versipelostatin, and

the enzyme that is encoded by the *ngnD* gene (Figure 1–31) are simply, at the moment, the least controversial of several enzymes that have been proposed to catalyze Diels–Alder reactions.[425,434]

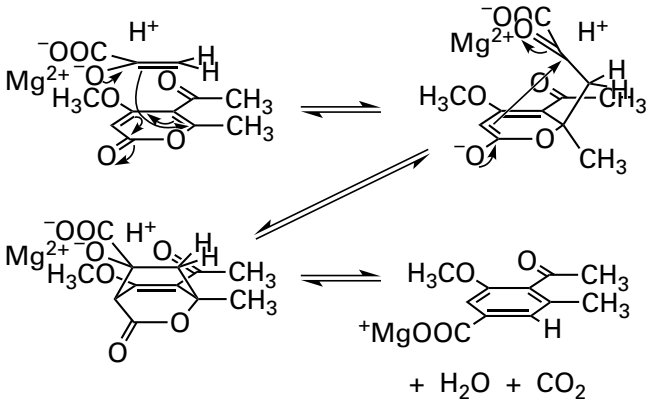
One problem with glibly assigning a pericyclic reaction to the mechanism of an enzyme is that the only mechanism for catalysis of an actual pericyclic reaction seems to be the **alignment of the portions of the reactant** or the two reactants. It should be pointed out, however, that such an alignment of reactants is the most effective way,[435] in which any active site dramatically increases the rate of a reaction. Furthermore, the alignment of the reactant or the reactants by the active site can also explain the **production of chiral products from achiral reactants**. In a reaction such as a cycloaddition, where there are four possible diastereomeric products for the uncatalyzed reaction, the fact that only one enantiomer is observed is strong evidence that the reaction proceeds under the steric control of an active site.

Another problem with the assignment of a pericyclic reaction as the mechanism of an enzyme is that there are usually **alternative mechanisms involving two transition states** and an intermediate rather than the single transition state required of a pericyclic reaction. For example, the formation of intermediate **1–79** in the active site of crotonyl-CoA carboxylase/reductase can be explained[299] by the direct transfer of a hydride from NADPH to (*E*)-but-2-enoyl-SCoA followed by a nucleophilic addition of the resulting enolate to the $NADP^+$ in a nonproductive side reaction. Enzymatic reactions that were at one time considered to be concerted cycloadditions sometimes turn out to proceed through entirely different mechanisms. For example, at one time it was believed[436,437] that the reaction catalyzed by macrophomate synthase from *Macrophoma commelinae* included a Diels–Alder cycloaddition



(1–166)

in which the enol of pyruvate was the dienophile. Since then, evidence has been presented[438,439] that is more consistent with a mechanism in which a nucleophilic addition of the enolate of pyruvate to the α,β-unsaturated carbonyl of the exocyclic acetyl group, the carbon–carbon bond of which is also conjugated to the acyl group of the lactone, is followed by a nucleophilic addition of the enolate of the resulting adduct directly to the carbonyl of the pyruvyl group

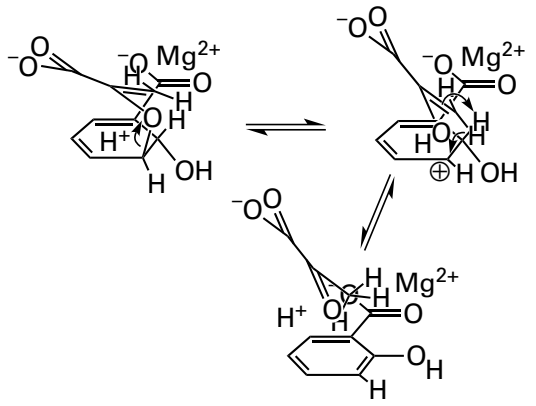


(1–167)

This mechanism involves two transition states and the intermediate adduct.

An enzyme, which is found in both *Yersinia enterocolitica* and *M. tuberculosis*, has an active site[440,441] that catalyzes the same reaction as that catalyzed by isochorismate lyase from *P. aeruginosa* (Equation 1–164), even though this other enzyme is unrelated structurally to isochorismate lyase from *P. aeruginosa* and hence does not share a common ancestor. The active site is completely different, and when the two substrates pyruvate and salicylate are occupying it, unlike what occurs in the active site of the enzyme from *P. aeruginosa*, the π molecular orbital system of the pyruvate is positioned at a 60° angle to the π molecular orbital system of the salicylate, rather than being parallel to it and stacked upon it. This observation is a strong indication that the reaction catalyzed by this other enzyme does not proceed by a pericyclic mechanism, which requires that the pyruvate and the salicylate be parallel to each other (**1–121**).

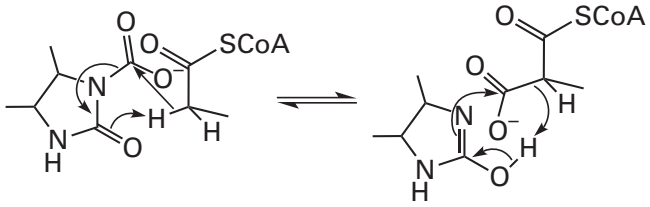
A mechanism, however, that is consistent with this stereochemical observation is one in which an elimination of the enol of pyruvate precedes the removal of a hydron from carbon 2 of the ring by the resulting enol



(1–168)

The enol of pyruvic acid should be a good leaving group ($pK_a = 7.3$), the resulting carbenium ion is delocalized over five carbons, and the enolate of pyruvate should be an excellent base (the pK_a of its conjugate acid is 26.6) for removing the hydron from carbon 2 of the ring. In the crystallographic molecular model of the complex between the enzyme from *Y. enterocolitica* and pyruvate and salicylate, the distance between oxygen 2 of the pyruvate and carbon 3 of the salicylate is 0.31 nm, and the distance betweeen carbon 3 of the pyruvate and carbon 2 of the salicylate is 0.38 nm. Both of these distances are within the respective sums of the van der Waals radii of the atoms involved, which is consistent with the proposed steps in the mechanism.

The irresistibility of pericyclic reactions often leads to a proposal that can be rejected by simple consideration of the stereochemistry of the participants. Consider the following mechanism proposed for carboxyl transfer from biotin[442]



(1–169)

Superficially, it resembles the mechanism of the reaction catalyzed by isochorismate lyase (Equation 1–164). When the details of Equation 1–169 are examined, however, a telling difficulty arises. Although the σ bond between the carbon and the hydrogen of the acyl-SCoA can be parallel to the π molecular orbital system of the urea, the σ bond between the upper right nitrogen of the urea and the carbon of the carboxy group cannot be parallel to the π molecular orbital system of the urea because it is of necessity orthogonal to it. Consequently, the transition state required if this were a pericyclic reaction is impossible. It is not surprising that this reaction has been demonstrated to occur in steps rather than by a concerted mechanism.[443,444]

In summary, a pericyclic reaction is an unequivocal example of a concerted reaction. In a concerted reaction, the making and breaking of two or more bonds occur within the same transition state. Reactions that have been shown to proceed through concerted mechanisms always proceed through simultaneous overlaps between occupied and unoccupied atomic or molecular orbitals that are stereochemically permitted. In addition, overlaps between two occupied molecular or atomic orbitals that would lead to electron repulsion must be avoided. Many more concerted mechanisms have been proposed than have been demonstrated to occur. In many instances, the proposal for a concerted mechanism, when examined closely, has significant problems associated with it.

Problem 1–1: The following reactions are simplified versions of actual reactions that occur in metabolism. In most of them, the complicated functional groups of the actual metabolites have been replaced by methyl or ethyl groups to make it simpler to write the compounds. Therefore, these specific reactions do not necessarily occur anywhere. Nevertheless, as written, the chemistry is identical to the chemistry of the reactions between the more complicated biological molecules that are catalyzed by enzymes. The majority of the chemical reactions that occur in metabolism are represented here. Most of the remaining reactions in metabolism are catalyzed by enzymes that use prosthetic

groups, and these will be discussed in more detail in the next chapter. Assume each reaction occurs in aqueous solution and that donors of hydrons (acids) and acceptors of hydrons (bases) are always available. Write complete chemical mechanisms for these reactions. Where hydrides are shown it is assumed that NAD^+ would be the carrier of them.

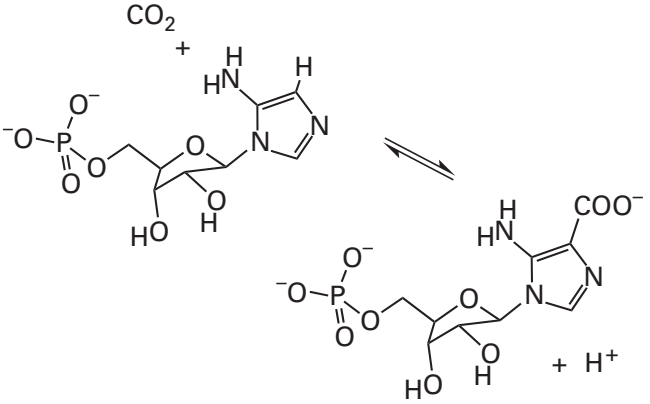
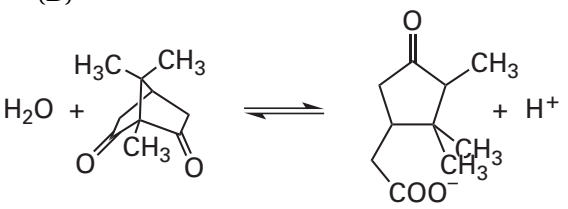
Problem 1–2: Write mechanisms for the following reactions:[445,446]

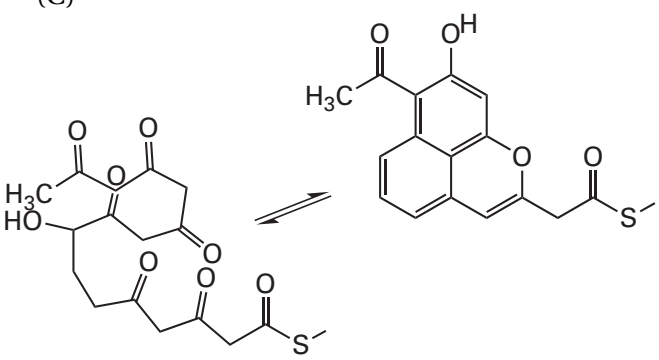
(A)



(B)



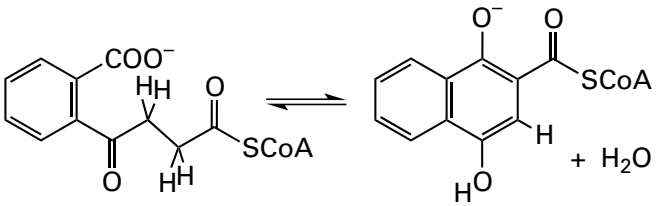
(C)



(D) 2-hydroxy-6-oxonona-2,4-diene-1,9-dioic acid $\rightleftharpoons$ succinate + 2-hydroxypenta-2,4-dienoic acid

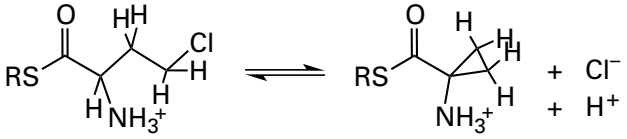
Problem 1–3: In animal cells, D-glucosamine is made from ammonium ion (NH_4^+) and D-fructose. Write the complete chemical mechanism for this reaction.

Problem 1–4: Write a mechanism[447] for the reaction catalyzed by 1,4-dihydroxy-2-naphthoyl-CoA synthase



What process drives the reaction to completion?

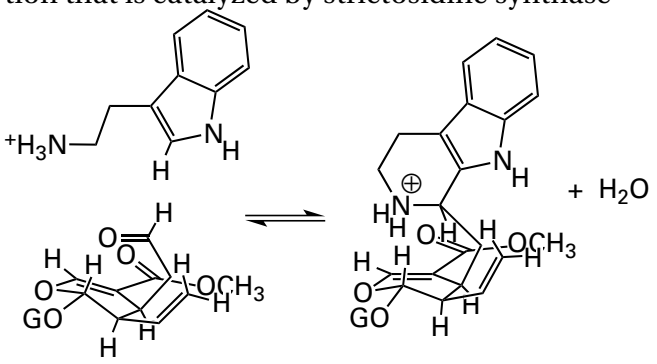
Problem 1–5: Write a mechanism[448] for the reaction that is catalyzed by coronamic acid synthase



where R is a small protein with a cysteine to which the L-2-amino-4-chlorobutyrate is attached.

Problem 1–6: Write a mechanism for Equations 1–142 and 1–144.

Problem 1–7: Write a mechanism[449] for the reaction that is catalyzed by strictosidine synthase

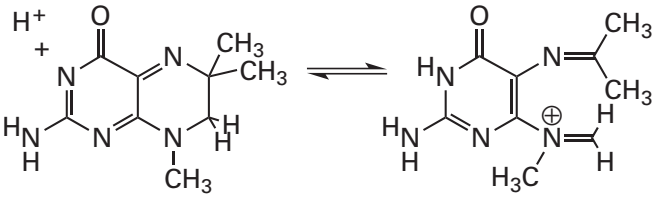


where G is a D-glucopyranosyl group.

Problem 1–8: Write mechanisms for the electrophilic aromatic substitutions of Equations 1–155, 1–156, and 1–157. Write resonance structures for the intermediate carbenium ions that explain their stabilities.

Problem 1–9: The indolyl group in L-tryptophan is susceptible to electrophilic aromatic substitution at nitrogen 1 and carbons 2, 5, 6, and 7, in addition to carbon 4 (Equation 1–155), and to electrophilic addition at carbon 3. Use the dimethylallyl carbenium ion **1–99** (Figure 1–26) as the electrophile and draw the most stable resonance form of the cationic intermediate in each of these six electrophilic aromatic substitutions and the product of the electrophilic aromatic addition at carbon 3.

Problem 1–10: Write a mechanism for this reaction



that involves only carbonyl chemistry rather than pericyclic chemistry.

Problem 1–11: Criticize the following proposal for a concerted reaction:

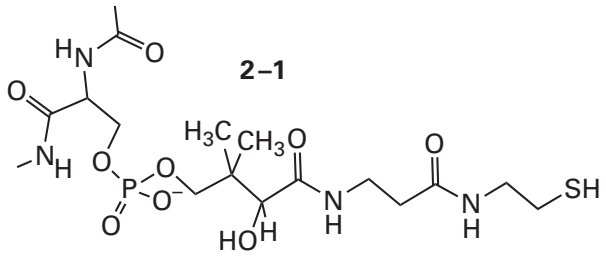
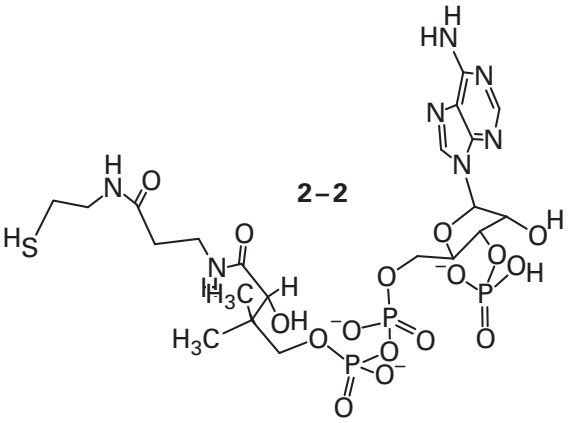
Chapter 2
Prosthetic Catalysis

In addition to the 20 unmodified side chains of the amino acids and the peptide bonds of the polypeptide backbone, which are provided unavoidably by the protein as catalysts for the chemical transformation performed by an enzyme, prosthetic groups can provide **complicated catalytic functional groups more or less permanently associated with the enzyme.** Prosthetic groups are often attached covalently to the protein as **posttranslational modifications**. In this instance, the prosthetic group is formally equivalent to an amino acid in that it is a covalent participant in the structure of the protein. Often, however, a prosthetic group is merely tightly but noncovalently bound to the protein. Although a tightly bound prosthetic group does not leave the enzyme readily and may remain associated with it for extended periods of time, it is possible for it to dissociate slowly from the protein even when the protein is in its native state. A noncovalently bound prosthetic group always dissociates when the protein is unfolded. As far as the reaction catalyzed by the enzyme is concerned, however, a noncovalently bound prosthetic group is a permanent feature of the molecular structure of the enzyme; and, in this sense, it is also indistinguishable from any of its amino acids. Although most prosthetic groups, other than lipids and polysaccharides, participate directly in the catalytic reactions catalyzed by the enzymes in which they are located, there are examples of otherwise catalytic prosthetic groups that do not seem to be involved in any way in catalysis and seem to perform a purely structural role.[1]

Examples of a **covalently bound prosthetic group** would be the 4′-phosphopantetheines attached covalently to serines as posttranslational modifications of animal fatty acid synthase[2] and fungal L-aminoadipate-semialdehyde dehydrogenase.[3]



4′-Phosphopantetheine is identical to the portion of coenzyme A (previously **1–66**)*



in which the essential sulfanyl group is located, but it is attached to a serine rather than adenosine 3′,5′-diphosphate. The sulfanyl group of the pantetheine, when it is a prosthetic group in the respective active sites, is acylated during enzymatic catalysis, and the resulting thioester participates as an enol in fatty acid synthase or is reduced to the monothiohemiacetal in L-aminoadipate-semialdehyde dehydrogenase. The role of the 4′-phosphopantetheine as a covalently attached prosthetic group in these reactions should be distinguished from its role as a coenzyme when it is incorporated into coenzyme A, even though in both cases the pantetheine is performing the same chemical function. As has already

*From here on, Equations and Structures from previous chapters will be reproduced in the present chapter. The intention is to make it easier for the reader. Instead of having to rummage through an earlier chapter, the reader will find the drawing in the present chapter, usually within pages of any reference to it, and each chapter is self-contained, at least as far as Equations and Stuctures.

been noted, a coenzyme such as coenzyme A, unlike a prosthetic group such as 4′-phosphopantetheine, enters and leaves the active site of the enzyme during every turnover and is functionally indistinguishable from a substrate.

An example of a **tightly but noncovalently bound prosthetic group** would be the NAD^+ that is tightly bound to UDP-glucose 4-epimerase (previously Equation 1–88)

$$\text{UDP-glucose} \rightleftharpoons \text{UDP-galactose} \qquad (2\text{–}1)$$

Because the NAD^+ is regenerated after each catalytic cycle of this enzyme, there is no need for the NAD^+, or the NADH, to enter and leave the active site, and they remain continuously bound as complementary prosthetic groups. The role of the NAD^+ as a prosthetic group in this reaction should be distinguished from its role in almost every other situation where it is a coenzyme, indistinguishable except in name from a substrate, that enters and leaves the active site during each turnover. Many of the prosthetic groups that are noncovalently associated with active sites, such as pyridoxamine 5′-phosphate and thiamine diphosphate, contain one or more phospho groups. These phospho groups can form strong attachments with properly organized cups of donors for hydrogen bonds.

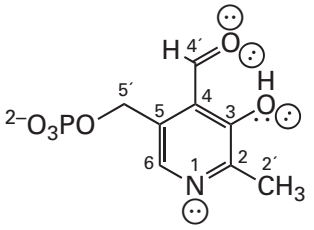
Most prosthetic groups have proven so versatile that they are **used in many different enzymatic reactions** to perform the same, particular function in the respective contexts. A few enzymes, however, carry prosthetic groups unique to themselves, such as the dipyrromethane covalently attached to the active site of hydroxymethylbilane synthase.[4-6]

Most prosthetic groups are **molecules synthesized separately** in their own respective metabolic pathways, each of which encompasses a sequence of successive enzymatic steps, such as the metabolic pathway producing riboflavin. A few, however, are the result of posttranslational modification of the polypeptides forming their enzymes. Such a posttranslational modification can be of a side chain, such as the successive oxidations that produce 2,4,5-trihydroxyphenylalanine[7] or the oxidation that produces dehydroalanine,[8] or it can be a modification of the peptide backbone, such as the one that produces the 4-methyleneimidazol-5-one formed from Serine 143 of histidine ammonia-lyase from *Pseudomonas putida*.[9]

Prosthetic groups exist because they effect chemical transformations beyond those that can be accomplished by the unmodified side chains of the amino acids.

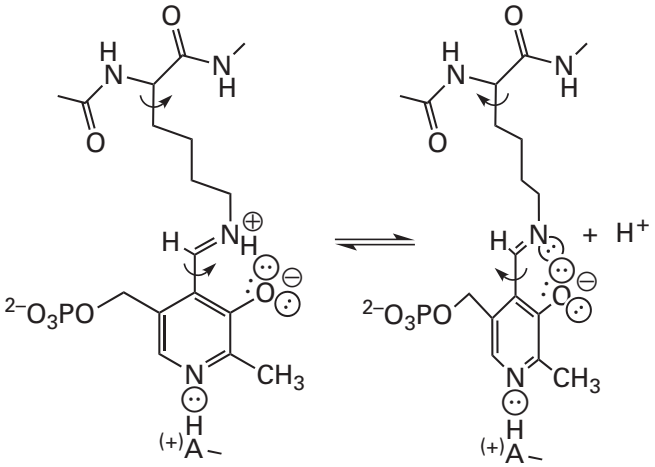
Pyridoxal 5′-Phosphate

Pyridoxal 5′-phosphate



2–3

when acting as a prosthetic group, is usually bound covalently to the resting enzyme as an internal pyridoximine with one of its lysines.[10-12]



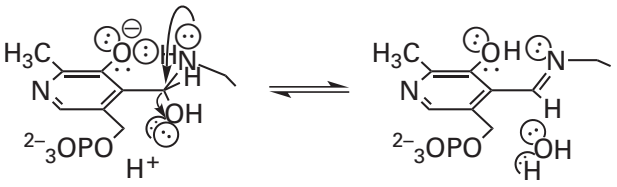
internal pyridoximine

(2–2)

Pyridoxal 5′-phosphate is a 4-azabenzaldehyde. Consequently, it is not prone to the many unfortunate side reactions in which aliphatic aldehydes participate with the amino acids of proteins.[13]

The initial **formation of an internal pyridoximine** between pyridoxal 5′-phosphate and the primary amino group of a lysine in the active site of the enzyme is a simple nucleophilic substitution at a carbonyl and proceeds through the hemiaminal.

The slow step in such a formation of an imine in aqueous solution is usually the loss of water from the hemiaminal, which is also the case in the formation of an internal pyridoximine.[14] The dehydration of a hemiaminal is susceptible to both acid and base catalysis (Figure 1–7). In the case of pyridoxal 5′-phosphate in solution, the phenolic oxygen catalyzes this dehydration intramolecularly.[15] This catalysis is thought to be due to its ability to act as an intramolecular base

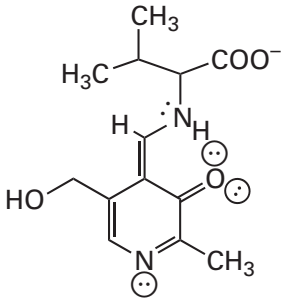


(2–3)

and remove the hydron from imino nitrogen immediately prior to or simultaneously to the breaking of the bond to the hydroxide. Such intramolecular base catalysis augments the push of the lone pair periplanar to the leaving group by increasing its electron density and may be essential within the active site of an enzyme that is shielded from the water, hydroxide, and bases in the surrounding solution, but acids or bases in surrounding side chains of amino acids could also provide catalysis for the formation of the internal pyridoximine.[14]

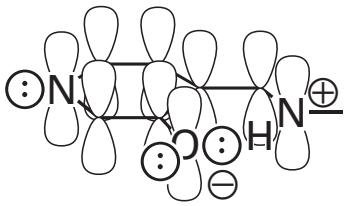
When it is free in solution, unassociated with an enzyme, the conjugate acid of a pyridoximine (left-hand side of Equation 2–2) is a **zwitterion**: its imino nitrogen is hydronated and its phenolic oxygen is unhydronated.[16] On the active site of an enzyme, such as tryptophan synthase from *Salmonella typhimurium*,[17,18] the internal pyridoximine is usually zwitterionic. In the **absorption spectrum** of the zwitterionic pyridoximine that forms between the amino group of L-valine and pyridoxal in solution, there are maxima of absorbance at 414 and 302 nm. Upon dissociation of the hydron from the iminium nitrogen to form the anionic conjugate base of this zwitterionic pyridoximine (right-hand side of Equation 2–2), the maximum absorbance shifts to 365 nm.[19]

The maximum absorbance at 414 nm manifested by the zwitterion results from the fact that it is an extensive **vinylogous amide**, which can be seen in the resonance structure[16]



2–4

This resonance structure states that the zwitterion of a pyridoximine, either in solution or in the active site of an enzyme, can be viewed as a ***π* molecular orbital system** encompassing nine atoms



2–5

that has nine molecular orbitals. The five molecular orbitals of lowest energy are occupied by five pairs of electrons. The hydrogen bond between the phenolic oxyanion and the nitrogen–hydrogen bond of the iminium holds the carbon–nitrogen double bond of the iminium ion in the plane of the pyridyl ring to reinforce the conjugation.[20]

When pyridoxal 5′-phosphate is in the active site of porcine aspartate transaminase as the internal pyridoximine (Equation 2–2), the maxima of absorbance for the zwitterion of the internal pyridoximine (left-hand side of Equation 2–2) occur at 430 and 340 nm,[12] and the maxima of absorbance for the zwitterion of the internal pyridoximine in the active site of aspartate transaminase from *Escherichia coli* also occur at 430 and 340 nm (Figure 2–1B).[12,21-26] The zwitterion of the internal pyridoximine between pyridoxal 5′-phosphate and the lysine in the active site of a particular enzyme has the higher maximum absorbance somewhere between 405 and 430 nm depending on the microenvironment that surrounds it. In the active site of aspartate transaminase from *E. coli*, the anionic conjugate base of the internal pyridoximine (right-hand side of Equation 2–2) has a maximum absorbance at 358 nm (Figure 2–1A), and in the active site of porcine aspartate transaminase, the maximum absorbance[12] is at 362 nm.

In the active sites of these aspartate transaminases and the active sites of their close relatives that nevertheless catalyze different reactions, the

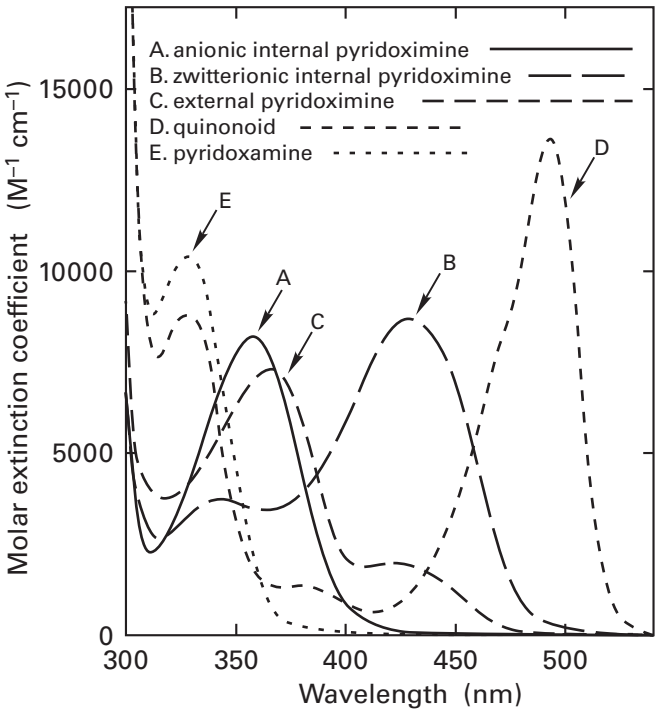


Figure 2–1: Absorption spectra of the pyridoxyl intermediates in the reaction catalyzed by aspartate transaminase from *E. coli*. (**A**) Spectrum[12] for an anionic internal pyridoxime (λ_{max} = 358 nm; ε_{358} = 8300 M^{-1} cm^{-1}),[24] for the enzyme in the absence of substrates, in a solution at pH 9. (**B**) Spectrum[12] for a zwitterionic internal pyridoxime (λ_{max} = 430 nm; ε_{358} = 8200 M^{-1} cm^{-1}),[24] for the enzyme in the absence of substrates, in a solution at pH 5. In (A) and (B), it was assumed that the internal pyridoxime was either completely in the anionic state or completely in the zwitterionic state at the respective pH. These conclusions were based on a spectrophotometric titration. (**C**) Spectrum[22] for an external pyridoxime (λ_{max} = 358 nm; ε_{358} = 7300 M^{-1} cm^{-1}; λ_{max} = 422 nm; ε_{422} = 2000 M^{-1} cm^{-1}),[24] for the enzyme in solutions containing high concentrations of 2-methyl-L-aspartate, at values of pH between 6 and 10.4. The spectrum was invariant with pH. Whether or not this spectrum represents a single species is unknown. It probably represents a fixed internal equilibrium between two species, one the anionic external pyridoxime (λ_{max} = 358 nm) and the other the zwitterionic external pyridoxime (λ_{max} = 422 nm), in a well-closed active site unaffected by the pH of the solution surrounding the enzyme.[22] This proposal is consistent with the fact that the ratio of the two peaks for the complex between aspartate aminotransferase varies with the species from which the enzyme has been purified.[22] (**D**) Spectrum for a quinonoid intermediate (λ_{max} = 494 nm; ε_{494} = 13,600 M^{-1} cm^{-1}),[21,26] for the enzyme in solutions containing high concentrations of L-*erythro*-3-hydroxyaspartate, at values of pH between 6 and 10.4. (**E**) Spectrum for a pyridoxamine in the active site (λ_{max} = 323 nm; ε_{323} = 9100 M^{-1} cm^{-1}),[25] for the enzyme at pH 8, in a solution containing L-cysteinesulfinate, a slow substrate that causes the pyridoxamine to accumulate, presumably stoichiometrically, in the active site. All extinction coefficients are based on the molarity of active sites in the solution. In spectra A, B, and E, only one species of the prosthetic group predominates and the molar extinction coefficient should be close to that for each of these unique species. In the case of spectrum D, it is clear that the majority of the active sites are occupied by the pyridoxamine. The actual molar extinction coefficient for the quinonoid intermediate has been estimated[23] to be 41,000 M^{-1} cm^{-1}.

anionic conjugate base of the internal pyridoxime predominates as the pH of the solution is raised. The **pK_a for the acid dissociation of the zwitterionic internal pyridoxime** (Equation 2–2) in the active site of porcine aspartate transaminase[12,27] is 6.8, and that for aspartate transaminase from *E. coli*[24] is 6.96. Because the value for the pK_a of the pyridoximine[27] formed in solution between *n*-butylamine and pyridoxal 5′-phosphate is 12.4, some feature of the active site must be responsible for the low value for the pK_a of the internal pyridoxime bound to the enzymes in this family.

The decrease in the pK_a of the internal pyridoximine brought about by these two active sites is probably the result of both the **hydronation of the pyridyl nitrogen 1 of the pyridoxal phosphate by the carboxy group of an aspartic acid** that forms a hydrogen bond to it and a twist of the double bond between carbon 4′ and nitrogen 4′ out of the plane of the pyridyl ring brought about by a pull exerted by the active site on the lysine of the internal pyridoximine. When [1-^{15}N]pyridoxal 5′-phosphate is an internal pyridoximine in the active site of aspartate transaminase from *E. coli*, nuclear magnetic resonance absorptions from the pyridinio nitrogen-15 indicate that, in the hydrogen bond, it is hydronated[28] and therefore the donor. The hydronation of the pyridyl nitrogen does not affect the position of the maximum of absorbance for a zwitterionic pyridoximine[19] but would definitely lower the pK_a of the zwitterion. It has been observed that, in a crystallographic molecular model of porcine aspartate transaminase,[29] the carbon–nitrogen double bond of the zwitterionic pyridoximine is rotated 35° out of the plane of the pyridyl ring. This rotation of the double bond out of the plane of the pyridyl ring would cause the iminium to be less conjugated to the pyridyl ring and cause it resemble a normal aliphatic iminium, the pK_a of which should be around 7.[30,31] When the lysine of the internal pyridoximine is mutated to an alanine and methylamine is used to produce a pyridoximine that should resemble an internal pyridoximine,[32] the pK_a of this $N^{4'}$-methylpyridoximine, which cannot be distorted sterically, is 10.2. This result suggests that if the pyridoximine in the active site is not twisted and can remain planar, the pK_a should be normal. In many of the enzymes that have internal pyridoximines in their active sites, however, their respective anionic conjugate bases do not form regardless of how high the pH of the solution is raised, presumably because the pK_a of the pyridoximine has been raised sufficiently by its surroundings that it is out

of the range of pH within which these enzymes remain folded. In these instances, presumably, the pK_a of the respective zwitterionic pyridoximine is increased rather than decreased by the active site. These shifts in the pK_a of the internal pyridoximine may have significance for the particular reactions catalyzed by these enzymes.

As was the case with aspartate transaminase, **the pyridyl nitrogen 1 of an internal pyridoximine is often hydronated by an acidic side chain in the active site**.[33] The pK_a of the pyridinio nitrogen 1 in a pyridoximine[16] is 5.6, so when an internal pyridoximine forms a hydrogen bond with the carboxy group from an aspartic acid (pK_a = 4.0) or a glutamic acid (pK_a = 4.3), the hydron in the hydrogen bond will be on the nitrogen. An internal pyridoximine, however, can also participate in a strong hydrogen bond with a side chain within the active site of the enzyme but remain unhydronated[34] because the partner in this type of hydrogen bond is not noticeably acidic. For example, in tryptophan synthase from *Salmonella enterica*, the pyridyl nitrogen 1 of the internal pyridoximine forms a hydrogen bond with a serine;[35] in cysteine synthase from *S. enterica*, it also forms a hydrogen bond with a serine;[36] and in alanine racemase from *Geobacillus stearothermophilus*, it forms a hydrogen bond with an arginine.[37] In the active site of tryptophan synthase from *S. enterica*, the hydron in the hydrogen bond between the serine and nitrogen 1 of the pyridyl group resides on the serine,[17] and in the active site of alanine racemase from *G. stearothermophilus*, the hydron in the hydrogen bond between the arginine and nitrogen 1 of the pyridyl group resides on the arginine,[28] as expected from the respective values of pK_a for these acids and the pyridyl nitrogen. In these instances, the pyridyl nitrogen is not hydronated.

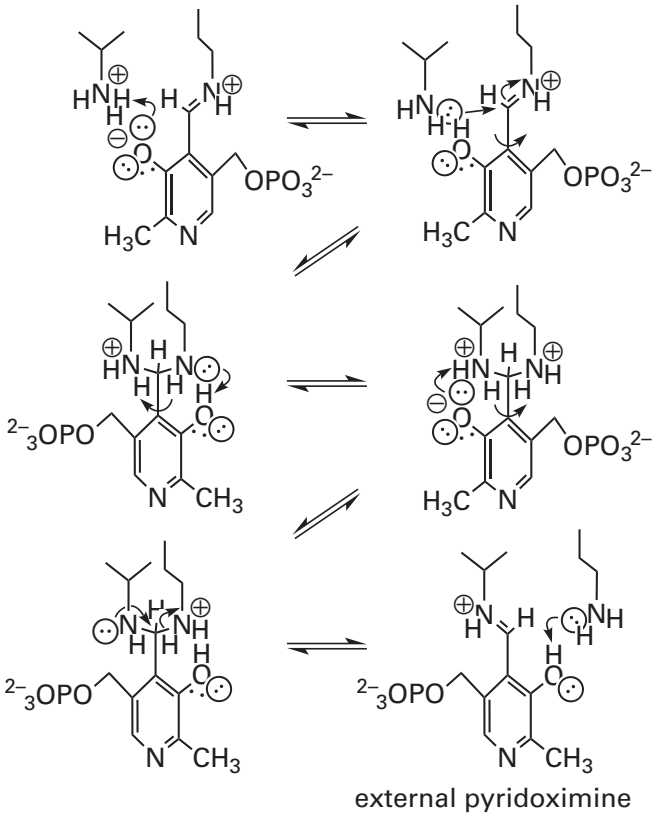

Figure 2–2: Transimination catalyzed by the phenolic oxygen of pyridoxal phosphate. The pyridoxal phosphate is initially the zwitterionic internal pyridoximine with a lysine from the protein (on the right side), and the reactant in the transimination is the conjugate acid of a primary amine (on the left side). As the reaction progresses, hydrons are transferred by the phenolato oxygen from the nitrogen of the reactant to the nitrogen of the lysine. The phenolato oxygen could shuttle both of the hydrons that are transferred from the entering ammonium ion to the dissociating lysinium ion, but other acid–bases may be involved as well. The phenolic oxygen performs each transfer by swinging back and forth between the two nitrogens in this symmetrical reaction.

Almost all the substrates upon which the internal pyridoximines of pyridoxal 5′-phosphate within active sites act prosthetically are primary amines, and the first step in every one of these reactions catalyzed by pyridoxal 5′-phosphate is to form the external pyridoximine between the nitrogen of that primary amine of the substrate and the 4′ imino carbon of the internal pyridoximine. Because the internal pyridoximine is an imine with a lysine in the active site, a **transimination**[38,39] performs the nucleophilic substitution at the carbonyl carbon (Figure 2–2). On an enzyme at neutral pH, the transimination would begin with the cationic conjugate acid of the amino group and the phenolic oxygen of the zwitterionic pyridoximine, the pK_a of which is elevated upon binding of the substrate.[32] This shift in pK_a ensures that the iminium nitrogen of the lysine in the internal pyridoximine is hydronated (Equation 2–2) upon binding of the hydronated primary ammonium of the substrate (Figure 2–2).

There had been some doubt[40] as to whether or not the intermediates in the proposed mechanism for the transimination of imines of pyridoxal 5′-phosphate presented in Figure 2–2 would be stable enough that the reaction could proceed through the

gem-diamine rather than passing through the aldehyde. It was subsequently shown,[39] however, that such a direct transimination in aqueous solution proceeds about twice as fast as the exchange through the indirect route in which the aldehyde, pyridoxal 5′-phosphate itself, is the intermediate. In an active site, shielded from water, the indirect route, which necessarily requires water to provide the oxygen of the aldehyde, would be even slower. Finally, the expected ***gem*-diamine intermediates have been observed in crystallographic molecular models** of mutant enzymes,[41-43] enzymes with which inhibitors have been complexed,[44] or enzymes to which normal substrates have bound nonproductively.[45] Each stratagem prevents the reaction from proceeding further and permits the *gem*-diamine to be observed.

When there is no **phenolic oxygen in an ortho position** to the iminium nitrogen of the imine of a benzaldehyde, a transimination involving that benzaldehyde proceeding in solution displays a requirement for catalysis by both acid and base.[38] This requirement is consistent with the unavoidable requirement to remove hydrons from the amine that is entering and the coincident unavoidable requirement to add hydrons to the amine that is leaving. When the transimination involves imines of pyridoxal 5′-phosphate, however, no requirement for acid or base catalysis is observed.[39] This lack of catalytic requirement can be readily explained by the fact that the phenolic oxygen is four atoms away from both nitrogens and can easily shuttle hydrons between them (Figure 2–2).

In the crystallographic molecular models of enzymes containing a *gem*-diamine of pyridoxal 5′-phosphate, the phenolic oxygen of the 3-hydroxypyridyl group sits on the concave side of the angle formed by the two carbon–nitrogen bonds of the *gem*-diamine, splitting the N–C–N bond angle and sitting within hydrogen-bonding distance of both of the nitrogens.[41] When a crystallographic molecular model of an enzyme containing the internal pyridoximine is superposed on the crystallographic molecular model of the same enzyme that has formed its external pyridoximine with the primary amine of one of its substrates, the two respective carbon–nitrogen bonds of the imines in the two different models form angles of about 100° with each other, as they would in a *gem*-diamine (109°), and again, the phenolic oxygens of the pyridoximines sit on the concave side of this bond angle between the two nitrogens (Figure 2–3).[46-50] This disposition is the one expected for a catalytic base shuttling hydrons between the two nitrogens.

The **freedom of motion required of the pyridoxyl group**, however, to perform this catalysis may not be permitted in the confines of some active sites. In this case, when the phenoxy oxygen is sterically prevented from accomplishing the hydronations and dehydronations, the active site must provide acids and bases to do so because direct transfer of a hydron between two nitrogens on the same carbon cannot occur. For example, in the active site of glycine *C*-acetyltransferase from *E. coli*, there is a histidine side chain positioned properly to perform hydronations and dehydronations of the glycine or the L-2-amino-3-oxobutanoate that are forming the external pyridoximine during the normal reaction in the respective direction, and one of the oxygens of the phospho group of the pyridoxal 5′-phosphate is positioned properly to perform hydronations and dehydronations of the lysine that forms the internal pyridoximine.[51]

Each transimination moves the respective pyridoxal 5′-phosphate from the lysine of the internal pyridoximine to the primary amine of the substrate. There is little electronic difference between an internal pyridoximine and an external pyridoximine. Nevertheless, the external pyridoximine between the active site of aspartate transaminase from *E. coli* and 2-methyl-L-aspartate, an analogue of the normal substrate, L-aspartate, in which the hydron α to the imino nitrogen has been replaced by a methyl group, has an **absorption spectrum** (Figure 2–1C) that resembles a mixture of a zwitterionic pyridoximine and its conjugate base, the anionic pyridoximine, even though the spectrum is invariant with pH.[22-24] Furthermore, the ratio of the peaks for absorbance that seem to originate from the zwitterionic external pyridoximine and its anionic conjugate base differ depending on the species from which the enzyme is purified, but the two molar extinction coefficients add up to around 9000,[22] a fact again suggesting that there is an internal equilibrium between the zwitterion and the anion of the external pyridoximine in a particular active site, and the equilibrium constant varies from species to species.

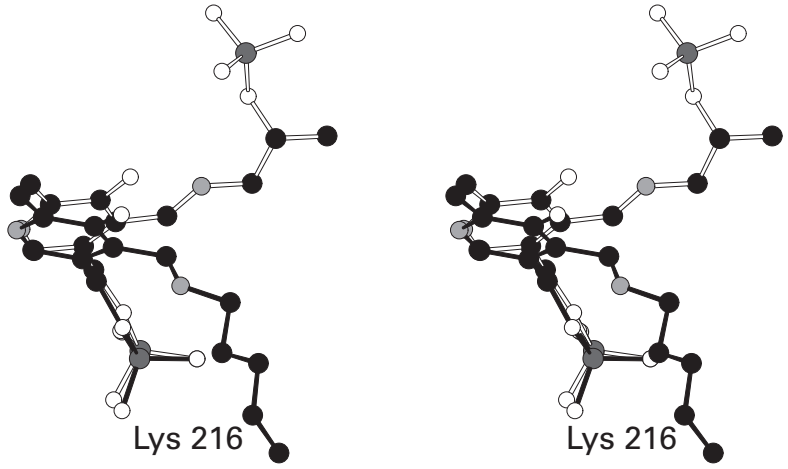

Figure 2–3: Positioning of the iminium nitrogens of the internal pyridoximine and an external pyridoximine adjacent to the phenolic oxygen on carbon 3 of the pyridyl group of pyridoxal 5′-phosphate by the active site of threonine-phosphate decarboxylase from *S. enterica*.[46] The stereodrawing[50] is the superposition of portions of two crystallographic molecular models. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large dark gray atoms are atoms of phosphorus. The internal pyridoximine (black bonds) of threonine-phosphate decarboxylase is found in the crystallographic molecular model of the enzyme purified directly from an overproducing strain of bacteria and crystallized without any alteration. The α carbon through carbon 6 of Lysine 216 and the entire pyridoximine 5′-phosphate are shown in the drawing. The external pyridoximine (white bonds) of the product, (*R*)-1-aminopropan-2-yl phosphate, was formed on the active site by mixing the enzyme with L-threonine phosphate before it was crystallized. At equilibrium, the most stable form of the enzyme under these conditions was found, by direct examination of the map of electron density, to be the external pyridoximine of the product, which is presented in its entirety in the drawing. The two crystallographic molecular models of the entire enzymes were superposed by the crystallographers, and the drawing is of the respective portions of that superposition. The bond between carbon 4′ of the pyridoxylidene and nitrogen 6 of the lysine and the bond between carbon 4′ of the pyridoxylidene and nitrogen 1 of the (*R*)-1-aminopropan-2-yl phosphate in the respective superposed models are at an angle of 106° to each other when viewed down the bonds between carbons 4 and carbons 4′ of the pyridoximines. The respective phenolic oxygens are both on the concave side of this bond angle in position to shuttle hydrons between the nitrogens. The dihedral angle between the plane of the pyridyl ring and the respective imino nitrogen along the bond between carbon 4 and carbon 4′ is 27° in the external pyridoximine and 60° in the internal pyridoximine, probably because the imino nitrogen is mostly hydronated in the former and mostly unhydronated in the latter (Equation 2–2). The hydrogen bond in the hydronated form holds the nitrogen in the plane of the ring so that the imine is conjugated with the pyridinio group, and the repulsion of the lone pairs in the unhydronated form opens up the angle. The 5′ phosphate is held tightly in position by the enzyme and therefore superposes closely, but the superposition illustrates that the pyridinio ring is able to pivot somewhat in the active site, which permits the phenolic oxygen freedom of movement to fulfill its role (Figure 2–2).

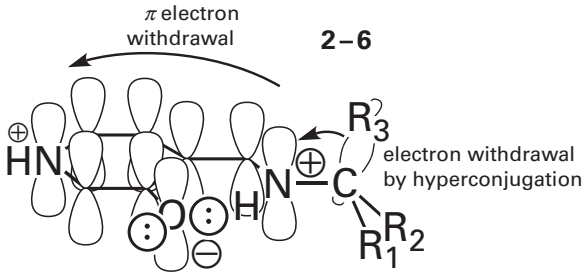
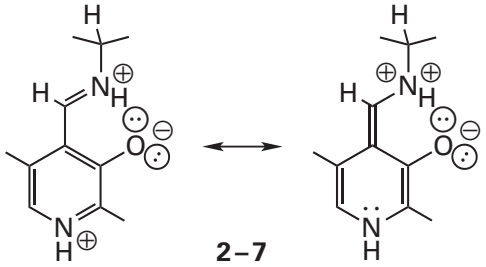
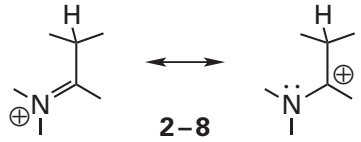
When the primary amine of a substrate is coupled as the external pyridoximine of pyridoxal 5′-phosphate and the pyridinio nitrogen 1 of the external pyridoximine is hydronated, the three σ bonds on the carbon of the substrate α to the iminium nitrogen become susceptible to heterolytic dissociation.[16] This susceptibility results from the hydronated pyridinio nitrogen withdrawing electron density from the other end of the π molecular orbital system and increasing the **hyperconjugation** of a σ bond that happens to be aligned parallel to the π molecular orbital system[52]



This withdrawal of electron density from the σ bond by hyperconjugation can be realized by writing a resonance structure in which the nitrogen equivalent of a carbenium ion is present on the iminium nitrogen

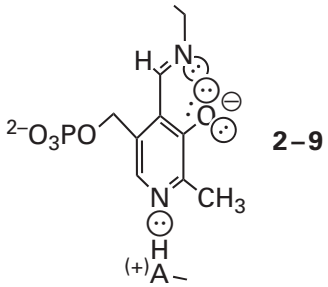


This resonance structure is not so satisfying as the depiction in **2–6** because it involves a dication missing two valence electrons on the iminium nitrogen, albeit somewhat stabilized by the adjacent phenylato oxygen. This resonance structure, however, illustrates that an imine of pyridoxal 5′-phosphate, with its pyridinio nitrogen hydronated, is a vinylogous iminium ion



with the exception that nitrogen replaces carbon at the cationic position and has the same effect of weakening a σ bond on the adjacent carbon that is parallel the π molecular orbital system.

For this electron withdrawal by hyperconjugation to operate, the double bond between carbon 4′ and nitrogen 4′ in the external pyridoximine must be **coplanar with the pyridyl ring** (**2–6** and **2–7**). In a crystallographic molecular model of aspartate transaminase from *E. coli*,[53] in which the internal pyridoximine is the anionic conjugate base,[30] the double bond between carbon 4′ and nitrogen 4′ of the pyridoximine is normal (91°) to the plane of the pyridyl ring

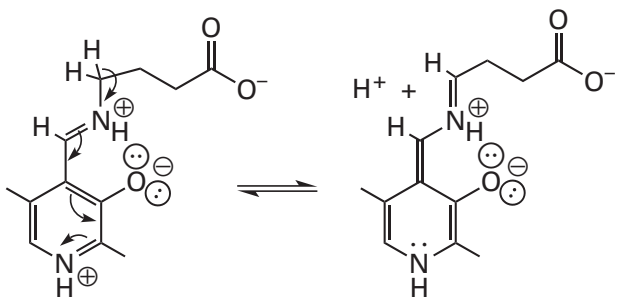


This arrangement is the expected result of electron repulsion between the lone pair of electrons on the phenolic oxygen and the lone pair of electrons on the now unhydronated imino nitrogen, as well as electron repulsion between the carbon–nitrogen double bond at carbon 4′ and the two σ bonds to carbon 4 in the pyridyl ring of pyridoximine 5′-phosphate. For the same reasons, this rotational isomer and its sibling, in which the carbon–nitrogen bond is pointed in the opposite direction, should also dominate in the anionic conjugate base of a pyridoximine when it is free in solution. In solution, the breaking of the conjugation (**2–5**) that results from this rotation of +90° or –90° around the bond between carbon 4 and carbon 4′ (see Equation 2–2) decreases the maximum of absorbance for a pyridoximine from 414 to 365 nm as it is dehydronated. The carbon–nitrogen double bond of the oxime of pyridoxal 5′-phosphate is coplanar with the ring of its pyridyl group because of a strong hydrogen bond (0.256 nm) between its imino nitrogen and its phenolic oxygen.[20] The homologous hydrogen bond between the nitrogen–hydrogen of the iminium and the phenolic oxygen enforces the planarity of an external pyridoximine when the imino nitrogen is hydronated. Because dehydronation of this hydrogen bond forces the double bond between carbon 4′ and nitrogen 4′ to be normal to the plane of the pyridyl ring and breaks the conjugation, **the catalytically active form of an external pyridoximine**

will always be the zwitterion, or its neutral tautomer, never its anionic conjugate base.

Because each of the three σ bonds on the carbon next to imino nitrogen 4′ of an external pyridoximine is weakened by this electron withdrawal by hyperconjugation, if the α carbon* of the external pyridoximine is bonded to an incipient electrophile, **that incipient electrophile can dissociate**.

If the α carbon of an external pyridoximine contains a hydrogen, that hydrogen can **dissociate as a hydron**. An example of this outcome is the first step of the reaction catalyzed by 4-aminobutyrate—2-oxoglutarate transaminase from *Pseudomonas fluorescens*, which proceeds with the dissociation of a hydron from the α carbon[54] of the external pyridoximine formed between 4-amino-butyrate and pyridoxal 5′-phosphate



(2–4)

In solution, formation of the pyridoximine between pyridoxal and glycine and hydronation of pyridyl nitrogen 1 decrease the pK_a for dissociation of the hydron from the α carbon of the glycine[55,56] from 29 to 17 and increase the rate of exchange for a hydrogen on the α carbon for a deuterium in ^2H_2O by a factor of 10^7. The hydronated pyridinio nitrogen is essential to this decrease in pK_a and increase in the rate of exchange.[57] Hydronation of both the pyridyl nitrogen and the phenolic oxygen of the pyridoximine lowers the pK_a of the α carbon of the glycine to 11, and hydronation of the pyridyl nitrogen, the phenolic oxygen, and the α carboxylato group of the glycine lowers the pK_a of the α carbon to 6. Each of these hydronations can be accomplished, if necessary, by acidic side chains in an active site.

To explain the ease with which a hydron can dissociate from the α carbon of an external pyridoximine (Equation 2–4) in the active site of an enzyme, it is usually assumed that the α carbon, nitrogen 4′, carbon 4′, and the pyridyl ring are all coplanar (**2–6** and **2–7**) and that the σ bond to the hydron that is to be removed is normal to that plane and parallel to the π molecular orbital system so that its electron density can be withdrawn onto the hydronated pyridinio nitrogen. In the **crystallographic molecular model**, however, of the external pyridoximine of 2-methyl-L-aspartate in the active site of aspartate transaminase from *E. coli*, which also proceeds normally with the removal of a hydron from the α carbon, the σ bond between carbon 4′ and nitrogen 4′ is twisted out of the plane (Figure 2–4).[53] This arrangement seems to result from a steric effect between the 2-methyl group, which is replacing the hydron on the usual substrate, L-aspartate, and the surrounding side chains in the active site, but in a crystallographic molecular model of the external pyridoximine between L-aspartic acid and 1-deazapyridoxal 5′-phosphate in the same active site, in which no such steric effect should occur, the same twist is observed.[58] Neither 2-methyl-L-aspartate, however, nor the external pyridoximine between L-aspartic acid and 1-deazapyridoxal 5′-phosphate is catalytically competent, so this twist may not be relevant to normal catalysis. In a molecular model of the external pyridoximine of L-alanine in the active site of pyridoxamine—pyruvate transaminase from *Mesorhizobium loti*, based on several crystallographic molecular models of the enzyme, rather than just one,[59] all the necessary atoms are coplanar with the pyridyl ring and the σ bond between the α carbon and the hydron that is removed in the normal enzymatic reaction is, as expected (**2–6** and Equation 2–4), normal to the plane of the π molecular orbital system of the pyridoximine and parallel to its constituent *p* orbitals.

*Because at least one (if not more) of the substrates for reactions catalyzed by pyridoxal 5′-phosphate is an α-amino acid and because the carbon attached to the amino group can be considered to be α to that amino group just as it is α to the carboxy group, the designation α carbon will be used for the carbon bonded to the primary amino group of a substrate in an external pyridoximine, β carbon for the carbon that is bonded to the α carbon, other than the carbon of a carboxy group, γ carbon for the carbon bonded to the β carbon, and so forth.

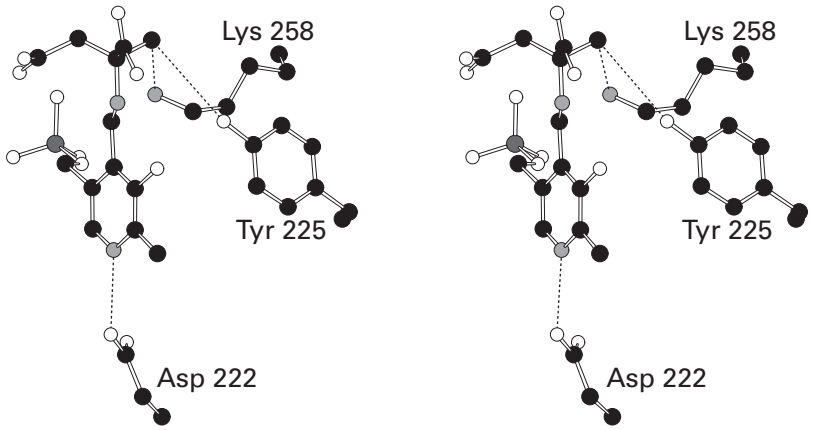


Figure 2–4: Use of the lysine of the internal pyridoximine as an acid–base to add or remove hydrons from the intermediates in a transamination. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large dark gray atom is a phosphorus. Aspartate transaminase from *E. coli* was mixed with the inhibitor 2-methyl-L-aspartate and then crystallized in its presence. In the map of electron density, it was found that 2-methyl-L-aspartate had formed the external pyridoximine within the active site of the enzyme.[53] Because the hydrogen on the α carbon of the aspartyl group has been replaced by a methyl group, the enzyme cannot proceed with its normal reaction and is locked in the conformation that would normally remove the hydron if it were there. The external pyridoximine and the side chains of Tyrosine 225, Aspartate 222, and Lysine 258, the lysine that forms the internal pyridoximine in the resting enzyme, are included in the stereodrawing[50] from the final crystallographic molecular model. The distances from the 6-amino group of Lysine 258 and the 4-hydroxyphenyl oxygen of Tyrosine 225 to the carbon of the 2-methyl group of the inhibitor, which assumes the position of the hydron that is normally removed during the transamination, are 0.38 and 0.36 nm, respectively (dotted lines). These distances are dictated by the van der Waals radii of the methyl, the amino, and the hydroxy groups and would be shorter if the methyl group were a hydrogen. The 6-amino group of Lysine 258 is also 0.32 nm away from carbon 4′, well within the sum of the length of the nitrogen–hydrogen bond and the van der Waals radii (0.38 nm). Consequently, it is in position to remove the hydron from carbon 2 of the substrate L-aspartate when it has formed an external pyridoximine and then put a hydron onto carbon 4′ of that pyridoximine. The angle between the plane of the pyridyl ring and the bond connecting carbon 2 of the 2-methyl-L-aspartate with the methyl carbon is 87°. Consequently, if the methyl group were a hydrogen, the carbon–hydrogen bond would be positioned by the enzyme almost precisely parallel to the π molecular orbital system of the pyridoximine as drawn in **2–6**. The π molecular orbital system of the α-carboxy group is also parallel to the bond connecting carbon 2 of the 2-methyl-L-aspartate with the methyl carbon and would provide further electron withdrawal. The dihedral angle between the plane of the pyridyl ring and the respective imino nitrogen along the bond between carbon 4 and carbon 4′ is 26° in the external pyridoximine, indicating that the imine is mostly hydronated and that the carbon–nitrogen double bond in the iminium ion is in conjugation with the pyridyl ring. The hydrogen bond between Aspartate 222 and the pyridinio nitrogen of the hydronated pyridoximine (0.289 nm) is indicated with a dotted line.

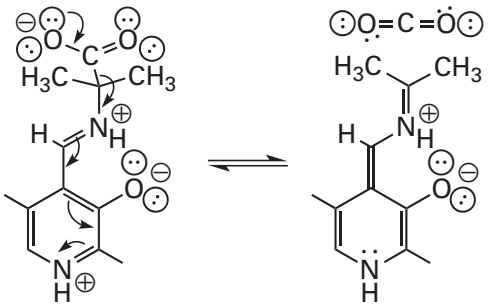
In many of these reactions in which a hydron is removed from the α carbon of the external pyridoxamine, the 6-amino group of the lysine from the enzyme that formed the original internal pyridoxamine with the pyridoxal 5′-phosphate (Equation 2–2) ends up immediately adjacent to the α carbon of the external pyridoxamine (Figure 2–4)[53,60,61] and is thought to be the base that removes the hydron.[62] In several of these enzymes, however, both the **6-amino group of the lysine and the 4-hydroxy group of a tyrosine** are positioned adjacent to the hydron on the α carbon (Figure 2–4)[53,63] and may cooperate in removing the hydron from it.[64] In the case of glycine hydroxymethyltransferase from *E. coli*, mutation of the lysine that forms the internal pyridoxamine to a glutamine decreases the rate of the conversion of glycine to serine by a factor of only 50.[65] This result suggests that there is a base other than that lysine that is available.

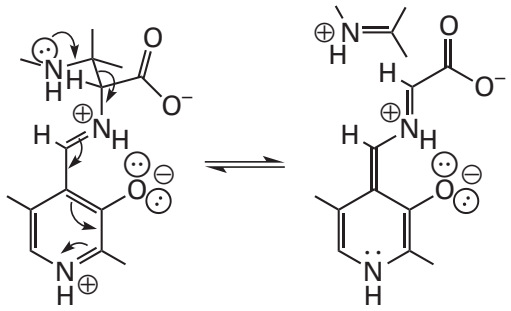
If the α carbon of an external pyridoxamine contains a carboxylato group, that carboxylato group can **dissociate as a molecule of carbon dioxide**. In this instance, as before, carbon dioxide behaves as if it were a hydron. An example of this outcome is the first step in the forward reaction catalyzed by 2,2-dialkylglycine decarboxylase (pyruvate) from *Burkholderia cepacia*,[66] which proceeds with the loss of carbon dioxide from the α carbon of the imine formed between a 2,2-dialkylglycine, such as 2,2-dimethylglycine, and pyridoxal 5′-phosphate



(2–5)

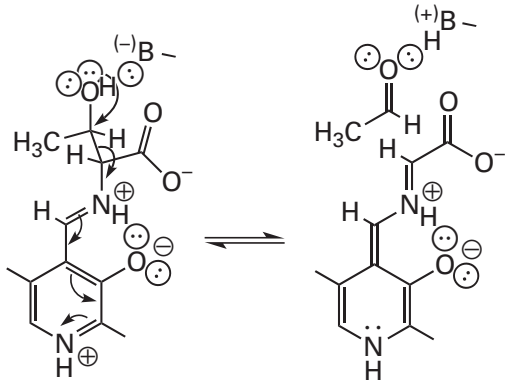
From examination of the crystallographic molecular model of the active site of the enzyme, it was concluded that the σ bond between the carbon α to the iminium nitrogen in the external pyridoxamine and the carboxylato group that dissociates in the usual enzymatic reaction is, again as expected (Equation 2–5 and **2–6**), parallel to the π molecular orbital system of the pyridoxamine. In crystallographic molecular models of the active site of porcine aromatic-L-amino-acid decarboxylase in a complex with an analogue of the substrate[36] and of glutamate decarboxylase from *E. coli* into which the pyridoxamine of L-glutamate has been inserted,[67] similar orientations of the respective carbon–carbon σ bonds leading to decarboxylation are enforced.

If the α carbon of an external pyridoxamine contains an incipient carbonyl carbon, for example, an external pyridoxamine with a β carbon to which a hydroxy group or an amino group is attached, that β carbon can **dissociate as a carbonyl group or imine**, respectively



quinonoid intermediate (2–6)

An example of this outcome is the first step of the reaction catalyzed by D-threonine aldolase from *Achromobacter xylosoxidans*,[68] which proceeds with the loss of acetaldehyde from the α carbon of the external pyridoxamine between D-threonine and pyridoxal 5′-phosphate

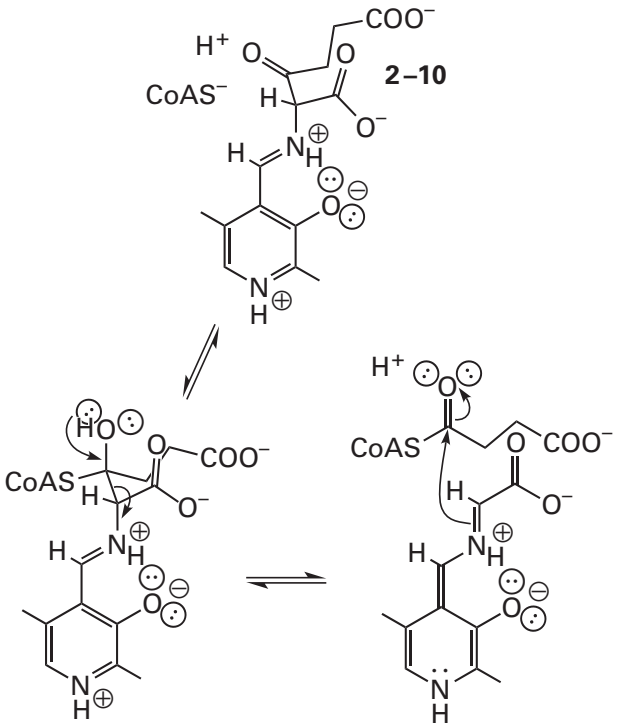


quinonoid intermediate (2–7)

In such a dissociation of a carbonyl group, a base is required to remove a hydron from the hydroxy group.[69,70]

If the α carbon of an external pyridoxamine contains an incipient acyl compound in the form of

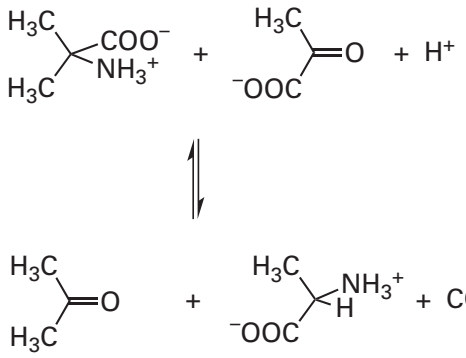
a β-oxo group, that β carbon can **dissociate as an acyl derivative** after addition of a nucleophile to the carbon of the β-oxo group. An example of this outcome is the second step in the retro Claisen condensation catalyzed by 5-aminolevulinate synthase,[71-73] which proceeds with the loss of succinyl-SCoA from the α carbon of the external pyridoximine formed between 5-amino-4-oxo-hexanedioic acid and pyridoxal 5′-phosphate



(2–8)

The σ bond that is weakened by the electron withdrawal of the adjacent pyridoximine in an external pyridoximine must be **aligned parallel to the π molecular orbital system** of that pyridoximine for the necessary overlap to occur,[74] as drawn in **2–6** and Equations 2–4 and 2–5. In an enzymatically catalyzed reaction, the necessary alignment is made as the substrate is bound in the active site. This alignment in part **decides which σ bond is broken** during the reaction. At least one of the substrates for an enzyme with an internal pyridoximine 5′-phosphate in its active site is usually one of the twenty canonical L-α-amino acids. For the external pyridoximine formed from an α-amino acid, the most critical discrimination is that between the hydron (Equation 2–4) and the carboxy group (Equation 2–5) on the α carbon. If the σ bond to the carboxylato group is aligned parallel to the π molecular orbital system of the pyridoximine, the enzyme will catalyze the decarboxylation of the amino acid; if the hydron is aligned parallel to the π molecular orbital system, it will catalyze a dehydronation at the α carbon of the amino acid.

2,2-Dialkylglycine decarboxylase (pyruvate)



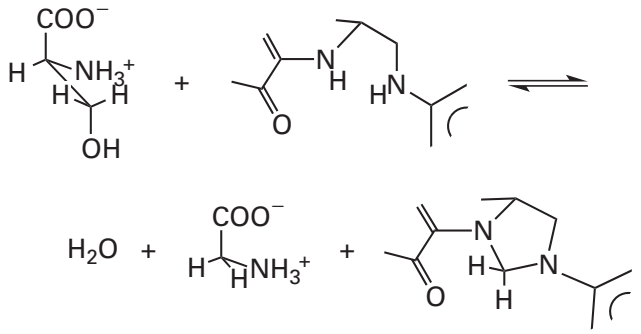
(2–9)

from *B. cepacia* normally catalyzes both a decarboxylation (of dimethylglycine in the forward direction of Equation 2–5) and a dehydronation (of L-alanine in the reverse direction of Equation 2–9). The active site is constructed so that when the σ bond to the carboxylato group of a dialkylglycine is parallel to the π molecular orbital system of its external pyridoximine, the two alkyl groups (R_1 and R_2 in **2–6**) fit comfortably into two open pockets, one that is larger and more polar and the other that is smaller and nonpolar. When the σ bond to the α hydrogen of L-alanine, the amino acid that is a reactant in the reverse direction, is parallel to the π molecular orbital system of its external pyridoximine, its carboxylato group fits into the larger, polar pocket and its methyl group fits into the smaller, nonpolar pocket.[66]

Each of a series of L-amino acids can be used as a reactant instead of the normal L-alanine in the reverse direction (Equation 2–9). As the size of the side chains on these L-amino acids is increased, the rates of their undesired decarboxylations increase as the larger side chain is shunted from the smaller pocket into the larger pocket and the σ bond to the carboxylato group is consequently positioned parallel to the π molecular orbital system rather than the hydrogen. When D-alanine is used as a reactant, because the methyl group can occupy the smaller, nonpolar pocket but its carboxylato group cannot occupy the smaller nonpolar pocket, its carboxylato group is forced to be parallel to the π molecular orbital system of the pyridoximine, and the D-alanine is decarboxylated rather than dehydronated. As the size of the side chains on a series of D-amino acids, however, is increased, the rates of their decarboxylations decrease as the

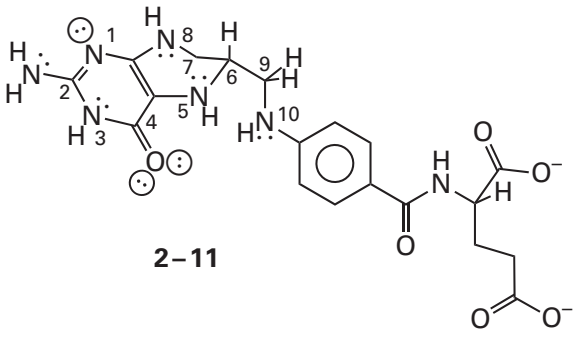
smaller pocket rejects the increasingly larger alkyl groups and the σ bond to the carboxylato group can no longer be positioned parallel to the π molecular orbital system.[75] All these results are consistent with the necessity of aligning the bond on the α carbon that is weakened by the pyridoximine parallel to the π molecular orbital system of that pyridoximine.

Glycine hydroxymethyltransferase catalyzes the formation of N^5,N^{10}-methylenetetrahydrofolate



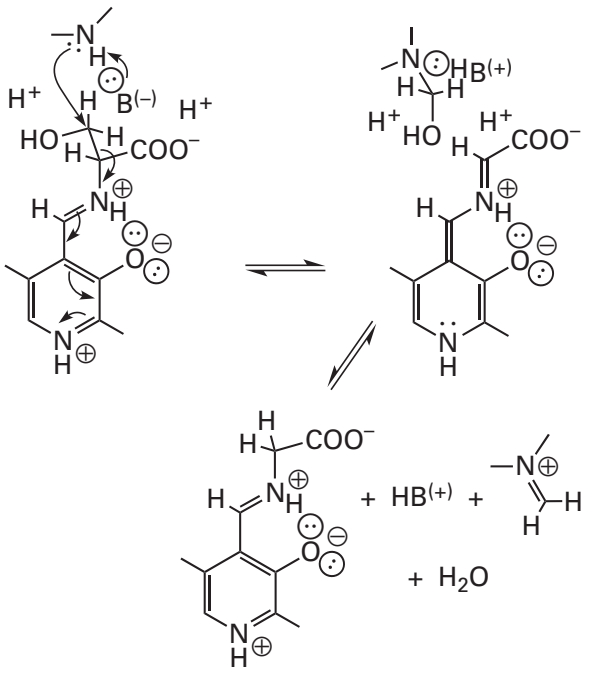
(2–10)

In the **crystallographic molecular model** of glycine hydroxymethyltransferase from *G. stearothermophilus* complexed with L-serine in the absence of tetrahydrofolate, the bond between the α carbon and the β carbon in the external pyridoximine of the L-serine is held parallel to the π molecular orbital system.[76] This orientation causes electron density to be withdrawn from this bond. This electron withdrawal makes the carbon of the hydroxymethyl group of the L-serine electrophilic. Because of this increased electrophilicity, nitrogen 5 of tetrahydrofolate (previously **1-81**)



2–11

even though it is a rather nonnucleophilic anilino nitrogen, is able to react with this carbon as a nucleophile in a concerted nucleophilic substitution with *N*-(5′-phosphopyridoxyl)carboxymethanimine as a leaving group.[77]



(2–11)

In free solution, pyridoxal 5′-phosphate, supplemented with metallic ions[78] such as **Cu^{2+}, Fe^{3+}, or Al^{3+}, can catalyze dissociations of electrophiles** from the carbon adjacent to an amine with which it has formed an imine. Because free rotation around the bond between the α carbon and the iminium nitrogen is unhindered in solution, all three of the substituents on the α carbon are vulnerable. If the α carbon contains a hydrogen, the usual reaction is loss of a hydron leading to transamination.[79] If, however, there is a carboxylate on the α carbon and no hydrogens, as in 2-aminoisobutyric acid or 2-methyl-L-serine, or there are two carboxylates, as in aminomalonic acid,[80] decarboxylation occurs. The addition of metallic ions to these nonenzymatic reactions suppresses decarboxylation and promotes the loss of alternate electrophiles from the α carbon, presumably because the metal ion forms a complex with the phenolic oxygen of the pyridoximine and the carboxylato group on the α carbon that prevents the σ bond between the carbon adjacent to the iminium nitrogen and the carboxy group in the pyridoximine from becoming parallel to the π molecular orbital system. The required Mn^{2+} in the active site of D-threonine aldolase (Equation 2–7), by associating with the hydroxy group of the D-threonine, orients the carbon–carbon bond between the α carbon and the β carbon that is to be cleaved parallel to the π molecular orbital system of the external pyridoximine.[68] The role of the Zn^{2+} in the active site of D-serine ammonia-lyase from *Saccharomyces cerevisiae*, however, is to associate with the

phospho group of the pyridoximine.[81] These two enzymes are unusual because only a few of the enzymes that use pyridoxal 5′-phosphate as a prosthetic group have a requirement for a divalent metallic ion, even though divalent metal ions can effectively orient the σ bonds of a pyridoximine in solution and catalyze their dissociation.

In all the reactions that have just been described in which a σ bond parallel to the π molecular orbital system of an external pyridoximine is weakened, it has been assumed that the **pyridinio nitrogen 1 of the external pyridoximine is hydronated before the σ bond on the carbon α to the imino nitrogen is broken**. When this nitrogen is hydronated, the electron density in that σ bond can be withdrawn into that electron sink (**2–6**). For this electron withdrawal to occur, however, the nitrogen must be there, and it must be hydronated.

The pyridoxal 5′-phosphate in an active site can be replaced with 1-deazapyridoxal 5′-phosphate in which **pyridyl nitrogen 1 is replaced by carbon**. When this replacement is performed on aspartate transaminase from *E. coli*, the resulting enzyme shows no detectable activity (<10^{-6} percent), and when it is performed on alanine racemase from *G. stearothermophilus*, the resulting enzyme again shows no detectable activity (<0.15%) with L-alanine as a reactant.[82] This altered alanine racemase from *G. stearothermophilus*, however, is able to catalyze the conversion of 3-chloro-L-alanine to pyruvate at a rate about 0.4% of that for the native enzyme, and cysteine synthase from *S. typhimurium* in which the same substitution has been performed is able to catalyze its reaction also at a rate about 0.4% of that for the native enzyme. The most difficult chemical steps in the latter two enzymatic reactions are eliminations, in the first case the elimination of a chloride and a hydron, and in the second case the elimination of an acetate and a hydron. In both eliminations, the hydron that dissociates is on the α carbon of the respective external pyridoximine. Both the chloride and the acetate are excellent leaving groups. It is possible that the absence of the pyridyl nitrogen causes the rate-limiting step of these eliminations to change from dissociation of the leaving group to removal of the hydron from the α carbon. If this is the case, a much larger decrease in the rate of removal of the hydron from the α carbon is masked by the change in the rate-limiting step. It is also possible that, in the absence of the pyridyl nitrogen, the mechanism of the elimination changes from one in which the hydron is removed first because of the weakening of the carbon–hydrogen bond to one in which removal of the hydron and dissociation of the leaving group are concerted.

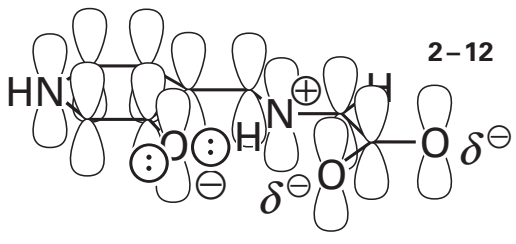
In enzymes in which an aspartate or a glutamate forms a hydrogen bond with the pyridinio nitrogen, that nitrogen is hydronated in the resting state. In these enzymes, when the aspartate is mutated to alanine, dramatic decreases in enzymatic activity are observed.[33,83,84] In other cases, however, such as tryptophan synthase, cysteine synthase, and alanine racemase, the pyridyl nitrogen of the internal pyridoximine does not participate in a hydrogen bond with an obvious acid. In these enzymes, the possibility arises that the **pyridyl nitrogen in the external pyridoximine is not hydronated** by the active site before the dissociation of the electrophile.[82] The first step in each of these enzymatic mechanisms, however, is the removal of a hydron from the α carbon in the external pyridoximine. After it is removed, even if the pyridyl nitrogen were not initially hydronated, the majority of the net negative elementary charge in the resulting π molecular orbital system in the resulting, unhydronated quinonoid intermediate would necessarily reside on the pyridyl nitrogen because of its electronegativity. Consequently, this nitrogen would probably be basic enough to remove a hydron from the adjacent arginine (pK_a = 13) or serine (pK_a = 14) already forming a hydrogen bond to it. It follows that, in the transition state for the removal of the hydron from the α carbon, a hydron is probably being transferred from the arginine or the serine to the pyridyl nitrogen.

Each of the steps in which an electrophile dissociates from the carbon immediately adjacent to the iminium nitrogen in an external pyridoximine (Equations 2–4 through 2–8) produces a quinonoid intermediate that is electron-rich and capable of push. The normal quinonoid intermediates in such enzymatic reactions are usually unstable and rapidly converted to the next intermediate in the respective reaction.[85] The quinonoid intermediate (λ_{max} = 494 nm; ε_{494} = 13,600 M^{-1} cm^{-1}), however, that is formed after removal of the hydron from the α carbon of the external pyridoximine of the inhibitor L-*erythro*-3-hydroxyaspartate[26] or that is formed after removal of the hydron from the slow substrate L-cysteinesulfinate ($t_{½}$ = 0.3 s; λ_{max} = 520 nm)[86] by the active site of aspartate transaminase from *E. coli* and the quinonoid intermediate formed from L-*erythro*-3-hydroxyaspartate by porcine aspartate transaminase (λ_{max} = 491 nm; ε_{491} = 20,800 M^{-1} cm^{-1})[23] are stable enough that their absorbance spectra

can be recorded (Figure 2–1D). A stable quinonoid intermediate is also formed when tryptophanase from *E. coli* is mixed with its substrate L-tryptophan ($k_{form} = 500\ s^{-1}$; $\lambda_{max} = 505$ nm).[87] When tyrosine phenol-lyase from *Citrobacter freundii* is mixed with 3-fluoro-L-tyrosine, an analogue of its substrate, a stable quinonoid intermediate is formed ($k_{form} = 100\ s^{-1}$; $\lambda_{max} = 502$ nm),[87] and when the enzyme is mixed with L-alanine, a stable quinonoid intermediate forms that can be crystallized.[88] When glycine hydroxymethyltransferase from *G. stearothermophilus* is mixed with glycine and tetrahydrofolate, a stable quinonoid intermediate ($\lambda_{max} = 495$ nm), produced by removal of the hydron from the external pyridoximine of the glycine (reverse of Equation 2–11), can be observed.[89] In the reaction catalyzed by kynureninase, the natural quinonoid intermediate, although of short lifetime ($t_{½} = 0.9$ s; $\lambda_{max} = 494$ nm) has been observed directly.[85]

A quinonoid intermediate is the **leaving group** in its dissociation from the respective electrophile, and as a result, it is an electron-rich species. The net effect of the dissociation of an electrophile from the respective α carbon to form one of these quinonoid intermediates is the **expansion of the π molecular orbital system** of the pyridoximine by one carbon and by the pair of electrons that was in the σ bond. This addition of two electrons to a π molecular orbital system that expands by only one carbon converts it from one that was electron-poor to one that is electron-rich. This excess electron density neutralizes the positive formal elementary charge on the hydronated pyridinio nitrogen (Equations 2–4 through 2–8).

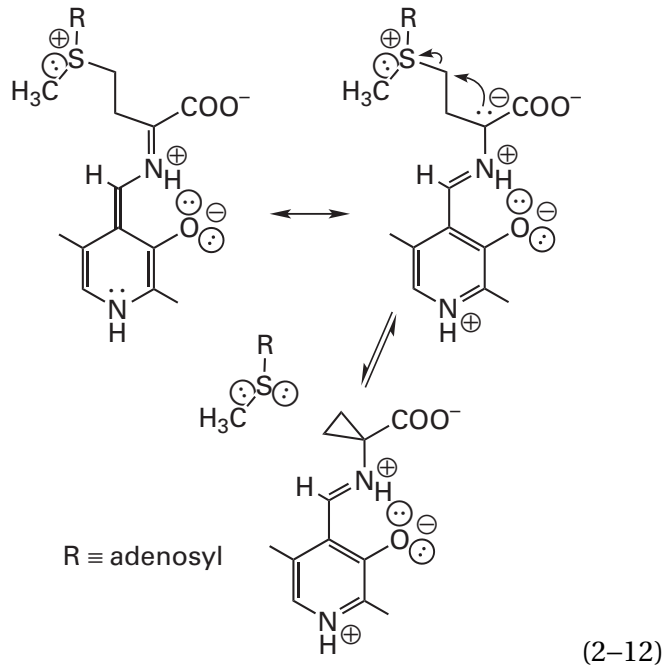
An example of the result of these changes is the quinonoid intermediate that is the product in Equations 2–6 and 2–7. The **π molecular orbital system of this quinonoid intermediate** can be represented as



Because it includes the carboxylato group, there are 13 *p* orbitals that combine to produce a π molecular orbital system with 13 π molecular orbitals, and the seven molecular orbitals of lowest energy are each occupied by a pair of electrons. The atoms in the entire π molecular orbital system in quinonoid intermediate **2–12** are coplanar. In the **crystallographic molecular model** of the stable quinonoid intermediate that forms when tyrosine phenol-lyase from *C. freundii* is mixed with L-alanine, which is a quinonoid intermediate that includes a carboxylato group, this complete planarity is unmistakable.[88] In crystallographic molecular models of the external pyridoximine and the quinonoid intermediate in the active site of tryptophan synthase from *S. enterica*, it can be seen that the carboxy group rotates into the plane of the quinonoid intermediate when it is formed from the external pyridoximine.[90] In quinonoid intermediates that lack a carboxylato group (Equations 2–4 and 2–5), only 10 *p* orbitals are combined, and the π molecular orbital system has 10 π molecular orbitals, and the six of lowest energy are each occupied by a pair of electrons. The occupation of the nonbonding molecular orbital with a pair of electrons in the former case (**2–12**) and of an antibonding molecular orbital in the latter case represents the electron excess in a quinonoid intermediate.

The simplest reaction involving a quinonoid intermediate is **racemization**. If a hydron is added back to the opposite side of the α carbon from which a hydron was removed by one base to form the quinonoid intermediate by another acid in the active site,[70] the stereochemistry at that α carbon is inverted. An example of such a racemization would be the reaction catalyzed by alanine racemase from *G. stearothermophilus*,[37] which equilibrates D-alanine and L-alanine.

Because of the excess electron density in the π molecular orbital system, **a quinonoid intermediate is basic and nucleophilic.** Its basicity is manifest in its ability to be hydronated at the carbon α to its iminio nitrogen, as it is in a racemase. Its nucleophilicity is manifest in its ability to add to a carbonyl carbon, as in the addition of the α-carboxyquinonoid intermediate to acetaldehyde in the reverse reaction of Equation 2–7. A dramatic example of the nucleophilicity of the α carbon in a quinonoid intermediate is its ability to displace methyl adenosyl sulfide in the concerted nucleophilic substitution that is the central step of the reaction catalyzed by 1-aminocyclopropane-1-carboxylate synthase[91,92]



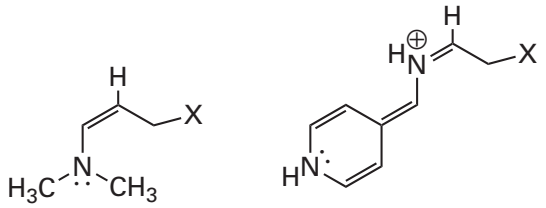
(2–12)

Although the carbon that adds to the carbonyl carbon, the acyl carbon, or the saturated electrophilic carbon in these three reactions appears at first glance to be an imino carbon because of the adjacent imino nitrogen, it is nucleophilic rather than electrophilic because of the electron excess in the complete π molecular orbital system. In all these instances, as illustrated in the resonance structure of Equation 2–12, dehydronation of the pyridinio nitrogen in concert with each nucleophilic addition enhances the nucleophilicity of the quinonoid intermediate and increases the rate of the nucleophilic addition. The active sites in which a weak acid, such as a serine or an arginine, forms the hydrogen bond with pyridyl nitrogen 1 would benefit from the dehydronation that the conjugate bases of these weak acids would necessarily accomplish.

The reverse reaction of Equation 2–8 is the metabolically relevant direction for the Claisen condensation catalyzed by 5-aminolevulinate synthase since the reaction is relied upon to produce 5-aminolevulinate, the precursor in heme biosynthesis. The quinonoid intermediate formed by the removal of a hydron from the α carbon of glycine (reverse of Equation 2–11) adds as a nucleophile to the acyl carbon of succinyl-SCoA in the Claisen condensation to produce the external pyridoximine of 2-amino-3-oxohexanedioic acid (**2–10**). The methyl ester at carbon 6 of 2-amino-3-oxohexanedioic acid has been isolated from a mixture of murine 5-aminolevulinate synthase, the methyl ester of glycine, and succinyl-SCoA. It was identified by gas–liquid chromatography followed by mass spectrometry.[73] These results suggest that the decarboxylation of the α carbon of **2–10** required to produce the final product, 5-aminolevulinic acid, which is 5-amino-4-oxopentanoic acid, occurs after the Claisen condensation (as shown in Equation 2–8) rather than before because the methyl ester cannot and was not decarboxylated during the formation of methyl ester of 2-amino-3-oxohexanedioic acid. This conclusion would make chemical sense because the carboxylato group dissociating as CO_2 would be both on the α carbon of an external pyridoxime and on a carbon that is adjacent to a carbonyl group, both of which would destabilize the σ bond to the carboxylato group.

There is a related (30% identity; 1.3 gap percent) enzyme, 8-amino-7-oxononanoate synthase, that performs a homologous Claisen condensation between L-alanine instead of glycine and 6-carboxyhexanoyl-SCoA instead of succinyl-SCoA to produce 8-amino-7-oxononanoic acid.[93,94] The production of this product also requires both the removal of a hydron and a decarboxylation at the α carbon of successive external pyridoximines. Both murine 5-aminolevulinate synthase[71,95] and 8-amino-7-oxononanoate synthase from *Lysinibacillus sphaericus* [96] exchange one of the hydrogens on glycine and L-alanine, respectively, for a different isotope of hydrogen in the absence of either of the second reactants for the respective enzyme, but these exchanges are significantly slower (250,000 times and 10 times, respectively) than the turnovers for the complete enzymatic reactions when the respective second reactant is present. Nevertheless, these exchanges are consistent with the removal of a hydron from the α carbon in the initial external pyridoximine, rather than the dissociation of carbon dioxide, before the actual Claisen condensation in the mechanisms of each of these enzymes.[97] Also consistent with this conclusion is that when 5-aminolevulinate synthase from *Rhodobacter sphaeroides* is mixed with only glycine, a quinonoid intermediate forms but no CO_2 is produced during the formation of this quinonoid intermediate.[98]

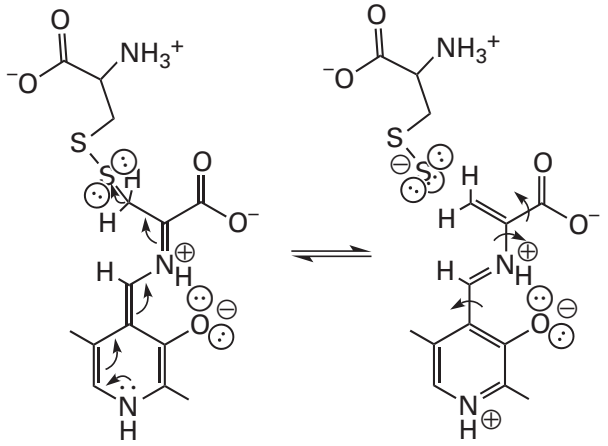
Because it is electron-rich, it cannot absorb the two electrons in another σ bond, but **a quinonoid intermediate can push**. In this role the quinonoid intermediate is acting as a vinylogous enamine



enamine **2–13** vinylogous enamine **2–14**

An enamine is electron-rich and can push out a leaving group (X in **2–13**). When the π molecular orbital system of the quinonoid intermediate is used to provide push, an elimination occurs.[99]

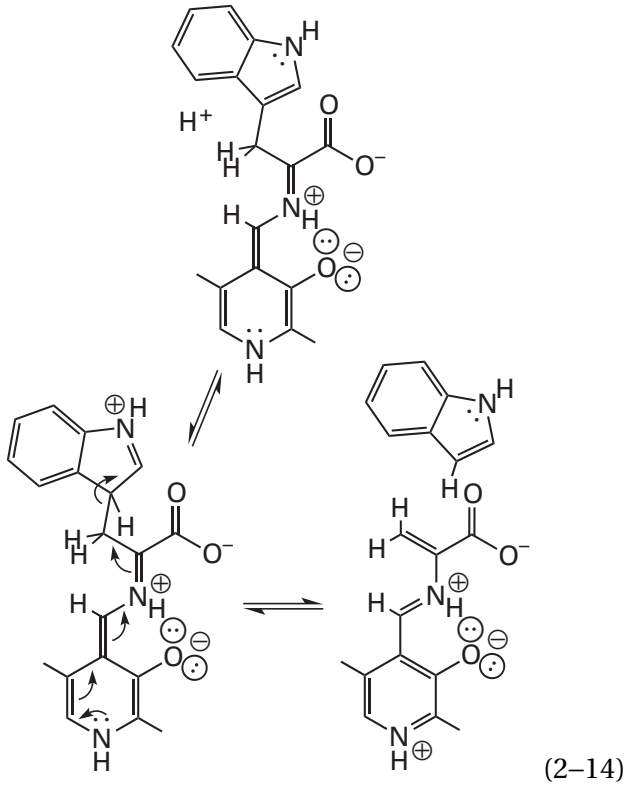
Examples of such an **elimination from a quinonoid intermediate** are encountered in one of the steps in the reaction catalyzed by L-cystine β-lyase from *Synechocystis*[100]



pyridoximine of 2-aminoacrylate

(2–13)

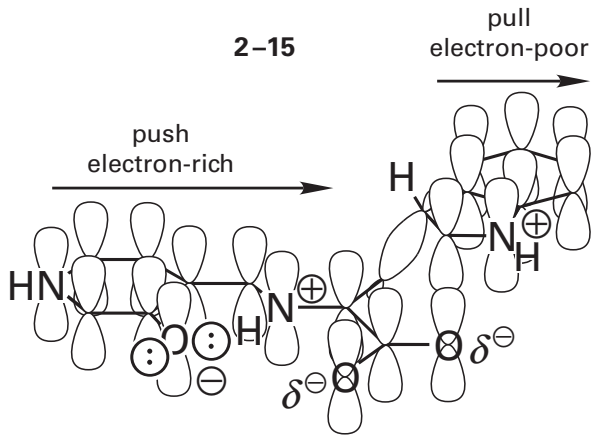
and one of the steps in the reaction catalyzed by tryptophanase[101]



(2–14)

In the latter instance, the indolyl group, when it has been hydronated on carbon 3, is an excellent leaving group because the two electrons in the σ bond connecting it to the quinonoid intermediate can enter its π molecular orbital system and complete an aromatic dectet. The bond is pushed away by the electron excess in the quinonoid intermediate and pulled into the indolyl group[102]

2–15



The most difficult step in this electrophilic aromatic substitution is the hydronation of the indolyl group, which might be assisted by the quinonoid intermediate if the hydronation and the dissociation are concerted. The related (41% identity; 0.7 gap percent) enzyme, tyrosine phenol-lyase, catalyzes the homologous reaction in which L-tyrosine is

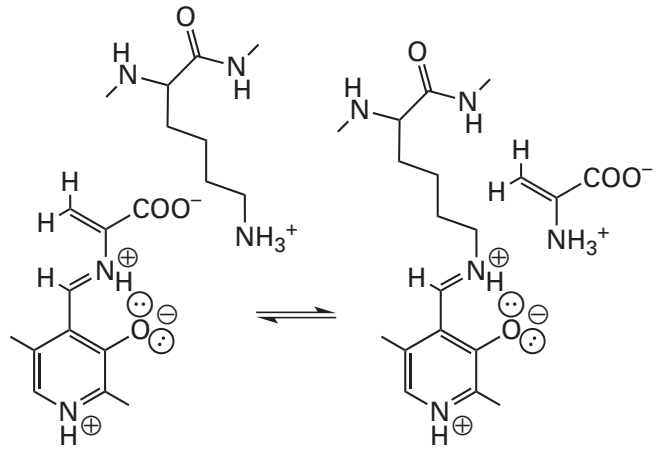
cleaved into phenol and the enamine of pyruvate rather than indole and the enamine of pyruvate. In the crystallographic molecular model[103] of the active site of a mutant of tyrosine phenol-lyase from *C. freundii*, occupied by 3-fluoro-L-tyrosine, the hydroxy group of Tyrosine 71 in the enzyme is only 0.31 nm from carbon 1 of the analogue, which is the carbon that would be hydronated during the electrophilic aromatic substitution (see first step in Equation 2–14), an observation consistent with it being the catalytic acid.

In the elimination from the quinonoid intermediate catalyzed by L-serine ammonia-lyase, the leaving group is the hydroxy group of the quinonoid intermediate formed from L-serine. In the active site of the enzyme, the phospho group of the pyridoxal 5′-phosphate forms a hydrogen bond with the hydroxy group and is thought to hydronate the hydroxy group as it leaves.[104]

The product resulting from an elimination of a leaving group from the β carbon of a quinonoid intermediate is the external pyridoximine of a 2-aminoacrylate (Equations 2–13 and 2–14). In the active sites of cysteine synthase from *S. typhimurium*[105] and cysteine lyase from *Fusobacterium nucleatum*,[106] the pyridoximine of 2-aminoacrylate (λ_{max} = 330 and 470 nm and λ_{max} = 320 and 460 nm, respectively) forms rapidly when the enzyme is mixed with *O*-acetyl-L-serine.[106] *O*-Acetyl-L-serine is itself not nucleophilic and does not generate a nucleophilic product that can add to the electrophilic carbon–carbon bond in the 2-aminoacrylate. The intermediate external pyridoximine of 2-aminoacrylate has been observed in a crystallographic molecular model[107] of the active site of cystathionine β-synthase (*O*-acetyl-L-serine) from *S. cerevisiae*.

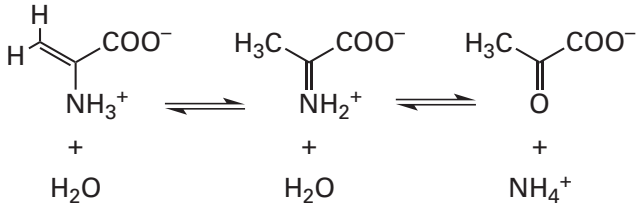
External pyridoximines of 2-aminoacrylate have also been stabilized and observed in active sites in the **crystallographic molecular models** of tryptophan synthase from *S. typhimurium*,[108,109] cysteine synthase from *Mycobacterium tuberculosis*,[110] and alliin lyase from *Allium sativum*.[110] In none of these three molecular models is the pyridoximine of 2-aminoacrylate planar throughout its complete π molecular orbital system. In the active site of tryptophan synthase, the carboxylate of the 2-aminoacrylate is rotated out of the plane defined by the truncated π molecular orbital system; in the active site of cysteine synthase, the completely planar 2-aminoacrylate is tilted out of the plane of the pyridoximine by a rotation about the bond between nitrogen 4′ and the α carbon of the acrylate; and in the active site of alliin synthase, the 2-aminoacrylate is tilted out of the plane of the pyridoximine by a rotation about the bond between carbon 4 and carbon 4′ of the pyridoximine. These three σ bonds are single σ bonds in the only resonance structure of the pyridoximine of 2-amino-acrylate (rotational arrows in Equation 2–13) that do not involve separation of charge and should be the weakest links in the π molecular orbital system. In butadiene, the out-of-plane conformers are at most only about 25 kJ higher in energy than the s-trans conformer.

The 2-aminoacrylate in the pyridoximine can be **released directly** by transimination with the lysine of the internal pyridoximine



(2–15)

as occurs in the reactions catalyzed by tryptophanase and L-cystine β-lyase. The 2-aminoacrylate released by the transimination tautomerizes to iminopyruvate, perhaps while still within the active site,[111] and the iminopyruvate released into solution rapidly hydrolyzes to pyruvate and ammonia



(2–16)

Another nucleophile can add, however, to the external pyridoximine of a 2-aminoacrylate at its β carbon, in the reverse of the reaction that has pushed away the leaving group. If this occurs, then the reaction can proceed in reverse until the amine is liberated from the pyridoxal 5′-phosphate with the

nucleophile that added to the β carbon simply substituting for the leaving group that left it, as in the reactions catalyzed by cysteine synthase, in which a sulfanide has replaced an acetate

O-acetyl-L-serine + HS^- $\rightleftharpoons$ acetate + L-cysteine (2–17)

O-phosphoserine sulfhydrylase,[112] in which a sulfanide has replaced a phosphate

O-phospho-L-serine + hydrogen sulfide $\rightleftharpoons$ $HOPO_3^{2-}$ + L-cysteine (2–18)

or L-seryl-tRNA^{Sec} selenium transferase,[113] in which a selenide has replaced a hydroxide

L-seryl-tRNA^{Sec} + selenophosphate $\rightleftharpoons$ $HOPO_3^{2-}$ + L-selenocysteinyl-tRNA^{Sec} (2–19)

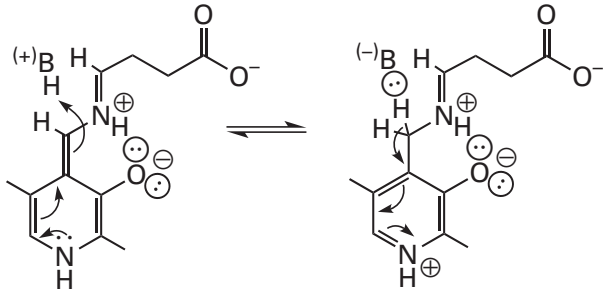
In the case of cysteine synthase (Equation 2–17) from *S. typhimurium*[114] and cysteine lyase from *F. nucleatum*,[106], the external pyridoximine of 2-aminoacrylate in the active site of the enzyme that has been formed from *O*-acetyl-L-serine, when deprived of access the usual nucleophilic cosubstrate, will react with a number of other nucleophiles to produce the respective amino acids in which the respective nucleophile replaces the acetyl group. In the reactions catalyzed by the active site of tryptophan synthase (indole-salvaging) within tryptophan synthase

L-tryptophan + H_2O $\rightleftharpoons$ indole + L-serine (2–20)

the external pyridoximine of 2-aminoacrylate produced from L-tryptophan by the elimination of indole (Equation 2–14 and **2–15**),[102] reacts with water to produce eventually L-serine rather than breaking down to pyruvate and ammonia, as occurs in the reaction catalyzed by tryptophanase (Equation 2–14).

The most remarkable aspect of the reactions catalyzed by cysteine synthase and *O*-phosphoserine sulfhydrylase is that each of these nucleophilic substitutions involves the replacement of a good leaving group, a carboxylate or a phosphate, respectively, by a strong nucleophile, the sulfanide. Rather than proceed through the simplest possible chemical mechanism, a concerted nucleophilic substitution, these enzymes use pyridoxal 5′-phosphate to rearrange hydrons and replace the carboxylate with a distant elimination involving two steps in each direction from the external pyridoximine. This solution seems at a glance not to be an intelligent design.

In many of the enzymatic reactions in which a quinonoid intermediate is formed from a prosthetic pyridoxal 5′-phosphate, rather than exploiting its electron density to push a leaving group from the β carbon, the next step is to exploit its basicity by adding a hydron to carbon 4′ to form the *N*-(5′-phosphopyridoxyl)imine, as occurs in the reaction catalyzed by 4-aminobutyrate—2-oxoglutarate transaminase (Equation 2–4)



N-(5′-phosphopyridoxyl)imine (2–21)

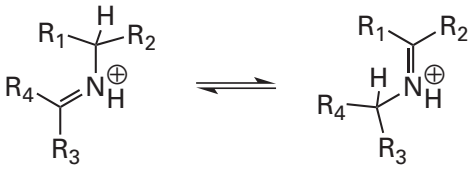
Carbon 4′ is one of the alternating basic positions in the vinylogous enamine (**2–14**). In the reaction catalyzed by 4-aminobutyrate—2-oxoglutarate transaminase, the removal of a hydron from the α carbon of the external pyridoximine (Equation 2–4) and the addition of a hydron to carbon 4′ of the resulting quinonoid intermediate (Equation 2–21) produce the *N*-(5′-phosphopyridoxyl)-imine, *N*-(5′-phosphopyridoxyl)-3-carboxypropanimine.

The imine in an *N*-(5′-phosphopyridoxyl)imine is disconnected from the remaining **π molecular orbital system** of the pyridyl group by the saturated position at carbon 4′.[85] Two of the 12 π electrons in the π molecular orbital system of the quinonoid intermediate become the two electrons in the new σ bond to the hydron that has associated. The remaining *p* orbitals and π electrons are divided into two unequal sets by the hydronation. Eight of the π electrons remain in the seven π molecular orbitals formed from the seven *p* orbitals of the 3-hydroxy-

pyridyl group. Two π electrons remain in the double bond of the imine (Equation 2–21).

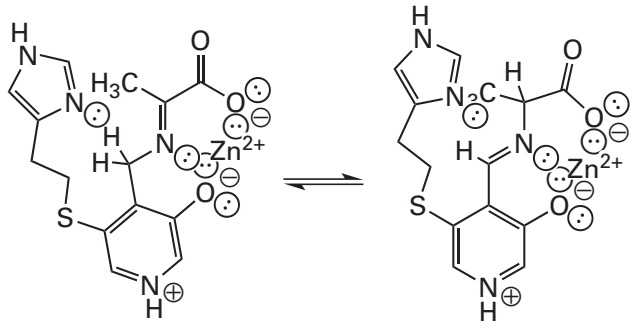
The *N*-(5′-phosphopyridoxyl)imines formed from L-aspartate and L-glutamate, *N*-(5′-phosphopyridoxyl)-1,2-dicarboxyethanimine and *N*-(5′-phosphopyridoxyl)-1,3-dicarboxypropanimine, respectively, have been crystallized in the active site of aspartate transaminase from *Gallus gallus*.[115] In the **two crystallographic molecular models**, the carbon–hydrogen σ bond that would be broken during removal of the hydron from carbon 4′ of the 5′-phosphopyridoxyl group to re-form the quinonoid intermediate (reverse of Equation 2–21) is parallel to the pyridyl ring. This orientation places this σ bond in hyperconjugation with the π molecular orbital system of the hydronated pyridinio ring so that the π molecular orbital system of the pyridinio ring can withdraw electron density from the bond and promote removal of the hydron from carbon.

The two steps that produce any *N*-(5′-phosphopyridoxyl)imine, removal of a hydron from the α carbon and addition of the hydron to carbon 4′, are the two steps in the **tautomerization of an iminium** (the sum of Equations 2–4 and 2–21)



(2–22)

In nonenzymatic situations, simple tautomerizations of this type are catalyzed by bases,[116] which remove the hydron from carbon during the slower of the two steps of the reaction.[117] A weak acid and a weak base together can catalyze the tautomerization of a pyridoxamine, presumably by catalyzing the removal of the hydron from the one carbon and the addition of the hydron to the other carbon.[15] An analogue of pyridoxal 5′-phosphate in which an imidazolyl group has been appropriately incorporated as an intramolecular catalyst can undergo this tautomerization



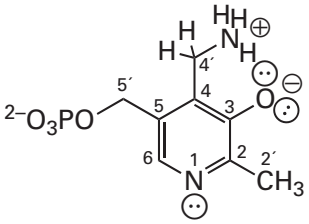
(2–23)

80 times more rapidly than another analogue identical to the first with the exception that the imidazolyl group has been replaced by a methyl group.[118] In this case Zn^{2+} was used as a Lewis acid to maintain the proper orientations within the molecule and promote the reaction. Even with the assistance of the pyridoxal 5′-phosphate in an active site of an enzyme in weakening these σ bonds between carbon and hydrogen, the removal of a hydron from the one carbon and the addition of a hydron to the other carbon are slower reactions than the carbonyl additions necessary to form the pyridoxamine in the first place.

In many cases, the **lysine that formed the internal pyridoxamine** and that is then responsible for removing the hydron from the α carbon (see Equation 2–4) can be positioned by the enzyme so that it is adjacent to both the α carbon and carbon 4′ of the external pyridoxamine (Figure 2–4).[53,60,61,119] In this orientation, the 6-amino group of this lysine can both remove a hydron from the α carbon and then add a hydron to carbon 4′ of the quinonoid intermediate. This arrangement is found in the active site of aspartate transaminase from *E. coli*. The respective *N*-(5′-phosphopyridoxyl)imine that normally participates in the enzymatic reaction, either *N*-(5′-phosphopyridoxyl)-1,2-dicarboxyethanimine or *N*-(5′-phosphopyridoxyl)-1,3-dicarboxypropanimine, can be formed directly from oxaloacetate or 2-oxoglutarate, respectively, and pyridoxamine 5′-phosphate in the active site of the enzyme. When the lysine that forms the internal pyridoxamine in aspartate transaminase from *E. coli* is mutated to alanine, the conversion of the respective *N*-(5′-phosphopyridoxyl)imine into L-aspartate or L-glutamate, which requires the tautomerization to occur, is 10^5 or 10^6 times slower, respectively, in the mutant than in the unmutated enzyme,[120] In the mutant enzyme, presumably, there is no other base present

that is even remotely as effective at removing the hydron from carbon 4′ of the respective *N*-(5′-phosphopyridoxyl)imine and then adding a hydron to the resulting quinonoid intermediate.

An *N*-(5′-phosphopyridoxyl)imine within an active site can be readily hydrolyzed to the corresponding aldehyde or ketone and pyridoxamine 5′-phosphate

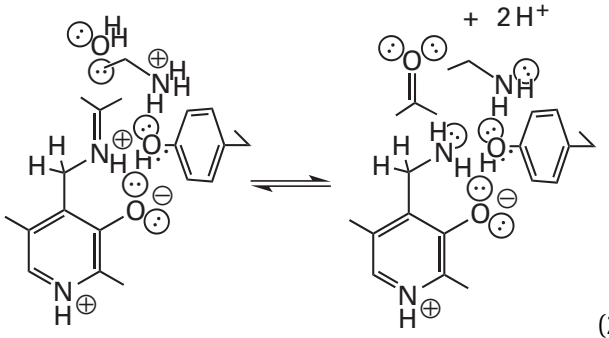


2–16

The upshot of the sequence of events ending in such a hydrolysis is that an **oxo group has replaced the original primary amino group** in the initial reactant. For example, in the reaction catalyzed by 4-aminobutyrate—2-oxoglutarate transaminase (Equations 2–4 and 2–21), when the *N*-(5′-phosphopyridoxyl)-3-carboxypropanimine is hydrolyzed, the products are 4-oxobutanoic acid (succinate semialdehyde), which is one of the products of the overall reaction, and pyridoxamine 5′-phosphate.

In contradistinction to pyridoxal 5′-phosphate, which is covalently attached to an active site as the internal pyridoximine, pyridoxamine 5′-phosphate is a noncovalent prosthetic group that is held in the active site of an enzyme only by strong noncovalent forces. When pyridoxal 5′-phosphate associates with an active site, the dissociation constant for that pyridoxal 5′-phosphate from the enzyme includes the equilibrium constant for the nucleophilic addition that covalently attaches it to the enzyme (Equation 2–3). The dissociation constant for pyridoxal 5′-phosphate from the active site of aspartate transaminase from *E. coli*[83] is 0.4 pM. This dissociation constant is much smaller than the dissociation constant for pyridoxamine 5′-phosphate (1.3 nM) because, even though the rest of the pyridoxamine 5′-phosphate is identical to pyridoxal 5′-phosphate, it does not participate in the covalent attachment. The absorption spectrum of pyridoxamine 5′-phosphate when it is associated with the active site of aspartate transaminase from *E. coli* (Figure 2–1E) has a maximum of absorbance at 323 nm. The short wavelength results from the absence of extended conjugation.

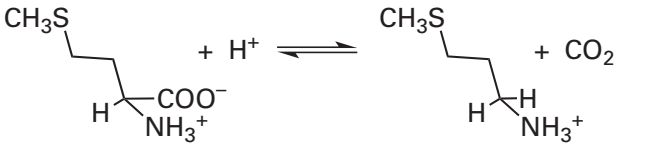
The hydrolysis of an *N*-(5′-phosphopyridoxyl)-imine to form the carbonyl group and the pyridoxamine 5′-phosphate cannot proceed unless there is an acid to provide a hydron that can be added to the iminium nitrogen to make it a competent leaving group, and another hydron is required if the pyridoxamine 5′-phosphate is to end up as zwitterion **2–16**. In the active site of aspartate transaminase from *E. coli*, there is a tyrosine that forms a hydrogen bond (0.28 nm) to the phenolic oxyanion of the *N*-(5′-phosphopyridoxyl)-1,2-di-carboxyethanimine formed from L-aspartate,[115] and the lysine that participated in the internal pyridoximine is near enough (0.39 nm) to reorient and form a hydrogen bond with the tyrosine. The hydron on the lysinium can be shuttled to the imino nitrogen of the *N*-(5′-phosphopyridoxyl)imine during its hydrolysis to provide the mandatory hydron



(2–24)

When the tyrosine is mutated to a phenylalanine, the rate of enzymatic activity decreases by a factor of 500 and *N*-(5′-phosphopyridoxyl)-1,2-dicarboxyethanimine accumulates (70%) in the active site, a fact indicating that the hydrolysis of the *N*-(5′-phosphopyridoxyl)imine has been decreased so dramatically by the mutation that it is now the rate-limiting step in the enzymatic reaction.[24,25] The side chain of the lysine is probably flexible enough to pick up another hydron during the hydrolysis to provide the hydron needed to produce the zwitterion of the pyridoxamine 5′-phosphate.

Amino acid decarboxylases are enzymes that catalyze the dissociation of the carboxylato group as CO_2 (Equation 2–5) from an α-amino acid rather than removing the hydron. In the normal reaction of a decarboxylase, the carboxy group dissociates and is replaced by a hydron; for example, in the reaction catalyzed by methionine decarboxylase[121]

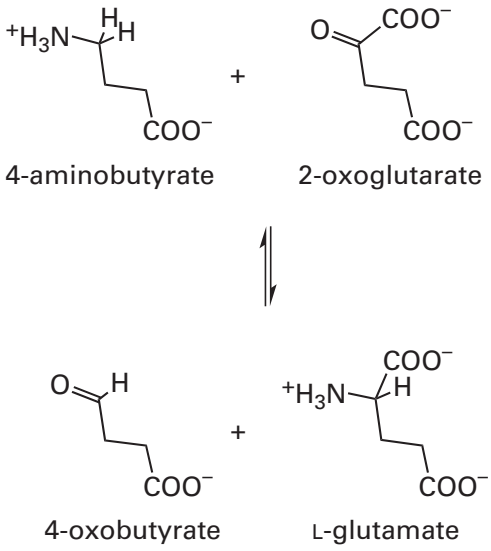


(2–25)

Again, it is usually assumed that the 6-ammonio group of the lysine of the internal pyridoximine, which is liberated upon formation of the external pyridoximine (Figure 2–2), hydronates the quinonoid intermediate (Equation 2–5) at the α carbon following dissociation of the CO_2.[122] The active site in a decarboxylase must be constructed, however, so that the ammonio group of this lysine that is responsible for hydronating the α carbon, or any other acid, cannot hydronate carbon 4′ of the quinonoid intermediate that results from the decarboxylation (Equation 2–21) to produce the *N*-(5′-phosphopyridoxyl)imine, which can then hydrolyze. Methionine decarboxylase from *Dryopteris filixmas* fails to prevent the hydronation of carbon 4′ completely; and during its normal reaction (Equation 2–25), pyridoxamine 5′-phosphate and 3-(methylsulfanyl)propanal are slowly formed as side products in a reaction that inactivates the enzyme.[122]

The formation of an *N*-(5′-phosphopyridoxyl) imine and its hydrolysis are, however, **essential steps in a transamination**. The overall reaction in a transamination is the conversion of an amino group into a oxo group at one carbon and the conversion of an oxo group into an amino group at another carbon resulting in the transfer of ammonia or an amine between the two carbons. In the first sequence of steps in a transamination, the amine of the reactant is converted into a ketone or aldehyde coincident with the conversion of the imino group of the initial internal pyridoximine into the amino group in pyridoxamine 5′-phosphate. In the second sequence of steps in a transamination, which is the reverse of the first sequence of steps, a different ketone or aldehyde that is the other reactant in the enzymatic reaction is converted into the respective amine, coincident with conversion of the pyridoxamine 5′-phosphate into the internal pyridoximine 5′-phosphate, so that the active site can start again.

An **example of a transamination** is that catalyzed by 4-aminobutyrate—2-oxoglutarate transaminase



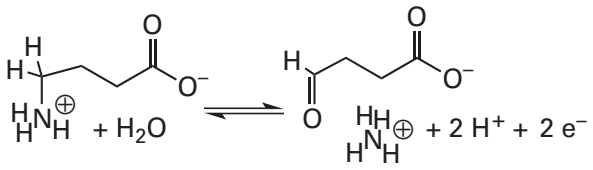
4-aminobutyrate 2-oxoglutarate

4-oxobutyrate L-glutamate

(2–26)

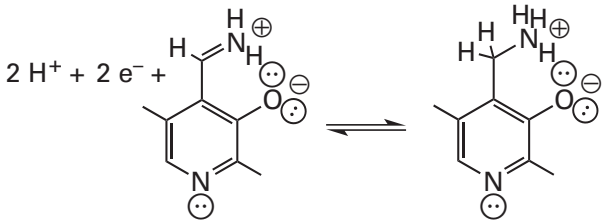
In the forward direction, the external pyridoximine of 4-aminobutyrate is formed from the internal pyridoximine (Figure 2–2), the α hydron is removed (Equation 2–4), carbon 4′ of the quinonoid intermediate is hydronated (Equation 2–21), the resulting *N*-(5′-phosphopyridoxyl)-3-carboxypropanimine is hydrolyzed to produce 4-oxobutyrate and pyridoxamine 5′-phosphate (reverse of Figure 1–7), the 2-oxoglutarate replaces the 4-oxobutyrate, and the reaction proceeds in reverse.

The conversion of 4-aminobutyrate to 4-oxobutyrate in the first half of the overall reaction is an oxidation, the conversion of a carbon from the oxidation state of an alcohol to the carbonyl oxidation state



(2–27)

The oxidant in the reaction is the pyridoximine 5′-phosphate



(2–28)

This latter half-reaction demonstrates that a pyridoximine of pyridoxal 5′-phosphate and pyridoxamine 5′-phosphate are at different oxidation states. In the second half of the overall reaction, 2-oxoglutarate oxidizes the pyridoxamine 5′-phosphate back to a pyridoximine of pyridoxal 5′-phosphate while being reduced to a primary amine.

In the complex between the active site of aspartate transaminase

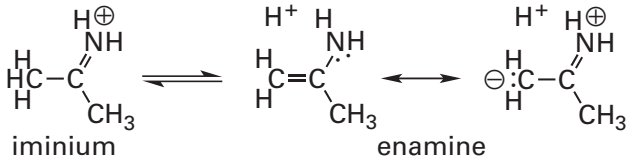
L-aspartate + 2-oxoglutarate
$\rightleftharpoons$ oxaloacetate + L-glutamate

(2–29)

from *G. gallus* and the inhibitor L-*erythro*-3-hydroxyaspartate, the **hemiaminal that is the transient intermediate** (Figure 1–7) in the hydrolysis of the *N*-(5′-phosphopyridoxyl)-1,2-dicarboxy-2-hydroxyethanimine is stabilized by the adjacent, unnatural hydroxy group and can be directly observed.[123]

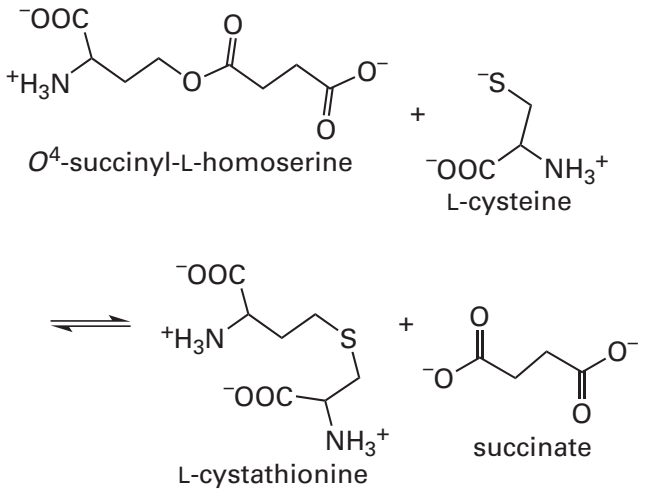
Transaminations are also catalyzed nonenzymatically by pyridoxal 5′-phosphate in the presence of metallic ions. For example, 2-oxoglutarate and L-alanine are transformed into L-glutamate and pyruvate by pyridoxal 5′-phosphate in solution in the presence of $CuSO_4$.[124]

Just as electron density is withdrawn from any one of the σ bonds on the α carbon of an external pyridoximine (2–6), the iminium in an *N*-(5′-phosphopyridoxyl)iminium withdraws electron density from any one of the σ bonds on the β carbon of the substrate and promotes the dissociation of an electrophile from that β carbon. This electron withdrawal is a property of any iminium (previously Equation 1–113)



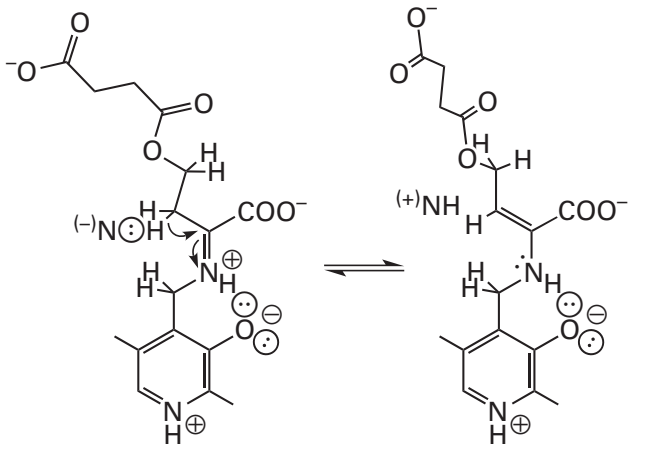
(2–30)

If there is a **hydrogen on the β carbon**, it can be removed as a hydron. For example, cystathionine γ-synthase



(2–31)

catalyzes a nucleophilic substitution in which the sulfido group of L-cysteine is the nucleophile and succinate is the leaving group. In one of the steps catalyzed by the enzyme, the hydrogen on the β carbon of O^4-succinyl-L-homoserine is removed as a hydron[125] from the *N*-(5′-phosphopyridoxyl)-1-carboxy-3-hydroxy-3-*O*-succinylpropaniminium ion

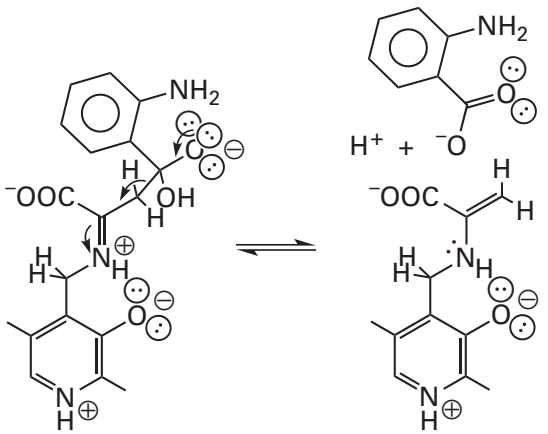


(2–32)

This removal is a simple manifestation of the acidity of a hydron on the carbon adjacent to an iminium (Equation 2–30). The 6-amino group of the lysine that formed the internal pyridoximine, and that is thought to be the base that just removed the hydron from the α carbon of the external pyridoximine and the acid that then hydronated carbon 4′ of the quinonoid intermediate to form the *N*-(5′-phosphopyridoxyl)imine, can also swing up next to the β carbon of that *N*-(5′-phosphopyridoxyl)imine,[60] and its amino group is the prime

candidate for the base that removes the hydron from it in the normal reaction.

If there is a **oxo group on the γ carbon**, the hydrate of that carbonyl group can dissociate from the β carbon as the carboxylic acid in a retro-Claisen condensation, as in the reaction catalyzed by kynureninase[126]

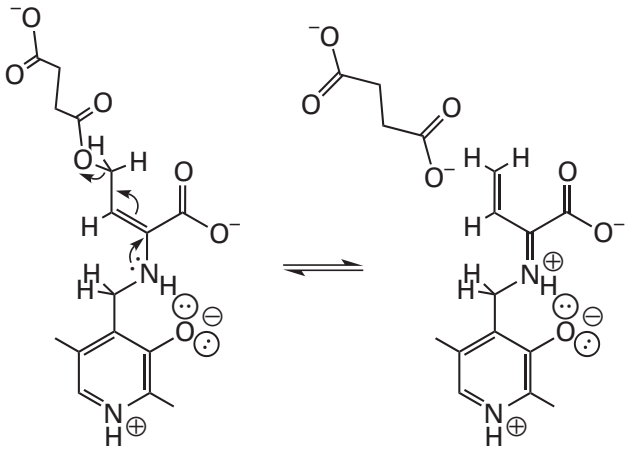


N-(5′-phosphopyridoxyl)enamine
(2–33)

If there is a **hydroxy group on the γ carbon**, it can dissociate from the β carbon in a retroaldol reaction as the respective carbonyl carbon.

When an electrophile dissociates from the β carbon of an *N*-(5′-phosphopyridoxyl)iminium as a result of electron withdrawal by the adjacent iminium (Equation 2–33), an *N*-(5′-phosphopyridoxyl)enamine is formed. As is the case with all enamines (Equation 2–30), an *N*-(5′-phosphopyridoxyl)enamine is electron-rich, basic, and nucleophilic. If the electrophile that dissociated was other than a hydron, the enamine **can be hydronated** on the β carbon, and the reaction can proceed backward until the product, in which the electrophile that dissociated has been replaced by a hydron, is released. This reaction in one direction followed by the reaction in reverse is what happens in the reaction catalyzed by kynureninase (Equation 2–33), in which the products are anthranilate and L-alanine, the amino acid ultimately resulting from hydronation of the β carbon of the *N*-(5′-phosphopyridoxyl)-1-carboxyethenamine. The hydronation of the β carbon converts it to a methyl group.

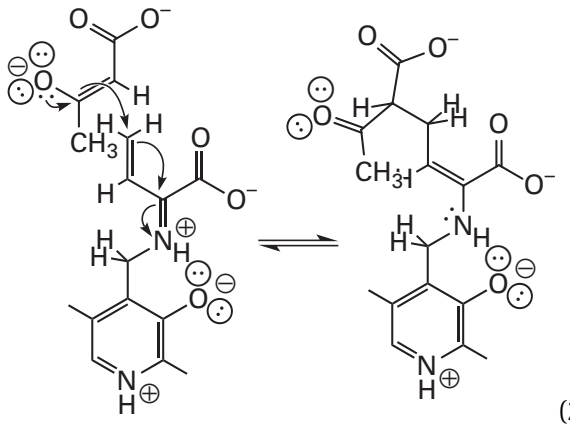
In the next step of the reaction catalyzed by cystathionine γ-synthase (Equations 2–31 and 2–32), however, the electron excess in the *N*-(5′-phosphopyridoxyl)enamine is used to **push out a leaving group** to extend the reach of the pyridoxal 5′-phosphate to the γ carbon of the amine that was the original reactant



N-(5′-phosphopyridoxyl)-
1-carboxyprop-2-en-1-imine
(2–34)

The intermediate in this elimination is an ***N*-(5′-phosphopyridoxyl)-2-propen-1-imine**, in this particular case, *N*-(5′-phosphopyridoxyl)-1-carboxy-2-propen-1-imine.[127] To complete the reaction, the succinate that is the leaving group is replaced by the sulfido group of L-cysteine, a nucleophile, and the steps producing the 1-carboxy-2-propen-1-imine are reversed to produce L-cystathionine. Again, an excellent leaving group, succinate, is replaced by an excellent nucleophile, the sulfido group of L-cysteine. It would seem that a much simpler enzyme could have been designed in which this reaction was a simple concerted nucleophilic substitution.

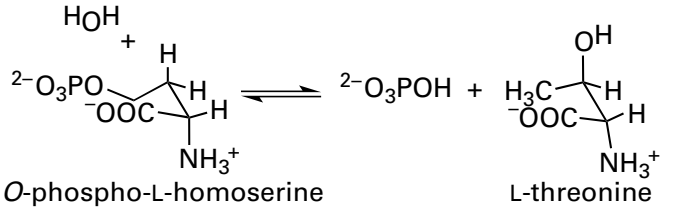
An *N*-(5′-phosphopyridoxyl)-2-propen-1-imine is **electrophilic at the γ carbon**. In the reaction catalyzed by cystathionine γ-synthase, the nucleophile that adds to this electrophilic carbon is the sulfido group of L-cysteine. In the reaction catalyzed by the product of the *cndF* gene in *Penicillium citrinum*, *N*-(5′-phosphopyridoxyl)-1-carboxy-2-propen-1-imine is formed in the active site from O^4-acetyl-L-homoserine rather than O^4-succinyl-L-homoserine (Equations 2–31 and 2–34). The enolate of acetoacetate ($pK_a = 16.1$; Figure 1–23) then adds nucleophilically to the *N*-(5′-phosphopyridoxyl)-1-carboxy-2-propen-1-imine[128]



(2–35)

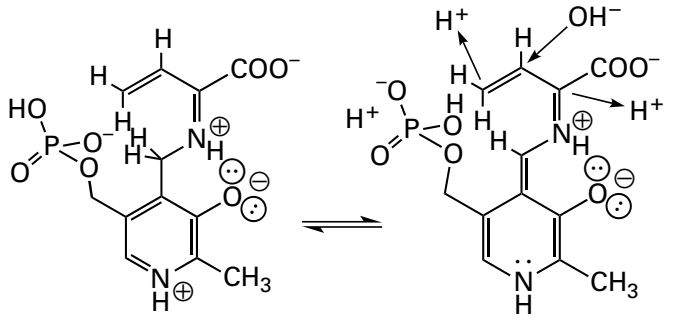
The resulting *N*-(5′-phosphopyridoxyl)enamine is then hydronated on the β carbon, the hydron on carbon 4′ is transferred in the usual tautomerization to the α carbon of the resulting *N*-(5′-phosphopyridoxyl)imine, and the resulting external pyridoximine is transiminated to the L-amino acid. At some point along the way, the carboxylate on the δ carbon of the incipient amino acid, which is on a carbon adjacent to a carbonyl group is decarboxylated. The final product is (*S*)-2-amino-6-oxoheptanoic acid.

In an *N*-(5′-phosphopyridoxyl)prop-2-en-1-imine, the two hydrogens on carbon 4′ of the 5′-phosphopyridoxyl group remain acidic, and one of them can be removed as a hydron. For example, in the reaction catalyzed by threonine synthase from *M. tuberculosis*



(2–36)

N-(5′-phosphopyridoxyl)-1-carboxyprop-2-en-1-imine is formed as an intermediate after the phospho group of the of the *O*-phospho-L-homoserine leaves as phosphate, an excellent leaving group, just as it is formed as an intermediate after the O^4-succinyl group of O^4-succinyl-L-homoserine leaves as succinate, also an excellent leaving group, in the reaction catalyzed by cystathionine γ-synthase (Equation 2–34). The next step in the reaction of threonine synthase, however, is the removal of one of the acidic hydrons on carbon 4′ of the pyridoxyl group to produce the **quinonoid intermediate of ethenyl glycine (2–18)**



2–17 **2–18**

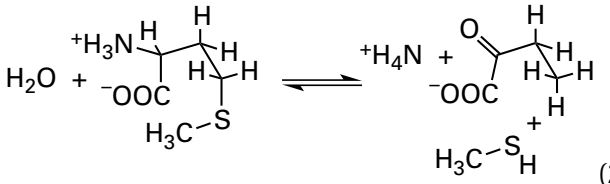
(2–37)

If the quinonoid intermediate of ethenyl glycine is completely planar within the active site and if it is fully conjugated, 15 *p* orbitals from 15 atoms participate in this **ultimate, fully conjugated π molecular orbital system**. The key to understanding the potential of this quinonoid intermediate of ethenyl glycine is to realize that the imino nitrogen has become a bystander. From here on, the additions are controlled solely by the neutral pyridyl nitrogen 1 or the hydronated cationic pyridinio nitrogen 1 in succession. The product of the enzymatic reaction, L-threonine, results from the addition of a hydron, an electrophile, to the γ carbon that is nucleophilic because of the excess electron density in the π molecular orbital system; the addition of a hydroxide, a nucleophile, to the β carbon that is now electrophilic because of the deficit of electron density in the shorter π molecular orbital system; and the addition of a hydron, an electrophile, to the α carbon that is now nucleophilic and basic because of the excess electron density in the even shorter π molecular orbital system (arrows in **2–18**).

In the crystallographic molecular model of threonine synthase from *Thermus thermophilus*, the active site of which is occupied by *N*-(5′-phosphopyridoxyl)-(*E*)-2-imino-5-phosphonopent-3-enoate, an analogue of the *N*-(5′-phosphopyridoxyl)imine of ethenyl glycine (**2–17**), except for the fact that the 5-phosphono group has not dissociated because it cannot, the π molecular orbital systems on each side of the saturated carbon 4′ are coplanar.[129] Were the analogue the actual quinonoid intermediate of ethenyl glycine, the assumption is that it would be completely planar and fully conjugated over all 15 atoms. A nonbridging phospho oxygen from the phospho group on carbon 5′ of the 5′-phosphopyridoxyl group is only 0.33 nm from carbon 4′ of the 5′-phosphopyridoxyl group,[130] and it has been proposed that this base removes the hydron from carbon 4′ and then hydronates the

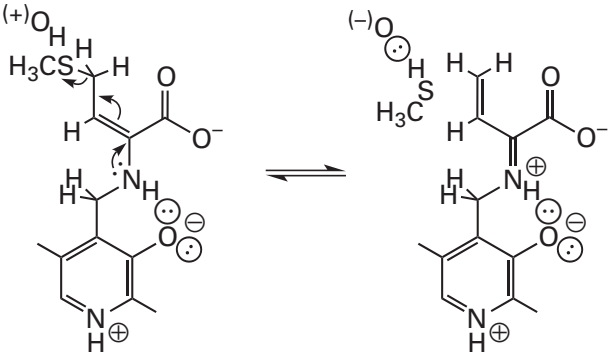
γcarbon of the quinonoid intermediate of ethenyl glycine (Equation 2–37).[131] The hydronation of the γ carbon would require that the natural 1-carboxyprop-2-enimine assume the s-cis conformation as in **2–18**, rather than the s-trans conformation seen in the crystallographic molecular model and drawn in Equation 2–34. In another crystallographic molecular model of the same enzyme with its active site occupied by the same external pyridoximine but also occupied by a phosphate, presumably residing where the phosphate that is the product of the overall reaction sits before it leaves, one of the oxygens of this phosphate is located in a position from which it could remove a hydron from a molecule of water as it adds to the β carbon of the quinonoid intermediate of ethenyl glycine (**2–18**).

A quinonoid intermediate of ethenyl glycine is also formed in the elimination catalyzed by methionine γ-lyase



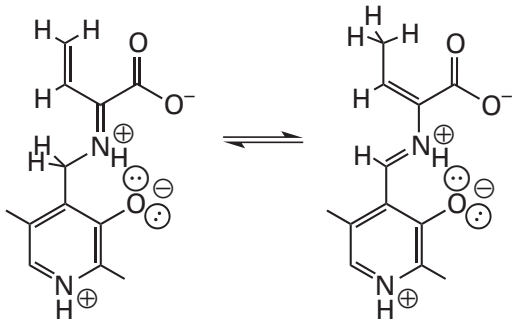
(2–38)

As in the case of cystathionine γ-synthase (Equation 2–34), the leaving group, methanethiol, is pushed out by the *N*-(5′-phosphopyridoxyl)enamine[132-134]



(2–39)

to give the *N*-(5′-phosphopyridoxyl)-1-carboxyprop-2-en-1-imine. A tyrosine in the active site performs the role of catalytic acid that hydronates the leaving group. As in the case of threonine synthase, a hydron is then removed from carbon 4′ of the 5′-phosphopyridoxyl group to produce the quinonoid intermediate of ethenyl glycine (**2–18**), and a hydron is added to carbon 4 of the quinonoid intermediate to accomplish a tautomerization



(2–40)

The product of this tautomerization is the pyridoximine of 2-aminobut-3-enoic acid, which is transiminated to give 2-aminobut-3-enoic acid free in solution. This 2-aminobut-3-enoic acid is converted nonenzymatically to the ultimate product of the reaction, 2-oxobutanoic acid (Equation 2–38). In the active sites of the enzymes from *P. putida*[132] and *Entamoeba histolytica*,[134] the catalytic base that removes the hydron from the carbon 4′ of the pyridoxyl group is the lysine forming the internal pyridoximine and the catalytic acid that adds the hydron to carbon 4 of the 1-carboxyprop-2-enimine is a tyrosine, again a cooperation of these two amino acids.

With *N*-(5′-phosphopyridoxyl)-1-carboxyprop-2-en-1-imine and its conjugate base, the quinonoid intermediate of ethenyl glycine, extension of the π molecular orbital system of the pyridoxal 5′-phosphate into an α-amino acid reaches its extreme. The hydronated pyridinio nitrogen at the base of the external pyridoximine functions to withdraw electrons from a σ bond around the α carbon in the external pyridoximine of the α-amino acid that was the original reactant. Upon removal of a hydron from the α carbon, the pyridyl nitrogen becomes a secondary amine and the π molecular orbital system that has been extended by one atom onto the α carbon becomes electron-rich because the two electrons that were in the σ bond to the hydrogen have been added to it. Carbon 4′ of the quinonoid intermediate is hydronated, causing the π molecular orbital system of the 3-hydroxypyridinio group to become dissociated from that of the iminium and the system to become electron-deficient because two of its electrons are now in the σ bond to the hydrogen. The nitrogen of the primary amino group of the α-amino acid that was in the original reactant then functions as a hydronated, cationic iminium to withdraw electron density from a σ bond to the β carbon. Upon dissociation of an electrophile from this carbon and the extension of

the π molecular orbital system by one atom, the electron-deficient iminium has become an electron-rich enamine as a result of the addition of the two electrons from the σ bond. This electron excess is then able to push away a leaving group from the γ carbon of the original α-amino acid. Upon dissociation of an electrophile from this carbon and extension of the π molecular orbital system by one atom, the electron-rich enamine has become an electron-poor, electrophilic 1-carboxyprop-2-enimine as a result of the dissociation of both electrons that were in the σ bond to the leaving group. A hydrogen on carbon 4′ can be readily removed as a hydron from this electron-poor, electrophilic intermediate to connect the two adjacent π molecular orbital systems. The resulting quinonoid intermediate of ethenyl glycine is now electron-rich and basic as a result of the incorporation of two electrons that were in the σ bond to the hydrogen, while the π molecular orbital system has only increased in size by one carbon atom.

Each of these extensions and the subsequent contractions of the successive π molecular orbital systems are usually represented by a series of arrows. "It must be concluded that pyridoxal phosphate was created to provide satisfaction and enlightenment to those enzymologists and chemists who enjoy pushing electrons."[135] The pushing of electrons with arrows, however, is simply a means to indicate the extensions and contractions of the π molecular orbital systems.

The basis for the ability of the two nitrogens, the hydronated pyridinio nitrogen and the hydronated iminio nitrogen, to promote opposite reactions on the same carbon and the same reaction at adjacent carbons is that they are an **odd number of atoms apart** from each other in the external pyridoximine. The influence of these two nitrogens could be propagated even beyond the γ carbon of an amine if incipient electrophiles and leaving groups were properly alternated so that the expanding π molecular orbital systems were not required to become excessively electron-rich or excessively electron-poor.

At each step in the extension of the π molecular orbital systems over the substrate, the electrophile that has just dissociated can be replaced by a different electrophile or the leaving group that has just dissociated can be replaced by a different nucleophile. In the reaction catalyzed by glycine hydroxymethyltransferase (Equation 2–10), the hydroxymethyl group that dissociates as a formal formaldehyde is replaced by a hydron. In the reaction catalyzed by cystathionine γ-synthase, the oxygen of the succinate that dissociates (Equation 2–34) is replaced by the sulfido group of L-cysteine. After these replacements are made, the reaction can proceed in reverse, passing backward through the same steps that led to loss of the electrophile or expulsion of the leaving group to regenerate the amine in which only the one substitution has occurred, as with glycine hydroxymethyltransferase or cystathionine γ-synthase (Equation 2–31), or in which two substitutions have occurred, as with threonine synthase (Equation 2–36).

At each step in the reactions catalyzed by pyridoxal 5′-phosphate, on the way forward or on the way back, the **nitrogen of the original amine** is formally either the nitrogen of an external pyridoximine that can be transiminated to regenerate the internal pyridoximine and a significantly altered derivative of the original amine (Equation 2–15) or the nitrogen of an *N*-(5′-phospho-pyridoxyl)imine that can be hydrolyzed to form pyridoxamine 5′-phosphate and the significantly altered or the unaltered ketone or aldehyde in which an oxo group replaces the original amino group (Equation 2–21). The array of possibilities is breathtaking.

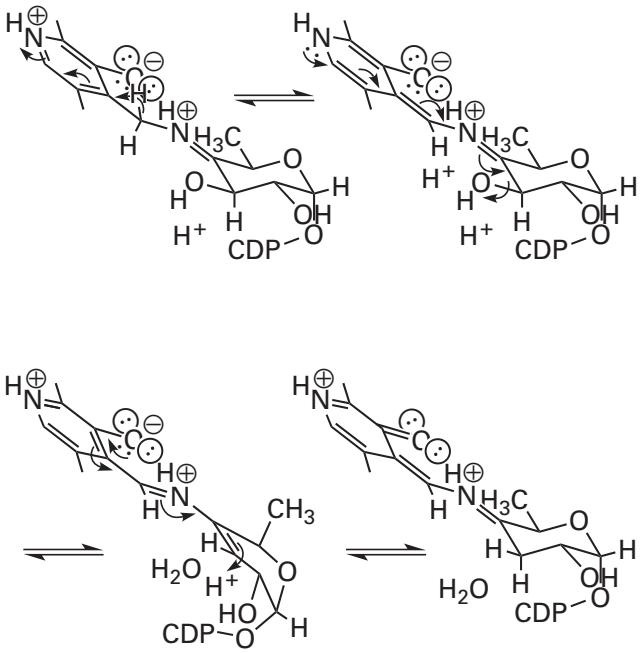
There are peculiar variations on this common theme for the mechanism of the reactions catalyzed by pyridoxal 5′-phosphate.

Pyridoxamine 5′-phosphate is used as a prosthetic group to **deoxygenate carbon 3 of a nucleotide 4-dehydro-6-deoxyhexose**.[136-139] For example, within the active site of CDP-4-dehydro-6-deoxyglucose reductase

$$\begin{aligned}&\text{CDP-4-dehydro-6-deoxy-D-glucose} + \\ &\quad 2\,e^- + 2\,H^+ \rightleftharpoons H_2O + \\ &\qquad \text{CDP-4-dehydro-3,6-dideoxy-D-glucose}\end{aligned} \qquad (2\text{–}41)$$

from *Yersinia pseudotuberculosis*, there is a tightly associated, prosthetic pyridoxamine 5′-phosphate. CDP-4-dehydro-6-deoxyglucose reductase, although it displays no homology in its sequence of amino acids, has a fold that is superposable on the fold of aspartate transaminase, and when four of the amino acids in its sequence are mutated to the respective amino acids that occupy those positions in aspartate transaminase, the mutant displays aspartate transaminase activity,[140] which seems to confirm the evolutionary relationship. Nevertheless, the unmutated enzyme catalyzes a quite different reaction.

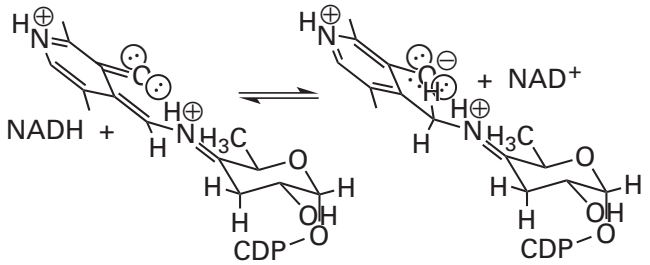
The pyridoxamine 5′-phosphate in the active site of CDP-4-dehydro-6-deoxyglucose reductase forms an *N*-(5′-phosphopyridoxyl)imine with the carbonyl group at carbon 4 in CDP-4-dehydro-6-deoxy-D-glucose by the usual nucleophilic substitution of an amino nitrogen for a carbonyl oxygen. Rather than the resulting iminium withdrawing electron density from the β carbon in the imine, however, as it usually would, a hydron is removed from carbon 4′ of the pyridoxamine 5′-phosphate, causing the iminium to become conjugated to the 5′-phospho-pyridoxyl group, and an electron-rich quinonoid intermediate is formed as the two electrons in the carbon–hydrogen bond that was just dissociated join the π molecular orbital system. The quinonoid intermediate then provides push to the elimination of the hydroxy group on carbon 3 of the hexose



(2–42)

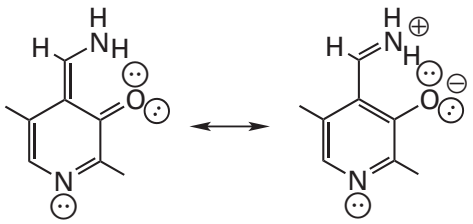
By removing the hydron from carbon 4′, the effect of the pyridoxamine 5′-phosphate on carbon 3 of the hexose has been shifted from its iminio nitrogen to its pyridinio nitrogen, from electron withdrawal, which would lead to the dissociation of a hydron, to electron donation, which leads to the loss of a leaving group. This shift allows the resulting quinonoid intermediate to push out the hydroxy group. A more novel aspect of the reaction, however, is the next step. Instead of withdrawing electron density from the distal carbon–carbon double bond, as usually happens, for example, with the external pyridoxamine of an 2-aminoacrylate, the pyridoxamine recruits the normally overlooked excess electron density of the **anionic, unhydronated 3-hydroxy group** of the pyridoxamine 5′-phosphate, which has gone unmentioned so far in the discussion. This recruitment pushes more electron density into the 2-aminoacrylyl group to permit its hydronation at carbon 3 rather than the usual addition of a nucleophile. This addition of a hydron is coincident with the oxidation of the pyridoxamine 5′-phosphate.[141-143]

There are two ways in which the **oxidized pyridoxamine 5′-phosphate within the adduct** between the now 4-dehydro-3,6-dideoxyhexose and the oxidized pyridoxamine 5′-phosphate is reduced to pyridoxamine 5′-phosphate so that it can begin the next turnover. It can be **reduced by a separate flavoprotein that is in turn reduced by NADH** or NADPH



(2–43)

to give the *N*-(5′-phosphopyridoxyl)imine of CDP-4-dehydro-3,6-dideoxy-D-glucose by addition of two electrons and the addition of a hydron to carbon 4′ of the 5′-phosphopyridoxyl group. Hydrolysis of the resulting *N*-(5′-phospho-pyridoxyl)imine produces CDP-4-dehydro-3,6-dideoxy-D-glucose, the product of the reaction, and pyridoxamine 5′-phosphate. There is, however, a related enzyme (31% identity; 1.5 gap percent), GDP-4-dehydro-6-deoxy-α-D-mannose 3-dehydratase, also from *Y. pseudotuberculosis*, that performs the same reaction on GDP-4-dehydro-6-deoxy-α-D-mannose, the reduction of carbon 3 of the 4-dehydro-6-deoxy-α-D-mannose from an alcohol to the saturated carbon. In the active site of this enzyme, however, the final imine homologous to the one in Equation 2–42 is hydrolyzed directly to the oxidized pyridoxamine 5′-phosphate, which is the external pyridoximine of ammonia



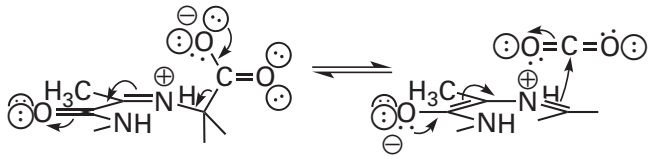
(2–44)

This pyridoximine is hydrolyzed to ammonia and pyridoxal 5′-phosphate, which is then **reduced by L-glutamate** in the usual way to the pyridoxamine 5′-phosphate needed for the next turnover (see Equations 2–26 and 2–29). In this instance, the reduction occurs after the dissociation of the imine, and it is performed by glutamate rather than NADH.

UDP-4-Amino-4,6-dideoxy-*N*-acetyl-β-L-altrosamine transaminase from *Helicobacter pylori*, which is related to CDP-4-dehydro-6-deoxyglucose reductase from *Y. pseudotuberculosis* (25% identity; 1.3 gap percent) and GDP-4-dehydro-6-deoxy-α-D-mannose 3-dehydratase from *Y. pseudotuberculosis*, also contains a prosthetic pyridoxamine 5′-phosphate in its active site, the sole purpose of which is to convert the 4-oxo group of a nucleotide 4-dehydro-6-deoxyhexose into a 4-amino group by a simple transamination rather than performing any reduction of its carbon 3.[144]

A prosthetic group that provides a catalytic capacity similar to that of pyridoxal 5′-phosphate is the covalently attached *N*-pyruvoyl group.[145,146] This group is found in several enzymes that decarboxylate α-amino acids, such as histidine decarboxylase,[145,146] adenosylmethionine decarboxylase,[147] and aspartate 1-decarboxylase.[148] The prosthetic group is a posttranslational modification. In a series of autocatalytic reactions, the peptide bond amino-terminal to a particular serine in the active site is hydrolyzed and the resulting amino-terminal serine is dehydrated to a *N*-pyruvoyl group.

As with pyridoxal 5′-phosphate, during the decarboxylation catalyzed by one of these posttranslationally modified active sites, an imine is formed between the respective amino acid and the *N*-pyruvoyl group. The amido group that is the peptide bond to the amino-terminal *N*-pyruvoyl group is held in the plane of the hydronated iminio group by a π molecular orbital system of five atoms, and it withdraws electron density from the σ bond to the carboxylato group, which is held by the enzyme parallel to the seven atoms and parallel to the π molecular orbital system[148]



(2–45)

In this instance, the electronegative acyl oxygen of the amido group rather than the pyridinio nitrogen of the external pyridoximine withdraws the electron density. The carbon from which the CO_2 leaves is normally hydronated by an acid on the enzyme to complete the decarboxylation, but in at least one instance, this acid or some other one occasionally hydronates carbon 2 of the *N*-pyruvoyl group (analogous to carbon 4′ of pyridoxal 5′-phosphate) and the enzyme is slowly inactivated by the consequent transimination.[147]

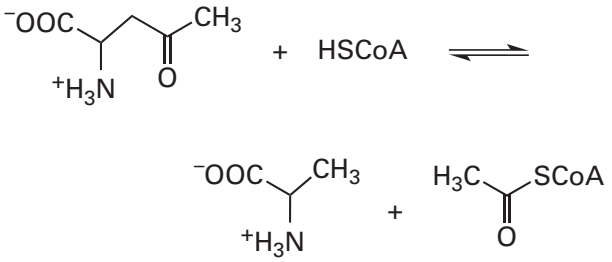
Problem 2–1: Write a complete mechanism for Equation 2–26 under catalysis by pyridoxal 5′-phosphate.

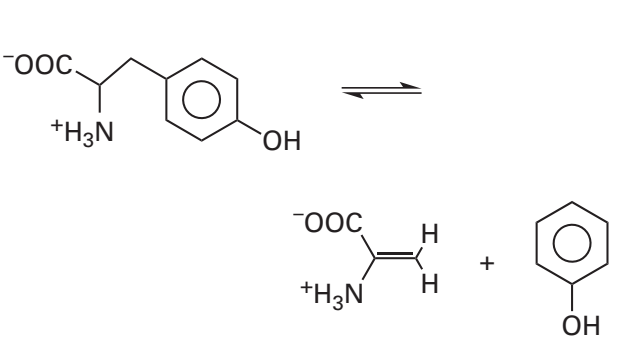
Problem 2–2: Write a complete mechanism for glycine hydroxymethyltransferase (Equation 2–10) incorporating Equation 2–11.

Problem 2–3: Write mechanisms for the following reactions that are mediated by pyridoxal 5′-phosphate:

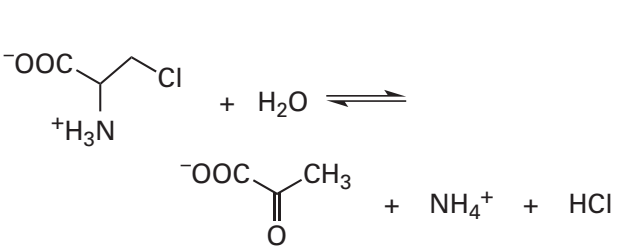
(A)



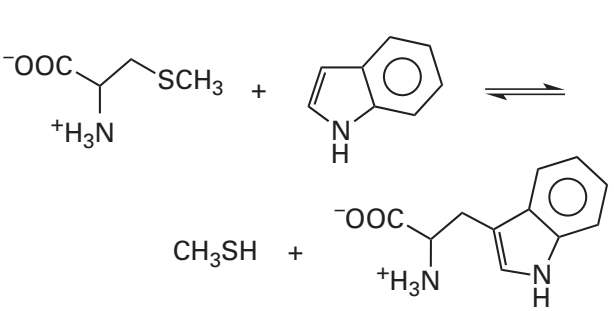
(B)



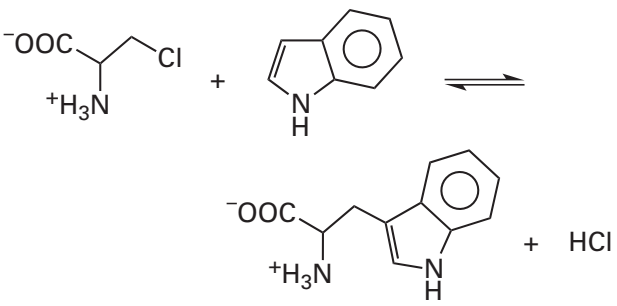
(C)



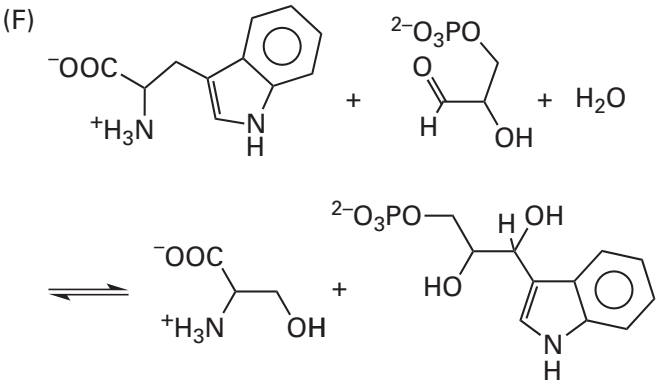
(D)



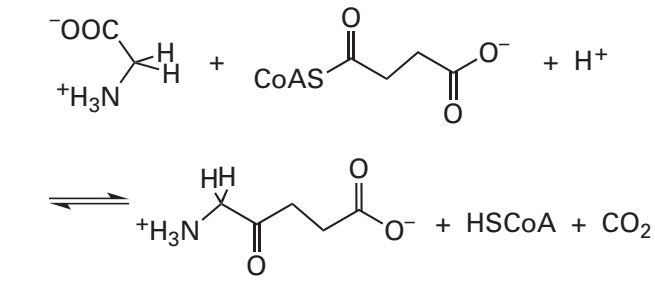
(E)



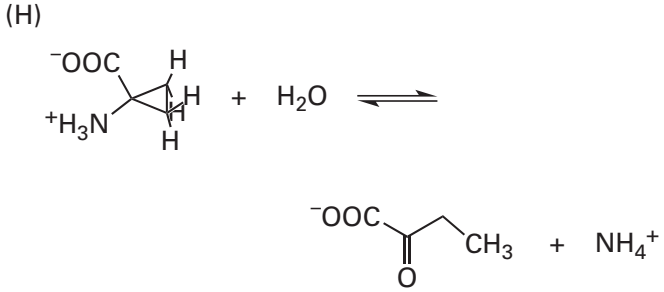
(F)



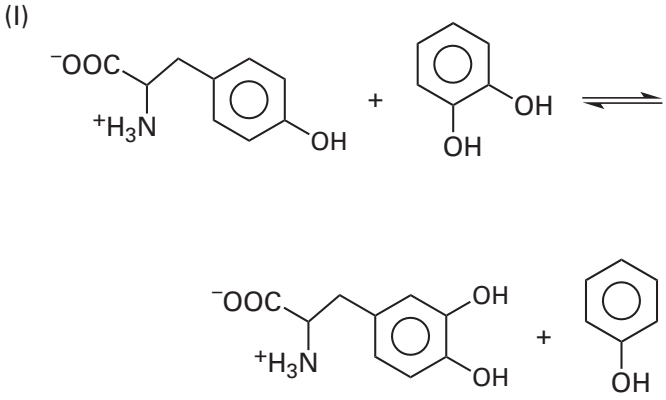
(G)



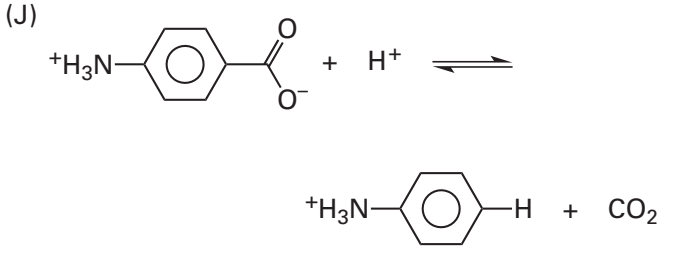
(H)



(I)



(J)



Problem 2–4: Write a mechanism involving pyridoxal 5′-phosphate for the reaction

$$\text{L-serine} + \text{indole} \rightleftharpoons H_2O + \text{L-tryptophan}$$

Show how the same enzyme would also catalyze the reaction[149]

$$\text{pyridoxamine 5′-phosphate} + \text{3-(3-indolyl)pyruvate} \rightleftharpoons \text{pyridoxal 5′-phosphate} + \text{L-tryptophan}$$

Problem 2–5: Write complete mechanisms for the catalysis performed by 5-aminolevulinate synthase[71]

$$\text{glycine} + \text{succinyl-SCoA} + H^+ \rightleftharpoons \text{HSCoA} + CO_2 + \text{5-aminolevulinate}$$

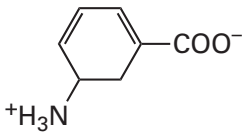
and serine *C*-palmitoyltransferase[150]

$$\text{L-serine} + \text{palmitoyl-SCoA} + H^+ \rightleftharpoons \text{HSCoA} + CO_2 + \text{3-dehydro-D-sphinganine}$$

both of which use pyridoxal 5′-phosphate as a prosthetic group.

Problem 2–6: Write a complete mechanism for the reaction catalyzed by cystathionine γ-synthase (Equation 2–31). In your mechanism, label the intermediates as internal pyridoximine, external pyridoximine, quinonoid intermediate, *N*-(5′-phosphopyridoxyl)imine, and *N*-(5′-phosphopyridoxyl)-enamine.

Problem 2–7: The compound gabaculine



inhibits 4-aminobutyrate—2-oxoglutarate transaminase by forming an aromatic, anilinium adduct with the pyridoxal 5′-phosphate that is the prosthetic group for this enzyme.[151] Write the mechanism for the formation of this adduct.

Problem 2–8: Write the mechanism of the D-serine ammonia-lyase reaction

$$\text{D-serine} \rightleftharpoons NH_4^+ + \text{pyruvate}$$

as it is catalyzed by the pyridoxal 5′-phosphate bound to the enzyme. Show clearly the role of the pyridoxal 5′-phosphate in each step of the reaction. In each step, label every sp^2 carbon conjugated to the aromatic ring. Watch closely the expansion and then contraction of the π system as atoms are turned from sp^3 into sp^2 and back into sp^3. What step in the reaction requires the pyridoxal the most?

Problem 2–9: Write a complete mechanism for the reaction catalyzed by threonine synthase (Equation 2–36) as it is catalyzed by pyridoxal 5′-phosphate.

Problem 2–10: Glutamate-1-semialdehyde 2,1-aminomutase from *Pisum sativum* is an enzyme with either the internal pyridoximine of pyridoxal 5′-phosphate or pyridoxamine 5′-phosphate in its active site, depending on its history. It converts (*S*)-2-amino-4-carboxybutanal (L-glutamate 1-semialdehyde) to 1-amino-4-carboxy-2-oxobutane (5-aminolevulinate).[152]

(a) When 4,5-diaminopentanoic acid is added to a solution of the enzyme, the absorbance at 416 nm, arising from the internal pyridoximine of pyridoxal 5′-phosphate, decreases as the absorbance at 345 nm, arising from pyridoxamine 5′-phosphate, increases stoichiometrically.

(b) When 4,5-dioxopentanoic acid is added to a solution of the enzyme, the absorbance at 345 nm, arising from the pyridoxamine 5′-phosphate, decreases as the absorbance at 416 nm, arising from the internal pyridoximine of pyridoxal 5′-phosphate, increases stoichiometrically.

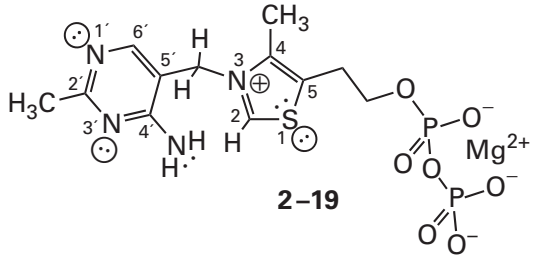
(c) When a mixture of 4,5-dioxopentanoic acid and 4,5-diaminopentanoic are added to a solution of the enzyme, 1-amino-4-carboxy-2-oxobutane is produced at a rate equal to 40% of the rate of the normal reaction catalyzed by the enzyme.

(d) Increasing the fraction of pyridoxamine 5′-phosphate in the enzyme causes an equivalent increase in the rate of the normal reaction catalyzed by the enzyme.

(A) Write out the structures of the two substrates for the enzyme.
(B) Write a mechanism for the normal reaction catalyzed by the enzyme that involves both the internal pyridoximine of pyridoxal 5′-phosphate and pyridoxamine 5′-phosphate, that involves a *gem*-diamine, and that explains all these results.

Thiamine Diphosphate

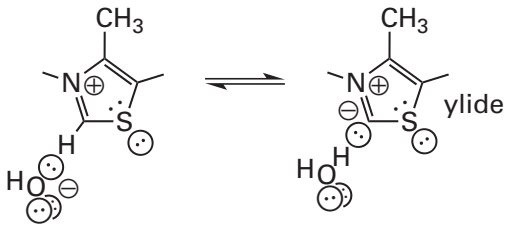
Thiamine diphosphate



2–19

is a **prosthetic group that is tightly, but noncovalently, bound to the active sites of the enzymes** in which it has a functional role. Thiamine diphosphate is complicated enough that several locations in its structure were sequentially proposed to be the functionally important site[153] before it was identified as carbon 2, sandwiched between the iminium nitrogen and the sulfur in the thiazolium ring.[154] Although enzymes using it as a prosthetic group have a strict requirement for thiamine diphosphate, perhaps because the diphospho group nails it into the active site, the dephospho parent, thiamine, is almost identical chemically to thiamine diphosphate because the diphosphate is so far removed from the thiazole ring. In model studies in solution, thiamine is often used as the catalyst, and it is assumed that the chemistry observed is very similar if not identical to the chemistry that would have been observed with thiamine diphosphate.

Carbon 2 of thiamine is acidic and readily exchanges its hydron with a deuteron in solution[154] by forming the zwitterionic ylide



(2–46)

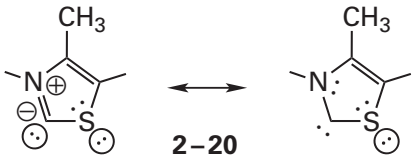
The observed rate constant for exchange of the hydron on carbon 2 of thiamine,[155] at pH 3.5 and 30 °C, is 1.8×10^{-4} s^{-1}, and this observed rate constant is directly proportional to [OH$^-$] with a slight inflection at the pK_a of the aminopyrimidine (5.5) that lowers the rates of exchange by a factor of 2.5 at the higher values of pH.[156,157] The pK_a for the dissociation of the hydron from carbon 2 of thiamine has been measured directly using a rapid kinetic titration to avoid the rapid decomposition of the thiazolium ring that occurs at high concentrations of hydroxide.[158] Nitrogen 1′ is the most basic nitrogen in the 4′-aminopyrimidinyl group in thiamine. When it is hydronated so that the 4′-aminopyrimidinium is cationic, the pK_a for the dissociation of the hydron from carbon 2 is 17.7; when the 4′-aminopyrimidinyl group is neutral, the pK_a is 18.0.[157,159] There are several reasons why thiamine, in which carbon 2 is not α to a carbonyl or acyl group, nevertheless is such a strong carbon acid.

First, because it is within an aromatic heterocycle, **hybridization of the acidic carbon** is sp^2, sp^2, sp^2, p. Because it is formed from one of the sp^2 atomic orbitals of the carbon atom, the σ bond to the hydrogen holds the pair of bonding electrons closer to the nucleus. The sp^2 atomic orbital also holds the lone pair of electrons formed upon dissociation of the hydron closer to the nucleus than if the carbon were hybridized sp^3, sp^3, sp^3, sp^3. These properties cause the carbon–hydrogen bond to be more acidic and the conjugate base to be less basic[153] than those in carbon acids in which carbon is hybridized sp^3, sp^3, sp^3, sp^3.

Second, **the conjugate base of thiamine is an ylide**. An ylide is a compound in which an anionic carbon (or another anionic atom) is attached directly to a heteroatom carrying a fixed formal positive elementary charge. In the case of thiamine, the anionic carbon is produced by dissociation of a hydron from carbon 2 and the heteroatom carrying the fixed positive formal elementary charge is nitrogen 3. Nitrogen 3 has no vacant bonding orbital able to absorb the adjacent negative formal elementary charge by resonance. 1,3-Dimethylimidazoliums, the conjugate bases of which are ylides, display carbon acidity similar to that of 3-methylthiazoliums.[158] In the case of the ylide that is the conjugate base of thiamine (Equation 2–46), the negative formal elementary charge on carbon 2 is stabilized by the electrostatic field of the adjacent formal positive elementary charge on nitrogen 3. The stabilization in the ylide can be seen in semiempirical calculations of the electronic structure of the ylide of thiamine,[160] The adjacent nitrogen with a positive elementary

charge in thiamine from which the hydron on carbon 2 has not dissociated, the conjugate acid of the ylide, weakens the σ bond between the hydrogen and carbon 2. This effect is manifested in the deshielding of carbon 2 observed in the nuclear magnetic resonance spectrum.[161]

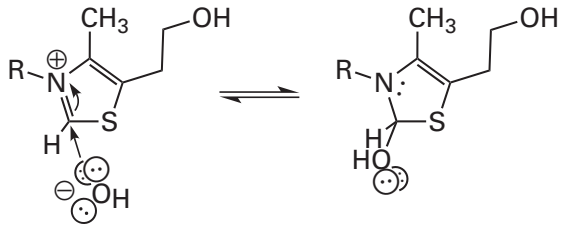
Third, the ylides that are the conjugate bases of *N*,*N*′-dialkylimidazoles and *N*-alkylthiazoles, such as thiamine, are further stabilized by **a delocalization that causes them to resemble a carbene**,[162] as illustrated by the resonance form



2–20

Fourth, **the neighboring sulfur stabilizes the negative elementary charge** in the σ lone pair on carbon 2 of the ylide of thiamine by $dp\pi$ overlap. This effect can be observed by comparing the rate of hydrogen exchange of 3,4-dimethylthiazolium and 1,3,4-trimethylimidazolium.[156] Although the respective carbon–hydrogen bonds in these two ions are similarly situated with respect to the heteroatoms and the only difference between them is the substitution of a neutral sulfur with a neutral methylated nitrogen, the hydrogen on carbon 2 of 3,4-dimethylthiazolium exchanges 3000 times faster than does the hydrogen on carbon 2 of 1,3,4-trimethylimidazolium. The salient difference is that sulfur has vacant *d* orbitals of suitable size and energy level to accept electron density within the plane of the ring while nitrogen does not.

Finally, the **4′-aminopyrimidinyl group on nitrogen 3 of thiamine enhances its acidity**. 3,4-Dimethylthiazolium ion (with a methyl group at carbon 3) exchanges the hydrogen on carbon 2 about 10-fold less readily than thiamine [with a (4-amino-2-methylpyrimidin-5-yl)-methyl group at carbon 3].[161] This difference results from the fact that the 4′-aminopyrimidine attached through a methylene at nitrogen 3 of the thiazole in thiamine diphosphate (**2–19**) withdraws electrons inductively from that nitrogen.[157] This inductive electron withdrawal is also reflected in the greater susceptibility[163] of thiamine than 3,4-dimethyl-5-(2-hydroxyethyl)thiazolium to addition of hydroxide at carbon 2



(2–47)

This electron withdrawal is inductive[157] and takes place through the σ bonds between nitrogen 3 and the 4′-aminopyrimidine because there is a saturated benzylic carbon between the two unsaturated rings.

The first step in the enzymatic reactions catalyzed by thiamine diphosphate is removal of the hydron on carbon 2 to form the ylide of thiamine. In the unoccupied active site of human pyruvate dehydrogenase (acetyl-transferring), the pK_a for the hydron on carbon 2 of the prosthetic group has been estimated[164] to be around 9. This value of pK_a is considerably less than that for thiamine diphosphate in solution. In the unoccupied active sites of pyruvate decarboxylase from *S. cerevisiae*, pyruvate decarboxylase from *Zymomonas mobilis*, and transketolase from *S. cerevisiae*, the rate constants[165] at which the hydrogen on carbon 5 of the thiamine diphosphate exchanges for a deuterium in ^2H_2O are 1 s^{-1}, 100 s^{-1}, and 60 s^{-1} at 4 °C. The value of pK_a and these rate constants demonstrate that the ylide of thiamine diphosphate forms readily in the active site of an enzyme, even in the absence of a substrate. One reason for this facile acid dissociation is the assistance of the 4′-anilino nitrogen of thiamine diphosphate (**2–19**) itself.

Although there is no indication that it acts as an intramolecular base to remove the hydron from carbon 2 when it is in free solution,[157] the **4′-amino group of thiamine is intimately involved in the removal of the hydron from carbon 2** when thiamine diphosphate is within the unoccupied active site of an enzyme. In the active sites of enzymes using thiamine diphosphate prosthetically, the thiamine is invariably[166-174] in a conformation in which its own 4′-amino nitrogen, which is five atoms away from carbon 2, ends up within 0.30–0.35 nm of carbon 2 (Figure 2–5A).[172,175,176] If 4′-desaminothiamine diphosphate is incorporated into an active site rather than thiamine diphosphate, the rate at which the hydron on carbon 2 is exchanged for a deuteron decreases by a factor of 30,000 to 700,000.[165]

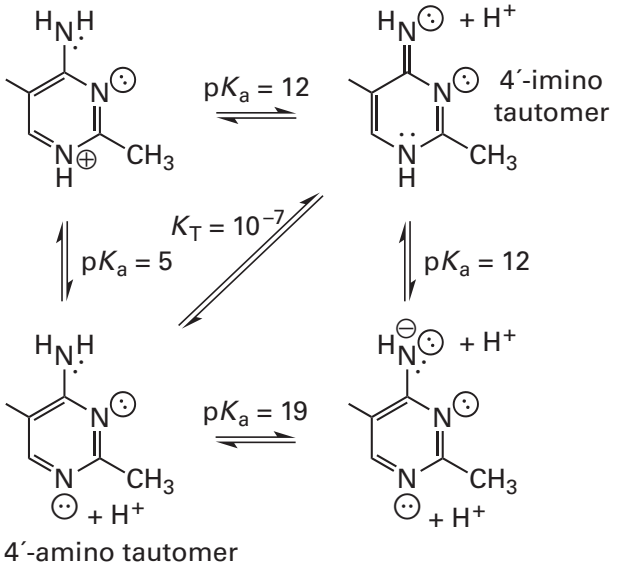
Figure 2–5: Stereodrawings[50] of three crystallographic molecular models of active sites containing prosthetic thiamine diphosphates in three different states: the initial unmodified thiazole, the adduct between the ylide of the thiazole and a carbonyl group, and an α-hydroxy enamine incorporating the thiazole. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, large light gray atoms are sulfurs, and large dark gray atoms are atoms of phosphorus. In each active site, the carboxylate of a glutamate side chain forms a hydrogen bond with nitrogen 1′ of the thiamine diphosphate; the imidazolyl group of a histidine forms a hydrogen bond with a molecule of water, the hydroxy group of the initial adduct, or the hydroxy group of the α-hydroxy enamine, respectively; and nitrogen 4′ of the 4′-aminopyrimidine of the thiamine diphosphate forms a hydrogen bond to the same molecule of water or the same hydroxy groups. **(A)** The thiamine diphosphate within the active site of pyruvate dehydrogenase (acetyl-transferring) from *E. coli*.[172] The gene encoding the enzyme was transferred to a plasmid, overexpressed in cultures of *E. coli*, purified, and crystallized. The thiamine diphosphate, Glutamate 571, Histidine 640, and a molecule of water (white sphere) from the resulting crystallographic molecular model are presented in the drawing. The molecule of water is in the plane of the thiazole, immediately adjacent to the hydrogen on carbon 2 of the thiazole and only 0.30 nm from carbon 2, a distance much shorter than that dictated by a van der Waals contact, so the interaction is shown as a hydrogen bond. **(B)** The intermediate analogue, 2-(1″-hydroxy-1″-methylphosphonoethyl)thiamine diphosphate, within the active site of pyruvate dehydrogenase (acetyl-transferring) from *E. coli*.[175] The cloned and purified enzyme was cocrystallized with 2-(1″-hydroxy-1″-methylphosphonoethyl)thiamine diphosphate, an analogue of 2-(1″-carboxy-1″-hydroxyethyl)thiamine diphosphate, the adduct formed between pyruvate and thiamine diphosphate in the first step of the enzymatic reaction. In this analogue of the intermediate, the normal carboxy group is replaced by a methylphosphonyl group that cannot be decarboxylated. The σ bond between the methylphosphonyl group and the 1-hydroxyethyl group at carbon 2 of the thiamine diphosphate, which is homologous to the normal σ bond to the carboxy group, is firmly held normal to the plane of the π molecular orbital system of the thiamine by the two hydrogen bonds to the hydroxy group. **(C)** 2-(1″,2″-Dihydroxyethylidene)-2,3-dihydrothiamine diphosphate (Equation 2–57), an α-hydroxy enamine incorporating the thiazole within the active site of transketolase from *S. cerevisiae*.[176] The gene encoding the wild-type enzyme was overexpressed in cultures of *S. cerevisiae*, purified, and cocrystallized with 3-hydroxypyruvate. The 3-hydroxypyruvate, unlike one of the usual ketones that is a substrate for the enzyme, is decarboxylated, and in the absence of an aldehyde to act as an acceptor, the decarboxylated product, 2-(1″,2″-dihydroxyethylidene)-2,3-dihydrothiamine diphosphate, is stable. Nitrogen 4′ of the thiamine diphosphate is 0.30 nm from the hydroxy oxygen, 0.29 nm from the α carbon, and 0.31 nm from the carbon 2 of the thiazole, distances much shorter than those dictated by a van der Waals contact, so the three interactions are shown as hydrogen bonds, even though in the latter two cases there are no hydrogens with which to form a hydrogen bond. The thiamine diphosphate, Glutamate 418, and Histidine 481 from the resulting crystallographic molecular model are presented in the drawing.

The lone pair of electrons on the 4′-amino group in thiamine is not basic ($pK_a = 0$)[157] because it resides on an anilino nitrogen and consequently is conjugated with the pyrimidinyl ring. The σ lone pair of electrons, however, within the plane of the pyrimidinyl ring on the **4′-imino group of the 4′-imino tautomer of the 4′-aminopyrimidinyl group is basic**[157]



(2–48)

The lone pair of electrons on the 4′-imino tautomer should be basic enough (the pK_a of its conjugate acid is 12) to remove the hydron from carbon 2 of the thiazolium ion to produce the ylide.

In solution, however, the 4′-imino tautomer is unstable relative to the tautomer in which the hydron resides on the nitrogen of the 4′-amino group rather than on nitrogen 1′ ($K_T = 10^{-7}$). In most of the enzymes that use thiamine diphosphate prosthetically, nitrogen 1′ of the 4′-aminopyrimidine forms a **hydrogen bond to the carboxyl oxygen of a glutamic acid** (Figure 2–5).[167-172,174,177] This hydrogen bond, by fixing a hydron on nitrogen 1′ because the carboxy group (p$K_a = 4.3$) is a stronger acid than the hydronated pyrimidinyl group (p$K_a = 5$), should stabilize the desired 4′-imino tautomer by lowering the pK_a of nitrogen 4′ from 19 to 12 (Equation 2–48). When this glutamate in pyruvate decarboxylase from *S. cerevisiae* is mutated to a glutamine, its enzymatic activity decreases by a factor of 2500,[178] and the rate of exchange for a hydron for a deuteron at carbon 2 of the thiamine diphosphate within the active site decreases by a factor of greater than 300.[165]

Because it has a nonpolar side chain, Isoleucine 415 in pyruvate decarboxylase from *S. cerevisiae*, which covers one face of the 4′-amino-

pyrimidine of the thiamine diphosphate, should also stabilize the 4′-imino tautomer by promoting dissociation of the hydron from the 4′-amino group when nitrogen 1′ is hydronated and the 4′-aminopyrimidine is cationic (Equation 2–48). Mutating Isoleucine 415 to valine or alanine decreases the enzymatic activity of pyruvate decarboxylase by factors of 10 or 200, respectively.[179]

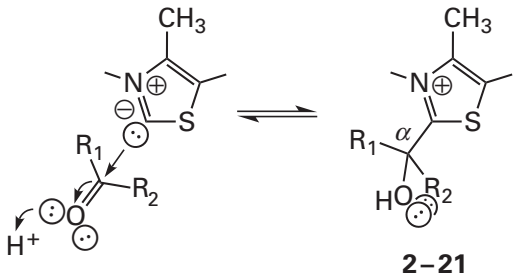
That the 4′-imino tautomer does form when thiamine diphosphate is bound by an enzyme for which it is a prosthetic group is indicated by the existence of a maximum absorption around 305 nm in the **circular dichroic spectra** of complexes between those enzymes and thiamine diphosphate.[180-182] The ultraviolet absorption spectrum of the neutral conjugate base of 1-methyl-4-aminopyrimidinium, the stable homologue of the 4′-imino tautomer, has a maximum absorption at 307 nm in dimethyl sulfoxide.[183] The circular dichroic absorption arising from the 4′-amino tautomer (Equation 2–48) when thiamine diphosphate is bound by an enzyme has a maximum at around 330 nm. In the active sites of pyruvate oxidase from *Lactobacillus plantarum* and human pyruvate dehydrogenase (acetyl-transferring), both circular dichroic absorptions, the one with maximum absorbance around 305 nm and the one with maximum absorbance around 330 nm, are observed in approximately equal ratio.[164] This observation indicates that the active site of each of these enzymes, for all the reasons just mentioned, has increased the tautomeric ratio from 10^{-7} to around 1. For each of these enzymes, the two maximum absorptions decrease in magnitude in concert as the solution is acidified as expected for a pair of tautomers turning into their common conjugate acid (Equation 2–48). The apparent pK_a for this conversion of the tautomeric pair to the conjugate acid is 5.6 for pyruvate oxidase and 7.1 for pyruvate dehydrogenase (acetyl-transferring). The apparent values of pK_a for the same conversion for thiamine diphosphate in the active sites of benzoin aldolase from *P. fluorescens* and benzoylformate decarboxylase from *P. putida* are 7.4 and 7.5. These observations and the fact that the tautomeric equilibrium is near 1 in each case suggest that the pK_a for the 4′-imino tautomer in the active site of each of these enzymes is close to that measured for the respective tautomeric mixture, rather than the pK_a of 12 that is observed in solution (Equation 2–48).

All these observations together indicate that, in an active site of an enzyme for which it is a prosthetic group, a significant fraction of the thiamine diphosphate is in the basic 4′-imino tautomer.

The two dihedral angles, however, that are enforced at the methylene carbon connecting nitrogen 3 and carbon 5′ by the active sites of most enzymes when they are unoccupied by substrate usually place nitrogen 4′ in an **unfavorable orientation** (Figure 2–5A) to remove the hydron from carbon 2, which is in the plane of the thiazole.[167-169,172,184] In crystallographic molecular models of the unoccupied active sites of most of the enzymes that use thiamine diphosphate as a prosthetic group, however, there is a molecule of water that forms hydrogen bonds to carbon 2 and the 4′-imino group. This molecule of water participates in a hydrogen bond with the 4′-imino group and the imidazolyl group of a histidine or to the acyl oxygen and carbamoyl nitrogen–hydrogen of a glutamine. Because it is positioned in line with the carbon–hydrogen bond, this molecule of water is in a much more favorable location than the 4′-imino group to remove the hydron from carbon 2. In the crystallographic molecular model of thiamine diphosphate within the active site of pyruvate dehydrogenase (acetyl-transferring) from *E. coli* (Figure 2–5A), the oxygen of the molecule of water is only 0.30 nm from carbon 2 of the thiamine diphosphate. This distance is considerably less than the distance that would be dictated by the sum (0.38 nm) of the van der Waals radii[185] of a hydrogen (0.115 nm) and an oxygen (0.15 nm) and the length of a carbon–hydrogen bond (0.11 nm). The fact that the distance is so short and the fact that this molecule of water is in line with the carbon–hydrogen bond both suggest that this molecule of water, relaying the basicity of the 4′-iminopyrimidine, is the base that catalyzes the exchange of that hydrogen by removing the hydron from carbon 2 of the thiamine diphosphate in the unoccupied active site.

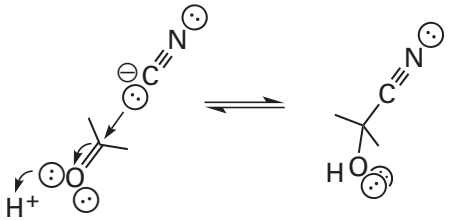
So far the discussion has described the behavior of the unoccupied active site of an enzyme that has a prosthetic thiamine diphosphate. The situation changes significantly when a substrate associates with the active site.

The ylide of thiamine diphosphate reacts with an aldehyde or a ketone to form the product of an addition to a carbonyl



(2–49)

This adduct is analogous to the cyanohydrin that forms between an aldehyde or a ketone and cyanide



(2–50)

In a cyanohydrin, a weakly basic carbanion that has three bonds to a heteroatom adds to an aldehyde or a ketone.

During formation of the adduct with thiamine diphosphate, the 4′-amino group of the thiamine diphosphate usually ends up in a hydrogen bond with the α-hydroxy group* of the adduct (Figure 2–5B)[175,186] after the addition has occurred. The imidazolyl group of the histidine that had formed a hydrogen bond to the molecule of water adjacent to carbon 2 of the thiamine diphosphate (Figure 2–5A) also forms a hydrogen bond with this hydroxy group,[175,176,186] so the ultimate distribution of hydrons at this location is unclear, but in at least one other enzyme that uses thiamine diphosphate as a prosthetic group, the partner in this hydrogen bond is the carbamoyl nitrogen–hydrogen of a glutamine[167] rather than the imidazolyl group of a histidine. The glutamine would not be able to hydronate the oxygen.

The fact that the carbonyl oxygen of the reactant, now a hydroxy group, replaces the fixed molecule of water that participated in hydrogen bonds with the imidazolyl group of the histidine and the 4′-amino group of the thiamine diphosphate in the adduct between the reactant and thiamine diphosphate is consistent with this molecule of water being the base that removes the hydron from carbon 2 of the thiamine diphosphate in the normal sequence of events. After the it has transferred the hydron from carbon 2 to the 4′-amino group, it would be a molecule of water that can be easily displaced by the oxygen of the carbonyl as the now hydronated 4′-amino group hydronates the oxygen, and it becomes a hydroxy group.

There is no doubt that the thiazolium ring in an adduct between thiamine and a carbonyl group (**2–21**) is aromatic because every bond within the ring displays the shortening expected for a conjugated heterocycle.[187] The $3p$ atomic orbitals of sulfur in the cyclic π molecular orbital system, however, do not overlap efficiently with the $2p$ atomic orbitals of its two neighbors, and the more effective overlap is between a d orbital on sulfur and the p orbitals of the carbons and the nitrogen. Consequently the aromaticity is weak. This weakening of the aromaticity causes the nitrogen within the ring to be less like the nitrogen in an alkylpyridinium and more like the nitrogen of an iminium. The diminution of the aromaticity also explains the facility with which a hydroxide adds nucleophilically to carbon 2 of thiamine itself to form the hemiaminal (Equation 2–47),[158] even though this addition necessarily destroys the aromaticity of the ring.

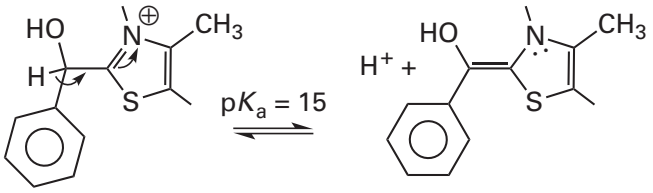
Because it resembles the cationic nitrogen in an iminium, the cationic nitrogen in the *N,N*-dialkylthioimidoester* in the thiazolio ring of an adduct between thiamine and a carbonyl group (2–21) withdraws electron density from the σ bonds around the former carbonyl carbon and promotes the dissociation of an incipient electrophile.

In the adduct between thiamine diphosphate and an aldehyde, one of the substituents bonded to the α carbon is a hydrogen, and this **hydrogen can dissociate as a hydron**. Adducts between thiamine and aldehydes (R_1 = H in **2–21**) are readily synthesized stable compounds, and the acidity of the hydrogen on the α carbon can be demonstrated by following its exchange with a deuteron in solution[188] or directly by observing the formation of its conjugate base.[189]

*As was the case with adducts of pyridoxal phosphate, the carbon atoms controlled by the thiazolyl group in thiamine diphosphate will be labeled α to indicate that the carbon atom is α to carbon 2 of the thiazole (Equation 2–22), β to indicate the carbon atom is once removed from carbon 2 of the thiazole, and so forth. The carbon designated as α is the carbon that was in the carbonyl group of the original ketone or aldehyde.

*Recall that a thioester resembles a ketone more than it does an ester, so a thioimidoester resembles an imine more than it does an imidoester.

Values of pK_a for these hydrons have been measured in solution for 2-(1″-hydroxyethyl)thiamine (R_1 = H and R_2 = CH_3 in **2–21**; pK_a = 19)[190] and 2-(1″-hydroxybenzyl)-4′-deamino-4′-hydroxythiamine (R_1 = H and R_2 = C_6H_5 in **2–21**; pK_a = 15)[191]



(2–51)

The removal of the hydron from the latter adduct (Equation 2–51) by bases the conjugate acids of which have a $\Delta pK_a \leq -3$ (previously Equation 1–10)

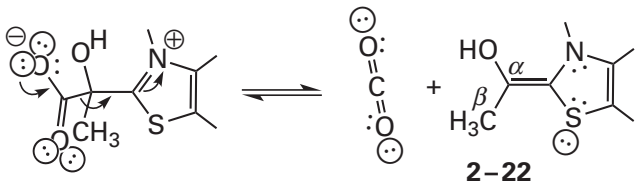
$$\Delta pK_{a,AB} \equiv pK_{a,HB} - pK_{a,HA} = \log \frac{K_{a,HA}}{K_{a,HB}} \equiv \log K_{eq,AB} \qquad (2–52)$$

shows a Brønsted coefficient of 1 as expected (Figure 1–1), but the rates are slower than those expected from the asymptotes in Figure 1–1 by a factor of 10^6 because the hydron is still being removed from carbon.[191]

In the adduct between thiamine diphosphate and a 2-oxo carboxylic acid, one of the substituents bonded to the α carbon is a carboxylate, and the **carboxylate can dissociate as carbon dioxide**. For example, in the reaction catalyzed by the enzyme pyruvate decarboxylase

$$\text{pyruvate} + H^+ \rightleftharpoons CO_2 + \text{acetaldehyde} \qquad (2–53)$$

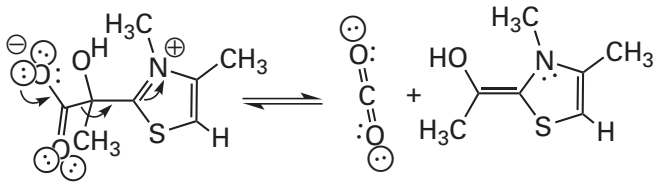
the immediate adduct between thiamine diphosphate and pyruvate (Equation 2–49; R_1 = COO^- and R_2 = CH_3) accounts for the decarboxylation



2–22

(2–54)

The analogous adduct of 3,4-dimethylthiazole and pyruvate has been synthesized and shown to decarboxylate readily[192]



(2–55)

when it is in solution but only when the carboxy group is unhydronated and anionic as written.

The adduct between thiamine itself and pyruvate has also been synthesized, and the rate constants and equilibrium constants for various steps in the **mechanism of its decarboxylation** (Figure 2–6) have been measured.[193] As is required by the fact that both thiamine and pyruvate are achiral, the hydroxyethylthiamine produced by the decarboxylation of the adduct of thiamine and pyruvate and its hydronation is racemic at the α carbon.[194] The decarboxylation of this adduct, once it has formed, is catalyzed by general acids, a fact suggesting that 2-(1″-hydroxyethylidene)-2,3-dihydrothiamine diphosphate (**2–22**), the α-hydroxy enamine* that results from the decarboxylation (Equation 2–55), in a noncovalent complex with the dissociated carbon dioxide, which is the immediate product of the decarboxylation, is hydronated from solution to prevent its recarboxylation (reverse of Equation 2–54) before the carbon dioxide diffuses out of the shell of solvent. The dissociation of carbon dioxide from the solvated encounter complex would be an irreversible, rate-limiting step and therefore must follow the hydronation to explain the general acid catalysis.

An interesting observation made during the study of the decarboxylation of the adduct between 3,4-dimethylthiazole and pyruvate (Equation 2–55) was that, as expected from a reaction in which separated formal elementary charges of opposite sign are neutralized, the decarboxylation is accelerated by performing it in nonpolar solvents rather than polar solvents. In water at 46 °C, the rate of the decarboxylation[192] was 0.48×10^{-3} s^{-1}, but in ethanol

*Just as the sulfur in an *N,N*-dialkylthioiminoester participates only weakly in the π molecular orbital system of an adduct between thiamine and a carbonyl group, the sulfur should also participate only weakly in the π molecular orbital system of 2-(1″-hydoxyethylidene)-2,3-dihydrothiamine diphosphate. Consequently, 2-(1″,2″-dihydoxyethylidene)-2,3-dihydrothiamine diphosphate behaves as an *N,N*-dialkyl-α-hydroxy enamine.

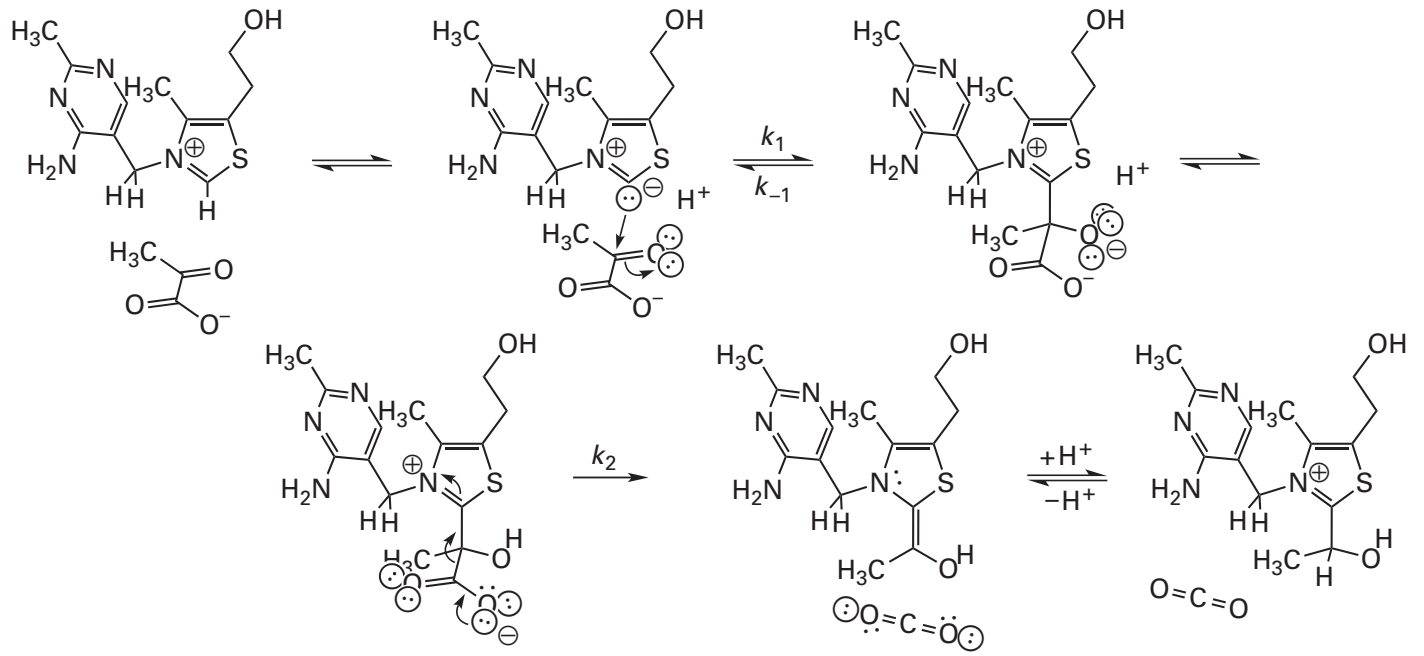


Figure 2–6: Mechanism of the decarboxylation of pyruvate catalyzed by thiamine in solution at 25 °C.[193] The ylide is formed by removing the hydron from carbon 2 ($pK_a = 18$). The adduct between thiamine and pyruvate forms in a bimolecular reaction ($k_1 = 6.5 \times 10^{-2}$ M^{-1} s^{-1}; $k_{-1} = 0.5$ s^{-1}). The oxyanion hydronates to form the conjugate acid ($pK'_a = 13.6$), 2-(1″-carboxy-1″-hydroxy-1″-methyl)thiamine. The 2-(1″-carboxy-1″-hydroxy-1″-methyl)thiamine then decarboxylates ($k_2 = 4 \times 10^{-5}$ s^{-1}) to form the enamine, which hydronates on carbon to give the final product. The final product is in turn the adduct of thiamine and acetaldehyde.

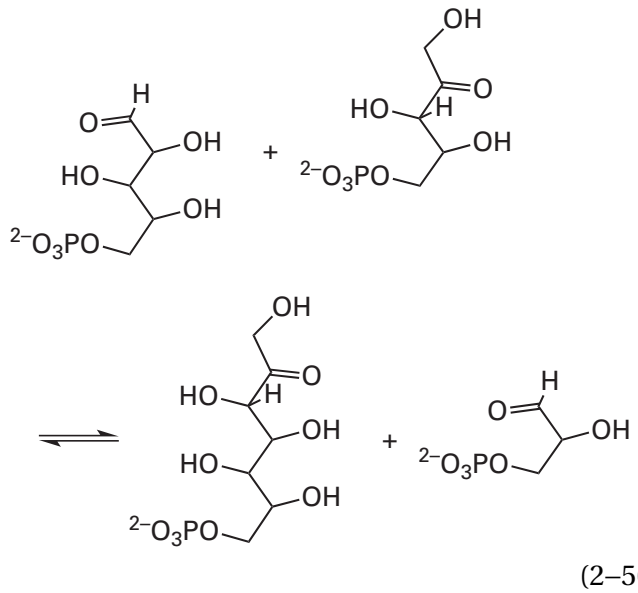
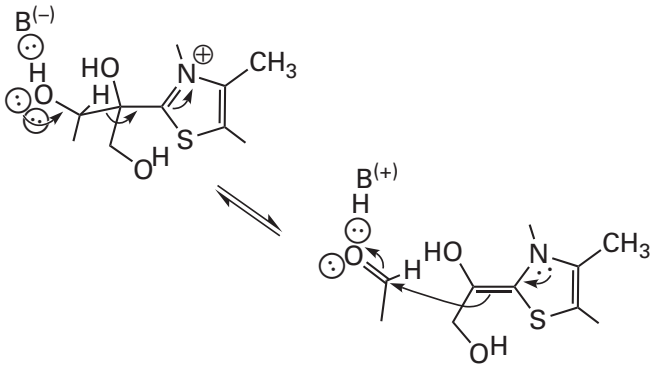
at 26 °C, the rate was 220×10^{-3} s^{-1}. An acceleration of 10^4 in the rate of the decarboxylation of the adduct between pyruvate and thiamine itself also occurs when the solvent is changed from water to ethanol,[195] and an acceleration of 4×10^3 in the rate of the analogous decarboxylation of the zwitterionic tautomer of 4-pyridylacetic acid occurs when the solvent is changed from water to 75% dioxane.[196] The suggestion has been made that enzymes using thiamine diphosphate to catalyze decarboxylations of 2-oxo carboxylic acids may accelerate these reactions in part by providing a **nonpolar environment**.[192]

In the adduct between thiamine diphosphate and an ***α*-hydroxy ketone** or thiamine diphosphate and an ***α*-hydroxy aldehyde**, one of the substituents bonded to the α carbon will be an incipient carbonyl group, and it can dissociate as the respective carbonyl compound. For example, in one of the reactions catalyzed by transketolase



(2–56)

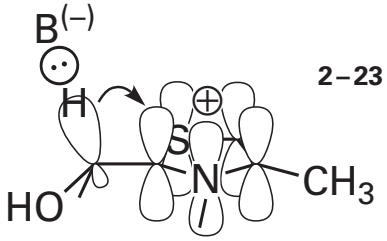
in which a two-carbon fragment is passed between two aldehydes, the product of the addition between thiamine diphosphate and either of the ketones that are substrates in the two respective directions loses the respective aldehyde as a product



(2–57)

and the two-carbon fragment that will be transferred to the other aldehyde ends up in an α-hydroxy enamine, 2-(1″,2″-dihydroxyethylidene)-2,3-dihydrothiamine diphosphate. In the case of the transketolase from *Streptomyces sahachiroi* involved in the biosynthesis of azinomycin, the same α-hydroxy enamine is formed, but it results from decarboxylation of the adduct of thiamine diphosphate with 3-hydroxypyruvate rather than the dissociation of an aldehyde.[197] In an α-hydroxy enamine formed from dehydronation, decarboxylation, or loss of a carbonyl, the α-hydroxy group is the oxygen that was the carbonyl oxygen of the original aldehyde or the original ketone to which the ylide of thiamine diphosphate added.

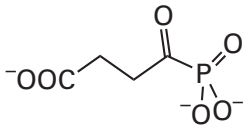
In the dehydronation, decarboxylation, or loss of a carbonyl group from the adduct between an aldehyde or a ketone and thiamine diphosphate (Equations 2–51, 2–54, and 2–57), as in the dehydronation, decarboxylation, or loss of a carbonyl or acyl group from the external pyridoximine between an amino acid and pyridoxal 5′-phosphate (**2–6** and Equations 2–4, 2–5, and 2–7), the **σ bond to be broken must be parallel to the π molecular orbital system of the double bond between carbon 2 and nitrogen 3 of the thiamine** and, by extension, the π molecular orbital system of the whole weakly aromatic heterocycle of the thiazole ring. This alignment permits the overlap necessary for the electronegativity of the cationic iminio nitrogen to withdraw electron density from the σ bond between the α carbon and the dissociating electrophile



2–23

and this electron withdrawal weakens that σ bond. The electron density in the occupied bonding molecular orbital of the σ bond is withdrawn into the unoccupied antibonding π molecular orbital of the thiazole that has two lobes in phase over carbon 2 and nitrogen 3.

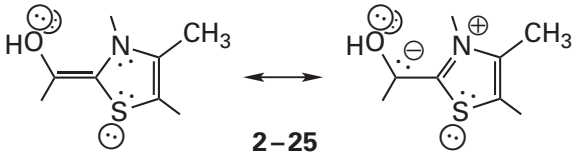
Analogues of 2-oxo carboxylic acids, such as succinylphosphonate



2–24

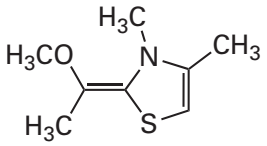
in which a phosphonate replaces a carboxylate, are excellent inhibitors of enzymes that use thiamine diphosphate prosthetically to decarboxylate the respective 2-oxo carboxylates.[198] They inhibit the enzyme by forming the usual adduct between its thiamine diphosphate and their respective carbonyl groups, but there is then no carboxylate to dissociate as carbon dioxide. In the complex between the adduct of thiamine diphosphate and methyl acetylphosphonate bound in the active site of pyruvate dehydrogenase (acetyl-transferring), the enzyme holds the σ bond between the α carbon and the phosphorus, which is the analogue of the σ bond between the α carbon and the carboxylate carbon in the normal reaction, almost perfectly parallel to the π molecular orbital system of the thiazolium ring and normal to its plane (Figure 2–5B).[175] The same orientation is observed in the complex between methyl benzoylphosphonate and thiamine diphosphate in the active sites of benzoin aldolase from *P. fluorescens*[199] and benzoylformate decarboxylase from *P. putida*.[200] One of the interactions dictating this alignment is the hydrogen bond between the 4′-amino group of the 4′-aminopyrimidinyl group in thiamine diphosphate and the hydroxy group of the adduct.

The α-hydroxy enamine that is the immediate product of dissociation of the electrophile from the adduct between thiamine diphosphate and an aldehyde or ketone (Equations 2–51, 2–54, and 2–57) is now nucleophilic at its α carbon



2–25

In the resonance form that places a nucleophilic lone pair of electrons on the exocyclic carbon, the thiazole ring is aromatic. Consequently, even though the aromaticity is weak, this carbon should be somewhat more anionic and nucleophilic than the carbon in an acyclic enamine. Nevertheless, in 2-(1′-methoxyethylidene)-2,3-dihydro-3,4-dimethylthiazole



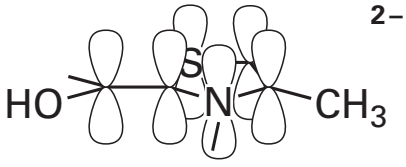
2–26

a methoxy analogue of an α-hydroxy enamine that incorporates a thiazole, synthesized[201]as a mixture of the *E* and *Z* isomers, no rotation around its exocyclic double bond could be detected by nuclear magnetic resonance spectroscopy at 100 °C, a fact indicating that, in spite of the aromaticity of the zwitterionic resonance form, the neutral resonance form of **2–25**, the α-methoxy enamine, is the major contributor to its electronic structure.

An **α-hydroxy enamine formed from thiamine** itself, by decarboxylation of the adduct between thiamine and a 2-oxo carboxylic acid (Equation 2–54), is unstable and **decomposes in solution** in a reaction that rapidly cleaves the bond between nitrogen 3 and the 4′-aminopyrimidine.[202] The properties of this decomposition suggest that it is a pericyclic reaction. It is thought that the enzymes using thiamine diphosphate prosthetically avoid this decomposition, which would be catastrophic, by sterically preventing their thiamines from assuming the conformation necessary for the pericyclic reaction to occur.[203]

While the respective α-hydroxy enamines that incorporate the thiazole of thiamine diphosphate can be observed spectroscopically as intermediates while enzymatic reactions are occurring,[204] they are normally in a low molar ratio to the active sites present. It has been possible, however, to **trap such α-hydroxy enamines** within the active sites of enzymes. In the normal reaction catalyzed by transketolase from *S. cerevisiae*, the α-hydroxy enamine that incorporates the thiazole of thiamine diphosphate is formed reversibly and in low yield from D-xylulose 5-phosphate (Equation 2–56) or a homologous ketone, but one forms irreversibly in the active site in the absence of an aldehyde that can act as an acceptor by the decarboxylation of 3-hydroxypyruvate, which is not a natural substrate for the enzyme. 2-(1″,2″-Dihydroxyethylidene)-2,3-dihydrothiamine diphosphate (Equation 2–57), the α-hydroxy enamine trapped in this way, is stable enough to be observed crystallographically (Figure 2–5C).[176] In this complex between the active site of transketolase and this α-hydroxy enamine that incorporates the thiazole, the hydrogen bonds between the α-hydroxy group of the initial adduct and the imidazolyl group and the 4′-imino group of the 4′-iminopyrimidine (Figure 2–5B) remain intact. 2-(1″-Hydroxyethylidene)-2,3-dihydrothiamine diphosphate (**2–22**), the α-hydroxy enamine formed by the decarboxylation of pyruvate, has been observed crystallographically in the active site of 1-deoxy-D-xylulose-5-phosphate synthase from *Deinococcus radiodurans*, and the same two hydrogen bonds also remain intact.[186] Because it is so basic, however, an α-hydroxy enamine incorporating the thiazole of thiamine diphosphate in the active site of an enzyme usually becomes adventitiously hydronated during the time required to make crystallographic measurements.[205,206] An α-hydroxy enamine that incorporates the thiazole of thiamine diphosphate has also been stabilized so that it can be trapped transiently in the active site of benzoylformate decarboxylase by using 4-nitrobenzoylformate as a substrate[207] rather than benzoylformate. The nitro group withdraws electron density from the basic carbanionic α carbon, discourages its hydronation, and stabilizes the α-hydroxy enamine.

The **π molecular orbital system of an α-hydroxy enamine that incorporates a thiazole** is formed from the *p* orbitals of six atoms



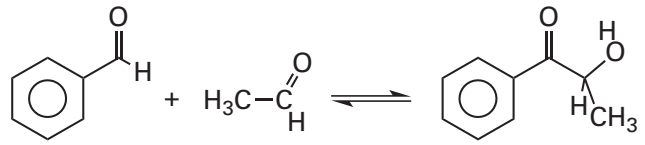
2–27

as is the case in 5-methylene-1,3-cyclopentadiene. The π molecular orbital system of an α-hydroxy enamine that incorporates a thiazole is occupied by eight electrons. In the crystallographic molecular model of 2-(1″,2″-dihydroxyethylidene)-2,3-dihydrothiamine diphosphate (Equation 2–57) in the active site of transketolase (Figure 2–5C)[176] and that of 2-(1″-hydroxyethylidene)-2,3-dihydrothiamine diphosphate (**2–22**) in the active site of 1-deoxy-D-xylulose-5-phosphate synthase,[186] the α carbon is trigonal and its two substituents, the hydroxy group and the hydroxymethyl group or the methyl group, respectively, are coplanar with the thiazole as expected from **2–27**. This coplanarity is not because of the two hydrogen bonds to the α-hydroxy group because it is only in the initial tetrahedral adduct, in which the hydroxy group is out of the plane of the thiazole, that the hydrogen bonds have the optimal geometry (Figure 2–5B); rather, it must be an electronic requirement. The π molecular orbital system contains four pairs of π electrons in its six molecular orbitals. The occupancy of the antibonding orbital of lowest energy by two electrons makes it electron-rich at the exocyclic carbon over which there is a full lobe.

Because of its electron excess, the α-hydroxy enamine that incorporates a thiazole is basic and nucleophilic at its α carbon. The simplest manifestation of this basicity is that the α carbon is readily **hydronated by an acid**. This is what occurs to the α-hydroxy enamine formed in the active site of pyruvate decarboxylase (Equation 2–54) in the next step of the enzymatic mechanism. The hydron that is added then becomes the hydrogen of the aldehyde in the acetaldehyde (Equation 2–53) as the resulting adduct dissociates (reverse of Equation 2–49).

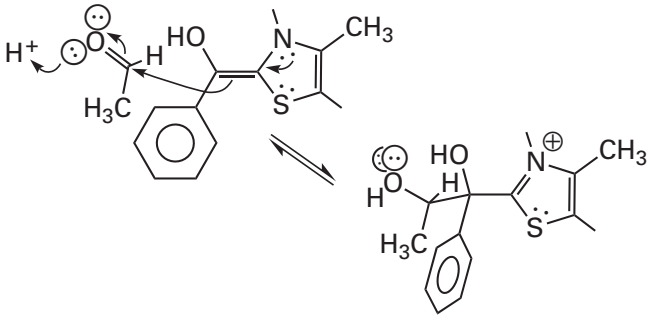
In solution, the hydronation of the α carbon of an α-hydroxy enamine that incorporates a thiazole (see Equation 2–51) is slow. For the α-methoxy enamine 2-(methoxyphenylmethylidene)-3,4-dimethylthiazole the rate of hydronation by a molecule of water,[208] a weak acid ($pK_a = 15.5$), is 0.02 M^{-1} s^{-1}. For the α-hydroxy enamine, 2-(hydroxyphenylmethylidene)-4′-deamino-4′-hydroxythiamine, the rate constants of hydronation by a series of general acids[191] with values of pK_a between 6 and 12 are in the range 1000–100,000 M^{-1} s^{-1}. These latter rate constants are independent of the pK_a of the general acid and are far less than the encounter-controlled limit that would be observed for such an exothermic transfer of a hydron to a heteroatomic base (Figure 1–1), but they are consistent with the slow rate constants for the hydronation of carbon. These slow rates are a further indication that the resonance form with the neutral enamine, in which the thiazole is not aromatic and the carbon is not anionic, is the major contributor to the electronic structure of **2–25**,[189] just as the resonance form of an enamine, in which the pair of electrons is on the nitrogen, is the major contributor to its electronic structure. They also indicate that the density of negative charge on the nucleophilic α carbon in an α-hydroxy enamine that incorporates a thiazole is minuscule.

Another manifestation of the nucleophilicity of the α carbon in an α-hydroxy enamine that incorporates a thiazole is its **addition to a carbonyl group.** In solution, thiamine, like cyanide (Equation 2–50), can catalyze the **formation of α-hydroxy ketones**,[158] for example, the benzoin condensation of benzaldehyde and acetaldehyde[188]



(2–58)

In this reaction the carbonyl carbon of the acetaldehyde, as an electrophile, has replaced the hydrogen that was originally on the α carbon of the benzaldehyde and that dissociated as a hydron, an electrophile, from the adduct between benzaldehyde and thiamine. The hydron that has dissociated is replaced by the acetaldehyde through the nucleophilic addition of the α-hydroxy enamine that incorporates the thiamine to the carbonyl carbon



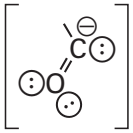
(2–59)

This nucleophilic addition is accompanied by restoration of the aromaticity in the thiazolium ring. The product, 2-hydroxy-1-phenyl-1-propanone, then dissociates in the reverse of the original formation of the adduct between benzaldehyde and thiamine.

In the transketolase reaction (Equations 2–56 and 2–57), the aldehyde that is a reactant, other than the one that has dissociated as a product, adds to the α-hydroxy enamine that incorporates thiamine diphosphate to produce the adduct between the ketone that is the other product and thiamine diphosphate. The ketone that is the product then dissociates from the adduct.

There are also instances in which an α-hydroxy enamine that incorporates a thiazole **adds as a nucleophile to even weaker electrophiles** than an aldehyde, such as an *N*-acylimine in solution,[209] the carbonyl group of a 2-oxo carboxylic acid in the active site of acetolactate synthase,[210] or the β carbon of an α,β-unsaturated carboxylic acid in a Michael addition within the active site of 2-succinyl-6-hydroxy-2,4-cyclohexadiene-1-carboxylate synthase.[211,212] In the active site of 2-succinyl-5-enolpyruvyl-6-hydroxy-3-cyclohexene-1-carboxylic-acid synthase from *E. coli*, 2-(1″-hydroxy-3″-carboxypropylidene)-2,3-dihydrothiamine diphosphate, the α-hydroxy enamine formed by decarboxylation of the adduct between 2-oxoglutarate and thiamine diphosphate, participates in a **Michael addition** to a carbon–carbon double bond in isochorismate. In a crystallographic molecular model of the α-hydroxy enamine in the active site in the absence of isochorismate,[213] the α carbon is not planar but tetrahedral because a lone pair of electrons localized on it is the donor in a hydrogen bond with the 4′-amino group of thiamine diphosphate. It has been proposed that this hydrogen bond concentrates the nucleophilic electron density on the α carbon in preparation for the Michael addition to increase its nucleophilicity.

If the α carbon of the α-hydroxy enamine that incorporates thiamine diphosphate adds to a hydron, the adduct between thiamine diphosphate and an aldehyde is formed;[214] if it adds to carbon dioxide, the adduct between thiamine diphosphate and a 2-oxocarboxylic acid is formed; and if it adds to an aldehyde or ketone, the product of addition between thiamine diphosphate and an α-hydroxy ketone is formed (Equations 2–51, 2–54, and 2–57). Each of these reactions can be considered to be the **addition of an electrophile to the synthon**



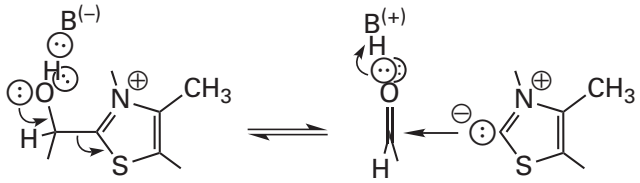
2–28

that was produced by the dissociation of an electrophile from a carbonyl carbon. Considered in this way, the enzymatic reactions in which thiamine diphosphate is used as a prosthetic group are reactions in which one electrophile dissociates from this synthon and a different electrophile adds. In pyruvate decarboxylase (Equation 2–53), a hydron substitutes for carbon dioxide; in transketolase (Equation 2–56), one aldehyde substitutes for another; and in 1-deoxy-D-xylulose-5-phosphate synthase[215,216]

$$\text{pyruvate} + \text{D-glyceraldehyde 3-phosphate} + H^+ \rightleftharpoons CO_2 + \text{1-deoxy-D-xylulose 5-phosphate} \qquad (2\text{–}60)$$

an aldehyde substitutes for carbon dioxide. In these exchanges of the one electrophile for another, the initial electrophile leaves the initial adduct between thiamine diphosphate and the initial aldehyde or ketone, and the electrophile substituting for it reacts with the α-hydroxy enamine to form the final carbonyl adduct of thiamine diphosphate. These carbonyl adducts of thiamine diphosphate can be detected and quantified as the enzymatic reaction is occurring.[217]

As has already been mentioned in passing, the final step in a reaction catalyzed by thiamine diphosphate, following nucleophilic addition of the electrophile to the α-hydroxy enamine that incorporates thiamine diphosphate, is generation of the new aldehyde or ketone by **dissociation of the thiazole from the new carbonyl adduct.** This dissociation is assisted by the fact that the hydroxy group on the incipient carbonyl carbon in the adduct is fairly acidic ($pK_a = 12$),[192] and the removal of its hydron by a base[192,193] either prior to or during the dissociation of the product catalyzes the formation of the product



(2–61)

In summary, the **prototypical mechanism** of an enzyme using thiamine diphosphate prosthetically has the following steps. The hydron on carbon 2 of the thiamine diphosphate is removed. The resulting ylide of the thiamine diphosphate adds to the carbonyl

group of an aldehyde or a ketone to form the adduct, the hydroxy group of which ends up in hydrogen bonds to a histidine from the protein and the 4′-amino group of the 4′-aminopyrimidine of thiamine diphosphate (Figure 2–5B), one of which has provided the hydron on the hydroxy group. An electrophile—a hydron, carbon dioxide, or an aldehyde—leaves the α carbon of the adduct to produce the α-hydroxy enamine that incorporates the thiazole (Figure 2–5C). A different electrophile adds to the α-hydroxy enamine to form a different adduct between thiamine diphosphate and a different aldehyde or ketone. The hydron of the hydroxy group of the new carbonyl adduct is removed either before or while the new aldehyde or ketone dissociates, and the ylide of thiamine diphosphate is hydronated on carbon 2.

The puzzle is to define the roles of the 4′-amino group of the 4′-aminopyrimidine in these steps. In the active site of an enzyme, the 4′-amino group of thiamine diphosphate usually forms a hydrogen bond to the α-hydroxy group in both the initial adduct and the α-hydroxy enamine that incorporates the thiazole and abuts the α carbon (Figure 2–5B and 2–5C).[175,176,186] Often there is a histidine in the active site that also forms a hydrogen bond to the same hydroxy group. These dispositions certainly imply that these are the catalytic acids and bases acting on the α-hydroxy group and that the 4′-amino group is a catalytic acid–base that is able to act on the α carbon. One of them hydronates the oxygen of the carbonyl group as the ylide of thiamine diphosphate adds to its carbon, and one of them dehydronates the α-hydroxy group as the ylide of the thiamine dissociates from final adduct to give the ketone or aldehyde that is the final product. In the crystallographic molecular model of 2-(1″,2″-dihydroxyethylidene)-2,3-dihydrothiamine diphosphate (Equation 2–57) occupying the active site, nitrogen 4′ of the 4′-amino-pyrimidinyl group is 0.30 nm from the oxygen of the α-hydroxy group but it is also 0.30 nm from the α carbon of the α-hydroxy enamine (dashed lines in Figure 2–5C). The distance to the α carbon atom is well within van der Waals contact, and this fact indicates that this nitrogen has been forced up against the α carbon by the enzyme. These orientations and distances should permit the 4′-amino group to swing over to the α carbon from the hydroxy group of the α-hydroxy enamine and hydronate it, if indeed the α carbon is supposed to be hydronated,[218] or the 4′-imino group to swing over to the α carbon in the initial adduct and dehydronate it, if indeed it is supposed to be dehydronated. While these movements are occurring, the imidazolyl group of the histidine would maintain the hydron on the hydroxy group.

The next piece of the puzzle is the identity of **the catalytic base that removes the hydron from carbon 2** of thiamine diphosphate to form the ylide and initiate the reaction. Up to this point it has been assumed that it is the molecule of water between the 4′-amino group and carbon 2 (Figure 2–5). It has been observed, however, that, in a single turnover of pyruvate decarboxylase from *S. cerevisiae*, 45% of the tritium in [2-^{3}H]thiamine diphosphate in the active site becomes the hydrogen of the formyl group in the acetaldehyde that is the product.[219] It seems to be the case that the 4′-amino nitrogen of the 4′-aminopyrimidinyl group has to hydronate the α carbon of the α-hydroxy enamine after the initial adduct of pyruvate decarboxylates (Figure 2–5C). If so, nitrogen 4′ of the 4′-imino tautomer of the 4′-aminopyrimidinyl group would seem to be the base that removes the hydrogen from carbon 2 of thiamine diphosphate.[170]

In the crystallographic molecular model of the unoccupied active site (Figure 2–5A), however, nitrogen 4′ is separated from carbon 2 of the thiamine diphosphate by the fixed molecule of water. If the base that removes the triton from carbon 2 in the normal sequence of steps is this molecule of water, relaying the basicity of either the 4′-imino tautomer or the histidine, it should leave the active site with the triton because it is displaced by the carbonyl oxygen of the reactant when it associates. Consequently, the fact that tritium is transferred in high yield seems to argue against this molecule of water as a candidate for the base that removes the hydron from carbon 2 in the usual reaction and seems to leave only the 4′-imino group of thiamine diphosphate.

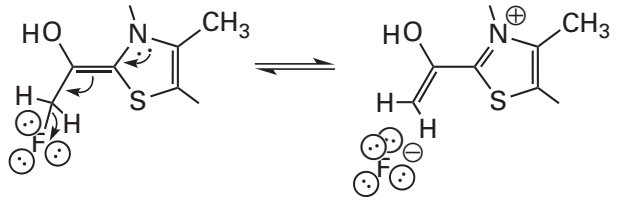
Nevertheless, the foregoing dispositions and considerations are consistent with the following sequence of events. Before the pyruvate associates with the active site of pyruvate decarboxylase, displacing the molecule of water, the molecule of water freely rotates to equilibrates the triton on carbon 2 of thiamine diphosphate with the hydron on its 4′-imino group. The fact that exchange of the hydrogen on carbon 2 with a hydrogen in the solvent when an active site is unoccupied by a reactant is much slower than the turnover of a reactant would give the molecule of water sufficient time to accomplish this equilibration without dissociating into the solution. At an instant when the ylide of thiamine diphosphate and the tritiated 4′-imino group are

present, the carbonyl group of the pyruvate displaces the molecule of water while Histidinium 640 hydronates its oxygen. The decarboxylation occurs, producing the α-hydroxy enamine. The 4′-[*N*-^{3}H]amino group of the thiamine diphosphate tritonates the α carbon of the α-hydroxy enamine. During dissociation of the tritiated product from its adduct with thiamine diphosphate, the resulting 4′-imino group or the imidazolyl group of the histidine removes the hydron from the α-hydroxy group that the imidazolino group added to it. The only problem with this explanation is that 45%, not less than 33%, of the tritium is transferred.

In the active site of transketolase occupied by 2-(1″,2″-dihydroxyethylidene)-2,3-dihydrothiamine diphosphate (Figure 2–5C), the 4′-imino group is 0.31 nm from carbon 2 of the thiazole of the α-hydroxy enamine, well within van der Waals contact, and the imidazolyl group of the histidine is forming a hydrogen bond with the α-hydroxy group. The only problem with assigning to the 4′-imino group the role of removing the hydron from carbon 2 of the thiamine to initiate the reaction is the **orientation of nitrogen 4′**. Unlike the molecule of water in the unoccupied active site containing the unmodified thiamine diphosphate, which would seem to remove the hydron from carbon 2 in the absence of a substrate, nitrogen 4′ of the prosthetic thiamine diphosphate is not in the plane of the thiazole (Figure 2–5A) where the hydrogen to be removed is located (Equation 2–46) to initiate the reaction, nor is it in the plane of the thiazole (Figure 2–5C) in the location in which the hydron is to be added to the ylide to complete the reaction. One possibility is that, both after the reactant adds at the beginning and following the dissociation of the carbon–carbon bond to the incipient carbonyl carbon at the end, the thiazole pivots to place nitrogen 4′ in its plane.

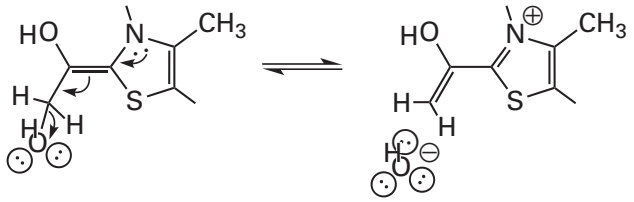
Both the conversion of the carbonyl in the reactant and the hydronated thiazole in thiamine diphosphate into the adduct between the two and a hydron in the first step of the reaction and the conversion of the adduct between what will be the carbonyl in the product and thiamine diphosphate into the carbonyl of the product and thiamine diphosphate hydronated at carbon 2 at the end of the reaction are formally electrophilic aromatic substitutions. In an actual electrophilic aromatic substitution, the carbonyl group would first add to carbon 2 from the face of the thiazole opposite the 4′-aminopyridine and produce a tetrahedral carbon on which there would be a dramatically acidic hydrogen now pointed at nitrogen 4′ and now in the correct orientation for transfer as a hydron. Even though this gedanken view of the situation is energetically unlikely because the electrophile is so weak and carbon 2 is already so acidic, the removal of the hydron from carbon 2 and the addition of the carbonyl group to carbon 2 could actually be a concerted electrophilic aromatic substitution. By this mechanism in the approach of the system to the roughly tetrahedral transition state, the incoming carbonyl carbon would push the hydrogen on carbon 2 toward the nitrogen of the unhydronated 4′-imino nitrogen, weaken its bond to the carbon, and align it for removal by the 4′-imino nitrogen while the bond to the carbonyl carbon is being formed; or in reverse, the dissociation of the adduct, the incoming hydronated 4′-amino group would push the bond between carbon 2 and the α carbon out of the plane of the thiazole and the hydronated 4′-amino group would enter the almost tetrahedral transition state from a position oblique to the plane of the thiazole.

In a few of the reactions that rely on a prosthetic thiamine diphosphate, the excess electron density of an α-hydroxy enamine that incorporates thiamine diphosphate provides push to expand the π molecular orbital system further out onto and beyond the β carbon of the aldehyde or ketone that was the reactant. One example is the elimination from the β carbon that occurs following decarboxylation of the unnatural adduct formed in the active site of pyruvate decarboxylase from *E. coli* between fluoropyruvate and thiamine diphosphate[220,221]



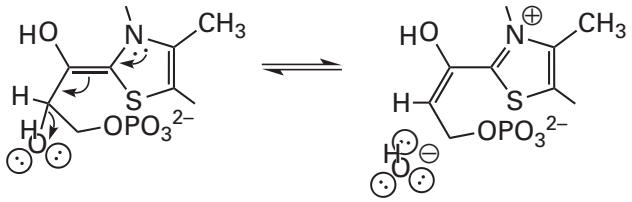
(2–62)

Another example is the elimination from the β carbon that occurs following dissociation of the aldehyde, D-glyceraldehyde 3-phosphate, from the natural adduct formed in the active site of phosphoketolase from *Bifidobacterium breve* between D-xylulose 5-phosphate and thiamine diphosphate[205]



(2–63)

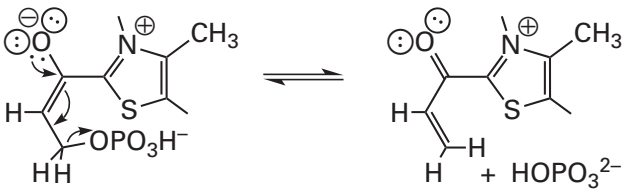
A third example is the elimination from the β carbon that occurs following dissociation of a hydron from the natural adduct formed in the active site of N^2-(2-carboxyethyl)arginine synthase from *Streptomyces clavuligerus* between D-glyceraldehyde 3-phosphate and thiamine diphosphate[222]



(2–64)

Each of these three eliminations creates an enol incorporating the α carbon and the β carbon that is conjugated to the iminium within the thiamine diphosphate. In the cases of pyruvate decarboxylase and phosphoketolase, the same enol is hydronated at the β carbon, which is a methylene (Equation 2–63), to form 2-acetylthiamine diphosphate.

In the case of N^2-(2-carboxyethyl)arginine synthase, the removal of a hydron from the α-hydroxy group creates an enolate that pushes out the phospho group to **extend the π molecular orbital system onto the γ carbon** while forming 2-(acryloyl)thiamine diphosphate[223]



(2–65)

To complete the enzymatic reaction, the phosphate that just left is replaced by the α-amino group of an L-arginine that adds as a nucleophile to the α,β-unsaturated ketone in the reverse of Equation 2–65. The resulting enolate, in which the α-amino group of L-arginine has replaced the phospho group, is then hydronated on the β carbon to give the ketone, and the resulting 2-acylthiamine diphosphate is hydrolyzed with the ylide of thiamine diphosphate as the leaving group to produce thiamine diphosphate and the product N^2-(2-carboxyethyl)-L-arginine.

There are enzymatic reactions in which adducts of thiamine diphosphate are oxidized or reduced. For example, in the reactions catalyzed by both pyruvate synthase[224]

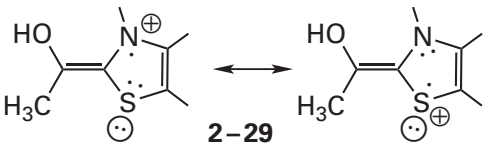
$$\begin{aligned}\text{pyruvate} + 2\ \text{oxidized ferredoxin} \\ + \text{HSCoA} \rightleftharpoons \text{CO}_2 + \\ 2\ \text{reduced ferredoxin} + \text{H}^+ + \text{acetyl-SCoA}\end{aligned} \quad (2\text{–}66)$$

and pyruvate oxidase[225]

$$\begin{aligned}\text{pyruvate} + \text{O}_2 + \text{HOPO}_3^{2-} + \text{H}^+ \rightleftharpoons \\ \text{CO}_2 + \text{H}_2\text{O}_2 + \text{acetyl phosphate}\end{aligned} \quad (2\text{–}67)$$

the pyruvate is oxidized in the forward direction by two electrons in an oxidation that turns it into carbon dioxide and an acetyl group. As such, these two reactions are **oxidative decarboxylations**. In both active sites, the 2-(1″-hydroxyethylidene)-2,3-dihydrothiamine diphosphate (**2–22**) produced by decarboxylation of the adduct of pyruvate and thiamine diphosphate (Equation 2–54) is oxidized and in the process reduces oxidized ferredoxin or reduces an oxidized prosthetic flavin, which in turn reduces molecular oxygen to H_2O_2.

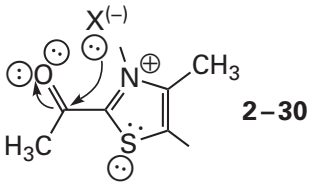
2-(1″-Hydroxyethylidene)-2,3-dihydrothiamine diphosphate (**2–22**) is an electron-rich α-hydroxy enamine, the oxidation of which by the transfer of two electrons restores the aromaticity of the thiazole. Its oxidation in the respective active sites of these two enzymes proceeds in **two successive one-electron steps**. In the active site of pyruvate synthase in the forward direction, each of the two molecules of oxidized ferredoxin, one after the other, can accept only a single electron from the α-hydroxy enamine; and in the reaction catalyzed by pyruvate oxidase from *L. plantarum*, the electrons have been shown to be transferred in the forward direction, one at a time, from the α-hydroxy enamine to the prosthetic flavin in the active site.[226] For both pyruvate synthase from *Moorella thermoacetica*[227,228] and pyruvate oxidase from *L. plantarum* ,[226] the **intermediate radical cation**



2–29

resulting from transfer of just one electron from 2-(1′′-hydroxyethylidene)-2,3-dihydrothiamine diphosphate during the normal catalytic reaction has been observed; and in the case of pyruvate oxidase, it is stable enough to be observed crystallographically.[229] In cyclic voltammetry, 2-(1′-methoxyethylidene)-2,3-dihydro-3,4-dimethylthiazole (**2–26**) is an electrochemical one-electron reductant with a reduction potential of +70 mV relative to a standard hydrogen electrode.[230] By increasing its π electron density, relative to a hydrogen, the methoxy substituent decreases the reduction potential of the enamine by 250 mV, from +320 to +70 mV, and an unhydronated hydroxy group should decrease it even further. 2-(1′-Hydroxyethylidene)-2,3-dihydro-3,4-dimethylthiazole is able to reduce an analogue of flavin nonenzymatically.[231]

Upon transfer of the second electron, the 2-(1′′-hydroxyethylidene)-2,3-dihydrothiamine diphosphate (**2–22**) in each of the active sites has been converted into **2-acetylthiamine diphosphate**



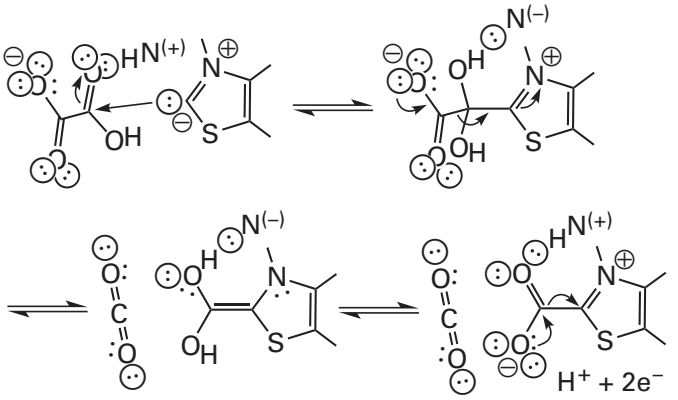
2–30

which then engages in a nucleophilic substitution with either coenzyme A or phosphate, with the ylide of thiamine diphosphate as the leaving group.

Oxalate oxidoreductase

$$\text{oxalate} + 2\ \text{oxidized ferredoxin} \rightleftharpoons 2\ CO_2 + 2\ \text{reduced ferredoxin} \qquad (2\text{–}68)$$

from *M. thermoacetica* is related (24% identity; 3.0 gap percent) to pyruvate synthase (Equation 2–66) and also catalyzes an oxidative decarboxylation in which the two electrons generated in the reaction are transferred to two molecules of oxidized ferredoxin. In this instance, however, the adduct between thiamine diphosphate and oxalic acid (Equation 2–49; $R_1 = COO^-$; $R_2 = OH$) rather than thiamine diphosphate and pyruvate (Equation 2–49; $R_1 = COO^-$; $R_2 = CH_3$) is formed initially



(2–69)

This nucleophilic substitution is an example of the **ylide of thiamine diphosphate that adds to an acyl group** rather than a carbonyl group. The reactions catalyzed by pyruvate synthase (Equation 2–66) and pyruvate oxidase (Equation 2–67) in reverse are also examples of addition of the ylide of thiamine diphosphate to acyl derivatives, acetyl-SCoA and acetyl phosphate, respectively.

The adduct between thiamine diphosphate and oxalic acid in the active site of oxalate oxidoreductase is then decarboxylated, as in the case of pyruvate in the active site of pyruvate synthase. The resulting **dihydroxymethylenethiamine diphosphate**, an even more electron-rich and more reducing α-hydroxy enamine, is then oxidized by transfer of two electrons to two successive oxidized ferredoxins. The resulting intermediate is a derivative of carbonic acid from which the ylide of thiamine diphosphate leaves while the second CO_2 is formed.

Both the initial adduct between the ylide of thiamine diphosphate and the oxalate and dihydroxymethylenethiamine diphosphate have been observed in crystallographic molecular models of oxalate oxidoreductase from *M. thermoacetica*.[232] As expected, the catalytic acid–base that forms a hydrogen bond to the α-hydroxy group in both of these intermediates is nitrogen 4′ of the 4′-aminopyrimidinyl group in thiamine diphosphate, but unlike the situation in the active sites of pyruvate dehydrogenase (acetyl-transferring) (Figure 2–5B) and transketolase (Figure 2–5C), the other participant in a hydrogen bond with the α-hydroxy group is the guanidinio group of an arginine, which would ensure that the hydron on the hydroxy group is within the hydrogen bond to nitrogen 4′.

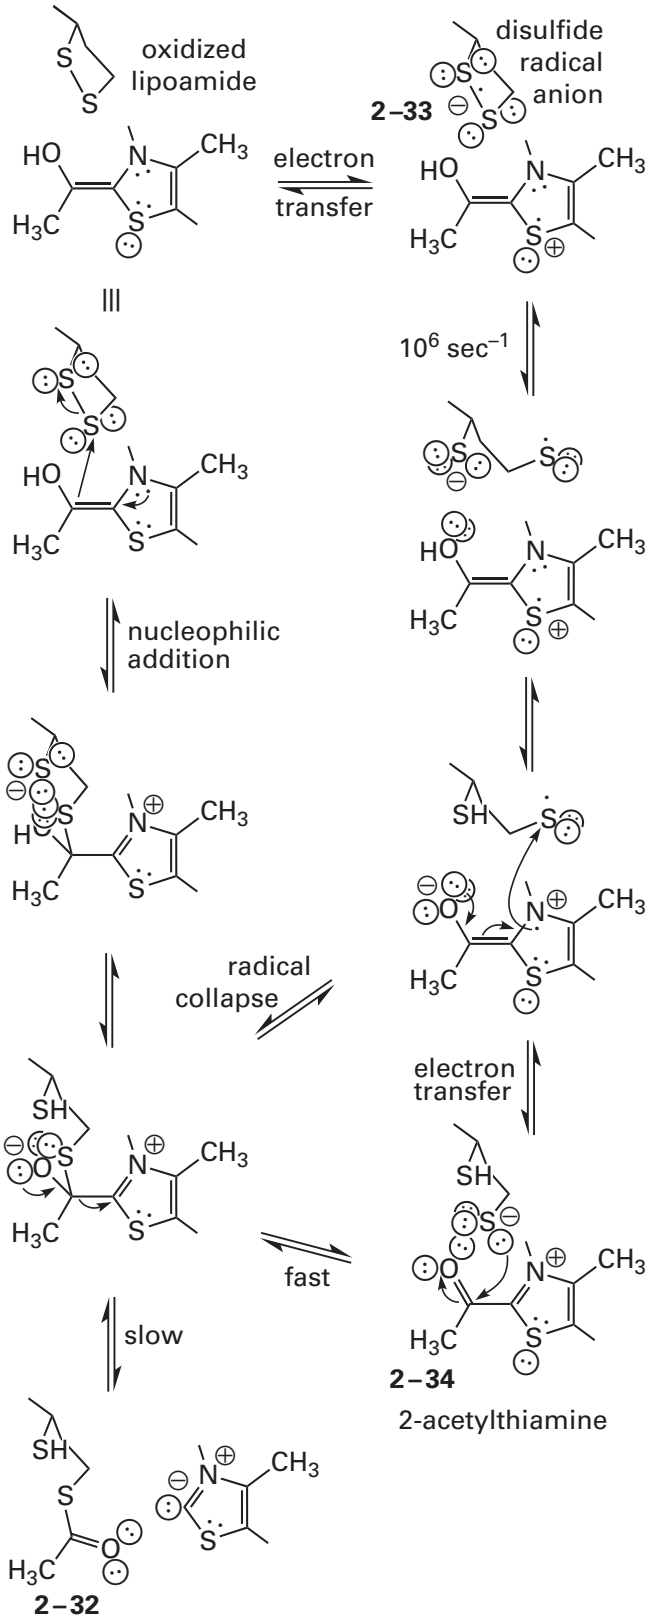


Figure 2-7: Formation of N^6-(*S*-acetyldihydrolipoyl)lysine in the reaction catalyzed by pyruvate dehydrogenase (acetyl-tranferring). There are two possibilities for the mechanism of this reaction, electron transfer[234] or heterolysis.[233] In the first step of the former mechanism (top line and to the right), the electron-rich enamine loses an electron to the disulfide to form the radical anion of the disulfide and radical cation of the thiamine. The radical anion of a disulfide fragments to sulfido group and thiyl radical and the second electron is transferred to the thiyl radical, to give the dithiolate and 2-acetylthiamine. The distal sulfido group adds nucleophilically to the carbonyl carbon of the 2-acetylthiamine to form a tetrahedral intermediate. Another alternative is to have the two radicals collapse directly to the tetrahedral intermediate. In the first step of the heterolytic mechanism (middle left), the enamine as a nucleophile displaces a sulfido group from the disulfide and forms the tetrahedral intermediate. At this point the mechanisms converge and the acetyl group is transferred through the tetrahedral intermediate to one of the sulfido groups of N^6-(dihydrolipoyl)lysine.

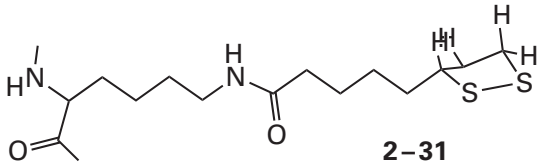
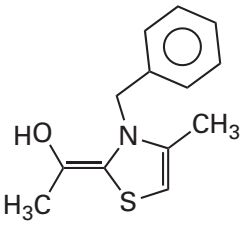
The reactions catalyzed by the three related enzymes **pyruvate dehydrogenase (acetyl-transferring), oxoglutarate dehydrogenase (succinyl-transferring), and 3-methyl-2-oxobutanoate dehydrogenase (2-methylpropanoyl-transferring)** are also oxidative decarboxylations. For example, the α-hydroxy enamine incorporating thiamine diphosphate that is formed immediately upon decarboxylation of the adduct of pyruvate and thiamine diphosphate (Equation 2–54) by pyruvate dehydrogenase (acetyl-transferring) reduces the disulfide in N^6-(lipoyl)lysine



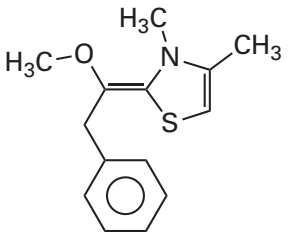
to produce the acetyl thioester of N^6-(dihydrolipoyl)-lysine (**2–32** in Figure 2–7).[233,234] N^6-(Lipoyl)lysine is a prosthetic group that is covalently attached through an amide between lipoic acid and the 6-amino group of a lysine in the polypeptide of a different enzyme, dihydrolipoyllysine-residue acetyltransferase, that forms a noncovalent complex with pyruvate dehydrogenase (acetyltransferring) and presents the lipoyl group to its active site. In the active sites of oxoglutarate dehydrogenase (succinyl-transferring) and 3-methyl-2-oxobutanoate dehydrogenase (2-methylpropanoyl-transferring), the homologous adducts between 2-oxoglutarate or 3-methyl-2-oxobutanoate are formed and decarboxylated, and the resulting succinyl group or 2-methylpropanoyl group is transferred to N^6-(lipoyl)lysine

in the respective acceptor.* There are two possible mechanisms by which the reductive transfer of an acetyl group to N^6-(lipoyl)lysine in the active site of pyruvate dehydrogenase (acetyl-transferring) could take place.

One possibility is a **nucleophilic substitution**. The α-hydroxy enamine that incorporates thiazole, 2-(1′-hydroxyethylidene)-2,3-dihydro-3-benzyl-4-methylthiazole (**2–35**)



2–35



2–36

is nucleophilic enough to participate in a nucleophilic substitution at one of the two sulfurs in an acyclic disulfide,[233] and the α-methoxy enamine 2-(1′-methoxy-2′-phenylethylidene)-2,3-dihydro-3,4-dimethylthiazole (**2–36**) is nucleophilic enough to participate in an intramolecular nucleophilic substitution at one of the sulfurs in the cyclic disulfide of an ester of lipoic acid.[235] If one of these sulfurs is methylated, to mimic the hydronation that would occur in the active site of an enzyme, the α-methoxy enamine 2-(1′-methoxy-2′-phenylethylidene)-2,3-dihydro-3,4,5-trimethylthiazole will participate in a nucleophilic substitution with the other sulfur.[236]

All these results suggest that, within the active site of pyruvate dehydrogenase (acetyl-transferring), 2-(1″-hydroxyethylidene)-2,3-dihydrothiamine diphosphate (**2–22**), the α-hydroxy enamine produced by the decarboxylation of the adduct between thiamine diphosphate and pyruvate (Equation 2–54), should be nucleophilic enough to participate as the nucleophile in a concerted nucleophilic substitution with the disulfide of N^6-(lipoyl)lysine as the electrophile (left side of Figure 2–7). The nucleophilic attack of the electron-rich α-hydroxy enamine resembles the nucleophilic attack of a sulfido group during a thiol–disulfide exchange.[237] If the disulfide is hydronated on the sulfur that is to leave, the nucleophilic substitution liberates one of the sulfurs as a thiol while the other sulfur becomes bonded to the α carbon of the α-hydroxy enamine. This nucleophilic addition of the α-hydroxy enamine creates a **tetrahedral intermediate with the thiazolium as a potential leaving group**. Upon its dissociation, initiated by removal of the hydron from the hydroxy group, the thioester would be the product, and the reaction catalyzed by the enzyme would be accomplished.

The second possibility, however, for the mechanism of pyruvate dehydrogenase (acetyl-transferring) would involve **two transfers, each of one electron**, as in the active sites of pyruvate synthase, pyruvate oxidase, and oxalate oxidoreductase, between the α-hydroxy enamine 2-(1″-hydroxyethylidene)-2,3-dihydrothiamine diphosphate and the disulfide of the oxidized N^6-(lipoyl)lysine (right side of Figure 2–7) to reduce the disulfide to the dithiol and oxidize the α-hydroxy enamine to 2-acetylthiamine diphosphate.[238] The α-hydroxy enamine formed at the active site of pyruvate dehydrogenase (acetyl-transferring) is able to reduce two equivalents of ferricyanide in two successive transfers, each of one electron.[234,238] This observation demonstrates that the radical cation of the α-hydroxy enamine that incorporates thiamine diphosphate, which is shown in the first step of the mechanism for pyruvate dehydrogenase (acetyl-transferring) and which is produced by two successive transfers, each of one electron (right side of Figure 2–7), can be formed in an active site. The radical cation of the α-hydroxy enamine 2-(1″-hydroxy-3″-carboxy-propylidene)-2,3-dihydrothiamine diphosphate, the homologue of **2–29**, has been observed in the active site of oxoglutarate dehydrogenase (succinyl-transferring) when the α-hydroxy enamine is in a complex with the enzyme.[239] The radical cation in this case, however, is believed to result from oxidation of the α-hydroxy enamine by molecular oxygen rather than by the lipoyl disulfide. It was concluded that this radical cation is the result of an adventitious side reaction. Nevertheless, this side reaction demonstrates that the radical cation can be generated in this active site.

The **radical anion of a disulfide** (**2–33**)[240,241] would also be a transient intermediate in the mechanism involving transfer of the electrons one at a time (right side of Figure 2–7). Disulfides can be reduced in two one-electron steps in a reaction

*Dihydrolipoyllysine-residue succinyltransferase and dihydrolipoyllysine-residue (2-methylpropanoyl)transferase form homologous noncovalent complexes with oxoglutarate dehydrogenase (succinyl-transferring) and 3-methyl-2-oxobutanoate dehydrogenase (2-methylpropanoyl-transferring), respectively, also presenting N^6-(dihydrolipoyl)lysine.

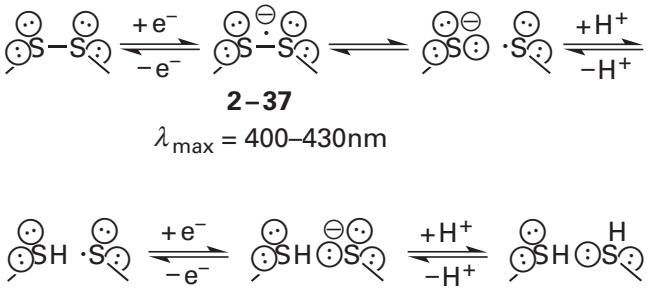


Figure 2–8: One-electron reduction of a disulfide.[240] In the first step, an electron is provided by a reductant to produce the radical anion of the disulfide, **2–37**, with a characteristic electronic absorption at 400–430 nm. This radical anion fragments rapidly (1 μs^{-1}) to form a sulfido group and a thiyl radical. The sulfido group can be hydronated, and the thiyl radical can accept a second electron to produce a second sulfido group.

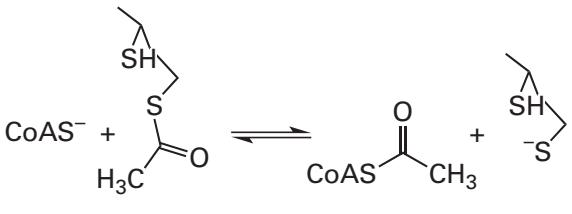
involving such a radical anion of a disulfide (**2–37**) as an intermediate (Figure 2–8).[240] The one-electron reduction potential of a disulfide, however, is –400 mV.[242,243] The enzyme would have to increase the one-electron reduction potential of the disulfide in N^6-(lipoyl)lysine, for example, by hydronating one of the sulfurs,[236] or decrease the reduction potential of the α-hydroxy enamine,[230] for example, by dehydronating the hydroxy group, for productive transfer of an electron to occur.

Once it has been formed, the rate at which a radical anion of a disulfide spontaneously fragments to a sulfido group and a thiyl radical is 1 μs^{-1}, more than fast enough for this step to participate in the enzymatic reaction. In cyclic radical anions of disulfides, however, such as that of N^6-(lipoyl)-lysine (**2–31**), the equilibrium for ring opening to the sulfido group and thiyl radical is strongly in favor of the closed form, but hydronation of the radical anion of the disulfide shifts the equilibrium constant for ring opening to around 1.[241] Therefore, hydronation of the disulfide in N^6-(lipoyl)lysine by an acid in the active site either before or during transfer of the electron would be necessary both to increase its reduction potential and to promote ring opening. The pK_a of a radical anion of a disulfide is between 4 and 5.[244] The thiyl radical formed in the ring opening would then accept the second electron, either directly or by forming a bond to the radical on the α carbon of the radical cation of the α-hydroxy enamine of thiamine diphosphate by colligation. The unpaired electron in the radical cation is in the antibonding π molecular orbital with a full lobe over the α carbon.

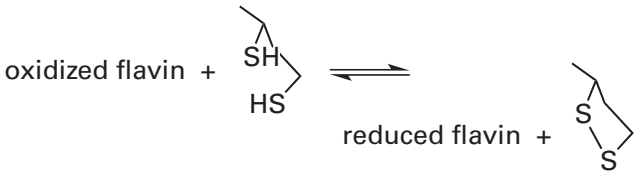
It has been shown that **2-acetylthiamine diphosphate** (**2–30** and **2–34** in Figure 2–7), when it is formed on the active site of pyruvate dehydrogenase (acetyl-transferring), produces N^6-(*S*-acetyllipoyl)-lysine as rapidly as does the α-hydroxy enamine, 2-(1″-hydroxyethylidene)-2,3-dihydrothiamine diphosphate (**2–22**).[245] 2-Acetylthiamine diphosphate has been synthesized[246] and used as a standard to demonstrate that while pyruvate dehydrogenase (acetyl-transferring) is actively catalyzing its reaction, 0.4% of its thiamine diphosphate is present as 2-acetylthiamine diphosphate.[238] These observations have been cited as evidence for the mechanism involving the successive transfer of two electrons because it has been stated that, on the nucleophilic path (left side of Figure 2–7), 2-acetylthiamine diphosphate should not be an intermediate.[238] If the tetrahedral intermediate proposed for the nucleophilic mechanism (left side of Figure 2–7) is examined closely, however, it is clear that sulfur is the better leaving group. It necessarily follows that, in either mechanism, 2-acetylthiamine diphosphate would be formed and unformed many times before the tetrahedral intermediate would decompose to yield N^6-(*S*-acetyllipoyl)lysine.

To complete the reaction catalyzed by the complete pyruvate dehydrogenase system, the acetyl group on N^6-(*S*-acetyllipoyl)lysine is transferred to coenzyme A by dihydrolipoyllysine-residue acetyltransferase, in a simple nucleophilic substitution that liberates N^6-(dihydrolipoyl)lysine



(2–70)

and N^6-(dihydrolipoyl)lysine is converted by dihydrolipoyl dehydrogenase from the reduced to the oxidized form



(2–71)

in an oxidation–reduction catalyzed by the prosthetic group flavin.

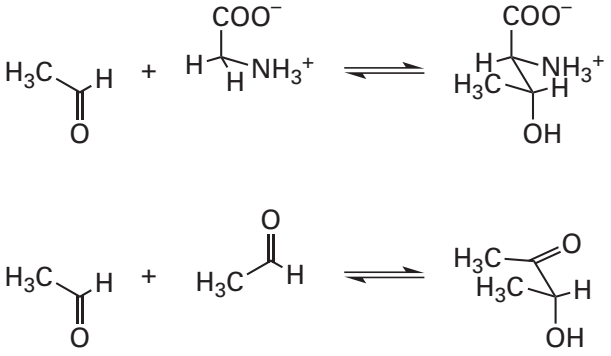
Problem 2–11: Write a mechanism for the transketolase reaction (Equation 2–56) catalyzed by thiamine diphosphate.

Problem 2–12: There are two enzymes that can catalyze, respectively, the two reactions



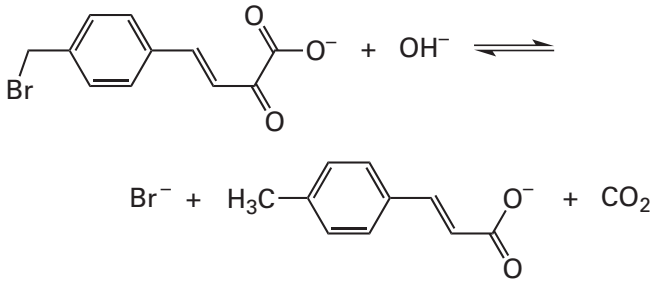
In both of these reactions, a hydron is replaced by acetaldehyde. The two enzymes, however, use different prosthetic groups. Write a mechanism for each reaction, using the proper prosthetic group in each case.

Problem 2–13: 4-(*p*-Chlorophenyl)-2-oxobut-3-enoic acid is an irreversible inhibitor of pyruvate decarboxylase (Equation 2–53).

(A) Write the mechanism of the reaction between this inhibitor and the thiamine diphosphate on the enzyme.

(B) Show by drawing resonance structures why this compound forms an irreversible, covalent adduct with the thiamine diphosphate within the enzyme.

Problem 2–14: Write a mechanism explaining how pyruvate decarboxylase is able to catalyze[247,248]



Problem 2–15: Write a mechanism explaining how transketolase is able to catalyze[249]

D-xylulose 5-phosphate $\rightleftharpoons$
hydroxyacetaldehyde +
glyceraldehyde 3-phosphate

Problem 2–16: Write a mechanism for the reaction catalyzed by phosphoketolase[205] and N^2-(2-carboxyethyl)arginine synthase.[223]

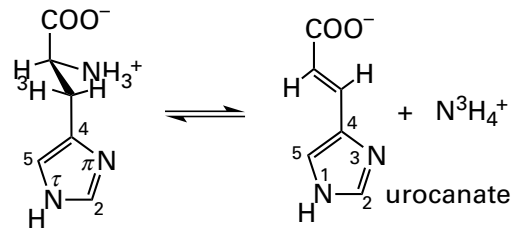
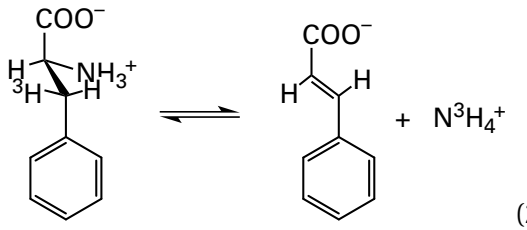
Histidine **ammonia-lyase** from *P. putida*[9]



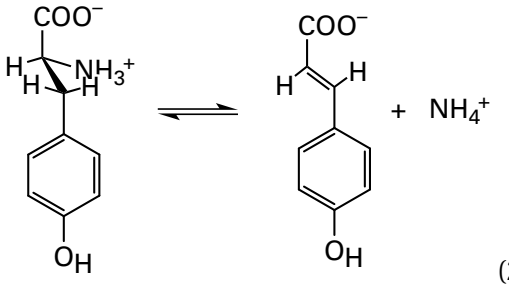
(2–72)

phenylalanine ammonia-lyase from *Rhodosporidium toruloides*[250] and *Petroselinum crispum*[251]



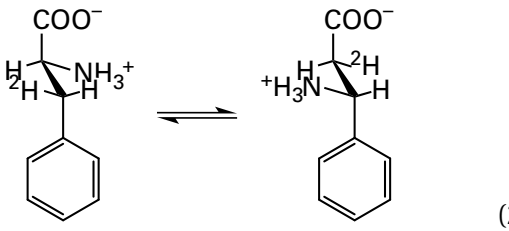
(2–73)

tyrosine ammonia-lyase from *R. sphaeroides*[252]



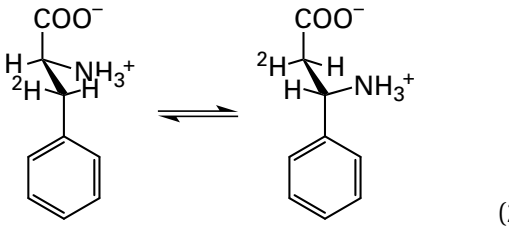
(2–74)

phenylalanine **aminomutase** (L-β-phenylalanine forming) from *Taxus wallichiana*[253]



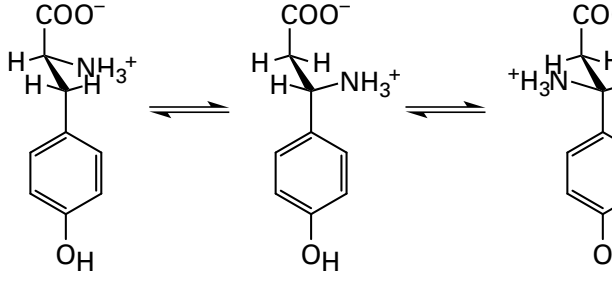
(2–75)

phenylalanine aminomutase (D-β-phenylalanine forming) from *Enterobacter agglomerans*[254]



(2–76)

and tyrosine 2,3-aminomutase from *Streptomyces globisporus*[255,256]



(2–77)

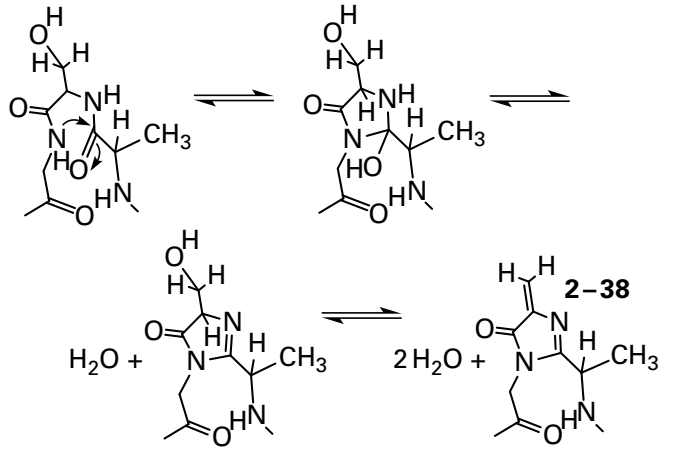
are all homologous enzymes (26–43% identity; ≤2.5 gap percent) catalyzing closely related reactions. The **only difference among the six reactions** is that in the first three reactions, ammonia is eliminated to give the unsaturated product, while in the latter three reactions, ammonia is eliminated and then added back to the resulting carbon–carbon double bond at the carbon adjacent to the one it left. In fact, phenylalanine aminomutase (L-β-phenylalanine forming) from *Taxus cuspidata* produces both L-β-phenylalanine and *trans*-cinnamate, the product of the elimination (Equation 2–73);[257] tyrosine 2,3-aminomutase from *S. globisporus* produces both 3-amino-3-(4-hydroxyphenyl)propanoate and *trans*-4-hydroxycinnamate, the product of the elimination (Equation 2–74);[255] and site-directed mutation can change phenylalanine aminomutase (L-β-phenylalanine forming) from *T. wallichiana* into a phenylalanine ammonia-lyase.[258]

In each of the six eliminations, **the *pro-S* hydron is always removed** from the β carbon of the respective amino acid.[257,259-262] The **stereochemistries of the aminomutases** are more complicated. Phenylalanine aminomutase (L-β-phenylalanine forming) from *T. wallichiana* proceeds predominantly with retention of configuration at both the α and β carbons of the substrates (Equation 2–75)[257,261] so that (*R*)-3-amino-3-phenylpropanoate is the kinetic product. Retention of configuration requires that the carbon–carbon bond of the intermediate *trans*-cinnamate (see Equation 2–73) flip over by rotating around the carbon–carbon bond to the phenyl group before the ammonia and the hydron are added back.[253] Phenylalanine aminomutase (D-β-phenylalanine forming) from *E. agglomerans* proceeds with inversion of configuration at both the α and β carbons of the substrates (Equation 2–76)[262] so that (*S*)-3-amino-3-phenylpropanoate is the other substrate, a fact consistent with the carbon–carbon bond of the intermediate *trans*-cinnamate remaining fixed in its configuration as the ammonia and the hydron are added back. Tyrosine 2,3-aminomutase from *S. globisporus* has both (*R*)-3-amino-3-(4-hydroxyphenyl)propanoate and (*S*)-3-amino-3-(4-hydroxyphenyl)propanoate as the other substrates, but (*S*)-3-amino-3-(4-hydroxyphenyl)propanoate is the kinetic product.

The *pro-S* hydrons on the β carbons of the respective L-amino acids that are the substrates for these enzymes must be acidic enough so each of them can be transferred to the 4-oxidophenyl group of a tyrosine[252,254,263-265] that is located at the homologous position in each active site and that acts as a catalytic base. Mutation of this tyrosine in the active

site of tyrosine 2,3-aminomutase to a phenylalanine[263,266] completely eliminates the enzymatic activity.

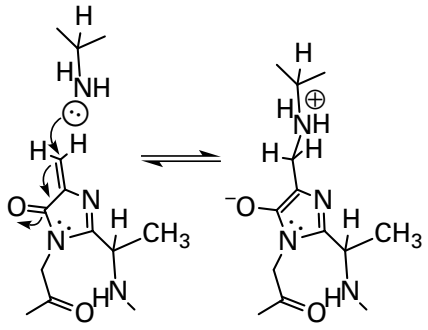
Each active site in these enzymes uses a prosthetic group, 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one (**2–38**), that is formed by a **posttranslational modification of the polypeptide** of the enzyme within the internal sequence –ASG–. The modification proceeds by a nucleophilic addition to an acyl carbon followed by two dehydrations



(2–78)

The posttranslational modification is present at the homologous location in each of the proteins.[9,267]

3,5-Dihydro-5-methylidene-4*H*-imidazol-4-one is a strong electrophile at its methylene carbon[268] because addition of a nucleophile, for example a primary amine, to that carbon gives an aromatic product



(2–79)

while the reactant, 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one, by itself is not aromatic. The distal carbon of the methylene group is the electrophilic center. Modification of the distal carbon of the prosthetic 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one in the active site of histidine ammonia-lyase from *P. putida* by nucleophilic addition of the conjugate base of nitromethane[260] or cyanide,[269] in the active site of tyrosine 2,3-aminomutase from *S. globisporus* by nucleophilic addition of cyanide[255] to its distal carbon, or in the active site of phenylalanine ammonia-lyase from *P. crispum* by nucleophilic addition of cyanide[270] inactivates the respective enzyme. These facts identify the distal carbon as the crucial location in the prosthetic group. One of the two equivalent, nucleophilic sulfido groups of the conjugate base of (2*S*,3*S*)-1,4-bis(sulfanyl)butane-2,3-diol forms an adduct with the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one at its distal carbon, which can be observed in a crystallographic molecular model of the active site of phenylalanine ammonia-lyase from *P. crispum*.[251]

There is a crystallographic molecular model of the active site of phenylalanine ammonia-lyase from *R. toruloides* in which the adduct between ammonia and the distal carbon of 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one is present.[250] There is a crystallographic molecular model of the active site of phenylalanine aminomutase (D-*β*-phenylalanine forming) from *E. agglomerans* (Equation 2–76) in which an equilibrium mixture of L-phenylalanine and D-*β*-phenylalanine is present. In this model, the amino group of each substrate in turn forms a nucleophilic adduct with the distal carbon of the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one (Equation 2–79).[254] There is a crystallographic molecular model of the complex between L-tyrosine and the active site of the inactive mutant of tyrosine 2,3-aminomutase from *S. globisporus* (Equation 2–77), in which the catalytic tyrosine has been changed to a phenylalanine. In this model, the amino group of the reactant L-tyrosine has formed a nucleophilic adduct with the distal carbon of the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one.[263] There are crystallographic molecular models of the complex between the active site of tyrosine 2,3-aminomutase from *S. globisporus* and (3*S*)-3-amino-2,2-difluoro-3-(4-hydroxyphenyl)propanoate[266] and the complex between the active site and (3*S*)-3-amino-2,2-difluoro-3-(4-methoxyphenyl)-propanoate,[264] both inhibitors of the enzymatic activity. In each of these two complexes, the amino groups of the respective inhibitors have also formed nucleophilic adducts with the distal carbon of the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one.

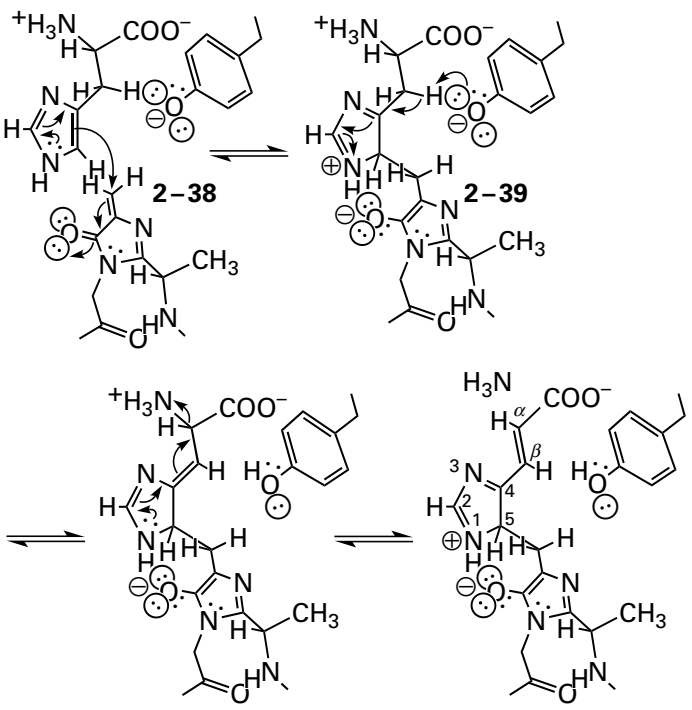
On the basis of all these observations, the currently favored mechanism for these enzymes that use 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one as a prosthetic group is that the **adduct between the distal carbon of the prosthetic 3,5-dihydro-**

5-methylidene-4*H*-imidazol-4-one and the amino group of the amino acid that is a reactant for the respective enzyme forms in the first step of the mechanism. Then, in each of the enzymatic eliminations catalyzed by the ammonia-lyases and the aminomutases, the adduct between ammonia and 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one is the leaving group, and in each of the additions catalyzed by the aminomutases, the adduct is the nucleophile that adds. In almost every other elimination that is catalyzed by an enzyme, however, the hydron that is removed during the elimination is α to a carbonyl group or an acyl group and, consequently, acidic ($pK_a = 9–27$; Figure 1-23), but **the β carbons on L-histidine, L-phenylalanine, and L-tyrosine are not acidic**. Consequently, while it would not be surprising that the removal of this hydron is the rate-limiting step in these enzymatic reactions,[261] it is also surprising that it can occur at all if this is the mechanism.

There are two serious **problems with this mechanism**. First, the adduct between the amino group on the substrate and the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one (Equation 2–79) turns the primary ammonio group into a secondary ammonio group. If anything, the resulting primary amine that would become the leaving group should be a poorer leaving group than ammonia itself because the resulting electron donation by hyperconjugation should increase the pK_a of its conjugate acid relative to that of the conjugate acid of ammonia. Second, this adduct places an additional saturated carbon between the imidazolone and the β carbon of the substrate in the adduct, so there is no way that the adduct with the amino group can solve the fundamental problem of the reaction, which is the extremely poor acidity of the β carbon ($pK_a \cong 43$ in L-phenylalanine and even greater in L-tyrosine).[271] There are no bases in an active site that are capable of removing a hydron from an acid with such a pK_a without some mechanism for lowering its pK_a dramatically.

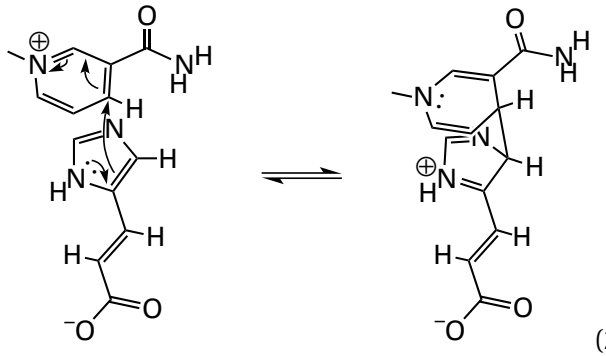
There is another mechanism, however, that avoids the former problem by avoiding an adduct with the amino group of the substrate and solves the latter problem by directly acidifying the β carbon.[9,272] This acidification is accomplished by withdrawing electron density from the σ bond between it and its hydron, much as pyridoxal 5′-phosphate does with a σ bond between the α carbon and its hydron in the external pyridoximine and as thiamine diphosphate does with a σ bond between a carbonyl carbon and a hydron, an even poorer acid. This other mechanism also explains why the only substrates for the enzymes that use 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one as a prosthetic group are the three aromatic amino acids.

In this mechanism, the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one, as already noted a strong electrophile, participates in an **electrophilic aromatic addition** to the imidazolyl group, the phenyl group, or the 4-hydroxyphenyl group of the respective substrate to produce an α,β-unsaturated iminium or a pentadienyl cation, respectively. For example, in the active site of histidine ammonia-lyase, adduct **2–39** would result from the electrophilic addition of the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one to the aromatic imidazolyl group of L-histidine



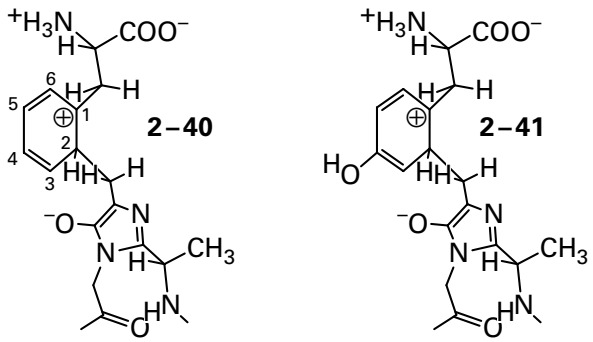
(2–80)

which is analogous to the electrophilic addition of NAD^+ to urocanate (previously Equation 1–85)



(2–81)

during the reaction catalyzed by urocanate hydratase. During the addition of the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one to the imidazolyl group (Equation 2–80), the aromatic π system of the imidazolyl group is lost but the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one has become aromatic in compensation. The homologous adducts of L-phenylalanine (**2–40**) and L-tyrosine (**2–41**)



each create a pentadienyl cation in conjugation with the σ bond of the respective β hydron. Electron withdrawal by the α,β-unsaturated iminium (Equation 2–80) or the pentadienyl cation acidifies the β carbon, which permits the oxidophenyl group of the tyrosine in the active site to remove its hydron. Following the removal of the β hydron, the electron excess in the resulting β,γ-unsaturated enamine or the 1,3,5-hexatriene that incorporates the β carbon is able to provide push to assist in the dissociation of the ammonia, just as an enolate provides push during an elimination. There is experimental evidence for such a mechanism.

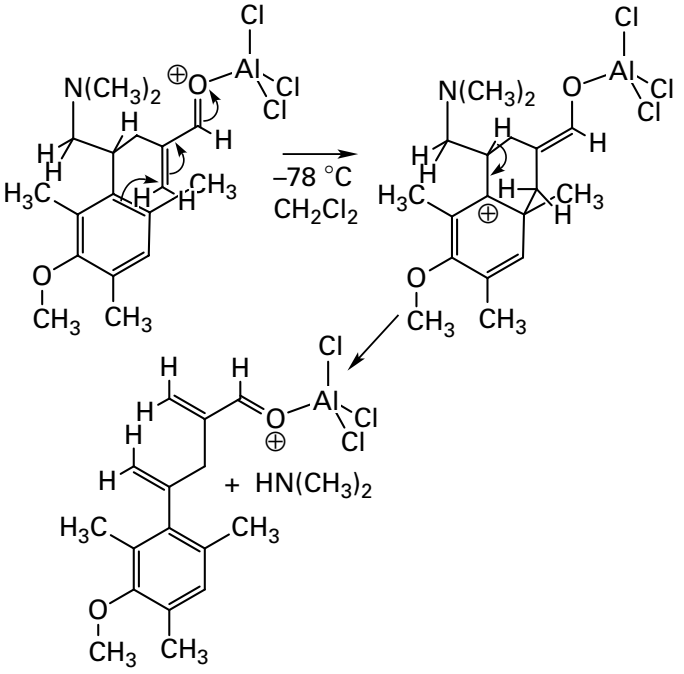
When L-[β,β,5-$^2H_3$]histidine was used as a reactant with histidine ammonia-lyase (Equation 2–72) from *P. fluorescens* in ^1H_2O for 24 h at pH 9 and 25 °C, 45% of the deuterium at carbon 5 in the product urocanate had been exchanged for protium.[273] This **isotopic exchange** is evidence for the existence of the covalent intermediate **2–39**. In intermediate **2–39** both the hydron on the β carbon of the histidine, the usual target, and the hydron on carbon 5, which are each equivalently placed γ to the iminio group on nitrogen τ (Equation 2–72) and conjugated to it, become acidic. The acidity at the β carbon initiates the elimination; the acidity at carbon 5 is adventitious but unavoidable and an unexpected signature for the intermediate. In the adduct between the α-amino group of L-histidine and 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one, the hydrogen on carbon 5 would not be acidic. One problem with this explanation for the observed isotopic exchange is that the conjugate base of the dissociation of a hydron at carbon 5 in intermediate **2–39** should be the stable bisaromatic product of an electrophilic aromatic substitution, and such a product should inactivate the enzyme. The active site, however, appears to be able to distort sterically the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one out of planarity at nitrogen 3,[274] an ability that may destabilize the aromatic form of the imidazolone whenever the imidazolyl group or the phenyl group reverts to its aromatic form by loss of the homologous hydron while in the adduct.

When the serine in the sequence –ASG– in the active site of phenylalanine ammonia-lyase from *P. crispum* that becomes 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one during the posttranslational modification (Equation 2–78) is mutated to an alanine, the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one cannot form. The catalytic constant for the production of *trans*-cinnamate from L-phenylalanine (Equation 2–73) has decreased by a factor of 5000 in the mutant. The wild-type enzyme is able to convert 4-nitro-L-phenylalanine to 4-nitro-*trans*-cinnamate, but with a catalytic constant one-third that for the conversion of L-phenylalanine to *trans*-cinnamate. The mutant, however, has a catalytic constant for the same reaction that is 70 times the catalytic constant for its conversion of L-phenylalanine,[8] so the mutation has decreased the **conversion of 4-nitro-L-phenylalanine to 4-nitro-*trans*-cinnamate** by only a factor of 20. The 4-nitro group, as usual, accomplishes electron withdrawal from carbon 1 of the phenyl group, just as 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one does in electrophilic adduct **2–40**, so the production of 4-nitro-*trans*-cinnamate should be much less affected by the ablation of the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one than the production of *trans*-cinnamate, as is observed.

There are crystallographic molecular models of a complex between *trans*-cinnamate and phenylalanine ammonia-lyase (Equation 2–73) from *Anabaena variabilis*;[275] complexes between *trans*-

cinnamate and two phenylalanine aminomutases (L-*β*-phenylalanine forming) (Equation 2–76), one from *T. wallichiana*[253] and one from *Taxus canadensis*;[276] and complexes between both *trans*-cinnamate and *trans*-4-hydroxycinnamate and tyrosine ammonia-lyase (Equation 2–74) from *R. sphaeroides*.[252] The ligands are either substrates for the respective enzymes or intermediates in the respective enzymatic reactions. In each of these crystallographic molecular models **the distal methylene carbon of the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-one sits between one of the ortho carbons of the respective phenyl ring and the *β* carbon of the substrate**, from which the amino group would have been removed. In two of the instances, the distal methylene carbon is within van der Waals contact (<0.39 nm) of the ortho carbon, as it should be if intermediate **2–40** is involved in the reaction, and in the others, it is less than 0.5 nm away.

There is also a **model reaction**[277] for the proposed mechanism



(2–82)

The elimination of the 4-dimethylamino group that is observed in this reaction is believed to proceed by intramolecular nucleophilic addition of the *π* system of the phenyl group to the electrophilic carbon in an aluminum trichloride adduct of a 3-oxoprop-1-en-2-yl group (arrows in Equation 2–82). This addition produces a pentadienyl cation in the phenyl ring, stabilized by a *p*-methoxy group and immediately adjacent to a carbon–hydrogen bond that the cation causes to be acidic. The dissociation of the hydron in this exocyclic carbon–hydrogen bond initiates the observed elimination of dimethylamine. If this is the mechanism of the elimination, then this reaction is a mimic for the proposed mechanism for the enzymes that involves electrophilic additions of the 3,5-dihydro-5-methylidene-4*H*-imidazol-4-ones to the respective aromatic substrates.

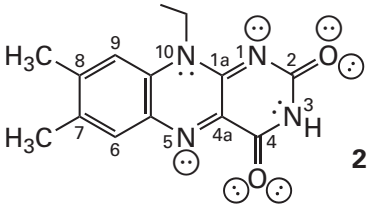
Schwede, T. F., Retey, J., and Schulz, G. E. (1999) Crystal structure of histidine ammonia-lyase revealing a novel polypeptide modification as the catalytic electrophile, *Biochemistry 38*, 5355–5361. https://doi.org/10.1021/bi982929q

Flavin

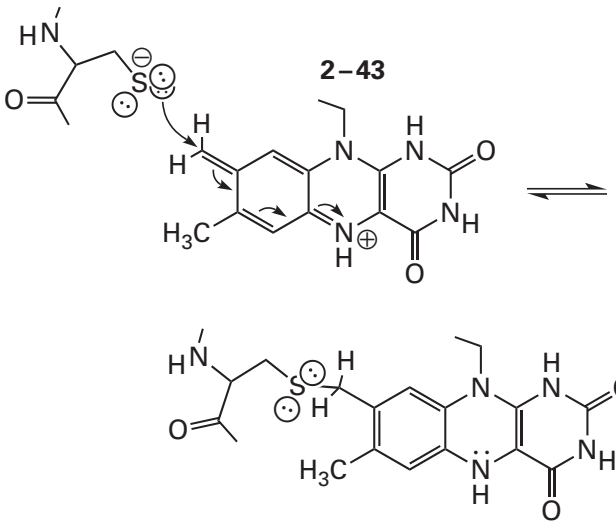
The various flavins have, as their catalytically active portion, a 7,8-dimethylisoalloxazine substituted at nitrogen 10



2–42

The substitution at nitrogen 10 is what distinguishes the various flavins: flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), and riboflavin. Although there are a number of instances, including a family of monooxygenases (EC 1.14.14), in which a flavin participates in an enzymatic reaction as a coenzyme,[278,279] flavins are usually either **covalently or noncovalently incorporated as prosthetic groups** into enzymes and remain bound tightly to the protein during the association of reactants and the dissociation of products.

When it is covalently attached to a protein, the bond to the 7,8-dimethylisoalloxazine is usually between the **carbon of the 8-methyl group** and a nucleophilic amino acid such as histidine,[280] cysteine,[281] or aspartate.[282] This presumably results[283] from a nucleophilic attack on the vinylogous *α,β*-unsaturated imine present in tautomer **2–43** of the conjugate acid of oxidized flavin (**2–42**)



(2–83)

The addition is catalyzed by the active site of the enzyme itself, but there are proteins in the cytoplasm that can accelerate the addition.[284]

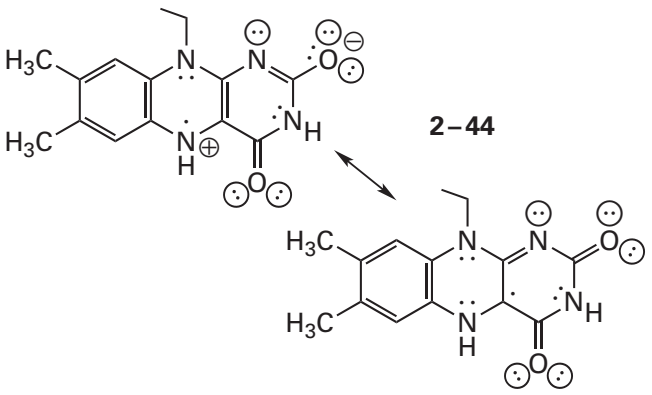
If the cysteine in sarcosine oxidase (formaldehyde-forming) from *Bacillus* to which flavin adenine dinucleotide would normally be covalently attached is replaced with alanine, the enzyme binds flavin adenine dinucleotide weakly; and it has to be added to the solution at fairly high concentration for enzymatic activity to be observed.[285] In enzymes in which it is not covalently attached, however, flavin is tightly bound to preclude its loss.

Because flavin is either covalently bound or very tightly bound to a protein and also has a bright yellow color in its oxidized state (**2–42**), which is usually its oxidation state after the specimen is homogenized, a protein with bound flavin can be purified simply by monitoring this color. The absorption spectrum of such a protein can be used to demonstrate that it has the prosthetic group bound to it, and this spectrum designates the protein as a **flavoprotein** or **flavoenzyme**. These terms are sometimes used to designate a protein before its specific function has been determined and a proper descriptive name has been assigned to it. An example would be "old yellow enzyme".

There are three stable oxidation states of flavin that differ sequentially by two one-electron steps (Figure 2–9).[286-289]

Neutral, **oxidized flavin** (**2–42**; HFl_{ox}, Figure 2–9) is the most electron-deficient form occurring naturally. It contains 18 π electrons in a π molecular orbital system with 16 π molecular orbitals constructed from 16 p orbitals. When it is completely unhydronated as the anion (Fl_{ox}^-, Figure 2–9) at high pH, it has seven σ lone pairs of electrons available for hydronation, giving the monohydronated and dihydronated isoalloxazine ample opportunity for tautomerization. In the abbreviations that follow, it will be assumed that the only completely unhydronated form of flavin present under normal circumstances is this anion, and the number of hydrons in each abbreviation, for example, HFl_{ox}, will be based on this designation. Neutral, oxidized flavin mononucleotide (FMN) in solution has a characteristic **absorption spectrum** (Figure 2–10)[290-294] with a maximum absorbance at 446 nm that gives the oxidized flavin its yellow color and a second maximum absorbance at 372 nm. The absorption centered at 446 nm is composed of at least three peaks of absorption that often become even more obvious when flavin is bound in the active site of an enzyme.

The addition of an electron to the neutral, monohydronated form of oxidized flavin (HFl_{ox}, Figure 2–9) forms the radical anion ($HFl^{\bullet -}$). At neutral pH, the radical anion takes up a hydron (pK_a of the conjugate acid is 8.3) to become the neutral radical ($H_2Fl^{\bullet}$, Figure 2–9). A **flavin semiquinone** is a flavin radical. The three normally accessible hydronation states are the radical anion, $HFl^{\bullet -}$, the neutral radical, $H_2Fl^{\bullet}$, and the radical cation, $H_3Fl^{\bullet +}$ (Figure 2–9). In each of these three states of hydronation for the flavin semiquinone, however, because the hydrons are added or removed from σ lone pairs of electrons orthogonal to the π molecular orbital system, if the molecule is fully conjugated, there are formally 19 π electrons in a π molecular orbital system constructed from 16 p orbitals regardless of its state of hydronation. In its neutral form, two of the seven σ lone pairs of electrons on its heteroatoms are occupied by hydrons. The resonance form of the flavin semiquinone, $H_nFl^{\bullet}$, presented in Figure 2–9 is based on its calculated distribution of spin density,[295] which is confined in large part to nitrogen 5 and carbon 4a



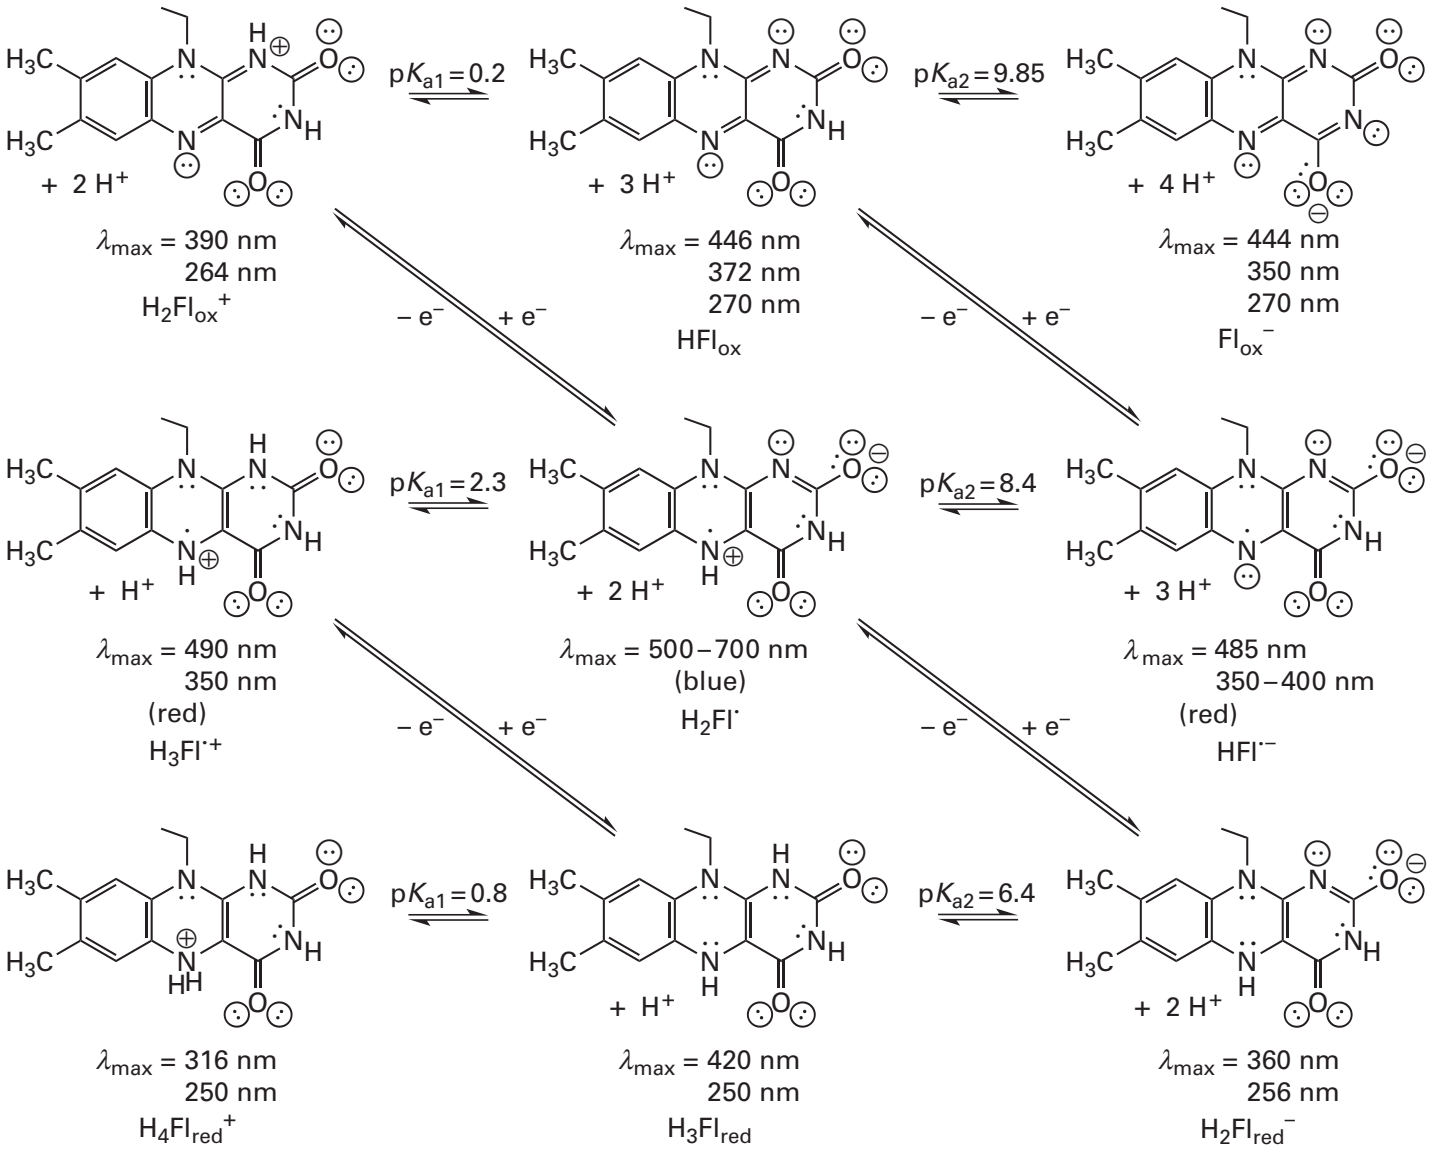


Figure 2–9: The three oxidation states of flavin and the normally accessible conjugate acids and bases at each oxidation state.[286-289] Three conjugate acid–bases of fully oxidized flavin are presented on the top row with their abbreviations and the characteristic maxima in their ultraviolet and visible spectra. Addition of one electron produces the semiquinone, which is a radical (middle row). The most unusual of the three conjugate acid–bases of the semiquinone is the blue neutral radical (λ_{max} = 570 nm). In forming this radical ($H_2Fl^{\bullet}$) directly from the cationic oxidized flavin ($H_2Fl_{ox}^{+}$), the two nitrogens switch basicity and, following a rearrangement of the hydrons, the neutral radical is the opposite tautomer.[289] Addition of a second electron produces fully reduced flavin (bottom row), three conjugate acid–bases of which are presented. The addition of each electron, as expected, increases the basicity of the acid–base to which the electron was added, hence the diagonal arrows for the additions of electrons.

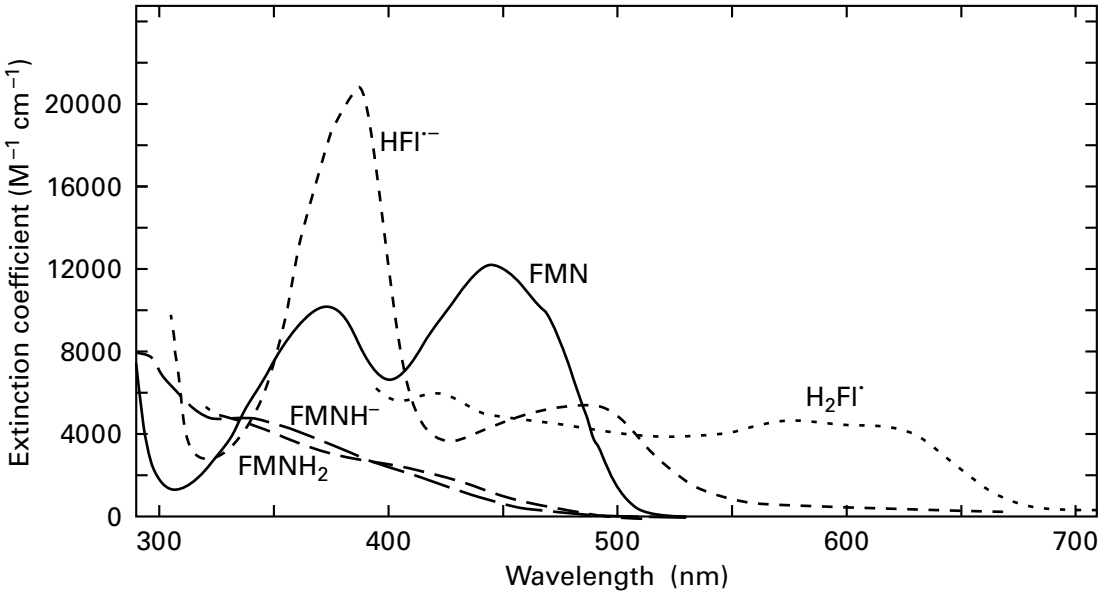

Figure 2–10: Absorption spectra of the five forms of flavin that predominate in the midrange of pH. The extinction coefficient of the spectrum for the neutral, oxidized form of flavin mononucleotide (FMN)[292] (λ_{max} = 446 nm; ε_{446} = 12,200 M^{-1} cm^{-1})[291] was used to scale each of the other spectra because each of these other published spectra had a spectrum of neutral oxidized flavin accompanying it. It was assumed that the extinction coefficient of neutral oxidized flavin in an active site was the same as in solution. The spectra[292] for the neutral reduced form of flavin mononucleotide ($FMNH_2$) and the anionic conjugate base of flavin mononucleotide ($FMNH^-$) have no pronounced maxima of absorbance in the visible range. The spectrum[2608] for the neutral flavin semiquinone ($H_2Fl^{\bullet}$) was obtained by Professor Beinert by reducing completely the oxidized form of the metal-free flavoprotein[294] from *A. vinelandii* with successive additions of $S_2O_4^{2-}$ at pH 7 until the reduction was complete. The initial spectrum of the oxidized flavoprotein provided the reference for the extinction coefficient. The spectrum[293] for the anionic conjugate base of flavin semiquinone ($HFl^{\bullet -}$) was obtained by reducing the oxidized form of L-amino-acid oxidase from *C. adamanteus* by photolysis at pH 7.6 in the presence of 90 mM ethylenediaminetetraacetate until the photoreduction was complete. Again, the initial spectrum of the oxidized flavoprotein provided the reference for the extinction coefficient.

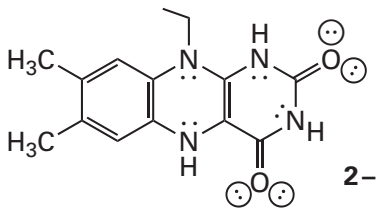
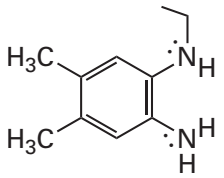
Because of the rapid disproportionation that occurs in solution, the **absorption spectra** of neutral flavin semiquinone, $H_2Fl^{\bullet}$, and the anionic conjugate base of flavin semiquinone, $HFl^{\bullet -}$, are most readily measured in flavoproteins in which these two forms are stabilized. The neutral flavin semiquinone stabilized in the flavoprotein from *Azotobacter vinelandii* (Figure 2–10) absorbs light of long wavelength (λ_{max} = 575 nm and 617 nm) because of its zwitterionic character (Figure 2–9), and this absorption gives it a blue color. The absorption at these long wavelengths is lost when either a hydron is added to one of the σ lone pairs to generate the radical cation, $H_3Fl^{\bullet +}$, or a hydron is removed from one of the σ lone pairs to generate the radical anion, $HFl^{\bullet -}$, neither of which can be zwitterionic. The absorption spectrum of the radical anion of flavin semiquinone in the active site of L-amino-acid oxidase from *Crotalus adamanteus* (Figure 2–10) has maxima of absorbance at 387 and 483 nm. In some flavoenzymes, the peak of absorbance between 350 and 400 nm for the radical anion splits into a broad symmetrical peak around 360 nm and a narrow symmetrical peak of lesser extinction coefficient around 400 nm.[293] These two peaks have coalesced in the case of L-amino-acid oxidase, and that coalescence accounts for the asymmetry in the peak of absorption.

The addition of an electron to the neutral, dihydronated, zwitterionic flavin semiquinone ($H_2Fl^{\bullet}$, Figure 2–9) forms the reduced flavin anion ($H_2Fl_{red}^-$, Figure 2–9). The 7,8-dimethylisoalloxazine that constitutes neutral, trihydronated **reduced flavin**



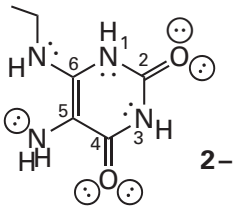
2–45

is conveniently divided in the middle along the axis of nitrogen 5 and nitrogen 10 into *N*-alkyl-1,2-diamino-4,5-dimethylbenzene



2–46

and N^6-alkyl-5,6-diaminouracil



2–47

In this gedanken dissection, reduced flavin is described as a chimera of a dianiline and the substituted base of a nucleic acid. In neutral reduced flavin (**2–45**), the lone pair of electrons on nitrogen 10 is conjugated to both the dimethylphenyl group, **2–46**, and the uracilyl group, **2–47**, and consequently is not basic, while the lone pair of electrons on nitrogen 5 is only conjugated to the dimethylphenyl group and not the uracilyl group, and it is weakly basic (the pK_a of its conjugate acid is 0.8; Figure 2–9).*

The pK_a of neutral reduced flavin for **dissociation of the hydron from nitrogen 1** is 6.4, so when it is in solution at pH 7, reduced flavin is an equilibrium 3:1 mixture of the anion, $H_2Fl_{red}^-$, and the neutral molecule, H_3Fl_{red}. In the active sites of an enzyme, however, the usual form of reduced flavin is $H_2Fl_{red}^-$. Consequently, within the active site of an enzyme, when neutral, oxidized flavin, HFl_{ox}, is reduced by two electrons to reduced flavin anion, $H_2Fl_{red}^-$, only one hydron usually has to be supplied by an acid in that active site, and in the reverse direction, only one hydron must be removed by the conjugate base of that acid. In the anionic form of the reduced flavin, as in any anion of an amide, the greatest density of negative charge is located on the oxygen on carbon 2 ($H_2Fl_{red}^-$, Figure 2–9) because of the disparity of electronegativity between the oxgen and the nitrogen.

Both the **absorbance** of neutral reduced flavin mononucleotide and the absorbance of its anionic conjugate base decrease monotonically between 320 and 500 nm with hints of peaks of absorbance at around 420 and 350 nm, respectively (Figure 2–10). Consequently, for flavins and flavoenzymes, there is an almost complete loss of absorbance at around 450 nm when oxidized flavin becomes reduced flavin.

Whether these three oxidation states of flavin, in the absence of steric effects, are normally **planar or bent** is unclear. Neutral reduced flavin (H_3Fl_{red}, **2–45**), if it is fully conjugated, has 20 π electrons in a π molecular orbital system constructed from 16 *p* orbitals. This **unusually electron-rich π molecular orbital system** is so electron-rich that it may well crack in half along its central axis. One way to relieve the pressure of the electron density would be to **bend the molecule** along an axis between nitrogen 5 and nitrogen 10. This bending would cause the hybridization on these two nitrogens to become [sp^3, sp^3, sp^3, sp^3] and allow them each to confine a pair of those 20 electrons as a σ lone pair and decrease the number of π electrons to 16. This bending would split the π molecular orbital system into two halves—the diaminodimethylbenzene and the diaminouracil. For this splitting to happen, the planes of these two rings must meet at an angle. Ab initio molecular orbital calculations predict that in reduced flavin this angle should be around 150°,[296] but the barrier between this bent conformation and a planar conformation should be a small one.[297]

The available **crystallographic molecular models** of reduced isoalloxazines, when they are not in enzymes, show various departures from planarity, but these departures seem to be due to steric effects, not electronic effects.[298-300] Nuclear magnetic resonance spectra of reduced flavins with no steric complications, in both nonpolar and polar solvents, indicate that these molecules are planar.[301] A planar stereochemistry would also be consistent with the acid–base behavior of the two nitrogens on the 1,2-diaminobenzene (pK_{a1} = 1.3 and pK_{a2} = 4.5), which are considerably less basic than those in 1,2-diaminoethane (pK_{a1} = 7.5 and pK_{a2} = 10.0). This fact indicates that the two nitrogens in a diaminobenzene, and presumably reduced flavin as well, have π lone pairs of electrons rather than σ lone pairs of electrons and are themselves planar. Furthermore, the exocyclic nitrogens of nucleic acid bases, such as 6-aminouracil, are usually planar. The particularly low pK_a (pK_a = 0.8) for nitrogen 5 of reduced flavin (Figure 2–9), which is considerably lower than that for the conjugate acid of aniline (pK_a = 4.6), cannot

*The pK_a of nitrogen 5 is still significantly less than that of 2-amino-4,5-dimethylaniline (pK_a of its monocationic conjugate acid is predicted to be 5). Presumably the low pK_a of nitrogen 5 results from σ electron withdrawal by the 5,6-diaminouracil.

be mistaken for the pK_a of a tetrahedral nitrogen (pK_a = 10) and more closely resembles the values of pK_a for the exocyclic nitrogens in nucleic acid bases. All these considerations indicate that, in solution, in spite of the calculations, reduced flavin seems to have a planar 7,8-dimethylisoalloxazine.

Oxidized flavin (HFl_{ox}) is generally assumed to be completely planar, owing to the conjugation that connects every atom in the three rings. This conclusion is usually based on the crystallographic molecular models of several 10-alkylisoalloxazines, which are perfectly planar.[302] Most of these analogues, however, have been cocrystallized with naphthalene-2,3-diol,[302-304] which sandwiches the isoalloxazines in the crystal and could thereby force them to be planar even if they were not already planar. Therefore, the distinction that is usually made between rigidly planar oxidized flavin and flexible, easily bent reduced flavin may not be so clear-cut as has been assumed, and it is probably not the case that constraining the flavin to one geometry can affect its reduction potential. The nature of the acid–bases around the flavin is probably far more important.[305]

In the **crystallographic molecular models of flavoproteins**, the prosthetic 7,8-dimethylisoalloxazines are planar (Figure 2–11),[306-311] slightly twisted (Figure 2–12),[312-315] or bent (Figure 2–13),[316] sometimes almost as extensively (155°) as predicted in the molecular orbital calculations.[317] The one consistent feature is that the 7,8-dimethylisoalloxazines are tightly surrounded by side chains and the main chain of the protein that hold them in a rigid grip[317,318] and prevent each of them from changing its conformation upon reduction or oxidation.[319] This rigid grip is in marked contrast to how loosely the pyridinium ring of pyridoxal 5′-phosphate, which must reorient during catalysis, is usually held within the active sites of enzymes that use it as a prosthetic group.

A reduced molecule and an oxidized molecule, such as oxidized flavin and reduced flavin, that can be interconverted by subtracting or adding only electrons and hydrons are a redox couple. The **reduction potential**, *E*, of a redox couple under a given set of conditions is the voltage it can provide to move electrons when they are electrochemically transferred from a standard hydrogen electrode to the oxidized molecules of the redox couple to form the reduced molecules. The **standard hydrogen electrode**

$$H_2 \rightleftharpoons 2\,H^+ + 2\,e^- \qquad (2\text{–}84)$$

is an electrode in which diatomic hydrogen gas at 10^5 pascals is poised electrochemically at equilibrium with two hydrons at pH = 0 in aqueous solution.

There are standard electrodes other than a standard hydrogen electrode that are easier to use in electrochemical measurements, but the voltages recorded with these other standard electrodes are usually corrected to voltages that would have been observed with a standard hydrogen electrode. For example, a saturated calomel electrode

$$2\,Hg(l) + 2\,Cl^- \rightleftharpoons Hg_2Cl_2(s) + 2\,e^- \qquad (2\text{–}85)$$

is a paste of Hg_2Cl_2 mixed with liquid mercury, and the concentration of Hg_2Cl_2 at saturation is held constant by using as a solvent a saturated solution of KCl. The voltage of this electrode is +0.241 V relative to a standard hydrogen electrode at 25 °C.

A simple example of a redox couple in an aqueous solution would be ferricyanide and ferrocyanide

$$[Fe^{3+}(CN^-)_6]^{3-} + e^- \rightleftharpoons [Fe^{2+}(CN^-)_6]^{4-} \qquad (2\text{–}86)$$

The voltage that this redox couple can produce to move electrons from molecules of H_2 gas at a standard hydrogen electrode to reduce ferricyanide to ferrocyanide, when the conditions are such that the activities of the ferricyanide and ferrocyanide are equal, is +360 mV. In general chemistry, in such a simple unimolecular oxidation–reduction, the reduction potential provided by the redox couple to move electrons from the standard hydrogen electrode to a mixture of the two members of the redox couple at equal activity at a pH of 0 is the **standard reduction potential**, E°.

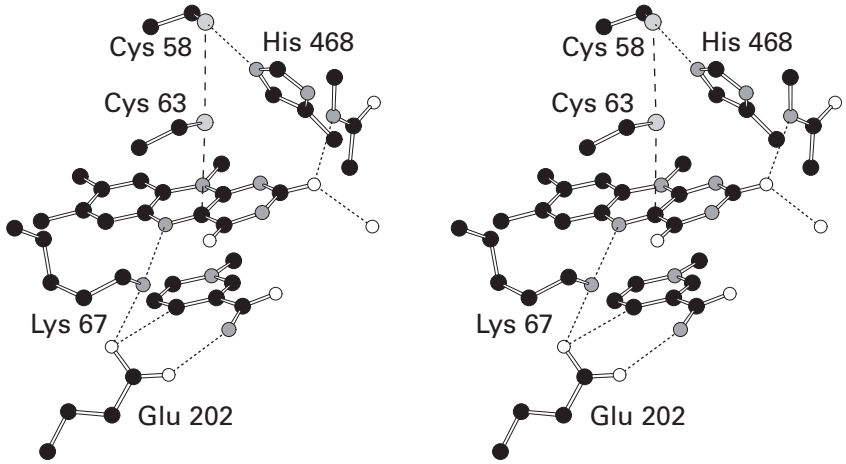


Figure 2–11: Crystallographic molecular model of the active site of reduced glutathione-disulfide reductase from human erythrocytes with bound NADH.[306] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. Crystals of human glutathione-disulfide reductase were transferred to solutions containing 10 mM NADH in 0.1 M potassium phosphate at pH 7.0. After 3 h, data sets to Bragg spacings of 0.185 nm were collected from these crystals, and the map of electron density was calculated by refinement, beginning with the phases from the refined data set of the enzyme without bound NADH. The stereodrawing[50] is from the resulting crystallographic molecular model. The 7,8-dimethylisoalloxazine of the flavin, which is planar in this active site, is in the center of the drawing, and the nicotinamide ring of the NADH is stacked below the flavin. Lysine 67 forms a hydrogen bond with nitrogen 5 of the flavin, and Glutamate 202 forms a hydrogen bond with Lysine 67 with one of its oxygens and a hydrogen bond with the carbamoyl nitrogen of the NADH with its other oxygen. The latter hydrogen bond can act as a pivot for the carboxy group. The amido nitrogen–hydrogen of the peptide bond between Leucine 339 and Threonine 340 and a molecule of water (white sphere) each donate a hydrogen bond to the oxygen of the 2-oxo group of the flavin. It is at this oxygen that the formal negative elementary charge of the monoanion of reduced flavin ($H_2Fl_{red}^-$) is located (Figure 2–9). Cysteine 58 and Cysteine 63 are the internal thiols that are oxidized to a disulfide by the enzymatic reaction. The two sulfurs of these cysteines are online with carbon 4a of the flavin (vertical thickly dashed line). The Histidine 468 in an identical, neighboring subunit of the enzyme forms a hydrogen bond to the distal sulfur of this pair of cysteines and removes the hydron from this sulfur during the oxidation. When the cystine forms, the dihedral angle, χ_3, along the sulfur–sulfur bond[310] is –138°, which is close to –150°, one of the six dihedral angles, 30°, 90°, 150°, –150°, –90°, and –30°, at which the two lone pairs and the carbon–sulfur σ bonds on each of the two sulfurs are as far from being parallel to each other as possible.[309] The crystallographers note that direct contact between nitrogen 5 of the flavin and the hydride of the nicotinamide is blocked sterically by the side chain of Lysine 67.[311] This steric effect may prevent direct transfer of a hydride to nitrogen 5 of the flavin from carbon 4 of the NADH.

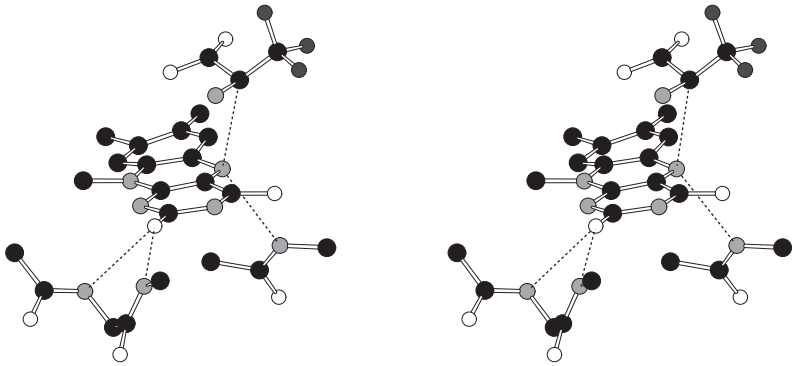

Figure 2–12: Stereodrawing[50] of the crystallographic molecular model of the active site of D-amino-acid oxidase from *R. toruloides* with bound D-trifluoroalanine.[312] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and small dark gray atoms are fluorines. Crystals of D-amino-acid oxidase were transferred to solutions containing 10 mM racemic trifluoroalanine. After several hours, data sets to Bragg spacings of 0.172 nm were collected from these crystals, and the map of electron density was calculated by molecular replacement and refinement. The stereodrawing[50] is from the resulting crystallographic molecular model. The 7,8-dimethylisoalloxazine of the flavin, which is slightly twisted in this active site, is in the center of the drawing. The hydrogen on carbon 2 of the D-trifluoroalanine, which is bound selectively by the enzyme and which is above the isoalloxazine in the drawing, is directed toward nitrogen 5 of the isoalloxazine. The amido nitrogen–hydrogen of the peptide bond between Alanine 51 and Glycine 52 (below the isoalloxazine) is the donor for a hydrogen bond to nitrogen 5 of the flavin. The amido nitrogen–hydrogen of the peptide bond between Glycine 337 and Tyrosine 338 and the amido nitrogen–hydrogen of the peptide bond between Tyrosine 338 and Glutamine 339 each donate a hydrogen bond to the oxygen of the 2-oxo group of the flavin. It is at this oxygen that the negative formal elementary charge of the monoanion of reduced flavin ($H_2Fl_{red}^-$) is located (Figure 2–9).

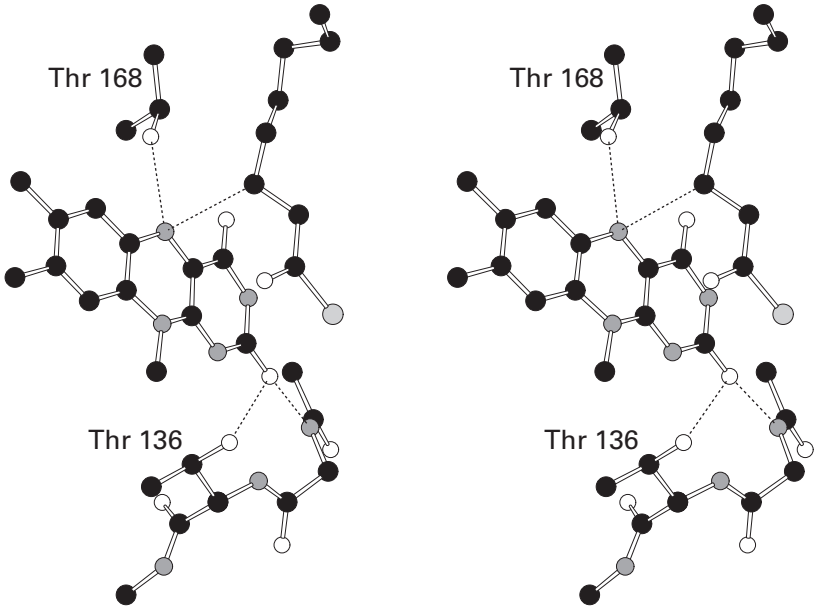

Figure 2–13: Crystallographic molecular model of the active site of porcine mitochondrial acyl-CoA dehydrogenase with bound octanoyl-SCoA.[316] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large light gray atom is a sulfur. Crystals of acyl-CoA dehydrogenase were grown over a period of a month in an anaerobic solution containing a concentration of octanoyl-SCoA equimolar to the concentration of active sites. Data sets to Bragg spacings of 0.24 nm were collected from these crystals, and the map of electron density was calculated by refinement, beginning with the phases from the refined data set of the enzyme without bound octanoyl-SCoA. The stereodrawing[50] is from the resulting crystallographic molecular model. The 7,8-dimethylisoalloxazine of the flavin, which is bent in this active site, is in the left center of the drawing. The *pro-S* hydrogen on carbon 3 of the octanoyl group of the octanoyl-SCoA, which is to the left of the isoalloxazine in the drawing, is directed toward nitrogen 5. Only the octanoyl group of the octanoyl-SCoA is shown. The oxygen–hydrogen of Threonine 168 is the donor of a hydrogen bond to nitrogen 5 of the flavin. The amido nitrogen–hydrogen of the peptide bond between Cysteine 134 and Valine 135 and the oxygen–hydrogen of Threonine 136 in the segment of polypeptide at the bottom of the drawing each donate a hydrogen bond to the oxygen of the 2-oxo group of the flavin. It is at this oxygen that the negative formal elementary charge of the monoanion of reduced flavin ($H_2Fl_{red}^-$) is located (Figure 2–9).

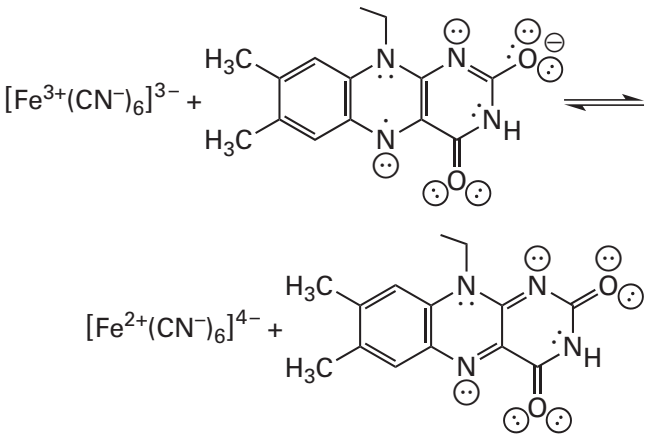
For biochemical reactions, however, the pH chosen for the standard state of the redox couple is 7.0. By convention, the standard pH for E°, the chemical standard reduction potential, is pH 0, and the standard pH for $E^{\circ\prime}$, the **biochemical standard reduction potential**, is pH 7. The standard hydrogen electrode, however, is always poised at a pH of 0. When standard reduction potentials of either type are stated, the chemical equation for the redox couple to which they refer is the one in which the oxidized species is the reactant and the reduced species is the product.

The more positive the reduction potential, the easier it is to reduce the oxidized molecules of the redox couple and the harder it is to oxidize the reduced molecules. **Electrons move spontaneously from redox couples that have more negative reduction potential to redox couples that have more positive reduction potential** when the redox couples are electrochemically connected. For example, the biochemical standard reduction potential for the redox couple of oxidized flavin and flavin semiquinone anion (Figure 2–9)

$$HFl_{ox} + e^- \rightleftharpoons HFl^{\cdot -} \tag{2–87}$$

is −340 mV,[288] and the biochemical standard reduction potential of ferricyanide is +0.440 V. Therefore, in the following complete stoichiometric chemical reaction



(2–88)

if reactants and products could be present at equal activity, the electron would move spontaneously from the redox couple with a biochemical standard reduction potential of −340 mV to the redox couple with a biochemical standard reduction potential of +440 mV, and this reaction would be favorable when proceeding from left to right. If these redox couples were separated into two compartments, both at pH 7, and connected electrochemically, a voltage of 780 mV moving electrons from flavin semiquinone anion to ferricyanide would be generated between the two compartments if the oxidized flavin and the flavin semiquinone anion could be present at their respective standard states.

The **free energy change of an oxidation–reduction under a particular set of conditions other than standard state**, ΔG, is related to the reduction potentials of the two redox couples under those same conditions by the equation

$$\Delta G = -nF\Delta E \tag{2–89}$$

where n is the number of electrons transferred from reductant to oxidant for the stoichiometric reaction as written, F is the Faraday constant (96,485 J V^{-1} mol^{-1}), and

$$\Delta E = E_{r,ox/p,red} - E_{p,ox/r,red} \tag{2–90}$$

where $E_{r,ox/p,red}$ is the reduction potential for the redox couple of the oxidized reactant that is being reduced and the reduced product that is the result of that reduction and $E_{p,ox/r,red}$ is the reduction potential for the redox couple of the reduced reactant that is being oxidized and the oxidized product that is the result of that oxidation. The designations of reactant and product are defined by the chemical equation as it is written, reactants on the left and products on the right, and the numerical values of E are the reduction potentials of the two redox couples under the particular conditions of the reaction. The more positive the difference between the reduction potentials of the two redox couples, the more negative is the change in free energy for the oxidation–reduction. In this case, net free energy is released during the reaction, and the reaction will proceed in the direction written. Under the same given conditions, however, if the difference in the reduction potentials is negative and the change in free energy is positive, the reaction will necessarily proceed in the direction opposite to that in which it is written.

The reduction potential, E, varies, just as does the free energy, with the **respective concentrations of the two molecules of the redox couple**. As the concentration of oxidized species is increased, the pair becomes easier to reduce, and contrariwise. Quantitatively

$$E = E^\circ - \frac{RT}{nF} \ln\left(\frac{\gamma_{red}[\text{reduced}]}{\gamma_{ox}[\text{oxidized}]}\right) \quad (2\text{–}91)$$

where γ_{red} and γ_{ox} are the activity coefficients of the reduced and oxidized species, respectively, and [reduced] and [oxidized] are their respective molar concentrations. It follows from Equations 2–89 and 2–91 that

$$\Delta G^\circ = -nF\Delta E^\circ \quad (2\text{–}92)$$

where ΔG° is the change in standard free energy when reactants and products are at standard state.

The pH of the solution has a significant effect on the reduction potential of a redox couple that has acidic or basic positions in its structure. When a flavin is free in solution, its reduction potentials change dramatically and predictably as the pH of the solution is changed. When a flavin is tightly bound as a prosthetic group in the active site of an enzyme, its reduction potentials are less affected by the pH of the solution because its acidic and basic positions are usually participating in hydrogen bonds with side chains of the amino acids and are insulated from the solution. Nevertheless, to understand the effects of these donors and acceptors for hydrogen bonds on the reduction potentials of the flavin, it is necessary to understand of the effects of pH on the same flavin when it is free in solution. Initially, the effect of pH on the reduction potential of a simple redox couple is discussed, then the effect of pH on the reduction potential of flavin, and finally the effect of the donors and acceptors for hydrogen bonds on the reduction potential of flavin in an active site.

In most situations, the addition of one or more electrons to the oxidized molecule of a redox couple dramatically changes the pK_a of the lone pairs of electrons in the molecule and causes the reduced molecule to be more basic. For example, the addition of an electron to the neutral form of oxidized flavin (HFl_{ox}) to form the radical anion ($HFl^{\bullet -}$) raises the macroscopic pK_a of its conjugate acid from 0.2 to 8.4 (Figure 2–9) because, with the additional electron, the flavin becomes more electron-rich and more basic and the hydron in the conjugate acid is held more tightly. In fact, **the addition of the electron to a molecule and the dissociation constant of one of its hydrons are linked**. For example, in the case of the reduction of oxidized flavin to the semiquinone and the dissociation of hydrons from reactant and product

$$\begin{array}{ccc} e^- + H_2Fl_{ox}^+ & \overset{K_{a1,ox}}{\rightleftharpoons} & HFl_{ox} + H^+ + e^- \\ E^\circ_{ox/sq,H_2Fl_{ox}^+} \Big\downarrow\Big\uparrow & & E^\circ_{ox/sq,HFl_{ox}} \Big\downarrow\Big\uparrow \\ H_2Fl^\bullet & \overset{K_{a2,sq}}{\rightleftharpoons} & HFl^{\bullet -} + H^+ \end{array} \quad (2\text{–}93)$$

where $K_{a1,ox}$ and $K_{a2,sq}$ are acid dissociation constants (Figure 2–9) and $E^{\circ\prime}_{ox/sq,H_2Fl_{ox}^+}$ and $E^{\circ\prime}_{ox/sq,HFl_{ox}}$ are biochemical standard reduction potentials. The linkage is through the standard free energies

$$E^{\circ\prime}_{ox/sq,H_2Fl_{ox}^+} - E^{\circ\prime}_{ox/sq,HFl_{ox}} = \frac{RT}{F} \ln\left(\frac{K_{a1,ox}}{K_{a2,sq}}\right) \quad (2\text{–}94)$$

It follows from this linkage relationship that just as **the addition of an electron increases the pK_a of the conjugate acid by increasing the total electron density of the molecule, the addition of a hydron increases the standard reduction potential of the redox couple by making the oxidized form more electropositive**. For example, hydronation of neutral oxidized flavin to form the cation ($H_2Fl_{ox}^+$) makes it easier to reduce in a one-electron reaction by +480 mV. For this reason, the nature of the acids that provide donors for hydrogen bonds to the σ lone pairs around the flavin when it is in the active site of an enzyme have a significant effect on the reduction potentials of the redox couple of oxidized flavin and flavin semiquinone and of the redox couple of flavin semiquinone and reduced flavin for an electron.

Frequently when one or more electrons are added to a molecule with σ lone pairs of electrons, the resulting increase in its basicity causes it to take up hydrons immediately. How many hydrons are taken up depends on the pH of the solution and the resulting changes in the values of pK_a for the molecule (Equation 2–94). In turn, the number of hydrons actually taken up, which is determined by the pH of the solution, affects the reduction potential.

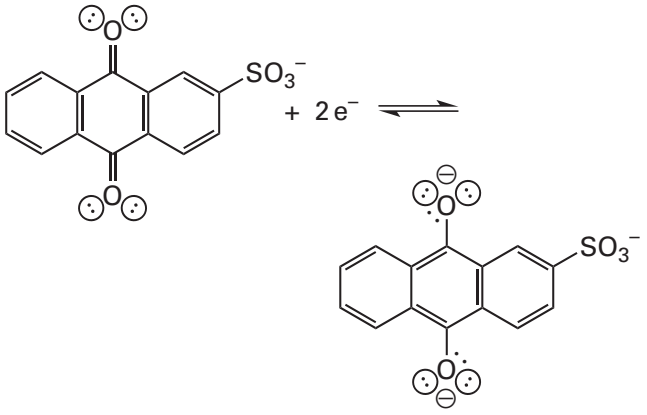
Under any particular set of circumstances, a **midpoint reduction potential, E_m, of a redox couple can be defined** as the potential measured when the total molar concentration of reduced participant, $[\text{reduced}]_t$, in all its ionization states and tauto-

mers, is equal to the total molar concentration of oxidized participant, $[\text{oxidized}]_t$, in all its ionization states and tautomers, and the conditions are such that the activity coefficients cancel, usually because the concentrations of the reactants are small. By this definition

$$E = E_m - \frac{RT}{nF} \ln\left(\frac{[\text{reduced}]_t}{[\text{oxidized}]_t}\right) \qquad (2\text{–}95)$$

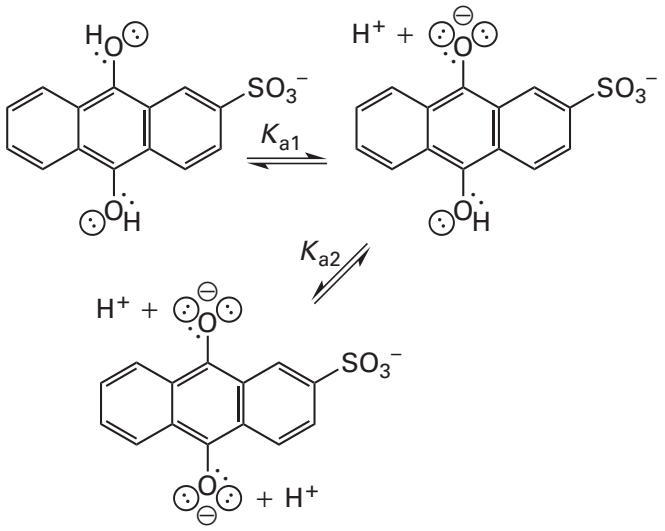
where E is the reduction potential of the solution. This equation should be compared with Equation 2–91. One difference is that the conditions are those of the solution at hand rather than standard state. Another difference is that the various tautomers and states of hydronation for the two participants in the redox couple are ignored, and only the total concentrations of the two participants are measured.

A simple example of the **effect of pH on the midpoint reduction potential** of a redox couple is encountered in the two-electron reduction of anthraquinone-2-sulfonate



(2–96)

The addition of two electrons to the monoanionic **quinone** to form the quinolate trianion raises the values of pK_a for the conjugate acids of the σ lone pairs of electrons on the two oxygens from below 0 to pK_{a1} = 8.0 and pK_{a2} = 11.3 for the first and second dissociations from the **quinol**, respectively[320]



(2–97)

It is easily shown that

$$[Q_{red}^{3-}] = [Q_{red}]_t \left(\frac{K_{a1}K_{a2}}{K_{a1}K_{a2} + K_{a1}[H^+] + [H^+]^2}\right) \qquad (2\text{–}98)$$

where $[Q_{red}^{3-}]$ is the concentration of the quinolate trianion and $[Q_{red}]_t$ is the total concentration of quinol in the trianionic, dianionic, and monoanionic forms. Because the concentration of the neutral conjugate acid of the sulfonato group is negligible at normal values of pH, it is not included in the equation. The redox couple of the monoanion of the quinone and the trianion of the quinol (Equation 2–96) has a chemical standard reduction potential, E°, of –380 mV.[320] This value of reduction potential is invariant with pH because no hydrons are involved when the monoanion of the quinone is reduced by two electrons to the trianion of the quinol. Therefore, at any pH, the observed reduction potential, E, will be equal to

$$E = -380 \text{ mV} - \frac{RT}{2F} \ln\left(\frac{[Q_{red}^{3-}]}{[Q_{ox}^{-}]}\right) \qquad (2\text{–}99)$$

if γ_{red}/γ_{ox} is assumed to be 1. Because the quinone is not a base within the range of pH considered, $[Q_{ox}^{-}] = [Q_{ox}]_t$

$$E = -380\ \text{mV} - \frac{RT}{2F}\ln\left(\frac{[Q_{red}]_t}{[Q_{ox}]_t}\right) - \frac{RT}{2F}\ln\left(\frac{K_{a1}K_{a2}}{K_{a1}K_{a2} + K_{a1}[H^+] + [H^+]^2}\right) \quad (2\text{–}100)$$

By definition (Equation 2–95), when $[Q_{red}]_t/[Q_{ox}]_t = 1$, $E = E_m$. Therefore,

$$E_m = -380\ \text{mV} - \frac{RT}{2F}\ln\left(\frac{K_{a1}K_{a2}}{K_{a1}K_{a2} + K_{a1}[H^+] + [H^+]^2}\right) \quad (2\text{–}101)$$

Equation 2–101 describes the actual behavior, as a function of the pH, of the midpoint reduction potential of anthraquinone-1-sulfonate (Figure 2–14).[320]

When $pH > pK_{a2}$ so that $[H^+] < K_{a2}$

$$E_m = -380\ \text{mV} = E^\circ \quad (2\text{–}102)$$

because only the quinolate trianion is present.

When $pK_{a2} > pH > pK_{a1}$ so that $K_{a2} < [H^+] < K_{a1}$

$$E_m = -380\ \text{mV} - \frac{RT}{2F}(pH - pK_{a2})\ln(10) \quad (2\text{–}103)$$

Because

$$-\frac{RT}{F}\ln(10) = -\frac{(8.314\ \text{J K}^{-1}\text{mol}^{-1})(298.2\ \text{K})(2.303)}{96{,}485\ \text{J V}^{-1}\ \text{mol}^{-1}} = -59.2\ \text{mV} \quad (2\text{–}104)$$

at 25 °C, the slope of the line in this region (dashed line in Figure 2–14) should be –29.6 mV (unit of pH)$^{-1}$ as is observed.

When $pK_{a1} > pH$ so that $K_{a1} < [H^+]$

$$E_m = -380\ \text{mV} - \frac{RT}{2F}(2pH - pK_{a2} - pK_{a1})\ln(10) \quad (2\text{–}105)$$

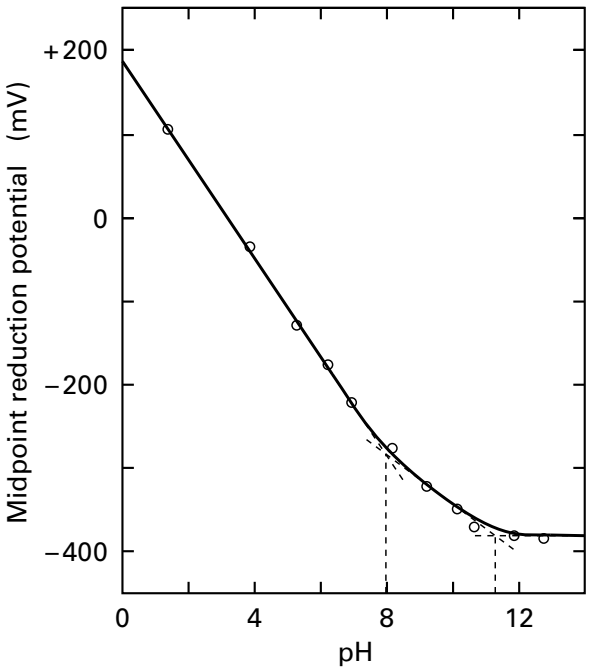


Figure 2–14: Midpoint reduction potential, E_m, of anthroquinone-2-sulfonate as a function of pH.[320] A 3 mM solution of the quinone at the desired pH was titrated with the strong reducing agent sodium hydrosulfite. The reduction potential of the solution was monitored directly with a platinum electrode after each addition. The solution was connected by a salt bridge to a calomel electrode to complete the circuit. The measured potential at the point at which half of the quinone had been reduced, determined by the direct titration, was taken as the midpoint reduction potential at that pH. These potentials are plotted in the figure as a function of pH. The solution also contained a hydrogen electrode that was used to calibrate the readings. The three dashed lines of increasing negative slope from right to left are the lines generated by Equations 2–102, 2–103, and 2–105, respectively, and the two values of pK_a are at the intersections of these lines, as indicated by the two vertical dashed lines.[320]

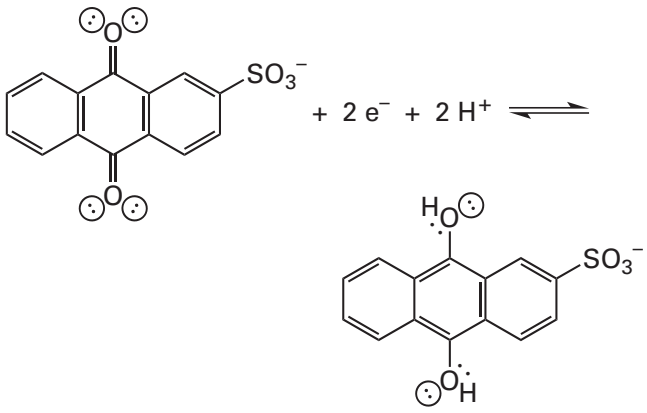
and the slope of the line in this region (dashed line in Figure 2–14) should be –59.2 mV (unit of pH)$^{-1}$ as is observed.

By solving mathematically for the intersection of the functions described by Equations 2–102 and 2–103 and the intersection of the functions described by Equations 2–103 and 2–105, it can be shown that these two intersections occur when $pH = pK_{a2}$ and $pH = pK_{a1}$, respectively (vertical dashed lines in Figure 2–14).

At values of pH greater than pK_{a2}, the midpoint reduction potential of the reaction is invariant with pH because it involves no hydron uptake (Equation 2–96). At values of pH less than pK_{a1}, the reaction involves the stoichiometric uptake of two hydrons for every two electrons



(2–106)

and the slope of the midpoint reduction potential reflects this stoichiometry. At values of pH between the two values of pK_a, the reaction involves the uptake of only one hydron for every two electrons and the slope is half the value that it has at values of pH less than pK_{a1}.

Unfortunately, the **tabulated standard reduction potentials** for most redox couples are for the sum of uptake of both electrons and hydrons as well as any subsequent chemical transformations at standard state. This causes the tabulated standard reduction potentials to be much more complicated, harder to understand, and difficult to correct. For example, the chemical equation for the tabulated reduction of sulfite, which is the reaction catalyzed by sulfite reductase

$$H_2SO_3 + 6\,H^+ + 6\,e^- \rightleftharpoons 3\,H_2O + H_2S \qquad E^\circ = +350\ \text{mV} \qquad (2\text{–}107)$$

is the reaction as written at standard state. In this instance, standard state is equimolar sulfurous acid and hydrogen sulfide at an activity of hydrons of unity (pH = 0). Corrections for both the actual pH of the solution and for the ionization of the reactant and the product as the pH is adjusted to this pH are required to obtain the midpoint reduction potential for this redox couple at a particular pH. This correction is made somewhat easier in the case of standard reduction potentials for biochemical reactions, for which the pH of the standard state is generally taken to be 7.0.

The **midpoint reduction potentials for riboflavin as a function of pH** in solution at 20 °C (middle curve in Figure 2–15)[288,321] reflect its various acid dissociation constants (Figure 2–9). For the redox couple of oxidized riboflavin and reduced riboflavin, involving transfer of two electrons as was the case for the reduction of anthraquinone-2-sulfonate, the midpoint reduction potential ($E_{m,ox/red}$ in Figure 2–15) shows two inflections, one at the pK_a of oxidized flavin (pK_a = 9.85) and one at the pK_a of reduced flavin (pK_a = 6.4). Below pH 6.4 and above pH 9.85, two hydrons are taken up for each two electrons, and the slope of the function is –59.2 mV (unit of pH)$^{-1}$. When the pH is between the pK_a of reduced flavin and the pK_a of oxidized flavin, only one hydron is taken up for every two electrons, and the slope of the function is –29.6 mV (unit of pH)$^{-1}$

For the redox couple of oxidized riboflavin and riboflavin semiquinone, involving transfer of one electron, the midpoint reduction potential ($E_{m,ox/sq}$ in Figure 2–15) should show two inflections, one at the pK_a of the oxidized flavin (9.85) and one at the pK_a of the flavin semiquinone (8.4). Below pH 8 and above pH 10, one hydron is taken up for each electron, and the slope of the function is –59.2 mV (unit of pH)$^{-1}$. The values of $E_{m,ox/sq}$ could be measured below pH 6 and above pH 10 where the concentration of the flavin semiquinone was significant enough to be detected, and the slopes of $E_{app,ox/sq}$ as a function of pH in these regions are –59.2 mV (unit of pH)$^{-1}$ as expected. Between the pK_a of the flavin semiquinone (8.4) and the pK_a of oxidized flavin (9.85), no hydrons are taken up for each electron, and the slope of the function should be zero (horizontal dashed line in Figure 2–15). Because the inflection of the curve for $E_{m,ox/red}$ is at pH 6.4 and the inflection of the curve for $E_{m,ox/sq}$ is at pH 9.85, the concentration of flavin semiquinone becomes immeasurably small relative to the concentrations of reduced and oxidized flavin between pH 6 and pH 10, and the values of $E_{m,ox/sq}$ could not be established in this region. For the redox couple of flavin semiquinone and reduced flavin, also involving the transfer of one electron, the midpoint reduction potential ($E_{m,sq/red}$ in Figure 2–15) should show two inflections, one at the pK_a of flavin semiquinone (8.4) and one at the pK_a of reduced flavin (pK_a = 6.4). Again and for the same reasons, the concentrations of flavin semiquinone could not be measured in the region between pH 6 and pH 10. The two inflections and the invariant region for the behavior of $E_{m,sq/red}$ as a function of pH are indicated by the dashed lines (Figure 2–15).

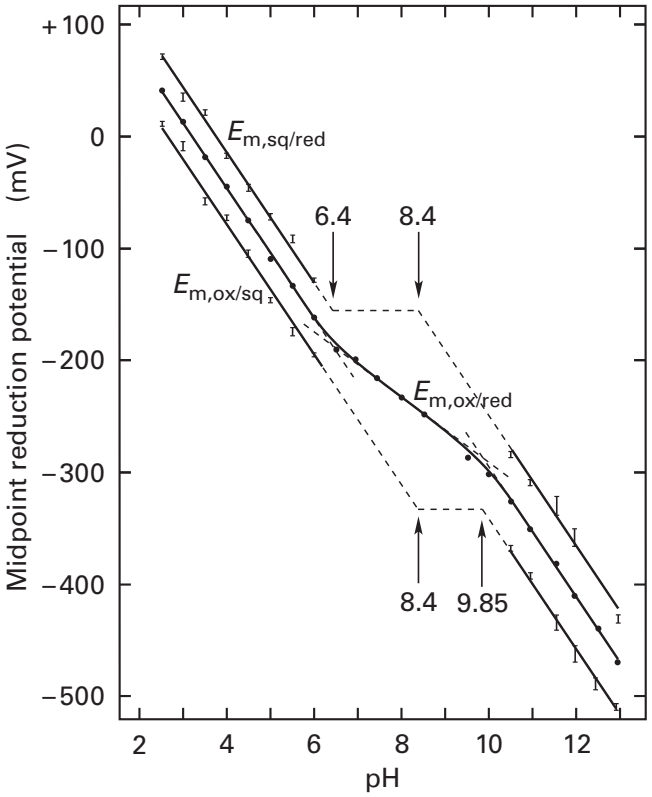


Figure 2–15: Midpoint reduction potentials of riboflavin as a function of pH.[288] A 30 μM solution of oxidized riboflavin, which was shown to be dilute enough that the dimerization of flavin semiquinone was negligible throughout each titration, at a given buffered pH and at 20 °C was flushed with nitrogen in a vessel containing a platinum electrode with which the reduction potential of the solution could be monitored. Measured volumes of the strong reductant sodium hydrosulfite were added to reduce systematically the riboflavin. The potential of the solution was followed as a function of the volume of reductant added to produce a titration curve of the reduction at the given pH. The complete titration curve was that of a two-electron reduction, and the final product was reduced riboflavin. The midpoint reduction potentials, $E_{m,ox/red}$, at the half-reduced point of each two-electron titration curve are plotted as a function of pH (middle curve). In the region below pH 6 and the region above pH 10, the midpoint reduction potentials as a function of pH displayed linear behavior, and the slope of the line in each region was 58 mV (unit of pH)$^{-1}$ (dashed lines), as expected from theory. The shapes of the individual titration curves in the regions from pH 2 to pH 6 and from pH 10 to pH 13 indicated that significant concentrations of flavin semiquinone were present at these values of pH. Each individual titration curve in these ranges of pH was fit to a theoretical function for the behavior of an equilibrium system of oxidized flavin, flavin semiquinone, and reduced flavin to estimate the amount of flavin semiquinone present, from which the midpoint reduction potential, $E_{m,ox/sq}$, for the redox couple of oxidized flavin and flavin semiquinone (lower lines) and the midpoint reduction potential, $E_{m,sq/red}$, for the redox couple of flavin semiquinone and reduced flavin (upper lines) could be calculated. These functions are plotted as well. The midpoint reduction potential $E_{m,ox/red}$ shows two clear inflections between the region of linear behavior below pH 6 and the region of linear behavior above pH 10. Between these two inflections the slope of the function is 29 mV (unit of pH)$^{-1}$ (dashed lines), again as expected. These inflections defined the pK_a of oxidized flavin (p$K_{a,ox}$ = 9.85) and reduced flavin (p$K_{a,red}$ = 6.4). The line of slope 58 mV (unit of pH)$^{-1}$ below pH 6 for the midpoint reduction potential $E_{m,sq/red}$ was extrapolated (dashed line), and a horizontal dashed line was drawn that intersected the line of slope 58 mV (unit of pH)$^{-1}$ above pH 10 for the midpoint reduction potential $E_{m,sq/red}$ at pH = 9.85. The intersection of these two dashed lines is an estimate of the pK_a of flavin semiquinone (p$K_{a,sq}$ = 8.4). The line of slope 58 mV (unit of pH)$^{-1}$ above pH 10 for the midpoint reduction potential $E_{m,ox/sq}$ was extrapolated (dashed line), and a horizontal dashed line was drawn that intersected the extrapolation of the line of slope 58 mV (unit of pH)$^{-1}$ below pH 6 for the midpoint reduction potential $E_{m,ox/sq}$ at pH 6.4. The intersection of these two lines is another estimate of the pK_a of flavin semiquinone (p$K_{a,sq}$ = 8.4).

When flavin is in a protein, the midpoint reduction potential for the two-electron reduction of oxidized flavin to reduced flavin, the one-electron reduction of oxidized flavin to flavin semiquinone, or the one-electron reduction of flavin semiquinone to reduced flavin is controlled, in part, by the acid–bases and the donors and acceptors in hydrogen bonds that surround the flavin. The midpoint reduction potentials of the flavin within a flavoprotein or the active site of a flavoenzyme can also be measured. A mediator such as methyl viologen is added to transfer electrons to and from the flavin within the protein and allow the oxidation–reduction on the active site to come to equilibrium with the potential established in the solution. In the absence of oxygen, successive portions of a strong reductant such as dithionite are added to the solution, and, at equilibrium, the total concentrations of reduced flavin $[Fl_{red}]_t$, flavin radical $[Fl^{\bullet}]_t$, and oxidized flavin $[Fl_{ox}]_t$ are measured spectrophotometrically. The electrochemical potential of the solution at equilibrium, E, is measured either with an electrode[322-324] or by determining spectrophotometrically the concentrations of the reduced and oxidized forms of a dye of known standard reduction potential also present in the solution.[325] The respective concentrations and potentials that have been measured for the successive reductive steps are plotted (Equation 2–95), and from the plot, E_m is obtained for the pH established by the buffer in the solution.

When flavin is bound as a prosthetic group within the active site of a protein, it is, depending on the structure of the site, more or less **shielded from the solution**. This shielding mutes the effects of the pH in the surrounding solution. In addition, acids and bases from side chains of the amino acids in the protein can form hydrogen bonds with the

σ lone pairs and acidic hydrons around the isoalloxazine (Figure 2–9). The **acids and bases from the protein** that form these hydrogen bonds add and remove, respectively, the hydrons transferred to and from the σ lone pairs of the flavin during its reduction or oxidation. In such situations, hydrons from the solution are not the ones transferred. If all the locations around the flavin were occupied by bases and acids from the protein, and both they and the flavin were completely surrounded by protein and isolated from the solution, the midpoint reduction potential of the flavin would be unaffected by the pH of the solution and determined only by the intrinsic values of pK_a for these bases and acids.

Consider the simplest situation in which the flavin is completely surrounded by the protein and the protein provides only one acidic amino acid, $^{(+)}$AH, and that acid is adjacent to the lone pair of electrons on nitrogen 5 of the neutral flavin semiquinone. The addition of an electron to neutral oxidized flavin, HFl_{ox}, to produce flavin semiquinone radical anion, $HFl^{\bullet -}$, and the subsequent transfer of the hydron from $^{(+)}$AH to nitrogen 5, to produce the particular tautomer of neutral flavin semiquinone, $H_2Fl^{\bullet}$, can be described by the following linkage

$$\begin{array}{ccc} e^- + {}^{(+)}AH{:}HFl_{ox} & \rightleftharpoons & {}^{(+)}AH{:}HFl^{\bullet -} \\ \rightleftharpoons & & \rightleftharpoons \\ e^- + {}^{(-)}A{:}H_2Fl_{ox}{}^{+} & \rightleftharpoons & {}^{(-)}A{:}H_2Fl^{\bullet} \end{array} \qquad (2\text{–}108)$$

where the four complexes denote hydrogen bonds between the acid, $^{(+)}$AH, or its conjugate base, $^{(-)}$A:, and the bound flavin. If these are the only forms present, it can be shown[326] that the midpoint reduction potential

$$E^{\circ}_{app,ox/sq} = E^{\circ\prime}_{HFl_{ox}} - \frac{RT}{F}\ln\left[\frac{\left(K_{a,H_2Fl^{\bullet}}\right)\left(K_{a,H_2Fl_{ox}{}^{+}}\right) + \left(K_{a,H_2Fl^{\bullet}}\right)\left(K_{a,AH}\right)}{\left(K_{a,H_2Fl_{ox}{}^{+}}\right)\left(K_{a,H_2Fl^{\bullet}}\right) + \left(K_{a,H_2Fl_{ox}{}^{+}}\right)\left(K_{a,AH}\right)}\right] \qquad (2\text{–}109)$$

where $E^{\circ\prime}_{HFl_{ox}}$ is the biochemical standard reduction potential for the reduction of neutral oxidized flavin in the active site in the absence of transfer of the hydron

$$^{(+)}AH{:}HFl_{ox} + e^- \rightleftharpoons {}^{(+)}AH{:}HFl^{\bullet -} \qquad (2\text{–}110)$$

and $K_{a,H_2Fl_{ox}{}^{+}}$ is the acid dissociation constant of the tautomer of oxidized flavin with hydrons on nitrogen 5 and nitrogen 3, $K_{a,H_2Fl^{\bullet}}$ is the acid dissociation constant for the same tautomer of flavin semiquinone, and $K_{a,AH}$ is the acid dissociation constant for the acid–base in the active site.

Equation 2–109 is the expression that would have resulted for the dependence of $E_{m,ox/sq}$ on pH in free solution if $K_{a,AH}$ were replaced by $[H^+]$. Therefore, if the intrinsic values of pK_a for flavin remain the same when the flavin is within the protein, then the plot of $E_{m,ox/sq}$ against pH for the one-electron reaction in solution ($E_{m,ox/sq}$ in Figure 2–15) would be equivalent to the plot of $E_{m,ox/sq}$ against the pK_a of the acid in the protein that provides the hydron to nitrogen 5 during the one-electron reduction. This relationship is a demonstration of the fact that, by definition, the activity of a hydron on an acid of a given pK_a is equal to the activity of a hydron in a solution with a pH equal to that pK_a. Although none of the values for pK_a in Equation 2–109 or the reduction potential of the oxidized flavin when it is in the active site can ever be known and the equation is of no practical use, nevertheless it shows how the intrinsic acidity of the particular acid that forms a hydrogen bond to nitrogen 5 can control the reduction potential of the flavin when it is within a flavoprotein and, by extension, how **the complete constellation of acid–bases surrounding the flavin controls its reduction potential**.

At the same fixed pH, the two-electron midpoint reduction potentials of flavin differ from one flavoprotein to another (Table 2–1).[322-325,327,328] The tabulated values span a range as large as that for the two-electron midpoint reduction potential of riboflavin between pH 4.5 and pH 8.5 (Figure 2–15). This variation must reflect the identities of the amino acids surrounding the prosthetic flavin in each of these active sites.

It is never the case, however, that the flavin is completely surrounded by the protein, isolated from the solution, and completely surrounded by acids and bases from the protein that in turn are not connected to the solution. If there are particular lone pairs of electrons or acidic hydrogens on the flavin that are exposed to the solution or that are connected to the solution through a network of hydrogen bonds rather than forming hydrogen bonds

Table 2–1: Reduction Potentials of Flavin in the Active Sites of Enzymes

enzyme	pH	temperature (°C)	$E^{\circ\prime}_{app}$ (mV)
salicylate 1-monooxygenase from *B. cepacia*[327]	7.5	10	–88
human medium-chain acyl-CoA dehydrogenase[324]	7.6	25	–114
human short-chain acyl-CoA dehydrogenase[322]	7.6	25	–162
[NAD(P)H] nitroreductase from *Enterobacter cloacae*[323]	7.5	25	–210
methylenetetrahydrofolate reductase [NAD(P)H] from *E. coli*[325]	7.2	25	–237
thioredoxin-disulfide reductase from *E. coli*[328]	7.6	1	–263

with side chains of amino acids in the active site that are not connected to the solution, then the pH of the solution determines whether these positions are hydronated or unhydronated.

Consequently, the midpoint reduction potentials of flavin in an active site are **unpredictably affected by the pH** of the solution. For example, when flavin adenine dinucleotide is the prosthetic flavin in the active site of porcine medium-chain acyl-CoA dehydrogenase,[324] its two-electron midpoint reduction potential ($E_{m,ox/red}$) decreases by –60 mV (unit of pH)$^{-1}$ between pH 6.5 and pH 7.5 at 25 °C. This slope suggests that two hydrons from the solution associate with the flavin upon its reduction by two electrons in this active site. When flavin, however, is in solution, the slope of the midpoint potential as a function of pH is –59.2 mV (unit of pH)$^{-1}$ only below pH 6 and above pH 10 (Figure 2–15). When flavin adenine dinucleotide is the prosthetic flavin in the active site of salicylate 1-monooxygenase from *B. cepacia*,[327] its two-electron midpoint reduction potential decreases by –26 mV (unit of pH)$^{-1}$ at 10 °C between pH 6.5 and pH 7.5. This slope suggests that only one hydron from the solution associates with the flavin upon its reduction by two electrons, as happens when flavin is in solution at 25 °C [–29.6 mV (unit of pH)$^{-1}$] between pH 7 and pH 9. When flavin mononucleotide is the prosthetic flavin in the active site of NAD(P)H nitroreductase from *E. cloacae*,[323] however, its two-electron midpoint reduction potential decreases by –38 mV (unit of pH)$^{-1}$ at 25 °C.

In addition to the effect of donors and acceptors for hydrogen bonds to the σ lone pairs of electrons and acidic hydrons of the isoalloxazine, variations in midpoint reduction potential also result from **other structural features** of the site in which the flavin is bound on the enzyme. A nearby negatively charged side chain within the site decreases the two-electron midpoint reduction potential of the flavin,[324] and a nearby positively charged side chain increases its two-electron midpoint reduction potential.[329,330] The substitution of the methyl group at position 8, as occurs when the flavin is covalently attached to a protein (Equation 2–83), with a group that withdraws electron density increases the two-electron midpoint reduction potential of the flavin, while substitution with a group that donates electron density decreases the two-electron midpoint reduction potential of the flavin.[331,332] The binding of substrates to the active site, because they end up immediately adjacent to the flavin, also affects the midpoint reduction potential of the flavin.[333]

The acid dissociation with a pK_a closest to pH 7 is the **ureido nitrogen 1 in reduced flavin** (Figure 2–9), and upon dissociation of the hydron, the majority of the net negative elementary charge is located on the carbonato oxygen, which is more electronegative than the nitrogen. When reduced

flavin is bound to a protein as a prosthetic group, the protein that surrounds the ureido group at positions 1 and 2 usually insulates nitrogen 1 and the carbonato oxygen on carbon 2. In this way, **the active site stabilizes either the neutral form of reduced flavin, H_3Fl_{red}, or its anionic conjugate base, $H_2Fl_{red}^-$.**[334] As previously noted, the form most often present in an active site is the conjugate base, which, coincidentally, is the more prevalent form at pH 7 in solution. The most commonly encountered form of oxidized flavin in an active site is the neutral form, HFl_{ox}. Consequently, when oxidized flavin in a protein is reduced by two electrons, nitrogen 1 either picks up a hydron or it does not.

Human glutathione-disulfide reductase (Figure 2–11),[306] D-amino-acid oxidase from *R. toruloides* (Figure 2–12),[312] and porcine medium-chain acyl-CoA dehydrogenase, when its substrate is bound (Figure 2–13),[316] are examples of proteins that stabilize the anionic conjugate base of reduced flavin with nitrogen 1 unhydronated.[334] In each of the crystallographic molecular models of these three enzymes, the **carbonato oxygen at position 2** of the flavin accepts two hydrogen bonds from two donors: an amido nitrogen–hydrogen from the polypeptide backbone and a molecule of water; two amido nitrogen–hydrogens from successive amides in the polypeptide backbone; and the hydroxy group of a threonine and an amido nitrogen–hydrogen from the polypeptide backbone, respectively. These donors for hydrogen bonds are typical of the donors that stabilize oxyanions that form in active sites during an enzymatic reaction. **Nitrogen 1 of the flavin** is the acceptor for a hydrogen bond from a threonine in the active site of porcine medium-chain acyl-CoA dehydrogenase, but there are no obvious donors for hydrogen bonds in the other two active sites. The donors for hydrogen bonds that stabilize the oxyanion are not, however, the only reason that the anionic conjugate base of reduced flavin is stabilized in preference to neutral reduced flavin by these proteins. In the crystallographic molecular model of ferredoxin—NADP reductase from *Nostoc*, a protein that stabilizes neutral reduced flavin,[334] the oxygen on carbon 2 of the flavin also engages in two hydrogen bonds, one with an amido nitrogen–hydrogen from the polypeptide backbone and the other with a molecule of water, and there is only a molecule of water, not an obvious acid, forming a hydrogen bond to nitrogen 1, presumably as an acceptor.[335] In choline oxidase, a histidinium ion adjacent to the amide at positions 1 and 2 of the flavin is thought to stabilize the anionic conjugate base of reduced flavin.[336]

In the case of **nitrogen 5 of the flavin**, a lone pair of electrons must be hydronated upon two-electron reduction (Figure 2–9), and donors and acceptors for hydrogen bonds must adjust to this change. In the flavodoxin of *Synechococcus*, the amido group in the polypeptide backbone between Asparagine 58 and Valine 59 flips upon reduction of the flavin so that the amido group that forms an N–H hydrogen bond with the lone pair of electrons on nitrogen 5 of oxidized flavin is replaced by the acyl oxygen of the same amido group that forms a hydrogen bond with the nitrogen–hydrogen of nitrogen 5 in reduced flavin.[337]

When a molecule of flavin is bound to a molecule of protein, its semiquinone radical is often stabilized by the protein. In free solution at all values of pH greater than 2 (Figure 2–15), the midpoint reduction potential for the redox couple of oxidized flavin and **flavin semiquinone** ($E_{m,ox/sq}$) is more negative than that for the redox couple of flavin semiquinone and reduced flavin ($E_{m,sq/red}$). This inversion means that, in solution, two flavin semiquinones participate in a **disproportionation**

$$H_lFl^{\bullet} + H_lFl^{\bullet} \rightleftharpoons H_mFl_{ox} + H_nFl_{red} \qquad (2\text{–}111)$$

with a negative standard free energy change as written ($K_{eq} = 10$ at pH 4.0 and $K_{eq} = 30$ at pH 11.5; Figure 2–15).[288] This disproportionation causes the concentration of flavin semiquinone to become almost immeasurable in the central region of pH.

At an electrode poised at a potential sufficiently negative to reduce oxidized flavin when it is in solution, the anionic flavin semiquinone ($HFl^{\bullet -}$) produced by transfer of an electron at the surface of the electrode immediately picks up a hydron from the solution, and the resulting neutral flavin semiquinone ($H_2Fl^{\bullet}$), because its reduction potential is more positive than that of the electrode, immediately picks up a second electron from the electrode. If no hydrons are available in the solution, however, the second electron is not transferred,[338] and the flavin remains as the radical anion. Denying the anionic flavin semiquinone a hydron is one way to stabilize it.

In an active site, a flavin semiquinone can be stabilized kinetically and thermodynamically. In an active site, a prosthetic flavin is isolated from the solution and sterically hindered from disproportionating at the encounter-controlled rate that it would display in solution. For example, the flavin

semiquinone formed from oxidized flavin adenine dinucleotide on porcine cytochrome-b_5 reductase by a hydrated electron disproportionates much more slowly (1×10^3 M^{-1} s^{-1}) than it would in solution[339] because it is isolated by the surrounding protein. This kinetic protection afforded by the protein is similar to the insulation from disproportionation that an active site affords to a sulfenic acid.[340] When flavin mononucleotide is dispersed at sufficiently low concentration in the absence of oxygen in an agarose matrix, which interrupts diffusion, the semiquinone of the flavin mononucleotide can be produced photolytically in high yield and its lifetime is several days.[341] The matrix precludes disproportionation, just as enclosing the semiquinone in protein does.

In an active site, flavin semiquinone can be stabilized thermodynamically when the environment created by the protein causes the midpoint reduction potential for the redox couple of oxidized flavin and flavin semiquinone ($E_{m,ox/sq}$) to be more positive than that of flavin semiquinone and reduced flavin ($E_{m,sq/red}$), rather than being more negative as it is in solution (Figure 2–15). There are a number of flavoproteins that have dramatically altered these reduction potentials to stabilize the flavin semiquinone (Table 2–2). Unlike flavin when it is free in solution, when flavin is the prosthetic group in a protein that stabilizes the flavin semiquinone thermodynamically, the spectrum of the flavin semiquinone is clearly observed in the midrange of reduction potential (Figure 2–10), and there is no difficulty in measuring changes in its concentration.[342]

By linkage, an active site must stabilize the flavin semiquinone because it binds the flavin semiquinone more tightly than both oxidized flavin and reduced flavin,[348] but the molecular reasons for this preference in association are not well understood, and it is probably due to a combination of factors. When the tyrosine stacked against the flavin in flavodoxin from *Desulfovibrio vulgaris* is mutated to an amino acid other than phenylalanine or tryptophan, the difference in the two one-electron midpoint reduction potentials (Table 2–2) decreases significantly.[330] In model compounds, the presence of an intramolecular donor for a hydrogen bond to nitrogen 5 of flavin

Table 2–2: One-Electron Reduction Potentials in Flavoproteins Stabilizing the Flavin Semiquinone

flavoprotein	$E^{\circ\prime}_{ox/sq}$[a] (mV)	$E^{\circ\prime}_{sq/red}$[a] (mV)
flavin mononucleotide[288]	–240	–170
glycine oxidase from *Bacillus subtilis*[343]	–42	–340

[a]Standard reduction potentials (pH 7.0) for the redox couples of oxidized flavin and flavin semiquinone ($E^{\circ\prime}_{ox/sq}$) and flavin semiquinone and reduced flavin ($E^{\circ\prime}_{sq/red}$).

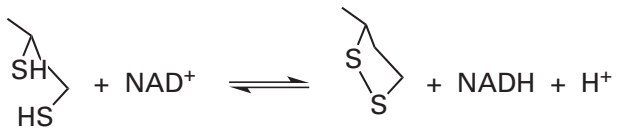
stabilizes the flavin semiquinone relative to oxidized and reduced flavin.[349] It is also the case that mutation of the amino acids participating in the hydrogen bonds to nitrogens 5 of flavins in flavodoxin from *Clostridium beijerinckii*[350] and electron-transferring flavoprotein from the methylotrophic bacterium W3A1,[351] respectively, decreases the difference in the two one-electron midpoint reduction potentials responsible for the stabilization of the flavin semiquinone. In flavocytochrome b_2 from *Spinacia oleracea*, the anionic flavin semiquinone is stabilized by an adjacent lysine with a positive elementary charge that encourages its formation from oxidized flavin but discourages the hydronation necessary for its reduction because it is not able to hydronate nitrogen 5.[352]

In some flavoenzymes that stabilize the flavin semiquinone, the form of the enzyme containing this flavin semiquinone is enzymatically active;[353] in others, however, flavin semiquinone, even though it is stabilized by the enzyme, is catalytically inactive.[354,355]

Each of the oxidation–reductions catalyzed by the flavins on flavoenzymes can usually be divided into two half-reactions, each exclusive to a redox couple. The prosthetic oxidized flavin or the prosthetic reduced flavin in the active site of a particular enzyme oxidizes or reduces, respectively, the particular reductant or the particular oxidant of the redox couple of substrates that is usually unique to that flavoenzyme and gives the flavoenzyme its name: for example, dihydrolipoyl dehydrogenase and the redox couple of N^6-(lipoyl)lysine and N^6-(dihydrolipoyl)lysine; (*S*)-mandelate dehydrogenase and the redox couple of 2-oxo-2-phenylacetate and (*S*)-mandelate; medium-chain acyl-CoA dehydrogenase and the redox couple of *trans*-oct-2-enoyl-SCoA and octanoyl-SCoA; D-amino-acid oxidase and the redox couple of pyruvimine and D-alanine; FMN reductase (NADPH) and the redox couple of oxidized flavin mononucleotide and reduced flavin mononucleotide; and glutathione-disulfide reductase and the redox couple of glutathione and glutathione disulfide. To simplify the present discussion, the redox couple unique to a particular flavoenzyme and giving that enzyme its name will be called the **nominal redox couple**.* The resulting reduced flavin or oxidized flavin is then oxidized or reduced, respectively, by a coenzymatic redox couple that is used in many different oxidation–reductions catalyzed by an array of enzymes—for example the redox couple of NAD^+ and NADH, the redox couple of ubiquinone and ubiquinol, the redox couple of oxidized electron-transfer flavoprotein and reduced electron-transfer flavoprotein, or the redox couple of oxidized ferredoxin and reduced ferredoxin—or a redox couple that is not considered coenzymatic but is also used in many different enzymatic reactions, such as the redox couple of oxygen and hydrogen peroxide. To simplify the present discussion, the widely used redox couple in this second half-reaction that returns the flavin to the oxidation state that it had before the first half-reaction occurred will be called the **general redox couple**. The general redox couple connects the particular reaction catalyzed by the enzyme to the overall reduction potential at which the cytoplasm is poised.

Because the nominal redox couple and the general redox couple alternate with each other on the active site, the flavin, as is required of a catalyst, does not participate in the chemical equation for the complete reaction. The facts, however, that the nominal redox couple by itself can either oxidize or reduce the prosthetic flavin and that the general redox couple, also by itself, can either oxidize or reduce the prosthetic flavin permit the overall reaction to be experimentally dissected. Depending on the respective reduction potentials, oxidation of the prosthetic flavin by either the nominal oxidant or the general oxidant can be observed in isolation, and reduction of the prosthetic flavin by either the nominal reductant or the general reductant can also be observed in isolation.

The **complete oxidation–reduction** is the oxidation or reduction of the nominal reactant and the reduction or oxidation, respectively, of the general reactant. Examples of complete oxidation–reductions catalyzed by flavoenzymes would be the reaction catalyzed by dihydrolipoyl dehydrogenase



(2–112)

the oxidation–reduction catalyzed by (*S*)-mandelate dehydrogenase from *P. putida*[356]

*A reviewer pointed out that this nomenclature is unprecedented. It is, however, useful.

(*S*)-mandelate + ubiquinone ⇌
2-oxo-2-phenylacetate + ubiquinol (2–113)

the oxidation–reduction catalyzed by medium-chain acyl-CoA dehydrogenase

octanoyl-SCoA +
oxidized electron-transfer flavoprotein
⇌ *trans*-oct-2-enoyl-SCoA +
reduced electron-transfer flavoprotein (2–114)

the oxidation–reduction catalyzed by ferredoxin: thioredoxin reductase from *Clostridium acetobutylicum*[357]

2 thioredoxin + 2 oxidized ferredoxin
⇌ thioredoxin disulfide +
2 H^+ + 2 reduced ferredoxin (2–115)

the oxidation–reduction catalyzed by D-amino-acid oxidase

D-alanine + H_2O + O_2 ⇌
NH_4^+ + pyruvate + H_2O_2 (2–116)

or the oxidation–reduction catalyzed by FMN reductase (NADPH) from *E. coli*

$FMNH^-$ + $NADP^+$ ⇌ FMN + NADPH (2–117)

The direction in which each oxidation–reduction proceeds depends, as always, on its equilibrium constant and the concentrations of reactants and products in the solution.

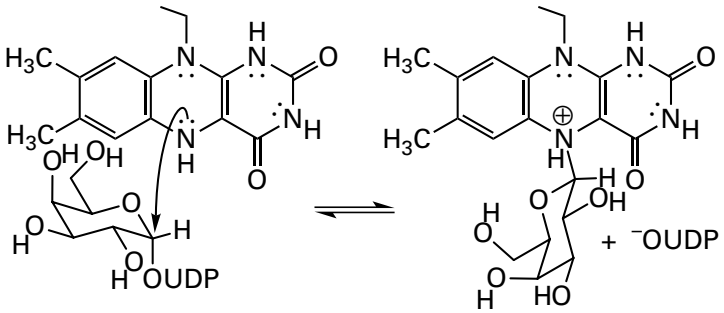
There are a few enzymatic reactions in which flavin is not used as a redox couple. These reactions should be considered before those in which it does participate as a redox couple because they reveal relevant capabilities of flavin.

In the active site of isopentenyl-diphosphate Δ-isomerase from *Staphylococcus aureus*, nitrogen 5 of the reduced flavin is used as a **catalytic acid–base**[358-360] to add a hydron to one or the other of the substrates, isopentenyl diphosphate or dimethylallyl diphosphate, and then accept a different hydron from the resulting intermediate tertiary carbenium ion to form the other substrate in a reaction involving no oxidation–reduction.

In the enzymatic reaction catalyzed by UDP-galactopyranose mutase

UDP-α-D-galactopyranose
⇌ UDP-α-D-galactofuranose (2–118)

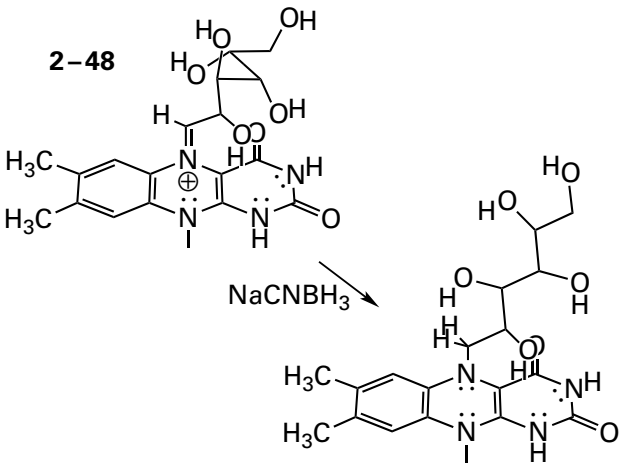
which also does not involve an oxidation or reduction, nitrogen 5 of the central 1,4-dihydropyrazine in reduced flavin is used as a **nucleophilic catalyst**. Nitrogen 5 forms a covalent intermediate with the D-galactopyranosyl group or the D-galactofuranosyl group of the respective reactant in a concerted nucleophilic substitution proceeding with inversion of configuration, with the diphosphate of the UDP as the leaving group, to give the hemiaminal ether between carbon 1 of the now β-D-galactopyranosyl or β-D-galactofuranosyl group and nitrogen 5 of the flavin



(2–119)

This hemiaminal ether, hydronated on nitrogen 5 as shown, has been observed in a crystallographic molecular model of the active site of a mutant of the enzyme from *Neosartorya fumigata*.[361] The unhydronated hemiaminal ether then opens to produce the iminium of the uncyclized D-galactosyl group at nitrogen 5 of the flavin (**2–48**). This iminium between flavin and the open form of D-galactose in the active site of UDP-galactopyranose mutase[362] from *Klebsiella pneumoniae* has been trapped with $NaCNBH_3$

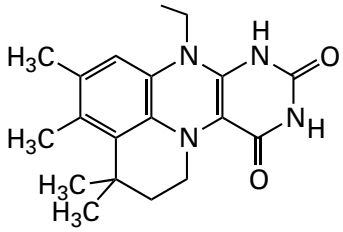
2–48



(2–120)

and the trapped product was identified by ultraviolet spectroscopy and mass spectrometry.[363] The reaction then proceeds in reverse to give either UDP-α-D-galactofuranose or UDP-α-D-galactopyranose as the respective product.

There are several other instances in which reduced flavin is a nucleophilic catalyst.[364] In the active site of thymidylate synthase (FAD), nitrogen 5 of reduced flavin nucleophilically adds to the electrophilic methylene carbon in N^5-methylenetetrahydrofolate.[365] In the active site of flavin prenyltransferase, nitrogen 5 of reduced flavin participates as the nucleophile in a nucleophilic substitution at carbon 1 of dimethylallyl phosphate with phosphate as the leaving group during the synthesis of prenylated $FMNH_2$[366]

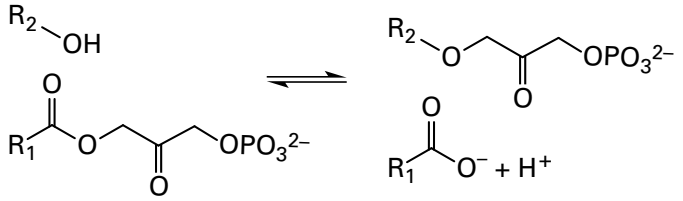


2–49

In the active site of monoamine oxidase, nitrogen 5 of reduced flavin nucleophilically adds to the electrophilic distal carbon of a propargylamine synthesized as a covalent inhibitor of the enzyme.[367]

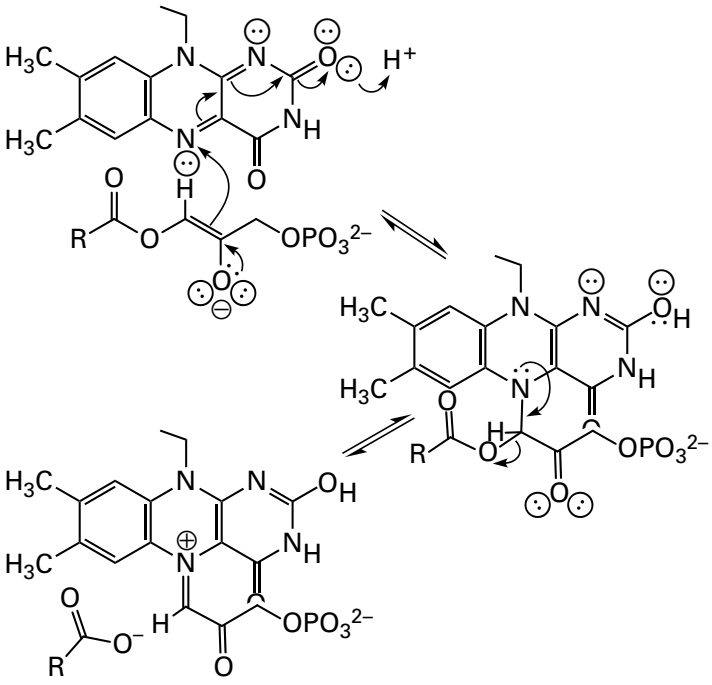
The strange aspect to these roles of nitrogen 5 of flavin as a catalytic acid or as a nucleophile is that the pK_a of the conjugate acid of nitrogen 5 in neutral reduced flavin is only 0.8 (Figure 2–9), as expected for an anilinium, a fact suggesting that it would be difficult to hydronate nitrogen 5 to form the catalytic acid and that nitrogen 5 should not be nucleophilic. The pK_a for the second dehydronation is well beyond the normal range of pH.

Oxidized flavin is also used as an **electrophilic catalyst**. The reaction catalyzed by alkylglycerone-phosphate synthase



(2–121)

where R_1 is a linear alkyl chain on a fatty acid esterified to glycerone phosphate and R_2 is a linear alkyl chain on a long-chain alcohol, is a formal nucleophilic substitution that involves no oxidation or reduction. The enolate of 1-acylglycerone 3-phosphate adds as a nucleophile to the electrophilic nitrogen 5 of oxidized flavin, and the resulting hemiaminal ester dissociates into the unhydronated fatty acid and the imine of 3-hydroxypyruvaldehyde 1-phosphate at nitrogen 5



(2–122)

The unhydronated fatty acid is replaced by the long-chain alcohol and the reaction proceeds in reverse to produce the 1-alkylglycerone 3-phosphate.

When alkylglycerone-phosphate synthase from *Cavia porcellus* that has been reconstituted with 5-carba-5-deazaflavin, a synthetic derivative in which nitrogen 5 of the flavin is replaced by a carbon, in place of the flavin, a stable adduct, homologous to the initial adduct in Equation 2–122, between

1-palmitoylglycerone 3-phosphate and the prosthetic flavin forms in the active site.[368] The reaction cannot proceed beyond this initial adduct because nitrogen 5 has been replaced by carbon, which has no lone pair of electrons. In the normal reaction, the enzyme is using nitrogen 5 of the oxidized flavin as an electrophile rather than an oxidant, much as urocanate hydratase (Equation 2–81) uses carbon 4 of a prosthetic NAD^+ as an electrophile rather than as an oxidant.

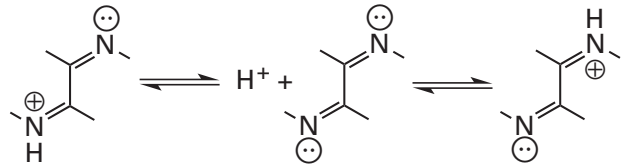
Prenylated $FMNH_2$ (2–49), a prosthetic group found in active sites of fungal and bacterial enzymes, seems to be used exclusively as a prosthetic catalyst in reactions that again involve no oxidation or reduction.[369] For example, the prenylated $FMNH_2$ in the active site of phenacrylate decarboxylase from *E. coli* forms an adduct with one of its several alternative reactants—(2*E*)-3-phenylprop-2-enoate, (2*E*)-3-(4-hydroxyphenyl)prop-2-enoate, or (2*E*)-4-hydroxy-3-methoxy-3-phenylprop-2-enoate—in a reversible **polar cycloaddition** with the respective (2*E*) double bond[370,371] to facilitate the respective decarboxylation of the carboxylate and replacement of the carbon dioxide with a hydron.

Each of these foregoing examples highlights a chemical property of the flavin that has bearing on the more common oxidation–reductions catalyzed by flavoenzymes. In at least one instance, however, the flavin bound by the enzyme does not seem to participate in the catalytic reaction at all.[372]

Because of the existence of the semiquinone, flavin can be both a one-electron oxidant and reductant and a two-electron oxidant and reductant, an ability that is essential to its dramatic versatility[283] but a fact that obscures the exact mechanism of its participation in a particular oxidation–reduction. Almost all the nominal oxidation–reductions catalyzed by flavoenzymes are formally two-electron oxidation–reductions of the nominal substrate; for example, the reaction catalyzed by (*S*)-mandelate dehydrogenase in which (*S*)-2-hydroxy-2-phenylacetate is oxidized to 2-oxo-2-phenylacetate, a simple oxidation of a secondary alcohol to a ketone. The general redox couples, however, that regenerate the initial oxidation state of the flavin are often one-electron participants such as ferredoxin. The capacity of flavin to act as both a one-electron oxidant and reductant and a two-electron oxidant and reductant leaves in question its specific mechanism of action in many of the nominal two-electron oxidation–reductions. In a formally two-electron oxidation–reduction, are the electrons transferred to and from flavin one at a time or together as a hydride? This question is further complicated by the nucleophilicity and electrophilicity of flavin just described. During the transfer of two electrons, is a covalent adduct formed between a nucleophilic substrate and electrophilic oxidized flavin or between an electrophilic substrate and nucleophilic reduced flavin?

Many of the two-electron reductants oxidized by flavin are nucleophiles, and the products of the oxidations are electrophiles that are reduced in the reverse direction. For example, the flavin in dihydrolipoyl dehydrogenase (Equation 2–71) oxidizes a pair of adjacent cysteines in the polypeptide to produce a cystine, which then oxidizes a lipoyl group. The flavin in monoamine oxidase oxidizes a primary amine to its imine. The flavin in medium-chain acyl-CoA dehydrogenase (Equation 2–114) removes two electrons from the enolate of octanoyl-SCoA. In reactions in which flavin oxidizes a nucleophile, such as a thiolate, amine, or enolate, the question arises of how the two electrons pass from the thiolate, the amine, or the enolate to the flavin during the oxidation.

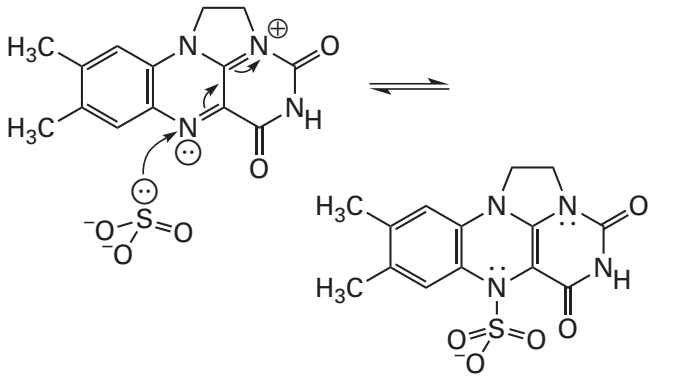
One possibility is that a thiolate, amine, or enolate is oxidized through **an intermediate produced by its nucleophilic addition to the flavin.** The electrophilic portion of oxidized flavin is the central 1,4-diazabutadiene



(2–123)

If a thiolate, amine, or enolate participates in a nucleophilic addition with oxidized flavin, the hydronated 1,4-diazabutadiene would be acting as the electrophile.

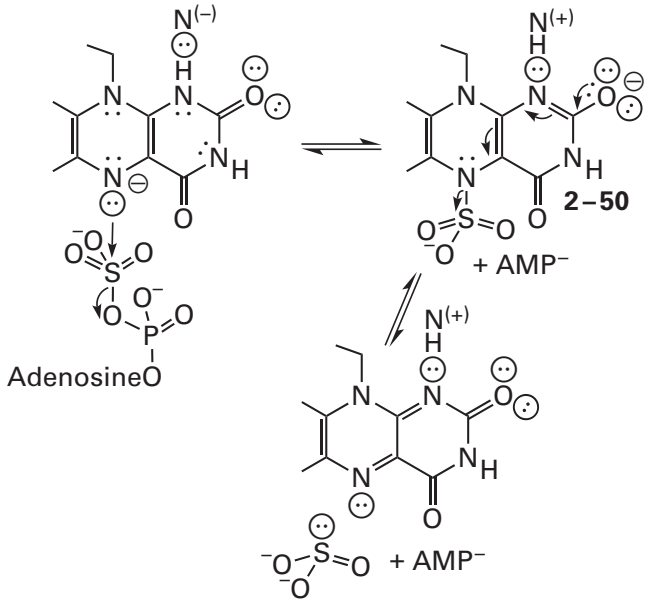
Because of the existence of this central 1,4-diazabutadiene, **nitrogen 5 of oxidized flavin is electrophilic** when nitrogen 1 is hydronated. Nitrogen 5 is the nitrogen analogue of the electrophilic β carbon in an α,β-unsaturated iminium ion (rightmost tautomer in Equation 2–123). That nitrogen 5 is electrophilic has been demonstrated by using sulfite as a nucleophile. When 7,8-dimethyl-1,10-ethenoisoalloxazinium is modified with sulfite, a crystalline product is obtained[373] that results from addition of the nucleophile to nitrogen 5



(2–124)

The formation of the adduct interrupts the conjugation of the isoalloxazine, and the strong absorption between 350 and 500 nm disappears. In its place is a peak of absorbance with a maximum at 308 nm (Figure 2–16).[373-375] This reaction demonstrates that when one nitrogen in the central diazobutadiene, in this instance nitrogen 1, is cationic, the other nitrogen is electrophilic.

The analogous adduct at nitrogen 5 (**2–50**)*



(2–125)

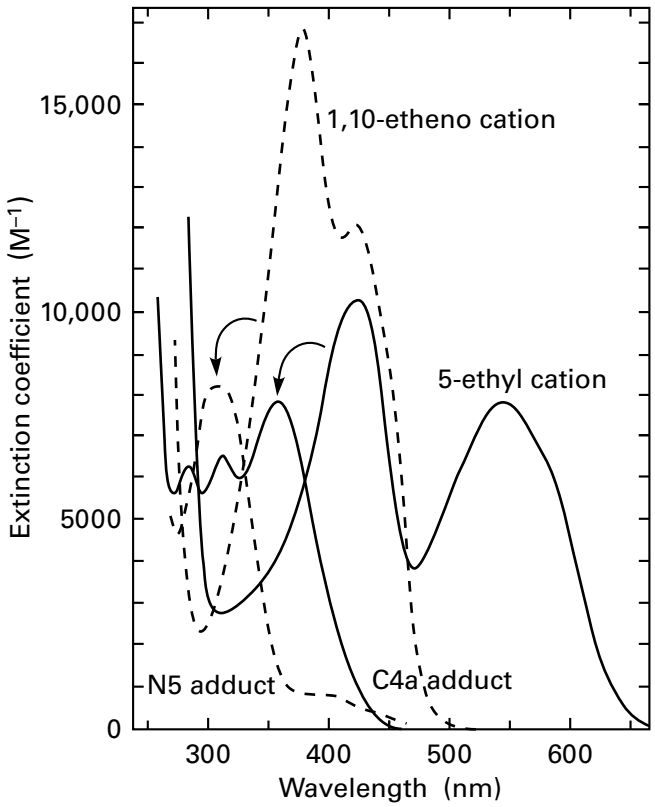


Figure 2–16: Absorption spectra of adducts to oxidized flavin. The spectrum[373] for the adduct of sulfite to nitrogen 5 (N5 adduct) of 7,8-dimethyl-1,10-ethenoisoalloxazinium (Equation 2–124) was obtained by adding sufficient $NaHSO_3$ to a 40 μM aqueous solution of 7,8-dimethyl-1,10-ethenoisoalloxazinium perchlorate at pH 7 to convert all of the isoalloxazinium to the adduct of sulfite at nitrogen 5. The spectrum of 7,8-dimethyl-1,10-ethenoisoalloxazinium (1,10-etheno cation) in the same solution was taken before the sulfite was added. The strong absorbance of the isoalloxazinium between 350 and 500 nm disappeared as the sulfite adduct formed. The spectrum[374] for the adduct of ethoxide to carbon 4a (C4a adduct) of 3,7,8,10-tetramethyl-5-ethylisoalloxazinium ion (Equation 2–128) was obtained by dissolving 3,7,8,10-tetramethyl-5-ethylisoalloxazinium perchlorate in ethanol. The spectrum[375] of the initial 3,7,8,10-tetramethyl-5-ethylisoalloxazinium ion (5-ethyl cation) was obtained by dissolving 3,7,8,10-tetramethyl-5-ethylisoalloxazinium perchlorate in 0.1 M sodium perchlorate at pH 3.

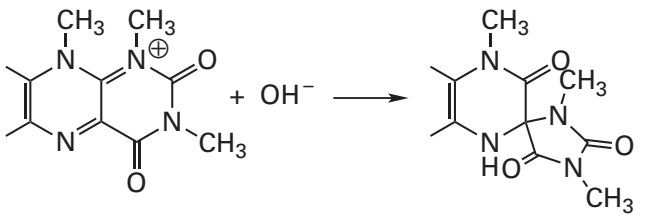
formed by the addition of sulfite to oxidized flavin,[376] is **an established intermediate in the enzymatic reaction** catalyzed by the flavoenzyme adenylylsulfate reductase from *Archaeoglobus fulgidus* and has been observed crystallographically.[377] The σ bond between sulfite and nitrogen 5 of the oxidized flavin in this intermediate is the relay station through which the two electrons pass during reduction of the phosphosulfate in 5′-adenylyl sulfate to sulfite in one direction and during oxidation of the sulfite to the phosphosulfate in the other direction. In one direction, this σ bond between sulfur and nitrogen 5 of the flavin is formed by the nucleophilic substitution of flavin for AMP^- at the electrophilic sulfur in the 5′-adenylyl sulfate, in which the nucleophile is the

*From here on the 7,8-dimethylphenyl ring of isoalloxazine will be truncated to two lines to save space in the equations. This truncation will become more and more appropriate as the equations become larger.

electron-rich nitrogen 5 of reduced flavin. In the other direction, it is formed by the nucleophilic addition of sulfite to electrophilic nitrogen 5 in the 1,4-diazabutadiene of oxidized flavin. The electrons arrive in the nucleophilic lone pair of electrons on nitrogen 5 of the reduced flavin in one direction and arrive in the nucleophilic lone pair of electrons on sulfite in the other direction, and the two electrons in the σ bond that they form leave the flavin on sulfite during the reduction and enter the flavin on sulfite during the oxidation, respectively. In the direction of oxidation of sulfite to form the phosphosulfate, Equation 2–124 suggests that nitrogen 1 will almost certainly be hydronated transiently to make the oxidized flavin more electrophilic.

In the enzymatic reaction catalyzed by nitroalkane oxidase from *Fusarium oxysporum*, the carbanionic conjugate base of a nitroalkane at the carbon α to the nitro group adds nucleophilically to nitrogen 5 of the prosthetic flavin in the active site. After the nitro group leaves and is replaced by a hydroxide, the pair of electrons that was the lone pair of electrons on the carbon α to the nitro group in the anionic conjugate base and that then formed the σ bond to nitrogen 5 is withdrawn into the flavin, reducing it and oxidizing the carbon to the aldehyde. The adduct at nitrogen 5 can be trapped with cyanide ion and observed in a crystallographic molecular model of the enzyme.[378]

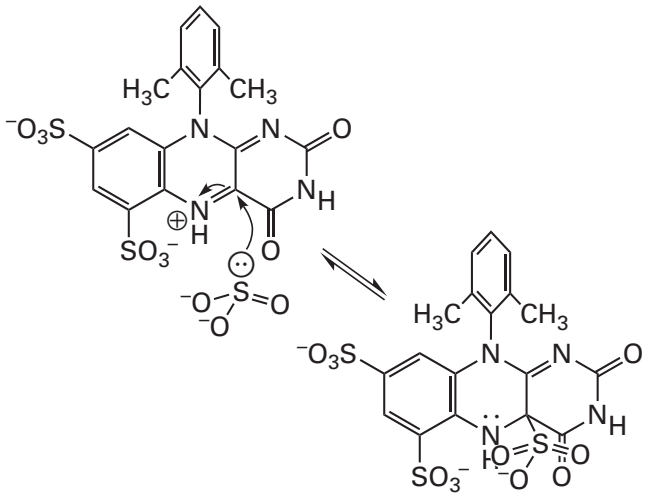
On paper, a 1,4-diazabutadiene (Equation 2–123) can also be **electrophilic at either of its two iminium carbons**, which would be carbon 1a and carbon 4a of oxidized flavin, depending on which nitrogen is hydronated. Several products have been isolated[379] that seem to arise from the nucleophilic attack of hydroxide, ammonia, or hydride at **carbon 1a** of 1,3,7,8,10-pentamethylisoalloxazine, but the addition of any one of these heteroatomic nucleophiles leads unavoidably to the decomposition of the pyrimidine ring



(2–126)

an outcome that would not be salutary for a flavoenzyme. This decomposition requires that nitrogen 1 be hydronated to cause carbon 1a to be electrophilic, and this requirement may explain why most flavoenzymes do not provide a catalytic acid to hydronate nitrogen 1 when flavin is reduced, and the reduced flavin is usually present as the anionic conjugate base. Because of this nucleophilic substitution at carbon 1a and the fact that nitrogen 1 and carbon 1a are always removed from the location at which substrates bind to the active sites of the available crystallographic molecular models for flavoenzymes, nucleophilic adducts at nitrogen 1 and carbon 1a of oxidized flavin have been discounted as intermediates in enzymatic reactions using flavin as a prosthetic group.

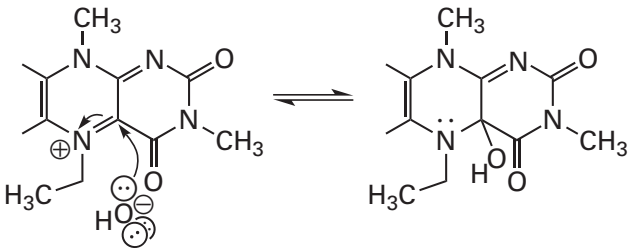
Carbon 4a in oxidized flavin is also electrophilic. Sulfite adds to 10-(2,6-dimethylphenyl)-6,8-disulfo-3-methylisoalloxazine[380] to produce a stable derivative at carbon 4a



(2–127)

Two equivocal aspects of this observation are that the sulfonates at positions 6 and 8 mildly withdraw electron density ($\sigma_p = 0.1$) from carbon 4a, increasing its electrophilicity, and that the sulfonate on carbon 6 sterically blocks nucleophilic attack at nitrogen 5. Even under these most favorable circumstances, an equilibrium mixture of adducts at both carbon 4a and nitrogen 5 is obtained.[381] When the sulfonates are not present, sulfite adds exclusively[373] to nitrogen 5. The behavior of the rate constant for the decomposition of 4a-(indolylmethyl)-3,7,8,10-tetramethylisoalloxazine, however, as a function of pH can be explained[382] as the result of a rapid equilibrium between the adduct at carbon 4a and the adduct at nitrogen 5. If this is the correct explanation, then in this compound these two locations should have almost equivalent electrophilicities.

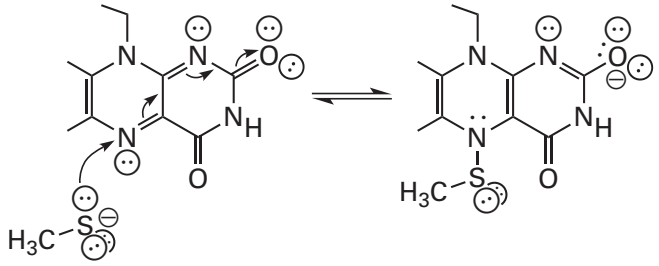
Stable, exclusive **nucleophilic adducts to carbon 4a** have been observed with oxidized 5-ethyl-3,7,8,10-tetramethylisoalloxazine. Either hydroxide ion[375]



(2–128)

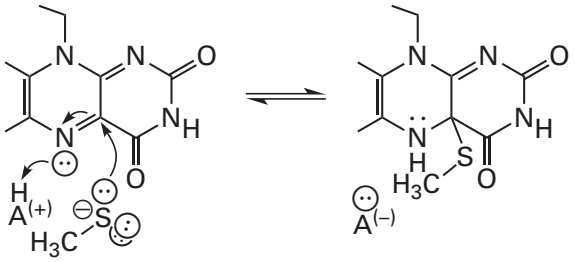
ethoxide,[374] or nitromethane ion ($^{-}$:CH_2NO_2)[383] can add reversibly to carbon 4a of this flavin. In the nucleophilic addition of hydroxide in Equation 2–128, the ethyl group accomplishes the same purpose as hydronation of nitrogen 5, only permanently, but it also sterically hinders addition to nitrogen 5. Nevertheless, this result suggests that, under acid catalysis at nitrogen 5, carbon 4a can be a competent electrophile. As was the case for adducts at nitrogen 5, the addition of a nucleophile at carbon 4a interrupts the conjugation of the oxidized flavin and eliminates its characteristic absorbance between 400 and 500 nm, but the absorption spectrum of an adduct at carbon 4a has a characteristic peak of absorbance between 350 and 400 nm (Figure 2–16).

For normal, oxidized, biochemical flavins, all the foregoing observations, on balance, suggest that **in solution, nitrogen 5 is much more electrophilic than carbon 4a**. This preference may arise from the fact that, because of the ureido oxygen on carbon 2, the addition of a nucleophile to nitrogen 5 can proceed without the need for hydronation of either nitrogen 1 or nitrogen 5



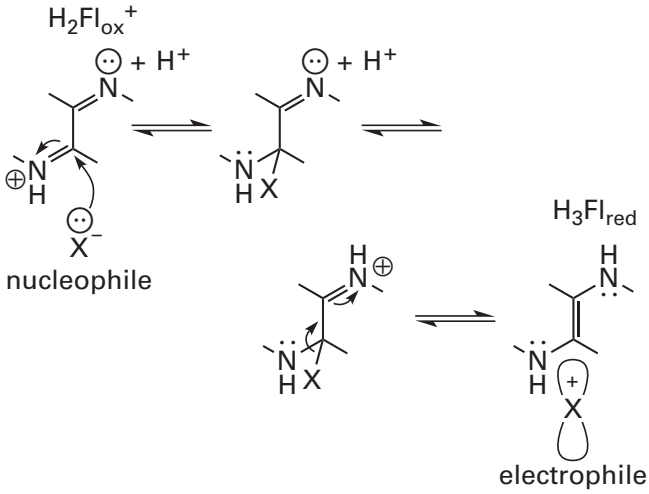
(2–129)

for example, in situations where an active site stabilizes the resulting oxyanion, while addition at carbon 4a requires acid catalysis



(2–130)

The desire for adducts to carbon 4a in oxidized flavin to be transient intermediates in the reactions catalyzed by flavin arises from the appeal of the following **mechanism for the oxidation of a nucleophile by flavin in which an adduct at carbon 4a is required**

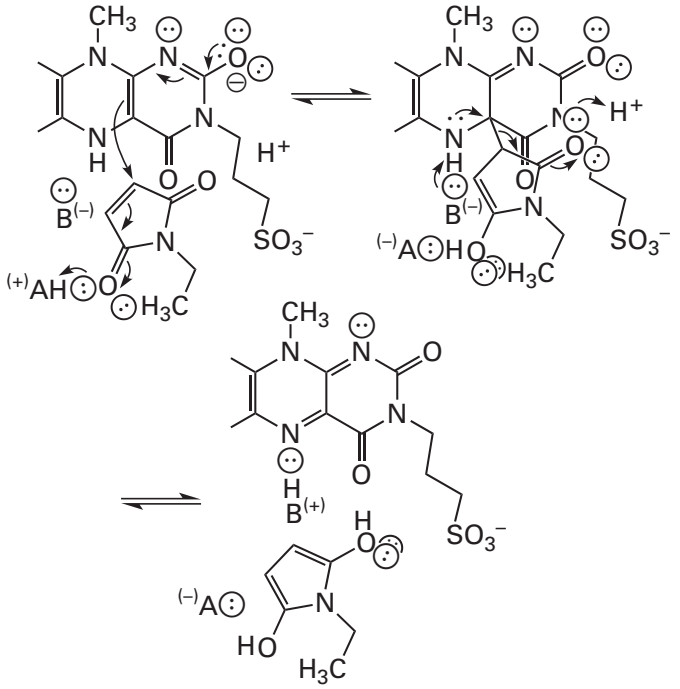


(2–131)

The nucleophilic position of the reactant enters the electrophilic position at carbon 4a with a lone pair of electrons that forms the new σ bond. That new σ bond is now parallel to the π molecular orbital of an adjacent iminium ion that absorbs its electrons. This withdrawal of the electrons releases an electron-deficient, electrophilic, oxidized product and produces reduced flavin. The two electrons entering with the nucleophile remain in the flavin when the electrophile is released. In the reverse direction, the nucleophilic enamine of the reduced flavin would attack the oxidized, electrophilic reactant to form the σ bond to carbon 4a, and the electrons in this σ bond would leave with the dissociating reduced, nucleophilic product. The σ bond to carbon 4a is the transfer point for the two electrons that reduce the oxidized flavin or the electrophile, respectively. In the crystallographic molecular model of 4a-isopropyl-3,7,8,10-tetramethyl-4a,5-dihydroisoalloxazine, which has four σ bonds at carbon 4a, the σ bond

to the isopropyl group at carbon 4a and the π bond of the imine at carbon 1a and nitrogen 1 are parallel,[300] as required in Equation 2–131.

This mechanism for transfer of two electrons through an adduct at carbon 4a has been **validated for several nonenzymatic reactions** catalyzed by flavins. During the reduction of maleimides by reduced 3-(3-sulfopropyl)-7,8,10-trimethylisoalloxazine, an adduct forms between a maleimide and the flavin that is an intermediate in the reaction.[384] The absorption spectrum of this intermediate identifies it as an adduct at carbon 4a

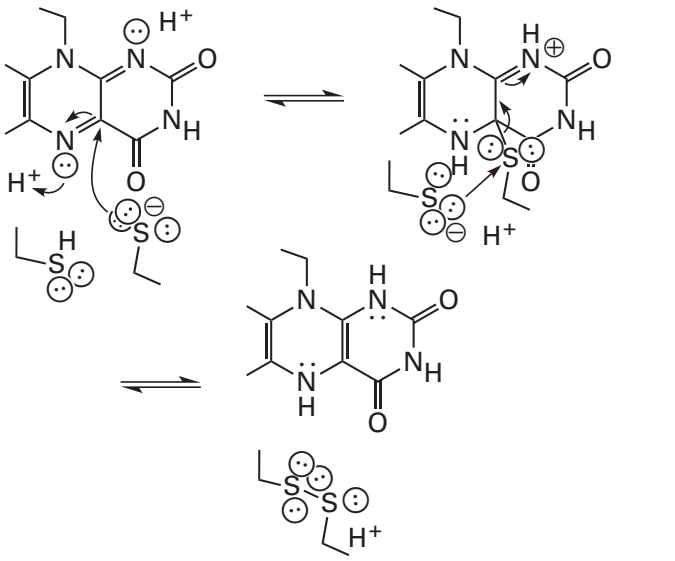


(2–132)

that would result from nucleophilic addition of the nucleophilic anion of reduced flavin to the electrophilic α,β-unsaturated imide. The adduct is formed in a reaction catalyzed by acid, and it decomposes with release of the reduced product in a reaction catalyzed by base.[384]

Benzylamine is oxidatively deaminated to benzylimine by 3,7,8,10-tetramethyl-5-ethylisoalloxazine in a reaction in which the benzylamine adds nucleophilically to carbon 4a. The resulting adduct dissociates in a rate-limiting step in which the electrons in the σ bond are absorbed by the isoalloxazine, reducing it (Equation 2–131), and the hydrogen on the benzylamine at the benzylic position is simultaneously removed by a base as a hydron, producing the benzylimine.[385]

In solution, thiols reduce flavins by forming an adduct at carbon 4a[386]



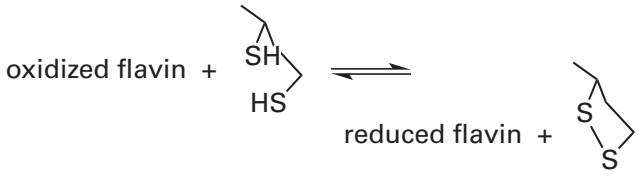
(2–133)

In the reverse direction, the reaction of the reduced flavin is the attack of an enamine on a disulfide and is equivalent to the attack of the enamine of thiamine diphosphate on N^6-(lipoyl)lysine (Figure 2–7). In the forward direction, a lone pair on one of the cysteines becomes a σ bond that is absorbed by the flavin in the second step.

A sulfanyl group is a nucleophile that is often oxidized by a prosthetic flavin. There is a family of related enzymes in which **two nucleophilic cysteines in each of the active sites are oxidized by flavin** and the product of the oxidation is a cystine, which is an electrophile. Glutathione-disulfide reductase is a flavoenzyme that catalyzes the reaction

$$NADP^+ + GSH + HSG \rightleftharpoons NADPH + H^+ + GSSG \quad (2–134)$$

where GSSG is oxidized glutathione, which contains an intermolecular cystine formed from the cysteines in two molecules of reduced glutathione, GSH. The flavoenzyme dihydrolipoyl dehydrogenase catalyzes a reaction



(2–135)

that is equivalent to the one catalyzed by glutathione-disulfide reductase. The flavoenzyme thioredoxin-

disulfide reductase catalyzes the reduction of a cystine in the small protein thioredoxin; the flavoenzyme mercury(II) reductase reduces a cystine in its active site to two cysteines, which then reduce Hg^{2+} to Hg^0; the flavoenzyme 2-oxopropyl-CoM reductase (carboxylating) catalyzes a nucleophilic substitution at the sulfur of a sulfide by a cysteine in its active site; and the flavoenzyme NADH peroxidase catalyzes the reduction of hydrogen peroxide to two molecules of water by reducing a cysteine-sulfenic acid, produced in its active site by the reduction of the hydrogen peroxide, back to a cysteine.

All six of these enzymes use either NADH or NADPH as the reductant, have homologous sequences, have superposable tertiary structures,[387-391] and have very similar if not identical mechanisms for the oxidations and reductions at the flavin. Each of the first five enzymes reduces the respective disulfide or the mercuric ion or catalyzes the nucleophilic substitution by first **reducing a cystine in its active site to two cysteines** and then using the two cysteines to reduce the substrate or one of the cysteines as a nucleophile. NADH peroxidase reduces the cysteine-sulfenic acid in its active site, which is the oxygen homologue of a cystine, to hydroxide and a sulfido group.[392]

In crystallographic molecular models of the five enzymes that each reduce a cystine in its active sites to two cysteines, as well as those of other related homologues, the axis of the sulfur–sulfur bond of the cystine in the active site of the oxidized enzyme and the line of centers between the two sulfurs of the two cysteines in the active site of the reduced enzyme points directly at carbon 4a of the flavin (Figure 2–11).[306,310,387,388,390,393-395] In the most accurate crystallographic molecular model of glutathione-disulfide reductase, the sulfur of the closest cysteine is 0.330 nm from carbon 4a of the flavin, which is within the sum of the van der Waals radii (0.35 nm) of the sulfur and the carbon.[310] The line of centers of the two sulfurs in this molecular model is tilted at an angle of 108° with respect to the bond between nitrogen 5 and carbon 4a, which defines the plane of the flavin, as the σ bond to the closest sulfur would be were it in an adduct at carbon 4a.

Porcine dihydrolipoyl dehydrogenase can be reduced, and one of the two resulting cysteines in the active site can be alkylated with iodoacetamide. When NAD^+ is added to the alkylated enzyme to oxidize the flavin, a spectral change occurs that has been assigned as arising from an adduct between the remaining unalkylated sulfido group and carbon 4a of oxidized flavin.[396] When the flavin adenine dinucleotide in thioredoxin-disulfide reductase from *E. coli* is replaced with 1-carba-1-deazaflavin adenine dinucleotide, in either the active site of the wild type[397] or a variant in which the cysteine farther from the flavin is mutated to serine,[398] and the respective enzyme is reduced, similar spectra, indicative of the formation of the respective 4a adducts, are also observed. When three of the four homologous cysteines in mercury(II) reductase from *E. coli* that are farthest from the flavin are mutated to alanines and the flavin in the enzyme is oxidized with $NADP^+$,[399] the enzyme also has a spectrum consistent with the formation of an adduct at carbon 4a of the flavin. All these spectrally identified intermediates have been presented as evidence for the **formation of an adduct at carbon 4a during the normal reduction of the cystine** or oxidation of the cysteines in the respective active sites of the unalkylated, native enzymes in this family (Equation 2–133).

Glutathione-disulfide reductase from *S. cerevisiae* can also be reduced and alkylated on only one of its two catalytic cysteines.[400] A crystallographic molecular model of this reduced and alkylated enzyme, in a complex with $NADP^+$, is available.[311] Although the unalkylated cysteine is the one closest to the flavin and although the closest atom in the flavin to the sulfur of this cysteine is carbon 4a, there is no bond between the sulfur of the cysteine and carbon 4a of the oxidized flavin. Therefore, the postulated adduct (Equation 2–133) does not form in glutathione-disulfide reductase. In fact, the only adduct that has been observed crystallographically between a sulfido group and carbon 4a in a flavin on an enzyme is one that forms between sulfide ion in solution and the flavin mononucleotide in sarcosine oxidase (5,10-methylenetetrahydrofolate-forming) from *Stenotrophomonas maltophilia*.[401] The lack of such a crystallographic observation cannot disprove the existence of an adduct at carbon 4a, but it is not encouraging.

It is possible that each flavoenzyme in this family of disulfide reductases purposely holds the disulfide of the cystine or the proximal cysteine in its active site at too great a distance to form an adduct with carbon 4a of the reduced or oxidized flavin, respectively, like the one that forms between a thiol and an oxidized flavin in solution (Equation 2–133), because it is faster to **transfer the two electrons between the cystine or the cysteines and the flavin**

one at a time without forming an adduct at carbon 4a than it is to transfer them together through the σ bond of an adduct at carbon 4a. As has been proposed for thiamine diphosphate (Figure 2–7), the electrons would be transferred between reduced flavin and the cystine in the active site in two one-electron steps that have a flavin semiquinone and a cystine radical anion as intermediates. An electron would be transferred from reduced flavin anion to the cystine to produce the disulfide radical anion and the flavin semiquinone. The radical anion of the disulfide would be hydronated on its distal sulfur by an adjacent catalytic acid. The hydronated disulfide radical would cleave to produce the hydronated sulfanyl group and the thiyl radical (Figure 2–8), and the thiyl radical would be reduced by the flavin semiquinone. In the reverse direction, one electron would be transferred from the sulfido group of the proximal cysteine to oxidized flavin to produce the flavin semiquinone and the thiyl radical, which would rapidly form, with the sulfido group of the distal cysteine, a radical anion of a disulfide[241] that would then transfer a second electron to the flavin.

One fact consistent with this possibility is that reduction of the cystine in the active site of thioredoxin-disulfide reductase from *E. coli* decreases the midpoint reduction potential of its flavin by 17 mV,[328] an observation indicating that the cystine and the flavin are electronically coupled. The mutation of the cysteine immediately adjacent to carbon 4a of the flavin adenine dinucleotide in NADH peroxidase from *Enterococcus faecalis*, the cysteine responsible for catalysis, raises the midpoint reduction potential of the flavin by 100 mV.[402] In both instances, the transfer of electron density from a sulfido group could be causing a decrease in the reduction potential. When the cysteine is there, the decrease occurs; when it is not, the decrease does not. Another observation consistent with two successive transfers, each of one electron, between reduced, nucleophilic substrates and oxidized flavin and between reduced flavin and oxidized, electrophilic substrates is the presence of an absorption in the optical spectra of complexes between these flavoenzymes and substrates arising from transfer of charge.

A **charge-transfer complex**[403] forms when a reductant, the donor, transfers an electron in a reversible equilibrium to an oxidant, the acceptor, when they come in contact with each other. Transfer of the electron creates a weak bond between the donor and acceptor that forms a complex between them with a particular dissociation constant. The magnitude of the dissociation constant depends on the equilibrium constant for, and the character of, the electron transfer. A charge-transfer complex will always have an absorption spectrum that contains one or more charge-transfer bands of relatively **long wavelength** (400–800 nm) resulting from the excitation of the transferred electron, which is shared between the donor and the acceptor in an otherwise unoccupied molecular orbital of relatively low energy spread over the complex between the donor and the acceptor rather than being confined exclusively to donor or acceptor.

Although a charge-transfer complex formed by transfer of an electron in the ground state always exhibits such a charge-transfer band in its spectrum, the existence of a charge-transfer band does not require transfer of charge in the ground state; it only requires transfer of charge in the electronically excited state.[404] In solution, the absorption of light by the donor may excite the electron into a charge-transfer orbital formed with an adjacent acceptor even if significant electron density is not transferred to the acceptor in the ground state. In a complex that forms for other reasons, the absorption of light by the donor may also excite the electron into a charge-transfer orbital with an adjacent acceptor even if there is no significant transfer of charge in the ground state.

Charge-transfer bands between the sulfido group of **the proximal cysteine, as a donor, and oxidized flavin, as an acceptor**, have been observed in the absorption spectra of dihydrolipoyl dehydrogenase from *E. coli*,[399,405-409] mercury(II) reductase from *E. coli* (Figure 2–17),[399,405,406,410] and NADH peroxidase from *E. faecalis*.[392,402] With the disclaimer that transfer of the electron may be occurring only in the electronically excited state, these charge-transfer bands demonstrate that a single electron can be transferred from the sulfido group of the proximal cysteine in the active site to the oxidized flavin. If this transfer of an electron does occur in a charge-transfer complex in the ground state even if the equilibrium constant for transfer of the electron is unfavorable, it provides a path for the first, and most difficult, of the two one-electron transfers. The hydronation of nitrogen 5, coincident with the full transfer of one electron, would be followed by formation of the bond between the resulting proximal thiyl radical and the sulfido group of the distal cysteine to form the radical anion of the disulfide, which would then transfer its unpaired

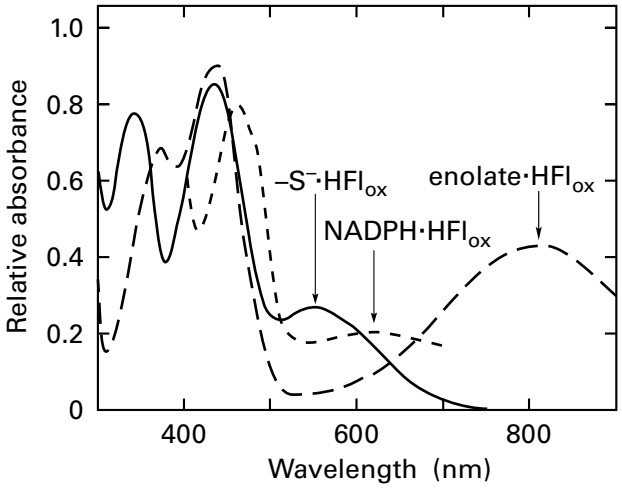


Figure 2–17: Absorption spectra of charge-transfer complexes in which oxidized flavin participates. The maxima of the charge-transfer absorptions are marked by the vertical arrows. The spectrum[399] for the charge-transfer complex (**–S⁻·HFl$_{ox}$**) between oxidized flavin and the sulfido group of the immediately adjacent cysteine in the active site of mercury(II) reductase from *E. coli* was obtained from a sample of a mutant form of the enzyme in which the other three cysteines in the active site had been mutated to alanine. The mutant, oxidized enzyme was dissolved at 2 °C in a solution at pH 9.05 to ensure that the sulfanyl group of the cysteine was the anionic conjugate base. The spectrum[405] for the charge-transfer complex (**enolate·HFl$_{ox}$**) between oxidized flavin and the enolate of 3-thiaoctanoyl-SCoA, octanoyl-SCoA in which carbon 3 is replaced by a sulfur to prevent the removal of the hydrogen on carbon 3 by the oxidized flavin, in the active site of porcine medium-chain acyl-CoA dehydrogenase was obtained from a sample of the oxidized enzyme dissolved in a solution at pH 8.0 to ensure that the enolate of 3-thiaoctanoyl-SCoA was fully formed on the active site. 3-Thiaoctanoyl-SCoA was present in the solution at a high enough concentration (10 μM) to saturate the active site of the enzyme. The spectrum[406] for the charge-transfer complex (**NADPH·HFl$_{ox}$**) between oxidized flavin and NADPH in the active site of the detachable domain of human NADPH—hemoprotein reductase that contains the active site of the intact enzyme in which the prosthetic flavin adenine dinucleotide is normally reduced by NADPH was ob-tained from a sample of the domain dissolved at 25 °C in a solution at pH 7.0 that was rapidly mixed with a solution of NADPH at a concentration high enough to saturate the active sites. The spectrum was gathered within 4 ms of mixing. For each of the three spectra, the absorbance is presented as a fraction of the maximum absorbance of the oxidized flavin in each enzyme that occurs around 450 nm and that was observed before the pH was raised to ionize the sulfanyl group, the 3-thiaoctanoyl-SCoA was added, or the NADPH was mixed with the enzyme, respectively.

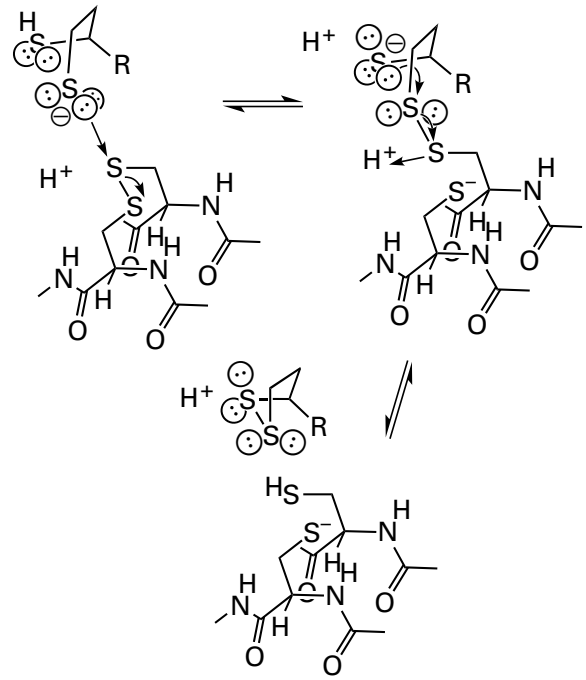
electron to the flavin semiquinone. The net result would be the reduction of oxidized flavin to reduced flavin and the oxidation of two cysteines to a cystine.

The ambiguity of mechanism for oxidation of the two cysteines or reduction of the disulfide in the active sites of these related enzyme illustrates the difficulty is assigning a mechanism to flavin because the existence of the semiquinone allows flavin to transfer electrons one at a time and the existence of adducts of flavin allows flavin to transfer electrons two at a time.

In the direction in which the sulfanyl groups in the respective substrates are converted to a disulfide and the flavin is reduced, the **last step** in the reactions catalyzed by glutathione-disulfide reductase, dihydrolipoyl dehydrogenase, and thioredoxin-disulfide reductase is the oxidation of the sulfanyl groups in their respective substrates by thiol–disulfide exchange with the cystine just formed in the active site. For example, the cystine formed in the active site of dihydrolipoyl dehydrogenase by the oxidized flavin (Equation 2–135) in turn oxidizes the pair of adjacent sulfanyl groups in N^6-(dihydrolipoyl)lysine by thiol–disulfide exchange

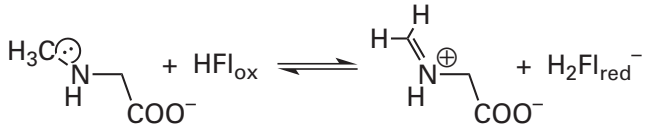


(2–136)

where R is the remainder of the lipoyl group in N^6-(dihydrolipoyl)lysine (Equation 2–70) and N^6-(lipoyl)lysine (**2–31**). In the opposite direction, the first step in the overall reaction catalyzed by dihydrolipoyl dehydrogenase is oxidation of the two cysteines in the active site to the cystine and

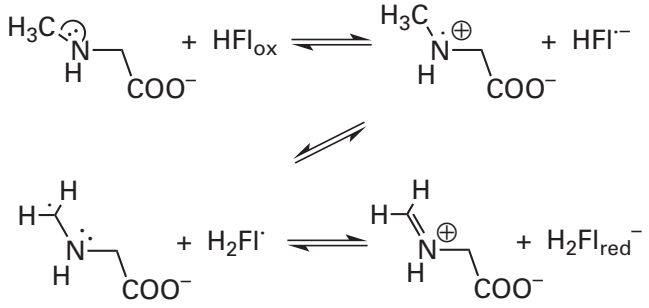
reduction of the disulfide in the reactant into two sulfanyl groups.

An amino group is a nucleophile that can also be oxidized by a prosthetic flavin. Flavoenzymes that oxidize amines also display **charge-transfer bands** in their absorption spectra under the appropriate circumstances. Sarcosine oxidase (formaldehyde-forming), which oxidizes *N*-methylglycine to *N*-carboxymethylmethanimine[411]



(2–137)

also oxidizes L-proline to the respective imine. L-Proline binds to the enzyme as the usual zwitterionic amino acid, the hydron is removed from the nitrogen, and a charge-transfer band (λ_{max} = 512 nm) between the neutral secondary amine and oxidized flavin is then observed.[412] In dimethylglycine oxidase, however, the charge-transfer band (λ_{max} = 400 nm) observed results from transfer of an electron from reduced flavin to the product of the reaction, *N*-carboxymethylmethanimine.[413] This type of charge-transfer band between an imine and reduced flavin was first observed with D-amino-acid oxidase.[414,415] These observations suggest that an electron can be transferred both between the lone pair of electrons on the amino group in the substrate and oxidized flavin and between the reduced flavin and the imine in the product. The chemistry that would lie between these transfers of electrons would be the removal of a hydron from the radical cation of the reactant[413] and the hydronation of the semiquinone anion of the flavin before an electron is transferred from the neutral radical to the flavin semiquinone



(2–138)

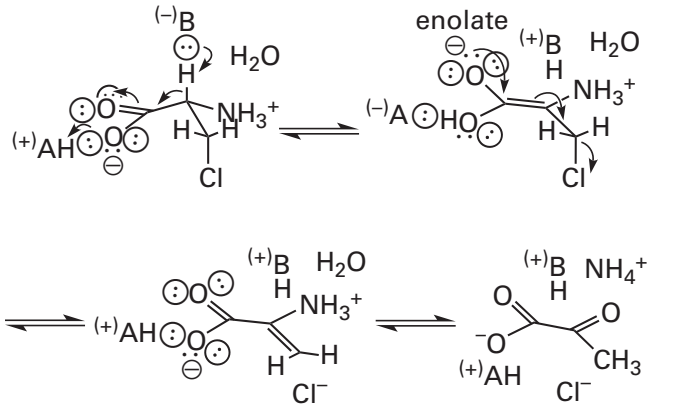
When 4-methylphenol is substituted with 4-bromophenol, a charge-transfer band is observed between the 4-bromophenol and the oxidized flavin in the active site of 4-methylphenol dehydrogenase (hydroxylating) from *P. putida*

$$\text{4-methylphenol} + H_2O \rightleftharpoons \text{4-hydroxybenzaldehyde} + 4\,H^+ + 4\,e^- \qquad (2\text{–}139)$$

There is a close correlation between the wavelength of this charge-transfer band, which registers the energy required to transfer the electron, and the rate of the normal enzymatic reaction for thirty-three variants of the enzyme, either various mutants or enzymes into which various analogues of the flavin had been substituted. The various enzymatic reactions spanned 5 orders of magnitude in rate constant.[416] The lower the energy required to transfer the electron from 4-bromophenol to the oxidized flavin, the faster was the dehydrogenation of the 4-methylphenol catalyzed by the enzyme. This correlation suggests that transfer of one electron is one of the steps in the normal enzymatic reaction.

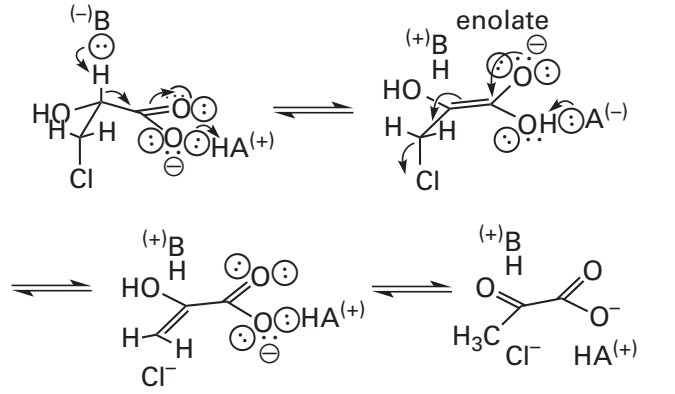
In many reactions, either enzymatic or non-enzymatic, in which flavin oxidizes a reactant with an acidic carbon adjacent to a carbonyl or an acyl group, the enolate of the reactant is an intermediate. For example, when flavin oxidizes carbons 2 and 3 of an acyl-SCoA or carbon 2 of lactate, the enolate or enol of acyl-SCoA or the enolate or enol of lactate, respectively, is an intermediate in the oxidation.[417]

The evidence for these intermediates in enzymatic reactions is the ability of various flavoenzymes to catalyze the dehydrohalogenation of halogenated analogues of their substrates. For example, porcine D-amino-acid oxidase, a flavoenzyme responsible for oxidizing various D-amino acids to the 2-oxo acids, readily dehydrohalogenates β-chloro-L-alanine,[418] presumably through a β-elimination from its enolate



(2–140)

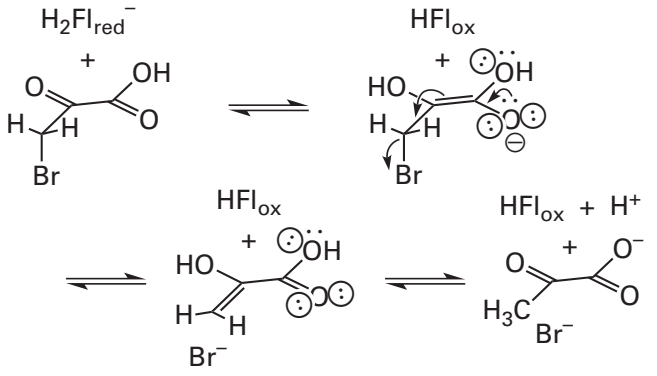
Lactate 2-monooxygenase, a flavoenzyme responsible for oxidizing lactate to acetate and carbon dioxide, has as its first step the oxidation of lactate to pyruvate. This enzyme also catalyzes the dehydrohalogenation of 3-chlorolactate[419]



(2–141)

and its ability to catalyze this reaction is consistent with the involvement of the enolate of lactate as an intermediate in the normal enzymatic reaction. Porcine medium-chain acyl-CoA dehydrogenase catalyzes a similar elimination of 1,2-dichlorosulfanylethene from 5,6-dichloro-4-thia-5-hexenoyl-SCoA.[420]

Dehydrohalogenation can also occur in the direction of reduction of the reactant. The reduced form of L-lactate dehydrogenase (cytochrome), an enzyme that also oxidizes lactate to pyruvate and hence the reduction of pyruvate to lactate, can catalyze the dehalogenation of bromopyruvate in a reaction that simultaneously oxidizes reduced flavin. In this reaction, reduced flavin produces the enolate of bromopyruvate, which then eliminates a bromide ion[421]

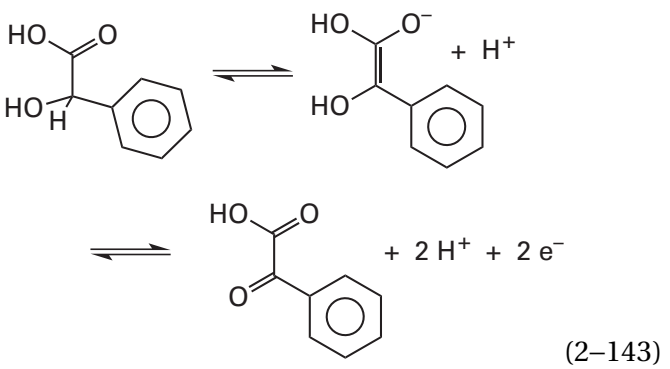


(2–142)

In crystallographic molecular models of the active sites of porcine medium-chain acyl-CoA dehydrogenase, L-lactate dehydrogenase (cytochrome) from *S. cerevisiae*, human isovaleryl-CoA dehydrogenase, and short-chain acyl-CoA dehydrogenase from *R. norvegicus* there is a catalytic base located in the proper position and orientation to remove the respective α hydron on the carbon adjacent to the carbonyl group or the acyl group and form the enol or enolate of the reduced substrate.[316,422-425] When the glutamate that serves as the catalytic base[425] in short-chain acyl-CoA dehydrogenase from *R. norvegicus* was mutated to glutamine, no enzymatic activity could be detected,[426] and when the glutamate in human medium-chain acyl-CoA dehydrogenase was mutated to a glutamine, the rate of the enzymatic reaction decreased[427] by a factor of 10^4.

All these observations have been interpreted to mean that, in the normal oxidation of the respective substrate, its enol or enolate is first formed, and then **two of the electrons in the electron-rich highest occupied molecular orbital of the π molecular orbital system of the enolate are transferred to the oxidized flavin** to oxidize the substrate and reduce the flavin.

Charge-transfer bands have been observed with flavoenzymes that oxidize the enolates of their substrates. (*S*)-Mandelate dehydrogenase, which oxidizes the enol of (*S*)-mandelate

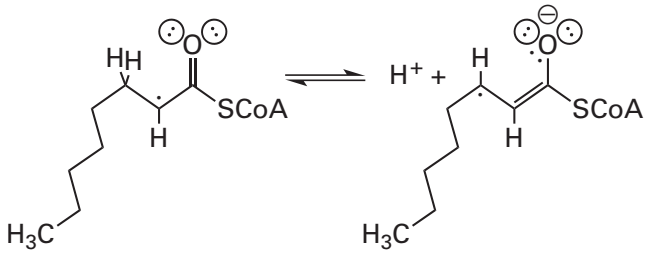


(2–143)

displays a charge-transfer band between 500 and 700 nm. Because the rate of formation of the charge-transfer band is slower when 2-deuteriomandelate is used as the reactant[428] and its formation requires an acyl or carbonyl oxygen α to the hydrogen being removed from the reactant,[429] the charge-transfer band has been assigned as one resulting from electron transfer between the enolate of (*S*)-mandelate and oxidized flavin.

The enolate of octanoyl-SCoA (or of other fatty acyl coenzymes A) is oxidized by medium-chain acyl-CoA dehydrogenase (Equation 2–114) to 2-octenoyl-SCoA (or other α,β-unsaturated fatty acyl coenzymes A). When the enzyme containing oxidized flavin is mixed with octanoyl-SCoA in the absence of electron-transferring flavoprotein, which is its normal general oxidant, the oxidized flavin in the active site oxidizes one octanoyl-SCoA to 2-octenoyl-SCoA, which remains on the active site. This complex between porcine medium-chain acyl-CoA dehydrogenase, reduced flavin, and octenoyl-SCoA displays a broad charge-transfer band between 500 and 700 nm.[430-432] When an analogue of octanoyl-SCoA that can be enolized but cannot be oxidized, such as 3-thiaoctanoyl-SCoA,[433] 2-octynoyl-SCoA,[434] or phenylacetyl-SCoA,[435] is mixed with the oxidized porcine or human medium-chain acyl-CoA dehydrogenase, the α hydron is removed from the analogue by the base in the active site to form the enolate,[434,435] and the absorption spectrum (Figure 2–17) of the complex between the enolate and the oxidized flavin displays a charge-transfer band of long wavelength (λ_{max} = 800 nm).[405]

There are other examples. A transient intermediate with a charge-transfer band (λ_{max} = 565 nm) that has been assigned to electron transfer from the enolate of butyryl-SCoA to oxidized flavin[436,437] has also been observed in rapid kinetic studies of porcine medium-chain acyl-CoA dehydrogenase. Phosphopantothenoylcysteine decarboxylase also displays a charge-transfer band between its enolate and oxidized flavin.[438] If these charge-transfer bands indicate the ability to transfer an electron in the respective ground states, then the chemical steps between transfer of an electron from the enolate of the acyl-SCoA to oxidized flavin, and transfer of an electron from the radical anion of the acyl-SCoA to neutral flavin semiquinone, would be removal of a hydron from the β carbon of the α radical of the acyl-SCoA



(2–144)

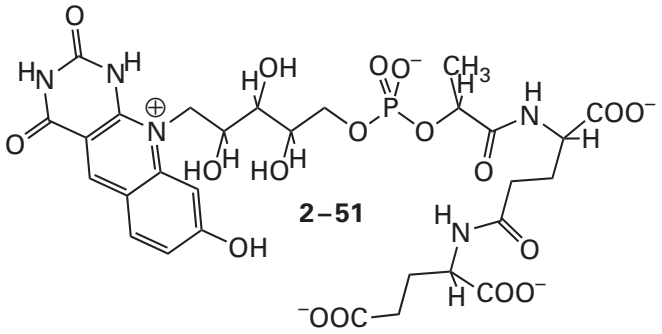
and hydronation of the anionic conjugate base of flavin semiquinone, a hydronation required to occur before the semiquinone can be reduced by one electron (Figure 2–9).

The existence of these charge-transfer bands in the spectra of these flavoenzymes suggests that the **electrons can be passed between the enolate of the substrate and the flavin one at a time.** If so, there must be radical intermediates: flavin semiquinone (Figure 2–9), which would not be surprising since it has been observed routinely in particular active sites, and radicals formed from the substrates (Equations 2–138 and 2–144). The feasibility of one-electron mechanisms involving flavin has been established by calculating standard free energies of formation of radical intermediates.[439] It has even been shown that reduced 3,5,7,8,10-pentamethylisoalloxazine will react with several electron-deficient carbonyl compounds to yield flavin semiquinone, recognized by its blue color, and presumably the carbonyl radical anion,[440] which would be the conjugate base of the radical intermediate in the reduction of an aldehyde or ketone (such as pyruvate) to an alcohol (such as lactate), a reaction always thought to result from direct transfer of a hydride. It has also been observed that scavengers of radicals can lower the yields of enzymatic oxidations catalyzed by flavin that pass through enolates.[441] When flavoenzymes react with analogues of their respective nucleophilic substrates designed to fragment characteristically when they become the respective radical intermediates upon transfer of the first electron, the expected products of those fragmentations are

produced,[442,443] but it has also been shown that such fragmentations can be equivocal.[444] There are also other experimental results obtained with some of the same enzymes suggesting that, in the oxidations of the normal substrates, radical intermediates are not formed.[445]

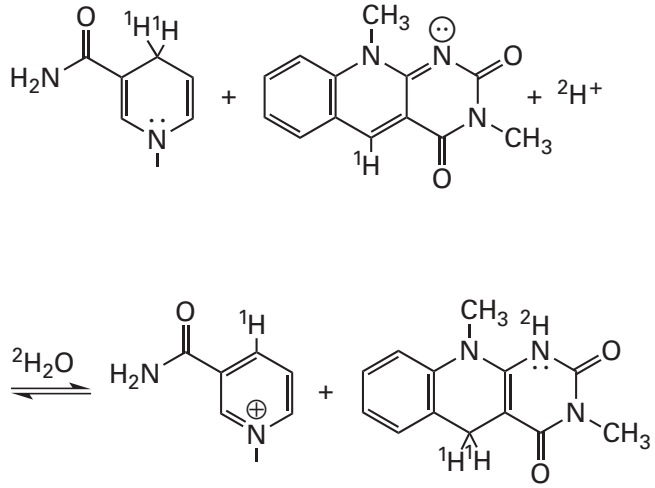
The mechanisms for the oxidations of the thiolates, enolates, and amines that are suggested by the existence of the various charge-transfer complexes and the fragmentations of analogues of the substrates expected from the formation of their radicals all involve transfer of an electron from the reactant to the flavin to produce the respective radical or radical cation of the reactant and flavin semiquinone radical anion, hydronation of the flavin semiquinone radical anion (Figure 2–9), and transfer of the second electron to the neutral flavin semiquinone, either after or coincident with dehydronation of the appropriate carbon in the radical or radical cation of the reactant. These are, however, the same oxidation–reductions for which mechanisms involving nucleophilic adducts (Equations 2–127 through 2–133) have been proposed as well. These two alternatives are mutually exclusive. Because the two respective members of each of the redox couples in each of these reactions, the reactant and the oxidized product and the oxidized flavin and the reduced flavin, differ from each other by the equivalent of a hydride and a hydron, there is a third, also mutually exclusive alternative.

There is evidence for many enzymes using flavin as an oxidant or a reductant that the mechanisms proceed by direct transfer of a hydride rather than either formation of a nucleophilic adduct or two one-electron transfers. One set of observations in favor of direct transfer of a hydride in two-electron oxidation–reductions of flavin comes from experiments with **5-carba-5-deazaflavins**, in which nitrogen 5 of the isoalloxazine (**2–42**) has been substituted by a carbon. These analogues of flavin retain a hydrogen nucleus at position 5 but in a carbon–hydrogen bond rather than as a hydron that can participate in acid–base exchange in a nitrogen–hydrogen bond as occurs with flavin. A naturally occurring 5-carba-5-deazaflavin is *N*-{*N*-[*O*-(7,8-didemethyl-8-hydroxy-5-deazaphosphoriboflavin)-(*S*)-lactyl]-γ-L-glutamyl}-L-glutamate, coenzyme F_{420} (previously **1–69**)



which is used as a coenzyme in methanobacteria.[446] Various enzymes transfer the equivalent of a hydride to and from carbon 5 of this 5-carba-5-deazaflavin.[447,448] The existence of this coenzyme as an acceptable natural analogue of flavin suggests that the unnatural, synthetic substitution of a carbon for nitrogen 5 in a flavin is also acceptable.

In a solution prepared with deuterium oxide, ^2H_2O, NADH is able to reduce 5-carba-5-deaza-3,10-dimethylisoalloxazine

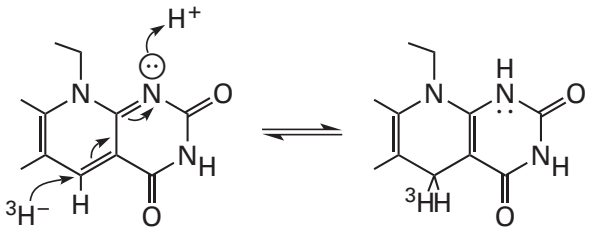


(2–145)

by direct transfer of its hydrogen to carbon 5 of the 5-carba-5-deazaflavin with no interchange with deuterons in the solvent.[449] This observation is consistent with a direct transfer of a hydride and rules out the successive transfer of two electrons, one at a time, punctuated by hydron transfers in this instance because it is unlikely that a hydron lost from carbon 4 of NADH would be transferred directly to carbon 5 of the deazaflavin in free solution. 5-Carba-5-deaza-1,5-dihydro-3,10-dimethylisoalloxazine, the reduced form of 5-carba-5-deaza-3,10-dimethylisoalloxazine, is able to transfer the hydrogen on its carbon 5 directly to the carbonyl carbon of pyridoxal 5′-phosphate,[450] and this ability demonstrates that a reduced flavin, albeit one

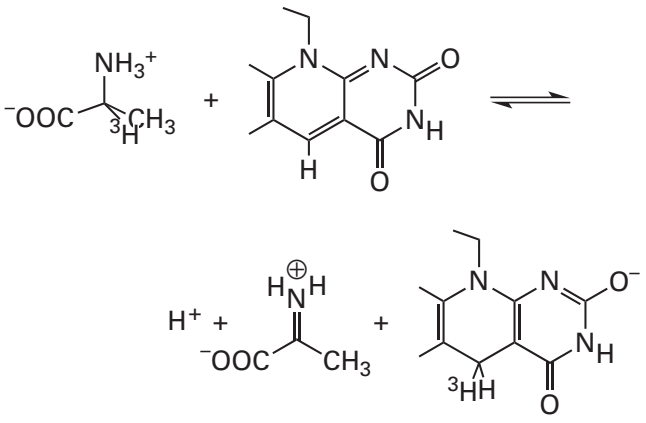
missing nitrogen 5, can directly transfer a hydride to a substrate.

The situation is more ambiguous on the active site of an enzyme, however, where the two reactants are held adjacent to each other and formal transfer of a hydride cannot be distinguished from a shielded, directed transfer of a hydron between the reactants. Nevertheless, in each of several enzymatically catalyzed reactions the reduced substrate, the hydrogen of which is labeled as tritium, has been shown to **transfer the tritium, ostensibly as a formal tritide ion, directly to carbon 5 of a 5-carba-5-deazaflavin** that has been substituted for the normal flavin



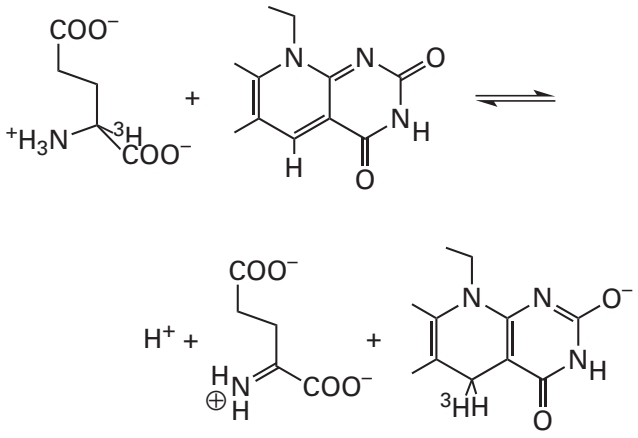
(2–146)

usually in quantitative yield. Examples of donors for hydride in the respective enzymatically catalyzed reductions of a 5-carba-5-deazaflavin have been D-[α-^{3}H]alanine in the active site of porcine D-amino-acid oxidase[451]



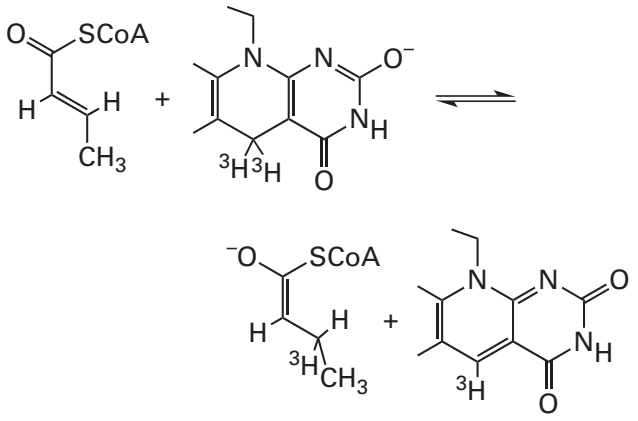
(2–147)

and L-[α-^{3}H]glutamate in the active site of methylamine—glutamate *N*-methyltransferase from *Aminobacter aminovorans*[452]



(2–148)

An oxidized substrate can also be reduced by labeled 5-dihydro-5-carba-5-deazaflavin. When crotonyl-SCoA is reduced with [5,5-$^3H_2$]-5-carba-5-deazaflavin in the active site of short-chain acyl-CoA dehydrogenase from *Megasphaera elsdenii*[453]



(2–149)

one of the tritiums on the [5,5-$^3H_2$]-5-carba-5-deazaflavin is transferred during a reduction that produces the enol of [3-^{3}H]butyryl-SCoA.

The flavoenzyme porcine methylenetetrahydrofolate reductase (NADPH)

$$N^5,N^{10}\text{-methylenetetrahydrofolate} + \text{NADPH} + \text{H}^+ \rightleftharpoons N^5\text{-methyltetrahydrofolate} + \text{NADP}^+$$

(2–150)

transfers the tritium from (5*S*)-[5-^{3}H]-5-carba-5-deaza-8-demethyl-8-hydroxyflavin quantitatively to form either (4*S*)-[4-^{3}H]NADPH or N^5-([^{3}H]methyl)-tetrahydrofolate.[454] This result shows that the hydride on a 5-carba-5-deazaflavin can be transferred with high stereospecificity to the oxidant in either of the

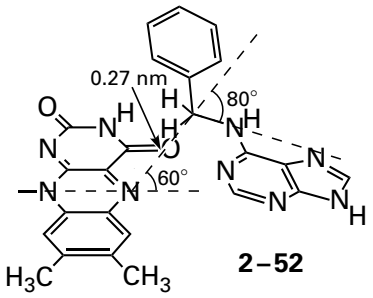
redox couples, the general and the nominal, of the respective enzymatic half-reactions. The flavoenzyme UDP-*N*-acetylmuramate dehydrogenase catalyzes transfer of the deuterium on carbon 4 of (4*S*)-[^{2}H]NADPH to carbon 11 of UDP-*N*-acetylmuramate with no detectable dilution of the deuterium through exchange with hydrons in solution.[455] This observation suggests that the deuterium is transferred as a hydride from NADPH to the 5-carba-5-deazaflavin and then as a hydride from the flavin to UDP-*N*-acetyl-3-*O*-(1-carboxyethenyl)-D-glucosamine. Before and after each step, the hydrogen is on carbon.

When the formal transfer of a hydride from reduced 5-carba-5-deazaflavin to the β carbon of crotonyl-SCoA (Equation 2–149) was carried out by the enzyme short-chain acyl-CoA dehydrogenase from *M. elsdenii*, the rate was equal to the rate of transfer of a hydride from reduced flavin to the β carbon of crotonyl-SCoA catalyzed by the same enzyme.[453] If the rate-limiting step in these enzymatic half-reactions actually is formal transfer of the hydride, this result suggests that, at least in this case, the reaction of the 5-carba-5-deaza analogue reproduces the normal reaction.

In each of the reactions just described, the hydrogen is required to be on carbon to begin with and on carbon at each step. If it were ever on a heteroatom, it would have been susceptible to exchange. Consequently, these results may not be relevant to reactions involving the oxidation–reduction of thiols discussed above.

In the crystallographic molecular models of the complexes between many flavoenzymes that catalyze formal transfers of hydrides from carbon and their nominal substrates, the carbon on the nominal substrate from which the equivalent of a hydride is removed is often found immediately adjacent to nitrogen 5 of the flavin and points its carbon–hydrogen bond at nitrogen 5.[313,316,456-468] An example would be the complex between D-amino-acid oxidase from *R. toruloides* and D-3,3,3-trifluoroalanine (Figure 2–12).[313] D-3,3,3-Trifluoroalanine is not a substrate for the enzyme[469] because of the electron withdrawal of the three fluorines. In the crystallographic molecular model, the distance between the α carbon of D-trifluoroalanine, from which the hydride would be removed if it were D-alanine, to nitrogen 5 of the flavin is 0.31 nm, well within van der Waals contact. The α carbon–nitrogen 5–nitrogen 10 angle is 104°, close to the angle observed in a covalent, nucleophilic adduct at nitrogen 5 (116°) of flavin,[470] a fact indicating that the hydride would be on a proper trajectory to form a σ bond with nitrogen 5. The carbon–hydrogen bond is not pointed directly at nitrogen 5, but the D-trifluoroalanine is tilted only about 30° out of alignment. The distance and the orientation are almost ideal for direct, in-line transfer of a hydride between the carbon and the nitrogen.

The orientation of the carbon–hydrogen bond is even closer to ideal in the crystallographic molecular model of the complex between cytokinin dehydrogenase from *Zea mays* and the poorly oxidized substrate N^6-benzyladenine. The distance between nitrogen 5 of the flavin and the benzyl carbon, from which the equivalent of a hydride is removed, is 0.27 nm; the benzyl carbon–nitrogen 5–nitrogen 10 angle is 120° (180° – 60°). The carbon–hydrogen bond on the benzyl carbon, which remains reduced in the complex, is tilted only about 10° out of alignment with the line of centers between nitrogen 5 and the benzyl carbon[461]



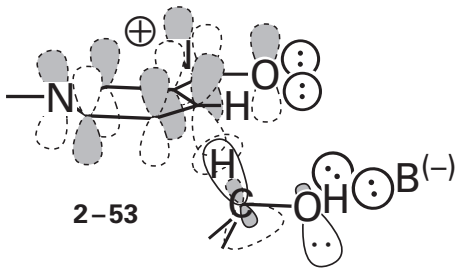
2–52

In the complex between porcine medium-chain acyl-CoA dehydrogenase (Equation 2–114) and octanoyl-SCoA, the octanoyl-SCoA may well be reduced to octenoyl-SCoA and the flavin oxidized, but octanoyl-SCoA was nevertheless inserted into the electron density. In the resulting crystallographic molecular model of the complex between the enzyme and octanoyl-SCoA, the distance between nitrogen 5 of the flavin and the β carbon of octanoyl-SCoA, from which a hydride would be transferred, is 0.30 nm, well within the sum of the van der Waals radii; the β carbon–nitrogen 5–nitrogen 10 angle is 106°; and the β carbon–hydrogen is tilted about 35° out of alignment with the line of centers (Figure 2–13).[316]

All these orientations and distances seem to demand that direct in-line transfer of a hydride from substrate to flavin occur during the normal oxidation–reduction in these cases. Yet complexes between several of these enzymes, in particular D-amino-acid oxidase[471] and porcine medium-chain acyl-CoA

dehydrogenase, and their substrates, both when the substrate is reduced and the flavin is oxidized and when the substrate is oxidized and the flavin is reduced, display charge-transfer bands.

One difference between direct, formal transfer of a hydride to carbon 4 of nicotinamide, for example in the case of alcohol dehydrogenase (previously **1–76**)



2–53

and direct, formal transfer of a hydride to nitrogen 5 of flavin, for example in the case of cytokinin dehydrogenase (**2–52**), is that carbon 4 of nicotinamide has a hydrogen on it while nitrogen 5 of flavin has a lone pair of electrons. Much more than the hydrogen, this lone pair of electrons on the nitrogen should hinder direct, formal transfer of a hydride by electron repulsion. On the opposite face of the flavin from the position assumed by the nominal substrate that donates the equivalent of a hydride, there is usually a donor for a hydrogen bond.[472] The donor is 0.28–0.34 nm from nitrogen 5 at an angle of 120°–170° to the line of centers between nitrogen 5 and nitrogen 10 of the flavin (Figures 2–12 and 2–13). This is a location ideal (see **2–42**) for **drawing the σ lone pair of electrons on nitrogen 5 into a hydrogen bond** and away from the hydrogen of the nominal substrate that is to be transferred as a hydride.

This donor for a hydrogen bond can be either a nitrogen–hydrogen from the backbone of the polypeptide (Figure 2–12), the donor on a side chain such as the nitrogen–hydrogen of an arginine or the oxygen–hydrogen of a threonine (Figure 2–13), or a molecule of water that forms a hydrogen bond to the 6-amino group of a lysine.[473] It is, however, always a weak acid ($pK_a > 10$), probably because the lone pair, after being pulled away from the hydride being transferred, becomes a delocalized pair of electrons in reduced flavin (Figure 2–9) and should not be localized by hydronation, which would be the drawback of a stronger acid. In the direction of reduction of the nominal substrate, the donor for the hydrogen bond localizes the otherwise delocalized lone pair of electrons (**2–45**) and as a result pushes the hydrogen on nitrogen 5 out of the plane of the ring (see Figure 2–9). These effects would promote the formal transfer of a hydride from nitrogen 5. When the lysine in the active site of tryptophan 2-monooxygenase from *Pseudomonas savastanoi* that performs this role on the opposite face of the flavin is mutated to a methionine,[474] the rate of reduction of the prosthetic flavin by L-tryptophan decreases by a factor of at least 10^5.

In contrast to the frequent examples of orientations of substrates as expected for a direct in-line transfer of a hydride, there are instances in which a π molecular orbital system in a substrate is stacked upon the isoalloxazine. This arrangement is analogous to the stacking of a π molecular orbital system upon nicotinamide adenine dinucleotide (Figures 1–16 and 1–19). In the crystallographic molecular model of the complex between octanoyl-SCoA and porcine acyl-CoA dehydrogenase, the flat π molecular orbital system of the thioester stacks on the π system of the flavin (Figure 2–13).[316,475] The larger π molecular orbital of the enol of the thioester, formed by removing the α hydron, would stack as well. In the crystallographic molecular model between the oxidized form of UDP-*N*-acetylmuramate dehydrogenase from *E. coli* and the oxidized form of its substrate, the carboxyethenyl group of the substrate, which is a carboxyenol ether, is also stacked on the flavin.[476,477] In the crystallographic molecular models of the complexes between the respective substrates and D-amino-acid oxidase (Figure 2–12) and succinate dehydrogenase from *Shewanella putrefaciens*,[456,457] the π molecular orbital system of a carboxylate in the substrate stacks on the π molecular orbital system of the flavin. And in the crystallographic molecular models of complexes between substrate and polyunsaturated fatty acid isomerase from *Cutibacterium acnes*, the π molecular orbital system of a conjugated diene stacks on the π molecular orbital system of the flavin.[462]

In each of these instances, which all involve acyclic, unsaturated nominal substrates, the stacking of a π molecular orbital system in the substrate upon the π molecular orbital system of the flavin does not prevent the hydrogen on the substrate that participates in formal transfer of a hydride to the flavin from assuming the proper orientation and sitting the proper distance from nitrogen 5 of the flavin for direct in-line transfer of a hydride (Figures 2–12 and 2–13). There are, however, several examples of nominal substrates with cyclic π molecular orbital systems in which the almost complete **stacking of a cyclic π molecular orbital system of the substrate**

on the π molecular orbital system of the flavin does seem to place the carbon–hydrogen bond of the substrate in an orientation that should be unfavorable if not forbidden for direct transfer of a hydride.[478-482] The nicotinamide rings of NAD^+ and $NADP^+$ illustrate this problem most dramatically because of their departure from the reasonable positioning performed by other active sites in which the hydride to be removed is in line with the carbon on which it sits and nitrogen 5 of the flavin and at the proper angle for transfer.

Many flavoenzymes use the **general redox couples NAD^+ and NADH and $NADP^+$ and NADPH** as carriers of a hydride in a half-reaction to regenerate the oxidized or reduced flavin, respectively, in preparation for the reduction or the oxidation of the nominal reactant in the next round. Crystallographic molecular models of NADH or NADPH in a complex with the reduced form of the flavin in the active site[306,478,483,484] or crystallographic molecular models of NAD^+ or $NADP^+$ in a complex with the oxidized form of the flavin in the active site[485] or both of these pairings[486] show that, in each case, **the π molecular orbital system of the nicotinamide stacks upon the π molecular orbital system of the flavin** (Figure 2–11).[311] These are not complexes that are normally involved in the enzymatic reaction because they pair reduced flavin with NADH (the reduced form of the nicotinamide) or oxidized flavin with NAD^+ (the oxidized form of the nicotinamide). Consequently, one might argue that they are irrelevant to the actual mechanism of formal transfer of the hydride, but the only atom that is duplicated in or that is missing from the respective complexes is the hydrogen that would normally be transferred between them. Because this is the smallest possible difference and because both flavin nucleotides and nicotinamide nucleotides are large molecules, these complexes probably represent the actual orientation of the ring of the nicotinamide and the rings of the flavin, at least in the Michaelis complex and probably during the actual transfer of the hydride. In the active site of FMN reductase (NADPH) from *E. coli*, the FMN that is the substrate, rather than an NAD^+, also stacks upon the prosthetic $FMNH^-$ in the active site.[487]

The difficulty with all these stacked orientations is that, although carbon 4 of the nicotinamide is always directly adjacent to nitrogen 5 of the flavin in the stack, the distance between them is **fixed at 0.32 nm by the van der Waals radii of the atoms** in the respective rings of π orbitals, and the carbon–hydrogen bond of the hydride on the reduced nicotinamide points well away from nitrogen 5. In a **theoretical calculation of the orientation** that must exist in the transition state for transfer of a hydride between the nicotinamide and the prosthetic flavin in the active site of ferredoxin—$NADP^+$ reductase from *Anabaena*, the plane of the nicotinamide is required to be tilted with respect to the plane of the flavin at a 60° angle before hydride transfer can occur.[488] In a crystallographic molecular model of NADH bound in the active site of a mutant of ferredoxin—$NADP^+$ reductase from *Z. mays* (40% identity; 2.3 gap percent), the nicotinamide, as usual, is stacked upon the flavin.

In order for a nicotinamide that is stacked upon a flavin to tilt through the angle required by this calculation and other similar calculations, either nitrogen 1 of the nicotinamide ring, which is firmly anchored in the active site by the adenosylribose to which it is covalently attached, or nitrogen 10 of the flavin (in the case of ferredoxin—$NADP^+$ reductase, flavin adenine dinucleotide), which is firmly anchored to the active site by its D-ribityl group, would have to move 3 nm. The tilting of one or both of the rings also seems to be sterically precluded in the rather crowded confines of most active sites. For example, in the complex between NADPH and glutathione-disulfide reductase (Figure 2–11), the nicotinamide ring is sandwiched between the flavin and the hydroxyphenyl ring of a tyrosine.[310] All three π molecular orbital systems—tyrosine, nicotinamide, and flavin—are parallel to each other in the stack.

It seems, therefore, that these theoretical calculations of the transition state, if they actually define the required orientation for either direct hydride transfer, rule out the direct transfer of a hydride between carbon 4 of nicotinamide and nitrogen 5 of isoalloxazine if they are stacked one one top of the other in the Michaelis complex, as they are in most if not all crystallographic molecular models of complexes between nicotinamide-adenine dinucleotides and flavoenzymes. Indeed, it would seem that if the calculated orientations are the actual orientations required for hydride transfer, then the active sites that perform transfer of a hydrogen between a nicotinamide and an isoalloxazine would be assembled by natural selection to hold the nicotinamide and the isoalloxazine in those orientations upon their initial association, just as other reactants are held in such favorable orientations in situations in which π molecular orbitals do not stack (**2–52**). It would seem that **in-line transfer of a hydride is precluded** by the actual dispositions. There are

several other possibilities for transfer of the hydrogen between nitrogen 5 of the flavin and carbon 4 of the nicotinamide.

The first possibility is **tunneling**. Theoretical calculations and observed kinetic isotope effects suggest that the formal transfer of a hydride between carbon 4 of nicotinamide and nitrogen 5 of flavin in such a situation could occur by hydrogen tunneling,[489] which is the process generally invoked to explain abnormal, idiopathic kinetic isotope effects in the transfer of a hydron. There are other results, however, suggesting that formal transfer of a hydride from NADH to flavin does not involve hydrogen tunneling.[490] Furthermore, carbon 4 of the nicotinamide and nitrogen 5 of the flavin are farther apart than atoms between which hydrogen tunneling usually occurs, and they are unable to come closer together while stacked upon each other. In the crystallographic molecular model of the complex between 1,4,5,6-tetrahydronicotinamide adenine dinucleotide and the active site of morphinone reductase from *P. putida*, the plane of the tetrahydronicotinamide ring is parallel to the plane of the isoalloxazine ring of the prosthetic flavin and stacked upon it.[491] Theoretical calculations, however, of the transition state for transfer of a hydride from carbon 4 of the nicotinamide to nitrogen 5 of the flavin during the normal reaction in the active site of this enzyme require that, in order to accomplish the transfer of the hydride, when the full effects of tunneling are included, the plane of the nicotinamide ring must tilt away from the plane of the isoalloxazine through an angle of almost 90° so that a normal in-line transfer of the hydride between carbon 4 of the nicotinamide and nitrogen 5 of the flavin, which would bring the two atoms close enough so that tunneling can occur, can be accomplished.[492]

The second possibility is **transfer of an electron, followed by transfer of a hydron from carbon 4 to nitrogen 5, and finally transfer of the second electron**. The standard free energy change for transfer of an electron from reduced nicotinamide ($E^{\circ\prime} = +270$ mV) to oxidized flavin ($E^{\circ\prime}_{ox/sq} = -240$ mV), were each of them in free solution, is +50 kJ mol^{-1}, which is significantly unfavorable ($K_{eq} = 10^9$). Likewise, in the other direction, the standard free energy change for transfer of an electron from reduced flavin ($E^{\circ\prime}_{red/sq} = -130$ mV) to oxidized nicotinamide ($E^{\circ\prime} = -930$ mV), again were each of them in free solution, is +77 kJ mol^{-1} ($K_{eq} = 10^{13}$). These changes in standard free energy seem to indicate that a mechanism of two one-electron transfers in successive steps is unrealistic in either direction because, in each direction, the first step is quite unfavorable. These are, however, changes in standard free energy for transfer of an electron in solution at pH 7. Furthermore, enzymatic active sites often lower free energies of activation for nucleophilic substitutions and additions and elimination–additions by similar amounts.

Unlike the situation in solution, in the active site of an enzyme, the nicotinamide is stacked upon the flavin, and the formation of a charge-transfer complex in this circumstance may permit the rate of the initial transfer of an electron to be rapid enough to participate in the overall reaction. There are many instances in which the first step in the enzymatic reduction by NADH or NADPH of oxidized flavin bound to an active site as a prosthetic group is formation of a complex between the reduced nicotinamide and the oxidized flavin that displays a **charge-transfer band**.[325,406,493,494] These charge-transfer bands are evanescent because reduction of the oxidized flavin follows immediately. For example, when NADPH is mixed with the domain of human NADPH—hemoprotein reductase that contains the active site for reduction of the prosthetic oxidized flavin adenine dinucleotide, within the first 4 ms the NADPH binds to the active site and forms a charge-transfer complex with the oxidized flavin, with a charge-transfer band that has a maximum of absorbance at around 620 nm (Figure 2–17).[406] The formation of this charge-transfer complex precedes removal of the hydrogen nucleus from NADH or NADPH because when the protium on carbon 4 of NADH or NADPH is replaced with a deuterium, the rates of decay of the charge-transfer bands in the next step of several of these enzymatic reactions are decreased[495,496] by a factor of 2–7.

The existence of the charge-transfer band indicates that, in the complex between NADH or NADPH and oxidized flavin in the active site, the nicotinamide and the flavin are **electronically coupled** and that transfer of an electron between the two, under favorable circumstances, will be essentially instantaneous. Consequently, if a hydron must be removed from the NADH or NADPH coincident with transfer of an electron, the removal of that hydron would be the rate-limiting step in the transfer of the electron. This view of the situation is consistent with the fact that when the protium on carbon 4 of NADH or NADPH is replaced with a deuterium, the rate of reduction of oxidized flavin decreases[497-500] by a factor of 3–8. These kinetic isotope effects are consistent with dissociation of a hydron from carbon

but also with dissociation of a hydride from carbon. If the situation is such that the reduced flavin resulting from the formal transfer of a hydride from the nicotinamide to the flavin is not immediately oxidized, the product of the step in which the hydrogen has just been transferred from the nicotinamide to the flavin is now a complex between oxidized nicotinamide and reduced flavin that displays its own characteristic charge-transfer bands.[494,501-504]

With again the disclaimer that these two types of associations may not be charge-transfer complexes in the respective ground states, these results are consistent with **a mechanism in which an electron is transferred from reduced nicotinamide to flavin in a charge-transfer complex** while a hydron is being removed from the developing radical cation of the nicotinamide and a hydron is added to the resulting anionic flavin semiquinone, and then an electron is transferred immediately from neutral nicotinamide radical to neutral flavin semiquinone in a second charge-transfer complex. The fact that the intensity of the charge-transfer bands between nicotinamide and flavin correlated with the rates of normal reduction of the flavin in the reaction catalyzed by 4-hydroxybenzoate 3-monooxygenase [NAD(P)H] from *Pseudomonas aeruginosa*

$$\text{4-hydroxybenzoate} + \text{NADPH} + \text{H}^+ + \text{O}_2 \rightleftharpoons \text{3,4-dihydroxybenzoate} + \text{NADP}^+ + \text{H}_2\text{O} \qquad (2\text{–}151)$$

as the pH of the solution was varied[505] is consistent with participation of the transfer of an electron through a charge-transfer complex in the mechanism of its reaction.

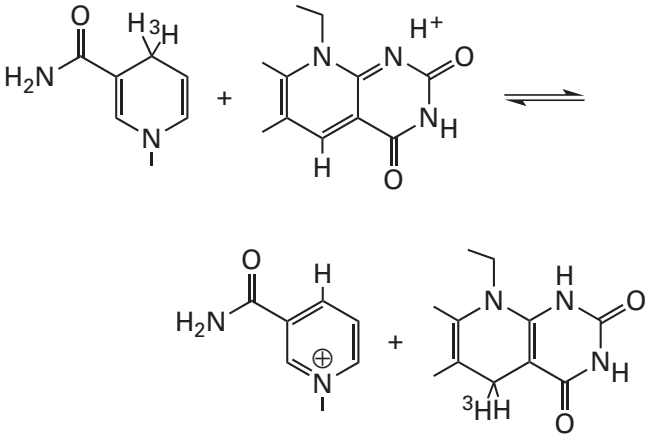
In the crystallographic molecular model of human glutathione-disulfide reductase with NADPH bound at the active site, stacked upon what is probably reduced flavin, the amino group of Lysine 67 is between carbon 4 of the nicotinamide and nitrogen 5 of the flavin. Even though the amino group of Lysine 67 is only 0.37 nm away from carbon 4 of the nicotinamide (Figure 2–11), within the sum of van der Waals radii, nitrogen 5 of the flavin is closer (0.304 nm),[306,310,311] but this contraction is probably the result of a normal hydrogen bond between the two nitrogens. From an examination of the crystallographic molecular model, it was concluded that a hydride could not be transferred from carbon 4 of the nicotinamide to nitrogen 5 of the flavin.[311] Instead, it was proposed that, during the reduction, two electrons would flow from the nicotinamide to the flavin while the hydrogen of NADPH is being removed as a hydron by the oxygen of Glutamate 202, which is within (0.33 nm) van der Waals contact (0.38 nm) of carbon 4.[310] The hydron would be relayed to the 6-amino group of Lysine 67, which is in a hydrogen bond (0.284 nm) with the same oxygen of Glutamate 202, and then transferred from the lysine to the adjacent (0.304 nm) nitrogen 5 of the flavin. Both the charge-transfer complex resulting from the stacking of nicotinamide on flavin and the concerted transfer of the hydron would promote the otherwise difficult movement of the first electron. Following transfer of the hydron, accompanied by transfer of the electron, the second electron would be transferred. When the lysine in dihydrolipoyl dehydrogenase from *E. coli*, the 6-amino group of which is immediately adjacent to nitrogen 5 of its prosthetic flavin and homologous to Lysine 67 in glutathione-disulfide reductase, is mutated to an arginine, the rate of its enzymatic reaction decreases by a factor of 1000.[329]

In the crystallographic molecular models of most if not all complexes between flavoenzymes and nicotinamides, there is a **acid–base adjacent to carbon 4 of the nicotinamide and nitrogen 5 of the flavin** in a position in which it could perform a similar tautomerization. It can be a glutamic acid and a lysine that together participate in a hydrogen bond,[484] the hydroxy group of a serine or a threonine,[483,485] or a molecule of water.[486] In each of these instances the acid–base is at least bidentate. When the serine sitting in this location in NADPH—hemoprotein reductase is mutated to alanine, its proficiency for catalysis of the reduction of its flavin by NADPH decreases by a factor of 100.[506]

The dihydroorotate from which a hydride is transferred to flavin in the active site of dihydroorotate dehydrogenase (fumarate) from *Lactococcus lactis* is stacked upon the flavin,[507] just as the nicotinamide is in the active sites of glutathione-disulfide reductase and other enzymes that catalyze transfer of a hydride from nicotinamide to flavin. The 6-ammonio group of Lysine 43 in dihydroorotate dehydrogenase (fumarate) forms a hydrogen bond to nitrogen 5 of the flavin and is in van der Waals contact with the carbon on the orotate from which the hydride is transferred. When Lysine 43 is mutated to an alanine, the catalytic proficiency of the enzyme decreases by a factor of 7500.[508]

One set of results, however, seems to provide results that contradict the view that NADH or NADPH reduces oxidized flavin by transfer of individual electrons coupled to transfer of a hydron.

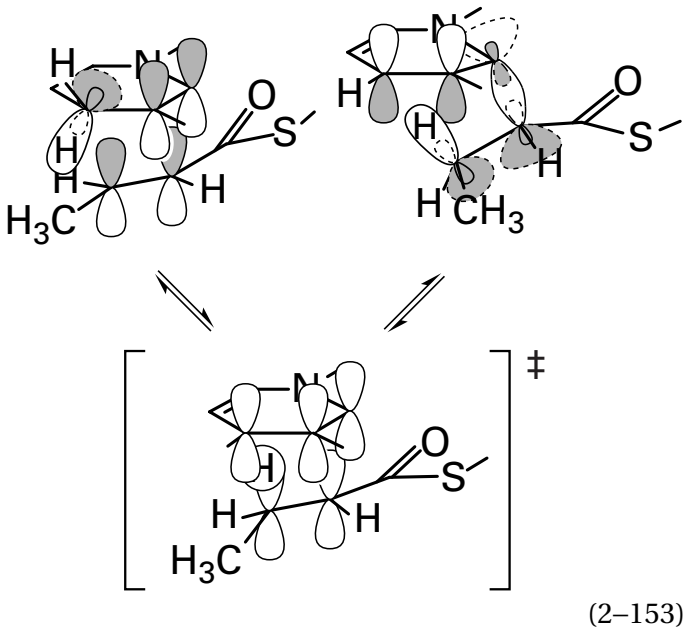
This contradiction is the fact that enzymes in which this oxidation–reduction occurs **transfer the hydrogen nucleus from the NADH or NADPH intact to 5-carba-5-deazaflavin** when it replaces the prosthetic flavin. For example, [4-^{3}H]NADH in the active site of FMN reductase (NADPH) from *Vibrio harveyi*[509] is transferred in the active site to 5-carba-5-deazaflavin



(2–152)

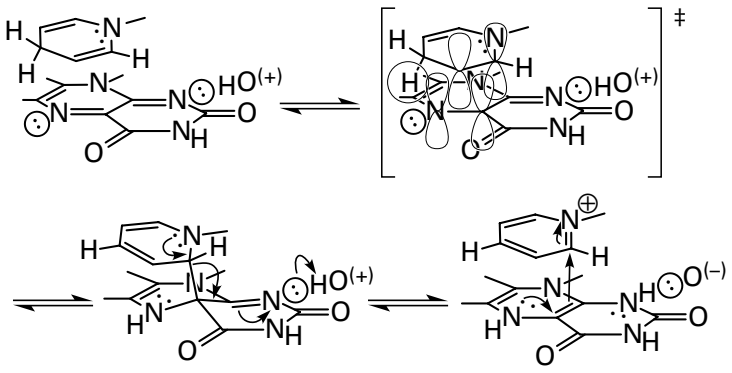
If it were stoichiometric, such a transfer of tritium would be unlikely if the hydrogen nucleus were being transferred as a hydron on a multidentate acid. During the transfer in this instance, however, less than stoichiometric transfer was observed, but the exact percent of transfer could not be determined because the isotope effect for tritium in the reaction was not determined, so it could have resulted from transfer of the hydrogen nucleus as a hydron in the shielded environment of the active site. Nevertheless, if it turns out that, in most cases, when the prosthetic flavin in an active site is replaced by 5-carba-5-deazaflavin and transfer of an isotope of hydrogen is observed to be quantitative, such observations would seem to rule out a mechanism in which a hydron is transferred between flavin and nicotinamide by a multidentate acid.

The third possibility would be transfer of the hydrogen from carbon 4 of reduced nicotinamide to oxidized flavin in an **ene reaction**. Precedent for this mechanism would be the cycloaddition that occurs in the active site of phenacrylate decarboxylase between prenylated $FMNH_2$ and the reactant (2*E*)-3-phenylprop-2-enoate,[370] an enzymatic ene reaction in the biosynthesis of pyridoxatin in *Aspergillus bombycis*,[510] and the apparent, but disputed, ene reaction between NADH and (*E*)-but-2-enoyl-SCoA (previously Equation 1–98)



(2–153)

A similar ene reaction should be able to occur between NADH and oxidized flavin



(2–154)

If this is indeed the mechanism for the formal transfer of the hydride, the transfer between carbon 4 of the NADH and nitrogen 5 of the flavin would be quantitative and 5-carba-5-deazaflavin would be as capable a participant in the reaction as flavin, if not a more capable participant. The precedent for the final step in the reaction, reversible nucleophilic addition of reduced flavin to NAD^+, would be the rapidly reversible nucleophilic addition of urocanate to NAD^+ in the hydration catalyzed by the active site of urocanate hydratase (Equation 2–81). Carbon 2 of NAD^+ is as electrophilic as carbon 4, if not more so. In the crystallographic molecular model of the active site of human glutathione-disulfide reductase (Figure 2–11), the nucleophilic double bond between carbon 1a and carbon 4a, which would add

to or dissociate from carbon 2 of the nicotinamide, is immediately adjacent to carbon 2. The distance from carbon 1a or from carbon 4a to carbon 2 is 0.35 or 0.37 nm, respectively. The distance between carbon 4 of the nicotinamide and nitrogen 5 of the flavin is 0.32 nm.

In summary, when oxidized flavin, HFl_{ox}, participates in a two-electron oxidation of a reactant, one or two hydrons and two electrons are removed from that reactant, and two electrons and one or two hydrons are added to the flavin to produce the anionic conjugate base of reduced flavin, $H_2Fl_{red}^-$, or neutral reduced flavin, H_3Fl_{red}. One hydron is usually removed from the reactant as a hydron by a catalytic base properly positioned in the active site. It is removed from a normally acidic position such as a thiol, an amine, or a carbon α to a carbonyl group or an acyl group by a properly positioned base in the active site. It is the other hydron and the two electrons on the resulting conjugate base, all of which end up formally on the oxidized flavin, that are in question. The hydron and the two electrons may be transferred directly as a hydride. The nucleophile left behind by the removal of the first hydron may form an adduct with nitrogen 5 or carbon 4a of the flavin, and the two electrons in the resulting σ bond may be absorbed by the flavin as it dissociates as a nucleophilic leaving group from the electrophilic product. Or the electrons may be transferred one at a time, and during the first transfer of the electron, the remaining hydron may be removed from the substrate radical as a hydron and a hydron added to flavin semiquinone as a hydron. The fact that experimental observations have been reported that are consistent respectively with each of these mechanisms may illustrate the remarkable versatility of flavin. The fact that two or three of these mutually exclusive mechanisms have often been proposed for the same enzymatic reaction, however, may illustrate our ignorance of what flavin actually does. It is possible that evolution by natural selection has been able to choose among these different possibilities and has settled on one or another of them for a particular enzymatic mechanism. Whether it has always made the same choice or made different choices with different flavoenzymes remains to be determined. It is also possible that the actual mechanism for a particular flavoenzyme is some hybrid of two or more of the possibilities, just as a concerted nucleophilic substitution is a mixture of a dissociative nucleophilic substitution and an associative nucleophilic substitution.

Complicating one's judgment of the mechanisms of flavin is the fact that it **participates in one-electron transfers** such as that catalyzed by adrenodoxin-$NADP^+$ reductase

$$2 \text{ reduced adrenodoxin} + NADP^+ + H^+ \rightleftharpoons 2 \text{ oxidized adrenodoxin} + NADPH \quad (2\text{–}155)$$

In this reaction, the redox couple of $NADP^+$ and NADPH oxidizes and reduces the flavin by the equivalent of the transfer of a hydride but the adrenal ferredoxin, the mitochondrial form (33% identity; 5.4 gap percent; human and *E. coli*) of a bacterial ferredoxin, is a one-electron redox couple, and the single electrons are passed one after the other from flavin with flavin semiquinone as an intermediate.[511]

The ability of a flavin to exist as the stable semiquinone (Figure 2–9) permits it to connect a two-electron oxidation–reduction to two successive transfers of single electrons. Flavin sits at the junction between many two-electron oxidoreductants and one-electron oxidoreductants.[283] The two members of almost all nominal redox couples that participate in oxidation–reduction of flavins in flavoenzymes, such as N^5,N^{10}-methylenetetrahydrofolate and N^5-methyltetrahydrofolate, crotonyl-SCoA and butyryl-SCoA, and 2-iminopropanoate and D-alanine, accept or donate the formal equivalent of a hydride and differ from each other by two electrons and one or two hydrons. The two members of several of the general redox couples that act as acceptors or donors to flavin, for example NAD^+ and NADH and O_2 and H_2O_2, also differ from each other by the formal equivalent of a hydride. With all these redox couples, two electrons are transferred to or from flavin and then two electrons are transferred from or to flavin, respectively. In many instances, however, the general redox couple regenerating the oxidized flavin or the reduced flavin, such as a prosthetic metallic ion, a prosthetic iron–sulfur cluster, or a prosthetic heme, is capable of transferring only one electron from or to the flavin. In such instances, the flavin must split a pair of electrons or join a pair of electrons, respectively.

The ability of flavin to split pairs of electrons into two single electrons or join two single electrons into a pair of electrons is one of its key roles in metabolism. When flavin splits a pair of electrons that it has accepted in a two-electron reduction such as a hydride transfer, each electron by

itself can then be **transferred successively** among a subset of the large array of prosthetic groups capable of participating only in one-electron transfer. A single electron transferred to flavin from one member of such a subset of prosthetic groups can also be joined by flavin with a second electron transferred successively on the same path. A prosthetic flavin can also bifurcate two electrons. When flavin **bifurcates two electrons,** they are split between two separate acceptors rather than passed successively to the same acceptor. For example, one of the prosthetic flavins in electron-transfer flavoprotein from *Acidaminococcus fermentans* bifurcates two electrons that it accepts in a hydride transfer from NADH by transferring one to a prosthetic iron–sulfur cluster in a ferredoxin and the other to another prosthetic flavin in the same molecule of electron-transfer flavoprotein situated in an environment that stabilizes the anionic semiquinone.[512] This capacity of flavin to split or join electrons serves as an introduction to biochemical one-electron transfer.

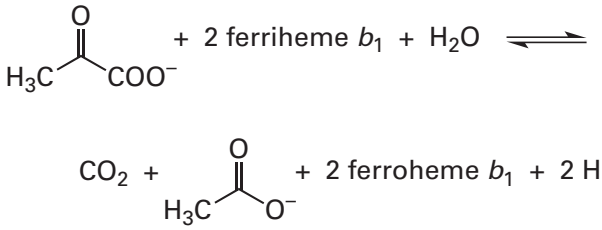
Problem 2–17: Sarcosine oxidase (formaldehyde-forming) from *Corynebacterium* is a flavoenzyme that catalyzes the reaction[513]

$$H_2O + \text{sarcosine} + HFl_{ox} \rightleftharpoons \text{glycine} + \text{formaldehyde} + H_3Fl_{red}$$

(A) Write a mechanism for the reaction as a direct hydride transfer. What provides the push?
(B) Write a mechanism for the reaction involving an adduct at nitrogen 5 of the flavin.
(C) Write a mechanism for the reaction involving an adduct at carbon 4a of the flavin.
(D) Write a mechanism for the reaction involving successive transfers of single electrons between sarcosine and flavin. Have the hydrogen nucleus removed as a hydron by a base.

Problem 2–18: Write the mechanism by which benzylamine is oxidatively deaminated to benzylimine by 3,7,8,10-tetramethyl-5-ethylisoalloxazine in a reaction in which the amine adds nucleophilically to carbon 4a of the prosthetic flavin.[385]

Problem 2–19: The following reaction is catalyzed by flavin and thiamine diphosphate acting together



Write a mechanism involving both prosthetic groups.

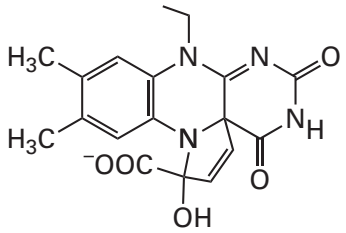
Problem 2–20: Show how the reaction catalyzed by the flavoenzyme dihydroorotate dehydrogenase (NAD^+)[514]

$$(S)\text{-dihydroorotate} + HFl_{ox} \rightleftharpoons \text{orotate} + H_3Fl_{red}$$

can be written as the formal transfer of a hydride to flavin and how it resembles the reaction catalyzed by D-amino-acid oxidase.

Problem 2–21: 2-Hydroxy-3-butynoate is capable of inactivating the flavoenzyme L-lactate oxidase in the following reaction

2-hydroxybut-3-ynoate + HFl_{ox} ⇌



Write a mechanism for this reaction involving hydron removal from 2-hydroxybut-3-ynoate at the carbon analogous to the carbon from which a hydrogen is removed in the regular reaction of lactate with the enzyme.

Problem 2–22: Each of the reactions to the right is catalyzed by either pyridoxal 5′-phosphate, thiamine diphosphate, or flavin.[515] The equations are not necessarily balanced and you may have to add electrons and hydrons to balance them. Balance the equations, decide which prosthetic group is required, and write a mechanism for the reaction involving that prosthetic group. If there are several possible mechanisms, choose only one. There is no exclusively correct mechanism, so the choice is one of personal preference, but the chemistry must be correct.

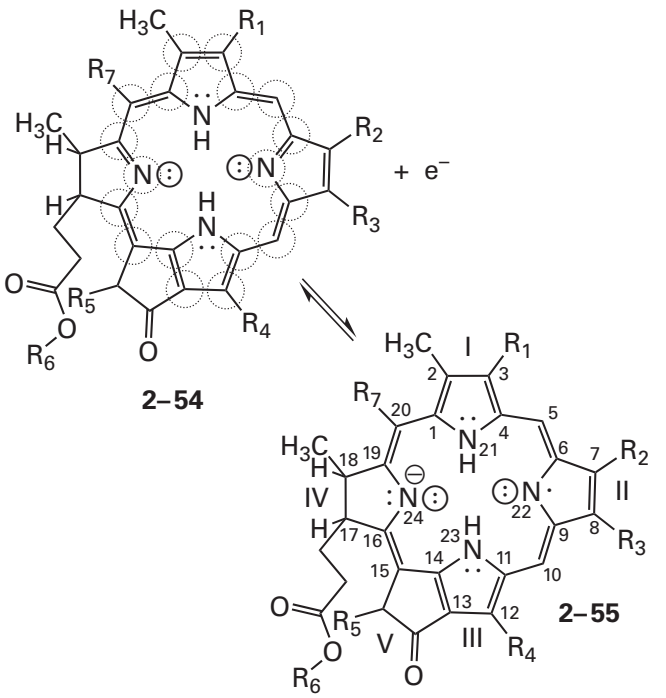
One-Electron Transfer

A prosthetic group capable of participating in transfer of single electrons is a redox couple the two members of which differ from each other by only one electron. If the biochemical standard reduction potential for such a one-electron redox couple is to be in the biochemical range of voltage (approximately −1000 to +1000 mV),[516] both members of the redox couple must have fairly stable electronic structures. For example, flavin semiquinone, because its unpaired electron is delocalized over a large π molecular orbital system, can be a stable organic radical within an active site and can join with either oxidized flavin or reduced flavin to produce in each case a reasonable one-electron redox couple.

There are a set of redox couples that transfer single electrons by forming stable organic radicals. Flavin, because its semiquinone is a stable organic radical, is an example of this class, but many of the members participate only in the transfer of one electron.

Pheophytins



(2–156)

are prosthetic groups capable of participating in one-electron transfer. In the radical anion of pheophytin (**2–55**), as in the radical anion of flavin (Figure 2–9), the unpaired electron is delocalized over a large π molecular orbital system. Within each pheophytin there is an **aromatic ring** of 18 atoms (designated by dotted circles in **2–54**), each of which contributes a *p* orbital to form an unbroken ring with 18 π electrons. In the various pheophytins, some of the carbon–carbon double bonds are reduced to carbon–carbon single bonds, but there is always an unbroken ring of 18 *p* orbitals, although not necessarily in the locations indicated in Equation 2–156. The unpaired electron is added and delocalized into the lowest unoccupied molecular orbital in this aromatic π molecular orbital system.[517] Ring IV has two saturated carbons that lie outside this aromatic π molecular orbital system, and in some of the pheophytins the double bond in ring II, which also lies outside the π molecular orbital system, is either reduced or isomerized into an exocyclic vinylidene group, which is formed from an ethyl group at R_3.

There are more than 15 different pheophytins, which differ from each other by the identity of the substituents around the ring. The substituents R_2, R_3, and R_4 are almost always saturated alkyl groups such as methyl, ethyl, propyl, and isobutyl, but three pheophytins have a formyl group for R_2 and another has an ethenyl group for R_3. The substituent R_1 is an ethenyl, formyl, acetyl, or 1-hydroxyethyl group. The substituent R_5 is either a methoxycarbonyl group or a hydrogen, the substituent R_6 is either a phytyl group or a hydrogen, and the substituent R_7 is either a methyl group or a hydrogen.

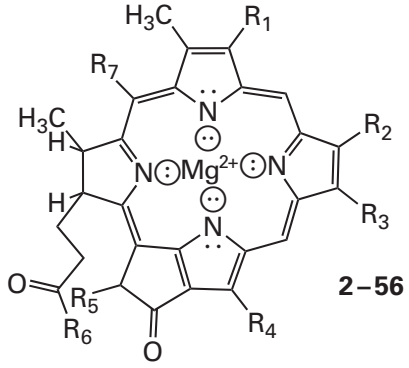
The most common pheophytins are pheophytin *a*, pheophytin *b*, bacteriopheophytin *a*, and bacteriopheophytin *b*. In pheophytin *a*, R_1 is an ethenyl group, R_2 is a methyl group, R_3 is an ethyl group, R_4 is a methyl group, R_5 is a methoxycarbonyl group, R_6 is a phytyl group, and R_7 is a hydrogen. Pheophytin *b* is identical to pheophytin *a* except that R_2 is a formyl group. Bacteriopheophytin *a* is identical to pheophytin *a* except that R_1 is an acetyl group and the double bond between R_2 and R_3 has been reduced to a single bond by the addition of a hydrogen to each carbon so that the carbons to which R_2 and R_3 are attached both have *R* stereochemistry. Bacteriopheophytin *b* is the same as bacteriopheophytin *a* except that the R_3 ethyl group has been oxidized to an ethylidene group.

Because the substituents and the ring itself are mostly hydrophobic, pheophytins are essentially insoluble in water and must be dissolved in organic solvents for observation when they are not in a protein or in the hydrocarbon of a phospholipid bilayer.

The **standard reduction potential** in dimethylformamide of the most aliphatic of the pheophytins, bacteriopheophytin *d*, which has alkyl substituents

or hydrogens at positions R_2 through R_7 and a 1-hydroxyethyl group at R_1, is –810 mV.[517] When a formyl group is found in place of the methyl group at R_2, the standard reduction potential of the pheophytin increases to –760 mV; when a methoxycarbonyl group is found in place of the hydrogen at R_5, it increases to –640 mV; and when a methoxycarbonyl group is found in place of the hydrogen at R_5 and an acetyl group in place of the 1-hydroxyethyl group at R_1, it increases to –510 mV. These increases in standard reduction potential result from the electron withdrawal exerted by the various substituents on the electron excess in the reduced state, the radical anion. It is also the case, as with flavin, that when a pheophytin is tightly bound to a protein as a prosthetic group, its standard reduction potential is different from the one it displays when it is dissolved in an organic solvent. It is usually more positive, probably because the protein provides donors that form hydrogen bonds with one or more of its oxygens or direct the positive poles of their dipoles toward the pheophytin.

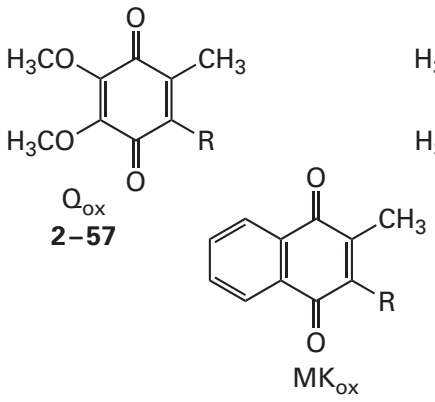
When the two hydrons on the nitrogens in the center of a pheophytin are replaced by Mg^{2+} and all four of the nitrogens become ligands to the metallic ion, the corresponding **chlorophyll**



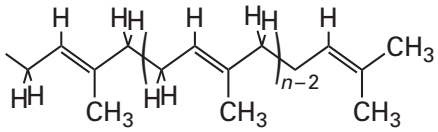
2–56

is formed. Because it replaces two hydrons, insertion of the Mg^{2+} does not alter the charge number of the prosthetic group, nor does the electrochemically inert Mg^{2+} participate in the one-electron oxidation–reduction. As a Lewis acid, it simply substitutes for the two hydrons, which are also Lewis acids. The Mg^{2+}, however, is a weaker Lewis acid than two hydrons, and as a result a chlorophyll has a standard reduction potential that is 200–300 mV more negative than the corresponding pheophytin (see Equation 2–109).[517] Even though chemically they are the same, chlorophylls are more widely recognized than the corresponding pheophytins because they give leaves their green color.

There are a number of **biochemically important quinones such as the ubiquinones** (**2–57**), the **plastoquinones** (**2–58**), the **menaquinones** (**2–59**) and **phylloquinone** (**2–59**)



There are also demethylmenaquinones, in each of which the methyl group on the quinone ring of the parent menaquinone is missing. When they are not tightly bound in an active site as prosthetic groups, each of these biochemical quinones transfers electrons between enzymes, and when in this role, they are **electron-transferring coenzymes**. The different versions of these quinones differ in the length of the polyisoprenyl groups attached at position R and the degree of unsaturation of those polyisoprenoids. The polyisoprenyl groups

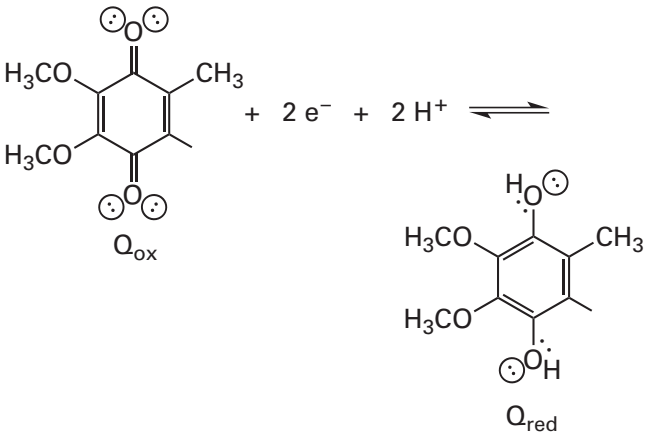


2–60

contain four or more **isoprenoid units** ($n \geq 4$) and can be saturated at any but the most proximal position. For example, in phylloquinone, which is only distinguished from the other menaquinones for historical reasons, the three more distal isoprenoid groups in the phytyl group ($n = 4$) attached at position R are all saturated while in menaquinones, which have the same quinone as phylloquinone but differ in the length of their polyisoprenoids, all the distal isoprenoid units are unsaturated. Because of its polyisoprenoid substituent, each of these quinones is as hydrophobic as the phospholipids forming the bilayer in which they are dissolved. Each of these quinones, like a phospholipid, is an **amphipathic molecule**, with the ring of the quinone providing the hydrophilic end and the polyisoprenoid tail providing the hydrophobic end.

When not tightly bound by membrane-bound proteins as prosthetic groups or weakly bound as coenzymes, these quinones are **solutes dissolved in a phospholipid bilayer**, either the plasma membrane of a bacterium, the inner membrane of a mitochondrion, a chromatophore, or the thylakoid of a chloroplast with which they are associated. When it is an amphipathic solute in one of these membranes, ubiquinone, plastoquinone, menaquinone, or phylloquinone has the diffusional properties of a phospholipid, and most of the time it translates in two dimensions through the bilayer with the quinone at the interface between the alkane and the water. The hydrophilic portion of one of these quinones, however, is much less hydrophilic than the hydrophilic portion of a phospholipid, and unlike phospholipids, they can pass rapidly back and forth across the bilayer between the interfaces.

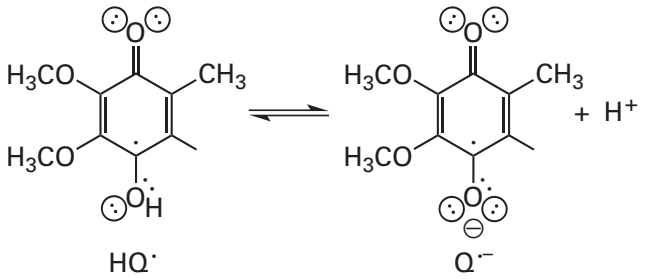
When they are free solutes in a phospholipid bilayer, these quinones can participate as coenzymes in the two-electron oxidation–reductions that produce the respective quinols. For example, the two-electron oxidation–reduction for ubiquinone is



(2–157)

Because the two sequential values of pK_a for the various quinols are greater than 10,[518] the transfer of the two electrons to the π molecular orbital system of the quinone always occurs in a cell with the uptake of two hydrons, one hydron on one of the σ lone pairs on one of the oxygens and the other hydron on one of the σ lone pairs on the other oxygen (as in Equation 2–97). These associations of hydrons cause the **midpoint reduction potentials**, E_m, to vary with pH (as in Figure 2–14) with a slope[519-522] of –59.2 mV (unit of pH)$^{-1}$. When it is a free solute in the membrane of a biological organelle, the biochemical standard reduction potential of a ubiquinone is +70 to +110 mV,[519,520,523] that of a plastoquinone is +80 to +110 mV,[521,522] and that of a menaquinone is around –60 mV.[524] The plasma membranes and the various organelles of the cells in different organisms each have their own particular quinones. For example, anaerobic archaea have only menaquinones in their plasma membranes while bacteria have both menaquinones and ubiquinones.

In addition to the quinone and the quinol (Equation 2–157), each of these quinones can exist as a **semiquinone**. For example, the semiquinone of ubiquinone is ubisemiquinone ($HQ^{\bullet}$), which is the conjugate acid of the ubisemiquinone radical anion ($Q^{\bullet -}$)



(2–158)

In methanol,[525] the pK_a for **ubisemiquinone** is 6.5, and when it is formed by the transfer of an electron to the quinone (pK_a < 0), the radical anion of the ubisemiquinone will pick up a hydron if the pH is less than its pK_a under the particular circumstances

$$H^+ + e^- + Q_{ox} \rightleftharpoons H^+ + Q^{\bullet -} \rightleftharpoons HQ^{\bullet} \qquad (2\text{–}159)$$

In many instances, however, because its pK_a is often even lower in a particular situation, a radical anion of a quinone remains unhydronated after it is formed, and the two hydrons necessary to form the neutral quinol are picked up only when the second electron arrives.[526,527]

Because they have stable semiquinones, each of these quinones is able to alternate between the oxidized state (the quinone) and the semiquinone or between the semiquinone and the reduced state (the quinol) in one-electron oxidation–reductions and between the quinone and the quinol in two-electron oxidation–reductions. This ability to participate in **both one-electron and two-electron oxidation–reductions** allows these quinones to receive two electrons together and then dispense each electron one at a time or to receive one electron

at a time and then dispense two electrons. Consequently, each of these quinones, like flavin, is able to split or join pairs of electrons. In a particular enzyme, the active site, the substrates, and the surrounding prosthetic groups determine whether one-electron or two-electron oxidation–reductions dominate or if electrons are split in one direction and joined in the other.

In solution, such as the solution of one of these quinones dissolved in a biological membrane, the semiquinone radical is in equilibrium with the quinol and the quinone by a one-electron transfer

$$Q_{ox} + H_2Q_{red} \rightleftharpoons 2\,HQ^{\cdot} \qquad (2\text{–}160)$$

in analogy to the similar disproportionation in which flavin participates (Equation 2–111). The equilibrium constant for the disproportionation of Equation 2–160 is the formation constant for the semiquinone radical

$$K_{f,HQ^{\cdot}} = \frac{[HQ^{\cdot}]^2}{[Q_{ox}][H_2Q_{red}]} \qquad (2\text{–}161)$$

The values of $K_{f,HQ^{\cdot}}$ at pH 7 for plastosemiquinone[528] and menasemiquinone[529] have been estimated to be 10^{-9} and 10^{-8}, respectively. These small values reflect the fact that, outside an active site, the radicals are unstable because the unpaired electron is not delocalized in the highest occupied molecular orbital in a large π molecular orbital system.

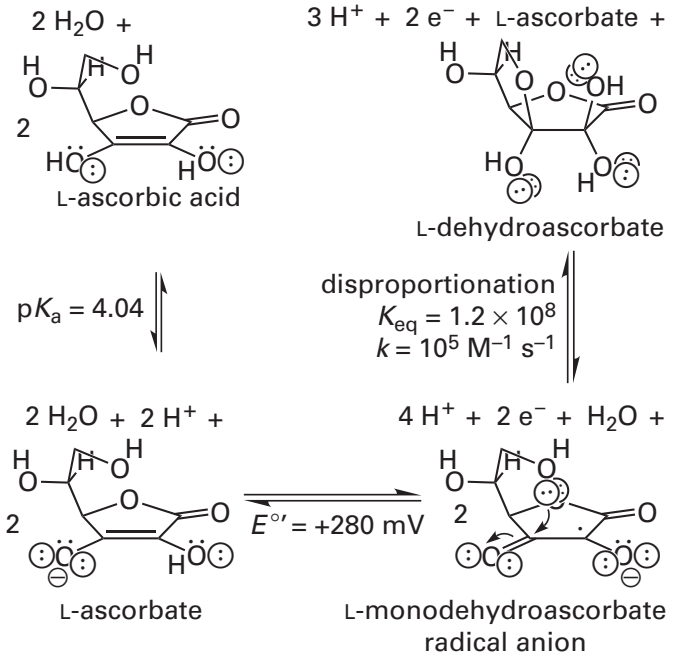
Because of these values for this equilibrium constant, when ubiquinone is in free solution in a biological membrane, no ubisemiquinone radical can be detected regardless of the ratio between the concentrations of quinone and quinol.[519] As with flavin, however, when ubiquinone is bound tightly to particular proteins involved in electron transfer, significant quantities of ubisemiquinone radical are observed as the concentrations of quinone and quinol are varied reciprocally.[530,531] In the most common situation, in which only one electron at a time is transferred to one of these quinones bound at an active site on an enzyme or one electron at a time is removed from one of these quinols, the resulting semiquinone radical has to be stable.[526,527] In large part, the **stability of these bound semiquinone radicals** results from the fact that they are isolated and unable to disproportionate as they would if they were free in solution in the surrounding bilayer of phospholipids. They are fixed in dispositions that preclude the conversion of two semiquinone radicals into a quinone and a quinol. Their stability, however, is also controlled by controlling their access to hydrons. Because a hydron is not required for the formation of the radical anion of the quinone upon one-electron reduction, if hydrons are not made available, the radical anion of the quinone cannot be further reduced[532] and is stable. If only weak acids are provided by the protein as donors for hydrogen bonds to the two carbonyl oxygens of the quinone, the semiquinone radical anion will also be stabilized.[533] In any case, the ability of one of these quinones to form a stable semiquinone radical or semiquinone radical anion when it is bound to an enzyme as a substrate or prosthetic group is essential because the quinone is usually required to accept electrons one at a time from other prosthetic groups.

L-Ascorbate is not incorporated into an active site as a prosthetic group, but it can provide a single electron as an electron-transferring coenzyme. For example, it is the electron-transferring coenzyme for peptidylglycine monooxygenase[534]

$$\begin{aligned}&\text{[peptide]-glycine} + 2\ \text{L-ascorbate} + O_2\\ &\quad\rightleftharpoons \text{[peptide]-(2S)-2-hydroxyglycine}\\ &\qquad + 2\ \text{L-monodehydroascorbate} + H_2O\end{aligned} \qquad (2\text{–}162)$$

In this instance, two molecules of L-ascorbate each provide in turn one electron to reduce two prosthetic Cu^{2+} ions on the enzyme to two Cu^{+}, which then in turn provide the two electrons required for catalysis.[535,536]

L-Ascorbate is the monoanionic conjugate base of ascorbic acid ($pK_a = 4.04$)[537] and is the principal form present at pH 7



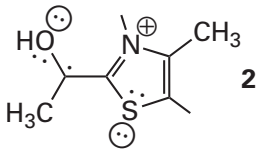
(2–163)

L-Ascorbate is capable of providing single electrons because the radical anion of L-ascorbate,[538] **L-monodehydroascorbate radical anion**, is a relatively stable species as a result of the **captodative effect**.[539] In the radical anion, the unpaired spin is delocalized over the three carbons and the three oxygens, mostly on the carbons but with significant spin density on the three oxygens. The adjacent oxygen donates electron density and the adjacent carbonyls withdraw electron density. L-Monodehydroascorbate radical anion is the analogue of the semiquinone of flavin or the semiquinone of ubiquinol and has almost the same equilibrium constant (8×10^{-9})[540] for disproportionation (see Equation 2–161) as the semiquinone of ubiquinol. In the enzymatic reactions for which it is an electron-transferring coenzyme, L-ascorbate provides a single electron with a biochemical standard reduction potential of +280 mV.[537,540-542]

Following the transfer of the electron and its dissociation from the active site, the resulting L-monodehydroascorbate radical ion rapidly (10^5 M^{-1} s^{-1})[543] disproportionates to give L-ascorbate and **L-dehydroascorbate**. Consequently, the concentration of L-monodehydroascorbate radical ion in the cytoplasm is so small that the enzymatic reactions in which L-ascorbate provides an electron do not proceed significantly in reverse. L-Dehydroascorbate is present in solution at neutral pH as the hydrate at carbon 2 of the internal lactone.[544] L-Dehydroascorbate is reduced by two electrons back to L-ascorbate by either monodehydroascorbate reductase (NADH) in plants and fungi or glutathione transferase, glutaredoxin, and protein disulfide-isomerase in animals.[543]

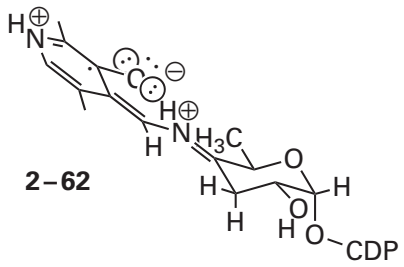
Because L-ascorbate is not used as a prosthetic group, L-monodehydroascorbate radical anion is not stabilized in an active site and is released as a product after the L-ascorbate has provided the electron. After its dissociation, it is present only evanescently. It follows that, unlike most other electron-transferring coenzymes, L-ascorbate only donates an electron; neither L-monodehydroascorbate radical anion nor L-dehydroascorbate, which are the oxidized forms of L-ascorbate, accepts one electron or two electrons, respectively, from an enzyme other than those that are responsible for the reduction of L-dehydroascorbate back to L-ascorbate. L-Ascorbate is also used, usually in concert with Fe^{2+}, to reduce prosthetic groups in the active sites of enzymes, for example, the iron ion in the active sites of a group of dioxygenases, that have been adventitiously oxidized. In such instances, the L-ascorbate is neither a prosthetic group nor a coenzyme but is used as a reductant that, when called upon, rescues the respective enzyme from occasional oxidative inactivation.

It has already been noted that a **2-(1′′-hydroxyethyl)thiamine radical cation** (Figure 2–7), which distributes its unpaired electron over seven atoms in a π molecular orbital system



2–61

is an intermediate in the reaction catalyzed by pyruvate synthase.[227] In addition, the *N*-(4,4′-anhydropyridoxyl)imine formed during the biosynthesis of a 3,6-dideoxymonosaccharide (Equation 2–42) is reduced to the *N*-(5′-phosphopyridoxyl)imine in two one-electron steps. In this reduction, an ***N*-(5′-phosphopyridoxyl)imine radical cation**, distributing its unpaired electron over 10 atoms in a π molecular orbital system



2–62

is an intermediate.[141,142] Each of these two radicals permits the respective prosthetic group to join two electrons that arrive separately to accomplish two-electron reductions. In each of these enzymatic oxidation–reductions, the electrons are transferred to or from these prosthetic groups, one at a time, from or to an iron–sulfur cluster.

There are also prosthetic redox couples that transfer single electrons by the one-electron reduction or oxidation of the ion of a transition metal. Iron–sulfur clusters and hemes are examples of prosthetic groups that, unlike flavin semiquinone radicals, pheophytin radical anions, chlorophyll radicals, quinone radicals, 2-(1″-hydroxyethyl)-thiamine radical cations, and *N*-(5′-phosphopyridoxyl)imine radical cations, accommodate the single electron added or removed in the ion of a transition metal rather than in an organic radical spread over an extended π molecular orbital system.

Iron is a common transition metal participating in prosthetic groups capable of one-electron transfer. When an iron ion is coordinated by six molecules of water, the standard reduction potential for the reaction

$$\left[Fe^{3+}(OH_2)_6\right]^{3+} + e^- \rightleftharpoons \left[Fe^{2+}(OH_2)_6\right]^{2+} \quad (2\text{–}164)$$

is +770 mV. When it is coordinated by six cyanides, the standard reduction potential for the reaction

$$\left[Fe^{3+}(^-CN)_6\right]^{3-} + e^- \rightleftharpoons \left[Fe^{2+}(^-CN)_6\right]^{4-} \quad (2\text{–}165)$$

is +360 mV. When it is coordinated by the four sulfido groups of four cysteines in rubredoxin, the biochemical standard reduction potential is −100 mV. When it is coordinated by six sp^2 nitrogens, four pyrrolinyl nitrogens from a mesoporphyrin and one from each of two imidazolyl groups, the biochemical standard reduction potential is −220 mV.[545] Just in these four simple examples, the biochemical standard reduction potentials of the variously coordinated iron ions span a range of 1000 mV. Most of these differences can be attributed to the identity of the ligands coordinating the iron ions.

The **bonding between iron and its ligands** ranges from mostly ionic with the hard oxygen bases to mostly covalent with the soft sulfur bases. When the ligands are hard bases such as water, cyanide, or nitrogen, six ligands are **arrayed octahedrally** around the iron; when they are soft bases such as sulfido groups or sulfides, four ligands are **arrayed tetrahedrally** around the iron. To sort out the bonding and the overall charge number of such a complex, one can first assume that the iron is the cation appropriate to its oxidation state and that the ligands are the anions or neutral molecules, and then the reader can make her own decision about whether each of the bonds between a ligand and the iron is ionic or covalent. From here on, in order to avoid making any unconditional decision about covalency, the following conventions will be used in figures and equations. Whenever an **oxidation number** can be assigned to a transition metal ion, it will be assumed that the transition metal ion has that charge number—for example, Fe^{III} will be designated as Fe^{3+}—and a charge number will be assigned to each atom of a ligand to a transition metal ion equivalent to the charge number it would bear if that ligand were removed from the ion of the transition metal along with the electron pairs that coordinate the ion. For example, in a tetrahedral complex of a ferrous iron, Fe^{II}, and the sulfido groups of four cysteines, the ferrous iron will be represented by the dication, Fe^{2+}, and the four sulfurs of four cysteines will be represented as the sulfido groups, each with a charge number of −1, giving the ferrous complex with the sulfurs of four cysteines a net charge number of −2. Then the reader can remember that the bonds between the iron ion and any oxygens are mostly ionic, the bonds between the iron ion and any sulfurs are mostly covalent, and the other bonds are intermediate between ionic and covalent. This strategy is applicable to the other prosthetic ions of transition metals in enzymes, such as vanadium, manganese, cobalt, nickel, copper, and molybdenum. In addition, in order again to avoid making any decision about covalency, thick dashed lines will be used to connect each transition metal ion and its ligands. This convention does not mean that these bonds are not covalent or not ionic, simply that they are somewhere in between completely covalent and completely ionic.

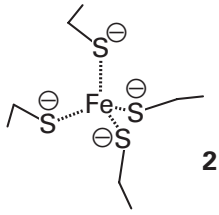
The **valence electronic structure** of elemental iron is $3d^6 4s^2$. An Fe^{2+} is dicationic because it is missing the two $4s$ electrons but still has six d electrons, and it is $3d^6$. An Fe^{3+} is tricationic because it is missing its two $4s$ electrons and one of its d electrons so that it is $3d^5$. An Fe^{3+} such as the Fe^{3+} in the hexahydrate, accepts and gives back one electron and passes reversibly between Fe^{3+} and Fe^{2+} because the electron in question at the end of the reduction

ends up in the unfilled 3*d* atomic orbital of lowest energy or one of the five degenerate unfilled 3*d* atomic orbitals of the Fe^{3+} to complete a pair, and in reverse, the electron in question at the end of the oxidation has left that filled 3*d* atomic orbital in the Fe^{2+} or a filled orbital of equal energy. It should be remembered that electrons cannot be followed in a reaction, so only the electron configurations at the beginning and the end of an electron transfer can be assigned.

Iron–sulfur clusters are arrays of iron ions, sulfide ions, and sulfido groups of cysteines. Each of these arrays contains one or more iron ions. Each iron ion is usually surrounded by four sulfurs, either as bridging sulfide ions, S^{2-}, which associate with two or three iron ions simultaneously, or as sulfido groups, $-S^-$, which usually associate with only one atom of iron. For a protein carrying an iron–sulfur cluster as a prosthetic group, the sulfide ions incorporated into the cluster are generated during its assembly by either thiosulfate sulfurtransferase[546,547] or 3-mercaptopyruvate sulfurtransferase,[548] and the sulfido groups are the conjugate bases of the sulfanyl groups of cysteines from the protein. These cysteines incorporate the iron ion, and hence the iron–sulfur cluster, somewhat covalently into the structure of the protein.

In an iron–sulfur cluster, four sulfurs are usually arranged **tetrahedrally around each iron ion**. If the four bonds between the four sulfurs and the iron were completely covalent bonds, then the lone pairs of electrons on the sulfurs would be occupying the four vacant $4sp^3$ atomic orbitals on the iron ion to form the four covalent bonds, which would be arranged tetrahedrally. If the four bonds were completely ionic bonds, then the four sulfurs would be arranged tetrahedrally around the iron ion because electron repulsion between the four sulfurs would be at a minimum in a tetrahedral arrangement. Sulfide is a large ion (0.184 nm) and an iron ion is much smaller (0.06–0.07 nm), so the crowding and the resulting electron repulsion would be significant. The actual bonding is probably somewhere in between these two possibilities.

Mononuclear iron–sulfur clusters, containing one atom of iron, necessarily have all four positions around the iron occupied by the sulfido groups of cysteines in the protein.[549] For example, in the mononuclear iron–sulfur cluster of a rubredoxin,[550,551] the four sulfurs of the four cysteines surround the iron in a tetrahedron modestly distorted by steric effects engendered by the protein (bond angles [S–Fe–S] range from 104° to 114°) with fairly constant iron–sulfur bond distances (0.227–0.233 nm)*



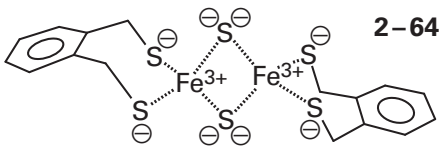
2–63

Rubredoxin from *C. pasteurianum* has a biochemical standard reduction potential of –100 mV[552] for the reaction

$$\left[Fe^{3+}(^{-}S-)_4\right]^- + e^- \rightleftharpoons \left[Fe^{2+}(^{-}S-)_4\right]^{2-} \quad (2\text{–}166)$$

This biochemical standard reduction potential is significantly more negative than that for the redox couple of ferricyanide and ferrocyanide (+360 mV) because the sulfur of a sulfido group is a more effective donor of electron density to iron than is the carbon of cyanide, so the cluster is a better reductant.

Dinuclear [2Fe–2S] iron–sulfur clusters† contain two iron ions, each coordinated tetrahedrally. In proteins containing these clusters, two of the positions around each iron ion are connected by two sulfide bridges, and the other two positions around each iron ion are occupied by the sulfido groups of cysteines (Figure 2–18).[553] This arrangement involves two irons, two bridging sulfides, and four sulfido groups. Such [2Fe–2S] iron–sulfur clusters are found in many of the **ferredoxins**, which are small proteins from animals,[554] plants (Figure 2–18), and bacteria[555] that act as electron-transferring coenzymes. A small **model compound** that contains such an iron–sulfur cluster complexed by two *o*-di(sulfanylmethyl)benzenes



2–64

has been synthesized, and a crystallographic molecular model of high accuracy has been obtained.[556]

*Already it can be seen that insisting that all the iron–sulfur bonds are covalent would require that the formal charge on a ferrous ion in the cluster to be be –2, which seems strange.

†The number of iron ions and sulfide ions in a cluster is traditionally indicated in brackets.

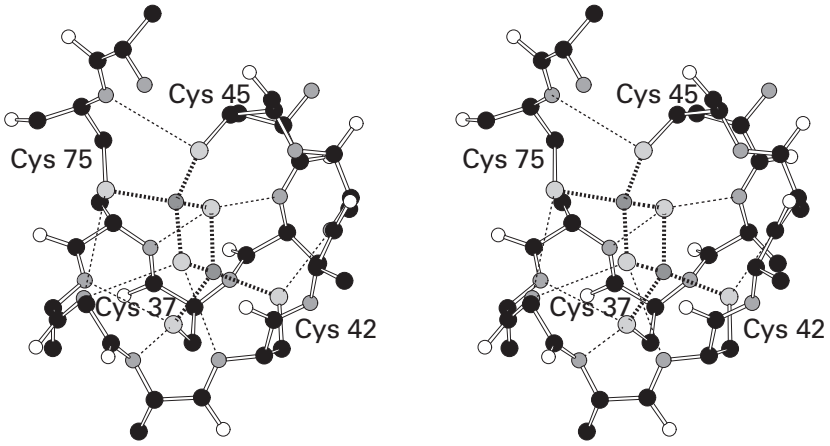


Figure 2–18: Stereodrawing[50] from a portion of the crystallographic molecular model of the [2Fe–2S] ferredoxin (94 aa) from *S. fusca* built from a map of electron density that was calculated from a data set to Bragg spacing of 0.14 nm.[553] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. In the iron–sulfur cluster, large light gray spheres are sulfides and small dark gray spheres are iron ions. The [2Fe–2S] iron–sulfur cluster in the protein is in the center of the drawing. Cysteine 75 provides a sulfur for a covalent bond to one of the iron ions of the cluster, and the amido nitrogen–hydrogen of the amino-terminal peptide bond of Cysteine 75 provides a dipole directed toward the sulfur of Cysteine 45. The segment of the polypeptide from Serine 36 to Cysteine 45 wraps around the iron–sulfur cluster as the stitches wrap around a baseball. Cysteines 37, 42, and 45 provide the other three sulfurs for the other three covalent bonds to the irons. The amido nitrogen–hydrogens of Serine 36, Arginine 38, Alanine 39, Glycine 40, Alanine 41, Cysteine 42, and Serine 44 in the respective peptide bonds of the polypeptide provide dipoles each directed toward a sulfide or the sulfur of a cysteine in the iron–sulfur cluster. These dipoles are connected to the sulfur to which they are directed by dotted lines. The side chains of only the cysteines are drawn.

In the central rhombus of a [2Fe–2S] iron–sulfur cluster, the angles at the sulfurs are more acute than the angles at the irons. Because the values of these bond angles are the same in the crystallographic molecular model of the model compound (75° and 105°, respectively) and that of the iron–sulfur cluster in the ferredoxin from *Scenedesmus fuscus* (76° and 103°, respectively) (Figure 2–18), the crystallographic molecular model of which was refined without constraints, they appear to represent undistorted energy minima. The iron–sulfide bond distances were also the same in the crystallographic molecular models of the model compound (0.221 ± 0.003 nm) and the ferredoxin (0.220 ± 0.003 nm). The cysteinyl sulfanyl–iron–cysteinyl sulfanyl bond angles are also less than the value for tetrahedral bonding (109.5°) in both the model compound (106°) and the ferredoxin (105°). All these comparisons suggest that steric effects in the protein do not distort the metallacycle and leave the impression that the metallacycle is quite rigid.

The model compound **2–64** crystallizes in its oxidized state, $[(Fe^{3+})_2(^{2-}S)_2(^{-}S-)_4]^{2-}$, and this state has been shown to display electronic, Mössbauer, and nuclear magnetic resonance spectra similar to those of the oxidized form of a dinuclear iron–sulfur cluster in a ferredoxin.[556] Consequently, the biochemical standard reduction potential for a ferredoxin is for the reaction

$$\left[(Fe^{3+})_2(^{2-}S)_2(^{-}S-)_4\right]^{2-} + e^- \rightleftharpoons \left[Fe^{2+}Fe^{3+}(^{2-}S)_2(^{-}S-)_4\right]^{3-} \quad (2\text{–}167)$$

Because the two irons are symmetrically coupled by the bridging sulfides, the odd electron in the reduced state is shared between them equally by occupying a molecular orbital spread symmetrically among the irons and the sulfurs.[557] Because the reduced form of the prosthetic group has an odd number of electrons, it gives an **electron paramagnetic spectrum**. The oxidized form, because it does not display an electron paramagnetic spectrum, must have no unpaired electron spins. The two Fe^{3+}, each formally a species with an odd number of electrons, share the two odd electrons as a pair in the same highest occupied molecular orbital spread over the metallacycle.

The **biochemical standard reduction potentials** of the [2Fe–2S] iron–sulfur clusters in proteins, in which the iron ions are coordinated with only the sulfido groups of cysteines, span a large range (Figure 2–19).[516] The biochemical standard reduction potential of the [2Fe–2S] ferredoxin from *S. oleracea*[558,559] is –420 mV, which is typical of a plant ferredoxin (–450 to –300 mV),[554] while that of bovine [2Fe–2S] ferredoxin is –270 mV, that of the [2Fe–2S] ferredoxin from the bacterium *P. putida*[554] is –230 mV, and that of the [2Fe–2S] ferredoxin from the bacterium *Anabaena*[560] is –180 mV. The biochemical standard reduction potential of one of the [2Fe–2S] iron–sulfur clusters in NADH:ubiquinone reductase (H^+-translocating) is –370 mV, matching it with that of the adjacent flavin ($E^{\circ\prime}_{ox/rad} = -390$ mV),[561,562] but that of the [2Fe–2S] iron–sulfur cluster in succinate dehydrogenase is +10 mV,[563] matching it with that of the redox couple of fumarate and succinate (+30 mV). These differences in standard reduction potential result in part from differences in the number, position, and orientation of several dipoles in the protein surrounding each of these clusters.

In **crystallographic molecular models** of [2Fe–2S] ferredoxins, six or seven amido nitrogen–hydrogen bonds from the polypeptide backbone are pointed at the various sulfurs around the two irons (Figure 2–18).[554,555,560,564,565] The nitrogens in these nitrogen–hydrogen bonds are 0.31–0.37 nm from the sulfurs at which they are pointed. The dipole moment of an *N*-alkylamide is parallel to its nitrogen–hydrogen bond, so this arrangement points the positive poles of the dipoles of these six or seven amido groups at the iron–sulfur cluster and should increase its standard reduction potential. When an alanine in the [2Fe–2S] ferredoxin from *Anabaena* is mutated to serine, putting the even weaker dipole of an alcohol next to the iron–sulfur cluster in addition to all the usual amido groups, its standard reduction potential increased by 24 mV.[566] The standard reduction potential for model compound **2–64**, the [2Fe–2S] iron–sulfur cluster of which is structurally identical to that in a ferredoxin, is –1250 mV in *N,N*-dimethylformamide,[556] a solvent that lacks nitrogen–hydrogen bonds, and it is thought that the **oriented dipoles of the nitrogen–hydrogen bonds** from the polypeptide backbone of the protein are responsible for raising the biochemical standard reduction potential of the iron–sulfur cluster into the range of –450 to –170 mV seen in the ferredoxins.

Figure 2–19: Ranges of the biochemical standard reduction potentials (millivolts) for prosthetic groups and small electron-transferring coenzymes of one-electron transfer. The ranges cited and referenced in the text are presented graphically. The biochemical standard reduction potentials for several redox couples of substrates or coenzymes of central importance in biochemical oxidation–reductions are also presented as individual points on the graph. [a]Biochemical standard reduction potential for reaction of Equation 2–169. [b]Electron-transferring flavoprotein. [e]Span of biochemical standard reduction potentials for prosthetic copper ions in small electron-transferring coenzymes and enzymes of oxidation–reduction.[516]

There are a number of variations on the ligands attaching a [2Fe–2S] iron–sulfur cluster to the protein surrounding the cluster.[567] One of the sulfido groups of a cysteine can be substituted with the imidazolyl group of a histidine,[568] or the sulfido groups of two of the cysteines can be replaced with the imidazolyl groups of two histidines. An example of the latter type of substitution would be a **Rieske [2Fe–2S] iron–sulfur cluster, in which there are two histidines as ligands to one of the irons instead of two cysteines** (Figure 2–20)[569-571] A substitution of the sulfido group of a cysteine by the imidazolyl group of a histidine increases the biochemical standard reduction potential of a [2Fe–2S] iron–sulfur cluster. The substitution of two cysteines by histidines increases the biochemical standard reduction potential even more than the substitution of only one cysteine.[567] There are also [2Fe–2S] iron–sulfur clusters in which one of the cysteines is substituted by an arginine,[572] which causes a decrease in the biochemical standard reduction potential.[567]

Because an imidazolyl group, when it is a ligand to an iron ion, uses the σ lone pair on only one of its nitrogens to coordinate the iron (Figure 2–20), the other σ lone pair on the other nitrogen is available for hydronation. This availability causes the midpoint reduction potential of these [2Fe–2S] iron–sulfur clusters to become **pH-dependent**. For the Rieske [2Fe–2S] iron–sulfur clusters in their oxidized, $[(Fe^{3+})_2(^{2-}S)_2(^{-}S-)_2(\text{imidazol-4-yl})_2]^0$ state, the conjugate acids of the respective nitrogens that are opposite each of the two nitrogens bound by the iron have acid dissociation constants with values of pK_a between 7 and 12, depending on the protein.[573] Reduction of the iron–sulfur cluster by one electron increases the values of pK_a by 2–5 units as expected from the increase in electron density, and dissociation of the two hydrons from these two available nitrogens decreases the biochemical standard reduction potential by 300–500 mV. For example, for the Rieske iron–sulfur cluster in quinol—cytochrome-*c* reductase from *R. sphaeroides*, the difference in biochemical standard reduction potential between the iron–sulfur cluster hydronated at both available nitrogens and the unhydronated iron–sulfur cluster is –440 mV. The first macroscopic pK_a is 7.6 for the oxidized iron–sulfur cluster and the second is 9.6 while the first macroscopic pK_a for the reduced iron–sulfur cluster is 12.4 and the second is also 12.4. By the use of nuclear magnetic resonance spectroscopy, it was possible to assign each of these values of pK_a to the individual histidines in the Rieske iron–sulfur cluster in quinol—cytochrome-*c* reductase from *T. thermophilus*.[574]

When both of the nitrogens are unhydronated, so the iron is coordinated by two imidazolates, the biochemical standard reduction potentials of Rieske [2Fe–2S] iron–sulfur clusters are between –450 and –100 mV, similar to those of [2Fe–2S] iron–sulfur clusters in which both irons are coordinated by sulfido groups. At neutral pH, however, when both imidazolyl groups are usually hydronated and formally neutral ligands, the biochemical standard reduction potentials are between –170 and +360 mV (Figure 2–19).[575-581] Consequently, the **hydronation of the available nitrogens on the histidines at neutral pH is responsible for the high** biochemical standard reduction potential**s** achieved by Rieske [2Fe–2S] iron–sulfur clusters. When the imidazolyl groups are hydronated and neutral, they donate less electron density than a sulfido group would, so the biochemical standard reduction potentials of hydronated Rieske [2Fe–2S] iron–sulfur clusters are much higher than those of [2Fe–2S] iron–sulfur clusters in which all the ligands are sulfido groups of cysteines. These high biochemical standard reduction potentials permit Rieske [2Fe–2S] iron–sulfur clusters to fulfill their assigned roles in electron transfer. The unusually high biochemical standard reduction potentials of some of these Rieske [2Fe–2S] iron–sulfur clusters permit a second electron to be added to them in a reduction that produces the diferrous $[(Fe^{2+})_2(^{2-}S)_2(^{-}S-)_2(\text{imidazol-4-yl})_2]^0$ state.[579]

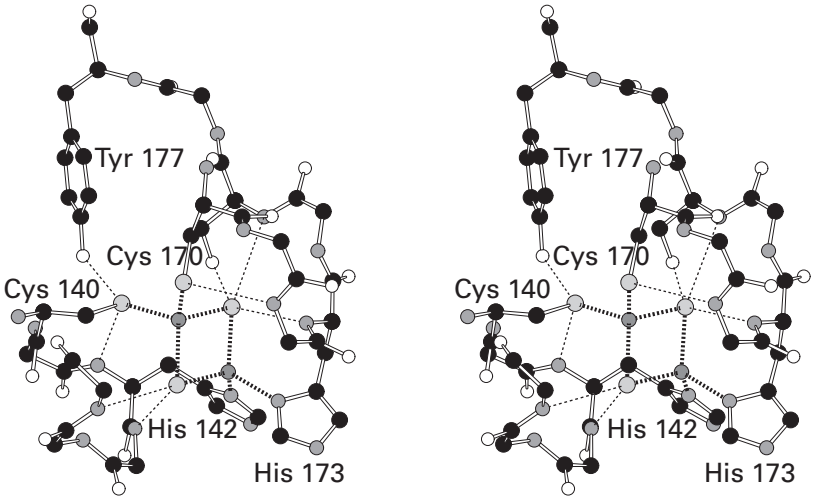

Figure 2–20: Stereodrawing[50] from a portion of the crystallographic molecular model of the domain of the [2Fe–2S] Rieske protein from *S. acidocaldarius* that contains its iron–sulfur cluster.[569] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. In the iron–sulfur cluster, large light gray spheres are sulfides and small dark gray spheres are iron ions. The complementary DNA for this domain, which comprises the sequence of amino acids for the full protein from Alanine 47 to Glycine 250, was expressed heterologously in *E. coli*. Serendipitously, during its expression the [2Fe–2S] Rieske iron–sulfur cluster was properly inserted. The resulting domain, with the intact iron–sulfur cluster, was purified and crystallized. A crystallographic molecular model was built from a map of electron density that was calculated from a data set to Bragg spacing of 0.111 nm. The [2Fe–2S] Rieske iron–sulfur cluster in the protein is just below the center of the drawing. The numbering of the amino acids in the sequence is that of the intact protein. The segment of the polypeptide in the crystallographic molecular model from Cysteine 140 to Cysteine 145 winds around the cluster below and to its left. Cysteine 140 and Histidine 142 form bonds to the left side of the upper iron ion and the back of the lower iron ion, respectively. The segment of the polypeptide from Cysteine 170 to Tyrosine 177 winds around the cluster above and to its right. Cysteine 170 and Histidine 173 form bonds to the forward side of the upper iron ion and the right side of the lower iron ion, respectively. The amido nitrogen–hydrogens of Histidine 142, Leucine 143, Cysteine 145, Cysteine 172, Histidine 173, Serine 175, and Tyrosine 177 in the respective peptide bonds of the polypeptide provide dipoles each directed toward a sulfide or the sulfido group of a cysteine in the iron–sulfur cluster. The 4-hydroxy group of Tyrosine 177 and the hydroxy group of Serine 175 also provide dipoles directed toward the sulfido group of Cysteine 140 and a sulfide in the iron–sulfur cluster, respectively. Each of these dipoles is connected to the sulfur to which it is directed by a dotted line. Only the side chains of the two cysteines and the two histidines forming bonds with the iron ions and the side chains of the tyrosine and the serine providing dipoles to the sulfurs are drawn.

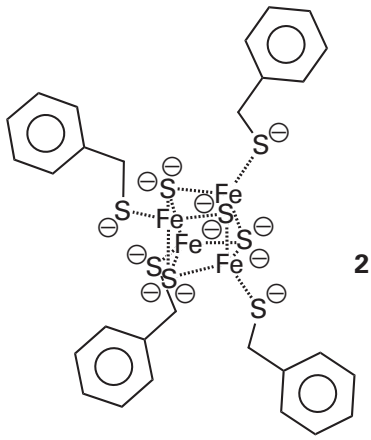
Unlike in the case of the Rieske [2Fe–2S] iron–sulfur clusters, the biochemical standard reduction potential of a [2Fe–2S] iron–sulfur cluster in which only one of the cysteines has been replaced by a histidine is pH-dependent at lower ranges of pH. In the midrange of pH, the slope of the function defining the variation in biochemical standard reduction potential as a function of pH is –50 mV (unit of pH)$^{-1}$ for an [2Fe–2S] iron–sulfur cluster in which only one of the cysteines has been replaced by a histidine.[582] For Rieske [2Fe–2S] iron–sulfur clusters in which two of the cysteines have been replaced by histidines, the slopes of the biochemical standard reduction potential as a function of pH in the alkaline regions are –110 mV (unit of pH)$^{-1}$.[573] These slopes are those expected if, for the former iron–sulfur cluster with only one imidazolyl group as a ligand, one hydron is taken up by the single available σ lone pair on the imidazolyl group for every electron added; and for the Rieske iron–sulfur clusters, two hydrons are taken up for every electron added by the two available σ lone pairs, one on each imidazolyl group.

A model compound for those [2Fe–2S] iron–sulfur clusters in which only one of the sulfido groups is replaced by an imidazolyl group[583] and model compounds for Rieske [2Fe–2S] iron–sulfur clusters in which two of the sulfanyl groups are replaced by imidazolyl groups[584] have been synthesized. In these synthetic model compounds, each sulfido group is a sulfidophenyl group and each imidazolyl group is a benzimidazolyl group. These model compounds also display values of pK_a that shift upon oxidation or reduction and reduction potentials that shift upon hydronation of the imidazolyl groups. For example, in the model compound for the [2Fe–2S] iron–sulfur cluster in which one of the four sulfidophenyl groups is replaced by a benzimidazolyl group, the reduction potential in acetonitrile increases by 240 mV when the distal nitrogen of the benzimidazolyl group is hydronated.[583]

The **structure of a Rieske [2Fe–2S] iron–sulfur cluster** is almost identical to that of a [2Fe–2S] iron–sulfur cluster in which all four ligands to the iron are sulfido groups of cysteines. The iron–sulfur bond lengths are 0.225 ± 0.002 nm, the S–Fe–S bond angles are 106°, and the Fe–S–Fe bond angles are 74° in crystallographic molecular models in which the iron–sulfur cluster was unconstrained during refinement.[569,585]

From three to seven amido nitrogen–hydrogen bonds from the polypeptide backbone are directed toward sulfurs of a Rieske [2Fe–2S]iron–sulfur cluster (Figure 2–20), with their nitrogens 0.31–0.37 nm from those sulfurs.[569,585-587] The dipoles of the hydroxy groups of a tyrosine and a serine are also directed toward sulfurs in several of these iron–sulfur clusters (Figure 2–20). When the tyrosine is mutated to a phenylalanine, the biochemical standard reduction potential decreases by –50 to –60 mV,[576-578] and mutation of the serine decreases the biochemical standard reduction potential potential by –100 to –130 mV.[576,577] The biochemical standard reduction potentials of these Rieske [2Fe–2S] iron–sulfur clusters are linearly related to the number of amido dipoles directed toward the iron–sulfur cluster, with a slope of around +70 mV dipole^{-1}.[585] Thus the wide range in standard reduction potential seen with Rieske [2Fe–2S] iron–sulfur clusters results, in part, from the wide range in the number of dipoles directed by the protein so that their positive poles are toward the iron–sulfur cluster.

Tetranuclear [4Fe–4S] iron–sulfur clusters have three positions occupied by bridging sulfides around each iron ion (Figure 2–21).[588] Each iron ion also is coordinated to the sulfido group of a cysteine from the protein to complete its tetrahedral coordination. There is a synthetic model compound for a [4Fe–4S] iron–sulfur cluster, in which the four positions that would be occupied by the sulfido groups of cysteines in a protein are occupied by phenylmethanethiolates[589]



2–65

This synthetic [4Fe–4S] iron–sulfur cluster is indistinguishable within its crystallographic molecular model of high accuracy from the [4Fe–4S] iron–sulfur clusters found in crystallographic molecular models of ferredoxins from data sets with Bragg spacing less than 0.1 nm and in which the atoms of

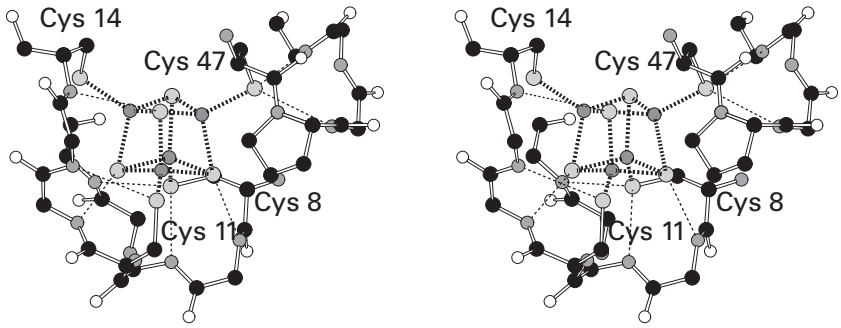


Figure 2–21: Stereodrawing[50] from a portion of the crystallographic molecular model of the ferredoxin (55 aa) from *Clostridium acidurici* that contains two [4Fe–4S] iron–sulfur clusters.[588] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. In the iron–sulfur cluster, large light gray spheres are sulfides and small dark gray spheres are iron ions. The molecular model was built from a map of electron density that was calculated from a data set to Bragg spacing of 0.094 nm. One of the two [4Fe–4S] iron–sulfur clusters in the protein is in the center of the drawing. The segment of the polypeptide in the crystallographic molecular model from Cysteine 8 to Cysteine 14 winds around the cluster both below and to its left. The sulfido groups of Cysteine 8, Cysteine 11, and Cysteine 14 form bonds to irons in the back, in the front, and to the left side of the iron–sulfur cluster, respectively. The segment of the polypeptide from Cysteine 47 to Alanine 51 is in the upper right corner of the cluster. Cysteine 47 forms a bond to the iron ion on the right side of the cluster. The amido nitrogen–hydrogens of Isoleucine 9, Serine 10, Glycine 12, Alanine 13, Cysteine 14, Valine 49, and Alanine 51 in the respective peptide bonds of the polypeptide provide dipoles each directed toward a sulfide or the sulfur of a cysteine in the iron–sulfur cluster. The amido nitrogen–hydrogen of Tyro-sine 30 in its peptide bond also provides a dipole directed toward the sulfur of Cysteine 8 in the iron–sulfur cluster. Each of these dipoles is connected to the sulfur to which it is directed by a dotted line. Only the side chains of the four cysteines forming bonds with the iron ions are drawn.

the iron–sulfur cluster were unconstrained during refinement (Figure 2-21).[588,590] The iron ions again occupy vertices with wider angles (104 ± 2° in both the model compound and the ferredoxins) than the vertices occupied by the sulfurs of the bridging sulfides (74 ± 2° in both the model compound and the ferredoxins). Again the impression is left that the cluster is a rigid structure.

These bond angles at the irons and the sulfurs are the same as those of a [2Fe–2S] iron–sulfur cluster. In fact, a [4Fe–4S] iron–sulfur cluster seems to be two [2Fe–2S] iron–sulfur clusters that have been stuck together. Two cysteines on the same face of each of the constituent [2Fe–2S] iron–sulfur clusters have been replaced by the two sulfides of the other. This impression is reinforced by the fact that, in [4Fe–4S] iron–sulfur clusters, in both the model compound **2–65**[589] and ferredoxins,[588,590] four of the iron–sulfur bonds that are parallel to each other and that connect two of the rhomboidal faces (the four horizontal bonds most parallel to the plane of the page in Figure 2–21) are shorter (0.224 nm in the model compound and 0.226 nm in the ferredoxins) than the other eight (0.231 nm in the model compound and 0.230 nm in the ferredoxins). This fact sets two of the faces across from each other in the iron–sulfur cluster apart from the other four and breaks the tetrahedral symmetry of the iron–sulfur cluster. Because it is observed in both the model compound and the proteins, this compression appears to be intrinsic to the structure.

As was the case with the [2Fe–2S] iron–sulfur clusters, there are **variations in the ligands attaching a [4Fe–4S] iron–sulfur cluster to the protein** forming an active site.[567] One of the sulfido groups of a cysteine can be substituted by the imidazolyl group of a histidine,[591,592] or the carboxylato group of an aspartate.[593] A substitution of the anionic sulfido group of a cysteine by the neutral imidazolyl group of a histidine again increases the biochemical standard reduction potential of a [4Fe–4S] iron–sulfur cluster. The midpoint reduction potential in tetrahydrofuran for a synthetic [4Fe–4S] iron–sulfur cluster increases by +340 mV when one of the four sulfido groups coordinating the cluster is replaced by 1,2,4,5-tetramethylimidazole.[594] The substitution of an anionic sulfido group by an anionic carboxylato group, however, has no consistent effect on the biochemical standard reduction potential.[567] Although almost all [4Fe–4S] iron–sulfur clusters are attached through their four iron ions to four ligands provided by the protein (Figure 2–21), there are instances in which a [4Fe–4S] iron–sulfur cluster is attached by only three cysteines, leaving one iron open for ligation,[595] or in which one of the irons expands its coordination to form a bond to an additional cysteine.[596,597]

Because there twice as many iron ions in a [4Fe–4S] iron–sulfur cluster, its successive, one-electron biochemical standard reduction potentials are fairly close to each other.[589,598] The **three biochemically accessible oxidation–reductions** are

$$\left[Fe^{2+}(Fe^{3+})_3(^{2-}S)_4(^{-}S-)_4\right]^{-} + e^{-} \rightleftharpoons \left[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4\right]^{2-} \quad (2\text{–}168)$$

$$\left[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4\right]^{2-} + e^{-} \rightleftharpoons \left[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4\right]^{3-} \quad (2\text{–}169)$$

$$\left[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4\right]^{3-} + e^{-} \rightleftharpoons \left[(Fe^{2+})_4(^{2-}S)_4(^{-}S-)_4\right]^{4-} \quad (2\text{–}170)$$

There has yet, however, to be a documented instance in which more than one of these redox couples is accessible for any particular protein containing a [4Fe–4S] iron–sulfur cluster. Instead, natural selection seems to have designed the environment around a given [4Fe–4S] iron–sulfur cluster to participate in only one specific oxidation–reduction that either requires the higher biochemical standard reduction potential of Equation 2–168 or the lower biochemical standard reduction potential of Equation 2–169. The diamagnetic, completely reduced and significantly anionic iron–sulfur cluster $[(Fe^{2+})_4(^{2-}S)_4(^{-}S-)_4]^{4-}$ of Equation 2–170 has been observed so far in only one protein, in which it is used as a strong two-electron reductant.[599,600] A [4Fe–4S] iron–sulfur cluster that is stable in this fully reduced form has been synthesized, but it was necessary to use four carbenes as the external ligands to the four iron ions rather than four thiolates. This synthetic cluster has a midpoint potential of –1300 mV in tetrahydrofuran.[601]

The diamagnetic species $[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4]^{2-}$ has an even number of electrons, and all are paired. This species lacks an electron paramagnetic resonance absorption. All the irons are coupled, so several electron pairs are delocalized among them by occupying molecular orbitals spread over the

entire iron–sulfur cluster. If one electron is removed from the highest occupied molecular orbital of these extended, pairwise occupied molecular orbitals (reverse of Equation 2–168) or one electron is added to the lowest unoccupied extended molecular orbital (Equation 2–169), each of the two species formed has an unpaired electron and each is paramagnetic and has a characteristic **electron paramagnetic resonance** absorption.[602] In the reduced species $[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4]^{3-}$ in a protein, two of the irons are a diferrous pair, and the other two share the unpaired electron that is delocalized over them.[603,604]

The tetranuclear [4Fe–4S] iron–sulfur clusters in proteins that normally participate as the redox couple in Equation 2–168 are referred to as **high-potential [4Fe–4S] iron–sulfur clusters**. The biochemical standard reduction potentials for these iron–sulfur clusters usually lie between +50 and +470 mV (Figure 2–19).[605-607] The iron–sulfur cluster in the high-potential iron–sulfur protein from *Allochromatium vinosum*, for example, has a biochemical standard reduction potential for Equation 2–168 of +350 mV. High-potential [4Fe–4S] iron–sulfur clusters are also found in enzymes such as benzylsuccinate synthase from *Thauera aromatica*.[608] This latter high-potential [4Fe–4S] iron–sulfur cluster has a biochemical standard reduction potential of +80 mV. There is a high-potential [4Fe–4S] iron–sulfur cluster in ferredoxin:thioredoxin reductase from *Synechocystis* in which one of the iron ions has the sulfido groups of two cysteines as ligands in the oxidized $[Fe^{2+}(Fe^{3+})_3(^{2-}S)_4(^{-}S-)_5]^{2-}$ state.[609] Upon reduction of the [4Fe–4S] iron–sulfur cluster with one electron, one of these two sulfido groups is released from the iron and displaces reduced thioredoxin from a mixed disulfide between one of its cysteines and another cysteine in the active site by thiol–disulfide exchange. Consequently, one of the sulfido groups coordinating the [4Fe–4S] iron–sulfur cluster reduces the disulfide between another cysteine in the enzyme and one of the cysteines of the thioredoxin.

The [4Fe–4S] iron–sulfur clusters in proteins that normally participate in Equation 2–169 are **low-potential [4Fe–4S] iron–sulfur clusters.** The biochemical standard reduction potentials for these low-potential iron–sulfur clusters usually lie between –790 and +80 mV (Figure 2–19).[562,605,607,610] For example, both of the [4Fe–4S] iron–sulfur clusters (Figure 2–21) in the ferredoxin from *C. acidurici* have a biochemical standard reduction potential of –430 mV, and each is reduced independently of the other.[611] 2-Deoxy-*scyllo*-inosamine dehydrogenase (AdoMet-dependent) from *Niallia circulans* contains a [4Fe–4S] iron–sulfur cluster,[612] attached to the protein by four cysteines, that has a biochemical standard reduction potential of –765 mV.

The distinction between high-potential and low-potential [4Fe–4S] iron–sulfur clusters is the redox couple, either that of Equation 2–168 or that of Equation 2–169, that is accessible to the members of each group. Although each [4Fe–4S] iron–sulfur cluster in a particular protein is confined to only one of these two common redox couples, the fact that one or the other redox couple is nevertheless available to natural selection is what causes the whole family of [4Fe–4S] iron–sulfur clusters to be able to span the largest range of biochemical standard reduction potentials among the families of one-electron prosthetic groups (Figure 2–19).

The biochemical standard reduction potential for the low-potential oxidation–reduction (Equation 2–169) of a synthetic [4Fe–4S] iron–sulfur cluster similar to **2–65** but with four *N*-(acetyl)-L-cysteine methyl esters rather than benzylthiols as ligands is –740 mV when it is dissolved in dimethyl sulfoxide.[613] In water, the biochemical standard reduction potential is –490 mV. The L-cysteine methyl esters make this model compound as similar as possible to a [4Fe–4S] iron–sulfur cluster in a protein. Because this synthetic [4Fe–4S] iron–sulfur cluster becomes more anionic upon reduction (Equation 2–169), the improved solvation provided by the water for the trianion $[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4]^{3-}$ relative to the dianion $[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4]^{2-}$ explains the observed increase in standard reduction potential. Because the reduced synthetic iron–sulfur cluster with the four *N*-acetyl-L-cysteine methyl esters is so anionic, the positive poles of the dipoles of the molecules of water surrounding it will be oriented toward the cluster, just as nitrogen–hydrogen bonds of the polypeptide backbone surrounding a [4Fe–4S] iron–sulfur cluster in a protein direct the dipoles of their amido groups toward the cluster (Figure 2–21). The fact that there are dipoles oriented toward the [4Fe–4S] iron–sulfur cluster in both situations explains in part why the standard reduction potentials for the synthetic iron–sulfur cluster in water and the natural iron–sulfur cluster in a ferredoxin are so similar.

[4Fe–4S] Ferredoxins are low-potential iron–sulfur proteins that function as electron-transferring coenzymes. The range (Figure 2–19) over which the biochemical standard reduction potentials of the various [4Fe–4S] ferredoxins are spread, –400 to –600 mV,[607] is somewhat puzzling because the

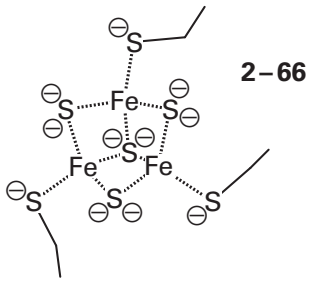
number of directed amido dipoles around the iron–sulfur clusters in most [4Fe–4S] ferredoxins is usually eight (Figure 2–21).[588,590,614] The differences in biochemical standard reduction potential may be due to variation in the distances between the oriented dipoles and the [4Fe–4S] iron–sulfur cluster[615] and variation in the **exposure of the [4Fe–4S] iron–sulfur cluster to the aqueous solvent**.[614,616] The oriented amido dipoles in these proteins increase the biochemical standard reduction potential for the redox couple of Equation 2–169 into the accessible range, and they increase the biochemical standard reduction potential for the redox couple of Equation 2–168 out of the accessible range.

The iron protein from nitrogenase contains the only [4Fe–4S] iron–sulfur cluster that participates in the **lowest-potential oxidation–reduction** (Equation 2–170), which requires that the biochemical standard reduction potentials for its [4Fe–4S] iron–sulfur cluster be increased considerably more than they normally are to bring this redox couple into the accessible range. This iron–sulfur cluster not only is surrounded by 10 oriented amido groups from the polypeptide backbone but also is the most exposed to the aqueous phase of any [4Fe–4S] iron–sulfur cluster for which a crystallographic molecular model is available.[617]

High-potential iron–sulfur proteins (HIPIP) are also electron-transferring coenzymes. The [4Fe–4S] iron–sulfur clusters in these proteins are confined by their surroundings to participate in the high-potential oxidation–reduction of Equation 2–168. They have significantly fewer oriented amido groups from the polypeptide surrounding an otherwise identical iron–sulfur cluster than in the case of the ferredoxins, usually only four or five,[607,614,618,619] and the dipoles that are present can account for the observed biochemical standard reduction potential.[616] The environment around the iron–sulfur cluster is also "decidedly hydrophobic."[620] The fact that there are fewer directed dipoles and the fact that the environment is considerably more nonpolar in these high-potential iron–sulfur proteins are the reasons that the biochemical standard reduction potentials for the high-potential oxidation–reduction of Equation 2–168 remain in an accessible range (+100 to +470 mV) and the reasons that the biochemical standard reduction potentials for the low-potential oxidation–reduction of Equation 2–169 remain in an inaccessible range.[605] When one of the oriented amido nitrogen–hydrogens in a high-potential iron–sulfur protein is mutated to an oxygen, the biochemical standard reduction potential decreases by 100 mV,[607] an observation indicating how dramatic an effect these dipoles have, but there are high-potential iron–sulfur proteins that have the same number of oriented dipoles surrounding the iron–sulfur cluster yet differ in biochemical standard reduction potential by as much as 240 mV.[618] Again, these differences may result from differences in the distances between the oriented dipoles and the [4Fe–4S] iron–sulfur cluster and from differences in the exposure of the iron–sulfur cluster to the aqueous phase.

There are **outer-sphere influences other than oriented nitrogen–hydrogen bonds** on the reduction potential of a [4Fe–4S] iron–sulfur cluster. For example, one of the [4Fe–4S] iron–sulfur clusters in hydrogenase (acceptor) from *E. coli* has the imidazolyl group of a histidine instead of the sulfido group of a cysteine as a ligand to one of the iron ions. The π molecular orbital system of the guanidinio group of an arginine is stacked against the imidazolyl group.[592] When this arginine is mutated to a leucine, the reduction potential of the [4Fe–4S] iron–sulfur cluster decreases by 60 mV, as expected for the mutation of a positively charged side chain to a neutral side chain.[621]

Trinuclear **[3Fe–4S] iron–sulfur clusters**, containing three atoms of iron



2–66

are [4Fe–4S] iron–sulfur clusters in which one of the four irons has dissociated from the iron–sulfur cluster because a cysteine from the protein that would normally form a strong bond with this iron is either absent or unable to do so.[622-624] In situations in which a naturally occurring [4Fe–4S] iron–sulfur cluster has lost an iron ion during purification or other manipulations of the protein, its trinuclear [3Fe–4S] iron–sulfur cluster can be often be converted back into a [4Fe–4S] iron–sulfur cluster by adding Fe^{2+}.[625,626] These [3Fe–4S] iron–sulfur clusters are adventitious. There are, however, a number of permanently trinuclear [3Fe–4S] clusters that are both natural and essential prosthetic groups.[627-631] Nevertheless, in these instances, the mutation to a cysteine of an amino acid adjacent to the vacant

position in the iron–sulfur cluster can convert the natural [3Fe–4S] iron–sulfur cluster to an unnatural [4Fe–4S] iron–sulfur cluster.[628,632] It is also possible to mutate a cysteine ligating one of the iron ions in a natural [4Fe–4S] iron–sulfur cluster and convert it into an unnatural [3Fe–4S] iron–sulfur cluster.[633]

In **crystallographic molecular models** of a ferredoxin that naturally contains a [3Fe–4S] iron–sulfur cluster[634] and in a model compound of a [3Fe–4S] iron–sulfur cluster,[635] the iron–sulfur bond lengths are 0.227 ± 0.002 and 0.2286 ± 0.0003 nm, respectively, which are indistinguishable from each other and from those in a [4Fe–4S] iron–sulfur cluster. The bond angles within the three intact rhombi are 104° at the three irons and 73° at the four sulfurs in crystallographic molecular models of both the ferredoxin and the model compound, also indistinguishable from those in a [4Fe–4S] iron–sulfur cluster. The three rhombi that are not held together at their vertices by a fourth iron atom open up slightly so that the three S–Fe–S bond angles outside the three intact rhombi (**2–66**) are 112° instead of 104°.

In its most oxidized state, a trinuclear [3Fe–4S] iron–sulfur cluster has an unpaired electron because it contains three Fe^{3+} atoms, each with an odd number of electrons, but pairs of electrons from every other substituent. At pH 7, the **biochemical standard reduction potential**[636,637] for the trinuclear [3Fe–4S] iron–sulfur cluster in the ferredoxin from *A. vinelandii* is –400 mV. The oxidized form displays an absorption in electron paramagnetic resonance but the reduced form does not,[638] so the reduced form must have no unpaired electrons. Therefore, the formal reaction in which this iron–sulfur cluster participates is

$$\left[(Fe^{3+})_3(^{2-}S)_4(^{-}S-)_3\right]^{2-} + e^- \rightleftharpoons \left[Fe^{2+}(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_3\right]^{3-} \quad (2\text{–}171)$$

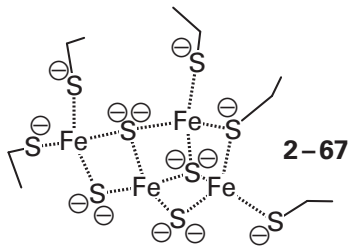
There is spectral evidence that the pair of electrons formed upon addition of one electron to the [3Fe–4S] iron–sulfur cluster (Equation 2–171) is distributed over only two of the three iron ions,[639] a fact which suggests that one of the irons is actually an unconjugated Fe^{2+} and the other two form a conjugated pair of Fe^{3+} ions. In this reduction, one hydron is taken up by the ferredoxin from *Sulfolobus acidocaldarius* at pH 7,[640] and for the ferredoxin from *A. vinelandii*, one hydron is also taken up but only at values of pH less than 6.[637]

The biochemical standard reduction potentials for [3Fe–4S] iron–sulfur clusters in proteins are between –400 and +65 mV (Figure 2–19).[630,640] Those for just the [3Fe–4S] ferredoxins are between –400 and –140 mV. The [3Fe–4S] iron–sulfur clusters in crystallographic molecular models of two different ferredoxins, the one from *A. vinelandii*[634] and the one from *Desulfovibrio gigas*,[641] have six and eight amido nitrogen–hydrogens directed toward their sulfurs, respectively, which explains in part why the former has a more negative biochemical standard reduction potential than the latter by –290 mV. Trinuclear [3Fe–4S] iron–sulfur clusters in ferredoxins can also engage in a further two-electron reduction[640]

$$\left[Fe^{2+}(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_3\right]^{3-} + 2\,e^- \rightleftharpoons \left[(Fe^{2+})_3(^{2-}S)_4(^{-}S-)_3\right]^{5-} \quad (2\text{–}172)$$

in which two hydrons are taken up by the protein at pH 7 to neutralize the large increase in charge.

In the active site of ferredoxin:CoB-CoM heterodisulfide reductase from *Methanothermococcus thermolithotrophicus*, there are two identical **[3Fe–3S–Fe–S] iron–sulfur clusters** that can be considered the fusion of a [3Fe–4S] iron–sulfur cluster and a [2Fe–2S] iron–sulfur cluster[642]



2–67

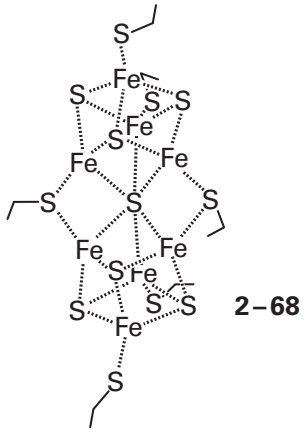
One of the sulfides in the [3Fe–4S] iron–sulfur cluster (**2–66**) that is the ligand to only two of the iron ions in that cluster and one of the iron ions that the sulfide coordinates are also a sulfide and an iron ion, respectively, in the [2Fe–2S] iron–sulfur cluster. One of the open sulfides in the [3Fe–4S] iron–sulfur cluster has been replaced by the sulfido group of a cysteine, and the open iron ion in the [2Fe–2S] iron–sulfur cluster is coordinated by two sulfido groups from two cysteines, as usual. In the homologous*

*Although the sequences do not align with a significant percentage of identity, every one of the cysteines in the two clusters occupies the same positions in the aligned sequences.

dihydromethanophenazine: CoB-CoM heterodisulfide reductase from *Methanosarcina thermophila*, the reduction potentials[643] of the two clusters are –100 and –400 mV, within the range of both [3Fe–4S] and [2Fe–2S] iron–sulfur clusters (Figure 2–19). The reduced form of each of the iron–sulfur clusters has an unpaired electron and their oxidation states have been assigned as $[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_5]^{4-}$. The two [3Fe–3S–Fe–S] iron–sulfur clusters in dihydromethanophenazine: CoB-CoM heterodisulfide reductase from *M. thermophila* were originally mistaken for two [4Fe–4S] iron–sulfur clusters, in which case that assignment would be reasonable (Equation 2–169). It is also possible, however, that the reduced form of a [3Fe–3S–Fe–S] iron–sulfur cluster with an unpaired electron could be $[Fe^{2+}(Fe^{3+})_3(^{2-}S)_4(^{-}S-)_5]^{2-}$ given the usual one-electron reduced states of a [3Fe–4S] iron–sulfur cluster (Equation 2–171) and a [2Fe–2S] iron–sulfur cluster (Equation 2–167).

A **[4Fe–3S] iron–sulfur cluster** has been observed in crystallographic molecular models of the small iron–sulfur subunits of the membrane-bound hydrogenases (acceptor) from *Cupriavidus necator*[644] and *Hydrogenovibrio marinus*.[645] The common structure of these clusters is again a variation on an [4Fe–4S] iron–sulfur cluster but one in which one of the sulfides is missing rather than one of the iron ions. Two of the three iron ions that would otherwise be coordinated by the missing sulfide are coordinated by the same sulfido group of a cysteine, and the third iron that would have been coordinated by the missing sulfide is coordinated by the sulfido group of an additional cysteine. In effect, two sulfido groups replace one bridging sulfide, and this arrangement distorts the cluster in the region where the single missing sulfide would otherwise be forming bonds with these three iron ions. In both of these [4Fe–3S] iron–sulfur clusters, the oxidized state, $[Fe^{2+}(Fe^{3+})_3(^{2-}S)_3(^{-}S-)_6]^{-}$, is accessible, and in the [4Fe–3S] iron–sulfur cluster from *H. marinus* in this oxidized state, a dehydronated nitrogen from a peptide bond in the polypeptide becomes a ligand to one of the irons, presumably to stabilize the oxidized participant in the redox couple, analogous to that in Equation 2–168.

There are several iron–sulfur clusters that have more than four irons and four sulfurs as well as additional transition metal ions such as molybdenum, copper, or nickel.[646] They appear to be expansions of [4Fe–4S] iron–sulfur clusters, just as a [4Fe–4S] iron–sulfur cluster seems to be the expansion of a [2Fe–2S] iron–sulfur cluster. For example, in the [8Fe–7S] P-cluster of nitrogenase[647]



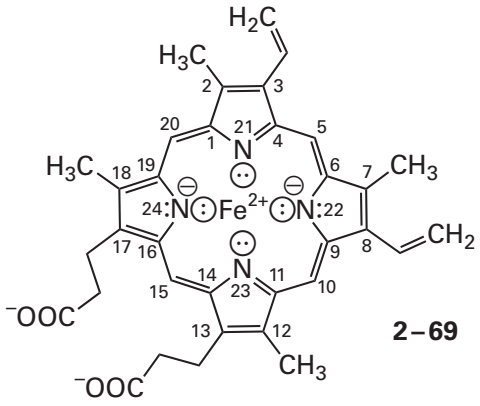
2–68

one of the sulfides of a [4Fe–4S] iron–sulfur cluster coordinates the three iron ions from a [4Fe–3S] iron–sulfur cluster that have open sites for coordination. The FeMo-cofactor of nitrogenase[647] is a [4Fe–3S] iron–sulfur cluster fused by three additional sulfide ions through its three open iron ions to the three open iron ions of a [3Fe–Mo–3S] iron–molybdenum–sulfur cluster, which is a [4Fe–3S] iron–sulfur cluster in which the iron ion in the fully coordinated site has been replaced with a molybdenum ion.

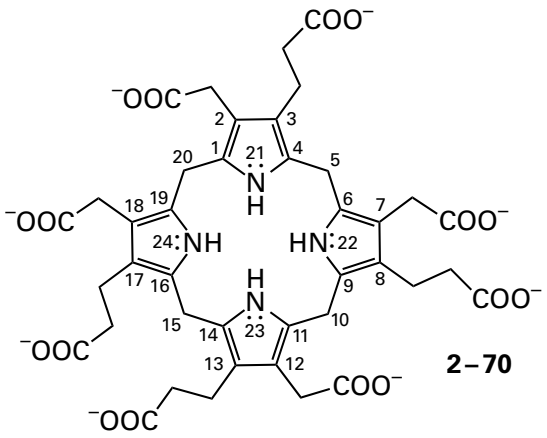
The various types of iron–sulfur clusters can be distinguished spectroscopically to identify the type present in a particular protein. Electron paramagnetic resonance spectra,[581,648] Mössbauer spectra,[649] ultraviolet–visible absorption spectra, and resonance Raman spectra[650] can all distinguish among [4Fe–4S], [3Fe–4S], and [2Fe–2S] iron–sulfur clusters. Electron paramagnetic spectra can also be used to sort out the different iron–sulfur clusters in a protein. For example, five of the individual electron paramagnetic spectra[562] of the seven [4Fe–4S] iron–sulfur clusters and the two [2Fe–2S] iron–sulfur clusters in NADH:ubiquinone reductase (H^+-translocating)[651] can be dissected from electron paramagnetic spectra of the protein taken at different temperatures.

A heme is a visibly colored prosthetic group, always surrounded by protein, that takes on many roles in one-electron transfer. For example, a **cytochrome** is a protein that contains one or more hemes as prosthetic groups and that acts as an electron-transferring coenzyme. Hemes are also prosthetic groups transferring electrons within enzymes responsible for oxidation–reduction.

The parent compound of most of the various hemes is **heme *b***



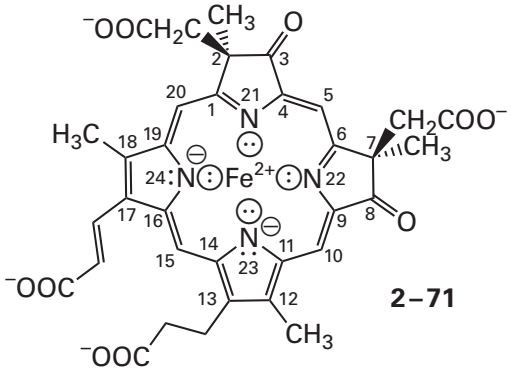
which is the complex between an iron ion and the **porphyrin,** protoporphyrin. Protoporphyrin is derived from uroporphyrinogen III



by the decarboxylation of the carboxymethyl groups at positions 2, 7, 12, and 18; the oxidative decarboxylation of the carboxyethyl groups at positions 3 and 8; and oxidation of the central ring coincident with its aromatization. Uroporphyrinogen III is also the precursor to the pheophytins (Equation 2–156) in a series of similar, even more complicated and varied modifications.

As does the magnesium ion in a chlorophyll, the iron ion in the center of a heme replaces two hydrons on the two nitrogens of the porphyrin. Unlike the pheophytins and their respective chlorophylls, however, only the hemes are prosthetic groups, not the respective uncomplexed porphyrins lacking the iron ion. Also, unlike the magnesium ion in a chlorophyll, which is inert to oxidation and reduction in the biochemical range of standard reduction potential, the iron ion in a heme is oxidized or reduced by removing or adding one electron. The iron ion is oxidized to Fe^{3+} or reduced to Fe^{2+}.

There are several **modified versions of heme *b*** that also act as prosthetic groups. Heme *o* is heme *b* in which the ethenyl group at position 3 has been elongated to a 1-hydroxy-5,9,13-trimethyltetradeca-4,8,12-trienyl group (a 1-hydroxyfarnesyl group), which is a long, hydrophobic polyisoprenoid.[652] Heme *a* is heme *o* in which the methyl group at position 18 has been oxidized to a formyl group. Heme *d* is heme *b* in which the double bond at positions 12 and 13 has been oxidized to a trans vicinal diol, a modification that does not affect the aromaticity, and the 2-carboxyethyl group at position 13 has formed a lactone with the hydroxy group now at position 13.[653] Heme d_1



however, is not derived from heme *b* but from uroporphyrinogen III (**2–70**) itself, the common precursor to heme *b* and heme d_1. The carboxyethyl groups at positions 3 and 8 have been oxidized completely to oxo groups while the carbons at the 2 and 7 positions have been methylated with the result that the two respective pyrrolyl groups are no longer unsaturated at positions 2 and 7, and the 2-carboxyethyl group at position 17 has been oxidized to a 2-carboxyethenyl group.[654,655] The unsaturation of the two pyrrolyl groups again does not affect the aromaticity. Siroheme is the complex between an iron ion and a porphyrin which is also a derivative of uroporphyrinogen III (**2–70**), in which the bonds between carbons at positions 2 and 3 and between carbons at positions 7 and 8 are saturated and carbon 2 and carbon 7 are methylated with the same stereochemistry as in heme d_1 (**2–71**).

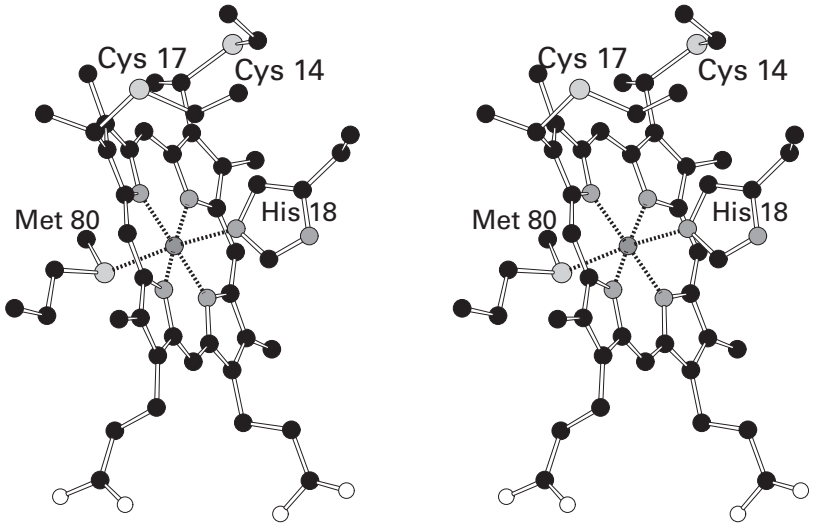


Figure 2–22: Stereodrawing[50] from a portion of the crystallographic molecular model of cytochrome *c* (103 aa) from *T. alalunga* built from a map of electron density that was calculated from a data set to Bragg spacing of 0.15 nm.[656] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, large light gray atoms are sulfurs, and the small dark gray sphere is an iron ion surrounded by its ligands. The heme *c* in the protein is in the center of the drawing. Cysteine 14 and Cysteine 17 have formed covalent adducts with the two former ethenyl groups at the top of the heme. Histidine 18 and Methionine 80 provide the two axial ligands to the iron ion.

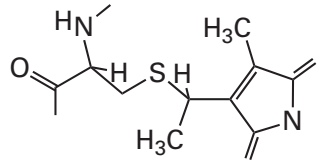
Heme *c* is a heme *b* that is **attached covalently** to the polypeptide of a cytochrome by two sulfides



2–72

that are the respective products of nucleophilic addition between two cysteines from the protein and the two ethenyl groups at positions 3 and 8 of heme *b* (Figure 2–22).[656] The heme in hydroxylamine reductase from *Nitrosomonas europaea* is covalently attached to the protein through an adduct between an ortho carbon of Tyrosine 467 that replaces the hydrogen on the methine carbon 5 of heme *b* and the 4-hydroxy group of Tyrosine 467 that has nucleophilically added to carbon 4 of the heme *b* as well as the two sulfides **2–72** from two cysteines.[657] The heme P460 from *N. europaea* is covalently attached to the protein through an adduct between the amino group of Lysine 70 that replaces[658] the hydrogen on methine carbon 5 of heme *b* as well as the two sulfides **2–72** from two cysteines.[659] Both of these latter modifications at the methine carbon require oxidative additions catalyzed by the respective hemes.

An iron ion in a heme, unlike an iron ion in an iron–sulfur cluster, is **octahedrally coordinated**. The four nitrogens of the porphyrin provide four of the ligands, the **equatorial ligands**. The other two, the **axial ligands**, which are opposite each other across the iron, are provided by the protein, the solvent, or solutes in the solution. For example, in eukaryotic cytochromes *c*, the two axial positions are occupied by the lone pair of electrons of the sulfur of a methionine and the lone pair of electrons of the τ nitrogen within the imidazolyl group of a histidine (Figure 2–22). The structure of the heme *c* in the crystallographic molecular model of cytochrome *c* is almost indistinguishable[656] from the crystallographic molecular model of a model compound (Figure 2–23)[660] which was built to incorporate the central features of the heme in cytochrome *c* and which should represent the most stable orientation of the six atoms around the iron unperturbed by steric effects. The protein, however, does move its axial ligands slightly so that they are no longer directly above and directly below the iron ion (Figure 2–22).[656]

One of the axial ligands to the iron ion in a heme is usually[661-663] the τ nitrogen in the imidazolyl

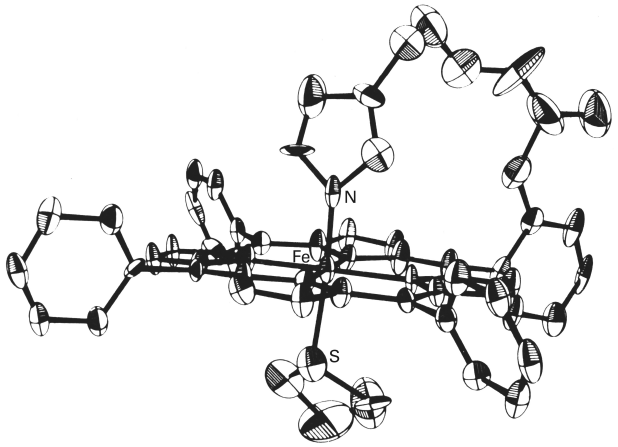


Figure 2–23: Drawing of the crystallographic molecular model of a synthetic heme[660] that incorporates the ligation found in cytochrome *c*. The metallic ion is Fe^{2+}, and the porphyrin is 5,10,15,20-tetraphenylporphyrin. To one of the phenyl groups an *o*-amino group has been added, and this was used to attach *N*-(4-carboxybutyl)imidazolyl group in anilide linkage. This chain of atoms provided an imidazolyl group as the fifth ligand to the Fe^{2+}. The sixth ligand is thiolane, which provides a sulfide to simulate the sulfide in the methionine in cytochrome *c*. The imidazolyl group is above the porphyrin in the drawing, the thiolane is below the porphyrin, and the Fe^{2+} is in the center of the porphyrin. The nitrogen of the imidazolyl group that provides a ligand to the iron, the iron ion, and the sulfur in the thiolane are labeled. Reprinted with permission from reference 660. Copyright 1979 American Chemical Society. https://doi.org/10.1021/ja00507a040

group of a histidine, but the other can be the τ nitrogen in an imidazolyl group of another histidine, the neutral sulfide of a methionine, the amino nitrogen of the amino terminus of the protein, the phenolato oxygen of a tyrosine, a molecule dissolved in the aqueous phase, or a molecule of water. For example, the heme *b* subunit of bovine quinol—cytochrome-*c* reductase contains two hemes *b*. The axial ligands for the iron ion in one heme *b* are the τ nitrogens from the imidazolyl groups of Histidine 83 and Histidine 182, and the axial ligands for the iron ion in the other heme *b* are the τ nitrogens from the imidazolyl groups of Histidine 97 and Histidine 196.[664,665] Cytochrome *c* from *Thunnus alalunga* contains a heme *c*, and the axial ligands to the iron ion in that heme *c* are Histidine 18 and Methionine 80 of the cytochrome (Figure 2–22). The heme *f* subunit of plastoquinol—plastocyanin reductase from *Brassica rapa* contains a heme *c*, and the axial ligands to the iron ion in that heme *c* are the imidazolyl group of Histidine 25 and the amino-terminal primary amine of the protein.[666-669] The most unusual axial ligand to a heme is a cysteine that is found in assimilatory sulfite reductases that contain siroheme. In these

enzymes, the cysteine is simultaneously bound to the iron ion of the siroheme and to one of the iron ions of a [4Fe–4S] iron–sulfur cluster,[661,670,671] which permits this complex to deliver two electrons at a time in three separate steps,[672] as is required for the conversion of sulfate to hydrogen sulfide catalyzed by the enzyme.

In many instances there is only one permanent axial ligand, and the other axial position is open to several different ligands. For example, bovine cytochrome-*c* oxidase contains a heme *a* the iron ion of which has the τ nitrogen in the imidazolyl group of Histidine 376 of subunit I as one of its axial ligands, but the opposite side of the iron ion is uncoordinated by the protein and is occupied by a molecule of water, a molecule of oxygen, or another ligand from the aqueous phase.[673] One of the hemes *c* in cytochrome c_{554} from *N. europaea* has the τ nitrogen in the imidazolyl group of Histidine 64 as one of its axial ligands, and there is no permanent axial ligand

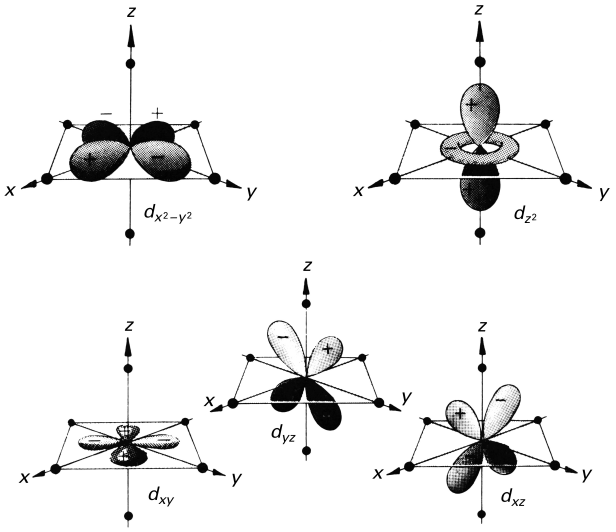

Figure 2–24: The five *d* orbitals of iron in the orientation they assume in the octahedral coordination complex found in hemes.[675] The six ligand positions of the octahedral arrangement are the six small filled circles defining the *x*, *y*, and *z* coordinates. Because three of the orbitals, d_{zy}, d_{yz}, and d_{zx}, lie between the repulsive lone pairs of electrons of the ligands, their energies are lower than the two orbitals, $d_{x^2-y^2}$ and d_{z^2}, that overlap the lone pairs of electrons of the ligands. The basicity of the axial ligands at the fifth and sixth positions controls the energy of the d_{z^2} orbital. The ligands at the four *x* and *y* positions are always the nitrogens of the heme. Reprinted with permission from reference 675. Copyright 1979 Annual Reviews Inc.https://doi.org/10.1146/annurev.bi.48.070179. 001551

on the other side of the iron.[674] When only one of the axial ligands is derived from the protein surrounding the heme, that fixed ligand is designated the **proximal ligand**. Hemes with an open axial coordination site usually catalyze chemical reactions that will be discussed later.

The octahedral coordination of an iron ion in a heme has consequences for the **electronic configuration of the iron ion.** An Fe^{2+} has six 3*d* electrons ($3d^6$), and an Fe^{3+} has five 3*d* electrons ($3d^5$). These are the electrons farthest from the nucleus of the iron ion. Oxygen ligands or nitrogen ligands in octahedral coordination of an iron ion, as are those to the iron in a heme, stabilize either a high-spin state or a low-spin state. The $d_{x^2-y^2}$ and d_{z^2} orbitals are on the axes of octahedral ligation, and the d_{xy}, d_{xz}, and d_{yz} orbitals are between the axes (Figure 2–24).[675] Each ligand directs a lone pair of electrons at the iron ion, and those lone pairs of electrons repel the 3*d* electrons of the iron ion, raise their energy, and split the degeneracy of the *d* orbitals (Figure 2–25A). If the ligands are such that they do not raise the energy of the $d_{x^2-y^2}$ and d_{z^2} orbitals sufficiently by electron repulsion relative to the energy of the d_{xy}, d_{xz}, and d_{yz} orbitals, then, in the case of Fe^{2+}, five of the six *d* electrons will distribute one into each of the five *d* orbitals; the remaining electron will enter either a d_{xy}, d_{xz}, or d_{yz} orbital; and four of the five *d* orbitals will contain an unpaired spin (Figure 2–25B).[676] In the case of Fe^{3+}, the five *d* electrons will distribute one into each of the five *d* orbitals, and each *d* orbital will contain an unpaired spin (Figure 2–25B). In each case, the iron ion will be in a **high-spin state**. If the ligands are such that they do raise the energy of the $d_{x^2-y^2}$ and d_{z^2} orbitals sufficiently by electron repulsion relative to the energy of the d_{xy}, d_{xz}, and d_{yz} orbitals, then, in the case of Fe^{2+}, the six *d* electrons will distribute in pairs into each of the d_{xy}, d_{xz}, and d_{yz} orbitals; and none of the five *d* orbitals will contain an unpaired spin (Figure 2–25C). In the case of Fe^{3+}, four of the five *d* electrons will distribute in two pairs into two of the d_{xy}, d_{xz}, and d_{yz} orbitals; the fifth *d* electron will enter the remaining d_{xy}, d_{xz}, or d_{yz} orbital; and only one of the *d* orbitals will contain an unpaired spin (Figure 2–25C). In each case, the iron ion will be in a **low-spin state**. The identity of the ligands to the Fe^{3+} and Fe^{2+} in a particular redox couple determine both its spin state and its biochemical standard reduction potential. Only the biochemical standard reduction potential, however, determines the ability

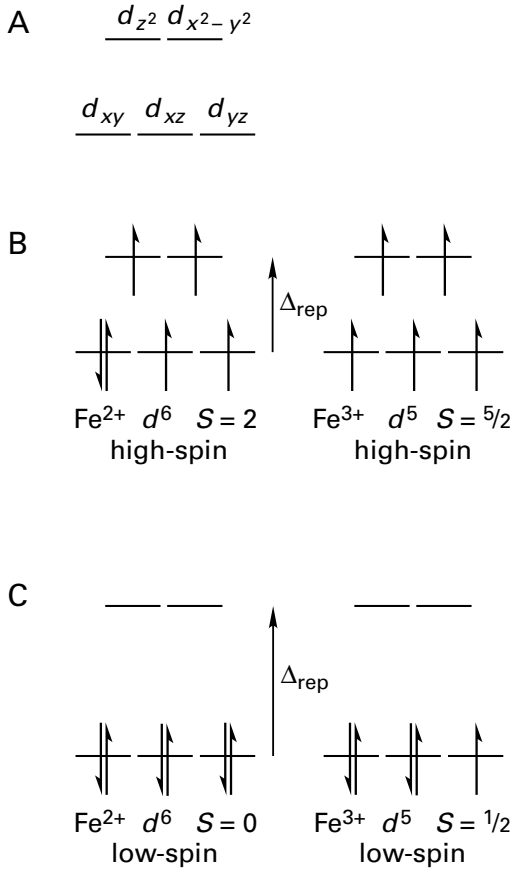

Figure 2–25: Distribution of 3*d* electrons in low-spin and high-spin Fe^{2+} and Fe^{3+} in octahedral coordination.[676] (**A**) The ligands, by electron repulsion, split the energy levels of the five 3*d* atomic orbitals of the iron so that the $d_{x^2-y^2}$ and d_{z^2} orbitals, which are aligned with the six ligands to the iron (Figure 2–24), have a higher energy for occupation by an electron than the d_{xy}, d_{xz}, and d_{yz} orbitals, which lie in between the ligands. (**B**) If the difference in energy (Δ_{rep}) due to the repulsion is small, then the electrons distribute by Hund's rule, which is that every orbital in a sublevel is singly occupied before any orbital is doubly occupied and all of the electrons in singly occupied orbitals have the same spin (to maximize total spin). The six *d* electrons of Fe^{2+} (d^6) distribute one into each of the five *d* orbitals, leaving one to occupy one of the d_{xy}, d_{xz}, and d_{yz} orbitals, which have a lower energy of occupation, giving a spin state of $^4/_2$. The five *d* electrons of Fe^{3+} (d^5) distribute one into each of the five *d* orbitals to give a spin state of $^5/_2$. These two distributions are high-spin. (**C**) If the difference in energy (Δ_{rep}) due to the repulsion is too large, then Hund's rule breaks down. The six *d* electrons of Fe^{2+} distribute in three pairs into each of the d_{xy}, d_{xz}, and d_{yz} orbitals, giving a spin state of 0, and the five *d* electron of Fe^{3+} distribute in two pairs into two of the d_{xy}, d_{xz}, and d_{yz} orbitals, and the remaining electron occupies the other, giving a spin state of $^1/_2$. These two distributions are low-spin.

of a particular redox couple of coordinated Fe^{3+} and Fe^{2+} to participate in an enzymatic one-electron oxidation–reduction.

When passing reversibly between Fe^{3+} and Fe^{2+}, an iron ion in a heme accepts and gives back one electron. During the reduction of the Fe^{3+} in a heme, the electron in question at the end of the reduction ends up in the unfilled 3*d* atomic orbital in the low-spin state of the Fe^{3+} (Figure 2–25C) or in one of the unfilled 3*d* atomic orbitals of lowest energy in the high-spin state of the Fe^{3+} (Figure 2–25B) to complete a pair. In reverse, at the end of the oxidation the electron has left the 3*d* atomic orbital in the Fe^{2+} that was filled or a filled orbital of equal energy. Regardless of whether the iron ion is high-spin or low-spin, the *d* orbital that is filled or that becomes unfilled is **a d_{xy}, d_{xz}, or d_{yz} orbital**. The identity of the ligands determines the energy of that d_{xy}, d_{xz}, or d_{yz} orbital, even though they are not directed toward the ligand, and hence the biochemical standard reduction potential of the iron, regardless of spin state. Whether the iron is high-spin or low-spin, however, does affect the rates at which single electrons can be exchanged; the high-spin states are more reactive in single electron transfer.[676]

The biochemical standard reduction potentials of the iron ions in the hemes involved in one-electron oxidation–reduction span the range from –550 to +450 mV (Figure 2–19).[677-680] For example, in hydroxylamine dehydrogenase from *N. europaea*, the biochemical standard reduction potentials of its eight distinct hemes *c* span the range from –410 to +290 mV.[681] The type of heme seems to be of little consequence because the ranges of biochemical standard reduction potential for cytochromes with different types of hemes overlap extensively. Although the ranges for the cytochromes with hemes *c* (–410 to +400 mV) and with hemes *b* (–200 to +400 mV) are the largest, these are also the most common types of cytochromes and have had the most opportunity for the standard reduction potentials to be manipulated by natural selection.

Variation in the **substituents on the porphyrin** affects the biochemical standard reduction potential of the iron ion in the heme to a degree. When the two ethenyl groups on heme *b* are reduced to ethyl groups, the biochemical standard reduction potential of its biscyano complex decreases by –35 mV; and when one of the ethenyl groups is replaced with a formyl group, it increases by +70 mV.[682] These shifts in standard reduction potential result from increases

(or decreases) in basicity of the nitrogens of the porphyrin resulting from increases in electron donation (or electron withdrawal) at its edges that stabilize (or destabilize) the oxidized Fe^{3+} relative to the reduced Fe^{2+}.

The **identity of the axial ligands** also affects the biochemical standard reduction potential of the iron ion in a heme in solution. When two waters are replaced as the axial ligands of heme *b* by two imidazolyl groups, which are more basic than molecules of water, the biochemical standard reduction potential decreases by –50 mV.[545] When one of those imidazolyl groups is then replaced by a sulfide, which is less basic than water, the biochemical standard reduction potential increases by +110 mV. This latter effect is due both to the decrease in basicity of the ligand and to the ability of the unfilled $3d$ atomic orbitals on sulfur to overlap favorably with the filled $3d$ orbitals on iron.[683]

The effects of the axial ligands are manifested as well in the standard reduction potentials of hemes in proteins. The two hemes *b* in the quinol—cytochrome-*c* reductase from *Rhodobacter capsulatus*, which each have two histidines as axial ligands, have biochemical standard reduction potentials of –90 and +50 mV while the heme *b* of cytochrome b_{558} from *E. coli*, which has a histidine and a methionine as axial ligands,[684] has a biochemical standard reduction potential of +180 mV.[685] Among cytochromes *c*, small proteins that act as electron-transferring coenzymes, those with hemes *c* with one histidine and one methionine as axial ligands have biochemical standard reduction potentials between +100 and +400 mV while those with two histidines have biochemical standard reduction potentials between –400 and –100 mV.[686]

Nevertheless, neither the variation of the substituents around the heme nor the identity of the axial ligands can explain the majority of the **variation in the observed standard reduction potentials** of hemes. For example, among those cytochromes *c* with a single heme *c* with axial ligands from one histidine and one methionine, the biochemical standard reduction potentials vary from +100 to +400 mV.[687] The single heme *b* with two histidines as axial ligands in cytochrome b_5 has a biochemical standard reduction potential of –100 mV[688] while one of the hemes *b* with two histidines as axial ligands in quinol—cytochrome-*c* reductase from *R. capsulatus* has a biochemical standard reduction potential of +50 mV.[575] Aspects of the environment surrounding the heme—such as charged side chains of amino acids in its vicinity, identity of donors or acceptors in hydrogen bonds to the imidazolyl groups of its axial histidines, steric distortions of the heme, extent of its removal from the surrounding solution, surface charge of the protein, and ionic strength of the surrounding solution—all have been shown to affect its standard reduction potential.[680,689,690] For example, when a valine in cytochrome c_{6A} from *Arabidopsis thaliana* is replaced by a glutamine,[691] which is the amino acid at the homologous position in cytochrome c_6 from *Phormidium laminosum*, the biochemical standard reduction potential of the heme increases by +110 mV. This observation explains in part the difference in the biochemical standard reduction potential of cytochrome c_{6A} (+71 mV) and cytochrome c_6 (+325 mV). The heme in the native structure of methyl-accepting chemotaxis protein is distorted significantly out of planarity by the protein. As mutations are made surrounding the heme that decrease this distortion and make the heme more planar,[692] the biochemical standard reduction potential decreases from +166 to –5 mV. In cytochromes with multiple hemes that are close together, each successive electron that is taken up by the cytochrome causes a decrease in the standard reduction potential for the next because of the successive accumulation of negative charge.[674,677,693]

Copper is the second most common transition metal participating in biochemical one-electron transfers. The configuration of valence electrons in elemental, metallic copper, Cu^0, is $3d^{10}4s^1$. The cuprous ion, Cu^+, missing the single $4s$ electron, is the only stable monovalent ion of the transition metals of the fourth period because it has a completely filled $3d$ shell. The cupric ion, Cu^{2+}, is a dication with a partially filled $3d$ shell ($3d^9$), which is the case with all other stable cations of transition metals of the fourth period. In the biochemical oxidation–reductions of prosthetic copper ions, Cu^+ gives up one electron during its oxidation to Cu^{2+}, and Cu^{2+} takes up one electron during its reduction to Cu^+. Unlike the various prosthetic groups containing iron that participate in one-electron transfer, in which the iron has inorganic sulfides or a porphyrin as ligands, prosthetic copper ions usually have lone pairs of electrons only from sulfurs, nitrogens, or oxygens of side chains of amino acids in the protein, acyl oxygens of the polypeptide backbone, or molecules of water as ligands (Figure 2–26).

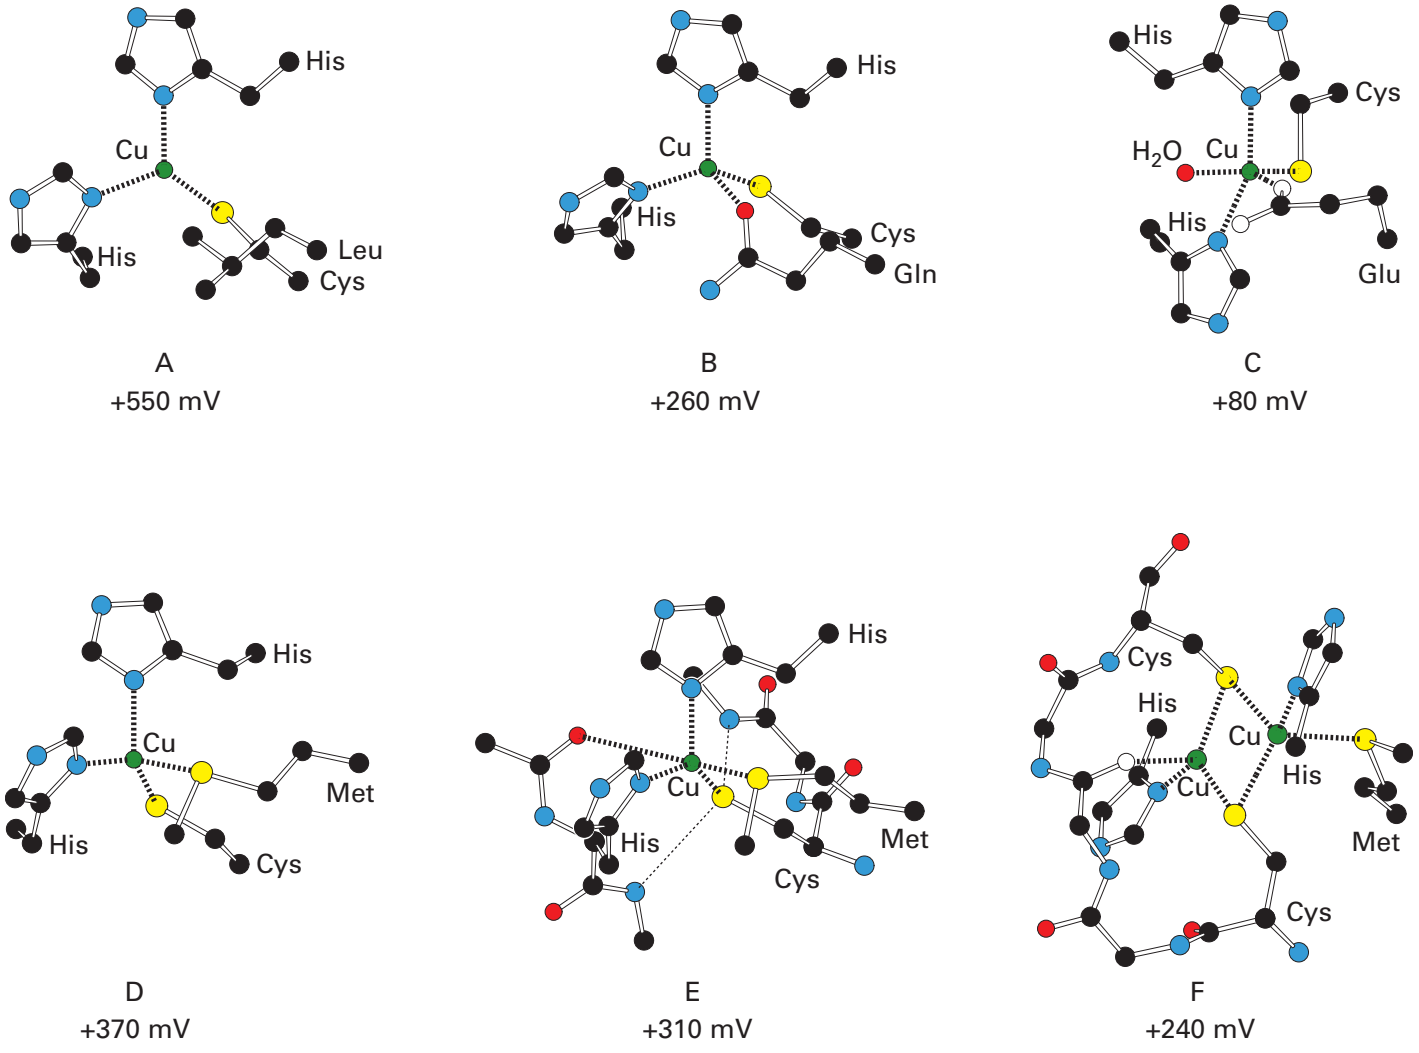

Figure 2–26: Arrangements of the ligands around prosthetic copper ions. Black atoms are carbons, red atoms are oxygens, blue atoms are nitrogens, large yellow atoms are sulfurs, and small green spheres are copper ions surrounded by their ligands. The drawings[50] are of mononuclear copper ions in crystallographic molecular models of (**A**) laccase from *C. cinerea*;[695] (**B**) stellacyanin from *C. sativus*;[740] (**C**) nitrocyanin from *N. europaea*;[742] (**D**) plastocyanin from *P. nigra*;[707] (**E**) azurin from *P. putida*;[722] and (**F**) the dinuclear CuA cluster from cytochrome-*c* oxidase of *T. thermophilus*.[746] The biochemical standard reduction potentials listed are relative to the standard hydrogen electrode and are for a standard state of pH 7.

The simplest arrangement of ligands, which defines the **core ligands present in most of the prosthetic groups containing only one copper ion,**[694] is that found in laccase from *Coprinopsis cinerea* (Figure 2–26A).[695] The copper ion is coordinated by the π nitrogens of two histidines and the sulfur of a cysteine. The bond lengths between the three ligands and the copper are 0.20, 0.21, and 0.22 nm, respectively; the three ligands are arranged trigonally around the copper; and four atoms (the copper, the two nitrogens, and the sulfur) are in the same plane. Again, this arrangement of ligands can be explained as the result of covalent bonding resulting from the occupation of three vacant $4sp^2$ atomic orbitals of the copper ion, the softest of the transition metals, by the lone pairs of electrons on the ligands or as the result of ionic bonding between the lone pairs of electrons and the positive copper ion in which steric and electronic repulsive forces the ligands and their lone pairs to be as far apart as possible, hence trigonal. Laccase is a member of a family of enzymes, each of which contains a prosthetic copper ion that is responsible for removing a single electron from its respective substrate.[696,697] In the case of

laccase, the prosthetic Cu^{2+} removes an electron from a benzenediol. The biochemical standard reduction potential of the copper ion in the active site of laccase from *C. cinerea* is +550 mV,[694] which is more than sufficient to permit the Cu^{2+} to remove an electron from a 1,2-dihydroxybenzene to give its semiquinone. This high biochemical standard reduction potential is in part a result of the fact that there are only three ligands to the copper ion from the protein, so the electron density around the cation is relatively low, which makes the Cu^{2+} more electropositive and more easily reduced. Although trigonally complexed copper is unusual outside a protein, there is a model compound for the prosthetic copper ions in this family of enzymes in which this configuration of ligands is achieved.[698,699]

The **most common arrangement of ligands** for mononuclear, prosthetic copper ions[700-706] is that found in plastocyanin from *Populus nigra* (Figure 2–26D).[707] The core configuration of two nitrogens from two histidines and one sulfur from a cysteine, with respective bond lengths to the copper of 0.19, 0.21, and 0.21 nm,[708-710] is expanded to include the sulfur from a methionine with a long bond to the copper of 0.28 nm. The addition of this ligand, although it is more distant, nevertheless converts the planar, trigonal configuration of ligands into a roughly tetrahedral one.[709] This arrangement of ligands can be explained as the result of covalent bonding resulting from the occupation of four vacant $4sp^3$ atomic orbitals of the copper ion by the lone pairs of electrons on the ligands or ionic bonding between the lone pairs of electrons and the positive copper ion in which steric and electronic repulsion forces the ligands and their lone pairs to be a far apart as possible, hence tetrahedral.

The additional **lone pair of electrons from the sulfide** in the methionine, as expected, decreases the biochemical standard reduction potential of the prosthetic copper ion.[694] If the methionine is mutated to a glycine, the biochemical standard reduction potential of the copper ion increases by about +100 mV,[711] but this observation is equivocal because the space opened by deleting the side chain of the methionine can permit a molecule of water to become the fourth ligand to the copper.[712] When the methionine, however, is mutated to 2-aminohexanoate, which fills the space that the methionine occupied, the biochemical standard reduction potential of the copper ion also increases by +100 mV.[713] When the methionine in amicyanin from *Paracoccus denitrificans* is replaced with a leucine,[714] the biochemical standard reduction potential increases by +130 mV. That the basicity of the lone pair of electrons on methionine is responsible for decreasing the biochemical standard reduction potential of the prosthetic copper ion is supported by the fact that when the methionine is mutated to 6,6,6-trifluoromethionine, a far less basic sulfide, the biochemical standard reduction potential of the copper ion increases by +40 mV. The increase of +100 and +130 mV in biochemical standard reduction potential of the copper ion that is caused by mutating the methionine to a 2-aminohexanoate and a leucine, respectively, however, is much less than the increase of +330 mV that occurs when one of the more intimately associated histidines that are ligands to the copper ion is mutated to a glycine.[715]

The biochemical standard reduction potential of the prosthetic copper ion in plastocyanin from *P. nigra* (Figure 2–26D) is +370 mV,[716,717] but the biochemical standard reduction potentials for prosthetic copper ions with the same four ligands with the same bond lengths[710] vary between +210 and +680 mV.[694,711,712,716-721] These differences are caused, in part, by differences in the distance between the copper ion and the nearby dipole of an acyl oxygen from the polypeptide backbone and by differences in the number of amido nitrogen–hydrogens directed toward the sulfur of the sole cysteine that is a ligand to the copper ion.[694] For example, in the crystallographic molecular model of azurin from *P. putida* (Figure 2–26E),[722,723] the **acyl oxygen from the peptide bond** preceding Histidine 46, which provides one of the π nitrogens that coordinate the copper ion, has been positioned by the protein so close to the prosthetic copper ion that it has become a fifth ligand at a distance of 0.30 nm, and there are two amido nitrogen–hydrogens pointed toward the sulfur of the cysteine that is a ligand to the copper. The distances from the sulfur to the two nitrogens of these nitrogen–hydrogens are 0.35–0.36 nm, well within the sum of the van der Waals radii of sulfur (0.18 nm) and hydrogen (0.11 nm) and the length of a nitrogen–hydrogen bond (0.10 nm). These **oriented nitrogen–hydrogens** are reminiscent of those in the polypeptide backbone surrounding iron–sulfur clusters (Figures 2–18, 2–20, and 2–21).

The biochemical standard reduction potential of the azurin from *P. putida* is +310 mV.[724] In rusticyanin from *Acidithiobacillus ferrooxidans*, there are also two nitrogen–hydrogens in the same relative positions in the sequence of amino acids directed

toward the cysteine, but the acyl oxygen is 0.6 nm away from the copper ion rather than 0.30 nm.[702] The biochemical standard reduction potential of rusticyanin is +680 mV.[694] This increase in standard reduction potential is thought to be due mainly to removal of the lone pair of electrons of the acyl oxygen from the vicinity of the copper.[694] In auracyanin from *Chloroflexus aurantiacus* which also has the same two homologous nitrogen–hydrogens directed toward the sulfur, the biochemical standard reduction potential of the copper ion is less that that of azurin (+210 mV),[721] even though the distance between the copper and the oxygen (0.35 nm)[705] is greater than that in azurin (0.30 nm).

The two nitrogen–hydrogen bonds from the polypeptide backbone directed toward the sulfido group of the cysteine in the crystallographic molecular models of the azurins, rusticyanin, and auracyanin are located in the peptide bond to the carboxy-terminal side of one of the coordinated histidines and the peptide bond two positions carboxy-terminal to the coordinated cysteine (Figure 2–26E). Because they direct the positive pole of the dipoles of their respective amido groups toward the sulfur, they should increase the standard reduction potential of the prosthetic copper ion.[694] In pseudoazurin from *Alcaligenes faecalis*, the amino acid two positions carboxy-terminal to the cysteine is a proline, so there is only one nitrogen–hydrogen directed toward the sulfido group of the cysteine.* When that proline is mutated to an isoleucine, to restore the second hydrogen bond,[725] the biochemical standard reduction potential of the copper ion increases[726] from +280 to +450 mV as expected. The basic blue protein from *Cucumis sativus*, however, does not have a proline at this position and instead has two nitrogen–hydrogens directed toward the sulfur, and the distance from its acyl oxygen to the copper ion (0.38 nm)[727] is the same as that in the pseudoazurin from *A. faecalis* (0.38 nm),[701] yet the biochemical standard reduction potential (+310 mV)[718] is almost the same as that (+280 mV) of pseudoazurin. The copper ions in plastocyanin from *Ulva prolifera*[728] and auracyanin from *C. aurantiacus*[705] are both the same distance from the respective acyl oxygens (0.35 nm). The latter has two nitrogen–hydrogens directed toward the copper while the former has only one, yet the biochemical standard reduction potential of the latter (+210 mV) is significantly more negative than that of the former (+370 mV)[720] instead of the other way around.

All these results suggest that **the biochemical standard reduction potential of a prosthetic copper ion in these proteins is not determined only by the distance between the copper ion and the acyl oxygen and the number of amido nitrogen–hydrogens directed toward the sulfur of the cysteine**.[694] Rather, the biochemical standard reduction potential of the copper ion in a protein seems to be determined by a large array of interactions of the amino acid side chains that surround it. For example four mutants of azurin from *P. aeruginosa* were constructed by mutating just two amino acid side chains in the immediate vicinity of the copper ion, a phenylalanine and an asparagine, neither of which is a ligand to the copper.[729] In the mutants, the biochemical standard reduction potential of the copper ion was decreased by as much as –90 mV or increased by as much as +240 mV.

The prosthetic copper ion in an azurin displays **the full complement of five paradigmatic ligands**. It is surrounded by the sulfurs of a cysteine and a methionine, the nitrogens of two histidines, and an acyl oxygen of the polypeptide backbone (Figure 2–26E). The two sulfurs, the two nitrogens, and the oxygen span, respectively, the complete biochemical spectrum from soft to hard Lewis bases. This list of ligands, however, is not a complete one. For example, one of the copper ions in peptidylglycine monooxygenase from *R. norvegicus*, the one responsible for transfer of single electrons to the active site, is coordinated only by the π nitrogens from the imidazolyl groups of three histidines.[730]

Copper ion is a soft Lewis acid, and in most of its prosthetic groups, it forms a strong, notably short, mostly covalent σ bond with the soft **sulfido sulfur of a cysteine**[731] In addition, in the oxidized cupric state, there is significant **transfer of electron density** from a *p* orbital on this sulfur, occupied by one of its lone pairs of electrons, to the $d_{x^2-y^2}$ orbital of the Cu^{2+}, occupied by its single unpaired electron.[732,733] Consequently, the sulfur must be hybridized *p*, sp^2, sp^2, sp^2. This transfer of electron density is responsible for the strong blue color of all these mononuclear, prosthetic copper ions, and it is thought that the electron entering, or leaving, the copper ion during its reduction, or oxidation, can pass through the *p* orbital on the sulfur that participates in this transfer of electron density.[731] The

*In this pseudoazurin, as well as most of the other proteins with this arrangement of ligands around the copper ion, the nitrogen of the peptide bond immediately adjacent to the respective cysteine is only 0.35 nm from its sulfur,[694] but the dipole of its amide is normal to the vector between the nitrogen and the sulfur (Figure 2–26E) and should have little effect on the standard reduction potential.

sulfur of a methionine is also a soft Lewis base, but as a sulfide it is only weakly basic ($pK_a \cong -9$) relative to the sulfido group of the cyteine ($pK_a = 8.7$), so it is only a weak ligand, a fact reflected in its bond length of 0.28 nm.

The **two nitrogens of the histidines**, although as basic as the sulfido group of the cysteine, are harder bases and do not form such a strong association with the soft copper. The distances between these nitrogens and the copper ion are the same as that between the sulfur of the cysteine and the copper ion even though their van der Waals radii (0.16 nm) are smaller than that of the sulfur (0.18 nm).[185] From crystallographic molecular models of the complex between laccase from *Melanocarpus albomyces* and 2,6-dimethoxyphenol, an analogue of a 1,2-dihydroxybenzene that would be a natural substrate, it was concluded that the electron that is removed by the enzyme and that ultimately ends up on the prosthetic copper ion passes through one of the imidazolyl groups that are ligands to the copper, rather than the cysteine. This imidazolyl group sits between the respective substrate and the copper ion.[734]

The **acyl oxygen of a peptide bond** is an even harder base. The main effect of its lone pair of electrons is to push the cysteine and the two histidines back into a trigonal plane (see Figure 2–26A). The acyl oxygen cannot participate in covalent bonding because it is a hard base and also because it is a weak base ($pK_a = -1$). Consequently, the return to trigonal coordination must be the result of electron repulsion, in which case this reorientation suggests that the tetrahedral orientation distorted by this electron repulsion was not the result of covalent bonding in the first place. The acyl oxygen also lowers the biochemical standard reduction potential of the copper by donating electron density, even though its distance from the copper ion is 0.28–0.32 nm in the azurins.[722,723,735,736]

In the set of prosthetic copper ions[737-739] represented by that of stellacyanin from *C. sativus* (Figure 2–26B),[740] the sulfur of the methionine found in the plastocyanins (Figure 2–26D) has been replaced with the **acyl oxygen in the side chain of glutamine**. The prosthetic copper ion of the stellacyanin from *C. sativus* has a biochemical standard reduction potential of +260 mV,[741] which is about −100 mV less positive than prosthetic copper ions that have methionine as a ligand, such as that in the plastocyanin from *P. nigra* ($E^{\circ\prime} = +370$ mV). In stellacyanin from *C. sativus*, two nitrogen–hydrogens are directed at the sulfur of the cysteine, and the acyl oxygen of the peptide bond to the amino-terminal side of the histidine is at the same distance as it is in the plastocyanin from *P. nigra* (Figure 2–26D). The difference in biochemical standard reduction potential between the stellacyanins and the plastocyanins is due, in part, to the greater basicity of the lone pair of electrons on the acyl oxygen of a glutamine ($pK_a = -1$) relative to that of the lone pair of electrons on the sulfur of a methionine ($pK_a \cong -9$). Consistent with this conclusion is that when the methionine that is the ligand to the prosthetic copper ion in azurin from *P. putida* (Figure 2–26E) is mutated to isosteric 4-methoxy-2-aminobutyrate, which replaces a sulfide with an ether, the oxygen of which has a basicity ($pK_a \cong -4$) closer to that of the acyl oxygen of the side chain of a glutamine, the biochemical standard reduction potential of the prosthetic copper ion decreases by −120 mV.[713] In the stellacyanin from *C. sativus*, the distance between the acyl oxygen of the glutamine and the copper ion (0.21–0.23 nm)[738-740] is significantly shorter than that between the sulfur of a methionine and the copper ion (0.27–0.31 nm),[709,710] which probably is the result of a steric effect because the oxygen is a hard base and less likely to engage in a covalent bond. The acyl oxygen of the glutamine (Figure 2–26B) is also much closer to the copper ion than is the more weakly associated acyl oxygen of the peptide bond (0.28–0.32 nm) in the azurins (Figure 2–26E).

The prosthetic copper ion in nitrocyanin from *N. europaea* (Figure 2–26C)[742] illustrates **the effect of two oxygens** on the biochemical standard reduction potential. In addition to the three core ligands of two nitrogens from two histidines and the sulfur from a cysteine, with bond lengths to the copper of 0.20, 0.20, and 0.23 nm, additional ligands are the oxygen of a molecule of water ($pK_a = 0$) and the oxygen of the carboxylato group of a glutamate ($pK_a = 4.3$) at distances of 0.22 and 0.21 nm, respectively, from the copper. These two oxygens, especially the more basic oxygen from the glutamate, cause the biochemical standard reduction potential of the prosthetic copper ion to be quite low (+80 mV),[743] at the lower end of the range of biochemical standard reduction potentials for prosthetic copper ions (Figure 2–19). In nitrocyanin, the copper has five ligands surrounding it that are all intimate and almost equidistant from the metallic ion and oriented so that they are almost as far apart from each other as possible. It seems likely that the orientation of the four harder ligands other than the sulfido group is determined almost entirely by electron repulsion and steric effects.

When an electron is added to a mononuclear, prosthetic Cu^{2+} during its reduction, the sulfur or sulfurs, the nitrogens, and the oxygen or oxygens of the **ligands move away from the copper** as a result of repulsion between the new electron and their lone pairs of electrons. Because of their strong interactions with the copper ion, the core ligands (the two nitrogens of the histidines and the sulfur of the cysteine) are least affected and usually move out by only about 0.01 nm.[735,738,739] Occasionally, however, one of the two histidines moves away more dramatically;[708,744] in at least one instance by more than 0.1 nm.[745] Upon reduction, the sulfur of the methionine or the acyl oxygen of the glutamine moves away from the copper ion more extensively, by 0.02–0.05 nm.[702] The acyl oxygen of the peptide backbone that is the fifth ligand in the azurins (Figure 2–26E), however, moves very little upon reduction, probably because it is farther away from the copper ion and far more rigidly positioned than the ligands on the side chains.

As with iron ions, prosthetic copper ions participating in the transfer of single electrons can be found in **clusters**. Unlike with iron, the clusters formed by copper ions do not contain sulfide, and they are considerably fewer in number. Two examples of such a cluster are the dinuclear CuA cluster from cytochrome-*c* oxidase of *T. thermophilus* (Figure 2–26F),[746] which is representative of the CuA clusters in other cytochrome-*c* oxidases,[673] and the dinuclear CuA cluster in nitrous-oxide reductase.[747] The central core of two copper ions and two sulfido groups in the dinuclear cluster of prosthetic copper ions in cytochrome-*c* oxidase resembles the central core of a [2Fe–2S] iron–sulfur cluster (Figures 2–18 and 2–20) in its planarity, the bond angles at the two sulfurs of the cysteines (65°), and the bond angles at the two coppers (110° and 118°), but the two sulfurs are not bridging sulfides but sulfido groups from two cysteines.

This central core of the two copper ions and two sulfido sulfurs is covalently bonded with a **molecular z**uted over all four of its atoms.[748] In the oxidized state, Cu^{2+}:Cu^{+}, the single unpaired electron is distributed equally between the two copper ions by the highest occupied molecular orbital of the conjugated system that it occupies. In the reduced state, Cu^{+}:Cu^{+}, the highest occupied molecular orbital of the core is filled by the added electron, and the cluster loses its intense purple color and its characteristic electron paramagnetic resonance spectrum.[748] The biochemical standard reduction potential for reduction of the dinuclear cluster of prosthetic copper ions in cytochrome-*c* oxidase of *T. thermophilus* is +240 mV.[749]

The **ligands to the two copper ions** of a CuA cluster, aside from the two cysteines, are those of the mononuclear copper ion in azurin (Figure 2–26E): two histidines, a methionine, and an acyl oxygen from the polypeptide backbone. The distances between the histidines and the respective coppers (0.19 and 0.21 nm) are typical, but the methionine (0.25 nm) and the acyl oxygen of the polypeptide backbone (0.26 nm) are closer to their respective copper ions than they are to the lone copper ion in the azurins.[746]

A model compound containing a central core almost identical to that in this cluster has been synthesized, but it is stable only in the mixed-valent, paramagnetic oxidation state,[750] unlike the prosthetic CuA cluster in a protein, the reduced, diamagnetic state of which is quite stable. The fact that the **synthetic cluster** is unstable illustrates the fact that when a prosthetic group containing metallic ions is synthesized outside the protein it often fails to display the same range of abilities that it does when it is within the protein, perhaps because the protein that surrounds it prevents its dissociation.

As with flavin, **the effect of pH on the reduction potential** for prosthetic groups participating in the transfer of single electrons is determined by the features of the protein that surrounds them and, in the case of prosthetic groups containing ions of transition metals, by the nature of the ligands provided by the active site for the metallic ions. For example, as has been already noted, the reduction potentials for the Rieske [2Fe–2S] iron–sulfur clusters and the [2Fe–2S] iron–sulfur clusters in which only one ligand is an imidazolyl group are predictably dependent on pH. The reduction potentials of high-potential [4Fe–4S] iron–sulfur clusters, however, are usually invariant with pH. The reduction potentials of some low-potential [4Fe–4S] iron–sulfur clusters are dependent on pH while those for other low-potential [4Fe–4S] iron–sulfur clusters are not. The biochemical standard reduction potential for the heme in bovine cytochrome *c* is +250 mV.[751] Upon addition of the electron, the central core of the heme in cytochrome *c* from *T. alalunga* (Figure 2–22) loses its net positive elementary charge and several amino acids near the sulfur of the methionine rearrange their orientations. These rearrangements are responses of the structure of the protein to the change in elementary charge at the iron.[752] Between pH 8 and pH 3, however, which includes the range

in which the protein normally functions, the reduction of bovine cytochrome *c* proceeds without the uptake of a hydron from the solution, so its biochemical standard reduction potential is not a function of pH.[751] Above pH 8, one hydron is taken up with the electron and no change in net charge on the protein occurs during the reduction. The opposite behavior is observed with plastocyanin, a protein that performs a role similar to that performed by cytochrome *c*. Below pH 6, one hydron is taken up with the electron by the plastocyanin from *P. crispum*, and above pH 6, none is taken up.[753]

The biochemical standard reduction potentials that have been noted above for the various prosthetic groups participating in the transfer of single electrons are usually ascertained by potentiometric titration or cyclic voltammetry.

In a **potentiometric titration**, the reduction potential of the solution is monitored with an electrode. Various small molecules that can be oxidized or reduced by one electron or two electrons are added to the solution as **mediators**. The mediators are ubiquitous redox couples with standard reduction potentials that span the range of reduction potential to be sampled. They are added to bring the potential of the electrode to the reduction potential of the solution by engaging in efficient and rapid oxidation and reduction at its surface; to bring the concentrations of the oxidized and reduced forms of the prosthetic group in the protein into equilibrium with the reduction potential of the solution by oxidizing and reducing it until equilibrium is reached; and to buffer the reduction potential of the solution by maintaining its reduction potential through the equilibrium concentrations of the oxidized and reduced forms of the several mediators (Equation 2–91).

The **reduction potential of the solution is adjusted systematically** in one of two ways. In the first strategy, small portions of a strong reductant, or a strong oxidant, are added in succession to decrease, or increase, the reduction potential of the solution. In the second strategy, the electrode is used to impose a succession of voltages. In the latter instance, the electrode must have a surface area of sufficient capacity to bring the potential of the solution to equilibrium all by itself in a reasonable interval.

After each adjustment, one waits for **equilibrium** to be established. For the titration to be accurate, the measurements must be taken at equilibrium. If the equilibrium is only slowly established and sufficient time is not taken, the ultimate value obtained for the biochemical standard reduction potential will be in error.

After each adjustment, the **reduction potential of the solution that is registered by the electrode** is recorded, and the concentrations of the oxidized form or the reduced form or both forms of the prosthetic group are ascertained spectroscopically. Usually, the reduction potential of the solution is systematically decreased and then systematically increased, or vice versa, to be sure that the same spectra are obtained at the same reduction potential in each direction,[754] a coincidence that demonstrates the reversibility of the oxidation–reduction and the fact that equilibrium was reached in each measurement.

The potentiometric titration of a prosthetic group participating in the transfer of single electrons can be **monitored by gathering visible absorption spectra**. For example, the visible absorption spectrum of equine cytochrome *c* between 500 and 580 nm was monitored as a function of the measured reduction potential of a solution containing cytochrome *c* and the mediators *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine ($E^{\circ\prime}_{2e^-}$ = +260 mV), 2,3,5,6-tetramethyl-1,4-benzenediamine ($E^{\circ\prime}_{2e^-}$ = +240 mV), 5-methylphenazinium methyl sulfate ($E^{\circ\prime}_{2e^-}$ = +80 mV), and 5-ethylphenazinium ethyl sulfate ($E^{\circ\prime}_{2e^-}$ = +55 mV). Ferric ethylenediaminetetraacetate was also present to shuttle single electrons to the mediators from the iron of the heme. The reduction potential of the solution was systematically increased by adding portions of a solution of potassium ferricyanide and was recorded with a gold electrode. The concentration of the reduced form of heme *c* in cytochrome *c* was assessed by its absorbance at 550 nm (Figure 2–27).[755] The data were fit to Equation 2–91 to obtain a value for the biochemical standard reduction potential of the heme *c* in the cytochrome. The value obtained, 257 ± 0.4 mV, agrees closely with the value (256 ± 3 mV) for the same protein that was determined earlier with less accuracy.[751]

The different hemes can be most readily distinguished by their **absorption spectra** in the visible region, between 500 and 580 nm. For example, the ferrous forms of the two different hemes *b* and the heme *c* in quinol—cytochrome-*c* reductase have sharp, characteristic absorption bands at 552.4, 560, and 565.6 nm, respectively, and the three can be followed separately in a potentiometric titration to determine each of their biochemical standard reduction potentials.[756] The strongest visible absorption of a heme is usually at around 400 nm, the Soret band,

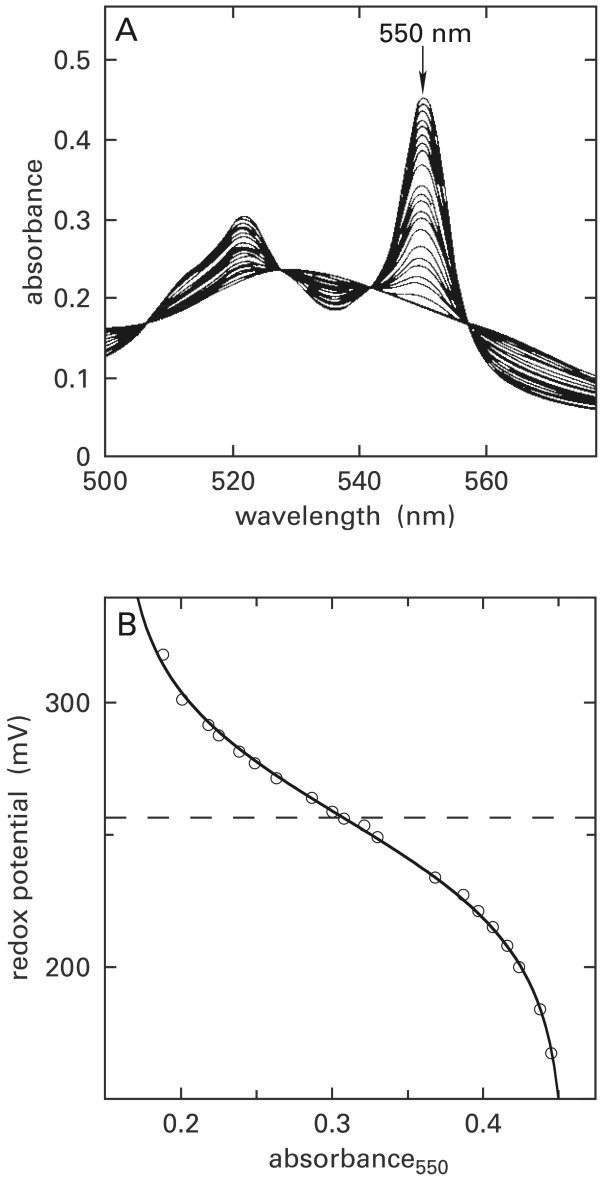

Figure 2–27: Potentiometric titration of equine cytochrome *c*.[755] A solution of the protein (16 μM) in 4.5 M urea, 0.3 mM ferric chloride, 10 mM ethylenediaminetetraacetate, 10 μM *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine, 35 μM 2,3,5,6-tetramethyl-1,4-benzenediamine, 35 μM 5-methylphenazinium methyl sulfate, 35 μM 5-ethylphenazinium ethyl sulfate, and 0.05 M sodium phosphate at pH 7.0 at 25 °C was added to the chamber of an apparatus that permitted the solution to be in contact with a gold-plated platinum electrode and at the same time have its absorbance monitored. The heme *c* in the protein was in the reduced state and was held at an initial reduction potential of 100 mV. Successive additions of a 13 mM solution of potassium ferricyanide were added and, after the solution reached equilibrium, the reduction potential of the solution was recorded as well as an absorption spectrum from 500 to 580 nm. **(A)** Superposed spectra, one for each potentiometric step in the oxidation. The absorbance at 550 nm decreases with each addition of ferricyanide. **(B)** Potentiometric titration. The reduction potentials (millivolts) of the solution at equilibrium are plotted against the absorbance at 550 nm. Equation 2–91 was fit to the data (solid curve). The parameters obtained from the fit were the absorbance of fully reduced cytochrome *c* in the solution, 0.453 ± 0.0003; the absorbance of the fully oxidized cytochrome *c* in the solution, 0.159 ± 0.0007; and the biochemical standard reduction potential of equine cytochrome *c*, +257 ± 0.4 mV (horizontal dashed line).

and potentiometric titrations can also be monitored in this region of the spectrum because the absorption shifts to longer wavelengths upon reduction of the heme,[757,758] but the different hemes all have similar shifts in absorption in this range during a potentiometric titration and cannot be distinguished so readily.

It is also possible to monitor a potentiometric titration with **electron paramagnetic resonance spectra**. For example, the reduction potential of a solution containing lysine 2,3-aminomutase from *Clostridium subterminale*, *S*-adenosyl-L-methionine, and the mediators 1,1′-trimethylene-2,2′-dipyridyl bromide and 4,4′-dimethyl-1,1′-trimethylene-2,2′-dipyridyl bromide was adjusted systematically to voltages in the range between –375 and –525 mV by adjusting the potential of a gold electrode to the desired voltage and waiting for equilibrium to be reached. At each voltage, following equilibration, a sample was removed from the solution and frozen, and the electron paramagnetic resonance spectrum of the [4Fe–4S] iron–sulfur cluster in the enzyme was measured (Figure 2–28A).[595] The differences in the derivatives of the absorption between the maxima of the derivative at 0.345 T and the minima of the derivative at 0.356 T were plotted as a function of the measured reduction potential (Figure 2–28B). These differences are directly proportional to the magnitude of the actual absorption and hence the concentration of the reduced, paramagnetic form of the iron–sulfur cluster (Equation 2–169). The data were fit to Equation 2–91 to obtain a value for the biochemical standard reduction potential (–437 ± 5 mV) of the iron–sulfur cluster in the active site of lysine 2,3-aminomutase.

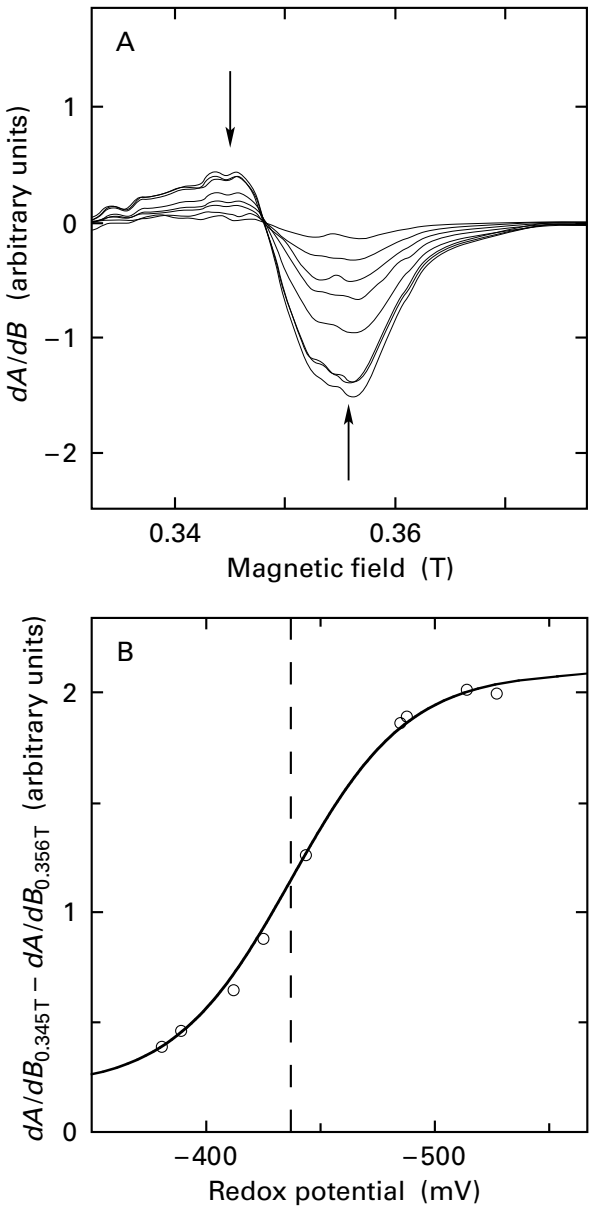

Figure 2–28: Potentiometric titration of the [4Fe–4S] iron–sulfur cluster in lysine 2,3-aminomutase from *C. subterminale*.[595] A solution (1 mL) of the enzyme (40 μM in active sites) in 42 μM *S*-adenosyl-L-methionine, 200 mM KCl, 100 μM of the mediator 4,4′-dimethyl-1,1′-trimethylene-2,2′-dipyridyl bromide, 100 μM of the mediator 1,1′-trimethylene-2,2′-dipyridyl bromide, and 150 mM *N*-(2-hydroxyethyl)piperazine-*N*′-3-propanesulfonate at pH 8.0 was added to the chamber of an of an apparatus at room temperature that permitted the solution to be in contact with a gold electrode poised at a particular potential. After equilibrium was reached between the electrode and the [4Fe–4S] iron–sulfur clusters in the solution, a portion of the solution was immediately frozen, and its electron paramagnetic resonance spectrum was recorded. **(A)** The spectra produced by the apparatus are plots of the first derivative (dA/dB) of the absorption (A; in arbitrary units) of microwave electromagnetic energy, at the fixed carrier frequency of 9.256 GHz, as a function of the flux density of the applied magnetic field (B; in Tesla). The magnetic field was varied from 0.29 T to 0.39 T. **(B)** The differences between the first derivatives (dA/dB) at 0.345 T and the first derivatives (dA/dB) at 0.356 T, which are measures of the concentration of unpaired electrons in the solution, are plotted as a function of the reduction potentials (millivolts) to which each solution was brought to equilibrium before it was frozen. Equation 2–91 was fit to the data (solid curve). The parameters obtained from the fit were the magnitude of the difference at full oxidation, 0.39 ± 0.14; the magnitude of the difference at full reduction, 4.18 ± 0.05; and the biochemical standard reduction potential of the [4Fe–4S] iron–sulfur cluster, -437 ± 5 mV (vertical dashed line). Adapted with permission from reference 595 Copyright 2006 American Chemical Society.https://doi.org/10.1021/bi0519497

Hemes also display electron paramagnetic spectra arising from the unpaired electron in the oxidized ferric form, and potentiometric titrations can be performed by monitoring the intensity of this signal. Most ferric hemes have the central unsplit absorption of their unpaired electron at around $g = 2.29$ and cannot be distinguished in this range, but the different hemes in a protein that contains more than one heme can often be distinguished because each will have characteristic absorptions arising from differences in hyperfine coupling, and each can be potentiometrically titrated independently by monitoring its characteristic hyperfine absorption.[759] Likewise, differences in hyperfine couplig permit the different iron–sulfur clusters in a protein to be distinguished[562] and potentiometrically titrated individually.[760,761] A drawback of using electron paramagnetic resonance to follow a titration is the requirement for much larger quantities of prosthetic group to gather the required data. It is also possible to use both visible spectra and electron paramagnetic spectra in concert to monitor the individual potentiometric titrations of the different prosthetic groups in the same protein.[643]

Cyclic voltammetry is also used to determine the biochemical standard reduction potential of a prosthetic group that participates in a redox couple. In a cyclic voltammogram (Figure 2–29),[762] the current entering or leaving an electrode suspended in a solution is monitored as a function of the potential of that electrode. The initial solution contains a certain concentration of the fully oxidized or the fully reduced prosthetic group within its protein. If the prosthetic group is fully oxidized, the initial potential of the electrode is made sufficiently positive that negligible

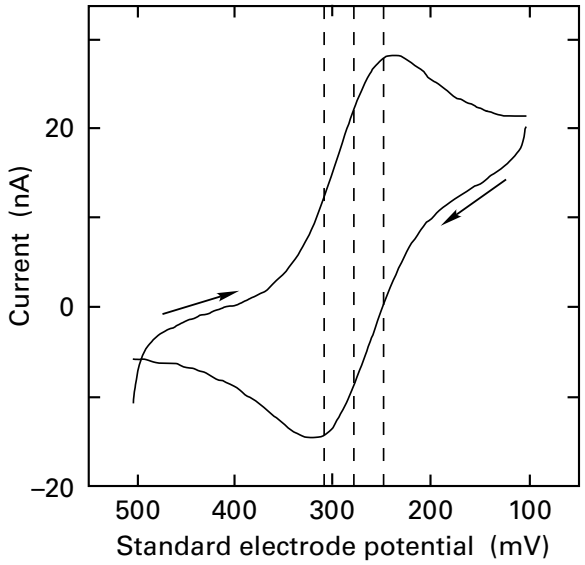

Figure 2–29: Cyclic voltammogram of the prosthetic copper ion in isoform 2 of azurin from *Methylomonas*.[762] A solution of the protein in 0.1 M potassium phosphate at pH 7.0 was added to the chamber of a voltammometer in which there were a Ag/AgCl reference electrode, a platinum wire counter electrode, and a working electrode with a smooth surface of gold that had been modified with bis(4-pyridyl)disulfide. The chamber was flushed with argon. The voltage was then scanned between +300 and −100 mV at 2 mV s^{-1} and then back again, as indicated by the arrows, and the current at the working electrode (nanoamperes) was monitored as a function of its standard potential (millivolts). The two outer vertical dashed lines indicate, respectively, the positions of the maxima of positive and negative current when background has been subtracted from the data for the two sweeps. The distance between these two vertical lines is 60 mV, a number indicating that the apparatus is monitoring a one-electron oxidation–reduction. The central dashed line is halfway between the outer two and is at the biochemical standard reduction potential (+280 mV) of the copper ion in the azurin. Adapted with permission from reference 762, Journal of Biological Inorganic Chemistry, Copyright 1999 Springer Nature. https://doi.org/10.1007/pl00010653

reduction of the prosthetic group occurs. The potential of the electrode is then decreased from the initial value at a certain linear rate (volts $second^{-1}$) until it is significantly more negative than the reduction potential of the prosthetic group. It is then immediately increased at the same rate back to the initial potential, and the full cycle is then repeated until the measurements are reproducible. If the prosthetic group is fully reduced, the initial potential of the electrode is made more negative than its standard reduction potential and is increased at a certain linear rate and then decreased.

Assume that the prosthetic group is initially oxidized and the potential of the electrode is being lowered. At the immediate surface of the electrode, if the rate of the voltage change is slow enough, the concentrations of the oxidized and reduced forms of the prosthetic group will be at the equilibrium appropriate to the voltage at the surface, as determined by Equation 2–91. Initially, if the potential of the electrode is high enough, the concentration of the oxidized form at equilibrium will be its concentration in the solution. As the potential of the electrode decreases, the concentration of the oxidized form of the prosthetic group at the immediate surface of the electrode will decrease below its concentration in the solution. The current due to this decrease will be negligible, but the decrease in the concentration of the oxidized form at the immediate surface of the electrode will create a **concentration gradient** of the oxidized form between the surface of the electrode and the rest of the solution containing the oxidized form at a constant concentration.[763,764] A diffusive flux of the oxidized form will move down this concentration gradient, delivering the oxidized form to the electrode by simple diffusion. Its reduction transfers electrons to the electrode. This **diffusive flux** of the oxidized form down the concentration gradient to the surface of the electrode and its subsequent reduction produces the observed current.

The concentration gradient increases as the voltage decreases, and the concentration of oxidized form at the immediate surface of the electrode becomes smaller and smaller. When the potential of the electrode, however, passes through the reduction potential of the prosthetic group and becomes significantly less than its reduction potential, the concentration of the oxidized form at the immediate surface of the electrode becomes essentially zero and, consequently, invariant. The concentration gradient then decreases as more and more of the oxidized form in the solution surrounding the electrode is consumed, and the current then decreases even though the potential of the electrode is still decreasing.

During a negative sweep such as the one just described, if the oxidation–reduction at the surface of the electrode is always at equilibrium as the voltage is changing[762] and if the diffusion coefficients of the oxidized and reduced forms of the redox couple are the same, **the peak of the current due to reduction of the prosthetic group** (Figure 2–29) under the conditions of the experiment occurs at a potential at a distance $(1.109 \pm 0.002)\ RT(nF)^{-1}$ below the reduction potential of the redox couple,[765]

which at 25 °C is 28.5/n mV. The diffusive current at this peak, i_p (amperes), that arises from only the reduction of the oxidized prosthetic group diffusing to the electrode is defined by the equation

$$i_p = 0.4463\, nFAC\left(\frac{nFvD}{RT}\right)^{1/2} \qquad (2\text{–}173)$$

where A is the surface area (centimeters^2) of a planar electrode, C is the initial concentration (moles centimeter^{-3}) of oxidized prosthetic group in the solution, D is its diffusion coefficient (centimeters^2 second^{-1}), and v is the rate (volts second^{-1}) at which the potential of the electrode is decreasing.[763-766] Both the dimensionless constant 1.109 (given earlier in the text) and the dimensionless constant 0.4463 (Equation 2–173) are the products of terms arising from the diffusion equations.

Upon the positive, return sweep of voltage (Figure 2–29), all the same things happen in reverse, and a peak of current of the opposite sign but of the same magnitude is observed with its maximum at a distance (1.109 ± 0.002) $RT(nF)^{-1}$ above the reduction potential of the redox couple, again only if the oxidation–reduction at the surface of the electrode is always at equilibrium as the voltage is changing. If the oxidation–reduction is fully reversible, successive sweeps should give superposable traces of current.

A cyclic voltammogram provides **several pieces of information** (Figure 2–29). First, if the current in the reverse direction is centrosymmetric to that in the forward direction, as it is in Figure 2–29, and currents in successive sweeps are superposable, the **oxidation–reduction is reversible**. Second, if the oxidation–reduction is reversible and the currents are centrosymmetric, the **reduction potential** of the redox couple is halfway between the potentials at which the two peaks of current occur, at the same potential as that of the point of centrosymmetry. Third, if the oxidation–reduction is reversible, if the oxidized and reduced forms of the prosthetic group are at equilibrium with the potential of the electrode at all voltages, and if the current observed is corrected for background currents that are not due to the redox couple by performing voltammetry on an identical solution not containing the redox couple, then the distance between the maxima of the two peaks (outer vertical dashed lines in Figure 2–29) should be 57/n mV, so this distance provides a determination of n, **the number of electrons involved in the oxidation–reduction**.[767] If the system does not remain at equilibrium as the voltage is decreased or increased, this distance will be greater than 57/n mV, so if it is not too much greater, the value of n can still be determined because n must be an integer. Fourth, if the current observed is corrected for background currents, the corrected current at its peak, which should arise only from the diffusion of oxidant or reductant to the electrode, can be used to estimate the **diffusion coefficient of the protein** containing the prosthetic group.[762,766] From the cyclic voltammogram of isoform 2 of azurin from *Methylomonas* (Figure 2–29), it could be concluded that the oxidation–reduction of the prosthetic copper ion was reversible, that its biochemical standard reduction potential was +280 mV, that only one electron was involved in the oxidation–reduction (ΔE = 61 mV), and that the diffusion coefficient of the azurin was 6×10^7 cm^2 s^{-1}. By varying the rate of the potential sweep and demonstrating that the peak current is directly proportional to its square root (Equation 2–173), it is also possible to show that the current due to the oxidation–reduction is encounter-controlled,[766] a property that is necessary if an accurate diffusion coefficient is to be measured.

Cyclic voltammetry can also be used to determine the same information for hemes in cytochromes[768] and iron–sulfur clusters in ferredoxins and other proteins.[769] If there are several prosthetic groups in a protein,[770] each produces its own individual peak of current on the same cyclic voltammogram. If the several peaks of current overlap too closely, the contributions of the individual prosthetic groups to the cyclic voltammogram can be resolved by eliminating successively each of the prosthetic groups but one by site-directed mutation, performing cyclic voltammetry on each mutant to determine the reduction potential of each prosthetic group in isolation from the others, and then showing that the individual peaks of current sum to give the cyclic voltammogram of the unmutated protein.[771]

Cyclic voltammetry of isoform 2 of azurin from *Methylomonas* was so successful because it is a small protein (124 aa)* with a large diffusion coefficient. One of the drawbacks of cyclic voltammetry arises from the slower rates of diffusion for larger molecules of protein. These slow rates produce smaller currents at the same molar concentration, so they require that higher molar concentrations (0.1 μM–1 mM) of a large protein be used, which is a practical limitation.

*The abbreviation aa is for "amino acids".

In one widely used variation of cyclic voltammetry, which overcomes the requirement for high concentrations of protein, **a thin film of the protein can be adsorbed to the electrode**.[772-774]

There are several ways to produce this thin film on the surface of the electrode. The electrode can be modified so that it has covalently attached amino groups or carboxy groups to which the protein can be attached covalently by amide linkages to carboxy groups or amino groups, respectively, on its surface. The surface of the electrode can be modified so that it is hydrophobic and can absorb hydrophobic patches on the surface of the protein. Fixed molecular elementary charges can also be attached to the surface of the electrode to form a layer of fixed charge. This fixed charge retains the molecules of the protein adjacent to the surface by ion exchange.[775] In each instance, the layer containing the protein is so thin that very little protein is necessary for accurate measurements [on the order of 1 pmol (cm^2 of electrode surface)$^{-1}$].

When cyclic voltammetry is performed on these films, the peaks of current in the forward and reverse directions are still centrosymmetric about the reduction potential of the prosthetic group, but their separation depends on the rate of the sweep in voltage,[776,777] a fact that precludes using the separation to define n, the number of electrons involved in the oxidation–reduction being observed. The number of electrons involved in the oxidation–reduction, however, is proportional to the square of the current at the electrode, i_e^2, and inversely proportional to the peak width at half-height, two independent relationships that can be used to determine the value of n. Because the film contains so little of the protein and its stoichiometric prosthetic group and because the currents measured are from the direct reduction or oxidation of only the prosthetic groups in the protein at the surface rather than arising from the continuous diffusion of prosthetic groups from the bulk solution, the peaks of current due to the oxidation or reduction of the prosthetic group at the surface are quite small and the ratio between the signal and the background is much less, a fact requiring accurate measurement and careful subtraction of background from the signal.[778-780]

The advantage of using a film of protein is that the diffusive currents are almost eliminated, and as a result, the peaks of current are narrower and almost symmetrical. This property permits the peaks from several different prosthetic groups to be examined simultaneously[715,779,781] or permits the investigator to step through several different oxidation states of the same prosthetic group[640] in the same voltammogram. The disadvantage of this procedure is that the protein is not in free solution, so there is always the possibility of denaturation at the surface or steric effects.

The prosthetic groups that are one-electron redox couples are incorporated into electron-transferring coenzymes and enzymes that catalyze oxidation–reductions, and they transfer electrons between or within these enzymes. With few exceptions—the quinones such as ubiquinone, which are often prosthetic groups but are usually free solutes dissolved in a membrane; flavins, which are usually prosthetic groups but in occasional situations are coenzymes in free solution; and L-ascorbate, which is always a free solute—the various prosthetic groups involved in one-electron transfer in living organisms are always tightly bound to particular proteins. Pheophytins and chlorophylls are bound noncovalently in the active sites of proteins but are surrounded so extensively by the polypeptide that they remain attached to the protein over its lifetime. Iron–sulfur clusters do not exist outside proteins and are covalently bound through the cysteines. The hemes of hemoproteins can also be covalently bound through peripheral locations on the heme, as in the case of cytochrome *c* (Figure 2–22 and **2–72**), but in most hemoproteins they are noncovalently bound by the polypeptide that embraces them, and they never leave the protein in which they are enclosed during its lifetime.* Prosthetic copper ions are coordinated to the ligands provided by the polypeptide of the protein and are usually bound covalently to the sulfur of a cysteine (Figure 2–26). Even quinones such as ubiquinone, which are usually free solutes in the membrane, are tightly bound when they are functioning as prosthetic groups at particular locations in a protein, and they may or may not exchange occasionally over the lifetime of the protein. The proteins to which these prosthetic groups participating in the transfer of single electrons are permanently or almost permanently bound vary considerably in their sizes, locations within the cell, complexities, and roles in metabolism.

The largest of these proteins are **enzymes that participate in electron transport chains** and catalyze the transfer of electrons between two widely separated locations. These enzymes are embedded

*In fact, heme that escapes from protein is toxic.[782]

in biological membranes and are large enough to dwarf the phospholipid bilayers that they span. They vary in size from the reaction centers of photosynthetic bacteria, which have asymmetric units of three different subunits and a total of 850 amino acids,[783] to mammalian NADH:ubiquinone reductases (H^+-translocating) with asymmetric units of 45 different subunits and a total of more than 8000 amino acids.[784] The membranes in which these enzymes are dissolved are plasma membranes of bacteria, the inner membranes of mitochondria, the chromatophores of bacteria, and the thylakoids of chloroplasts.

There are also **enzymes that are dissolved in the cytoplasm** or other aqueous phases within the cell and that are responsible for oxidation–reductions. These enzymes are fairly large because they often contain several of the prosthetic groups for one-electron transfers involved in the oxidation–reductions for which they are responsible. Typical asymmetric units for these enzymes vary in size from a single subunit with 300 amino acids to three different subunits with a total of 1200 amino acids.

Operating as lighters among these argosies are small proteins that act as coenzymes responsible for transferring electrons between these large proteins by diffusing rapidly through the cytoplasm or another cellular space or by diffusing over a biological membrane. These small **electron-transferring coenzymes** rapidly associate with and dissociate from the large enzymes and, depending on the circumstances, can either enter or leave with the electron that they are responsible for carrying.

The small electron-transferring coenzymes use prosthetic flavins, prosthetic iron–sulfur clusters, prosthetic hemes, and prosthetic copper ions as carriers of single electrons.

Flavodoxin and **electron-transferring flavoprotein** are small and not-so-small electron-transferring coenzymes, respectively, that each have a single flavin within themselves.[785,786] Flavodoxins are usually monomeric proteins with 140–170 amino acids,[787] and electron-transferring flavoproteins are usually heterodimers with about 600 amino acids in the asymmetric unit.[788] Flavodoxins stabilize the neutral flavin semiquinone significantly, so the biochemical standard reduction potential for the redox couple of neutral oxidized flavin and neutral flavin semiquinone is –240 to –180 mV and that for neutral flavin semiquinone and reduced flavin anion is –500 to –370 mV (Figure 2–19).[789,790] The fact that the former standard reduction potential is so much more positive than the latter, unlike the situation with free flavin (Figure 2–15), favors one-electron transfer, usually that between the redox couple of neutral oxidized flavin and neutral flavin semiquinone (Figure 2–9).[791] If, however, the reductant is strong enough the redox couple of neutral flavin semiquinone, which is created by the first electron, and neutral reduced flavin is available to accept a second electron.[789] If the second electron is accepted, the reduction becomes a two-electron reduction rather than a one-electron reduction. Unlike flavodoxin, electron-transferring flavoprotein stabilizes the anionic semiquinone of its flavin, which cannot be reduced further (Figure 2–9), and usually cycles as an electron-transferring coenzyme between neutral oxidized flavin and anionic flavin semiquinone, a one-electron redox couple with biochemical standard reduction potentials of –200 to 0 mV in these proteins (Figure 2–19).[790]

Rubredoxins and ferredoxins are small, water-soluble proteins with iron–sulfur centers. Rubredoxins are usually monomeric but can be oligomeric,[549] and their monomer or subunit contains 45–60 amino acids and a single iron ion.[551,792] Ferredoxins are monomeric proteins that usually have 60–120 amino acids, but there are a few large ferredoxins resulting from multiple gene duplications with as many as 10 iron–sulfur clusters and 250 amino acids.[793,794] The small unmultiplicated ferredoxins have either a single [2Fe–2S] iron–sulfur cluster,[795] a single [4Fe–4S] iron–sulfur cluster,[598] two [4Fe–4S] iron–sulfur clusters,[796,797] or a [4Fe–4S] iron–sulfur cluster and a [3Fe–4S] iron–sulfur cluster[634] covalently attached to the protein through cysteines. The biochemical standard reduction potentials of the [2Fe–2S] ferredoxins are in the range –450 to –175 mV, and those of the [4Fe–4S] ferredoxins are in the range –600 to –400 mV (Figure 2–19). In the ferredoxins with two [4Fe–4S] iron–sulfur clusters, each iron–sulfur cluster usually accepts an electron independently of the oxidation state of the other iron–sulfur cluster at essentially the same biochemical standard reduction potential, and the protein is able to carry two electrons, one on each iron–sulfur cluster.[798]

There are **small, water-soluble cytochromes**, such as cytochrome *c*, and there are also small anchored, membrane-bound cytochromes, such as cytochrome b_5, that act as small electron-transferring coenzymes between larger enzymes. Cytochrome b_5

can diffuse rapidly over the membrane of the endoplasmic reticulum while carrying an electron between enzymes also located in this membrane. Although there are water-soluble cytochromes containing hemes *b* that are small electron-transferring coenzymes,[799] most of the cytochromes that perform this function contain hemes *c*. These cytochromes *c* are usually, but not always,[800] monomeric proteins. They usually contain 80–140 amino acids, but there are examples of larger cytochromes *c* that are the products of gene duplication.[690] Most cytochromes *c* contain a single heme *c* (Figure 2–22),[801] but some contain more than one heme *c*.[802] The cytochromes *c* that are the products of gene duplication contain two hemes in two separate superposable domains.[803] There are also small unduplicated cytochromes *c* with three closely opposed hemes (70 aa)[804,805] and four hemes (120 aa)[806,807] and a larger membrane-bound cytochrome *c* with four hemes.[808] The hemes *c* in the cytochromes *c* have biochemical standard reduction potentials between –410 and +450 mV (Figure 2–19), which is the broadest range for the small electron-transferring coenzymes. One of the most negative biochemical standard reduction potentials is for one of the hemes *c* in cytochrome c_3, where its four hemes are in such close proximity that the reduction of each heme in turn decreases the biochemical standard reduction potential of the next to be reduced.[809]

The **small electron-transferring coenzymes containing prosthetic copper ions** are usually monomeric proteins but can be homooligomers.[810] Their monomers or subunits contain 90–200 amino acids. Although most are in free solution in one of the aqueous phases in a cell, a few are membrane-bound,[811] presumably diffusing between their donors and acceptors within the same membane. Their range of biochemical standard reduction potential is the same as that for prosthetic copper ions in general (Figure 2–19). Although, for historical reasons, they have many different names—such as amicyanins, auracyanins, azurins, halocyanins, mavicyanins, nitrosocyanins, phytocyanins, plastocyanins, pseudoazurins, rusticyanins, stellacyanins, sulfocyanins, and umecyanins—these small electron-transferring coenzymes with single prosthetic copper ions are all related to each other.[705,742] Within the sequence of amino acids for each member of this group of proteins, one of the histidines that coordinates the copper ion is 35–66 amino acids amino-terminal to the cysteine to which that copper ion is covalently bound; the other histidine is 3–8 amino acids and the methionine is 5–12 amino acids carboxy-terminal to the cysteine. Although they all seem to be the same protein found in the same or different species of organisms, they are nevertheless distinguished from each other because they are specific to the particular enzymes between which they carry electrons. For example, amicyanin accepts single electrons from methylamine dehydrogenase (amicyanin),[812] plastocyanin accepts single electrons from plastoquinol—plastocyanin reductase, azurin accepts single electrons from nitrite reductase (NO-forming),[813,814] amicyanin accepts single electrons from cytochrome *c*-551*i*,[745] and plastocyanin accepts single electrons from photosystem I. The names often reflect the function or location of one of their partners in the transfer of an electron.

Even though each type has its more limited range, as a group the various small electron-transferring coenzymes containing flavins, iron–sulfur clusters, hemes, or prosthetic copper ions provide biochemical standard reduction potentials that span continuously the range from –600 to +740 mV (Figure 2–19), which is almost coincident with the range from the ferredoxin that accepts[815,816] the excited electron from an iron–sulfur center (–550 mV) in photosystem I to molecular oxygen, the strongest biological oxidant (+820 mV) unbound to protein. Within this biological range are all the standard reduction potentials of the prosthetic groups in the enzymes of biological oxidation–reduction that donate electrons to or accept electrons from these small electron-transferring coenzymes.

There are a number of enzymes, both soluble in the aqueous phases within a cell and embedded in cellular membranes, that catalyze the oxidation or reduction of a particular substrate and the subsequent reduction or oxidation, respectively, of one of the small electron-transferring coenzymes by passing single electrons among prosthetic groups within themselves. For example, the flavin in L-lactate dehydrogenase (cytochrome) from *S. cerevisiae*[817,818] or *Wickerhamomyces anomalus*[819]

$$\text{L-lactate} + 2\ \text{ferricytochrome } c \rightleftharpoons 2\ \text{H}^+ + \text{pyruvate} + 2\ \text{ferrocytochrome } c \qquad (2\text{–}174)$$

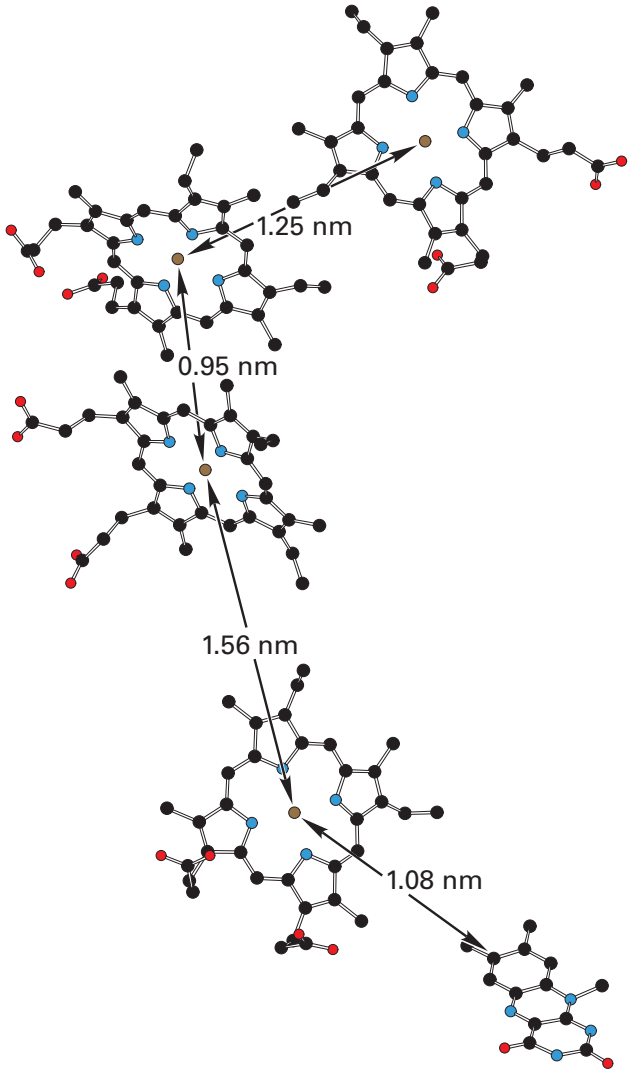

Figure 2–30: Disposition of flavin and four hemes *c* in the crystallographic molecular model of fumarate reductase from *S. frigidimarina*.[456] Black atoms are carbons, red atoms are oxygens, blue atoms are nitrogens, and rusty brown spheres are iron ions. When *S. frigidimarina* is grown under anaerobic conditions, the biosynthesis of this particular fumarate reductase is induced because the purpose of the enzyme is to dispose of the excess electrons from anaerobic glycolysis by reducing fumarate to succinate. The gene for the enzyme was transferred to a plasmid and expressed at a high level in cells of *Shewanella*. The enzyme was purified from the expression system and crystallized. The drawing[50] is of the flavin and the four hemes *c* in the resulting crystallographic molecular model. The distances between the iron ions in the adjacent hemes are noted, as well as the distance from the iron ion in the closest heme to the π molecular orbital system of the flavin.

when it is playing its normal role in metabolism, oxidizes lactate to pyruvate by hydride transfer, and then the resulting two electrons in the reduced flavin are transferred one at a time to a heme *b*, also in the enzyme. From the heme *b*, each electron is transferred to a small, electron-transferring coenzyme, the cytochrome *c* (109 aa in both) in the cytoplasm of each of these two fungi, when it is transiently bound to the L-lactate dehydrogenase (cytochrome).[818,819] Each molecule of ferrocytochrome *c* dissociates from L-lactate dehydrogenase (cytochrome) following its reduction and is eventually replaced on its binding site by a molecule of ferricytochrome *c*, which can then be reduced in turn. One of the intermediate steps in this reaction is

$$H_2Fl^-_{red} + \text{heme } b_{ox} \rightleftharpoons H_2Fl^{\cdot} + \text{heme } b_{red} \qquad (2\text{–}175)$$

in which the stability of the flavin semiquinone is used to accomplish the transfer of only one electron from the flavin to the heme *b*, which can only accept one electron at a time. After the first electron has been passed on to a molecule of cytochrome *c*, the flavin semiquinone then passes the second electron to the heme *b*.

In fumarate reductase from *Shewanella oneidensis* [820] or *Shewanella frigidimarina*,[456,821] when it is playing its normal role in metabolism, the heme *c* on cytochrome CymA, a small electron-transferring coenzyme in the cytoplasm of the bacterium, provides one electron at a time, and each electron is passed consecutively through four hemes *c*,[821] which are covalently bound to the enzyme as prosthetic groups (Figure 2–30),[456] to a flavin also in the enzyme. The flavin joins the electrons in pairs and uses them to reduce fumarate to succinate in a hydride transfer.[822]

In the normal directions of catalysis in the cytoplasm, L-lactate dehydrogenase (cytochrome) uses the flavin in its active site to sunder two electrons, and fumarate reductase uses the flavin in its active site to join two electrons. When these enzymes are catalyzing their reactions in the reverse direction, the flavin in L-lactate dehydrogenase (cytochrome) joins two electrons, and the flavin in fumarate reductase splits two electrons.

Unlike the examples of L-lactate dehydrogenase (cytochrome) and fumarate reductase, it is often the case that, even though one of these enzymes with

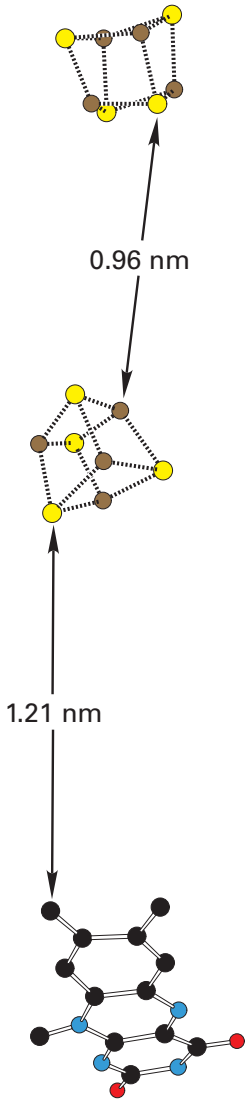

Figure 2–31: Disposition of flavin and two [4Fe–4S] iron–sulfur clusters in the crystallographic molecular model of adenylyl-sulfate reductase from *A. fulgidus*.[377] Black atoms are carbons, red atoms are oxygens, and blue atoms are nitrogens. In the iron sulfur clusters, yellow spheres are sulfides, and rusty brown spheres are iron ions. The enzyme was purified and crystallized in a glove box under strictly anaerobic conditions from cells of *A. fulgidus* that had been cultivated under anaerobic conditions. The distance between the iron–sulfur clusters is noted, as well as the distance from the closest iron–sulfur cluster to the flavin.

multiple prosthetic groups has been purified and extensively characterized, the small electron-transferring coenzyme that provides or removes the electrons during its reaction within the cell is as yet unknown. For example, it was only after many years that the previously[823] **unknown electron acceptor** that removes electrons one at a time from the heme *b* in cellobiose dehydrogenase (acceptor) was identified as another enzyme, lytic cellulose monooxygenase (C4-dehydrogenating), for which cellobiose dehydrogenase (acceptor) provides electrons.[824-826] The heme *b* in cellobiose dehydrogenase (acceptor) in turn removes electrons one at a time from the flavin after it has been reduced by transfer of a hydride during the dehydrogenation of cellobiose to cellobiono-1,5-lac-tone.[823] The identity of the immediate electron donor that provides electrons one at a time to the two [4Fe–4S] iron–sulfur clusters in adenylyl-sulfate reductase from *A. fulgidus* (Figure 2–31) is still unclear.[377] These electrons are passed along one at a time to regenerate the reduced flavin from the oxidized flavin produced upon dissociation of the sulfite from adduct **2–50** during the reduction of adenylyl sulfate (Equation 2–125). Recent studies of mutants suggest that the ultimate source of the electrons is the multiheme cytochrome *c* subunit of menaquinone reductase Qrc in the plasma membrane of the bacterium,[827] but whether that enzyme provides the electrons directly or by reducing an electron-transferring coenzyme which then reduces the peripheral [4Fe–4S] iron–sulfur cluster in adenylyl-sulfate reductase is unknown at the moment. As the experience with cellobiose dehydrogenase illustrates, the natural donor or acceptor of electrons from a particular enzyme, if it is unknown at first, is usually ascertained later on.

When the natural electron donor or acceptor for a particular enzyme that catalyzes an oxidation–reduction in which electrons are transferred one at a time is not known, an **adventitious donor or acceptor** can usually be discovered. In the case of cellobiose dehydrogenase (acceptor) from *Phanerochaete chrysosporium*, either 2,6-dichloroindophenol or equine cytochrome *c* can act as an acceptor of the electron in an assay of the enzyme,[823] while in the case of adenylyl-sulfate reductase from *A. fulgidus*, ferricyanide is used routinely as the one-electron donor in the assay for the enzyme.

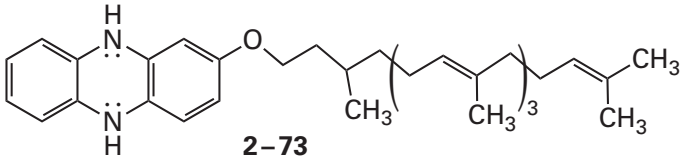
There is a family of related enzymes to which dimethyl sulfide:cytochrome c_2 reductase belongs. Each member of this family transfers electrons removed from their respective substrate, dimethyl sulfide in the case of dimethyl sulfide:cytochrome c_2

reductase, through a chain of four [4Fe–4S] iron–sulfur clusters to a prosthetic heme *b* on the enzyme. One might expect that the midpoint potentials of the [4Fe–4S] iron–sulfur clusters would increase as the electron moved from one cluster to the next to encourage efficient transfer of the electron. The midpoint potentials in sequence, however, for dimethyl sulfide:cyto-chrome c_2 reductase from *Rhodovulum sulfidophilum* are +180, −340, +70, and +300 mV. Several of the other enzymes of the family show the same unexplained pattern.[828]

In several enzymes, **one or more one-electron carriers sit between two flavins**. In one direction, one of the flavins splits two electrons and the other ultimately joins them; in the opposite direction, the roles are reversed. For example, in dihydroorotate dehydrogenase (NAD^+) from *L. lactis*, one of the prosthetic flavins removes two electrons from dihydroorotate, oxidizing it to orotate. The reduced flavin passes the electrons one at a time to a [2Fe–2S] iron–sulfur cluster, from which they are transferred to another flavin in the protein that joins them in pairs and then reduces NAD^+ to NADH.[829,830] One of the flavins in porcine dihydropyrimidine dehydrogenase ($NADP^+$) is reduced by transfer of a hydride from either 5,6-dihydrouracil or 5,6-dihydrothymine during its oxidation to uracil or thymine, respectively, and the reduced flavin then passes the electrons one at a time to a [4Fe–4S] iron–sulfur cluster in the protein. From this iron–sulfur cluster, each electron is passed consecutively through three more [4Fe–4S] iron–sulfur clusters to another flavin in the enzyme that joins them in pairs and uses them to reduce $NADP^+$ to NADPH.[478,831] The single flavin in trimethylamine dehydrogenase from *Methylophilus methylotrophus* oxidizes trimethylamine to dimethylamine and formaldehyde. The reduced flavin passes the resulting two electrons one at a time to a [4Fe–4S] iron–sulfur cluster in the enzyme, from which they are transferred one at a time to a flavin not in the protein but in the electron-transferring coenzyme, electron-transferring flavoprotein.[832]

There are many enzymes that **perform two-electron oxidation–reductions of their substrates by transferring single electrons one after the other among one-electron prosthetic groups** without the necessity for flavin to join or split a pair of electrons or transfer a hydride. For example, there are two homologous enzymes, dihydromethanophenazine:CoB-CoM heterodisulfide reductase from *M. thermophila*[643] and H_2:CoB-CoM heterodisulfide,ferredoxin reductase from *M. thermolithotrophicus*,[642] which must use the same mechanism to reduce the heterodisulfide between 2-sulfanylethanesulfonate (coenzyme M; HSCoM) and *N*-[(7-sulfanyl)heptanoyl]-L-threonine *O*-phosphate (coenzyme B, HSCoB). The former enzyme contains two [3Fe–3S–Fe–S] iron–sulfur clusters (**2–67**) and is a subunit in a stable, membrane-embedded heterodimer the other subunit of which contains two hemes *b*. The latter enzyme also contains two [3Fe–3S–Fe–S] iron–sulfur clusters but is in a multienzymatic complex containing several other subunits in which there are twelve iron–sulfur clusters and a prosthetic flavin. The active site of each of the CoB-CoM heterodisulfide reductases is the two [3Fe–3S–Fe–S] iron–sulfur clusters, which are the only prosthetic groups common to both enzymes. An intermediate in the reduction of the heterodisulfide has been observed crystallographically in H_2:CoB-CoM heterodisulfide,ferredoxin reductase from *M. thermolithotrophicus* in which the sulfido group of 2-sulfanylethanesulfonate has become a fifth ligand to one of the iron ions coordinated by only two sulfides in the [3Fe–3S] portion of the [3Fe–3S–Fe–S] iron–sulfur cluster, and the sulfido group of *N*-[(7-sulfanyl)heptanoyl]-L-threonine *O*-phosphate is adjacent to an iron ion in the second [3Fe–3S–Fe–S] iron–sulfur cluster.[642] It has been proposed that the two reduced [3Fe–3S–Fe–S] iron–sulfur clusters, acting in concert, each transfer an electron to the disulfide and that, during the reduction, 2-sulfanylethanesulfonate ends up as a ligand to the iron ion.

Following the reduction of the heterodisulfide, the two resulting oxidized [3Fe–3S–Fe–S] iron–sulfur clusters in dihydromethanophenazine: CoB-CoM heterodisulfide reductase from *M. thermophila* receive electrons from the two hemes *b* in the other subunit. These hemes *b* receive the electrons in turn one at a time from the electron-transferring coenzyme, dihydromethanophenazine

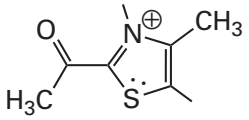


2–73

dissolved in the plasma membrane,[643] which presumably passes through a semiquinone intermediate. The two resulting oxidized [3Fe–3S–Fe–S] iron–sulfur clusters in H_2:CoB-CoM heterodisulfide, ferredoxin reductase from *M. thermolithotrophicus* receive electrons passed through six iron–sulfur clusters, the prosthetic flavin, and then three iron–sulfur clusters. These electron-transferring prosthetic

groups are located in three other subunits in the multienzymatic complex. The electrons are ultimately derived from the reduction of molecular hydrogen to two hydrons and two electrons.

In pyruvate synthase from *Desulfocurvibacter africanus*, the electron-poor adduct 2-acetylthiamine diphosphate



2–74

formed by a nucleophilic substitution at the acyl carbon of acetyl-SCoA by the ylide of thiamine diphosphate, accepts electrons one at a time, with a thiamine radical (Figure 2–7) as an intermediate, from a [4Fe–4S] iron–sulfur cluster in the protein. This [4Fe–4S] iron–sulfur cluster receives electrons one at a time from two other [4Fe–4S] iron–sulfur clusters, the two [4Fe–4S] iron–sulfur clusters in a reduced ferredoxin, associated reversibly with the enzyme, that brings the electrons in.[833]

The large membrane-spanning enzymes that catalyze transfers of electrons in the electron transport chains in bacterial cells, mitochondria, chromatophores, and chloroplasts differ from these water-soluble enzymes of oxidation–reduction because each membrane-spanning enzyme is able to conserve a portion of the free energy of its respective exergonic transfer of an electron. The donor of the electron or pair of electrons to each of these membrane-bound enzymes has a significantly more negative biochemical standard reduction potential than the oxidant that accepts those electrons. For example, the biochemical standard reduction potential of NADH is –310 mV, that of ubiquinone or plastoquinone dissolved as a solute in a phospholipid bilayer is +100 mV, that of mammalian cytochrome *c* is +260 mV, that of the blue copper protein plastocyanin[834,835] is +380 mV, and that of molecular oxygen is +820 mV (Figure 2–19). In these electron transfers, ubiquinone, plastoquinone, cytochrome *c*, and plastocyanin are electron-transferring coenzymes. NADH:ubiquinone reductase (H^+-translocating) transfers two electrons from NADH to ubiquinone; quinol—cytochrome-*c* reductase and its cousin, plastoquinol—plastocyanin reductase, transfer two electrons from ubiquinol or plastoquinol to two cytochromes *c* or two plastocyanins (Figure 2–26D), respectively; and cytochrome-*c* oxidase transfers four electrons from four cytochromes *c* to molecular oxygen. The differences in biochemical standard reduction potential among these steps (150–570 mV) translate into differences of free energy of –14 to –54 kJ for every mole of electrons passing through each of these enzymes. The energy is conserved and used for a number of purposes such as the synthesis of $MgATP^{2-}$ or the transport of metabolites against their concentration gradient across the membrane of a bacterial cell, the inner membrane of a mitochondrion, the chromatophore of a photosynthetic bacterium, or the thylakoid of a chloroplast. This energy realized by these enzymes from their respective oxidation–reductions is stored in the electrochemical gradient of hydrons across the respective membrane.

Mitochondria are the descendants of aerobic, **nonphotosynthetic bacterial cells**, and the inner membrane of a mitochondrion is the descendant of the plasma membrane of the ancestral bacterial cell. The interior of a mitochondrion, inside the boundary of its inner membrane, is the descendant of the cytoplasm of the ancestral bacterial cell. With the exception of alkaliphilic bacteria, both the interior of a mitochondrion and the cytoplasm of a bacterial cell are basic relative to the exterior of the mitochondrion and the exterior of the bacterial cell, respectively. With the exception of acidophilic bacteria, between the interior and exterior of a mitochondrion, or between the cytoplasm and the exterior of a bacterial cell, there is an electric potential, positive on the exterior and negative on the interior.

In photosynthetic bacteria other than cyanobacteria, photosynthesis occurs in chromatophores. **Chromatophores** are either invaginations of the plasma membrane or separate vesicles in the cytoplasm that arise from the pinching off of invaginations of the plasma membrane of a photosynthetic bacterium. The interior of a chromatophore in a photosynthetic bacterium is the descendant of the exterior, extracytoplasmic solution now surrounding the photosynthetic bacterium. **Chloroplasts** are the descendants of a photosynthetic bacterium. Each chloroplast has an outer membrane that is the descendant of the plasma membrane of that photosynthetic bacterium. Inside this outer membrane of a chloroplast or the plasma membrane of a cyanobacterium, there are **thylakoids**, which are flattened vesicles of membrane that are descendants of the

chromatophores that were in the ancestral photosynthetic bacteria. The interior solution inside a thylakoid is the descendant of the exterior, extracytoplasmic solution that surrounded the ancestral photosynthetic bacteria. The stromal solution or the cytoplasm surrounding the thylakoids, between them and the outer membrane of the chloroplast or the plasma membrane of a cyanobacterium, respectively, is the descendant of the cytoplasm of the ancestral photosynthetic bacterium. Because of all these ancestries, the interior of a chromatophore (or thylakoid) is acidic relative to the cytoplasmic (or stromal) solution that surrounds it, and the electric potential in the cytoplasm of a photosynthetic bacterium (or the stromal solution of a chloroplast) is negative relative to the electric potential in the interior of a chromatophore (or thylakoid).

As a consequence of this evolutionary history, the exterior surface of the plasma membrane of a bacterial cell, the exterior surface of the inner membrane of a mitochondrion, the interior surface of the membrane of a chromatophore, and the interior surface of the membrane of a thylakoid face a positive, acidic solution. The opposite surfaces of these four membranes face a negative, basic solution.*

In the process of transferring electrons from NADH or the electron-transferring coenzyme that provides the electrons to the electron-tranferring coenzyme or molecular oxygen that receives the electrons, NADH:ubiquinone reductase (H^+-translocating), ubiquinone, quinol—cytochrome-*c* reductase, plastoquinol—plastocyanin reductase, and cytochrome-*c* oxidase each transport hydrons from the negative, basic side of the respective membrane to the positive, acidic side of the membrane. The resulting current of hydrons, in the absence of the transport of any counterions, is what causes the positive, acidic side on the exterior of a mitochondrion or bacterium or the interior of a chromatophore or thylakoid to have a positive electric potential relative to the negative, basic side and to be more acidic than the negative, basic side on the interior or exterior, respectively. The sum of the free energy stored in the electric potential and the free energy stored in the gradient of hydrons together is the free energy stored in the **electrochemical gradient of hydrons**.

The electrochemical gradient of hydrons between the two sides of a cellular membrane of phospholipid produces a hydron motive force. A **hydron motive force** is a difference in the free energy of a hydron between the two sides. The hydron motive force between the exterior and interior of a mitochondrion or a bacterial cell is such that the free energy of a hydron on the exterior is more positive than the free energy of a hydron in the interior. The hydron motive force between the interior and exterior of a chromatophore or a thylakoid is such that the free energy of a hydron in the interior is more positive than the free energy of a hydron on the exterior. Consequently, when a hydron moves from the positive, acidic compartment to the negative, basic compartment in any of the cells or organelles, the free energy change is negative and favorable. This favorable free energy change is used to perform work.

The most central enzymes catalyzing these electron transfers and the associated transport of hydrons are **quinol—cytochrome-*c* reductase**[836,837] and its sibling **plastoquinol—plastocyanin reductase**.[838] The former enzyme is located in the plasma membranes of bacteria and the inner membranes of mitochondria, and it oxidizes ubiquinol to ubiquinone (**2–57**; +100 mV)[519,520,523] and reduces cytochrome *c* (Figure 2–22; +260 mV).[686] The latter enzyme is located in the membranes of chromatophores and the membranes of the thylakoids in chloroplasts, and it oxidizes plastoquinol to plastoquinone (**2–58**; +100 mV)[521,522] and reduces plastocyanin (Figure 2–26D; +380 mV).[834,835]

The **biological significance of the redox couple of ubiquinone and ubiquinol** and the redox couple of plastoquinone and plastoquinol is their ability to transfer hydrons across the membranes of mitochondria, bacterial cells, chromatophores, and chloroplasts. When one of these quinones is reduced to the quinol, two hydrons are taken up to make the neutral quinol (Equation 2–157). Those two hydrons must come from some aqueous solution. When one of these quinols is oxidized to the quinone, two hydrons are released. Those hydrons must be released into some aqueous solution. When ubiquinone is reduced to ubiquinol, the active site on the enzyme in which this reduction occurs, for example, the active site of NADH:ubiquinone reductase (H^+-translocating) in mitochondria and bacterial cells,[839-841] faces the interior of the bacterium or mitochondrion or the exterior of a chromatophore or thylakoid on the negative, basic side of the membrane that encloses each organelle or organism. This orientation causes the hydrons that add to the quinone when it is reduced to the quinol to be taken up from the more basic, more negative solution, and this uptake increases its basicity and decreases

*Exceptions to this rule are the hydron gradient in alkaliphilic bacteria and the electric gradient in acidophilic bacteria.

its electric potential. When ubiquinol is oxidized to ubiquinone or plastoquinol is oxidized to plastoquinone, the active site in the enzyme at which it is oxidized, for example, the active site in plastoquinol—plastocyanin reductase in chromatophores or thylakoids, faces the exterior of the bacterium or mitochondrion or the interior of a chromatophore or a thylakoid, which is on the positive, acidic side of the membrane enclosing each of them. This orientation causes the hydrons dissociating from the quinol as it is oxidized to the quinone to be released into the more acidic solution.

During the various reactions catalyzed by the enzymes that use them as coenzymes, two hydrons are taken up from the negative, basic solution during the reduction of ubiquinone or plastoquinone by two electrons; the ubiquinol or the plastoquinol diffuses across the membrane; two hydrons are released to the positive, acidic solution during its reoxidation; and the ubiquinone or plastoquinone diffuses back across the membrane. Because the quinone is reduced by a prosthetic group in the active site of the reductase with a more negative biochemical standard reduction potential than the prosthetic group in the active site of the oxidase by which it is later oxidized, the movement of hydrons up their electrochemical gradient from the basic interior to the acidic exterior is driven by the movement of electrons down a **gradient of standard reduction potential**. This strategy accounts for a portion of the electrochemical gradient across these membranes. This strategy works because the quinone is a weak base, the quinolate dianion is a strong base, and neither the cationic conjugate acid of the quinone nor the anionic conjugate base of the quinol is present in significant concentration—nor can they pass readily across the membrane—but it also helps that the semiquinone radical is prone to rapid disproportionation while in solution in a bilayer of phospholipids.

Although the number of different subunits in the asymmetric units in homodimeric quinol—cytochrome-*c* reductase and its homodimeric sibling plastoquinol—plastocyanin reductase differs,[665,842-845] they are clearly related to each other[844,846] and catalyze the same transfers of electrons between their respective reactants and products by passing them in the same sequence among a **Rieske [2Fe–2S] iron–sulfur cluster, two hemes *b*, and a heme *c***,[846-848] which are each bound within their own subunits within the respective enzymes.[849-856]

Plastoquinol—plastocyanin reductase, in addition to these four prosthetic groups in common with those of quinol—cytochrome-*c* reductase, has an additional heme *c*, which is covalently attached by only one sulfide linkage,[857] as well as a chlorophyll *a* and a β-carotene as prosthetic groups.[844,845,858]

The electron transfers catalyzed by these two enzymes among these prosthetic groups constitute the **Q-cycle**.[859,860] The Q-cycle adds a layer of complexity to the oxidation–reduction catalyzed by these enzymes but allows them to transport hydrons across the membranes by using only the respective quinol to carry them across. The simplest place to start in a description of the Q-cycle is the association of a molecule of the appropriate quinol with the enzyme at the quinol binding site (Q_p) facing the aqueous phase on the positive, acidic side of the membrane in which it is located (Figure 2–32).[861,862] An electron is removed from that quinol (+100 mV) by the Rieske [2Fe–2S] iron–sulfur cluster (+300 mV)[575,847] adjacent to the binding site, at the same time that two hydrons dissociate from the quinol into the aqueous phase on the positive, acidic side of the membrane. The resulting radical anion of the semiquinone, which is a much stronger reductant than the quinol, remains in the site. The radical anion of the semiquinone reorients within the binding site[863] so that it now sits next to heme b_p (–100 mV),[575] one of the two hemes *b* in the enzyme (Figure 2–32), and an electron is transferred from the radical anion of the quinone to this heme b_p.*

This sequence of events accomplishes a **bifurcation of the two electrons** by causing each of them to move on a different path. The bifurcation can be achieved because each of these prosthetic groups, the Rieske [2Fe–2S] iron–sulfur cluster and heme b_p, is only a one-electron redox couple; because the Rieske [2Fe–2S] iron–sulfur cluster has nothing in its vicinity to oxidize so that it could take up a second electron; and because only the radical anion of the semiquinone, not the quinol, is a strong enough reductant to reduce heme b_p while the quinol, although

*In many discussions of quinol—cytochrome-*c* reductase, the subscripts o and i are used for the two quinone binding sites, but these designations cannot be applied to the same sites in plastoquinol—plastocyanin reductase because these sites are on the inside and outside of this enzyme, respectively, rather than the outside and inside. Consequently, in this discussion, which emphasizes the similarities of these two enzymes, the subscripts p and n, for positive and negative, will be used for the binding sites for both quinones and the two hemes *b*.

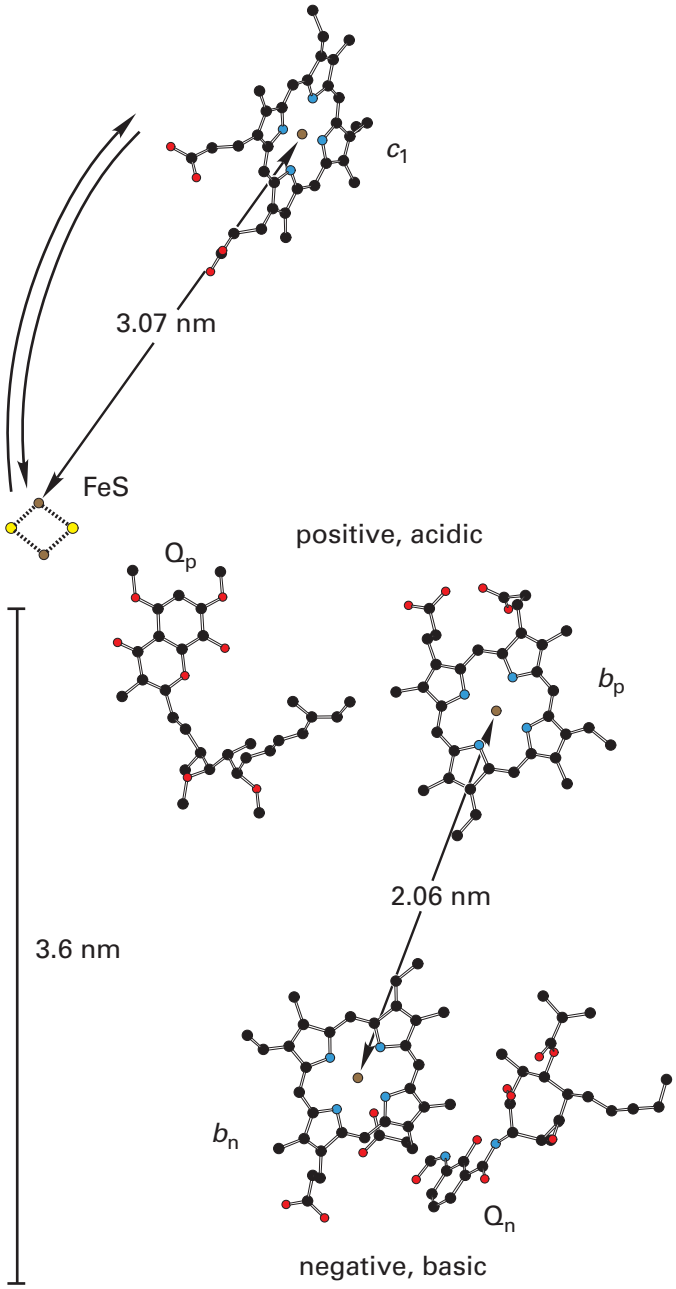


Figure 2–32: Disposition of heme *c*, the Rieske [2Fe–2S] iron sulfur cluster, two hemes *b*, and two quinones in the crystallographic molecular model of bovine quinol—cytochrome-*c* reductase.[861] Black atoms are carbons, red atoms are oxygens, and blue atoms are nitrogens. In the iron–sulfur cluster, yellow spheres are sulfides and rusty brown spheres are iron ions. Intact bovine mitochondria were dissolved in a solution of the detergent dodecyl β-D-maltopyrano-side, and quinol—cytochrome-*c* reductase was purified from the resulting solution by chromatography. Stigmatellin and antimycin A are two inhibitors of the enzyme: stigmatellin binds tightly to the quinone site Q_p on the positive, acidic side of the inner mitochondrial membrane, and antimycin A binds tightly to the quinone site Q_n on the negative, basic side of the inner mitochondrial membrane. These two inhibitors were added to a solution of the enzyme, which was then crystallized with them occupying their respective sites. In this drawing[50] of the prosthetic groups in the resulting crystallographic molecular model, the heme *c* is labeled c_1, the Rieske [2Fe–2S] iron–sulfur cluster is labeled FeS, the heme *b* on the positive, acidic side of the membrane is labeled b_p, the heme *b* on the negative, basic side of the membrane is labeled b_n, stigmatellin is labeled Q_p for the site it occupies, and antimycin A is labeled Q_n for the site it occupies. The approximate position of the planar hydrophobic core of the membrane, which is about 3.6 nm in width, is indicated with the bar. The ability of the Rieske [2Fe–2S] iron sulfur cluster to swing back and forth between heme *c* and quinone site Q_p is indicated by the double arrows. In the crystallographic molecular model, however, the Rieske [2Fe–2S] iron sulfur cluster occupies a stationary position next to quinone site Q_p. The distances between iron ions in the prosthetic groups are noted.

a weaker reductant, is nevertheless a strong enough reductant to reduce the Rieske [2Fe–2S] iron–sulfur cluster. In bovine quinol—cytochrome-*c* reductase, the rate-limiting step in this bifurcation is the removal of the first electron from the quinol by the Rieske [2Fe–2S] iron–sulfur cluster. Following this step, the reduction of heme b_p occurs immediately, so the reduction of the Rieske [2Fe–2S] iron–sulfur cluster and heme b_p occur at the same rate,[864] presumably because the radical anion of the semiquinone is such a strong, reactive reductant. Under certain circumstances, a low amount (0.01–0.1 mole fraction) of the radical anion of the semiquinone, however, can be detected after mixing quinol—cytochrome-*c* reductase from *R. capsulatus* and ubiquinol,[865] a fact that demonstrates its existence. The quinone (Equation 2–157) that is the product of the bifurcation dissociates from the binding site on the positive, acidic side of the membrane but remains as usual in solution in the bilayer.

The **Rieske [2Fe–2S] iron–sulfur cluster is on a loosely tethered domain that can swing back and forth** between the Q_p binding site for quinones on a subunit on the positive, acidic side of the membrane and the prosthetic heme c_1 (Figure 2–32) bound to another subunit of quinol—cytochrome-*c* reductase, or the respective subunit of plastoquinol—plastocyanin reductase containing heme *f*. Both of these hemes are hemes *c*, and both of them are also on the portion of the protein in the aqueous phase on the positive, acidic side of the membrane but quite distant (3 nm) from the site for reducing the quinol.[843,862,866-870] The reduced Rieske [2Fe–2S] iron–sulfur cluster swings through the solution within

its domain from the binding site for quinones to the heme c_1 or heme *f* of the respective enzyme,[667,849,850] its electron is transferred to the heme *c* (+230 mV)[871] in this subunit, and the oxidized Rieske [2Fe–2S] iron–sulfur cluster swings back to the binding site for quinones. The reduced heme c_1 on the subunit of quinol—cytochrome-*c* reductase reduces the heme *c* in a molecule of the small electron-transferring coenzyme cytochrome *c*, or the reduced heme *f* on the subunit of plastoquinol—plastocyanin reductase reduces the copper ion (Figure 2-26D) in the small electron-transferring coenzyme plastocyanin. In either case, the heme *c* in the respective enzyme becomes oxidized as a result. The small electron-transferring coenzymes dissociate and carry the electron away. While all these steps are occurring, the other electron, which had been transferred to the heme b_p (–100 mV), transfers to the heme b_n (+50 mV),[575,872] which is across the enzyme, and hence across the membrane, on its negative, basic side.

A second quinol binds to the binding site for quinones on the positive, acidic side of the membrane, and its two electrons are also bifurcated. The now adjacent, reoxidized Rieske [2Fe–2S] iron–sulfur cluster again removes the first electron; two hydrons are released from the quinol into the aqueous phase on the positive, acidic side of the membrane; the radical anion of the quinone reorients in the binding site; heme b_p, reoxidized after transferring the first electron to heme b_n with the significantly more positive biochemical standard reduction potential and adjacent to the portion of the site now occupied, removes the second electron from the second quinol; and the quinone dissociates from the binding site. At this point, both heme b_p and heme b_n are reduced.

Heme b_n in quinol—cytochrome-*c* reductase is adjacent to the other binding site for quinones (Q_n) on the enzyme (Figure 2–32), which is across the membrane exposed to the solution on its negative, basic side.[862] In the case of plastoquinol—plastocyanin reductase, however, the extra heme *c* in the enzyme, which is electronically coupled to its heme b_n,[873] sits between heme b_n and the binding site Q_n for plastoquinone, and one of the oxygens on the plastoquinone may actually occupy the sixth position on the iron ion in this additional heme *c* when it is bound to this site, permitting it to be reduced directly by that iron ion.[874] The electron on the reduced heme b_n (+50 mV)[575] is transferred to a quinone in the binding site Q_n (Figure 2–32),[862,875] either directly or through the heme *c*, respectively, and this transfer of an electron reduces the quinone to the radical anion. Under appropriate circumstances, a small concentration (0.05–0.25 mole fraction) of the semiquinone can be observed in the Q_n binding site of quinol—cytochrome-*c* reductase from *S. cerevisiae* during its turnover.[876-878] The electron on the reduced heme b_p is transferred to heme b_n, and this second electron on heme b_n is transferred to the radical anion of the quinone as the radical anion of the quinone picks up two hydrons from the aqueous phase on the negative, basic side of the membrane to produce the quinol.[872] The quinol is then released from its binding site on the negative, basic side of the membrane.

Under normal circumstances, the concentration of semiquinone in the Q_n binding site is negligible. This observation suggests that the electrons reducing the quinone arrive one right after the other from two reduced hemes *b*. As noted above, quinol—cytochrome-*c* reductase is a homodimer, which contains two hemes b_p and two hemes b_n, each pair symmetrically arrayed around the twofold axis of symmetry. The two hemes b_p are as close to each other as a heme b_p and a heme b_n on the same subunit, and electrons can be transferred between the symmetrically arrayed hemes b_p as readily[879] as between a heme b_p and a heme b_n. This arrangement may provide additional insurance that the ubiquinone at the Q_n site is reduced by two almost simultaneously arriving electrons.

While all these reactions are occurring, the reduced Rieske [2Fe–2S] iron–sulfur cluster is swinging in its domain from the quinone binding site on the positive, acidic side of the membrane to heme *c* in the heme c_1 subunit or the heme *f* subunit, which it then reduces. That heme *c* in turn reduces another molecule of cytochrome *c* or plastocyanin, respectively, which carries away the electron.

Consequently, the **overall reaction** catalyzed by the respective enzyme is

$$\begin{aligned} 2\,H^+_{neg} + 2\,\text{quinol} + 2\,\text{acceptor}_{ox,pos} \\ + \text{quinone}_{neg} \rightleftharpoons \text{quinol}_{neg} + \\ 2\,\text{acceptor}_{red,pos} + 2\,\text{quinone} + 4\,H^+_{pos} \end{aligned} \quad (2\text{–}176)$$

where pos designates the positive, acidic side of the enzyme, neg designates the negative, basic side of the enzyme, the quinol is either ubiquinol or plastoquinol, the quinone is either ubiquinone or plastoquinone, and the acceptor is either cytochrome *c* or

plastocyanin. The stoichiometry stated in this equation for the hydrons released and taken up on the two sides of the membrane agrees with the numbers measured directly, and this reaction seems to account for all the hydron movements catalyzed by this enzyme.[880] The only purpose for the transfer of electrons from the quinol to cytochrome *c* or plastocyanin down the gradient of standard reduction potential, which is formally transferring hydrons from the negative, basic side of the membrane to the positive, acidic side, is accomplished. The free energy available from oxidation of the quinol and reduction of cytochrome *c* or plastocyanin has been transformed into a chemical gradient of hydrons and an even more dominant electric potential, together comprising an electrochemical potential. The quinols and quinones, which are free solutes miscible in the hydrocarbon of the phospholipid bilayer, rapidly equilibrate across the membrane, with the caveat that neither the monoanionic nor the dianionic conjugate bases of the respective quinols are able to equilibrate across the membrane at a rate that is of any consequence to the overall flux of reducing equivalents through the system.

The hydrons that appear on the positive, acidic side of the membrane are hydrons that were on the two oxygens of ubiquinols or plastoquinols that associated with the enzyme at a site on its positive, acidic side and were then oxidized; the enzyme did not transport these two hydrons across itself from the negative, basic side to the positive, acidic side of the membrane. The hydrons that disappear from the negative, basic side of the membrane are hydrons that were taken up by the two oxygens of ubiquinone or plastoquinone that associated with the enzyme at a site on its negative, basic side as it was reduced to the respective quinol; the enzyme did not transport these two hydrons across itself from the negative, basic side to the positive, acidic side of the membrane. Consequently, this strategy, which is the **formal transport of hydrons**, should be distinguished from the actual **active transport of hydrons** through the portion of the protein embedded in the membrane and spanning it. This distinction is a real one because two other enzymes in the electron transport chain in a mitochodrion perform the active transport of hydrons through the portion of the enzyme that spans the membrane. This active transport requires that there be a continuous path for these hydrons to follow from one side of the enzyme to the other and a physical mechanism to couple the favorable transfer of the electrons to the unfavorable transport of the hydrons, which is not the case for the formal transport of hydrons catalyzed by quinol—cytochrome-*c* reductase and plastoquinol—plastocyanin reductase.

The key to the mechanism of the Q-cycle is the bifurcation of the electrons from the quinol at the binding site for quinones on the positive, acidic side of the membrane; one is transferred to the Rieske [2Fe–2S] iron–sulfur cluster and the other to heme b_p. If both electrons were to pass to the two hemes *b*, heme b_p and heme b_n, quinol would become quinone on the positive, acidic side of the membrane, releasing two hydrons to the aqueous phase on that side, and quinone would become quinol on the negative, basic side of the membrane, absorbing two hydrons from the aqueous phase on that side of the membrane. The stoichiometric reaction would only be the formal transfer of two hydrons from the negative, basic solution to the positive, acidic solution without any net oxidation–reduction. Because the release of hydrons on the positive, acidic side and the absorption of hydrons from the negative, basic side that would occur in this formal transport of hydrons would be significantly endergonic, given the established electrochemical gradient, the reaction would not occur in the direction written; rather, it would occur in the opposite direction, formally transporting hydrons from the more positive, acidic side of the membrane to the more negative, basic side of the membrane and dissipating the electrochemical gradient of hydrons.

Another real concern is the short circuit that would occur if the Rieske [2Fe–2S] iron–sulfur cluster were electronically coupled to heme *c* in the heme c_1 subunit or heme *f* subunit while it was removing an electron from the quinol at the binding site on the positive, acidic side of the membrane. If it were, two electrons would be removed from the quinol instead of one, one ending up on heme *c* (+250 mV) and the other on the Rieske [2Fe–2S] iron–sulfur cluster (+300 mV), and they would be passed from there to cytochrome *c* or plastocyanin. This transfer of these two electrons would be dramatically exergonic ($\Delta E^{\circ\prime}$ = 170–300 mV)[881,882] and certain to occur, and it would defeat completely the strategy used by the enzyme to transfer hydrons formally from the negative, basic side of the membrane to the positive, acidic side because there would be no electrons passing through the membrane to reduce the quinone on the negative, basic side of the enzyme. This **damaging short circuit is prevented** by the fact that the domain in which the Rieske [2Fe–2S] iron–sulfur cluster is located swings a

significant distance through the solution between the binding site for quinones on the positive, acidic side of the membrane and heme *c* in the heme c_1 subunit or heme *f* subunit. For example, in bovine quinol—cytochrome-*c* reductase, when the Rieske [2Fe–2S] iron–sulfur cluster is in position to receive the electron from the ubiquinol, it is 2.70 nm from the closest atom in the π molecular orbital system of the heme *c* (Figure 2–32), too great a distance for effective transfer of an electron. Furthermore, because the domain in which the Rieske [2Fe–2S] iron–sulfur cluster is located is only loosely tethered to the rest of the protein, there is no path through the protein that an electron can follow between the iron–sulfur cluster and heme *c*. Consequently, at any instant, the Rieske [2Fe–2S] iron–sulfur cluster can only be electronically coupled to the quinol or the heme *c*, never to both at the same time. This mutual exclusion precludes the transfer of an electron rapidly and directly from the quinol through the Rieske [2Fe–2S] iron–sulfur cluster to the heme c_1 subunit or heme *f* subunit.

The fact that the quinone binding site on the positive, acidic side of the membrane is constructed in such a way that the quinol can be electronically coupled at a given instant only to the Rieske [2Fe–2S] iron–sulfur cluster or heme b_p, and must reorient to pass between the two,[863] prevents an electron from a reduced heme b_p from being transferred to an oxidized Rieske [2Fe–2S] iron–sulfur cluster that has swung back after it has been oxidized by heme *c*, an unlikely event but one that would also short-circuit the overall reaction.

Nitrate reductase (quinone) spans the plasma membrane of *E. coli* and performs a reaction that also oxidizes a quinol to a quinone and formally transports two hydrons from the negative, basic cytoplasm to the positive, acidic extracytoplasmic solution. This reaction, however, is simpler than that catalyzed by quinol—cytochrome-*c* reductase because it does not require the bifurcation of two electrons. The enzyme oxidizes either menaquinol or ubiquinol to the respective quinone, transfers the electrons across the enzyme and hence the membrane, and uses them to reduce nitrate to nitrite on the other side. The oxidation of the quinol occurs at a site on the extracytoplasmic side of the bacterial membrane and releases the two hydrons into the positive, acidic extracytoplasmic solution, just as does the oxidation catalyzed by quinol—cytochrome-*c* reductase. The reduction of the nitrate (NO_3^-) and two hydrons to nitrite (NO_2^-) and a molecule of water occurs at a site on the cytoplasmic side of the membrane, and the two hydrons that end up on the molecule of water are removed from the negative, basic, cytoplasmic, solution. The quinol is oxidized in two one-electron steps by a heme *b* on the enzyme near its extracytoplasmic surface, and each electron is first passed to a heme *b* in the membrane-spanning portion of the enzyme near its cytoplasmic surface, just as they are in quinol—cytochrome-*c* reductase (Figure 2–32), but the two hemes *b* are only 1.7 nm apart. Each electron is then passed through a [3Fe–4S] iron–sulfur cluster and a chain of four [4Fe–4S] iron–sulfur clusters to its ultimate destination, a molybdopterin at which the nitrate is reduced to nitrite and a molecule of water.[883] In this instance, the overall reaction, the formal reduction of nitrate to nitrite and the molecule of water by the quinol, provides the driving force for the formal transport of the hydrons against their electrochemical gradient. In the absence of an electrochemical gradient of hydrons, this reduction would be significantly exergonic.

The reduction catalyzed by nitrate reductase (quinone) illustrates why quinol—cytochrome-*c* reductase cannot oxidize ubiquinol on the positive, acidic side of the enzyme, pass both electrons through a series of prosthetic groups across the membrane, and reduce a ubiquinone (rather than nitrate) on the negative, basic side of the enzyme because the reaction would be isoergonic in the absence of the electrochemical gradient of hydrons. Consequently, there would be no free energy available to transport the hydrons against their concentration gradient, and the reaction could only operate in reverse.

The ubiquinol that is the substrate for quinol—cytochrome-*c* reductase in mitochondria and heterotrophic bacteria is produced from ubiquinone by a number of different enzymes embedded in the same membrane in which quinol—cytochrome-*c* reductase, ubiquinol, and ubiquinone are dissolved. This coembedment assures that the active sites for reduction of quinones and oxidation of quinols are dissolved in the same solution as their substrates.

Succinate dehydrogenase[884,885] is a flavoenzyme that spans the mitochondrial inner membrane or bacterial plasma membrane.[563] Succinate is oxidized to fumarate (+30 mV) at the prosthetic flavin (-80 mV)[563,886] in the cytoplasmic portion of the enzyme. The two electrons are passed one at a time through three iron–sulfur clusters:[887-889] a [2Fe–2S] iron–sulfur cluster (+10 mV), then a [4Fe–4S] iron–sulfur cluster (–180 mV), and then a [3Fe–4S] iron–sulfur cluster (+70 mV). The electrons are then

passed to a ubiquinone associated with an active site also on the cytoplasmic side of the membrane. This ubiquinone is reduced one electron at a time to ubiquinol (+100 mV), with ubisemiquinone as an intermediate. The only purpose of succinate dehydrogenase is to oxidize succinate to fumarate and transfer the electrons to ubiquinone to produce ubiquinol; no hydrons pass across the membrane, either formally or by active transport. The reason for this lack of hydron transport is that the difference in biochemical standard reduction potential between succinate and ubiquinol (–70 mV) is too small. If the ubiquinone were reduced in an active site on the extracytoplasmic side of the enzyme, the free energy in the electrochemical gradient would reverse the normal direction of the reaction. It seems that the main reason that the enzyme spans the membrane is to ensure access to the ubiquinone and the ubiquinol dissolved in the hydrocarbon.

Succinate dehydrogenase contains a heme *b*, which is not necessary for the enzymatic reaction.[890] Electrons cannot be transferred efficiently between the iron–sulfur clusters and this heme *b* when the binding site for ubiquinone is unoccupied, but they are rapidly transferred back and forth between the heme *b* and ubisemiquinone when the ubisemiquinone is in the site.[891] It seems to be the case that the function of the heme *b* is to stabilize the ubisemiquinone by sharing its unpaired electron while it waits for the second electron. One of the two hemes *b* in nitrate reductase (quinone) from *E. coli* stabilizes the adjacent menasemiquinone that is an intermediate in the transfer of an electron performed by this enzyme.[892]

Under anaerobic conditions, **fumarate reductase (quinol)** is produced in bacteria.[893-896] Fumarate reductase (quinol) is related to succinate dehydrogenase (37% identity; 1.4 gap percent for *E. coli*). It catalyzes the same reaction as succinate dehydrogenase through the same prosthetic groups, but anaerobiosis requires that it mostly reduce fumarate to succinate. Consequently, instead of the ubiquinone (+100 mV) used by succinate dehydrogenase, fumarate reductase (quinol) uses menaquinone (–60 mV) as its substrate. Because the biochemical standard reduction potential of the redox couple of fumarate and succinate is +30 mV, the reaction runs efficiently in one direction with succinate dehydrogenase (ubiquinone) because succinate is enough of a reductant to reduce ubiquinone effectively, and it runs efficiently in the other direction with fumarate reductase (quinol) because fumarate is enough of an oxidant to oxidize menaquinone effectively. Fumarate reductase (quinol) also does not transport hydrons across its membrane.[897,898]

As many as eight different flavoenzymes in the interior of a mitochondrion oxidize their respective nominal substrates and reduce the same general substrate, the flavin in electron-transferring flavoprotein dissolved in the interior solution.[899] The reduced flavin (–20 mV) in the electron-transferring flavoprotein is then reoxidized at the interior surface of the mitochondrial inner membrane by the membrane-anchored enzyme **electron-transferring-flavoprotein dehydrogenase**.[899-901] During the oxidation of the reduced flavin in electron-transferring flavoprotein, the two electrons are distributed singly,[900] one to the prosthetic flavin (+20 mV) in the enzyme, which becomes the semiquinone, and the other to the prosthetic [4Fe–4S] iron–sulfur cluster (+50 mV) in the enzyme.[899,902] They are then passed one at a time to the ubiquinone bound in the active site for its reduction to produce ubiquinol. In this instance, both the active site at which the electron-transferring flavoprotein is oxidized and the site for the reduction of ubiquinone to ubiquinol are in the interior of the mitochondrion, so no hydron transport is involved in the transfer of the electrons. In fact, the enzyme does not even span the inner membrane of the mitochondrion but is only embedded in it by a hydrophobic portion of its surface.

The largest of the enzymes that reduce ubiquinone to ubiquinol in mitochondria and bacterial plasma membranes is **NADH:ubiquinone reductase (H^+-translocating)**,[903-906] which dwarfs the membrane that it spans. Reduced nicotinamide-adenine dinucleotide is oxidized by the flavin within the enzyme[907] by hydride transfer, and the two electrons on the reduced flavin are then transferred one at a time through at least seven of the nine iron–sulfur clusters in the enzyme from *T. thermophilus* (Figure 2–33),[651,908-910] two of which are [2Fe–2S] clusters and seven of which are [4Fe–4S] clusters.[911,912] The [4Fe–4S] iron–sulfur cluster 2.05 nm off the main chain does not participate in electron transfer[913] and exists in only a few bacteria. Aside from the fact that this latter [4Fe–4S] iron–sulfur cluster is missing, the arrangements and orientations of the iron–sulfur complexes in the NADH:ubiquinone reductases (H^+-translocating) in the inner membranes of the mitochondria from animals are the same[839] as their arrangements and orientations in the enzyme from *T. thermophilus*.

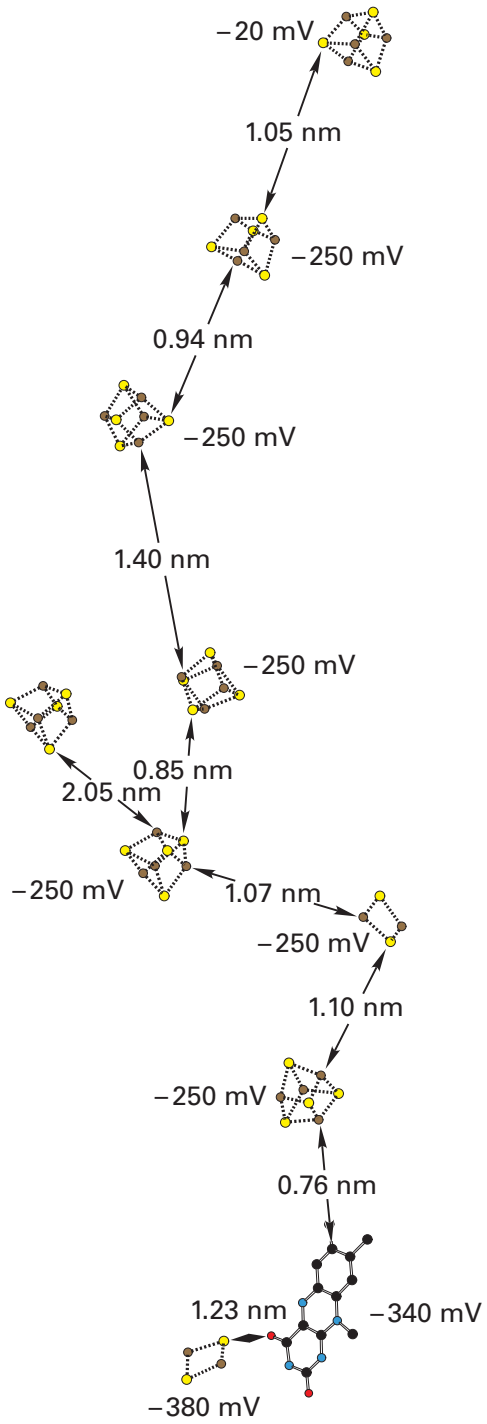

Figure 2–33: Disposition of flavin and nine iron–sulfur clusters, seven [4Fe–4S] and two [2Fe–2S], in the crystallographic molecular model of a portion of NADH:ubiquinone reductase (H^+-translocating) from *T. thermophilus*.[651] Black atoms are carbons, red atoms are oxygens, and blue atoms are nitrogens. In the iron–sulfur clusters, yellow spheres are sulfides and rusty brown spheres are iron ions. Membranes from fragmented bacteria were dissolved in a solution of the detergent dodecyl β-D-maltopyranoside, and the hydrophilic portion of NADH:ubiquinone reductase (H^+-trans-locating) was purified chromatographically.[909] The protein was then crystallized. The drawing[50] is of the flavin and the nine iron–sulfur clusters in the resulting crystallographic molecular model. The distances between the closest atoms in adjacent iron sulfur clusters are noted, as well as the distance from the closest atoms in the two closest iron sulfur clusters to the π molecular orbital system of the flavin. The midpoint potentials listed are those for NADH:ubiquinone reductase (H^+-translocating) from *C. livia* within intact mitochondria.[908,910]

Six of the seven iron–sulfur clusters in the main chain for electron transfer[890,908,910] have the same biochemical standard reduction potential (–250 mV)* and are used to span the distance (>10 nm) in steps of 0.8–1.4 nm between the site for oxidation of NADH and the site at which ubiquinone is reduced.[561] The last iron–sulfur cluster (–20 mV) in the chain is a sink for the electron to pull it along this chain of iron–sulfur clusters. The flavin has a biochemical standard reduction potential of –340 mV, so the initial rise in potential between the flavin and the initial iron–sulfur cluster pushes the electrons forward through the chain.

Ubiquinone is reduced by two electrons on the negative, basic side of the membrane and picks up two hydrons from that solution. The NADH is oxidized to NAD^+ and two electrons, also on the negative, basic side of the membrane, and releases one hydron into that solution. In addition to the resulting net of one hydron removed from the negative, basic solution, known as the scalar hydron, four additional hydrons from the negative, basic side of the membrane are transported to the positive, acidic side for every two electrons passed from NADH to ubiquinone.[915] A strategy for formal transfer of

*There are electrostatic interactions between the clusters in this region of the protein. The reduction of one cluster can lower the midpoint potentials of its neighbors.[914]

hydrons similar to the Q-cycle does not seem to be involved since all the prosthetic groups among which the electrons are transferred are located on the negative, basic side of the membrane outside the membrane-spanning portions of the protein, which contains no prosthetic groups of oxidation–reduction.[651,916-921] Consequently, these four hydrons are actively transported through the enzyme.

In mitochondria, the three reactions catalyzed by NADH:ubiquinone reductase (H^+-translocating), succinate dehydrogenase, and electron-transferring-flavoprotein dehydrogenase, as well as several other oxidation–reductions, receive electrons from diverse sources, but each transfers the electrons to one of the quinones, in particular ubiquinone, to form ubiquinol. This common product passes the electrons derived from each of these enzymes to the central clearinghouse of quinol—cytochrome-*c* reductase. As the concentration of ubiquinone and ubiquinol in the mitochrondrial inner membrane is varied experimentally, the kinetics of electron transfer between either NADH:ubiquinone reductase (H^+-translocating) or succinate dehydrogenase, acting as the donor, and quinol—cytochrome-*c* reductase, acting as the acceptor, are consistent with the following sequence of events. The ubiquinone bound to the donor receives the electrons. The resulting ubiquinol dissociates from the donor, diffuses at random within the mitochondrial membrane, collides with the acceptor, associates with the acceptor, and transfers the electrons to it.[922-924] When ubiquinone is added back to mitochondria that have been depleted of endogenous ubiquinone, the behavior of the increase in electron transfer among these enzymes is also consistent with the postulate that each of them has access to the same mobile pool of ubiquinone and ubiquinol dissolved in the phospholipid bilayer of the membrane.[925]

The reduced cytochrome *c* produced by quinol—cytochrome-*c* reductase in mitochondria and the plasma membranes of bacteria is reoxidized by **cytochrome-*c* oxidase**,[926,927] an enzyme that spans the membrane and catalyzes the reaction[928,929]

$$8\ H^+_{neg} + 4\ \text{ferrocytochrome}\ c_{pos} + O_2 \rightleftharpoons 2\ H_2O + 4\ \text{ferricytochrome}\ c_{pos} + 4\ H^+_{pos} \quad (2\text{–}177)$$

The electron from the ferrocytochrome *c* is first transferred[746] to the dinuclear CuA cluster of copper ions (+240 mV) (Figure 2–26F), and from there to a heme *a* (+250 to +380 mV)[930,931] with the imidazolyl groups of two histidines as axial ligands (heme *a*), and finally to a heme *a* (heme a_3) with only one imidazolyl group from a histidine as a ligand. Heme a_3 is immediately adjacent to an additional prosthetic copper ion coordinated by three imidazolyl groups from three histidines with their nitrogens in a planar trigonal array.[673,746,932] The ultimate receptacle of the electrons is a molecule of oxygen bound between the iron of heme a_3 and the copper ion and occupying simultaneously the vacant sites for ligands on each of them. The site to which the oxygen binds is on the negative, basic side of the membrane. Four of the eight hydrons taken up on this side, the scalar hydrons, end up on the two molecules of water. The other four hydrons are actively transported along a path through the portion of the enzyme that spans the membrane.

One of the two quinol oxidases[933-935]

$$2\ \text{ubiquinol} + O_2 \rightleftharpoons 2\ H_2O + 2\ \text{ubiquinone} \quad (2\text{–}178)$$

located in bacterial plasma membranes is closely related to cytochrome-*c* oxidase.[936] In this quinol oxidase, however, a heme *o*[937,938] replaces heme a_3 and a heme *b*[939] replaces heme *a* of cytochrome-*c* oxidase. The prosthetic copper ion adjacent to heme *o*, in the active site where the oxygen is reduced, is still present, but the CuA copper cluster, which is the entry in cytochrome-*c* oxidase for the electron from cytochrome *c*, is missing. The enzyme has a site with high affinity for ubiquinol and ubiquinone[940,941] where electrons are removed one at a time from ubiquinol and transferred to heme *b*, with a radical anion of ubisemiquinone as an intermediate,[942] and then to heme *o*. Again, reduction of oxygen consumes four hydrons from the negative, basic side of the membrane, but oxidation of two molecules of ubiquinol produces four hydrons on the positive, acidic side of the membrane, and consequently the enzyme accomplishes the formal transport of four hydrons. An additional four hydrons are transferred by active transport through the protein from the negative, basic side to the positive, acidic side of the membrane during the complete reaction catalyzed by the enzyme.[943]

The transfer of electrons between quinol—cytochrome-*c* reductase and cytochrome-*c* oxidase is mediated by cytochrome *c*, each molecule of which accepts an electron from the reductase and donates that electron to the oxidase. Cytochrome *c*

performs this transfer by accepting an electron from quinol—cytochrome-*c* reductase, dissociating from it, diffusing at random through the solution between the outer and inner mitochondrial membranes until it collides with the site for its oxidation on cytochrome-*c* oxidase, associating with that site, and donating the electron.

At physiological ionic strength, cytochrome *c* binds tightly to the cytoplasmic surface of the inner mitochondrial membrane, presumably to quinol—cytochrome-*c* reductase or cytochrome-*c* oxidase at a given instant. When cytochrome *c* is bound tightly to the mitochondrial membrane and then crosslinked to it, the protein to which it becomes covalently attached is cytochrome-*c* oxidase, not quinol—cytochrome-*c* reductase.[944] A similar result is obtained when mixtures of cytochrome *c* and purified cytochrome-*c* oxidase are crosslinked.[945] This observation is puzzling because a complex between cytochrome-*c* oxidase and cytochrome *c* has never been crystallized.

At low ionic strength, cytochrome *c* binds specifically and with high affinity to the heme c_1 subunit purified from quinol—cytochrome-*c* reductase, and there is a crystallographic molecular model of a specific complex between cytochrome *c* and the heme c_1 subunit in an intact molecule of quinol—cytochrome-*c* reductase from *S. cerevisiae*. In this complex, which forms at high concentrations of cytochrome *c* and quinol—cytochrome-*c* reductase at physiological ionic strength, the two hemes *c* from the respective proteins are only about 0.5 nm apart.[946] In more dilute solution, however, the transfer of electrons between purified heme c_1 subunit from bovine quinol—cytochrome-*c* reductase and cytochrome *c* is a purely bimolecular reaction at normal ionic strengths,[947] and at physiological ionic strength, the dissociation constant of cytochrome *c* from the heme c_1 in quinol—cytochrome-*c* reductase from *R. capsulatus*[948] was greater than 0.5 mM. These facts are inconsistent with the existence of a strong, long-lived complex between these two proteins in mitochondria[949] and suggest that, in a mitochondrion, cytochrome *c* may have to associate many times with quinol—cytochrome-*c* reductase before the electron is transferred.

The possibility that cytochrome *c* is bound to both proteins simultaneously has been roundly discounted. The crystallographic molecular model of the complex between cytochrome *c* and the heme c_1 subunit in quinol—cytochrome-*c* reductase[946] places the cytochrome *c* in a location that makes it sterically impossible to bind simultaneously to any location on cytochrome-*c* oxidase, let alone the site thought to be its binding site on cytochrome-*c* oxidase.[950] Furthermore, there is a crystallographic molecular model of a large complex containing both cytochrome-*c* oxidase and quinol—cytochrome-*c* reductase that is thought to represent the state in which these enzymes exist in the mitochondrial membrane. In this complex, the exterior surface of cytochrome-*c* oxidase is so distant from the exterior surface of quinol—cytochrome-*c* reductase that cytochrome *c* could not come close to bridging the gap,[924] and cytochrome *c* must be added to the solution in which this complex is dissolved in order to observe electron transfer between the two enzymes.[951]

In the chromatophores of most photosynthetic bacteria, the ubiquinol oxidized to ubiquinone by quinol—cytochrome-*c* reductase is the product of reduction of ubiquinone by a photosynthetic reaction center, and the reduced cytochrome *c* or high-potential [4Fe–4S] iron protein[952-954] produced by quinol—cytochrome-*c* reductase is oxidized by a photosynthetic reaction center. A **photosynthetic reaction center** is a membrane-spanning enzyme that forces an electron to move from a donor of more positive standard reduction potential to an acceptor of more negative standard reduction potential by coupling that movement to the consumption of the energy in a photon of visible light. A photon of visible light or an exciton resulting from the absorption of a photon of light by prosthetic groups in antenna proteins and passed to the reaction center by electronic energy migration is absorbed to form the electronically excited state of a prosthetic group. The excited electron in this electronically excited state has a much more negative standard reduction potential than it did in the ground state. As a result, the excited electron can pass spontaneously to other prosthetic groups that have more positive standard reduction potentials than the electronically excited state. A photosynthetic reaction center can be viewed as a cage that encloses and positions an array of prosthetic groups that perform one-electron transfers. This array of prosthetic groups in the reaction center from the photosynthetic purple bacterium *R. sphaeroides* (Figure 2–34)[955-957] describes the path taken by the excited electron.

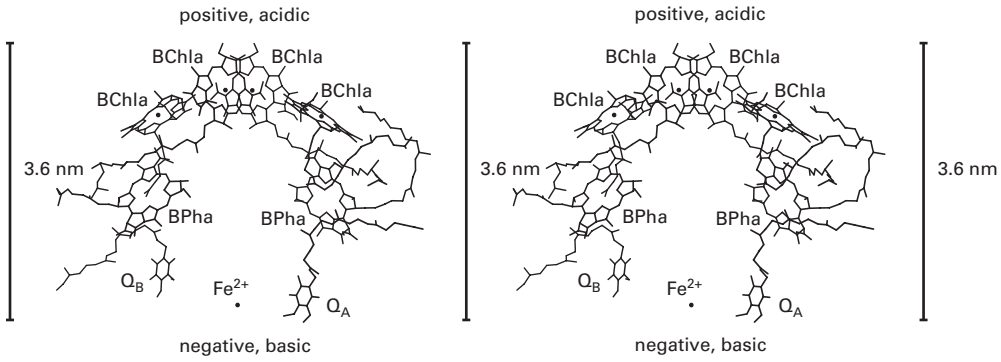

Figure 2–34: Stereodrawing[50] of the disposition of four bacteriochlorophylls *a* (BChla), two bacteriopheophytins *a* (BPha), two ubiquinones (Q_A and Q_B), and a prosthetic Fe^{2+} in the crystallographic molecular model of photosynthetic reaction center from the bacterium *R. sphaeroides*.[955] The bacteriochlorophylls have magnesium ions in their centers, and the bacteriopheophytins are empty. The path of the electron is from the top of the figure downward. It begins in the electronically excited state of the special pair, which is the rotationally pseudosymmetric dimer of bacteriochlorophylls *a* at the top of the array. The local twofold rotational axis of pseudosymmetry within the reaction center itself runs vertically through the Fe^{2+} and the center of the special pair. On each side of the array, right and left, a bacteriochlorophyll *a* bridges the space between the special pair and each of the symmetrically positioned bacteriopheophytins *a*, but the electron, under normal circumstances, transfers from the special pair through the bacteriochlorophyll *a* on the right side of the array in the drawing to the bacteriopheophytin *a* also on the right side. Below each of the bacteriopheophytins is an ubiquinone. The two ubiquinones are on opposite sides of the Fe^{2+}. The electron is transferred from the bacteriopheophytin *a* on the right side of the array to the ubiquinone on the right side (Q_A) and from the ubiquinone on the right side to the ubiquinone on the left side (Q_B). The approximate position of the planar hydrophobic core of the membrane, which is about 3.6 nm in width, is indicated with the bar. The phytyl chains on most of the bacteriochlorophylls *a* and bacteriopheophytins *a* are not complete in the crystallographic molecular model, and the polyisoprenoid on one of the ubiquinones is incomplete also. The polyisoprenoid on the other ubiquinone was truncated in the drawing to save space.

The central prosthetic group in a photosynthetic reaction center in the chromatophore of a photosynthetic purple bacterium is the **special pair** formed from two[958] bacteriochlorophylls (Figure 2–35).[959,960] Two of the pyrrolyl groups, one from each bacteriochlorophyll, are stacked against each other. The two bacteriochlorophylls* of the special pair are arrayed about a twofold rotational axis of pseudosymmetry that runs between the two stacked pyrrolyl groups and is horizontal in the drawing of Figure 2–35. The stacking of the pyrrolyl groups, the resulting overlap of their two aromatic π molecular orbital systems, and the relative orientation of the transition dipoles of the two bacteriochlorophylls that is produced by the juxtaposition shifts the absorption of light by the pair of bacteriochlorophylls to longer wavelengths (800–1000 nm) than that of a lone bacteriochlorophyll (765–785 nm). This shift in the absorption to lower energy permits the special pair to be a much more efficient sink for the exciton that is transferred to it from the prosthetic groups in the light-harvesting antennae, which absorb light of shorter wavelengths and higher energy.

The twofold rotational axis of pseudosymmetry that produces the overlap in the special pair in a photosynthetic purple bacterium exists because two of the three subunits[961] of the reaction center, subunits L and M, are homologous in sequence (30% identity; 2 gap percent),[962] superposable on each other's native structure,[963] span the membrane, and necessarily are arrayed around a twofold rotational axis of pseudosymmetry normal to the plane of the membrane.[964] This rotational axis of pseudosymmetry within the protein relates the two bacteriochlorophylls of the special pair. Because these two subunits in the protein arose from the same common ancestor, the first oligomer containing a reaction center must have been an α_2 dimer of identical membrane-spanning subunits that coincidentally brought the two bacteriochlorophylls together in the proper orientation to display the unique properties of a special pair. In fact, in the crystallographic molecular model of one bacterial reaction center, that from *Heliobacterium modesticaldum*, the structures of the two subunits that surround the prosthetic groups are superposable respectively on the L and M subunits of the other bacterial reaction centers, but both of these two subunits in this reaction center are identical in their sequence of amino acids and are arrayed around a perfect, crystallographic twofold rotational axis of symmetry.[965]

At the same time that the primordial dimerization occurred, each of the identical subunits also brought along one copy of each of the remaining prosthetic groups necessary for the reaction catalyzed by the enzyme: a second bacteriochlorophyll and a bacteriopheophytin. Each subunit also contributed a binding site for ubiquinone or menaquinone. Consequently, in a reaction center, each of these features is duplicated around the twofold rotational axis of pseudosymmetry (Figure 2–34).

Crystallographic molecular models from data sets with short Bragg spacing are available for the photosynthetic reaction centers from the purple bacteria *Blastochloris viridis*,[959,960] *R. sphaeroides* (Figure 2–34), [956,957] and *Thermochromatium tepidum*,[966] which closely resemble each other.[967] The special pair in the photosynthetic reaction center from *R. sphaeroides* absorbs light of wavelength 865 nm, where photons have energies of 138 kJ mol^{-1} (equivalent to a difference in reduction potential of −1430 mV), while the special pair in the reaction center from *B. viridis* absorbs light of wavelength 960 nm,[968] where photons have energies of 124 kJ mol^{-1} (equivalent to a difference in reduction potential of −1290 mV). The reaction centers from *B. viridis* and *R. sphaeroides* accept electrons from a cytochrome *c* and the reaction center from *T. tepidum* accepts electrons from a high-potential iron–sulfur protein, but most photosynthetic bacteria use a high-potential iron–sulfur protein as the electron donor.[969]

Either the absorption of an exciton transferred from an antenna protein by electronic energy migration or the absorption of light within the reaction center itself in a photosynthetic purple bacterium produces an **electronically excited state**. There are several ways for a photon of light to be absorbed within a reaction center that has been purified and lacks its antenna.[970] Although it can be absorbed directly by the special pair, light can also be absorbed by either of the two bacteriochlorophylls that are adjacent to the special pair and symmetrically positioned around the axis of pseudosymmetry (Figure 2–34). Regardless, however, of where the light is absorbed by the purified reaction center, the immediate ($t_{½}$ < 200 fs) result is the same electronically excited state of the special pair in which one electron has been transferred from the highest occupied π molecular orbital of the special pair in its

**Blastochloris viridis* contains bacteriochlorophylls *b* and bacteriopheophytins *b*, while *R. sphaeroides* and *T. tepidum* contain bacteriochlorophylls *a* and bacteriopheophytins *a*.

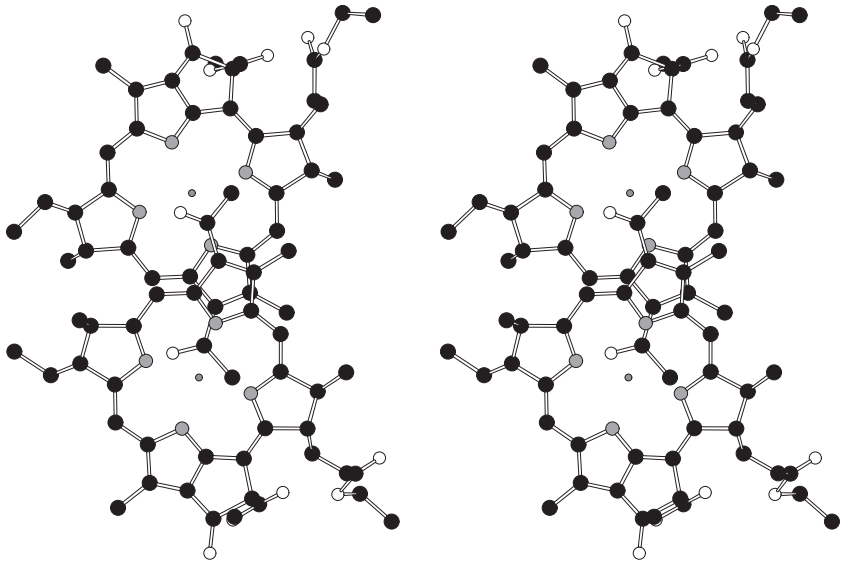

Figure 2–35: Stereodrawing[50] of the special pair of bacteriochlorophylls *b* in the crystallographic molecular model of the photosynthetic reaction center from *B. viridis*.[960] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and small dark gray spheres are magnesium ions. The two bacteriochlorophylls *b* of the special pair are held in orientations displayed symmetrically about the twofold rotational axis of pseudo-symmetry of the protein itself. The rotational axis runs horizontally in the plane of the page between the two bacteriochlorophylls *b* and causes them to overlap at the same pyrrole from each. The tetraisoprenoid phytyl groups attached in ester linkage to the 3-(2-carboxyethyl) groups at the carbons 17 of each of the bacteriochlorophylls *a* (R_6 in **2–54**) were not drawn beyond their first two carbons.

ground state to its lowest unoccupied π molecular orbital. Crystallographic molecular models of the special pair in the active site of the reaction center from *B. viridis* in the first 5 ps indicate that, in the initial excited state, the two bacteriochlorophylls move even closer together as they share the excited electron.[971] From here on, unless otherwise noted, the fate of this one electron, now alone in the highest occupied π molecular orbital in the electronically excited state of the reaction center of *R. sphaeroides*, will be followed.

Normally, after the immediate electronic relaxation of the excited state ($t_{½}$ = 0.12 ps),[972] the electron in the electronically excited state of the special pair would return within several nanoseconds to the π molecular orbital of lower energy from which it came and that now contains only one electron, and this process would emit a quantum of light of longer wavelength (920 nm) as fluorescence. In fact, a short time after the absorption of the photon, such fluorescence emission can be observed from a population of electronically excited reaction centers, but it decays rapidly (200 ns^{-1}; $t_{½}$ = 4 ps).[972,973]

The quenching of this fluorescence is due to the **transfer of the excited electron** from the special pair to the lowest unoccupied π molecular orbital on one of the bacteriopheophytins (Figure 2–34) in the enzyme.[973] This transfer is favorable because **the excited electron in the special pair has become a much stronger reductant** than it was when it was in the ground state. After the immediate, automatic relaxation of the electronically excited state, the biochemical standard reduction potential of the special pair has experienced, relative to the ground state, a decrease equivalent to the energy in a quantum of light of a wavelength equal to that of its fluorescent emission (920 nm; $\Delta E^{\circ\prime}$ = –1350 mV).

The transfer of the electron to the bacteriopheophytin creates a radical anion on the bacteriopheophytin (Equation 2–156) and leaves a radical cation behind on the special pair.[974] As soon as the excited electron is passed to the bacteriopheophytin, the π molecular orbital that it occupied on the special pair is no longer occupied but has become the lowest unoccupied π molecular orbital of the special pair. The special pair is now no longer electronically excited because the excited electron has left, and **the radical cation of the special pair is in its ground state**.

Because a bacteriochlorophyll, not involved in the special pair, lies between the special pair and the bacteriopheophytin (Figure 2–34), it is assumed that **transfer of the electron occurs through the bacteriochlorophyll**.[973] There is spectroscopic evidence for the transfer of the electron through this bacteriochlorophyll,[972] and when the bacteriopheophytin is replaced with pheophytin *a*, which has a more negative biochemical standard reduction potential, the electron can be trapped on the bacteriochlorophyll before it returns to the ground state of the special pair (2 ns^{-1}; $t_{½}$ = 430 ps).[975] Under normal circumstances, however, the electron passes through this bacteriochlorophyll to the bacteriopheophytin so rapidly (k_{in} = 100 ns^{-1}, $t_{½}$ = 7 ps; k_{out} = 200 ns^{-1}, $t_{½}$ = 4 ps)[970,972] that it does not reside detectably on the bacteriochlorophyll.[976,977]

In the ground state as opposed to the electronically excited state, the equation for the transfer of an electron from the special pair to this adjacent bacteriochlorophyll would be

$$\mathrm{BChl{\cdot}BChl + BChl \rightleftharpoons BChl{\cdot}BChl^{\cdot+} + BChl^{\cdot-}} \qquad (2\text{–}179)$$

In the ground state, the half-reaction of this overall oxidation–reduction that occurs at the bacteriochlorophylls in the special pair would be

$$\mathrm{BChl{\cdot}BChl^{\cdot+} + e^{-} \rightleftharpoons BChl{\cdot}BChl} \qquad (2\text{–}180)$$

and the half-reaction that occurs at the adjacent bacteriochlorophyll (BChl) would be

$$\mathrm{BChl + e^{-} \rightleftharpoons BChl^{\cdot-}} \qquad (2\text{–}181)$$

As is normally the case for the formation of a radical cation of one molecule and the formation of a radical anion of the same molecule or another, similar molecule, in the ground state, the biochemical standard reduction potential for Equation 2–180 is much more positive than that for Equation 2–181 ($\Delta E^{\circ\prime}$ = +1290 mV)[972] because it involves separation of charge and unpairing of electrons. It follows that, in the ground state, an electron cannot be transferred from a bacteriochlorophyll in the special pair to the adjacent bacteriochlorophyll, but the biochemical standard reduction potential for Equation 2–180 is decreased by –1350 mV upon the formation of the relaxed electronically excited state. This decrease in the standard reduction potential causes the transfer of the electron to the adjacent bacteriochlorophyll on its way to the bacteriopheophytin to become favorable.

When either Histidine L173 or Histidine M202 in the enzyme is mutated to a leucine, one or the other of the bacteriochlorophylls in the special pair loses its magnesium ion; and, as a result, the rate at which the electron is transferred to the bacteriopheophytin is decreased, the lifetime of the electronically excited state is decreased, and the quantum yield of the transfer of the excited electron to the bacteriopheophytin decreases from nearly 1.0 in the native enzyme to about 0.5 in the mutant.[978,979]

As a result of the primordial dimerization that created the special pair, each dimeric reaction center originally contained two **identical paths for electron transfer**. When the gene duplicated and the two subunits began to evolve independently, one of the two paths was shut down. Under normal circumstances, the transfer of the excited electron occurs between the special pair and only the bacteriochlorophyll and its adjacent bacteriopheophytin in the L subunit of the enzyme (on the right side of Figure 2–34). It has been proposed that, at least in part, this preference is due to the hydroxy group of a tyrosine that is oriented so that the positive pole of its dipole is directed toward the bacteriochlorophyll in the L subunit, which would make it the more effective oxidant. The orientation of this dipole stabilizes the radical anion on this particular bacteriochlorophyll (Equation 2–181).[980] The same position in the sequence of amino acids for the homologous subunit is occupied by a phenylalanine. When the identity of these amino acids is switched by site-directed mutation, a portion of the electron transfer is diverted artifactually into the opposite bacteriopheophytin on the M subunit.[981]

If the excited electron can be delocalized to the bacteriopheophytin in the first place, it must be able to **return to the highest occupied π molecular orbital in the ground state of the radical cation of the special pair** that is now occupied by an unpaired electron. If its transfer beyond the bacteriopheophytin is blocked by reducing the ultimate acceptor of the electron,[974] the trapped electron eventually returns to this highest occupied π molecular orbital in the ground state of the radical cation of the special pair, which is at a much lower energy than the highest occupied π molecular orbital on the radical anion of the bacteriopheophytin that it now occupies. Were it to return to the special pair, the energy of the electronically excited state would be dissipated inconsequentially as heat and fluorescence. The rate of decay of the electronically excited state under these circumstances (70 μs^{-1}; $t_{½}$ = 10 ns in *B. viridis* and 50 μs^{-1}; $t_{½}$ = 14 ns in *R. sphaeroides*)[974,982] is less than it would have been if all the excited electron density had remained in the highest occupied π molecular orbital on the excited special pair rather than spreading between the two locations. This decrease in rate is due to the fact that the biochemical standard reduction potential of the electron on the bacteriopheophytin *b* is about +70 mV more positive than in the relaxed electronically excited state of the special pair,[972] and this difference in biochemical standard reduction potential causes most of the electron density to reside on the bacteriopheophytin at equilibrium.

Under normal circumstances, the electron that is now on the bacteriopheophytin transfers **from the bacteriopheophytin to the quinone (Q_A) bound in the A site** adjacent to the bacteriopheophytin at a rate (5 ns^{-1}; $t_{½}$ = 150 ps)[982] that is significantly more rapid that the rate at which it would return to the ground state of the radical cation of the special pair. The product of this next transfer is the radical anion of the semiquinone. In the reaction center from *B. viridis*, this quinone is menaquinone, while in the reaction center from *R. sphaeroides* (Figure 2–34), it is ubiquinone, and each of these respective quinones is bound tightly to the A site as a **prosthetic group**. A crystallographic molecular model of the reaction center from *B. viridis* 300 ps after the absorption of a photon indicates that, upon the arrival of the electron, the now radical anion in the A site moves much closer to the closest imidazolyl group that is a ligand to the iron ion.[971]

At this point, the excited electron located in the semiquinone radical anion of the semiquinone is a good distance (Figure 2–34) from the hole in the highest occupied π molecular orbital in the radical cation of the special pair where it was located before the excitation. Because the biochemical standard reduction potential of the radical anion of the semiquinone is +750 mV more positive than the relaxed electronically excited state of the special pair (Figure 2–36),[968,982] the electron has also lost a significant amount of its original energy. In exchange for this expenditure of –72 kJ mol^{-1} of free energy associated with this increase in standard reduction potential (Figure 2–36), **the electron has gained time**. The observed rate constant[982-984] for the reaction

$$P^{\cdot+}BPhQ_A^{\cdot-} \rightleftharpoons PBPhQ_A \qquad (2\text{–}182)$$

is 8 s^{-1} ($t_{½}$ = 90 ms). This rate constant is considerably smaller than the rate constant for the return of the

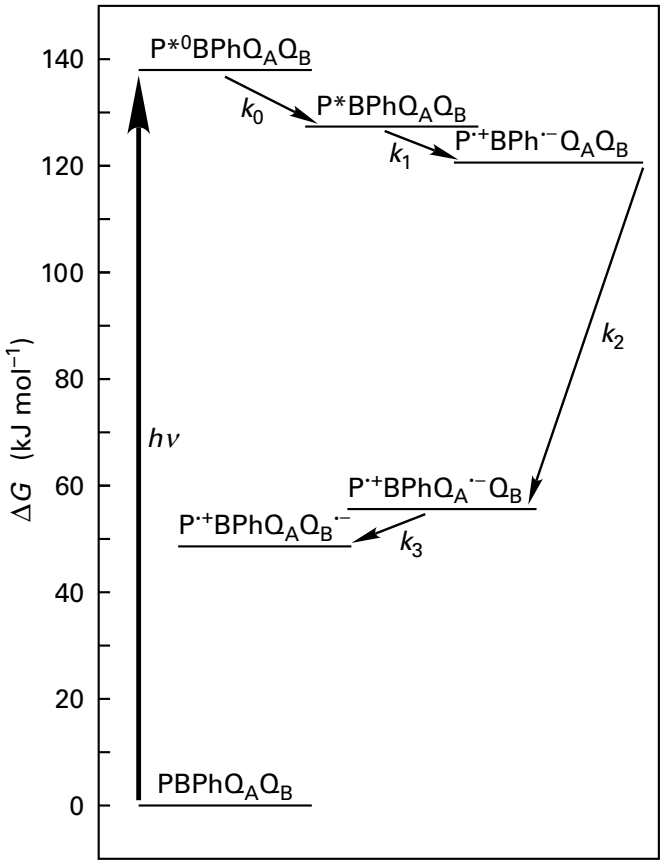

Figure 2–36: Energy diagram for the path of the electron in bacterial photosynthesis.[968,982] The four successive prosthetic groups on the path of the electron (Figure 2–34) are the special pair (P), the bacteriopheophytin (BPh), the tightly bound quinone (Q_A), and the loosely bound quinone (Q_B). The instantaneously populated electronically excited state of the special pair is indicated by P^{*0}; the vibrationally relaxed electronically excited state of the special pair is indicated by P*; its radical cation is indicated by $P^{\bullet +}$; and the successive radical anions are indicated by $BPh^{\bullet -}$, $Q_A^{\bullet -}$, and $Q_B^{\bullet -}$. The energy levels and rate constants are those for the reaction center from *R. sphaeroides*. The energy levels of the various steps relative to the ground state are presented in kilojoules mole^{-1}. The rate constants for transfer of the electron between the various steps are $k_0 = 6000\ ns^{-1}$ ($t_{½} = 0.12$ ps); $k_1 = 200\ ns^{-1}$ ($t_{½} = 4$ ps); $k_2 = 5\ ns^{-1}$ ($t_{½} = 150$ ps); and $k_3 = 5 \times 10^3\ s^{-1}$ ($t_{½} = 140\ \mu s$). Before the electron has time to move from quinone A to quinone B, an electron from the cytochrome c_2 in intact cells of *R. sphaeroides* would normally fill the hole in $P^{\bullet +}$.

electron from the radical anion of the bacteriopheophytin to the radical cation of the special pair ($5 \times 10^7\ s^{-1}$; $t_{½} = 14$ ns). This difference in rate constants is a measure of the time gained by the electron by the expediture of the free energy originally in the electronically excited state. The rate constant for return of the electron to the radical cation of the special pair from the radical anion of the semiquinone (Equation 2–182), however, is still too large to provide sufficient time for the energy to be trapped efficiently. To overcome this dilemma, a second strategy is employed.

Long after the electron has been transferred from the bacteriopheophytin to the quinone (1–30 μs), the hole in the highest occupied π molecular orbital of the radical cation of the special pair, left behind by the departed excited electron and to which it might return, is filled by an **electron from a heme *c* on a cytochrome *c*** or the electron from a [4Fe–4S] iron–sulfur cluster on a reduced high-potential iron–sulfur protein. The enzyme from *B. viridis* binds its cytochrome *c* so tightly that it is purified with the enzyme and is present in the crystallographic molecular model (Figure 2–37).[959] The cytochrome c_2 from *R. sphaeroides* binds to its reaction center less strongly ($K_d = 0.34\ \mu M$)[985] and under normal circumstances transfers its electron to the reaction center in a bimolecular reaction, ($k = 1 \times 10^8\ M^{-1}\ s^{-1}$),[986] and the cytochrome c_2 from *R. capsulatus* at physiological ionic strength does not show any tendency to associate with its reaction center and transfers its electron to the reaction center in a bimolecular reaction with a similar rate constant ($7 \times 10^7\ M^{-1}\ s^{-1}$).[987]

Cells of *R. capsulatus*, in addition to the water-soluble cytochrome c_2, also contain a cytochrome *c* that is anchored in their plasma membranes. This cytochrome *c* diffuses over the surface of the membrane to provide electrons to the reaction centers.[988,989] In other photosynthetic bacteria, only cytochromes *c* that are anchored in the membrane and diffuse over its surface can provide electrons to the reaction center.[990] The cytochrome *c* in *R. sulfidophilum*, which is anchored in the membrane by an extension at its amino terminus and provides an electron to its reaction center, is homologous in sequence with the water-soluble cytochrome c_2 found in its cytoplasm (50% identity; 0.6 gap percent), so both are descended from a common ancestor.[991]

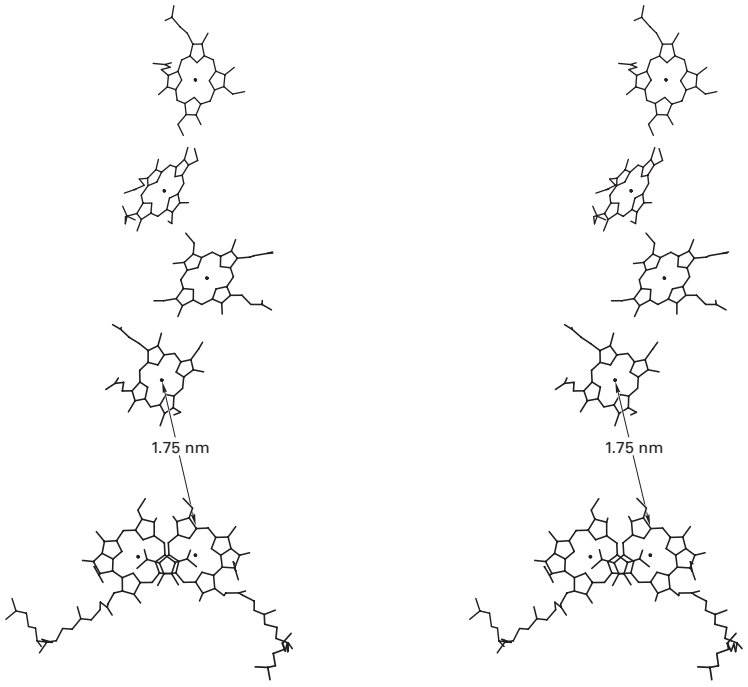

Figure 2–37: Stereodrawing[50] of the special pair of bacteriochlorophylls *b* and four hemes *c* in the tightly bound cytochrome *c* found in the crystallographic molecular model of the reaction center from *B. viridis*.[960] The cytochrome *c* that provides the electron to the radical cation of the special pair copurifies and cocrystallizes with the reaction center from *B. viridis* and is bound to it in the resulting crystallographic molecular model. The four hemes *c* of the cytochrome *c* are to the top of the drawing, and the special pair is at the bottom. The distance from the iron ion of the nearest heme *c* to the nearest carbon atom (carbon 9) within the aromatic π molecular orbital system of one of the chlorophylls *b* in the special pair is 1.75 nm (arrow in the drawing), but the nearest carbon of the double bond of the ethylidene group at position 8 of that chlorophyll *b* (R_3 in **2–54**), which is conjugated to the aromatic π molecular orbital system, is only 1.51 nm away from that iron ion.

In intact cells of photosynthetic bacteria, the **rate constant for the respective transfer of the electron** between the reduced heme *c* on the particular indigenous cytochrome *c* and the hole in the special pair of the reaction center varies from 1.4 μs^{-1} ($t_{½}$ = 0.5 μs) to 0.03 μs^{-1} ($t_{½}$ = 25 μs),[992] which is more than 3000-fold greater than the rate constant for transfer of the electron from the respective radical anion of the semiquinone back to the special pair.

After the excited electron has departed from it, **the radical cation of the special pair** (Equation 2–180), which is now in the ground state, is a **strong oxidant** that readily removes the electron from the reduced cytochrome *c*. Because this is a reaction that proceeds with a negative change of free energy ($\Delta E^{\circ\prime}$ = 200 mV; ΔG° = –19 kJ mol^{-1}), the concentration of the species $P^{\bullet+}BPhQ_A^{\bullet-}$ is decreased by the amount of $PBPhQ_A^{\bullet-}$ that is consequently formed

$$\frac{[PBPhQ_A^{\bullet-}]\,[\text{ferricytochrome } c]}{[P^{\bullet+}BPhQ_A^{\bullet-}]\,[\text{ferrocytochrome } c]} = 4 \times 10^4 \qquad (2\text{–}183)$$

Because so little $P^{\bullet+}BPhQ_A^{\bullet-}$ is present at any instant, the rate constant for the return of the electron from the radical anion of the semiquinone to the special pair (Equation 2–182) is decreased significantly.

The transfer of the electron from the cytochrome *c*, or the high-potential iron–sulfur protein, to the hole in the special pair makes the **overall reaction catalyzed by a photosynthetic reaction center in a purple bacterium upon the absorption of one photon**

$$\text{ferrocytochrome } c_{pos} + Q_{A,neg} + h\nu \rightleftharpoons Q_A^{\bullet-}{}_{neg} + \text{ferricytochrome } c_{pos} \qquad (2\text{–}184)$$

The electron is transferred from a donor of more positive biochemical standard reduction potential, the cytochrome *c*, to an acceptor of more negative biochemical standard reduction potential, the quinone bound at the A site, and the energy of the photon is used to drive the transfer. At this point, the system is still at a higher energy than the ground state, and it is capable of returning, albeit slowly, to the ground state. This return is prevented and the energy is conserved because the electron, at the moment on the radical anion of the semiquinone, subsequently dissociates entirely from the reaction center before the energy can be dissipated.

In a reaction center under normal circumstances, in addition to the quinone Q_A tightly bound as a prosthetic group on the A site (Figure 2–34), which receives the electron directly from the bacteriopheophytin immediately adjacent to it, there is a **second quinone**,[993] usually ubiquinone, even in *B. viridis*.[994] This ubiquinone (Q_B) is a loosely bound electron-transferring coenzyme at the B site, and under normal circumstances, it is freely exchanging with the pool of ubiquinone in the membrane. The B site at which the coenzymatic ubiquinone is located is related by the twofold rotational axis of pseudosymmetry of the LM dimer to the A site at which the prosthetic ubiquinone is found in the crystallographic molecular model of the reaction center from *R. sphaeroides* (Figure 2–34). The two quinones in a given reaction center are pseudosymmetrically displayed around a Fe^{2+} that sits upon the twofold rotational axis of pseudosymmetry. The electron is transferred from the radical anion of the semiquinone at site A to the ubiquinone at site B with a rate constant[995] of 5 ms^{-1} ($t_{½}$ = 140 μs).

The role of the iron ion in this transfer of the electron is unclear. Although reaction centers depleted of iron, either directly or by mutation of one of its ligands, display slower rates of electron transfer between quinone A and quinone B, [979,996] if the iron is replaced by other divalent cations, even ones incapable of participating in electron transfer, the rates of transfer are essentially the same as those of a native reaction center.[997]

Because of a difference in the amino acids that surround the quinones and their orientations in the two sites, quinone B has a more positive biochemical standard reduction potential than the prosthetic quinone in site A so that the equilibrium constant for the reaction

$$Q_A^{\bullet-}Q_B \rightleftharpoons Q_A Q_B^{\bullet-} \qquad (2\text{–}185)$$

is 15.[983,998] Consequently, under usual conditions of illumination the **first electron ends up on quinone B as a radical anion of the semiquinone**, which remains tightly bound to the reaction center until the arrival of a second electron.

The second electron arrives, as did the first, from an electronically excited state of the same special pair, which was regenerated upon the transfer of an electron from the cytochrome *c*. After it is regenerated with the electron from cytochrome *c*, the special pair can absorb the energy of a second photon or exciton to generate a new electronically excited state that passes its electron as before to the quinone in site A, and this transfer forms the radical anion of the semiquinone $Q_A^{\bullet -}$ next to the radical anion of the semiquinone $Q_B^{\bullet -}$ in site B. The radical anion of the semiquinone in site B is **hydronated rapidly** on one of its oxygens as the second electron is transferred from $Q_A^{\bullet -}$ to $Q_B^{\bullet -}$ to form the **ubiquinolate monoanion** Q_BH^-, so the product of the coupled hydron and electron transfers following the arrival of the second electron is $Q_AQ_BH^-$.[999] Site-directed mutation of Serine 223,[984,1000] Aspartate 213,[1001] or Aspartate 210[1002] in the L subunit of the reaction center from *R. sphaeroides* dramatically decreases the rate at which the second electron can be transferred from $Q_A^{\bullet -}$ to $Q_B^{\bullet -}$ by decreasing the rate at which $Q_B^{\bullet -}$ is hydronated. These results are consistent with the conclusion that hydronation of the radical anion of the semiquinone in site B must be concerted with the transfer of the electron to it from the radical anion of the semiquinone in site A.

If a solution of reaction centers is exposed to a saturating flash of light, the absorption spectrum of the radical anion of the semiquinone in site B appears, which remains stable in amplitude over 5 s. When a second saturating flash is administered, the absorption of this radical anion of the semiquinone disappears because the second electron has arrived at site B from the excited special pair and has produced the ubiquinolate monoanion Q_BH^-. If a third saturating flash is administered, however, the absorption of the radical anion of the semiquinone at site B reappears.[1003,1004] This last observation means that the ubiquinolate monoanion formed in the second flash has been replaced by ubiquinone or the third electron could not have been received. Because the radical anion of the semiquinone was bound stably at the instant of the second flash, the replacement must occur only after the ubiquinolate anion is formed.

Site-directed mutation of Glutamate 212[1005] in the L subunit of the reaction center from *R. sphaeroides* does not interfere with the transfer of the first hydron to the radical anion of semiquinone $Q_B^{\bullet -}$ but does interfere with the transfer of the second hydron, the one that hydronates the ubiquinolate monoanion Q_BH^- at site B. Because the side chain of this amino acid is an acid–base in site B in the crystallographic molecular model,[984] this result suggests that the ubiquinolate anion is **hydronated by the enzyme** before it is released from site B. This acid–base and Aspartate 210, Aspartate 213, and Serine 223 from the L subunit are thought to be responsible for ensuring that the two hydrons are efficiently provided and that they are derived from the aqueous solution on the negative, basic side of the membrane. Together they form a chain of acid–bases connected by hydrogen bonds that shuttle hydrons from the aqueous solution on the negative, basic side of the membrane to the two oxygens of the radical anion of the semiquinone or the ubiquinolate monoanion bound loosely as a coenzyme at site B.

The **complete reaction catalyzed by a photosynthetic reaction center in a bacterial chromatophore** upon absorption of the energy of two photons

$$2\,\text{acceptor}_{\text{red,pos}} + \text{quinone} + 2\,h\nu + 2\,\text{H}^+_{\text{neg}} \rightleftharpoons \text{quinol} + 2\,\text{acceptor}_{\text{ox,pos}} \tag{2–186}$$

where the acceptor is either a cytochrome *c* or a high-potential iron–sulfur protein. This equation is the sum of all the steps that have been described.

The energy in each photon of light that has been absorbed by a photosynthetic reaction center has been **divided among three purposes**. Part of it has been used to gain time and prevent the decay of the electronically excited state that would occur if the electron were permitted to return to the hole in the special pair. Part of it has been used to move an electron from a cytochrome *c* (+370 mV for *R. sphaeroides*) to ubiquinone, an acceptor of more negative biochemical standard reduction potential (+100 mV). And part of it has been used to remove two hydrons from the negative, basic side of the membrane.

Bacterial photosynthesis is a cyclic process. A reaction center in the chromatophore of a photosynthetic bacterium uses a photon of light to reduce ubiquinone and two hydrons to ubiquinol. The two hydrons come from the negative, basic solution on the exterior of the chromatophore and are transferred from that solution during the neutralizations

of the radical anion of the semiquinone and the ubiquinolate monoanion Q_BH^-. While it is reducing the ubiquinone with two successive electrons excited from the highest occupied molecular orbital of the special pair, the reaction center is oxidizing two cytochromes *c* or two high-potential iron–sulfur proteins dissolved in the positive, acidic solution on the interior of the chromatophore, which provide two electrons consecutively to the successive holes in the highest occupied molecular orbital in the special pair, which is situated on that side of the membrane (Figure 2–34). The ubiquinol produced at the negative, basic surface of the membrane then dissociates from site B on the reaction center and diffuses across the membrane to the Q_p site on quinol—cytochrome-*c* reductase on the positive, acidic side at which it is oxidized (Figure 2–32). When the ubiquinol is oxidized by quinol—cytochrome-*c* reductase at the Q_p site, it releases two hydrons to the positive, acidic side of the membrane. The two cytochromes *c* or two high-potential iron–sulfur proteins that dissociate in turn from the reaction center into the solution on the positive, acidic side diffuse through that solution[988] to the location on the heme c_1 subunit of quinol—cytochrome-*c* reductase at which they are reduced during the Q-cycle. The ubiquinones dissociate from the quinol—cytochrome-*c* reductase and diffuse across the membrane to be reduced by the reaction center, and the two reduced cytochromes *c* or the two reduced high-potential iron–sulfur proteins diffuse back to the reaction center to be oxidized.

The net result of this cyclic process (the sum of Equation 2–176 and Equation 2–186, realizing that quinones also migrate back and forth across the membrane) is that four hydrons are formally transported from the negative, basic solution on the exterior of the chromatophore to the positive, acidic solution on the interior of the chromatophore, against a significant electrochemical gradient of hydrons. The energy to perform the work of this formal transport of four hydrons is the energy in two photons of light.[1006] These photons may be absorbed consecutively by the reaction center itself, or more often, two photons of light are absorbed in an antenna and transferred to the special pair in the reaction center.

In the absence of the usual electron-transferring coenzyme, either cytochrome *c* or high-potential iron–sulfur protein, the heme c_1 on quinol—cytochrome-*c* reductase can itself provide an electron to the hole in the special pair during collisions within the membrane between the reaction center and heme c_1 on quinol—cytochrome-*c* reductase,[1007] but this process is not so effective as the transfer of the electron by the appropriate electron-transferring coenzyme.

In the chloroplasts of plants and in the membranes of cyanobacteria, photosynthesis is catalyzed by photosystem II and photosystem I. The plastoquinol oxidized by the central enzyme in the process, plastoquinol—plastocyanin reductase, is the product of reduction of plastoquinone at the quinol B site by excited electrons in the reaction center of photosystem II, and the reduced plastocyanin produced by plastoquinol—plastocyanin reductase is oxidized by providing electrons to the radical cation of the special pair in photosystem I. The core of both photosystem II[1008-1013] and photosystem I[1014-1017] is a photosynthetic reaction center. These two respective reactions centers are descendants of the reaction centers of photosynthetic bacteria. Their prosthetic groups are also positioned around a twofold rotational axis of pseudosymmetry, and that rotational axis of pseudosymmetry creates a special pair. Photosystem II has a special pair formed from two chlorophylls *a*; in addition, two chlorophylls *a* replace the two bacteriochlorophylls, two pheophytins *a* replace the two bacteriopheophytins, and two plastoquinones replace the menaquinone and ubiquinones of the bacterial reaction center. In photosystem I (Figure 2–38),[1018,1019] the special pair is also formed from two chlorophylls *a*; in addition, four chlorophylls *a* replace the two bacteriochlorophylls and the two bacteriopheophytins, and two phylloquinones replace the menaquinones and ubiquinones of the bacterial reaction center. All these substitutes play the same roles as their parental prosthetic groups in a bacterial reaction center.

In **photosystem II** in plants and cyanobacteria, the primary excitation of the electron and its transfer to pheophytin *a*[1020] differ somewhat from those in the bacterial reaction center because the special pair is more weakly coupled. The initial separation between the excited electron and the hole can occur in either of two locations. It can occur between one of the chlorophylls *a* of the special pair, which ends up with the hole, and the adjacent chlorophyll *a*, which ends up with the electron, on its way to pheophytin *a* as in the bacterial reaction center. It can also, however,

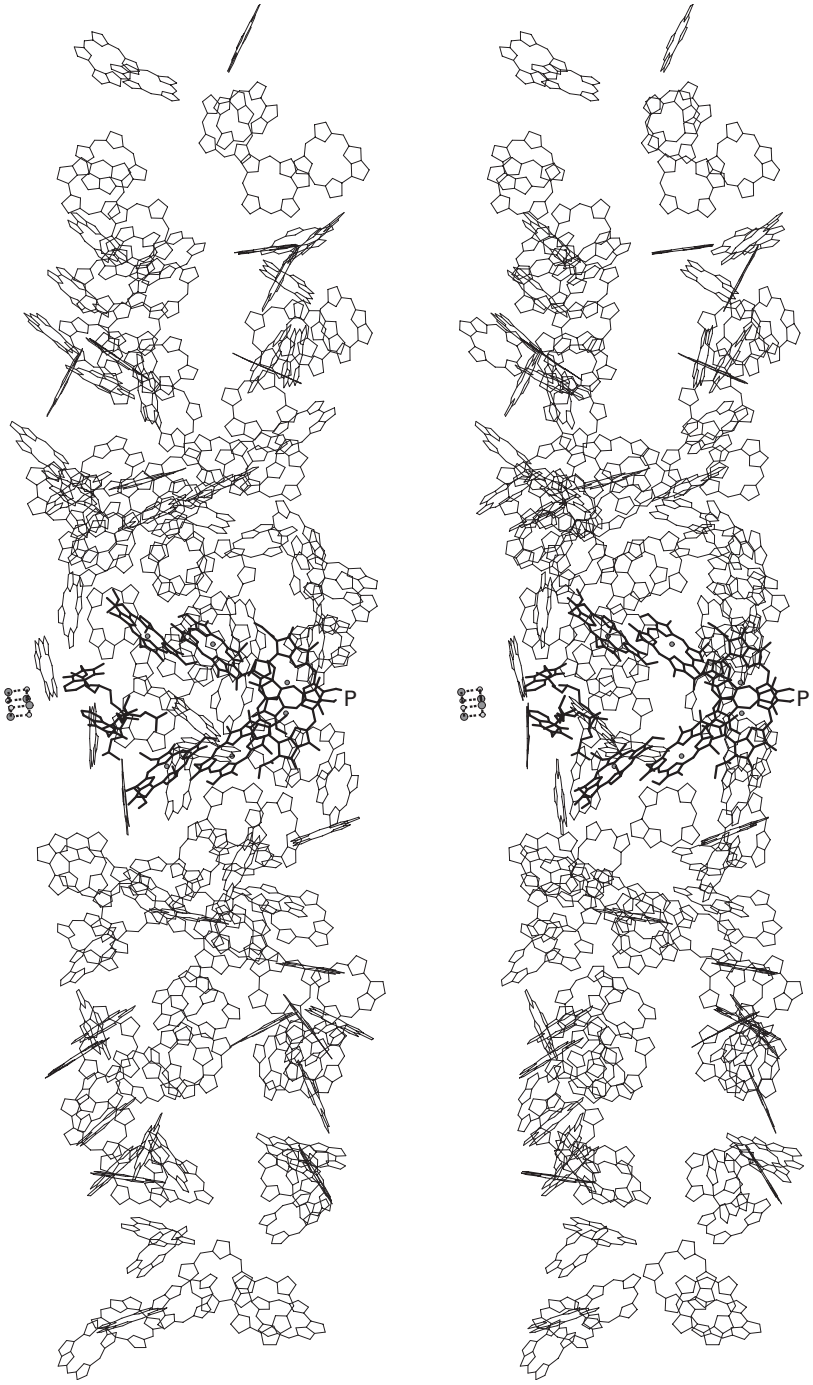

Figure 2–38: Stereodrawing[50] of the distribution of chlorophylls within the crystallographic molecular model of the reaction center of photosystem I from *P. sativum* and the antenna that surrounds it.[1018,1019] Only the central rings of the chlorophylls (thin bonds in the drawing), and not the carotenoids, of the antenna formed by the core protein and light-harvesting complex I are included in the drawing. The reaction center is formed from six chlorophylls *a* and two phylloquinones (thick bonds in the drawing) and a [4Fe–4S] iron–sulfur cluster. The [4Fe–4S] iron–sulfur cluster is embedded in the portion of the core protein that protrudes into the solution on the negative, basic side of the membrane. The special pair (P) is labeled. The plane of the membrane is vertical and perpendicular to the page. The twofold rotational axis of pseudosymmetry that creates the special pair is horizontal and in the plane of the page. The array of chlorophylls embedded in the protein spans the membrane of the thylakoid and defines its boundaries.

occur between this same chlorophyll *a* adjacent to the special pair, which ends up with the hole, and pheophytin *a*, which ends up with the electron. After the initial excitation at either location, the system almost immediately resolves into the normal distribution in which the excited electron is in the radical anion of pheophytin *a* and the hole is in the radical cation of the special pair. This resolution is accomplished by migration of the electron from the adjacent chlorophyll *a* to pheophytin *a* or migration of the hole from the adjacent chlorophyll *a* to the chlorophyll *a* of the special pair.[1021]

The subsequent transfer of the electron from pheophytin *a* to the two plastoquinones[1022] symmetrically bound around the iron ion[1023] in photosystem II is the same as in a bacterial reaction center. After the second electron arrives, the plastoquinol, which has taken up two hydrons from the negative, basic solution, dissociates into the phospholipid bilayer on its way across the membrane to the positive, acidic side of plastoquinol—plasto-cyanin reductase, just as the ubiquinol dissociates from the bacterial photosynthetic reaction center on its way to quinol—cytochrome-*c* reductase. The hole in the special pair, however, is a much stronger oxidant than the hole in the special pair in a bacterial reaction center[1024] because it is mainly located on only one of the two chlorophylls *a* in the special pair,[1021] rather than being delocalized over both. This is the advantage gained from the weaker coupling. This stronger oxidant removes an electron from the 4-oxido group of a particular[1025] tyrosine in the enzyme to form the neutral tyrosyl radical, rather than removing an electron from a cytochrome *c*.[1026,1027] The tyrosyl radical then removes an electron from a cluster of four manganese ions and a calcium ion[1011,1028] responsible for oxidizing water to molecular oxygen, an oxidation that ultimately releases four hydrons into the positive, acidic solution inside the thylakoid.

In **photosystem I** in plants and cyanobacteria, the primary excitation of the electron by a photon and its transfer to the chlorophyll *a* that takes the place of bacteriopheophytin also differ somewhat from those in the bacterial reaction center. The chlorophyll *a* adjacent to the special pair absorbs the photon, and the excited electron is immediately ($3\ ps^{-1}$) passed to the distal chlorophyll *a* that takes the place of the bacteriopheophytin in a bacterial reaction center. The hole then moves from the adjacent chlorophyll *a* to the special pair, and the electron moves from the distal chlorophyll *a* to the phylloquinone,[1029] to produce a distribution homologous to that in the bacterial reaction center, with the hole in the special pair and the electron in the ubisemiquinone.[1030] The hole in the special pair (+480 mV) is filled with an electron from the small electron-transferring coenzyme, reduced plastocyanin (+360 mV),[1031] that freely associates with and then dissociates from the reaction center on its positive, acidic surface on its way to the plastoquinol—plastocyanin reductase,[1032] just as the hole in the bacterial special pair is filled with an electron from a cytochrome *c* that then dissociates on its way to quinol—cytochrome-*c* reductase.

The unique feature of photosystem I (Figure 2–38) is that it produces a radical anion of the prosthetic phyllosemiquinone with a high biochemical standard reduction potential (–700 mV) by using a chlorophyll *a* (–1200 mV) as the acceptor of the excited electron rather than a pheophytin.[815] Because of the excitation process unique to photosytem I, the radical anion of this phyllosemiquinone is formed even more rapidly ($70\ ns^{-1}$; $t_{½} = 10$ ps) than the radical anion of the prosthetic ubisemiquinone in the bacterial system.[1030] This radical anion of phyllosemiquinone transfers its electron rapidly ($0.003\ ns^{-1}$; $t_{½} = 200$ ns) to a prosthetic [4Fe–4S] iron–sulfur cluster[1033,1034] with a biochemical standard reduction potential of around –700 mV[815] that sits on the twofold rotational axis of symmetry of the reaction center of photosystem I (Figure 2–38),[1016,1035] roughly in the location of the single Fe^{2+} in the bacterial reaction center (Figure 2–34). The electron is then transferred rapidly through two prosthetic [4Fe–4S] iron–sulfur clusters to a coenzymatic [2Fe–2S] ferredoxin loosely bound to the enzyme, which then dissociates into the solution on the negative, basic side of the membrane.[1036] The key to this sequence of events is that the radical anion of the phyllosemiquinone is not stabilized by the enzyme, so its full instability and hence its full, low biochemical standard reduction potential can be exerted. The fact that the small electron-transferring coenzyme is a [2Fe–2S] ferredoxin that can accept only one electron means that there is no need for the radical anion of the phylloquinone to wait for a second excited electron. The [2Fe–2S] ferredoxins in higher plants have biochemical standard reduction potentials[559] around –400 mV. The [2Fe–2S] ferredoxins reduced by photosystem I provide reducing equivalents to the plant cell or the cyanobacterial cell; an example would be the reduction catalyzed by ferredoxin—$NADP^+$ reductase, to produce NADPH ($E^{\circ\prime} = -310$ mV), the universal reductant used in biosynthesis, the generation of $MgATP^{2-}$, and in particular, for a plant cell, in carbon fixation.

In chloroplasts, there is a large membrane-spanning enzyme that is structurally homologous to NADH:ubiquinone reductase (H^+-translocating).[1037,1038] A molecular model of this enzyme in chloroplasts, derived from image reconstruction of electron micrographs,[1037] however, has only three of the usual eight iron–sulfur clusters present in most NADH:ubiquinone reductases (H^+-translocating) from mitochondria and bacteria: the upper three in Figure 2–33, which are closest to the membrane. It is possible that several subunits of the intact enzyme are missing in this molecular model,[1038] in particular those containing the other five usual iron–sulfur clusters (the lower five in Figure 2–33) more distal to the membrane and connecting the three that are present in the molecular model to the site at which NADH is oxidized in NADH:ubiquinone reductase (H^+-translocating). The quinone that is reduced by this enzyme while it actively transports hydrons from the negative, basic side of the membrane of the chloroplast to the positive, acidic side, as does NADH:ubiquinone reductase (H^+-translocating), is plastoquinone rather than ubiquinone; and the reduced plastoquinol is then a substrate for plastoquinol—plasto-cyanin reductase. The immediate source of reducing equivalents for this enzyme in the membranes of chloroplasts is unclear. The ultimate source is the reduced ferredoxin produced by photosystem I.[1039,1040] The structural homology with NADH:ubiquinone reductase (H^+-translocating) suggests that the immediate source of reducing equivalents for the enzyme in chloroplasts is the NADPH produced by ferredoxin—$NADP^+$ reductase. In any case, the reducing equivalents in ferredoxin are ultimately used to transport hydrons against their electrochemical gradient by passing through this homologue of NADH:ubiquinone reductase (H^+-translocating). Because the electrochemical gradient is the source of the energy used to synthesize $MgATP^{2-}$, this enzyme serves the purpose of balancing the needs of the cell for reducing equivalents, in the form of NADPH, and energy, in the form of $MgATP^{2-}$.

The achievement that has been accomplished by a photosynthetic reaction center is denying the excited electron access to the hole that it vacated by disconnecting it rapidly enough so that its return to the hole by the normal process of fluorescent decay is precluded. To accomplish this disconnection, the electron is shuttled at an extremely rapid rate to a quinone (ubiquinone, menaquinone, plastoquinone, or phylloquinone) distant enough from the hole and at a positive enough standard reduction potential that the return of the electron to the hole becomes so slow that the electron can be held long enough to be used as a reductant for the respective electron-transferring coenzyme (ubiquinone, plastoquinone, or ferredoxin) and long enough for the hole to be filled by an electron from the appropriate donor (cytochrome *c*, high-potential iron–sulfur protein, a cluster of four manganese ions and a calcium ion, or plastocyanin). This speed and this span can be accomplished because a continuous chain of closely spaced prosthetic groups connects the special pair with the respective quinone in site A (Figure 2–34) and because, along the way, the excited electron is passing through large aromatic π molecular orbital systems of bacteriochlorophylls and bacteriopheophytins that themselves each span a large distance (0.7 nm).[1041] In these enzymes, the **requirement that the electron travel over such a great distance** (about 4 nm) is dictated by two facts. First, the greater the dilution of the electron, the slower its return to the ground state will be. Second, the electron from the respective reduced electron-transferring coenzyme must be received by the hole in the special pair at one side of the membrane, and the excited electron must be added to the respective oxidized electron-transferring coenzyme at the other side of the membrane to create the respective gradient of hydrons. In the reaction center from *R. sphaeroides*, the distances between the closest points in the π molecular orbital systems are 0.63 nm from the special pair to bacteriochlorophyll and 0.65 nm from bacteriochlorophyll to bacteriopheophytin (Figure 2–34). These short distances ensure that the transfer of the excited electron is extremely rapid (200 ns^{-1}; $t_{½}$ = 4 ps). The distance between the closest points in the π molecular orbital systems is 1.09 nm from bacteriopheophytin to the quinone in site A. The greater distance may in part explain the less rapid transfer from bacteriopheophytin to the quinone in site A (5 ns^{-1}; $t_{½}$ = 150 ps), but it does accomplish the final jump to the negative, basic side of the membrane.

In many of the membrane-spanning enzymes catalyzing the transfer of electrons (Figures 2–32 and 2–33) and in many of the water-soluble enzymes catalyzing oxidation–reductions that proceed by the transfer of single electrons (Figures 2–30 and 2–31), there are chains of prosthetic groups that perform one-electron transfers and move electrons over considerable distances. These chains of

prosthetic groups can be formed from iron–sulfur clusters (Figures 2–31 and 2–33)[478] or hemes (Figure 2–30 and 2–32)[1042,1043] or, if the biochemical standard reduction potential of the hole into which the electron is donated is positive enough, the side chains of tryptophans[1044] and tyrosines.

The individual prosthetic groups in one of these chains are usually **spaced at distances that are less than particular limits**.[1045] Because the electron that is transferred to or from each prosthetic group occupies a molecular orbital spread over the entire π molecular orbital system in a flavin, chlorophyll, pheophytin, or quinone, the distance over which the electron is transferred between donor and acceptor in such situations is the distance from the closest edge of the respective π molecular orbital system (Figures 2–30 and 2–31). Because the electron occupies a molecular orbital spread over the entire cluster in a prosthetic group such as an iron–sulfur cluster or a copper–sulfur cluster, the distance over which the electron is transferred between donor and acceptor in such situations is the distance between the closest atoms in the two clusters (Figures 2–31, 2–32, and 2–33). Because the electron occupies an atomic orbital in a single copper ion or an iron ion in a prosthetic group such as a heme, the distance over which the electron is transferred between donor and acceptor in such situations[1046] may be the distance from the metallic ion itself (Figures 2–30 and 2–32).

The distances between the two orbitals in which the electron resides before and after it is transferred through chains of flavins, chlorophylls, pheophytins, quinones, iron–sulfur clusters, clusters of copper ions, and single copper ions are **usually from 0.4 to 1.4 nm** (Figures 2–30, 2–31, and 2–33).[478,651,894,1042-1045,1047,1048] Even in enzymes that have only two such prosthetic groups between which the electron is transferred, the distance between the two orbitals containing the transferred electron before and after the transfer usually fall in this range.[674,817,1049,1050] For example, in nitrite reductase (NO-forming) from *A. xylosoxidans*, the two copper ions between which electrons are transferred are 1.3 nm apart.[1051]

In an apparent exception to the rule, while the distance from the iron in a heme to the nearest electron donor or acceptor frequently falls within the range 0.4–1.4 nm, it is also often greater than 1.4 nm (Figures 2–30 and 2–32).[1047] For example, the distance between the iron in the heme *c* and the iron in the heme d_1 of nitrite reductase (NO-forming) from *Paracoccus pantotrophus* is 2.06 nm.[1691] Partly these larger distances are due to the fact that the heme itself is quite large and hard to approach very closely, especially by another heme, but it is probably the case that the **π molecular orbital system surrounding the iron in a heme** carries a certain fraction of the highest occupied atomic orbital of the iron containing the electron to be donated or of the lowest unfilled atomic orbital of the iron that will be accepting the electron. Consequently, the π molecular orbital system projects a portion of that atomic orbital beyond the iron, bringing it closer to the edge of the heme.

Although in some cases two prosthetic groups are close enough to touch each other,[1052] the space between the molecular orbitals or the iron or copper ions covered by these distances between the prosthetic groups is usually filled with the side chains and polypeptide backbone of the protein enclosing them. Consequently, the question of how the electron is transferred so rapidly from prosthetic group to prosthetic group in these situations is how is an electron transferred through protein.

During a one-electron oxidation–reduction between two redox couples separated from each other in a protein, an unaccompanied electron can transfer through unadulterated protein over a considerable distance (1.5–2.5 nm).[1045,1046,1053,1054] For example, when Histidine 33 in oxidized equine cytochrome *c* is used as one of the ligands to Ru^{3+}, the other five ligands to which are molecules of ammonia, the derivative that results is a cytochrome *c* in which the Fe^{3+} in heme *c* is 1.5 nm from the pentaamminoruthenium at Histidine 33. When Ru^{2+} coordinated with three 2,2′-bipyridines [$Ru(bpy)_3^{2+}$] is dissolved in an aqueous solution of this modified cytochrome *c* and excited by a flash of light with a wavelength of 532 nm, its electronically excited state is a strong enough reductant to transfer an electron rapidly to either Ru^{3+} or Fe^{3+} in the modified cytochrome *c*. This transfer of an electron occurs in a 5:1 molar ratio, respectively, between Ru^{3+} and Fe^{3+}. This kinetic product, in which most of the ruthenium ions are reduced and most of the iron ions remain oxidized, then converts to the thermodynamic product in which most of the iron ions are reduced and most of the ruthenium ions are oxidized.[1053] This conversion results from the intramolecular transfer of an electron from Ru^{2+} to Fe^{3+} through 1.5 nm of unadulterated protein with a rate constant of 20 s^{-1}, which is independent of temperature between

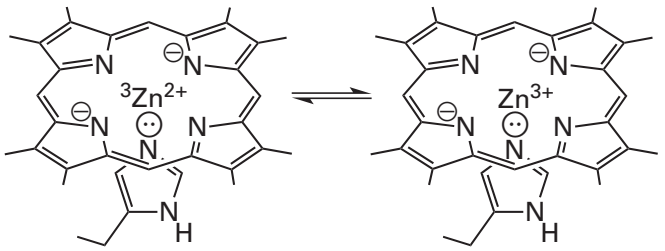
0 and 37 °C. This rate constant is for the approach to thermodynamic equilibrium of a reversible transfer of the electron between the ruthenium ion bound to the protein and the iron ion of the heme.[1055]

It is also possible to observe such an **unnatural transfer of an electron through a protein** without the necessity to modify it. The single disulfide in azurin from *P. aeruginosa* can be reduced to the radical anion of the disulfide by the radical anion $CO_2^{\bullet -}$. The electron in the resulting radical anion of the disulfide is then transferred across 2.0 nm of protein[1056] to the Cu^{2+} at a rate of 50 s^{-1}.

Because cytochrome *c* may not have evolved to transfer an electron from Histidine 33 to its heme and because azurin may not have evolved to transfer an electron from its disulfide to its copper ion, these observations of the transfer of electrons in these two proteins suggest that transfer of electrons may be able to occur through any protein. Azurin and cytochrome *c*, however, have evolved to catalyze electron transfer.

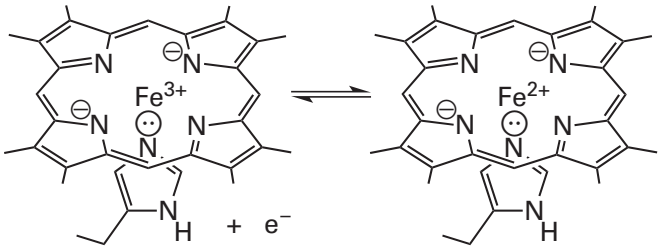
Hemoglobin is a protein that does not normally participate in oxidation–reduction; and it is a protein that definitely has not evolved to be able to support the transfer of electrons through itself. The protein normally contains four hemes *b*, one within each of its subunits. It is an $(\alpha\beta)_2$ heterotetramer, but α and β polypeptides are homologous in sequence, and the native structures of the α and β subunits are superposable. It is possible to separate α and β subunits and reconstitute the protein from these separated subunits. Therefore, a hemoglobin in which the α subunits contained an Fe^{3+} porphyrin and the β subunits contained a Zn^{2+} porphyrin could be constructed.[1057]

When a Zn^{2+} porphyrin is excited by absorbing a photon of light, the excited electron is particularly prone to a spin inversion that produces a triplet electronically excited state, $^3Zn^{2+}$ porphyrin, in good quantum yield. The lifetime of this phosphorescent triplet electronically excited state is much longer (greater than 10 ms) than that of the fluorescent singlet electronically excited state from which it was derived.[1058] The triplet electronically excited state is also a strong enough reductant ($E^{\circ\prime}$ = −1100 mV)



(2–187)

to transfer an electron[1054] to an Fe^{3+} porphyrin ($E^{\circ\prime}$ = +150 mV)



(2–188)

The free energy change of the overall reaction is quite favorable (ΔG° = −120 kJ mol^{-1}).

When hemoglobin containing a Zn^{2+} porphyrin in the β subunits and an Fe^{3+} porphyrin in the α subunits is photolyzed, the decay of the triplet state of the Zn^{2+} porphyrin is more rapid than it is when the Fe^{3+} porphyrin has been reduced to Fe^{2+} porphyrin prior to photolysis.[1054] If it is assumed that this increase in the rate of decay is due to transfer of the electron from the $^3Zn^{2+}$ porphyrin to the Fe^{3+} porphyrin, the first-order rate constant of that transfer is 100 s^{-1} at 25 °C.[1059] In the crystallographic molecular model of a molecule of hemoglobin, the shortest distance between a heme on a β subunit and a heme on an α subunit is 2.5 nm. This experiment demonstrates that the transfer of an electron can occur through any protein and reverses the question from "can an electron transfer through protein" to "how can an electron be prevented from transferring through protein." In this experiment, it is also the case that the electron passes between two subunits of an oligomeric protein.

Traditionally, transfers of electrons have been divided into inner-sphere and outer-sphere transfers. An **inner-sphere electron transfer** is one in which the electronic coupling between the donor (a reductant) and the acceptor (an oxidant) is strong (>20 kJ mol^{-1}) in the transition state. In the original examples of inner-sphere electron transfer, the donor and acceptor, which were transition metallic

ions, were strongly coupled because in the transition state they shared a ligand between themselves. For example, in the oxidation–reduction[1060]

$$\left[(NH_3)_5Co^{3+}Cl^-\right]^{2+} + \left[Cr^{2+}(H_2O)_6\right]^{2+} \rightleftharpoons H_2O + \left[(NH_3)_5Co^{3+}Cl^-Cr^{2+}(H_2O)_5\right]^{4+} \rightleftharpoons \left[(NH_3)_5Co^{2+}(H_2O)\right]^{2+} + \left[Cl^-Cr^{3+}(H_2O)_5\right]^{2+} \quad (2\text{–}189)$$

the transfer of the electron from Co^{2+} to Cr^{3+} occurs within the inner sphere created by the intermediate ion $[(NH_3)_3Co^{3+}Cl^-Cr^{2+}(H_2O)_5]^{4+}$. The electron passes through the chloride that the transition metallic ions share as a ligand and that strongly couples them electronically. An **outer-sphere electron transfer** is one that takes place with weak (<20 kJ mol^{-1}) electronic coupling between the donor and acceptor in the transition state. For example, the transfer of an electron in which two transition metallic ions retain all their ligands during their encounter in the transition state and no ligand is shared between them usually progresses with weak electronic coupling in an outer-sphere transfer.

In enzymatic reactions, inner-sphere transfer of an electron occurs when a bond, anywhere between ionic and covalent, is formed between a substrate and a transition metallic ion, which then oxidizes or reduces that substrate. For example, in nitrite reductase (NO-forming) from *A. faecalis*, the substrate, nitrite, replaces a dissociable ligand in the open coordination site of the prosthetic Cu^+ in the enzyme.[1061] An electron is transferred from the Cu^+ to the nitrite. reducing it to nitric oxide, which then dissociates from the Cu^{2+}. In laccase, an oxygen of the substrate, a benzenediol, replaces a dissociable ligand in the open coordination site of the Cu^{2+} in the enzyme.[695] An electron is instantaneously transferred from the benzenediol to that Cu^{2+}, oxidizing the benzenediol to the hydroxyphenoxy radical, which then dissociates from the resulting Cu^+.

In such **inner-sphere electron transfers**, because the transfer of the electron is to all intents and purposes instantaneous once the complex forms, the rate at which the **ligand initially occupying the open site on the metallic ion exchanges with the substrate** and the rate at which the product on the metallic ion exchanges with a ligand in solution determine the rate of the overall reaction. In aqueous solution, the ligand occupying the open site is usually a molecule of water. The rate constants with which molecules of water exchange at divalent metallic ions[1062,1063] are in excess of 10^4 s^{-1}. For Fe^{2+}, the rate constant is 3×10^6 s^{-1}; and for Cu^{2+}, it is 8×10^9 s^{-1}. The rate constant for exchange of water from $Fe^{3+}(OH_2)_6$, however, is slower, 3×10^3 s^{-1}; and that for chloride,[1064] the main anion in the cytoplasm, from $[Fe^{3+}(OH_2)_5Cl^-]^{3+}$ is slower still, 2.3 s^{-1}. Consequently, the exchange of a substrate into coordination with a prosthetic Fe^{3+} or a product out of coordination with a prosthetic Fe^{3+} will be slow.

Although the transfer of an electron between two prosthetic groups separated by 0.5–2.5 nm of protein is technically between a donor and an acceptor that share the same ligand, namely the protein itself, the distances involved and the number of atoms located in the intervening space cause the electronic coupling between donor and acceptor to be so weak that the transfer of the electron is unmistakably an **outer-sphere electron transfer.**

When the transfer of an electron is inner-sphere, one, two, or three bonds connect the donor and the acceptor, and as soon as the exchange of ligands occurs and these bonds have formed, the transfer of the electron is instantaneous. When transfer of an electron is outer-sphere, the electronic coupling between donor and acceptor is so weak that the **actual transfer of the electron is the slow step** in the reaction. Because the electronic coupling is so weak, the electron has to wait until all the atoms surrounding and between the donor and acceptor reach a configuration that is favorable to the transfer before the electron can transfer from the orbital it occupies on the donor to the orbital it will occupy on the acceptor.[1065]

Because an electron has almost no mass and because, once a favorable configuration has been achieved, the transfer of the electron from the donor to the acceptor is instantaneous, **the Franck–Condon principle requires that the position and momentum of all the nuclei in the system be the same before and after the transfer of the electron.**[1066] The equilibrium positions of the nuclei in the reactants, when the electron is on the donor, however, are different from their equilibrium positions in the products, when the electron is on the acceptor. For example, when the electron is on the donor, the donor is more negative by one elementary charge and the acceptor is more positive by one elementary charge than they are when the electron has transferred to the acceptor. Consequently, the coordination of the charges differs significantly in the reactants and

products of the electron transfer, and the atoms accomplishing that coordination are in significantly different locations. Likewise, the equilibrium bond lengths between a transition metallic ion and its ligands shorten when it loses an electron or lengthen when it gains an electron. The normal spontaneous fluctuations in the positions of the atoms surrounding and between the donor and the acceptor must bring those atoms into a configuration intermediate between their equilibrium configurations in the reactants and in the products, and that intermediate **configuration must be compatible with the transfer of the electron**.

The configuration of the atoms surrounding and between the donor and acceptor is compatible with transfer of the electron when the energy of that configuration is the same in the reactants and the products.[1065] In other words, the configuration of all the atoms surrounding and between the donor and the acceptor must be such that the **energy of the system is the same before and after the instantaneous transfer** of the electron from donor to acceptor.

The atoms surrounding and between the donor and the acceptor are constantly fluctuating in their position and momentum. When they happen to reach a configuration in which the energy before and after the transfer of the electron would be the same, the requirement of the Franck–Condon principle and the requirement that energy be conserved are both met, and the electron can transfer from donor to acceptor. Whether it transfers or not depends on the strength of the electronic coupling. The weaker the electronic coupling, the more often a compatible configuration will be realized before the transfer of the electron actually occurs.[1046]

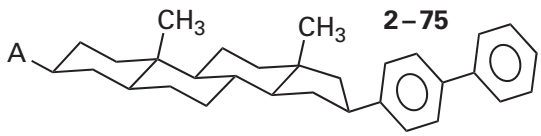
When an electron is transferred in the outer sphere between a donor and acceptor, such as a reduced prosthetic group and an oxidized prosthetic group in the same protein, the **equation derived from these considerations, the Marcus equation, defines the rate constant of this intramolecular electron transfer**[1067,1068]

$$k_{ET} = \frac{4\pi^2 {H_{AB}}^2}{h\,(4\pi\lambda\, k_B T)^{1/2}} \exp\left[-\frac{(\lambda + \Delta G^\circ)^2}{4\lambda k_B T}\right] \qquad (2\text{–}190)$$

where h is the Planck constant, k_B is the Boltzmann constant, H_{AB} is the **electronic matrix element** quantifying the coupling of the electronic state of the donor with the electronic state of the acceptor when both are in the configuration of the transition state,[1046] ΔG° is the change in the standard free energy of the overall oxidation–reduction (Equation 2–92), and λ is the reorganization energy. The **reorganization energy** is the difference between the free energy of a Franck–Condon state in which the position and momentum of the nuclei and their respective solvation are the same before and after the transfer of an electron and the sum of the free energies of the equilibrium nuclear configuration of the donor, the equilibrium nuclear configuration of the acceptor, and their respective solvations. In the case of self-exchange between an identical donor and acceptor, the reorganization energy is equal to the energy required to alter the nuclear configuration of the donor and acceptor and their solvation from their equilibrium configuration to a configuration that matches the equilibrium nuclear configuration of the products of the electron transfer and their their solvation, and it is often assumed that, in other instances, the reorganization energy is approximately equal to this energy.[1041,1046,1069]

For a given electron transfer, **the values of ΔG°, H_{AB}, and λ can be estimated** by following the temperature dependence of the rate constant for the transfer of the electron (Equation 2–190). The standard free energy of the overall oxidation–reduction at each temperature can be determined by measuring the respective standard reduction potentials (Equation 2–92) by potentiometric titrations. After these measurements are completed, the standard free energy at any given temperature is known, so the only two unknowns in Equation 2–190 are H_{AB} and λ. The measured rates of electron transfer as a function of temperature can be fit with the simplified equation to determine these two parameters.[1070-1072]

Because the reorganization energy is always a positive number, the unexpected prediction made by this equation is that the **rate of transfer for an electron should pass through a maximum as the standard free energy of the oxidation–reduction is decreased** to more negative values, as long as the structure of the reactants and products remain as similar as possible so that the reorganization energy remains about the same, while the reactant is varied to accomplish this decrease in the change of the standard free energy for the reaction. For example, in a series of 17-(4-biphenylyl)androstanes



the identity of A, the acceptor, was varied among a set of functional groups with different standard reduction potentials (Figure 2–39).[1069] When the resulting compounds were individually reduced by solvated electrons injected into the solution by an electron beam, the rate at which an electron was transferred from the radical anion of the 4-biphenylyl group, formed by the association of a solvated electron, to the respective acceptor could be measured. The rate constants for these electron transfers do go through a maximum as the standard reduction potential of the acceptor increases and the change in standard free energy for the transfer of the electron decreases. The data could be fit with Equation 2–190 with a reorganization energy of +75 kJ mol^{-1}.

The fact that the rate of an outer-sphere electron transfer passes through a maximum as its change in standard free energy is decreased is a consequence only of the fact that the equilibrium configurations of the atoms surrounding and between the donor and the acceptor lie at the bottom of a potential well for the reactants and the bottom of a different potential well for the products.[1065,1069] The fact that the data seem to fit the behavior predicted by Equation 2–190, and that such behavior was unexpected, validates the equation. This maximum in the rate of electron transfer as the change in standard free energy of the reaction is varied has been observed consistently for simple intramolecular chemical oxidation–reductions,[1073,1074] for intermolecular electron transfer between a donor in which an electron is widely delocalized and a series of small acceptors,[1075] and for intramolecular transfers of electrons through proteins (Figure 2–40).[982,1041,1076-1079] Such a maximum is also observed for the transfer of an electron from a Ru^{2+} ion on Histidine 33 of equine cytochrome *c* to the Fe^{3+} in its heme.[1080] The value for the change in free energy for the oxidation–reduction at the maxima of these observed curves is the negative of the value of the reorganization energy (Equation 2–190). The fits of Equation 2–190 to the data, however, are usually not so convincing as the fits in Figures 2–39 and 2–40, which were chosen for the present discussion to convince.

For transfer of an electron through protein, the reorganization energy is usually around +70 to +110 kJ mol^{-1}. For example, the reorganization energy

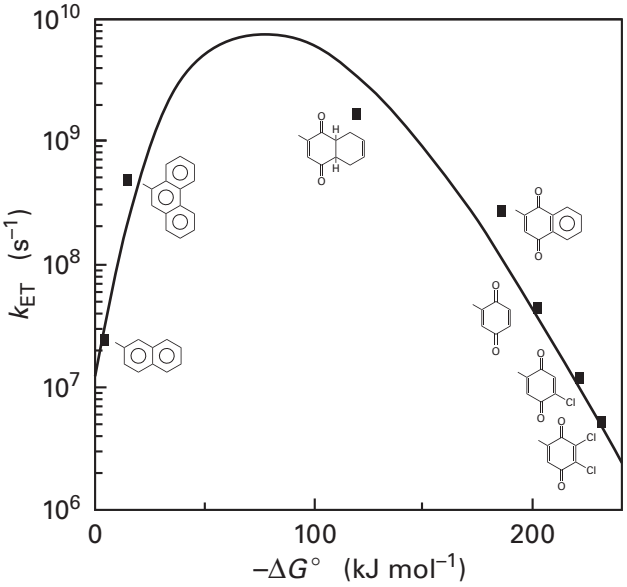


Figure 2–39: Dependence of the rate constant (k_{ET}) for intramolecular transfer of an electron within various versions of the 17-(4-biphenylyl)androstane **2–75** on the difference in standard reduction potential ($-\Delta G^\circ$) between the 4-biphenylyl group and the respective acceptor.[1069] Several versions of 17-(4-biphenylyl)androstane, each with a different acceptor for intramolecular transfer of an electron at carbon 3, were synthesized. The structures of the various functional groups acting as acceptors are drawn next to the points on the graph for their rates of intramolecular electron transfer. Each version was dissolved separately in di(*n*-butyl) ether. The respective solutions were each exposed to a intense, short pulse (30 ps to a few nanoseconds) of an electron beam from a linear accelerator. The resulting hydrated electrons that were formed instantaneously in the solution were trapped by biphenylyl groups to create biphenylyl radical anions, which absorb light of wavelengths between 400 and 650 nm. The decay in the concentration of the biphenylyl radical anion was followed by its absorbance. It was found that when an acceptor was located at carbon 3 of the androstane, the decay of the biphenylyl radical anion was hastened by intramolecular electron transfer. In appropriate cases, the appearance of the radical anion of the acceptor could also be followed. The rate constants for each intramolecular electron transfer (second^{-1}) calculated from these data are plotted as a function of the differences in standard reduction potential (kilojoules mole^{-1}) between a biphenylyl group and the respective acceptor. Note that the difference in rate constant between the most rapid transfer and the slowest transfer is greater than a factor of 100.

for transfer of an electron from bacteriopheophytin to quinone A in the reaction center of *R. sphaeroides* (Figure 2–34)[982] has been estimated to be +60 kJ mol^{-1}, that for the transfer of an electron between a ruthenium ion and the iron ion in the heme in cytochrome b_5 (Figure 2–40)[1076] has been estimated to be +90 kJ mol^{-1}, and that for the transfer

of an electron from the T1 prosthetic Cu^{+} to the NI prosthetic Cu^{2+} of laccase from *Toxicodendron vernicifluum*[1081] has been estimated to be +115 kJ mol^{-1}. The changes in standard free energy for most natural electron transfers in enzymes that catalyze oxidation–reductions are often significantly less than −70 to −80 kJ mol^{-1}. Under these circumstances, the **rate constant for transfer of an electron through protein increases almost exponentially as the change in standard free energy for the reaction decreases** (Equation 2–190).[1078,1082-1084]

Because the rate constant for transfer of an electron, within the normal range of changes in standard free energy, is also increased by decreasing the reorganization energy (Equation 2–190), it is possible that reorganization energy is subject to natural selection.[1065] For example, when the methionine that was placed by natural selection as a ligand to one of the copper ions in nitrite reductase from *A. faecalis* is removed by site-directed mutation,[1085] the reorganization energy for the transfer of an electron from this copper ion to the other copper ion in the enzyme increases by 40 kJ mol^{-1}.

The two parameters that determine the value of the rate constant for an electron transfer, the reorganization energy, λ, and the electronic matrix element describing the coupling of the electronic state of the reactant with the electronic state of the product, H_{AB}, can be separately factored in Equation 2–190 and therefore have independent effects on the rate constant. If the space between donor and acceptor within a protein were not filled by other atoms but were empty vacuum, the magnitude of the electronic coupling would be a function of only the distance between donor and acceptor because it would be determined by the degree of overlap that occurs between the wave functions of the molecular orbitals occupied by the electron on the donor and the electron on the acceptor.[1086]

In the realm of energies in which the reorganization energy is more positive than the change in standard free energy is negative, which is the normal situation in a molecule of protein, **the more negative the change in standard free energy, the greater the rate of electron transfer** (Equation 2–190). In the enzyme laccase, an electron is transferred over a distance of 1.23 nm through the protein between a mononuclear, prosthetic Cu^{+} coordinated by two histidines and a cysteine (Figure 2–26A), at which each of four benzenediols in turn are oxidized by one electron, and a trinuclear cluster of prosthetic copper ions coordinated by the imidazolyl groups of eight histidines,[1087] at which a molecule of oxygen is reduced by the four electrons to two molecules of

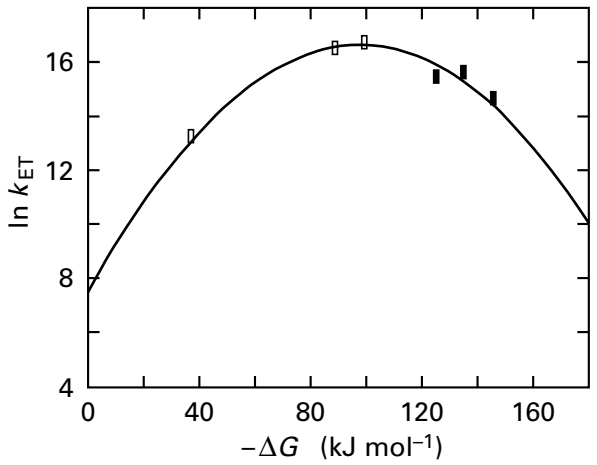

Figure 2–40: Dependence of the rate constant (k_{ET}) for intramolecular transfer of an electron through the folded polypeptide of cytochrome b_5 to and from the Fe^{3+} in its heme on the difference between the standard reduction potential ($-\Delta G^{\circ}$) of the heme and donors attached to the protein, each at the same location.[1076] The gene for cytochrome b_5 from *R. norvegicus* was mutated in the codon for Threonine 69 to to produce a codon for a cysteine. The mutated gene was expressed in *E. coli*, and the mutant protein was purified. The resulting Cysteine 69 is the only cysteine in the mutant, and it was modified in separate reactions with [4-(bromomethyl)-4′-methylbipyridine]bis(bipyridine)ruthenium(II), [4-(bromomethyl)-4′-methylbipyridine]bis(4,4′-dimethylbipyridine)ruthenium(II), and [4-(bromomethyl)-4′-methylbipyridine](bipyridine)(bipyrimidine)ruthenium(II). Each coordinated ruthenium dication that was attached to the protein through Cysteine 69 has a different standard reduction potential in its excited electronic state, and each has a different standard reduction potential in its ground electronic state. The three different modified proteins were dissolved separately and the resulting solutions were excited with short, intense flashes of light that formed the electronically excited states of the respective ruthenium dications. The transfers of an electron to and from the heme in each derivative were monitored at 424 and 556 nm; and the transfers of the electron from and to the ruthenium complexes were monitored at the isosbestic points for the heme at 439 and 547 nm. The natural logarithms of the rate constants (second^{-1}) fortransfer of the electron from the excited electronic state of Ru^{2+} to the Fe^{3+} of the heme (open symbols) and those for subsequent transfer of the electron from the resulting Fe^{2+} in the heme back to the ground electronic state of Ru^{3+} (filled symbols) are plotted as a function of the differences in standard reduction potential (kilojoules mole^{-1}) of the respective donor and acceptor.

water. The transfer between these two prosthetic groups is exergonic because the prosthetic, mononuclear copper ion has a less positive biochemical standard reduction potential than the trinuclear cluster. There are two homologous (25% identity; 1.4 gap percent) laccases, one from *Trametes versicolor* and one from *T. vernicifluum*, in which the biochemical standard reduction potentials for the prosthetic, mononuclear copper ion have significantly different values of +780 and +430 mV, respectively. This difference causes transfer of the electron from the former mononuclear copper ion through the protein to its trinuclear cluster (+1030 mV) to be less exergonic than transfer of the electron through the latter protein to its trinuclear cluster (+970 mV); in other words, the change in standard free energy, ΔG°, in Equation 2–190 is negative in both cases but is less negative in the former laccase (–25 kJ mol^{-1}) than in the latter laccase (–52 kJ mol^{-1}). The reorganization energies, λ, for the electron transfer have been estimated to be +115 and +110 kJ mol^{-1}, respectively, a difference that is most likely within the error of the estimations. The electronic matrix elements, $H_{AB,}$ have also been shown to be the same in the two proteins. The equivalence of these two factors is not surprising since the two proteins are homologues of each other. The observed rate of electron transfer in the laccase from *T. versicolor* is 20 s^{-1}, and the observed rate constant of electron transfer in the laccase from *T. vernicifluum* is greater than 700 s^{-1}. Both values are consistent with the respective values for the change in standard free energy.[1081]

It has been observed in many situations[1041,1088-1093] that, provided ΔG° and λ remain the same, **the function describing the distance dependence of the rate constant for transfer of electrons through molecules other than proteins** is[1067,1069]

$$k_{ET} = k_0 \exp\left[\beta\left(r - r_0\right)\right] \qquad (2\text{–}191)$$

where r is the distance between donor and acceptor, r_0 is the sum of their van der Waals radii or the closest distance they can approach each other, and k_0 is the rate constant for transfer of an electron when donor and acceptor are as close together as possible and the exponential term equals 1. For example, a series of compounds analogous to **2–75** was synthesized in which the donor again was the radical anion of the 4-biphenylyl group and the acceptor R was a naphthyl group (Figure 2–39). The rigid hydrocarbon separating the biphenylyl group and the naphthyl group was varied in length, and the donor and acceptor each occupied equatorial positions of the cyclohexyl rings of the rigid hydrocarbon. The variation in the rate constants for transfer of an electron between the biphenylyl and naphthyl groups satisfied Equation 2–191 with a value of β equal to –12 nm^{-1} (Figure 2–41A).[1069,1088] Although this was not the case in the measurements made with this series of compounds, the most reliable way to ensure that the effects of small changes in ΔG° and λ on the rate constants for transfer of an electron are minimized in such an experiment is to use a donor and an acceptor for which $-\Delta G^\circ \cong \lambda$ (Figures 2–39 and 2–40), a situation in which the derivative of the rate constant for exchange as a function of the change in free energy is 0.

The dependence on the distance *r* between donor and acceptor of the rate constant for transfer of an electron through protein has been extensively measured. In the most extensive set of experiments (Figure 2–42),[1045,1094] ruthenium ions were bound to histidines inserted by site-directed mutation at particular positions in the sequence of amino acids for isoform 1 of cytochrome *c* from *S. cerevisiae* (○; six different positions),[1095-1097] equine cytochrome *c* (○; two different positions),[1098] cytochrome b_{562} from *E. coli* (□; nine different positions),[1099] azurin from *P. aeruginosa* (●; six different positions),[1095,1100,1101] myoglobin from *Physeter macrocephalus* (▼; three different positions),[1046,1102] or high-potential iron–sulfur protein from *A. vinosum* (■; four different positions).[1103] In each case, the ruthenium ion was coordinated by two 2,2′-bipyridines, an imidazole, and the imidazolyl group of the particular histidine that had been placed on the surface of the particular protein.[1098] For each protein, the rate constants for transfer of an electron from Fe^{2+} in its heme, its Cu^+, or its reduced [4Fe–4S] iron–sulfur cluster to Ru^{3+} on the histidine were measured.[1098,1104] These electron transfers are all exergonic enough (ΔG° = –71 kJ mol^{-1} for cytochrome *c*, ΔG° = –76 kJ mol^{-1} for cytochrome b_{562}, and ΔG° = –73 kJ mol^{-1} for azurin) that they are in the range where $\Delta G^\circ \cong -\lambda$.[1080]

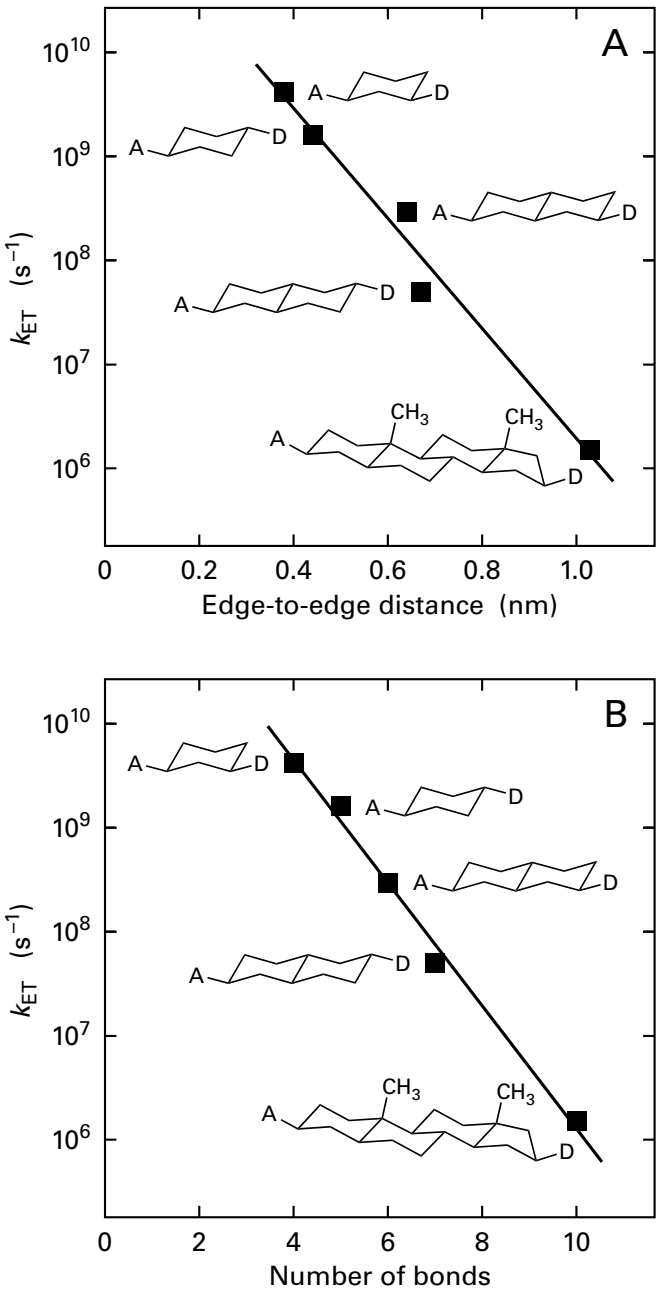

Figure 2–41: Dependence of the rate constant (k_{ET}) for intramolecular transfer of an electron between a 4-biphenylyl group and a 2-naphthyl group, held apart by various rigid hydrocarbons, on the distance between the 4-biphenylyl group and the 2-naphthyl group.[1069] *cis*-1-Naphthyl-3-(4-biphenylyl)-cyclohexane, *trans*-1-naphthyl-4-(4-biphenylyl)cyclohexane, *cis*-2-naphthyl-7-(4-biphenylyl)decalin, *trans*-2-naphthyl-6-(4-biphenylyl)decalin, and *cis*-1-naphthyl-17-(4-biphenylyl)androstane were synthesized. The structure of each of the hydrocarbons positioning the acceptor (A) and the donor (D) at fixed distances from each other is drawn next to the point for the respective rate of electron transfer. Each compound was dissolved separately in tetrahydrofuran. The respective solutions were each exposed to an intense, short pulse (30 ps to a few nanoseconds) of an electron beam from a linear accelerator. The resulting hydrated electrons that were formed instantaneously in the solution were trapped by biphenylyl groups to create biphenylyl radical anions. The decay in the concentration of each of the biphenylyl radical anions was followed by its absorbance. In each instance, it was found that the presence of the acceptor hastened the decay of the biphenylyl radical anion. The amount that the rate was accelerated by the presence of the acceptor was used to calculate the rate constant (second^{-1}) for each intramolecular electron transfer. The natural logarithms of these rate constants are plotted as a function of **(A)** the respective distances (nanometers) between the edges of the aromatic π molecular orbital systems of the biphenylyl group and the naphthyl group and **(B)** the respective number of carbon–carbon bonds between the two edges.

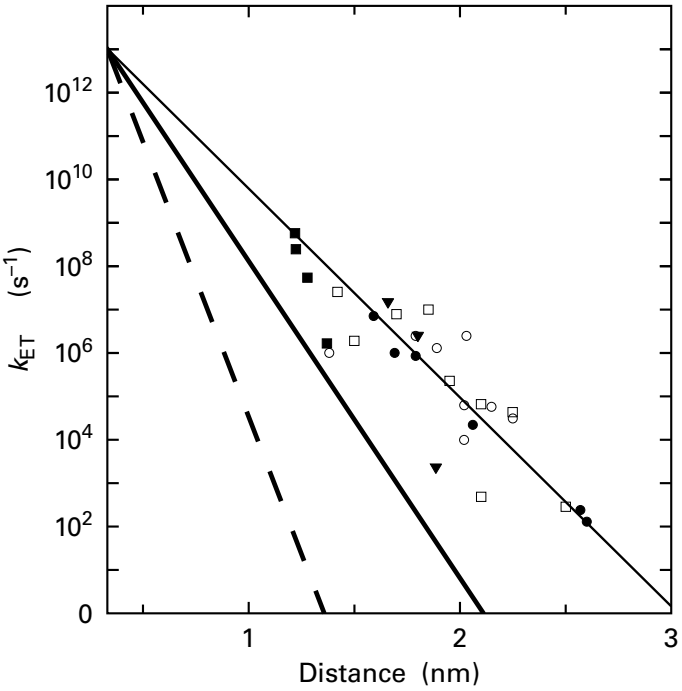

Figure 2–42: Dependence of the rate constant (k_{ET}) for intramolecular transfer of an electron through azurin (●),[1095] cytochrome *c* (○),[1046,1096-1098] cytochrome b_{562} (□),[1099] myoglobin (▲),[1046,1102] and high-potential iron–sulfur protein (■),[1103] as a function of the distance between donor and acceptor.[1094,1099] The amino acids at positions 83, 107, 109, 122, 124, and 126 in azurin from *P. aeruginosa*; at positions 39, 54, 58, 62, and 66 from isoform 1 of cytochrome *c* from *S. cervisiae*; at positions 33 and 72 from equine cytochrome *c*; at positions 12, 15, 19, 63, 70, 73, 86, 89, and 92 in cytochrome b_{562} from *E. coli*; at positions 70, 83, and 95 in myoglobin from *P. macrocephalus*; and at positions 18, 42, 50, and 81 in high-potential iron–sulfur protein from *A. vinosum* were changed one at a time to histidines by site-directed mutation. Each resulting histidine was modified with bis(bipyridine)ruthenium(II) carbonate followed by treatment with imidazole to produce a Ru^{2+} coordinated by two bipyridines, an imidazole, and the imidazolyl group of the respective histidine.[1104] Each modified cytochrome and high-potential iron–sulfur protein was exposed to a short (25 ns) intense pulse of light at 480 nm to form the electronically excited state of Ru^{2+}. An electron then transferred from this electronically excited state to the Fe^{3+} in the ferric heme of cytochrome *c* or the oxidized [4Fe–4S] iron–sulfur cluster of high-potential iron–sulfur protein to produce the ferrous heme or the reduced [4Fe–4S] iron–sulfur cluster and Ru^{3+}. The rate at which the electron transferred from the ferrous heme or the reduced [4Fe–4S] iron–sulfur cluster back to Ru^{3+} was then measured at wavelengths that monitor the transformation of ferrous heme to ferric heme and Ru^{3+} to Ru^{2+}. Each modified azurin or myoglobin was exposed to a short (25 ns) intense pulse of light at 480 nm to form the electronically excited state of the Ru^{2+}. The electron then transferred instantaneously from this electronically excited state to a quencher that had been added to the solution to create Ru^{3+}. The rate at which an electron transferred from the natural Cu^{+} of azurin or the natural Fe^{2+} in the heme of myoglobin to Ru^{3+} was then measured[1101] at wavelengths that monitor the transformation of cuprous azurin to cupric azurin, ferrous myoglobin to ferric myoglobin, and Ru^{3+} to Ru^{2+}. The rates for the transfers of the electrons (second^{-1}) are plotted on a common logarithmic scale as a function of the distances (nanometers) between the respective donors and acceptors as estimated from the crystallographic molecular models of the proteins. The thin solid line is a least-squares fit of the data, the thick solid line is the dependence on distance for transfer of an electron between Ru(2,2′:6,2′′-terpyridine)$_2^{2+}$ and $Fe(OH_2)_6^{3+}$ in a frozen glass of water,[1094] and the dashed line is the dependence on distance for transfer of an electron in the vacuum.[1045,1094]

From the crystallographic molecular models of the unmodified proteins, the distance from the ruthenium ion bound at each histidine to the ion of the transition metal or the nearest ion of the transition metal in the natural prosthetic group was calculated. When the common logarithms of the rate constants for these electron transfers are plotted as a function of these distances, the value of β obtained from a fit of Equation 2–191 to the data is –11 nm^{-1} (Figure 2–42).[1099] The linearity of the rate constants for high-potential iron–sulfur protein suggests that it might be more informative to plot the rate constants for each protein separately, but the scatter of the rate constants for the other proteins suggests that this approach would not reveal any significant differences among the different proteins.

The distances between natural redox couples in proteins can also be used to evaluate this correlation between the rate of electron transfer and distance. When the rate constants for transfer of an electron between the various pairs of prosthetic groups in the reaction center in *R. sphaeroides* (Figure 2–34) are adjusted from their actual values to the values they would have if ΔG° were equal to $-\lambda$, and the natural logarithms of these adjusted rate constants are plotted as a function of the edge to edge distances between the π molecular orbital systems of the prosthetic groups, a linear relationship is observed.[1041] The data in this latter correlation fit Equation 2–191 far more successfully than do the data in Figure 2–42, but these were rate constants that had been significantly adjusted, rather than the actual rate constants. The value of β for the fit of these distances in the reaction center to Equation 2–191 is –14 nm^{-1}.

One problem with the actual rate constants for the artificial electron transfers through protein (Figure 2–42) is that they do not fit Equation 2–191 with much success. This failure as well as theoretical arguments suggest that, rather than through an orbital overlap as would be the case in the vacuum, **the electron is transferred through unoccupied antibonding molecular orbitals** of a continuous sequence of covalent bonds[1105-1107] and hydrogen bonds[1108] that connect the donor of the electron to the acceptor of the electron.* Transfer of an electron also can occur through fixed molecules of water connecting two segments of polypeptide.[1094,1109-1112]

Certainly, transfers of electrons through protein, for which the values of β are –11 to –14 nm^{-1}, are **faster than they would be through the vacuum**, for which the values of β are –28 to –35 nm^{-1} for the same span of distances (dashed line in Figure 2–42),[1045,1094] or even between Ru(2,2′:6,2″-ter-pyridine)$_2^{2+}$ and $Fe(OH_2)_6^{3+}$ through an unbonded glass of molecules of water, for which the value of β is –17 nm^{-1} (thick solid line in Figure 2–42).[1094] The fact that transfer of an electron through a molecule of protein is so fast suggests that it is occurring by some process beyond the overlap of molecular orbitals occupied by the electron in the donor and the acceptor.

In this view, for each intramolecular transfer of an electron through a protein, there are several (or more than several) explicit but often tortuous **paths through the antibonding molecular orbitals** of the chemical bonds, hydrogen bonds, and fixed molecules of water between donor and acceptor, and associated with each path is a particular value of the electronic matrix element H_{AB}.[1113,1114] The actual transfer of the electron occurs along the path or paths with the highest values of H_{AB}.

This view is not inconsistent with the observation that rate constants of intramolecular transfer of an electron through molecules other than protein are usually exponential functions (Equation 2–191) of the distance between donor and acceptor (Figure 2–41A) because they are also exponential functions of the number of covalent bonds between donor and acceptor, and those covalent bonds are usually the same covalent bonds as the length is increased (Figure 2–41B). This equivalence of distance, the number of bonds, and their identity in synthetic molecules is due to the fact that they are usually built from regular repeating structures such as rigid rings of hydrocarbon or rigid regular polymers such as polyproline. Molecules of protein, however, are irregularly folded, irregular polymers interconnected by multiple hydrogen bonds and sometimes fixed molecules of water, so the lengths of the paths through the antibonding molecular orbitals of covalent bonds, hydrogen bonds, and molecules of water connecting donor and acceptor often are uncorrelated with the distance between donor and acceptor.

One indication that an electron might be transferred through a protein along a particular path of covalent and noncovalent bonds is the behavior of the rate constants for transfer of an electron to the prosthetic Cu^{2+} from Ru^{+} coordinated at each of the

*Hydrogen bonds are equivalent to covalent bonds in their ability to catalyze transfer of an electron.[1108]

respective histidines placed by site-directed mutation on the surface of azurin from *P. aeruginosa*. The positions chosen for the histidines in these experiments were along three continuous β strands, each of which contains one of the ligands to the copper ion, Histidine 46, Methionine 121, or Cysteine 112 (see Figure 2–26E). In this case, the distance from each Ru^{+} ion to the Cu^{2+} should be directly proportional to the number of covalent bonds between them, and the correlation between the distances and the common logarithms of the rate constants for transfer of an electron is a good one (filled circles in Figure 2–42). In the case of cytochrome *c*, however, the positions chosen for the histidines were scattered over the structure,[1095] and the correlation between the distances and the common logarithms of the rate constants is poor (open circles in Figure 2–42).

For transfer of an electron that proceeds through a path of the antibonding orbitals in a sequence of bonds connecting donor and acceptor[1113,1115]

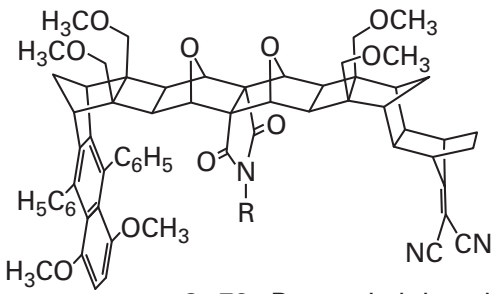
$$H_{AB} = H^{\circ}_{AB} \prod_{i=2}^{n_c} \varepsilon_{c,i} \prod_{j=1}^{n_s} \varepsilon_{s,j} \prod_{k=1}^{n_H} \varepsilon_{H,k} \qquad (2\text{–}192)$$

where H°_{AB} is the electronic coupling of the antibonding molecular orbitals immediately adjacent to molecular orbitals in the donor and the acceptor between which the electron is transferred, $\varepsilon_{c,i}$ is the decay parameter for the ith covalent bond of the n_c covalent bonds along the path, $\varepsilon_{s,j}$ is the decay parameter for the jth jump through space of the n_s jumps through space along the path, and $\varepsilon_{H,k}$ is the decay parameter for the kth hydrogen bond of the n_H hydrogen bonds along the path. The decay parameters quantify the decay of the electronic coupling at each step along the path. The value of H_{AB} is calculated for as many paths between donor and acceptor as time will permit, and the one or two giving the largest values are then assigned as the most likely.[242,1048,1114-1116] This exercise provides an explicit chain of covalent bonds, hydrogen bonds, and jumps through space that permits a visualization of the passage of the electron. Unfortunately, the number of parameters required for a calculation by Equation 2–192 is so large and their uncertainty so great that reliable values of rate constants for transfer of an electron cannot be calculated with it for comparison with experimental values.

Although the term electron transfer seems to imply that the same electron leaves the donor and arrives on the acceptor, it is obvious that this is not the case. If transfer occurs through bonds, these bonds contain pairs of electrons, none of which can be distinguished from the electron that is transferred from the donor. If electron transfer occurs through space, there are electrons in the space between donor and acceptor, none of which can be distinguished from the electron that is tranferred from the donor. Strictly speaking, electron transfer through bonds or through space should be referred to as **net electron transfer**.

The argument over outer-sphere intramolecular transfer of an electron is **whether it occurs through bonds (Equation 2–192)**[1113] **or through space (Equation 2–191)**.[1045] In the former view, the failure of the observed rate constants for intramolecular electron transfer through proteins (Figure 2–42) to follow Equation 2–191 is due to the intricacy of the various paths through bonds connecting donor and acceptor. In the latter view, the failure results from variations in the dielectric properties of the intervening medium, in particular the fraction of the space occupied by atoms and the fraction of the space that is vacant. Various molecules have been synthesized to contribute experimental justification for one or the other side in this argument.

There are results suggesting that electron transfer in solution occurs **through space**. For example, two calixarenes have been synthesized that covalently connect a zinc porphyrin with a pyromellitimide group by the same path of covalent bonds, but in one of these calixarenes, the edge of the zinc porphyrin is 0.5 nm from the edge of the pyromellitimide, and in the other, the edges are 1.5 nm apart. In benzene, transfer of an electron is observed between the zinc porphyrin and the pyromellitimide in the former but not in the latter.[1117] Transfer of an electron from the 1,4-dimethoxy-5,8-diphenylnaphthyl group to the 1,1-dicyanoethenyl group in



2–76 R = *p*-ethylphenyl
2–77 R = propyl

was measured in acetonitrile. When a phenyl group sits between the donor and acceptor (**2–76**), the rate constant for transfer of an electron ($0.64\ ns^{-1}$) is 2.6 times faster than the rate constant ($0.25\ ns^{-1}$) when a propyl group (**2–77**) sits between them, even though the through-bond paths are identical in each case.[1118,1119]

There are other results, however, suggesting that transfer of an electron in solution occurs **through bonds**. For example, the rate constants for transfer of an electron from a phthalimido group to a *tert*-butyl peroxy group actually increase as the number of α-aminoisobutyryl groups separating them, and the distance between them, increases.[1120] This observation suggests that the increase in the number of hydrogen bonds in the 3_{10} helix formed by these polymers of α-aminoisobutyric acid explains the increase in the rate constants.

It is possible that in some situations transfer of an electron proceeds through space while in other situations it proceeds through the antibonding molecular orbitals of bonds, and in still other situations by some combination of the two.

Side chains of aromatic amino acids such as tryptophan and tyrosine can act as intermediate relay stations through which a hole for an electron is relayed within a protein by hopping from one to the next.[1068,1121-1124] For example, in photoreduction of the oxidized prosthetic flavin in the active site of deoxyribodipyrimidine photo-lyase from *E. coli*, a hole for an electron is transferred from the electronically excited state of the prosthetic oxidized flavin in the active site to Tryptophan 306 on the surface of the enzyme following photolytic excitation of the flavin. Between the flavin and Tryptophan 306 are two others, Tryptophan 382 and Tryptophan 359, that act as relay stations to relay the hole from the electronically excited state of the oxidized flavin to Tryptophan 306.[1125]

While there has never been any doubt that electrons hop from one prosthetic group to another in instances where there is a chain of prosthetic groups, such as pheophytins, chlorophylls, iron–sulfur clusters, or hemes, that normally transfer an electron by successive one-electron reductions, the low standard one-electron reduction potentials for the side chains of tryptophan and tyrosine ($E^{\circ\prime} < -1800$ mV)[1126] to form their respective radical anions preclude transfer of an electron from a donor to one of them and from the resulting radical anion to the acceptor. The biochemical standard reduction potentials, however, for the radical cation of the indolyl group of tryptophan ($E^{\circ\prime} = +1000$ mV)[1127] and for the radical cation of the 4-hydroxyphenyl group of tyrosine ($E^{\circ\prime} = +800$ mV)[1128] are in the reasonable range. Consequently, rather than an electron hopping among the tryptophans and the tyrosines from donor to acceptor, **a hole hops from acceptor to donor.**

The difference is somewhat semantic. For example, in the case of photoactivation of deoxyribodipyrimidine photo-lyase, which reduces the oxidized flavin in its active site to flavin semiquinone, it has been shown[1125] that an electron first transfers from the indolyl group of the closest tryptophan, Tryptophan 382, to the photoexcited oxidized flavin, creating a hole in Tryptophan 382 in the form of an **indolyl radical cation** and the flavin semiquinone. The hole is then transferred to the next tryptophan, Tryptophan 359, when an electron transfers from it to the hole in Tryptophan 382, creating a hole in Tryptophan 359 in the form of an indolyl radical cation. Finally, the hole is transferred to Tryptophan 306 on the surface of the protein when an electron transfers from it to the hole in Tryptophan 359. The net result of this process is that an electron has been transferred from Tryptophan 306 to the photoexcited oxidized flavin.

In ribonucleoside-diphosphate reductase from *E. coli*, which reduces ribonucleoside diphosphates to deoxyribonucleoside diphosphates, a hole is transferred from a stable tyrosyl radical in another protein, which functions as an electron-transferring coenzyme during catalysis, to the sulfido group of Cysteine 439 in the active site of the enzyme to create a thiyl radical. The role of the electron-transferring coenzyme in the reaction is to be a one-electron oxidant and then a one-electron reductant, donating a hole to ribonucleotide reductase and then accepting back a hole each time the ribonucleoside-diphosphate reductase reduces a ribonucleotide to a deoxyribonucleotide. The peculiar aspect of the transfer of this hole is that it is endergonic;[1129] the difference in reduction potential between the tyrosyl radical and the thiyl radical has been estimated to be around +200 mV.* It is the change in overall free energy for enzymatic reduction by ribonucleoside diphosphate that pulls the hole to the sulfido group. There are two tyrosines in ribonucleoside-diphosphate reductase, Tyrosine 731

*Transfer of an electron from a donor of more negative reduction to an acceptor of more positive reduction potential is exergonic, but transfer of a hole from a donor of more negative reduction potential to an acceptor of more positive reduction potential, as is the case here, is endergonic.

and Tyrosine 730, immediately adjacent to the cysteine in the active site that could act as relay stations for the hole from the stable tyrosyl radical in the electron-transferring coenzyme and among which it would hop.[1130] In this instance, an electron in the 4-hydroxyphenyl group of Tyrosine 731 would transfer to a hole arriving from the tyrosyl radical in the electron-transferring coenzyme, then an electron in the 4-hydroxyphenyl group of Tyrosine 730 would transfer to the resulting hole in the radical cation of the 4-hydroxyphenyl group of Tyrosine 731, and then an electron in the sulfido group of Cysteine 439 would transfer to the resulting hole in the radical cation of Tyrosine 730, resulting in the thiyl radical necessary for catalysis.

The biochemical standard reduction potentials for the radical cations of tryptophan or tyrosine can be decreased by positioning a catalytic base adjacent to the nitrogen–hydrogen bond in the indolyl group or the oxygen–hydrogen bond in the 4-hydroxyphenyl group to accept the hydron from the respective radical cation, each of which is a stronger acid than the neutral, unoxidized group. The drawback of stabilizing the hole by removing a hydron from the radical cation, however, is that the rate of transfer of the electron to the hole from the next participant in the chain is decreased. In the case of photoreduction of deoxyribodipyrimidine photo-lyase, the nitrogen–hydrogen bonds on Tryptophan 382, Tryptophan 359, and Tryptophan 306 form hydrogen bonds with the acyl oxygen in the carbamoyl group on the side chain of Asparagine 378, a fixed molecule of water, and a fixed molecule of water, respectively, in the crystallographic molecular model of the protein,[1131] each of which is only a weak base, and in this instance the three successive radical cations remain hydronated and cationic.[1125] In the case of ribonucleotide reductase, however, in the crystallographic molecular model of the enzyme,[1132] the 4-hydroxy group of Tyrosine 731 forms a hydrogen bond with the 4-hydroxy group of Tyrosine 730, which also forms a hydrogen bond with the sulfanyl group of Cysteine 439. It has been proposed that when the hole arrives at Tyrosine 731 to form its radical cation, the 4-oxido group of the conjugate base of Tyrosine 730 removes a hydron from it. This transfer of a hydron turns the radical cation into the **neutral 4-hydroxyphenyl radical**. Then when the hole is transferred to Tyrosine 730, the resulting 4-oxido group of the conjugate base of Tyrosine 731 removes a hydron from it. Finally, when the hole arrives at the sulfanyl group of Cysteine 439, the resulting 4-oxido group of the conjugate base of Tyrosine 730 removes a hydron from it.[1133] The hydron transfers would serve the purpose of stabilizing the hole on each successive relay station.

When Tryptophan 306 in deoxyribodipyrimidine photo-lyase from *E. coli* is mutated to a phenylalanine, the hole ends up in one of the indolyl groups of the tryptophans that act as relay stations rather than on Tryptophan 306.[1134] When either Tyrosine 730 or Tyrosine 731 in ribonucleoside-diphosphate reductase from *E. coli* is mutated to a 3-aminotyrosine, which has a lower biochemical standard reduction potential for the redox couple of the 3-amino-4-phenoxyl group and the 3-amino-4-hydroxyphenyl group (+400 mV)[1135] than for the redox couple of a thiyl radical and a sulfanyl group (+900 mV),[1136] an electron is transferred from that 3-aminotyrosine to the hole in the tyrosyl radical rather than from the sulfanyl group of the cysteine in the active site.[1137] Each of these results has been presented as evidence that, in the normal reaction of each enzyme, the hole hops along the chain of relay stations (tryptophans and tyrosines) from the acceptor (either the electronically excited state of the flavin semiquinone or the tyrosyl radical in the electron-transferring coenzyme) to the donor (the tryptophan or the sulfido group). In the normal reaction of each mutated enzyme, however, a pre-established transfer of an electron must naturally occur from the normal donor to the normal acceptor, so it is not surprising that when the normal donor is eliminated, an even closer donor supplies the electron in its stead, or that when a better donor is placed immediately adjacent to the normal donor, the better donor would simply provide the electron rather than the normal donor.

It has also been observed that when a tyrosine or a tryptophan that could act as a relay station in a protein through which a hole is transferred is **substituted by mutation**, the rate for transfer of the electron decreases. For example, when either Tryptophan 382 or Tryptophan 359 in deoxyribodipyrimidine photo-lyase from *E. coli* is mutated to a phenylalanine, the photoexcited state of the flavin semiquinone decays before the electron can be transferred to it from Tryptophan 306.[1125] When Tyrosine 730 and Tyrosine 731 in ribonucleotide reductase from *E. coli* were mutated in turn to phenylalanine, the enzymatic activity of each mutant was less than 1% of the wild-type enzyme.[1138]

The effects of specific chemical modification of each of 12 lysines on the surface of equine cytochrome *c* on transfer of an electron between it and

bovine cytochrome-*c* oxidase,[1139] as well as computational descriptions of the docking of equine cytochrome *c* and bovine cytochrome-*c* oxidase,[1140] have tentatively defined the structure of the complex between them, in which electron transfer occurs between the heme in cytochrome *c* and the dinuclear CuA cluster of copper ions in cytochrome-*c* oxidase (Figure 2–26F). In that proposed complex, Tryptophan 143 in cytochrome-*c* oxidase from *R. sphaeroides* sits between the heme and the dinuclear CuA cluster. When Tryptophan 143 is mutated to phenylalanine, the rate constant for electron transfer between the reduced heme in equine cytochrome *c* and the oxidized dinuclear CuA cluster in cytochrome-*c* oxidase from *R. sphaeroides* decreases[1141] from 38×10^3 s^{-1} to 85 s^{-1}.

In tyramine β-monooxygenase from *Drosophila melanogaster*, Tyrosine 79 is stacked upon Histidine 172, which is a ligand to one of the two prosthetic copper ions in the enzyme. Tyrosine 79 lies between this copper ion and the other copper ion in the enzyme. When Tyrosine 79 is mutated to alanine, the rate for transfer of an electron from the one copper ion to the other, which in the native enzyme is not rate-limiting, becomes the rate-limiting step in the enzymatic reaction.[1142]

It is also possible to **accelerate an electron transfer by adding a relay station for the hole**. For example, the P450 peroxidase from *S. acidocaldarius* contains a heme with a sulfido group as its axial ligand. Lysine 97, on the surface of the enzyme, was mutated to cysteine, and a ruthenium ion coordinated by two 2,2′-bipyridines and a 1,10-phenanthroline was covalently attached to the sulfanyl group of the cysteine. The ruthenium ion ended up about 2.1 nm from the heme. Histidine 76 is adjacent to the heme and forms a hydrogen bond with one of its carboxyethyl groups.[1143] The homologous enzyme (30% identity; 1.9 gap percent) from *Bacillus megaterium* has a tryptophan in place of the histidine that also forms a hydrogen bond with the same carboxyethyl group of the heme.[1144] No transfer of an electron from an Fe^{3+} in the heme to a photolytically generated Ru^{3+} on the surface of peroxidase from *S. acidocaldarius* is observed in the native enzyme over the lifetime (100 μs) of the Ru^{3+}, but when Histidine 76 in the enzyme is mutated to tryptophan to create a relay station 0.7 nm from the heme and 1.2 nm from the ruthenium ion, an electron is transferred[1145] from the Fe^{3+} to the transient Ru^{3+} during its lifetime.

The rate for transfer of an electron through azurin from *P. aeruginosa* between its prosthetic Cu^{+} (Figure 2–26E) and a Ru^{3+} coordinated by a histidine added to the surface of the protein by site-directed mutation (filled circles in Figure 2–42) is accelerated by the addition of a relay station[1146] for the hole between Cu^{+} and Ru^{3+}. A single histidine was placed by site-directed mutation at position 107 on one strand of β-structure in azurin or at position 124 or 126 on another strand of β-structure in the protein to construct three mutants. A ruthenium ion coordinated by two 2,2′-bipyridines and an imidazole was then coordinated to the imidazolyl group of the inserted histidine in each of these three mutants.[1098] Cysteine 112, which is a ligand to the copper ion (Figure 2–26E), is at the carboxy-terminal end of the first strand of β-structure, and Methionine 121, which is also a ligand to the copper ion (Figure 2–26E), is at the amino-terminal end of the second strand of β-structure. The relay station chosen for the hole, a 3-nitrotyrosyl side chain ($E^{\circ\prime}$ = +1100 mV),[1128] was then placed in turn by mutation on the same strand of β-structure between the inserted histidine to which the ruthenium ion was attached and the respective ligand to the copper ion in each of the three mutants. The relay stations were placed at position 109 on the first strand of β-structure in the mutant with the inserted histidine at position 107, at position 122 on the second strand of β-structure in the mutant with the inserted histidine at position 124, and at position 122 on the second strand of β-structure in the mutant with the inserted histidine at position 126. Both positions to which nitrotyrosyl relay stations were added were amino acids in the wild-type protein, Methionine 109 and Lysine 122, that had side chains incapable of being oxidized and acting as a relay station for a hole, and the positions chosen in each case for the relay stations were between the respective positions chosen for the histidine and the ligand to the copper ion, either cysteine or methionine (Figure 2–26E).

The rate for transfer of an electron from Cu^{+} to Ru^{3+} was determined for each of the three mutants both with and without the inserted relay station. Addition of each nitrotyrosine as a relay station for the hole between Ru^{3+} and Cu^{+} in the three mutants increased the rates of electron transfer by factors of 30, 50, and 15, respectively.[1146] The neutral 3-nitrophenyl radical of nitrotyrosine has about the same biochemical standard reduction potential as a radical cation of the indolyl group of a tryptophan, but the

Ru^{3+} is such a strong oxidant that it is able to abstract an electron readily from the nitrotyrosyl group. This abstraction of an electron creates a hole on the nitrotyrosyl group, which is the hole into which the electron from Cu^{+} is then transferred in the instances in which the relay stations were present.

Hopping of a hole or an electron through one or more relay stations should **significantly increase the rate for overall transfer of an electron over long distance** from a donor to an acceptor. One way to understand this acceleration is to consider an idealized situation in which a relay station sits on the line of centers from donor to acceptor. Assume that the relay station is of an intermediate reduction potential between donor and acceptor, so the standard free energies of each oxidation–reduction are approximately the same. Assume also that the three respective electronic matrix elements and reorganization energies are similar enough that each transfer of the electron—the one from relay station to acceptor, the one from donor to the hole in the relay station, and the one from donor to acceptor in the absence of the relay station—is a function only of the distance between the participants (Equation 2–191). To make the mathematics simpler, it is also better to assume that the relay station is closer to the donor or closer to the acceptor. Suppose that the donor and acceptor are 3 nm apart, the relay station is 1.2 nm from the acceptor and 1.8 nm from the donor, and a β of 11 nm^{-1} (Figure 2–42) applies to this situation. Given the distance between them, the rate constant for transfer of the electron from donor to acceptor in the absence of hopping should be around 2 s^{-1}. Assume that the reverse reactions can be ignored, that the relay station relays a hole, and that the kinetic mechanism for transfer of the electron when the relay station is present is

$$\mathrm{D} \xrightarrow{k_2} \mathrm{RS} \xrightarrow{k_1} \mathrm{A} \qquad (2\text{–}193)$$

where D is the donor, RS is the relay station, and A is the acceptor. If k_1 is 500 μs^{-1} and k_2 is 1 μs^{-1} (Figure 2–42), the rate constant for transfer of the electron from donor to acceptor, after about 100 ns, should be equal to k_2 (1 μs^{-1}). The resulting acceleration of the rate (5×10^5) is significant.

The ideal case just examined, however, represents the maximum acceleration that can be achieved with the stipulated distances. If the reverse reactions are not negligible, if the relay station is not on the line of centers, if the interaction energies are not ideal, or if the differences in free energy of the electron between donor and relay station or between relay station and donor or both are not ideal, then the acceleration in the rate constant for transfer of an electron through a relay station will be less than in the foregoing demonstration, although the acceleration can still be significant. It is possible to take account of all these factors and estimate the rate to be expected for particular values of these parameters.[1122-1124]

In the case of photoreduction of the oxidized flavin in deoxyribodipyrimidine photo-lyase from *E. coli*, the rate constants for each step in which the hole is transferred from the electronically excited state of the flavin to Tryptophan 306 have been determined. Tryptophan 382 or Tryptophan 359 in the enzyme were substituted with phenylalanine, and effects of these mutations on the transient absorptions at 500 and 580 nm following photoexcitation were assessed. These are wavelengths at which the radical cations of the tryptophans absorb. The effects of these mutations on the transient absorption at 800 nm, a wavelength at which the electronically excited state of the flavin absorbs, were also ascertained.[1125] In this way, it was possible to dissect the transients into the contributions of these three chromophores as well as that from Tryptophan 306. The hole is passed from the electronically excited state of the flavin by an electron transfer from the indolyl group of Tryptophan 382 with a rate constant of 1200 ns^{-1}. The hole is then passed from the resulting radical cation of the indolyl group of Tryptophan 382 by an electron transfer from the indolyl group of Tryptophan 359 with a rate constant of 14 ns^{-1}. Finally, the hole is passed from the resulting radical cation of the indolyl group of Tryptophan 359 by an electron transfer from the indolyl group of Tryptophan 306 with a rate constant of 7 ns^{-1}.

There is some electron transfer from the ground state of the flavin semiquinone, which results from relaxation of the electronically excited state of the flavin after it has been reduced by the one electron. This electron transfer fills the hole on the radical cation of the indolyl group of Tryptophan 382 and short-circuits the ultimate oxidation of Tryptophan 306, but once the hole is beyond Tryptophan 382, there is no further short circuit. This situation is reminiscent of the race to move the electron away from the electronically excited state of the special pair to the ubiquinone in site B in the photosynthetic reaction center before it can return back to the ground state of the radical cation

of the special pair, except in this instance it is a hole returning to the source rather than an electron.

The acceleration observed when a 3-nitrotyrosine was installed as a relay station for transfer of an electron in azurin was as much as 50-fold. In this instance, however, the biochemical standard reduction potential of the relay station was not ideally matched to the biochemical standard reduction potentials of the donor and acceptor. In proteins containing chains of prosthetic groups through which an electron hops (Figures 2–30, 2–31, and 2–33) or proteins containing chains of aromatic groups through which a hole hops, it is entirely possible that natural selection has ensured that the differences in free energy and the interaction energies are more successfully matched, and the accelerations achieved by hopping are more significant. In any case, it is hard to see how an electron could be transferred over the large distances that often intervene between donor and acceptor in enzymes that accomplish rapid transfer of an electron without providing relay stations between which the electron or the hole can hop.

Other than a few instances, such as reaction centers and deoxyribodipyrimidine photo-lyase and perhaps cytochrome-*c* oxidase,[1147] the rate constants of normal intramolecular electron transfers between prosthetic groups within enzymes[1045] are usually between 10 s^{-1} and 10^5 s^{-1}. For example, when 5-deazariboflavin semiquinone is produced in solution by flash photolysis, it rapidly reduces the oxidized flavin in trimethylamine dehydrogenase from *M. methylotrophus* to the semiquinone. Transfer of the electron from this semiquinone, monitored by the decrease in its absorption at 470 nm, to the [4Fe–4S] iron–sulfur cluster in the enzyme[1148] has a rate constant of 60 s^{-1}. The rate constant for transfer of an electron from the flavin semiquinone to the heme *b* in L-lactate dehydrogenase (cytochrome) from *S. cerevisiae*[818] is 120 s^{-1}. When the heme *c* in nitrite reductase (NO-forming) from *P. pantotrophus* is rapidly reduced with a hydrated electron, an electron is transferred from it to the heme d_1 in the enzyme, measured by a decrease in absorption at 550 nm and an increase in absorption at 640 nm,[1149] with a rate constant of 1400 s^{-1}. These rates are a **compromise** between the change in standard free energy of the reaction, for which the greater the expenditure of free energy, the greater the rate (Equation 2–190), and the distance between donor and acceptor, for which the greater the distance, the slower the rate (Figure 2–42).[1045]

In the cases of a reaction center and deoxyribodipyrimidine photo-lyase, the unusually rapid rates for transfer of an electron or transfer of a hole, respectively, result from the short distances between the large aromatic π molecular orbitals of the prosthetic groups or between the tryptophans and the flavin, respectively, and the significant increases in standard reduction potential from one to the next in the case of the reaction center. In addition, neither photosynthesis nor photolytic repair of DNA would occur if the rates were not so fast because in each instance there is a race: between transfer of the electron away from the special pair and return of the electron to the ground state of the radical cation of the special pair, or between transfer of the hole away from the flavin and return of the hole to the ground state of the flavin semiquinone. The race is intense because the electronically excited state in each instance is produced photolytically, so the return of the electronically excited state to the ground state is rapid. This last fact explains why natural selection had to guarantee that transfer of the electron was as fast as possible. The fact that a reaction center is immersed in the nonpolar interior of a membrane is also consequential. Because a significant portion of the reorganization energy arises from dielectric reorganization of the solvent, the lower the permittivity of the surroundings, the lower the reorganization energy,[1065] and the larger the rate constant (Equation 2–190). This factor should increase not only the rate constants for transfers of electrons between the prosthetic groups in the reaction center but also those between all the prosthetic groups in those portions of other enzymes that are embedded in the phospholipid bilayers of biological membranes.

Transfer of an electron can occur between subunits of a protein, between domains in a protein, or between prosthetic groups on different molecules of protein. The two extremes of interprotein transfer are transfer of an electron between two subunits permanently associated with each other in the same protein and transfer of an electron during the transient collision of otherwise unassociated proteins. In between these extremes would be the case of an electron-transferring coenzyme that associates with an enzyme as a substrate, accepts or donates an electron while associated, and then dissociates from the enzyme.

Examples of **transfer of an electron between two subunits** associated with each other in the same protein would be transfer of an electron between the flavin on one subunit of the $\alpha\beta$ hetereodimer of

sulfide-cytochrome-*c* reductase (flavocytochrome *c*) from *A. vinosum* and the heme *c* on the other subunit[1150] and transfer of an electron between a heme *c* on a firmly associated subunit of the reaction center from *B. viridis* and the special pair.[959,960]

An example of a similar situation is transfer of an electron between prosthetic groups on two **separate domains** of the same protein that are connected by a single strand of polypeptide distant from the line connecting the two prosthetic groups,[1048,1151] such as between the flavin and the heme each in a separate domain in the NADPH—hemoprotein reductase (flavocytochrome P450 BM-3) of unspecific monooxygenase from *B. megaterium*[1152] or between heme in one domain and two prosthetic copper ions in a second domain naturally tethered to the first by a strand of polypeptide in nitrite reductase (NO-forming) from *Ralstonia pickettii*.[1112]

Domains in an enzyme can swing back and forth between donors and acceptors of electrons, as does the domain in quinol—cytochrome-*c* reductase (Figure 2–32). In NADPH—hemoprotein reductase from *R. norvegicus*, NADPH bound in the active site reduces an adjacent flavin in a prosthetic flavin adenine dinucleotide that then reduces the flavin in a prosthetic flavin mononucleotide. The reduced prosthetic flavin mononucleotide then passes one electron to the oxidized prosthetic heme in a molecule of heme oxygenase (biliverdin-producing) that associates reversibly with NADPH—hemoprotein reductase. Once the prosthetic heme on the first heme oxygenase (biliverdin-producing) is reduced, it dissociates. The next oxidized heme oxygenase (biliverdin-producing) associates with the enzyme, and its prosthetic heme is reduced by the second electron on the semiquinone of the prosthetic flavin mononucleotide, returning the flavin mononucleotide to its oxidized state.

The NADPH and the prosthetic flavin adenine dinucleotide are on a separate hinged domain from the domain in which the prosthetic flavin mononucleotide is located. When the reduced flavin adenine dinucleotide in the enzyme from *R. norvegicus* is reducing the flavin mononucleotide by two electrons, the hinge is closed, the two domains are in intimate contact with each other, and the 7-methyl groups of the two flavins, one on each of the domains, are in van der Waals contact with each other.[1052] When, however, the NADPH—hemoprotein reductase from *R. norvegicus* is associated with heme oxygenase (biliverdin-producing) from *R. norvegicus*, the hinge has opened so that the distance between the flavin adenine dinucleotide and the flavin mononucleotide is now 2.2 nm, but in the complex, the distance between the flavin mononucleotide and the prosthetic heme of the heme oxygenase (biliverdin-producing) is only 0.6 nm, close enough for rapid electron transfer.[1153] These necessary rearrangements of the domains in NADPH—hemoprotein reductase require that the flavin mononucleotide be reduced while the hinge is closed; when the hinge opens, the flavin mononucleotide can then reduce the prosthetic heme on heme oxygenase in the space created by the swinging away of the domain on which the NADPH and the prosthetic flavin adenine dinucleotide are located.

Examples of **transfer of an electron during the collision of two proteins** would be the self-exchange of an electron between two pseudoazurins ($k = 4 \times 10^3$ M^{-1} s^{-1}),[813] the self-exchange of an electron between two azurins from *P. aeruginosa* ($k = 3 \times 10^6$ M^{-1} s^{-1}),[1109] transfer of an electron between ferricytochrome *f* from *B. rapa* and a close homologue of its biological partner cupriplastocyanin from *Phaseolus vulgaris* (5×10^7 M^{-1} s^{-1}),[1154] and transfer of an electron between flavodoxin and its biological partner, photosystem I in *Synechocystis* ($k = 2 \times 10^8$ M^{-1} s^{-1}).[789]

The more common situation is one in which a small electron-transferring coenzyme provides an electron to or removes an electron from an enzyme of oxidation–reduction by forming a complex with the enzyme, and the **electron is transferred intermolecularly within the complex before it dissociates** rather than during a collision with its partner. For example, in *P. putida*, an electron is transferred from putidaredoxin—NAD^+ reductase to putidaredoxin in a complex between these two proteins that has a dissociation constant of 5 μM.[1155] Within the complex, the electron is transferred from the neutral flavin semiquinone of the reductase to the [2Fe–2S] iron–sulfur cluster of putidaredoxin at a rate of 230 s^{-1}. The dissociation constant between amicyanin and methylamine dehydrogenase (amicyanin) from *P. denitrificans*[1156] is also 5 μM, and the rate constant for transfer of the electron is 10 s^{-1}. The dissociation constant between bovine cytochrome *c* and bovine cytochrome-*c* oxidase[1157] is 20 μM, and the rate constant for transfer of the electron is 2600 s^{-1}. Cytochrome c_3 and flavodoxin from *D. vulgaris* form a complex with a dissociation constant of 60 μM in which an electron is transferred between them.[791]

Crystallographic molecular models for the normally transient complexes between an enzyme and a protein serving the role of an electron-transferring coenzyme are available for cytochrome-*c* peroxidase and isoform 1 of cytochrome *c* from *S. cerevisiae*,[1158] methylamine dehydrogenase (amicyanin) and amicyanin from *P. denitrificans*,[812,1159,1160] ferredoxin—$NADP^+$ reductase and ferredoxin from *Z. mays*,[1161] reaction center and cytochrome c_2 from *R. sphaeroides*,[1162] quinol—cytochrome-*c* reductase and isoform 1 of cytochrome *c* from *S. cerevisiae*,[946] human medium-chain acyl-CoA dehydrogenase and human electron-transfer flavoprotein,[1163] aralkylamine dehydrogenase (azurin) and azurin from *A. faecalis*,[1164] carbazole 1,9a-dioxygenase from *Janthinobacterium* and ferredoxin from *Pseudomonas resinovorans*,[1165] rubredoxin—NAD^+ reductase and rubredoxin from *P. aeruginosa*,[1166] ferredoxin—$NADP^+$ reductase and ferredoxin from *Pseudomonas*,[1167] nitrite reductase (NO-forming) and cytochrome c_{551} from *A. xylosoxidans*,[1168] methylamine dehydrogenase (amicyanin) and methylamine utilization protein MauG from *P. denitrificans*,[1169,1170] and L-ascorbate peroxidase and cytochrome *c* from *Leishmania major*.[1171] There is evidence from nuclear magnetic resonance spectra that the complex between methylamine dehydrogenase (amicyanin) and amicyanin is the one that exists in solution,[1160] and the complex between methylamine dehydrogenase (amicyanin) and methylamine utilization protein MauG performs the normal transfer of electrons within the crystal.[1169]

The prosthetic groups on the individual proteins in the crystallographic molecular models of these binary or ternary complexes are **usually within 1.4 nm of each other**,[1159,1161] as is the case for transfer of an electron between prosthetic groups within the same protein, but there is at least one example of a complex in which they are greater than 2.0 nm apart,[1045] which suggests that this complex may not be the natural one. In an electron micrographic reconstruction of the complex between the electron-transferring coenzyme and ribonucleoside-diphosphate reductase, however, the distance between the cysteine in the active site and the tyrosyl radical in the electron-transferring coenzyme, is 3.5 nm.[2610]

Continuous paths of covalent bonds between the prosthetic groups in crystallographic molecular models of these complexes do not exist because the prosthetic groups are on different proteins. Often a continuous path of covalent bonds in one protein can be connected to a continuous path of covalent bonds in the other by a hydrogen bond[1086,1162] or by a molecule of water in the interface fixed in position by hydrogen bonds,[1165,1166] but in other instances, the **connection between the two proteins** along the path is a van der Waals contact between one or more atoms in one protein and one or more atoms in the other rather than a hydrogen bond.[1158,1159,1164,1167,1168,1171] For the complex between quinol—cytochrome-*c* reductase and isoform 1 of cytochrome *c*, it has been proposed that transfer of an electron occurs through space rather than through σ bonds,[1172] even though two of the exocyclic carbon atoms, one from each heme, are in van der Waals contact.[946]

Cytochrome-*c* peroxidase from *S. cerevisiae* catalyzes the reaction

$$2\,H^+ + H_2O_2 + 2\ \text{ferrocytochrome } c \rightleftharpoons 2\,H_2O + 2\ \text{ferricytochrome } c \qquad (2\text{–}194)$$

which serves the purpose of eliminating hydrogen peroxide from the cytoplasm of the fungal cell. The hydrogen peroxide binds to a ferric heme on the enzyme. This complex is converted by the enzyme to a molecule of water; an oxoiron(IV),* $[(Fe^{4+})(^{2-}O)]$, at the heme; and a radical cation of the indolyl group ($\text{indolyl}^{\bullet+}$) of Tryptophan 191 in the enzyme.[1173-1175] Ferrocytochrome *c* from *S. cerevisiae* reduces the radical cation of the indolyl group in a bimolecular reaction[1176] with a rate constant of $2 \times 10^8\ M^{-1}\ s^{-1}$ at an ionic strength of 300 mM. An equilibrium is then established between the oxo-iron(IV) and the indolyl group of Tryptophan 191

$$H^+ + \left[Fe^{4+}O^{2-}\right]^{2+} + \text{indolyl} \rightleftharpoons \left[Fe^{3+}OH^-\right]^{2+} + \text{indolyl}^{\bullet+} \qquad (2\text{–}195)$$

where $[Fe^{3+}OH^-]^{2+}$ is the complex between Fe^{3+} in the heme and hydroxide.[1173] The equilibrium constant (K_{eq}) for this reaction is 0.4 at pH 6 and decreases as the pH is raised because the oxygen of the $[(Fe^{4+})(^{2-}O)]^{2+}$ must be hydronated before the electron can be transferred. A second molecule of ferrocytochrome *c* then reduces the radical cation of the indolyl group with a bimolecular rate constant[1176] of $3 \times 10^7\ M^{-1}\ s^{-1}$ at an ionic strength of 300 mM.

*Oxoiron(IV) is usually abbreviated $[Fe{=}O]^{2+}$ to indicate that there is thought to be both a σ bond and a π bond between the iron and the oxygen. In keeping with the decision to allow the reader to decide on bonding, ionic bonding is used here.

This rate constant is less than the first because the concentration of the radical cation of the indolyl group is decreased by the equilibrium (Equation 2–195).[1177] Addition of two electrons by two successive molecules of ferrocytochrome *c* returns the radical cation of the indolyl group of the tryptophan to the neutral indolyl group and returns the iron to the ferric oxidation state, and the hydroxide is hydronated to become water.

At high ionic strength (>100 mM), the **dissociation constant for the formation of a complex** between cytochrome-*c* peroxidase and cytochrome *c* from *S. cerevisiae* is so great (>10 μM)[1178] that there was no complex present in significant concentration in the foregoing experiments measuring the bimolecular rate constant for transfer of an electron from cytochrome *c* (at less than 1 μM) to cytochrome-*c* peroxidase (at less than 3 μM) and at an ionic strength of 300 mM.[1176] At low, unphysiological ionic strength (20 mM), however, cytochrome *c* from *S. cerevisiae* does form a complex with cytochrome-*c* peroxidase from *S. cerevisiae*[1179,1180] with a dissociation constant of 2 μM.[1178] A crystallographic molecular model of this complex places the iron in the heme of the cytochrome *c* 2.03 nm from the nearest edge of the π molecular orbital system of the radical cation of the indolyl group.[1158] The rate constant for transfer of an electron from heme *c* of ferrocytochrome *c* to the radical cation of the indolyl group[1181] within this complex[1182,1183] is 2 μs^{-1}. It is thought that this complex is the same as that formed transiently during the normal bimolecular transfer of the electron from cytochrome *c* to cytochrome-*c* peroxidase.

At high ionic strength, does transfer of an electron from the iron in ferrocytochrome *c* to the radical cation of the indolyl group of cytochrome-*c* peroxidase nevertheless occur only after this complex, albeit unstable, forms evanescently? Is the electron transferred intramolecularly only within a specific structurally defined complex, formed by the combination of two unique faces on the surfaces of cytochrome *c* and cytochrome-*c* peroxidase to form the unique interface observed in the crystallographic molecular model through which the electron passes,[1184] even though the reaction is kinetically bimolecular as if it resulted simply from the collision of cytochrome *c* and cytochrome-*c* peroxidase? These question can be asked of any transfer of an electron between two proteins that is kinetically bimolecular. Fundamentally, it is a question about the evolution of electron transfer. **Does natural selection have to produce a specific interface and a specific path for the electron to ensure that the required transfer of an electron occurs?**

There are experiments suggesting that any collision between two proteins is capable of accomplishing electron transfer. For example, an electron can be transferred with a rate constant of 2 ms^{-1} over a distance of 2.4 nm between a heme in cytochrome *c* in which a Zn^{2+} has replaced the iron to the Fe^{3+} in a cytochrome *c* adjacent to it in a crystal of cytochrome *c*.[1185] The contacts between molecules of protein in any crystal of protein are adventitious, arbitrary, and certainly not interfaces created by natural selection. The two molecules of cytochrome *c*, however, are held next to each other by the crystal. A specific complex between two faces forming an interface would hold the two proteins together, albeit fleetingly, and it may be that such an immobilization is required for transfer of an electron to occur.

That transfer of an electron from cytochrome *c* to the radical cation of the indolyl group proceeds within the specific complex between cytochrome-*c* peroxidase and cytochrome *c* at low ionic strength does not mean that it does so at high ionic strength. There is one result, however, suggesting that it does. A cysteine was introduced by site-directed mutation at position 193 in cytochrome-*c* peroxidase, which is in the middle of the interface in the specfic complex that forms at low ionic strength. This cysteine was then modified with 3-(*N*-maleimidyl-propionyl)biocytin, which is large enough to prevent the complex from forming. The rate for transfer of an electron from cytochrome *c* to cytochrome-*c* peroxidase at high ionic strength was decreased by a factor of 70 by this modification[1186] but not completely eliminated.

Two other questions are raised by cytochrome-*c* peroxidase. What is an oxoiron(IV) and how does the enzyme produce it?

Problem 2–23: The midpoint reduction potential of cytochrome *c* is invariant with pH between pH 2 and pH 7.8 and decreases with a slope of 60 mV (unit of pH)$^{-1}$ above pH 7.8.[751] Explain these observations in terms of the pK_a of an amino acid in oxidized cytochrome *c* and its pK_a in reduced cytochrome *c*.

Problem 2–24: Draw the structure of heme d_1. Draw circles around the 18 atoms that provide *p* orbitals to the aromatic π molecular orbital system of the heme. How many π electrons are there in this molecular orbital system?

Problem 2–25: The biochemical standard reduction potentials of the flavin adenine dinucleotide, the [2Fe–2S] iron–sulfur cluster, the [4Fe–4S] iron–sulfur cluster, the [3Fe–3S] iron–sulfur cluster, and the heme *b* of succinate dehydrogenase from *E. coli* are −80, +10, −170, +70, and +30 mV, respectively.[563] If the flavin is reduced to $FADH_2$ by two electrons from succinate while the other four centers are initially in the fully oxidized states, what is the distribution of those two electrons among the five centers at equilibrium? It is thought that the two electrons being transferred from reduced flavin to ubiquinone bound to the enzyme do not pass through the heme *b*. Why is it there?

Migration of Electronic Excitation

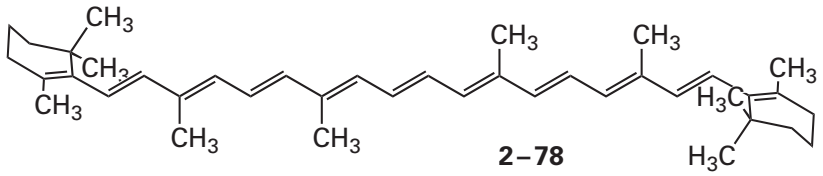
The photon responsible for excitation of an electron in a photosynthetic reaction center is almost never absorbed directly from the ambient light by the special pair; instead it is absorbed nearby by an array of accessory light-harvesting prosthetic groups. The electronically excited state produced upon absorption of a photon by a prosthetic group in this array then migrates* to the special pair in the reaction center through the array along a **network of the same or similar prosthetic groups**. The individual subunits of protein enclosing one or more of these light-harvesting prosthetic groups associate with each other to form antennae. An **antenna** is a large structure in a photosystem the prosthetic chromophores of which are responsible for absorbing photons of incident light and in which the resulting electronic excitation, an exciton, migrates to the special pair of the reaction center. The light-harvesting prosthetic groups in an antenna are positioned and oriented by the protein of the subunits in which they are found. Individual light-harvesting prosthetic groups or clusters of electronically coupled light-harvesting prosthetic groups capture photons of light, and within the network formed by the array each of the resulting electronically excited states migrates to a reaction center. The advantage of a large antenna is to increase the cross-sectional area associated with each reaction center that contains prosthetic groups capable of absorbing a photon and hence increase its ability to capture photons.

Migration of electronic excitation occurs among the light-harvesting prosthetic groups in the network. Any one of the light-harvesting prosthetic groups, or a cluster of these prosthetic groups, has two abilities. It can either absorb an ambient photon or act as **a conductor of electronic excitation** between its neighbors. Once a photon is absorbed by a light-harvesting prosthetic group or a cluster of light-harvesting prosthetic groups in an antenna, the electronic excitation rapidly migrates among the prosthetic groups it contains. Eventually it reaches the special pair in the reaction center with which

*As it migrates to the special pair of the reaction center, the electronic excitation is often considered to be an "**exciton**", as if it were a quasi-particle moving through the network, to distinguish it from the electronically excited state on a single, isolated chromophore. When, however, an exciton is located on one of the prosthetic groups transferring it, that prosthetic group is in an electronically excited state.

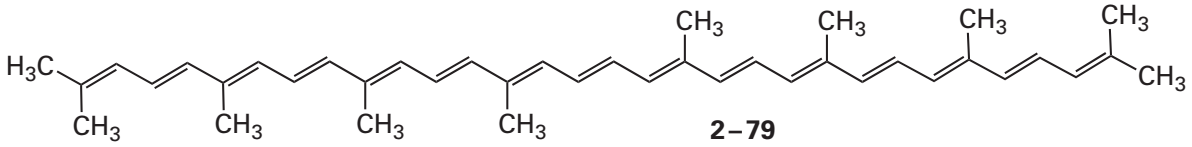
the antenna is associated, and migration of the electronically excited electron in the special pair takes over. The individual prosthetic groups found in these antennae that are responsible for absorption of the photon and migration of the resulting electronic excitation to the special pair are chlorophylls, carotenoids, and bilins.

Carotenoids contain extended, linear π molecular orbital systems. β,β-Carotene



2–78

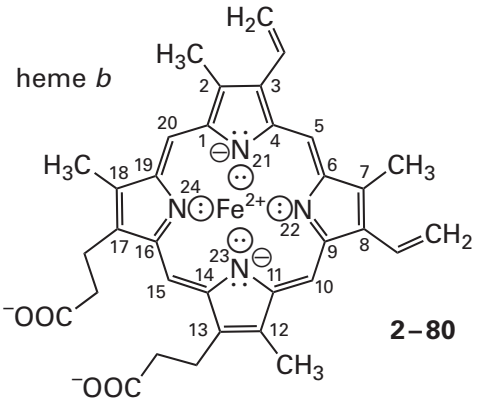
and its parent ψ,ψ-carotene (lycopene)



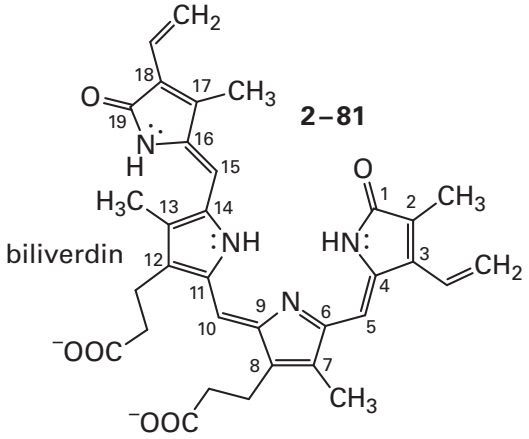
2–79

are examples of carotenoids.* They are octaisoprenoids that each contain 40 carbon atoms and a linear conjugated π molecular orbital system of 22 or 30 carbon atoms that is all trans and fairly rigid throughout its length. Rotation about the carbon–carbon bonds is hindered by the extended π molecular orbital system, as is rotation about the carbon–carbon bond in buta-1,3-diene. Most, if not all, of the carotenoids in a chloroplast or chromatophore are tightly bound to its proteins and each is uniquely oriented by its protein. Most carotenoids are related to ψ,ψ-carotene, and most differ from it only at the two ends, where the isoprenoid units are substituted, saturated, or cyclized as in β,β-carotene. Examples of carotenoids that are light-harvesting prosthetic groups, in addition to β,β-carotene, are neurosporene, chloroxanthin, zeaxanthin, violaxanthin, rhodopin, and peridinin.

Bilins are linear, extensively conjugated tetrapyrroles. All bilins are derived from biliverdin, which is derived from heme *b* (**2–80**) as are all hemes. **Biliverdin** (**2–81**) is produced by oxidative cleavage of heme *b* at carbon 5 by heme oxygenase (biliverdin-producing, ferredoxin) that uses three molecules of molecular oxygen to cleave the porphyrin



2–80

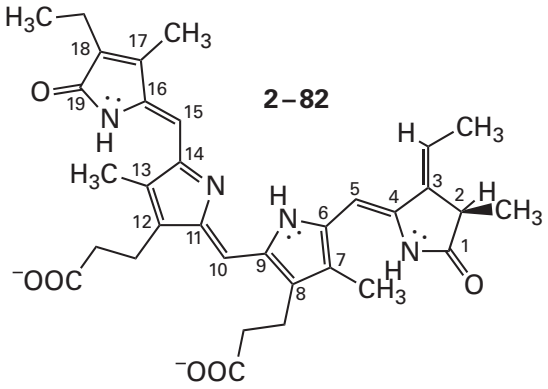


2–81

*Lycopene is the red color in tomatoes. Because of its long conjugated system, it absorbs light of fairly high energy, 380-520 nm, in the green to blue range, causing the tomato to have a red color.

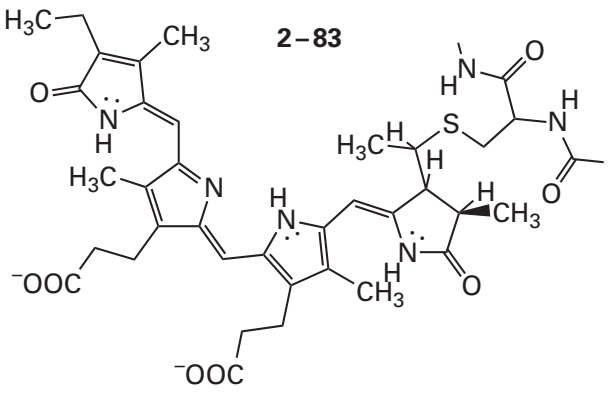
by turning carbon 5 into carbon monoxide. The oxygenation leaves oxo groups at carbons 4 and 6 of heme *b* while breaking the ring and releasing the iron.

Examples of bilins that are used as light-harvesting prosthetic groups are phycocyanobilin, phycoerythrobilin, 15,16-dihydrobiliverdin, and phycourobilin. In both **phycocyanobilin**[1187]



and **phycoerythrobilin**, a hydride has been added to the distal methylene of the ethenyl group at carbon 3 of biliverdin (**2–81**) and the resulting enolate is hydronated at carbon 2. In phycocyanobilin (**2–82**), the ethenyl group that was at carbon 18 of biliverdin (**2–81**) has been reduced to an ethyl group, but it remains a ethenyl group in phycoerythrobilin. In phycoerythrobilin, the double bond that was between carbons 15 and 16 of the biliverdin has been reduced rather than the ethenyl group. In **15,16-dihydrobiliverdin** only the double bond between carbons 15 and 16 of biliverdin has been reduced,[1188] but in phycourobilin the carbon–carbon double bonds between carbons 4 and 5 and carbons 15 and 16 in biliverdin have been reduced and the ethenyl groups at carbon 3 and carbon 18 have been reduced to ethyl groups. Running through a bilin is an extended π molecular orbital system that permits it to absorb visible light.

In most cases, phycocyanobilin is covalently attached to the proteins in which it is found through a sulfide to a cysteine side chain[1189,1190]



The sulfido group of the cysteine adds to the exocyclic carbon of the double bond of the 3-ethylidene group in phycocyanobilin (**2–82**) with a vinylogous enamine as an intermediate. Phycoerythrobilin[1191] and 15,16-dihydrobiliverdin[1192] are covalently attached to a cysteine with the same linkage at the same carbon, but they can also be covalently attached to a second cysteine at the distal carbon of their respective ethenyl groups at carbon 18 (see **2–81**).[1188,1193] The sulfido group of the cysteine adds to the carbon–carbon double bond in the respective ethenyl group, also with a vinylogous enamine as an intermediate.

Although the reaction centers in different classes of photosynthetic organisms are the same, the antennae associated with these reaction centers are wildly diverse from class to class in the identity of the prosthetic groups, their number, their distribution, and the mechanism for migration and capture of the excited electrons.[1194]

In higher plants and green algae, the antennae on the reaction centers of photosystems I and photosystems II are quite different from each other, but each is formed from a large number of subunits that are embedded in the phospholipid bilayer of the membrane and span it. All these subunits and the reaction center form large intact, discrete proteins. The protein in each extended antenna entraps from 50 to 170 molecules of chlorophyll, both *a* and *b*, and from 10 to 40 carotenoids, almost all within the membrane.

In some cyanobacteria and red algae, antennae are made from subunits that contain bilins rather than chlorophylls. These subunits form cylindrical disks, which stack upon each other to form cylindrical rods that are assembled into phycobilisomes. Rather than being embedded in the membrane of the thylakoid, phycobilisomes are arrays of these rods that radiate out into the negative, basic cytoplasmic solution surrounding the thylakoids, on

the opposite side of the reaction center from the special pair (Figure 2–34). They are attached to the reaction center by a central, multisubunit core.

In cryptophyte algae, the lumen of the thylakoid, on the positive, acidic side of the reaction center closest to the special pair, is packed with large multisubunit biliproteins, each of which binds eight bilins. This solution of biliproteins is the common antenna for reaction centers in the membrane of the thylakoid that encloses them. The antennae in dinoflagellates are also proteins that are not attached to the reaction center but dissolved at high concentration in the lumenal, positive, acidic space of the thylakoid. The protein in each identical subunit in these homotrimers entraps, instead of bilins, eight carotenoids and two chlorophylls.

In purple bacteria, each antenna consists of two concentric rings with a total of 32 subunits, each of which spans the membrane of a chromatophore. The two concentric rings surround the reaction center, and each subunit in the rings contains only one bacteriochlorophyll, either *a* or *b*, depending on the species.

In green sulfur bacteria, the antennae are large vesicles, each formed from a continuous bilayer of phospholipids containing some embedded proteins. Each vesicle contains large **crystalline arrays** that together contain 50,000 to 200,000 bacteriochlorophylls as well as carotenoids. These huge antennae are attached to the cytoplasmic membrane of one of these bacteria, in which reside the reaction centers, by proteins that each contain eight bacteriochlorophylls *a* that act as relays.

The crystallographic molecular models of **photosystem I** from *P. sativum* (Figure 2–38)[1018,1019,1195] contain its antenna. These molecular models constitute a paradigm for the photosynthetic antenna in a higher plant. **The antenna is almost completely embedded within the membrane** and consists of around 140 chlorophylls *a*, around 10 chorophylls *b*, and around 30 carotenoids.* The six chlorophylls *a* of the reaction center (thick bonds) and the [4Fe–4S] iron–sulfur cluster in the reaction are in the center of the photosystem. There is an external subunit on the negative, basic side of the photosystem, adjacent to the [4Fe–4S] iron–sulfur cluster within the reaction center, that contains the two additional prosthetic [4Fe–4S] iron–sulfur clusters (not shown in the drawing) that pass electrons to ferredoxin, the electron-transferring coenzyme that is the ultimate acceptor. In addition to this external subunit, 11 polypeptides, two long ones (758 aa and 734 aa) and nine short ones (40–168 aa), that are folded within the thylakoid membrane in intertwined associations of 32 membrane-spanning α helices comprise the core of the photosystem. On one side of this central core there are four additional subunits of light-harvesting complex I, each of which has three membrane-spanning α helices.

With the exception of the external subunit containing the two prosthetic [4Fe–4S] iron–sulfur clusters, most of the mass of the protein comprising the central core of the photosystem is embedded in the membrane, and segments from 9 of the 11 constituent polypeptides forming the central core span the membrane in one or more α helices. The two folded long polypeptides contain the reaction center. They are homologous (44% identity; 1.5 gap percent) to each other and arrayed around the usual twofold rotational axis of pseudosymmetry that creates the special pair and the pseudosymmetry of the reaction center. Although the two long folded polypeptides are also homologous in the portions of their structures that surround the reaction center to the L and the M subunit in a bacterial reaction center, in particular, five of the α helices from each of them, they are each around 450 amino acids longer than the respective folded polypeptides in an L or M subunit. Within this additional protein, these two large subunits, unlike the L and M subunits, enclose most of the prosthetic groups that form the antenna for the reaction center. The two large subunits each span the membrane with 11 α helices. In addition to surrounding the reaction center, these two long subunits entrap and orient among their membrane-spanning α helices around 10 β-carotenes and around 80 chlorophylls *a* in addition to the 6 chlorophylls *a* in the reaction center itself. These prosthetic groups are the contribution of these two large subunits to the antenna. Around 10 chlorophylls *a* and around 10 β-carotenes are enclosed by the 10 membrane-spanning α helices of the small subunits.

Associated with the core protein of photosystem I is another protein, **light-harvesting complex I**. Four subunits, with homologous sequences 252–275 amino acids in length, and hence superposable structures, comprise light-harvesting complex I that spans the membrane and encloses around 50 chlorophylls *a*, around 10 chlorophylls *b*, and around 10 carotenoids among its 12 membrane-spanning

*There is a slight disagreement between the two crystallographic molecular models of the same protein[1018] as to the number of prosthetic groups and the subunits with which they are associated.

α helices, three in each subunit. The four subunits of light-harvesting complex I are in a row, flush against the surface of the core protein within the membrane.

The rotational axis relating the two large subunits in photosystem I from *P. sativum* is a rotational axis of pseudosymmetry (passing through the special pair in Figure 2–38). Consequently, the surface of the pseudosymmetric heterodimer of the two large subunits within the membrane, which is composed of α helices spanning the membrane, is not duplicated across the rotational axis and is different on the opposite sides of the heterodimer. It turns out that there is only one face on the heterodimer within the membrane with which light-harvesting complex I associates. This face is not duplicated across the rotational axis. As a result, only one light-harvesting complex I of four subunits associates with the heterodimer of large subunits on only one of its sides, which makes the entire photosystem lopsided even though it has a rotational axis of pseudosymmetry.

The chloroplasts of plants contain an additional light-harvesting complex, **light-harvesting complex II**, that is also embedded in the membrane of the thylakoid, that absorbs around half the light used for photosynthesis, and that transfers the resulting electronic excitation to both photosystem I and photosystem II. It diffuses in the membrane as a protein separate from the two photosystems. Each monomer of this homotrimeric protein in the thylakoids of *S. oleracea* contains eight chlorophylls *a*, six chlorophylls *b*, and four carotenoids: two luteins, a neoxanthin, and a violaxanthin.[1196,1197] The transition dipoles of two of the chlorophylls *a* in each subunit of light-harvesting complex II are so strongly coupled that they act as a single chromophore with a dipole strength two times larger than that of an isolated chlorophyll *a*.[1198] This dimer of chlorophylls *a* gathers the electronic excitation from the others and passes it on to one or the other of the photosystems. In a thylakoid, the concentration of light-harvesting complex II is so high that it paves the membrane. Consequently, electronically excited states migrate among adjacent molecules of light-harvesting complex II on their way to a photosystem.[1199]

Photosystems II in higher plants,[1200] algae,[1013] and cyanobacteria,[1011] like photosystems I, are also asymmetric. In the molecular model of photosystem II from *S. oleracea* derived from image reconstruction from electron micrographs,[1200] the two subunits that are homologous to the L and M subunits and homologous to each other (25% identity; 2.2 gap percent) are, unlike those in photosystem I, only about 50 amino acids longer than their bacterial counterparts, and each encloses only one chlorophyll *a* and one β-carotene of the antenna. The remaining 48 chlorophylls *a*, 7 chlorophylls *b*, 8 β-carotenes, 3 luteins, 2 neoxanthins, and a violaxanthin of the antenna are distributed among 15 different membrane-embedded subunits of various sizes. As in photosystem I (Figure 2–38), all these prosthetic groups entrapped within the α helices of these subunits are within the membrane, and the antenna created, although significantly smaller, is similar to that in photosystem I. The partners in several pairs of these subunits are homologous to each other and distributed pseudosymmetrically around the twofold rotational axis creating the reaction center. In the molecular model, one homotrimer of light-harvesting complex II is docked at a site on photosystem II. Again, there is only one face on the membrane-embedded surface of the pseudosymmetric photosystem with which the trimer of light-harvesting complex II associates. Two photosystems II of higher plants, however, also participate in a larger complex in which they are arranged around a twofold rotational axis of true symmetry, and this larger complex contains two copies of an additional membrane-spanning subunit arrayed across the axis of symmetry and two additional symmetrically arrayed light-harvesting complexes II, for a total of four docked light-harvesting complexes II and two photosystems II.[1201]

In the asymmetric unit of the crystallographic molecular model of **photosystem I from the cyanobacterium** *Synechococcus elongatus*, there are 90 chlorophylls *a* responsible for harvesting light that are bound at locations distributed at random through the protein. Most of them are spaced far enough apart that their transition dipoles are not strongly coupled, but there are three pairs of chlorophylls *a* and a group of three chlorophylls *a* in which the π molecular orbital systems are stacked upon each other.[1016] These clusters are thought to be responsible for the absorption of light at longer wavelengths and to act as a sink for electronic excitation, which then migrates from them to the reaction center at the core of the photosystem.[1202] There are also 22 β,β-carotenes in each asymmetric unit of this photosystem I.

Phycobilisomes are additional antennae associated with reaction centers in the thylakoids of some cyanobacteria and red algae that harvest light of shorter wavelengths (450–650 nm). The units from which a phycobilisome is constructed are **cylindrical rods**, formed from two to five individual cylindrical disks stacked one upon the other.[1203] Each disk in one of these cylindrical rods is a **phycobiliprotein** the subunits of which each enclose one or two bilins.

The paradigm of such a phycobiliprotein would be **C-phycocyanin** from *Fremyella diplosiphon* (Figure 2–43)[1204]. The prosthetic group in this protein is phycocyanobilin (**2–82**), and it is an $(\alpha\beta)_6$ hexamer with dihedral symmetry of point group 322(D_3).[1205] The central core of each $(\alpha\beta)_6$ hexamer, along its threefold rotational axis of symmetry, is hollow, and the three twofold axes of symmetry normal to this threefold axis relate $\alpha\beta$ heterodimers in the opposed $(\alpha\beta)_3$ trimers composing the $(\alpha\beta)_6$ hexamer. The α polypeptides are homologous to the β polypeptides in sequence (22% identity; 1.8 gap percent), and the α subunits in the crystallographic molecular model are superposable on the β subunits. Each α subunit, however, has only one covalently attached phycocyanobilin, while each β subunit has two covalently attached phycocyanobilins, one in a location homologous to that occupied in an α subunit. In the $(\alpha\beta)_6$ hexamer, the eighteen prosthetic groups (one from each α subunit and two from each β subunit) are distributed evenly with the dihedral symmetry of the oligomer over the volume of the protein. The arrangement of the prosthetic groups in a rod formed from phycocyanin can be deduced from the spontaneous stacking of the individual $(\alpha\beta)_6$ hexamers of C-phycocyanin one on top of the other that occurs in the crystals of this protein.

Phycoerythrin and **allophycocyanin** are two phycobiliproteins closely related to phycocyanin, and their crystallographic molecular models are superposable on that of C-phycocyanin.[1193,1206] Each $\alpha\beta$ asymmetric unit of phycoerythrin, however, has three phycoerythrobilins as prosthetic groups,[1193] while each $\alpha\beta$ asymmetric unit of allophycocyanin has only two phycocyanobilins instead of three.[1206]

The cylindrical rods of $(\alpha\beta)_6$ hexameric phycobiliproteins are gathered into phycobilisomes, each of which contains 20–70 $(\alpha\beta)_6$ hexameric phycobiliproteins. There are four different ways that have been identified in electron micrographs in which the rods are assembled into phycobilisomes: hemidiscoidal,[1207] hemiellipsoidal,[1208] block-type,[1209] and bundle-type.[1210] The different ways in which the rods are assembled are determined by the particular collection of **linker proteins** that join the rods together. In each instance, however, the rods are arranged around a central core of phycobiliproteins that is attached to the negative, basic surface of the reaction center and that funnels each electronically excited state originating in the bilins in the rods and the core into the reaction center of a photosystem I in a thylakoid.[1190] Because the phycobiliproteins absorb light of shorter wavelengths, migration of the excited states into the membrane-embedded antenna of the associated photosystem II is exergonic. Each photosystem II in the thylakoid, however, is associated with a photosystem I in a megacomplex within the membranes of the thylakoids of cyanobacteria, and the electronic excitations gathered by the phycobilisomes can also migrate within this complex to photosystem II.[1211] Molecular models of the block-shaped phycobilisome from *Griffithsia pacifica*[1212] and the hemiellipsoidal phycobilisome from *Porphyridium purpureum*[1213] have been constructed from image reconstructions of electron micrographs.

The molecular model of the block-shaped phycobilisome from *G. pacifica* contains 62 $(\alpha\beta)_6$ hexameric phycobiliproteins and 72 linker proteins. The linker proteins, in addition to assembling the cylindrical rods, also have bilins within them and bring the total number of bilins in the phycobilisome to 2048. The cylindrical rods of two to five $(\alpha\beta)_6$ hexameric disks of the phycobiliproteins (Figure 2–43) radiate outward from the central core in a structure resembling a fan. The rods are held together in the structure by linker proteins that run down the hollow center of each rod, as well as linker proteins holding the rods to the core and linker proteins holding the phycobiliproteins in the core together. The distal phycobiliproteins in each rod radiating from the core are phycoerythrobilins. The linker proteins in the center of each rod, beyond those linker proteins within the first phycoerythrobilin in each rod, have phycourobilins within their sites for binding bilins. In about half of the rods, the phycobiliprotein most proximal to the core is a phycocyanobilin, and the phycobiliproteins in the core closest to the reaction center are allophycocyanins.. Because the linker proteins running through the center of each rod contain phycourobilins that have a maximum absorbance at 500 nm, because the phycoerythrobilins in

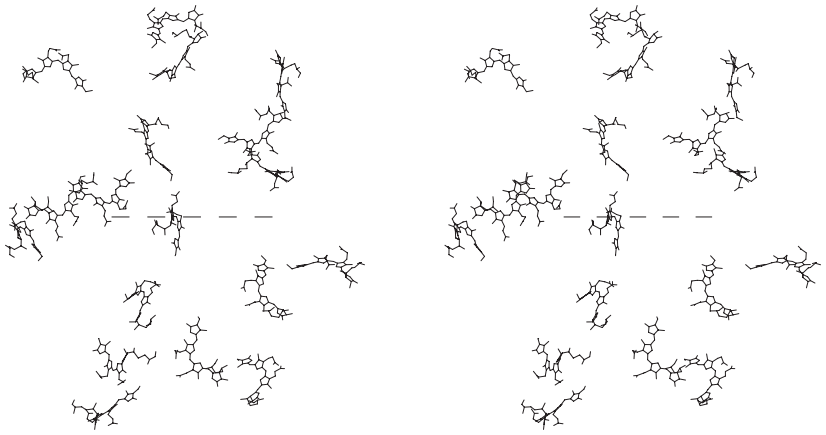


Figure 2–43: Stereodrawing[50] of the distribution of phycocyanobilins within the crystallographic molecular model of C-phycocyanin from *F. diplosiphons*.[1204] In the photosynthetic bacterium, $(\alpha\beta)_6$ hexamers of the protein, each assembled with dihedral symmetry of point group 322(D_3), stack one on top of each other to form the cylindrical rod of a phycobilisome, and this arrangement is preserved in the crystal, which is formed from continuous cylindrical columns of hexamers packed side by side. In the drawing, the distribution of the phycocyanobilins in a single hexamer from one of these columns is presented. A crystallographic threefold rotational axis of symmetry runs through the center of each column and, consequently, through the center of the distribution of phycocyanobilins in each $(\alpha\beta)_6$ hexamer. In the drawing, this exact threefold rotational axis of symmetry (dashed line) is horizontal and inclined at a 40° angle to the plane of the page.

the distal portion of each rod have maximum absorbances at 540 and 565 nm, because the phycocyanins have a maximum absorbance at 620 nm, and because the allophycocyanins have a maximum absorbance at 650 nm,[1206] this distribution of the various bilins, in addition to covering a wide range of absorption wavelengths, creates a gradient of energy for electronic excitation from absorption at shorter wavelengths to absorption at longer wavelengths, down the rod and into the core. The electronic excitation produced by absorption of a photon by one of the prosthetic groups is passed down this gradient in the rods in the direction of the photosystem.

In the hemiellipsoidal phycobilisome from *P. purpureum*, which contains 52 phycobiliproteins, the rods of two to four $(\alpha\beta)_6$ hexameric disks also radiate from the core, but the arrangement of the rods is wider and more splayed than in the block-shaped phycobilisome from *G. pacifica*. The same gradient—formed from distal linker proteins with phycourobilins (500 nm), distal phycoerythrobilins (540–565 nm), proximal phycocyanins (620 nm), and a core of allophycocyanins (650 nm)—is still found in this phycobilisome.

Two concentric elliptical rings—an inner ring of sixteen α subunits (60 aa), each contributing one membrane-spanning α helix, and an outer ring of sixteen β subunits (50 aa), each contributing one membrane-spanning α helix—together comprise **light-harvesting protein LH1**, which surrounds each reaction center in a **purple bacterium**.[1214,1215] The reaction center is in the center of these two concentric rings of sixteen membrane-spanning α helices, which cleave tightly to it and completely enclose it. These two rings of α helices entrap the thirty two bacteriochlorophylls *a* and sixteen spirilloxanthin molecules that comprise the primary antenna intimately associated with each reaction center. Although the structure is elliptical because the reaction center is not circular, it has a twofold rotational axis of symmetry that superposes the eight $\alpha\beta$ sectors in each half ellipse, each sector enclosing their two bacteriochlorophylls *a* and their spirilloxanthin, on the eight in the other half. In addition to this primary antenna, however, there is an additional protein in the chromatophores, light-harvesting protein LH2. **Light-harvesting protein LH2** from the purple bacterium *Rhodoblastus acidophilus* is an $(\alpha\beta)_9$ nonamer that spans the membrane of the chromatophore. The $\alpha\beta$ asymmetric units are arrayed around a ninefold rotational axis of symmetry and create two concentric rings each containing nine α helices. Each α subunit (53 aa) within the inner ring and each β subunit (41 aa) within the outer ring contributes one transmembrane α helix to the entire structure. Eighteen **bacteriochlorophylls *a*** in an eighteenfold rotationally symmetric circular array are enclosed between the two rings of nine α helices (Figure 2–44),[1216] and nine additional bacteriochlorophylls *a* are interspersed between the nine α helices of the β subunits in a more widely spaced ninefold rotationally symmetric circular array deeper in the membrane. There are also nine rhodopin D-glucosides arrayed around the ninefold rotational axis of symmetry.

The light-harvesting protein LH2 in purple photosynthetic bacteria, such as *R. acidophilus*, diffuses over the membrane of a chromatophore,[1217] colliding frequently with the primary antenna, light-harvesting protein LH1, or it is in a weak association with light-harvesting protein LH1. The fact that the electronically excited state resulting from capture of a photon by light-harvesting protein LH2 always ends up in its ring of 18 bacteriochlorophylls *a*, while moving among the bacteriochlorophylls *a* in this ring with a rate constant of around 10,000 ns^{-1}, means that whenever an excited molecule of this protein collides at random with a molecule of light-harvesting protein LH1 or is in a particular evanescent complex with light-harvesting protein LH1, the electronically excited state will arrive at the point of contact between the two proteins almost instantaneously. It then migrates within the complex from light-harvesting protein LH2 (λ_{max} = 860 nm) to light-harvesting protein LH1 (λ_{max} = 875 nm) with a rate constant[1218] of 200 ns^{-1}, and it eventually migrates to the special pair of the reaction center in the complex with a rate constant[1219] of 30 ns^{-1}.

The physical explanation for absorption of the photon by the arrays of light-harvesting prosthetic groups in an antenna and migration of the resulting electronic excitation among them is not entirely clear.[1194,1220-1223]

If two light-harvesting prosthetic groups, the chromophores, are far enough apart and the initial absorption of the photon is confined to only one of these two chromophores, the consequent migration of electronic excitation from the initially excited chromophore, the donor, to the other chromophore, the acceptor, can be described satisfactorily by the process of **radiationless transfer of energy by resonance**.[1224,1225] This formalism describes the migration of electronic excitation, without photon emission or absorption, to be the consequence of a

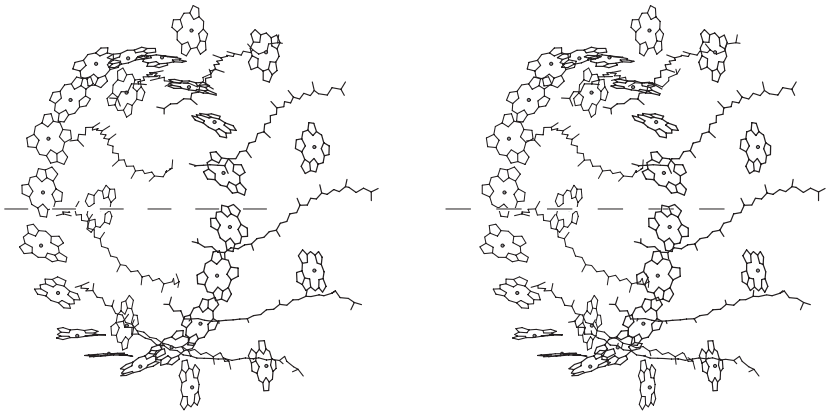

Figure 2–44: Stereodrawing[50] of the distribution of bacteriochlorophylls *a* and rhodopin glucosides within the crystallographic molecular model of light-harvesting protein LH2 from *R. acidophilus*.[1216] In the photosynthetic bacterium, $(\alpha\beta)_9$ nonamers of the protein, each assembled with cyclic symmetry of point group $9(C_9)$, are integral membrane-bound proteins that diffuse translationally in a crowded membrane. In the figure, the distribution of the prosthetic groups in the crystallographic molecular model of one of these $(\alpha\beta)_9$ nonamers is presented. A ninefold rotational axis of symmetry (dashed line) runs through the center each array and, consequently, through the center of each $(\alpha\beta)_9$ nonamer. The 27 bacteriochlorophylls *a* that are bound within the protein are distributed by this rotational axis of symmetry into two circular rings, one containing 18 bacteriochlorophylls *a* and the other 9 bacteriochlorophylls *a*. In the ring of eighteen, the bacteriochlorophylls *a* are tightly packed and touch each other, and each chlorin ring is perpendicular to the plane of the membrane. The ring of eighteen bacteriochlorophylls *a* is on the side of the protein facing the positive, acidic surface of the membrane. In the ring of nine, the bacteriochlorophylls *a* are in a larger circle and more widely spaced and each chlorin ring is parallel to the plane of the membrane. The ring of nine is in the center of the membrane. Only the chlorin rings of bacteriochlorophylls *a* have been drawn; phytol chains, 2-carboxyethyl groups, and alkyl groups on each of them were not drawn in order to simplify the figure. The nine rhodopin glucosides are the long polyisoprenoids located between the bacteriochlorophylls *a* in the ring of nine. They are also distributed by the ninefold rotational axis of symmetry and oriented roughly perpendicular to the plane of the membrane, and they span its hydrophobic core. Only the carotenoid portions of the rhodopin glucosides are drawn. The glucosyl groups are at the end of each rhodopin-glucoside farthest from the ring of eighteen bacteriochorophylls *a* on the negative, basic surface of the membrane. The glucosyl groups are hydrophilic enough to anchor that end of the polyisoprenoid at the surface of the membrane. The ninefold rotational axis of symmetry is exactly normal to the plane of the membrane.

dipole–dipole interaction the magnitude of which depends on the spectral overlap between the donor and acceptor states, the intermolecular distance between them, and the relative orientation of the transition dipole moments of the molecules. The symmetrically arrayed phycocyanobilins responsible for harvesting light in C-phycocyanin from *F. diplosiphon* (Figure 2–43), are spaced far enough apart that an electronically excited state produced by the absorption of a photon is always situated immediately only on one of the prosthetic groups, yet they are close enough together for efficient radiationless transfer of energy by resonance to occur.

The efficiency of radiationless transfer of energy by resonance, the ratio between the quanta transferred before the return of the electronically excited state to the ground state and the quanta absorbed that created that electronically excited state, depends inversely on r^6, where r is the distance between the transition dipoles of the chromophores. It has been estimated that R_0, the distance at which the efficiency for transfer of an electronic excitation between two phycocyanobilins in a C-phycocyanin by radiationless transfer of energy by resonance should be 50%, is 5.0 nm.[1226] In an individual phycobiliprotein and in the rods into which phycobiliproteins are assembled, each of the respective bilins, which in this case are the chromophores, is within 5 nm of at least one other,[1204] and many of the pairs of bilins are less than 3 nm apart.[1227] Since the dependence is to the sixth power, the difference between 5 and 3 nm is a factor of 20, which would increase the efficiency of transfer to 96%.

If prosthetic groups in an array, however, are close enough together and rigidly held in the proper orientation, the electronically excited state that results upon absorption of a photon is **delocalized over the entire array**, as is the case with a special pair. This delocalization results from the strong coupling of their adjacent, stationary transition dipoles. In effect, the electronic excitation is not actually migrating among the closely and rigidly held prosthetic groups but distributed instantaneously among them, as is the case in any delocalization.

The light-harvesting protein LH2 from *R. acidophilus* (Figure 2–44) illustrates the **two extremes in mechanism** for migration of electronic excitation. The eighteen bacteriochlorophylls *a* in the closely spaced continuous ring have strongly coupled transition dipoles, and at low temperature at least, the electronic excitation does not migrate among them but is delocalized among them. The nine bacteriochlorophylls *a* in the more widely spaced ring, however, absorb photons as individual chromophores and the electronic excitation migrates among themselves and to the ring of eighteen bacteriochlorophylls *a* by radiationless transfer of energy by resonance.

For the eighteen bacteriochlorophylls *a* in the closely spaced continuous ring, the electronically excited state that results upon absorption of a photon is delocalized over the entire ring at a temperature of 1.2 K.[1228] Although this complete delocalization requires the rigidity of the low temperature, at a temperature of 7 K, the electronic excitation migrates among the eighteen bacteriochlorophylls *a* in the ring with a rate constant[1229] of 10 ps^{-1} rather than instantaneously, and there is strong coupling of their transition dipoles at room temperature.[1230] The strong coupling of these eighteen bacteriochlorophylls *a* in the ring permits the electronic excitation to migrate among them more rapidly than the radiationless transfer of energy by resonance from one of the nine, more distant bacteriochlorophylls *a* to the ring of eighteen.[1231]

When one of the nine widely spaced bacteriochlorophylls *a* absorbs light, the electronically excited state that results upon absorption of a photon is localized initially in the bacteriochlorophyll *a* that absorbed the photon.[1228,1230] Migration of electronic excitation from one of the bacteriochlorophylls in the ring of nine to the ring of eighteen has a rate constant of 0.5 ps^{-1} at 77 K[1219] and 0.4 ps^{-1} at 300 K.[1232]

The strong coupling of the transition dipoles of bacteriochlorophylls *a* within the ring of eighteen and the relative orientation of those transition dipoles also **shift the absorption** of the bacteriochlorophylls *a* in this ring to longer wavelengths (850 nm), just as the enforced orientation of the transition dipoles in the special pair of a reaction center shifts the absorption of its bacteriochlorophylls *b* to longer wavelengths. The nine more widely spaced bacteriochlorophylls *a* in the ring at the center of the protein, however, absorb photons as individual chromophores with unperturbed absorption maxima at 800 nm. In each of the nine asymmetric units of light-harvesting protein LH2 from *R. acidophilus* (Figure 2–44), there is also a **carotenoid**, in this instance the D-glucoside of rhodopin (1,2-dihydro-1-hydroxy-ψ,ψ-carotene),[1233] that absorbs light with wavelengths from 450 to 550 nm. The resulting electronic excitation migrates from the carotenoid to the bacteriochlorophylls *a* with a rate

constant[1232] of 4 ps^{-1} and an efficiency approaching 100%.* Consequently the whole array is able to absorb light at 450–550 nm and 800–860 nm. Absorption at the shorter wavelengths, and hence higher energies, is funneled from the other prosthetic groups into the bacteriochlorophylls *a* in the ring of eighteen, from which it migrates to the antenna surrounding the reaction center.

The problem with describing migration of electronic excitation within the arrays of prosthetic groups in most photosynthetic antennae is that their spacing, orientation, and the rigidity with which the chromophores are held is **intermediate between the extremes of radiationless transfer of energy by resonance and electronic delocalization**. In many, if not most, situations, the magnitude of the electronic coupling between light-harvesting prosthetic groups is so large that the point dipole assumption of radiationless transfer of energy by resonance breaks down, but the spacing, orientation, and the rigidity with which the prosthetic groups are held is not such that widely distributed delocalization of the electronically excited state can occur. The situation is further complicated by the fact that migration of electronic excitation in an antenna can also display properties indicating that quantum coherence contributes significantly to the migration, even at ambient temperatures.[1220] It seems that natural selection has discovered several different means to transfer electronic excitation rapidly and with high efficiency. The issues in a physical description of migration of electronic excitation in a particular antenna are controversial enough and complicated enough to be beyond the scope of the present discussion. Nevertheless, efficiencies and rates of migration can be measured, and there is little doubt that the excitation is successfully funnelled from the point of initial absorption to the special pair.

The role of harvesting light is not confined completely to chlorophylls, carotenoids, and bilins. Deoxyribodipyrimidine photo-lyase, the photoreduction of which has been described, is a widely distributed enzyme responsible for photolytically repairing cyclobutadipyrimidine dimers that result from unavoidable photolytic damage to double-stranded DNA. In the different varieties of deoxyribodipyrimidine photo-lyase, either 5,10-methenyltetrahydropteroylpolyglutamate,[1234] 7,8-didemethyl-8-hydroxy-5-carba-5-deazariboflavin,[1235] flavin mononucleotide,[1236] or flavin adenine dinucleotide[1237] acts as a light-harvesting prosthetic group, absorbing a photon and transferring the electronic excitation to the anionic conjugate base of flavin adenine dinucleotide, $H_2Fl_{red}^-$, responsible for providing the excited electron to the cyclobutadipyrimidine.[1238] The unpaired electron in the highest occupied molecular orbital of the electronically excited state of the reduced flavin is passed through the indolyl group of an adjacent tryptophan to the cyclobutanyl group of the cyclobutadipyrimidine to form the radical anion of the cyclobutanyl group that then dissociates to produce the two undamaged pyrimidines.[1239]

*The transfer of electronic excitation from carotenoid to bacteriochlorophyll is usually less efficient. Depending on the type of carotenoid and the energy levels for excitation of the bacteriochlorophyll, the efficiency can be as low as 30%.

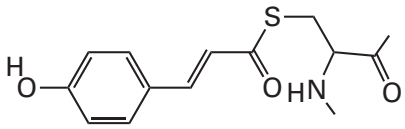
Problem 2–26: Draw the structure of heme *b*, the structure of phycoerythrobilin, the structure of phycocyanobilin, and the structure of 15,16-dihydrobiliverdin.[1240] Phycocyanobilin and phycoerythrobilin both have two isomers at carbon 3.

(A) Draw each of the isomers.
(B) Why should there be a reasonable equilibrium between the two isomers?
(C) Draw phycoerythrobilin and 15,16-dihydrobiliverdin attached at their two ends to cysteines.[1188,1193]

Photoisomerization

There are several prosthetic groups in which a particular double bond is isomerized from the initial *E* or *Z* conformation to the opposite conformation as a result of absorption of a photon of light. Such **photoisomerizations** also occur in nonenzymatic chemical reactions. For example, when a molecule of (*E*)-stilbene dissolved in a 4:1 mixture of ethanol and methanol at 25 °C absorbs a quantum of light at 313 nm, the *Z* isomer and *E* isomer are produced during the decay of the electronically excited state in a 1:1 ratio,[1241] even though (*Z*)-stilbene is significantly less stable in the ground state than (*E*)-stilbene. When a quantum of light is absorbed by a molecule of (*E*)-stilbene, an excited singlet state is produced in which the excited electron occupies an antibonding molecular orbital. The isomerizing bond is at a node in the antibonding orbital. The electron repulsion of the *p* orbitals across the isomerizing bond is relieved by twisting one side of the bond relative to the other. This torsional rotation produces a state in which the dihedral angle across the bond that is isomerizing is significantly less than the 180° of the ground state.[1242,1243] From this twisted transition state, the electronically excited state decays to the *E* isomer or the *Z* isomer in the observed ratio of 1:1.[1244]

One of the simplest biochemical prosthetic groups that undergoes photoisomerization is the (*E*)-4-hydroxycinnamic acid esterified to Cysteine 69



2–84

in **photoactive yellow protein** from *Halorhodospira halophila*.[1245,1246] Upon excitation with blue light of wavelength 445 nm, which is the maximum of its visible absorption within the protein, the quantum yield for the *Z* isomer from the electronically excited state is 0.64.[1247]

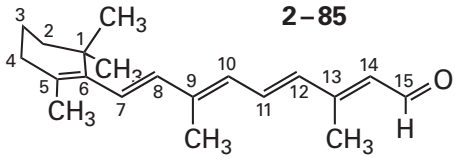
There are crystallographic molecular models of the various conformational changes that occur to the chromophore and its surroundings over an interval from 150 fs to 10 ms following the absorption of light.[1248-1252] From one of these crystallographic time courses, it could be determined that the rate constant for isomerization of the carbon–carbon double bond to the *Z* conformation[1248] is 3 ns^{-1}.

In crystallographic molecular models of the ground state, the peripheral 4-hydroxyphenyl group of the 4-hydroxycinnamoyl group is held firmly by two hydrogen bonds between its 4-hydroxy group and the 4-hydroxyphenyl group of Tyrosine 42 and the carboxy group of Glutamate 46. The thioester is in the trans conformation, and its acyl oxygen forms a hydrogen bond with the amido nitrogen–hydrogen bond of the cysteine to which it is esterifed, as in **2–84**. After an interval of 100 ns, two different conformations of the active site are observed in approximately equal concentrations.[1249] In one conformation, the two hydrogen bonds to the 4-hydroxy group remain intact, the thioester has flipped over in response to the photoisomerization but remains in the trans conformation,[1252] and its hydrogen bond to the amido group has broken. In the other conformation, the two hydrogen bonds to the 4-hydroxy group have broken, the thioester has not flipped over and remains in the trans conformation in the same location as it was in the ground state, and the 4-hydroxyphenyl group, freed from the hydrogen bonds, has flipped over.[1250] After an interval of 100 μs following the absorption of light, only one conformation of the *Z* isomer has become predominant. In this conformation, the two hydrogen bonds to the 4-hydroxy group have been broken, the 4-hydroxyphenyl group has flipped over, the thioester, which remains in the trans conformation, is no longer flipped over, the hydrogen bond between the amido group of the cysteine and the acyl oxygen of the thioester has reformed, and the thioester is in the same position as in the ground state.[1251] At this point, a global conformational change in the protein has occurred.[1253] This global conformational change initiates, for example, a repellent response of the bacterium *H. halophila* toward intense blue light.[1254] The prosthetic group slowly (3 s^{-1})[1255] returns thermally to the *E* isomer, and the conformation of the ground state is resumed to complete the **photocycle**.

Phytochrome is a protein that contains a **phytochromobilin**. Phytochromobilin is closely related to phycocyanobilin (**2–82**), the only difference being that the ethenyl group at carbon 18 in biliverdin (**2–81**) is not reduced to an ethyl group during its modification to phytochromobilin. Phytochromobilin is attached as usual through a sulfide linkage at carbon 3 (**2–83**). Upon absorption of light at 670 nm, the double bond at position 15 photoisomerizes from the more stable *Z* isomer (see **2–82**) to the *E* isomer.[1256,1257] The photoisomerization initiates a sequence of events that, in five discrete steps taking about 0.25 s, produces a conformational change of the protein[1258] that registers the fact that light has

been absorbed. This altered conformational change initiates responses to light in a higher plant that control germination of seeds, biosynthesis of chlorophyll, inhibition of stem elongation in the dark, expansion of leaves, and flowering.[1259] The return of the phytochromobilin to the *Z* isomer at at position 15, although exergonic, is achieved photochemically rather than thermally through another photoisomerization requiring light of 730 nm and with a composite rate constant[1260] of 200 s^{-1}. The return of the prosthetic group to the *Z* isomer following the second photoisomerization completes the photocycle.

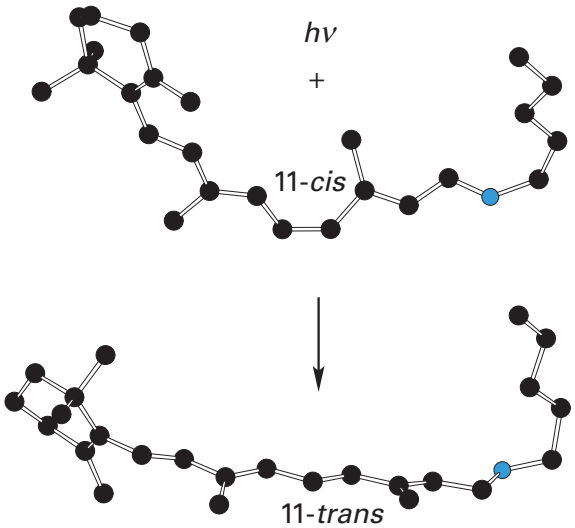
Retinal, which is the aldehyde of one half of *β*,*β*-carotene (**2–78**)



is a carotenoid that is covalently bound as a prosthetic group through an imine with a lysine in an opsin to produce a **rhodopsin**. An opsin is a protein composed of a single polypeptide of 250–450 amino acids, depending on the species, that is embedded in a biological membrane. The polypeptide is folded into seven *α* helices, each of which is about 20 amino acids long and spans the membrane, with loops of variable length connecting the helices.

The visual pigments in a mammalian eye are rhodopsins. They are a set of homologous proteins: visual rhodopsin, long-wave-sensitive visual rhodopsin, medium-wave-sensitive visual rhodopsin, and short-wave-sensitive visual rhodopsin. Their function is to register photons of visible light. The chromophore in each of these proteins is retinal, which is present in the active site as a retinyl group linked to the protein through an imine with the amino group of a lysine. In the dark-adapted retina, the retinyl group within **visual rhodopsin** is in the *Z* isomer at position 11. When retinal is in free solution in an organic solvent or in the phospholipid bilayer of the membrane in which the visual rhodopsin is located, this (7*E*,9*E*,11*Z*,13*E*)-retinal is the less stable isomer relative to (7*E*,9*E*,11*E*,13*E*)-retinal (*all-trans*-retinal). Nevertheless, in the dark and in solution, (7*E*,9*E*,11*Z*,13*E*)-retinal, like any other compound containing a cis double bond, does not isomerize spontaneously in the absence of a catalyst.

In the crystallographic molecular model of bovine visual rhodopsin,[1261-1263] the cis double bond at position 11 is twisted out of planarity by 45°, making the retinyl group even less stable. Upon the absorption of light by the (7*E*,9*E*,11*Z*,13*E*)-retinyl group attached to the lysine of the opsin in visual rhodopsin, the instantaneously formed Franck–Condon electronically excited state decays with a rate constant[1264] of 5 ps^{-1} to an excited intermediate in which the dihedral angle of the double bond at position 11 has increased even further as a result of repulsion from the antibonding molecular orbital occupied by the excited electron.[1265] This form of the electronically excited state, which is distorted even further toward the thermally more stable (7*E*,9*E*,11*E*,13*E*) isomer by the protein itself,[1266] then decays to a static 2:1 mixture of the *E* and *Z* isomers at position 11. In this mixture, the two stereoisomers do not equilibrate with each other. The isomerization of the retinyl group in the bovine visual rhodopsin, in addition to changing the double bond from cis to trans, causes the bond between nitrogen 7 of the lysine and carbon 15 of the retinyl group to rotate almost 180° and the cyclohexyl ring also to rotate 180°[1267]



(2–196)

The conformational change of the retinyl group in the visual rhodopsin from *Todarodes pacificus*, however, upon isomerization of the double bond at position 11 produced by the absorption of light, is much less dramatic.[1268]

Coincident with absorption of a photon and isomerization of the retinyl group from *Z* to *E*,[1269,1270] bovine visual rhodopsin undergoes a change in conformation in response to the dramatic change

that has occurred in the structure of the retinyl group (Equation 2–196). This change in conformation of the protein is the event that registers absorption of the photon and leads to visual perception.

Following the change in conformation of the visual rhodopsin, the thermally more stable (7*E*,9*E*,11*E*,13*E*)-retinal is released from the opsin and the less stable (7*E*,9*E*,11*Z*,13*E*)-retinal is regenerated in a sequence of enzymatic steps[1271] that proceed while the retinal and the other intermediates in the sequence are free solutes in the phospholipid bilayer of the membrane of the rod or cone. The enzyme that catalyzes the actual reisomerization, retinoid isomerohydrolase, couples the unfavorable conversion of the double bond at position 11 from trans to cis with the favorable hydrolysis of the ester between (7*E*,9*E*,11*E*,13*E*)-retinol and palmitic acid.[1272-1274] The isomerization involves an allylic carbocationic intermediate[1275] at positions 12, 13, and 14 resulting from the hydronation of carbon 11. The reassociation of (7*E*,9*E*,11*Z*,13*E*)-retinal with a molecule of opsin completes the photocycle.

There are a number of bacteria and archaea that have a **bacteriorhodopsin**, particular to their species, in their membranes. In contrast to the retinyl group in visual rhodopsin, the retinyl group in bacteriorhodopsin from *Halobacterium salinarum*, in the light-adapted, continuously cycling state immediately prior to the absorption of a quantum of light, exists as the thermally more stable (7*E*,9*E*,11*E*,13*E*) isomer. Also in contrast to visual rhodopsin, the *Z* isomer at carbon 13, rather than the *Z* isomer at position 11, is produced by the photoisomerization.[1276-1279] The initial absorption of a photon is followed by a photocycle with a number of different intermediates, distinguished by their absorption spectra.[1280] Crystallographic molecular models[1281,1282] of all the intermediates in this photocycle are available.[1281,1283-1288] The function of bacteriorhodopsin in *H. salinarium* is to use the energy stored in the photoisomerization to **move a hydron across the membrane**. The hydron is transported from the negative, basic solution on the one side of the membrane to the positive, acidic solution on the other. In the flavobacterium *Dokdonia eikasta*, there is a homologous (22% identity; 3.3 gap percent) bacteriorhodopsin that uses a similar mechanism to transport a sodium ion from a solution of low concentration to a solution of high concentration.[1289]

In the initial state, immediately prior to photoisomerization, the nitrogen–hydrogen bond of the hydronated iminium at carbon 15, adjacent to the *E* double bond at position 13 (see **2–85** and Equation 2–196) in the bacteriorhodopsin from *H. salinarum*, is pointed in the direction of the positive, acidic side of the membrane[1281] and is the donor in a hydrogen bond to a molecule of water pinned in place by hydrogen bonds[1290] to Aspartates 85 and 212. After the electronically excited state produced by absorption of a photon has relaxed and the double bond at position 13 has isomerized to the *Z* isomer, a torque is exerted on this imine by the *Z* configuration of the adjacent double bond. Both crystallographic molecular models[1290] taken at 16, 290, and 760 ns and solid-state nuclear magnetic spectra taken in the same interval[1291] indicate that as the isomerization proceeds, the hydronated iminio group swings past the hydroxy group of Threonine 89, which is a donor in a hydrogen bond with the carboxylato group of Aspartate 85 in the ground state, and that as it swings by, the hydron is transferred from the lysyl iminium to the hydroxy group of Threonine 89 and relayed through the hydroxy group to the carboxylato group of Aspartate 85 on the side of the retinyl group closest to the positive, acidic side of bacteriorhodopsin. The hydron is relayed from the carboxy group of Aspartic Acid 85 through two molecules of water to the guanidinio group of Arginine 82 and eventually to the positive, acidic side of the protein. Following the transfer, the two molecules of water dissociate from the protein as a result of slower conformational changes to the carboxy groups holding them in place that are induced by the isomerization of the retinyl group,[1290] so there is no path on which the hydron can return.

The unhydronated imino group has been turned by the torque of the adjacent *Z* double bond, so its lone pair of electrons, from which the hydron was transferred to the hydroxy group of Threonine 89, faces in the opposite direction toward the negative, basic side of the bacteriorhodopsin, just as the imine in visual rhodopsin rotates almost 180° following the photoisomerization of the retinyl group (Equation 2–196). Following this pivot, the lone pair of electrons on the imino nitrogen picks up a hydron relayed from the carboxy group of Aspartic Acid 96 on the negative, basic surface of the bacteriorhodopsin. A conformational change in the protein, induced by the photoisomerization of the retinyl group, opens a channel between the carboxy group of Aspartic Acid 96 and the lone pair of electrons on the imino nitrogen. This channel becomes occupied by three molecules of water that form a continuous

chain of hydrogen bonds, from the carboxy group of Aspartic Acid 96 to the lone pair of electrons on the imino nitrogen,[1292] through which a hydron from the negative, basic solution is transferred to the imino nitrogen. In this instance, the conformational change has assembled rather than disassembled a chain of molecules of water joined by hydrogen bonds.

Following all these more rapid steps, the more stable (7*E*,9*E*,11*E*,13*E*)-retinyl group is regenerated thermally with a rate constant of 200 s^{-1}. During this regeneration, the nitrogen–hydrogen bond of the hydronated iminium rotates back to the initial position, pointed in the direction of the positive, acidic side of the membrane.[1284] During this thermal isomerization, the hydron must remain on the nitrogen so that it is pointed to the positive, acidic side of the membrane. The net result is that one hydron is released into the solution on the positive, acidic side of the membrane and one hydron is taken up from the negative, basic side for every photon absorbed, and the free energy required to formally transport the hydron against the electrochemical gradient from the negative, basic solution to the positive, acidic side of the membrane is supplied by the photon of light absorbed by the retinyl group.

The answers to the most important questions, however, remain unclear. What forces the imine to be hydronated before it begins to flip during its conformational change in response to the photolytic isomerization of the retinyl group from all trans to 13-cis? What forces the imine to be dehydronated by the hydroxy group of Threonine 89 while it passes by so that, when it completes the flip, it is dehydronated? What forces the imine to be hydronated before it can flip back in response to the thermal isomerization of the retinyl group from 13-cis to all trans? What forces the iminium to remain hydronated as it presumably again passes by the hydroxy group of Threonine 89 so that it brings the hydron to the other side of the retinyl group? The answers to these questions probably rely on a careful tabulation of the positions of all the hydrons in the hydrogen bonds in which the hydroxy group of Threonine 89 participates and all the hydrogen bonds among the atoms that relay a hydron to the positive, acidic solution and a hydron from the negative, basic solution. Similar issues will arise later with regard to H^+-transporting two-sector ATPase.

The retinyl group is long and bulky. Because it is hydrophobic along its entire length, there are no donors or acceptors for hydrogen bonds to enforce a particular rotational isomer. In the various rhodopsins, the retinyl group is almost completely surrounded by mostly hydrophobic side chains.[1267] There can be little doubt that the **structure of the active site** formed by this constellation of hydrophobic amino acids surrounding a particular rhodopsin influences the course of the particular photocycle for which it is responsible. For example, the structure of the active site of bacteriorhodopsin must determine that the (7*E*,9*E*,11*E*,13*Z*) isomer is the major product of the photoisomerization rather than the (7*E*,9*E*,11*E*,13*E*) isomer and then must determine that the major product of the thermal equilibrium between the two isomers, when a photon has not just been absorbed, is the (7*E*,9*E*,11*E*,13*E*) isomer of the retinyl group, which happens to be the inherently most stable isomer in solution but not necessarily the more stable on an active site. The active site in visual rhodopsin distorts the double bond at position 11 in the (7*E*,9*E*,11*Z*,13*E*) retinyl group (Equation 2–196), presumably to weaken it, but does not distort it enough to break it and cause it to isomerize because, in the dark, the (7*E*,9*E*,11*Z*,13*E*) isomer remains unisomerized. The active site of visual rhodopsin then exploits the inherent stability of the (7*E*,9*E*,11*E*,13*E*) isomer, which the active site has caused to be the major photoproduct, to leverage the conformational change.

Oxides and Hydrides of Hydrogen, Nitrogen, Oxygen, and Sulfur

Molecular nitrogen is diatomic and has 10 valence electrons, and molecular oxygen is diatomic and has 12 valence electrons. The molecular orbital systems (Figure 2–45)[675] occupied by these electrons to form the bonds in molecular nitrogen (N_2) and molecular oxygen (O_2) are the same, and they are the same as the molecular orbital systems of the other diatomic molecules of the elements of the second period, such as molecular fluorine (F_2), carbon monoxide (CO), and nitric oxide ($NO^{\bullet}$) and the diatomic ions of the elements of the second period,[1293] such as the conjugate base of nitroxyl (ON^-), carbide ion (CC^{2-}), and cyanide ion (CN^-) as well as diatomic intermediates of atoms from the second period in enzymatic reactions. The nuclei, however, and, consequently, the energy levels of the respective molecular orbitals in each of these molecules and ions differ because the energy levels of the atomic orbitals that mix to form the molecular orbitals differ. In the diatomic molecules and ions in which the two atoms are different, the shapes of the molecular orbitals are asymmetric because of the differences in electronegativity of the two atoms. There are both σ molecular orbitals and π molecular orbitals between the two respective atoms in these diatomic molecule or diatomic ions.

The two **σ molecular orbital systems**, σ_s and σ_p, are formed by the combination of two $2s$ atomic orbitals, one from each atom, and the combination of two $2p_z$ atomic orbitals, one from each atom, respectively (Figure 2–45). The $2p_z$ orbitals are the $2p$ orbitals that lie along the line of centers between the atoms. These two pairs of atomic orbitals, s and p, combine to create two pairs of σ molecular orbitals. Each pair contains a bonding σ molecular orbital and an antibonding σ molecular orbital. Because all four of the constituent atomic orbitals, the two $2s$ atomic orbitals and the two $2p_z$ atomic orbitals, were cylindrically symmetric with the axis between the two nuclei before they mixed, the four molecular orbitals in the two σ molecular orbital systems that they create are also cylindrically symmetric around the axis between the atoms,[675,1294-1296] but they are asymmetric about axes perpendicular to the central axis when the atoms are different. The resulting four molecular orbitals are considered to be σ molecular orbitals because they form bonds and antibonds along the line of centers between the two atoms.

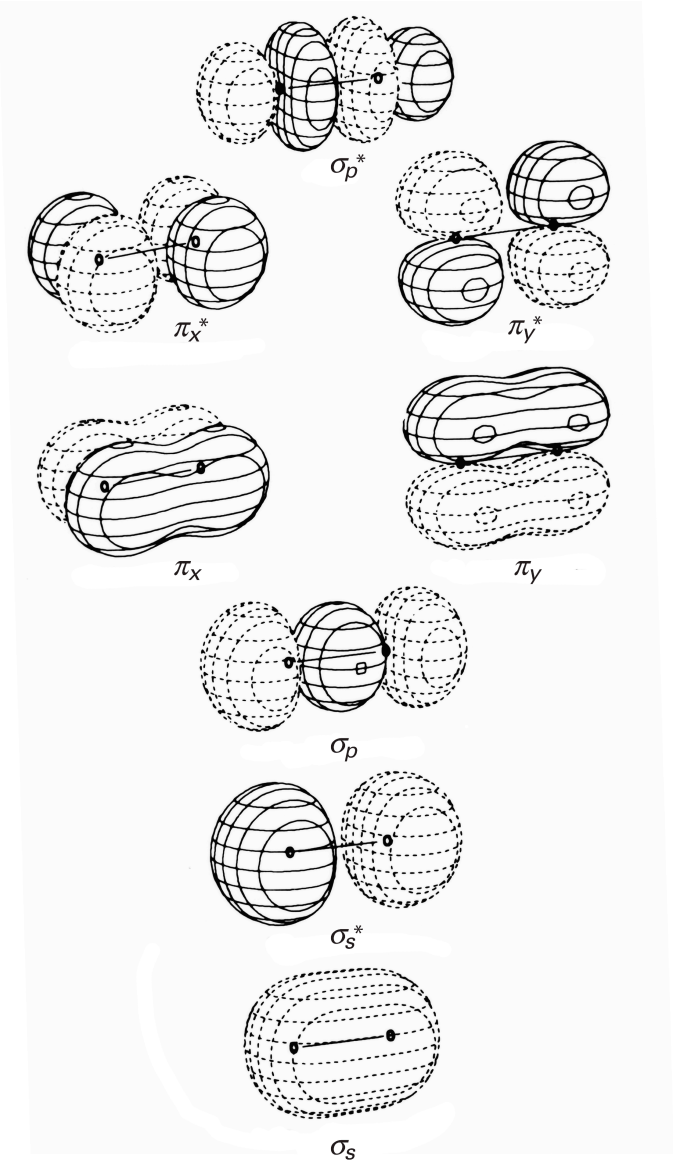

Figure 2–45: One of several ways to depict the molecular orbitals of the O_2 molecule.[675] The drawings of the individual molecular orbitals are distributed and labeled as they are in **2–87**. The two lowest, cylindrically symmetric σ molecular orbitals along the line of centers between the two oxygen atoms (σ_s and σ_s^*) are formed from the overlap of two s atomic orbitals, one from each oxygen atom. The two highest cylindrically symmetric σ molecular orbitals along the line of centers between the two oxygen atoms (σ_p and σ_p^*) are formed from the overlap of two p_z atomic orbitals, one from each oxygen atom. The two pairs of π molecular orbitals, which are orthogonal and degenerate to each other, are formed from the p_x orbitals (π_x and π_x^*) and the p_y orbitals (π_y and π_y^*) of the two oxygen atoms. In the ground state, the distribution of electrons in these orbitals is as in **2–87**. Reprinted with permission from reference 675. Copyright 1979 Annual Reviews, Inc.

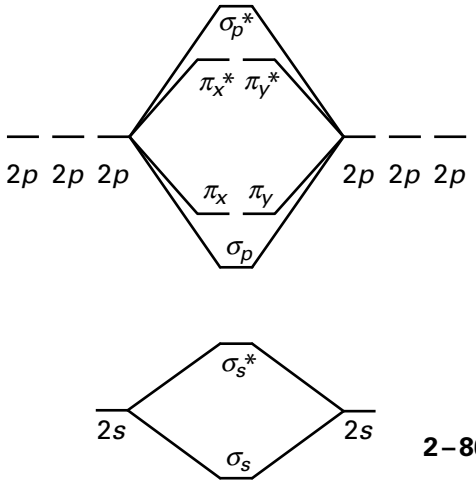
The two **π molecular orbital systems**, π_x and π_y, are formed as shown in Figure 2–45. The π_x molecular orbital system is formed by the overlap of the two parallel p_x orbitals, one from each atom, which creates a bonding π molecular orbital (π_x) and an antibonding π molecular orbital (π_x^*). The π_y molecular orbital system is formed by the overlap of the two parallel p_y orbitals, one from each atom, which also creates a bonding π molecular orbital (π_y) and an antibonding π molecular orbital (π_y^*). Because the p_x and p_y orbitals on each atom were orthogonal and degenerate, the two π molecular orbital systems they create are perpendicular to each other, orthogonal, and degenerate; as, for example, are the two π molecular orbital systems in ethyne.

The energy levels of these molecular orbitals are distributed in the order of the atomic orbitals that form them

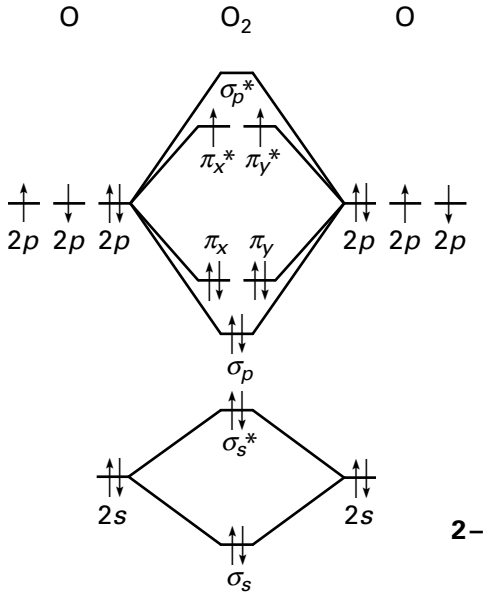


2–86

To the right and to the left, the diagram shows the energy levels of the atomic orbitals of the two atoms that mix among themselves to produce the molecular orbitals of the molecule, which are displayed in the center. The total number of molecular orbitals is always equal to the sum of the atomic orbitals that mixed together.

The first ten **valence electrons** in a diatomic molecule or ion fill the molecular orbitals in order of their energy: the two bonding σ molecular orbitals (σ_s and σ_p,) the antibonding σ molecular orbital of lowest energy (σ_s^*), and the two bonding π molecular orbitals (π_x and π_y). Because two bonding σ molecular orbitals and one antibonding σ molecular orbital are occupied by six electrons, there is a **net number of one σ bond**. Because two bonding π molecular orbitals are occupied by four electrons, there is a **net number of two π bonds**. This distribution of electrons completes the catalogue of occupied molecular orbitals of N_2, as well as CO, CC^{2-}, and CN^-. In each case, the five molecular orbitals of lowest energy are filled with the ten valence electrons, and there is a net number of three bonds between the two atoms, two π bonds and one σ bond. As a result, one way to represent molecular nitrogen is N≡N.

The remaining two valence electrons in **molecular oxygen**, however, are found in the two separate **antibonding π molecular orbitals**,[675,1294-1296] formed from overlap out of phase (Figure 2–45) of the two $2p_x$ and the two $2p_y$ atomic orbitals, respectively



2–87

The two orthogonal, antibonding π molecular orbitals, π_x^* and π_y^*, are degenerate, and by Hund's rule, each is occupied by an unpaired electron. This distribution of electrons causes molecular oxygen in its ground state to be a triplet diradical and paramagnetic. Only one of these two antibonding π molecular orbitals is occupied by the single unpaired electron in $NO^{\bullet}$, which is a stable radical.

The four electrons in the two bonding π molecular orbitals and the two electrons in the two antibonding π molecular orbitals in molecular oxygen produce the **equivalent of one π bond**. Consequently, molecular oxygen can be abbreviated as if it had a double bond, one σ bond and one π bond, O=O, as is the case in a carbon–carbon double bond. Another way of abbreviating it, however, would be :O≒O:, which accounts for all twelve valence electrons and indicates approximately where they are, but this representation is cumbersome and difficult to set in type. Even though the two unpaired electrons

are in separate antibonding orbitals, with a node between the two oxygens, they are delocalized over the two atoms of oxygen, and this delocalization does provide extra stabilization to the bonding in the π molecular orbital system beyond what would be realized by only a single π bond.[1297] The fact, however, that the antibonding molecular orbitals in the σ molecular orbital systems are filled weakens the oxygen–oxygen σ bond and makes it more susceptible to dissociation.

The two unpaired electrons of molecular oxygen in the two degenerate π molecular orbitals have spins of the same sign in the **triplet ground state**. Upon excitation in an appropriate fashion, one of the two electrons can have its spin inverted to create an **excited singlet state** in which the two electrons are of opposite spin. There are two excited singlet states: one in which the two electrons of opposite spin are in the same antibonding π^* molecular orbital and one in which they are split between the two antibonding π^* molecular orbitals. The triplet state of molecular oxygen engages in homolytic radical chemistry and single electron transfer. The heterolytic, singlet electronically excited state of molecular oxygen, in which the two electrons are in the same antibonding π^* molecular orbital, can participate as an electron-deficient dienophile in a cycloaddition reaction with an electron-rich diene and can participate in a [2 + 2] cycloaddition with an olefin to produce a dioxetane, and the pair of electrons in the π bond of an olefin as a nucleophile can add to one of the oxygen atoms in singlet oxygen acting as an electrophile to form a peroxirane.[1298]

In molecular oxygen, the two π molecular orbitals that are each occupied by an unpaired electron are antibonding but only half-filled. The addition of one electron to one of these two antibonding orbitals produces the **superoxide radical anion**

$$O_2 + e^- \rightleftharpoons O_2^{\cdot -} \qquad (2\text{–}197)$$

This reaction, even though it fills an orbital, is not a favorable one [$E^{\circ\prime}$ = –330 mV (standard state of 10^5 pascals of oxygen)][1299,1300] because the electron is added to an antibonding orbital. Unlike the other intermediates in the reduction of molecular oxygen, as well as molecular oxygen itself, the superoxide radical anion is a mild reducing agent.

The addition of a second electron to the remaining unfilled, antibonding π molecular orbital, which is very favorable under standard conditions, makes the dioxygen diamagnetic because all electrons are now paired. It also produces an electron-rich molecule, the peroxide dianion, that is quite basic and picks up two hydrons at pH 7 to form two oxygen–hydrogen σ bonds, one to each oxygen. This one-electron reduction and dihydronation forms **hydrogen peroxide**[1300,1301]

$$O_2^{\cdot -} + 2\,H^+ + e^- \rightleftharpoons H_2O_2 \qquad E^\circ = +940\ \text{mV} \qquad (2\text{–}198)$$

The **acid dissociation constants** of the conjugate acids of superoxide radical anion and of hydrogen peroxide define the character of the respective lone pairs of electrons in these two molecules. Molecular oxygen is not basic because the two pairs of nonbonding σ electrons it contains (Figure 2–45) are, at best, located in two *sp* atomic orbitals or, at worst, delocalized into molecular orbitals cylindrically symmetric to the axis of the molecule, and pairs of electrons in π bonds are always poor bases.

After an electron is added to molecular oxygen to produce the superoxide radical anion, the molecule becomes considerably more basic[1302]

$$HO_2^{\cdot} \rightleftharpoons H^+ + O_2^{\cdot -} \qquad pK_a = 4.7 \qquad (2\text{–}199)$$

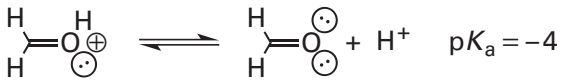
This basicity suggests that the σ electrons in superoxide radical anion are not all delocalized as they are in molecular oxygen. This pK_a is low enough relative to that of water (pK_a = 15.7) to suggest that there is considerably less *p* character in the σ lone pair of electrons accepting the hydron in superoxide radical anion than there is in an sp^3 σ lone pair of electrons on hydroxide, which is the conjugate base of water, even when the electron withdrawal of the other oxygen is taken into account.

The pK_a of dihydrogen superoxide radical cation[1301]

$$H_2O_2^{\cdot +} \rightleftharpoons H^+ + HO_2^{\cdot} \qquad pK_a = 1.2 \qquad (2\text{–}200)$$

is 1.2. This value suggests that the **basic lone pairs of electrons** in the conjugate base, hydrosuperoxide radical, are similarly hybridized to those in superoxide radical anion, the conjugate base of hydrosuperoxide radical (Equation 2–199). The two successive acid dissociations resemble the two successive acid dissociations in a diprotic acid. The only difference

between the basic lone pairs of electrons in hydrosuperoxide radical and superoxide radical anion is that in the former case the oxygen on which they reside is immediately adjacent to a hydroxy group and in the latter case they are immediately adjacent to an oxyanion. It is also the case that the pK_a for dihydrogen superoxide radical cation (Equation 2–200) is higher than the pK_a for the oxygen of the conjugate acid of formaldehyde



(2–201)

The replacement of a methylene carbon with a hydroxy group should only lower the pK_a of the sp^2 oxygen. This comparison suggests that there is more *p* character in the σ lone pair of electrons accepting the hydron in hydrosuperoxide radical than in the sp^2 σ lone pair of electrons on formaldehyde.

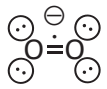
If the hybridizations of the basic lone pairs of electrons in superoxide radical anion and those in hydrosuperoxide radical are similar, if not the same, the conclusion that the basic lone pairs in these two molecules have less *p* character than a lone pair of electrons on the sp^3 oxygen of a hydroxide and more *p* character than the sp^2 oxygen on formaldehyde suggests that their hybridization is somewhere in between.

After a second electron has been added to molecular oxygen, there would be as many antibonding π electrons (four) as bonding π electrons (four) if the molecular orbital structure of molecular oxygen (**2–87**) were retained. For this reason, the π molecular orbitals become even weaker, and in a hydrogen-bonding solvent like water, they decompose completely into **localized σ lone pairs** of electrons on each oxygen. This rehybridization is reflected in the acid dissociation constant of **hydrogen peroxide**

(2–202)

which is that expected of a simple hydroxy group with a strong electron-withdrawing group attached to it [for example, pK_a(CF_3CH_2OH) = 12.5]. That only a single σ bond remains is also reflected in the long bond length (0.148 nm) of hydrogen peroxide. The dihedral angle between the two hydrogens (92°) in hydrogen peroxide can also be explained by the consideration that, were the value of this angle 90°, each of the two sp^3 lone pairs on one oxygen would be as far as possible from being parallel to either of the two sp^3 lone pairs on the other oxygen. This dihedral orientation of 92° minimizes electron repulsion.

In molecular oxygen, the σ molecular orbital system is delocalized and there are no basic lone pairs of electrons. In hydrogen peroxy ion, the basic lone pairs are similar if not the same as the oxygens on a hydroxy group that are hybridized sp^3. The hybridization of the lone pairs of electrons on the superoxide radical anion and the hydrosuperoxide radical is somewhere between sp^2 and sp^3. For the sake of argument and for simplicity, it will be assumed that the two oxygens in the superoxide radical anion, although they are weak bases, are effective **acceptors for hydrogen bonds** and that when superoxide radical anion is dissolved in water, a hydrogen-bonding solvent, it is hybridized so that, in one plane, each oxygen has two sp^2 lone pairs of electrons accepting hydrogen bonds and, in the orthogonal plane, there is a π molecular orbital system occupied by three electrons



2–88

This electronic structure in aqueous solution resembles, at each oxygen, the electronic structure at the oxygen of formaldehyde (Equation 2–201). It is promoted by the weakening of the π system to the benefit of the σ system, owing to addition of the extra electron to one of the antibonding π molecular orbitals on molecular oxygen. The result of the consequent breakdown of the π molecular orbital system to which the electron has been added is that the now-filled antibonding π molecular orbital becomes a localized σ lone pair of electrons on one oxygen and the associated, filled bonding π molecular orbital becomes a localized σ lone pair of electrons on the other oxygen. Either the occupation of the one antibonding π molecular orbital in the gas phase or this reconfiguration of the electronic structure in water lowers the bonding order from 2 to 1.5, which is reflected in the lengthening of the oxygen–oxygen bond from 0.121 nm in molecular oxygen to 0.133 nm in superoxide radical anion, about half the distance to the single bond in hydrogen peroxide.

There are two more one-electron steps in the reduction of oxygen to two molecules of water. When one electron is added to hydrogen peroxide, the σ bond dissociates and hydroxide and **hydroxyl radical** are produced.[1300,1303] The hydroxide ($pK_a = 15.7$) immediately associates with a hydron to form water as the ultimate product

$$H_2O_2 + H^+ + e^- \rightleftharpoons HO^{\cdot} + H_2O \qquad E^{\circ\prime} = +380\ \text{mV} \tag{2–203}$$

Hydroxyl radical is a strong and dangerous oxidant that can pull an electron[1300]

$$HO^{\cdot} + H^+ + e^- \rightleftharpoons H_2O \qquad E^{\circ} = +2310\ \text{mV} \tag{2–204}$$

or a hydrogen atom

$$HO^{\cdot} + H^{\cdot} \rightleftharpoons H_2O \qquad \Delta H^{\circ} = -500\ \text{kJ mol}^{-1} \tag{2–205}$$

from almost anything during its reduction to hydroxide or water.[1303] In biochemical situations, the two final steps in the reduction of molecular oxygen (Equations 2–203 and 2–204) are usually forced to be concerted[1300,1303]

$$H_2O_2 + 2\,H^+ + 2\,e^- \rightleftharpoons 2\,H_2O \qquad E^{\circ} = +1350\ \text{mV} \tag{2–206}$$

to avoid the production of hydroxyl radical.

There are several **chemical features of molecular oxygen** that must be taken into account by the prosthetic groups that react with it. Its σ lone pairs of electrons are neither basic nor nucleophilic. It is a triplet molecule, a diradical with two unfilled π molecular orbitals. These molecular orbitals are antibonding, so their occupation rearranges the electronic structure of the molecule.

There are flavoenzymes that use molecular oxygen as a general oxidant to reoxidize reduced flavin produced during oxidations of their respective nominal reactants.* For example, in glucose oxidase, oxidized flavin oxidizes D-glucose to D-gluconolactone, and the resulting reduced flavin is then reoxidized by molecular oxygen to then oxidize the next D-glucose. During the reaction catalyzed by glucose oxidase and the other flavoprotein oxidases, molecular oxygen is reduced by the two electrons from the reduced flavin to hydrogen peroxide (Equations 2–197 and 2–198). In most cases, oxidation of the nominal reactant is the purpose of the flavoprotein oxidase, and the hydrogen peroxide is an undesired product that is usually disproportionated to water and molecular oxygen by catalase. In the case of aryl-alcohol oxidase from *Pleurotus eryngii*, however, the production of hydrogen peroxide is the purpose of the enzyme, and the nominal substrate, an aromatic primary alcohol such as veratryl alcohol, is recycled.[1304]

When molecular oxygen is used in a flavoprotein oxidase as the final receptacle for the two electrons passing through the flavin, there is no reason to invoke any type of covalent intermediate between flavin and molecular oxygen;[352] **simple electron transfer** should be sufficient. The reduced form of flavin in glucose oxidase is the anion ($H_2Fl_{red}^-$ in Figure 2–9), and its standard two-electron reduction potential in glucose oxidase from *Aspergillus niger* is –174 mV,[1305] which is close to the two-electron biochemical standard reduction potential (–203 mV) of the anionic form, $H_2Fl_{red}^-$, of riboflavin when it is free in solution (Figure 2–15). If the offset for the one-electron biochemical standard reduction potential (+44 mV) for the redox couple of $H_2Fl^{\cdot}$ and $H_2Fl_{red}^-$ in glucose oxidase is similar to that for riboflavin, then the one-electron biochemical standard reduction potential for the flavin in glucose oxidase should be around -130 mV, but the enzyme may well stabilize the semiquinone, in which case the biochemical standard reduction potential would be more negative. On the basis of these considerations, **transfer of an electron from $H_2Fl_{red}^-$ to molecular oxygen** [$E^{\circ\prime} = -160$ mV (standard state of 1 M O_2 and 1 M $O_2^{\cdot-}$)][1295]

$$H_2Fl_{red}^- + O_2 \rightleftharpoons O_2^{\cdot-} + H_2Fl^{\cdot} \tag{2–207}$$

should be almost isoergonic.

In glucose oxidase, the rate for transfer of the first electron from reduced flavin anion ($H_2Fl_{red}^-$) to molecular oxygen to form **superoxide radical anion as an intermediate**[1306] is accelerated at least 100-fold when a histidine adjacent to the oxygen in the active site is hydronated so that it can form an ionized hydrogen bond to the superoxide radical anion[1307] or even transfer a hydron to the superoxide

*In such situations the flavoenzyme is usually called an "oxidase". The nominal reactant gives the particular name to the oxidase—for example, D-glucose and glucose oxidase—and the general oxidant is a molecule of oxygen.

radical anion ($\Delta pK_a = +2$). Because molecular oxygen is not a base while superoxide radical anion is (Equation 2–199), the hydrogen bond forms or the hydron is transferred as the electron is being transferred, a consequence that stabilizes the superoxide radical anion and makes the transfer more favorable. In glucose oxidase, this transfer of the electron between $H_2Fl_{red}^-$ and oxygen to form superoxide radical anion and the neutral flavin semiquinone ($H_2Fl^\bullet$ in Figure 2–9) is the rate-limiting step in the reoxidation of the flavin.[1307]

The superoxide radical anion formed transiently in certain flavoprotein oxidases[1308] rapidly accepts the second electron from the flavin semiquinone to **form hydrogen peroxide in a strongly exergonic reaction**, provided hydrons are available from immediately adjacent acids in the active site of the enzyme[352,1309] or from the water surrounding the enzyme

$$H_2Fl^\bullet + O_2^{\bullet -} + H^+ \rightleftharpoons HFl_{ox} + HO_2^- + H^+ \rightleftharpoons H_2O_2 + HFl_{ox} \quad (2\text{–}208)$$

The fact that molecular oxygen so readily reoxidizes reduced flavin by unembellished transfer of two electrons suggests that enzymes that are required to reoxidize reduced flavin with other oxidants, such as NAD^+, must purposely prevent molecular oxygen from doing so.[1310]

Reduced flavin anion ($H_2Fl_{red}^-$) in free solution, at early times in the reaction before other side reactions become important, reacts with molecular oxygen to produce superoxide radical anion,[286,291,1308,1311] albeit slowly (rate constant of around 100 $M^{-1}\,s^{-1}$). In these **reactions in solution**, the superoxide radical anion and the flavin semiquinone can dissociate before a second electron is transferred, but on an enzyme, the active site retains the superoxide radical anion long enough for a second electron to be transferred. Therefore, the reduction of molecular oxygen to hydrogen peroxide performed by reduced flavin, as the terminal step in the reactions catalyzed by flavoprotein oxidases, can be thought of as a simple two-electron transfer, within the encounter complex, to the π molecular orbital system of the molecular oxygen concerted with transfers of hydrons to the σ lone pairs of the developing peroxide dianion and hydroperoxide anion.

The involvement of **both superoxide radical anion and hydrogen peroxide** in the reoxidation of reduced flavin by molecular oxygen is illustrated by the reoxidation of reduced xanthine oxidase.[1312] Fully reduced xanthine oxidase has six more electrons than the fully oxidized enzyme: two on a prosthetic molybdenum ion, one in each of its two iron–sulfur clusters, and two in its reduced flavin. The reoxidation of the reduced complex by molecular oxygen occurs at the flavin. The first four electrons are removed by two molecules of oxygen during reoxidation, and they are transferred rapidly enough that two molecules of hydrogen peroxide are produced at the flavin. When only two electrons remain on the enzyme, however, the electrons are distributed over the other prosthetic groups at equilibrium such that the flavin exists as a mixture of oxidized flavin and its semiquinone. In an active site occupied at a particular instant by the semiquinone, only one electron can be transferred to molecular oxygen, and as a result, superoxide radical anion, rather than hydrogen peroxide, is produced. When xanthine oxidase is functioning normally, it produces a variable mixture of hydrogen peroxide and superoxide radical anion, depending on its steady-state level of reduction.

There is a remaining **difficulty with transfer of the electrons during the reoxidation of flavin**

$$H_2Fl_{red}^- + {}^3O_2 + H^+ \rightleftharpoons H_2O_2 + HFl_{ox} \quad (2\text{–}209)$$

Molecular oxygen is a diradical because the two unpaired electrons have parallel spins in the triplet ground state, $^3O_2$. The products of the reaction, oxidized flavin and hydrogen peroxide, and the reactant, reduced flavin, are all singlet molecules in which each of the electrons is paired with one of opposite spin. Therefore during the overall reaction, one electron must invert its spin. Such a **spin inversion** is normally a slow process, but it can be catalyzed.

Spin inversions can be **accelerated by electron transfer**. For example, in the active site of glucose oxidase, after transfer of the electron from reduced flavin to molecular oxygen to form $O_2^{\bullet -}$ and $H_2Fl^\bullet$, the two unpaired electrons of the still triplet state are now located, respectively, on flavin and superoxide radical anion rather than both being on molecular oxygen. Because they are single unpaired electrons on different atoms (nitrogen and oxygen) in different molecules (flavin and superoxide radical anion), spin inversion becomes rapid. There is no indication that the second step in reoxidation of the flavin in glucose oxidase, the step in which the triplet state of the separated electrons formally

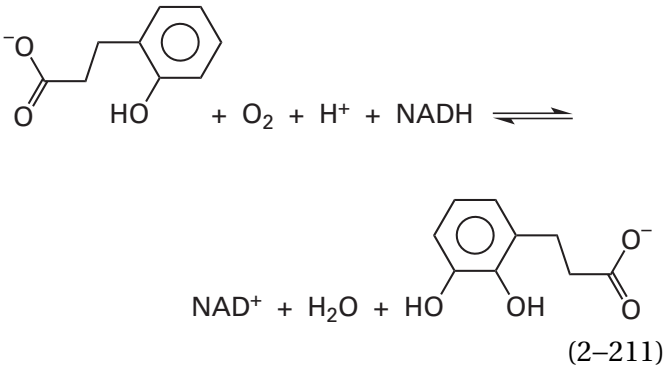
becomes a singlet state, is hindered by spin inversion.[1307]

Spin inversions are also **catalyzed by transition metallic ions.** For example, triplet oxygen combines with a ferroheme with an open site for ligation on Fe^{2+} to form a complex between the heme and oxygen, as in hemoglobin. The complex is diamagnetic,[1313] so its formation necessarily involves a spin inversion. As this spin inversion is essentially instantaneous, it can be concluded that it is catalyzed by Fe^{2+}. Transition metallic ions other than iron are also used to catalyze spin inversion. Galactose oxidase catalyzes the reaction

$$\text{D-galactose} + {}^3O_2 \rightleftharpoons H_2O_2 + \text{D-}\textit{galacto}\text{-hexodialdose} \quad (2\text{–}210)$$

During the reaction, spin inversion must take place because both products are singlet molecules. Instead of flavin, the reduced prosthetic group in the active site of galactose oxidase is a complex between a copper ion and a 2-(*S*-cysteinyl)tyrosine.[1314,1315] This complex, in its reduced state, is the immediate electron donor to triplet oxygen. Either transfer of an electron from the Cu^+ to triplet oxygen, to split the triplet between oxygen and Cu^+, or direct complexation of singlet oxygen with copper[1316] accomplishes the necessary spin inversion.

There are many monooxygenases that use flavin as a prosthetic group in the monooxygenation of a substrate by molecular oxygen. Examples are melilotate 3-monooxygenase[1317]

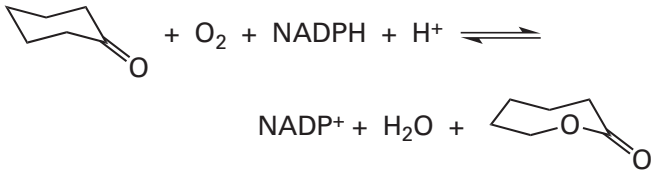


(2–211)

4-hydroxybenzoate 3-monooxygenase[1318]

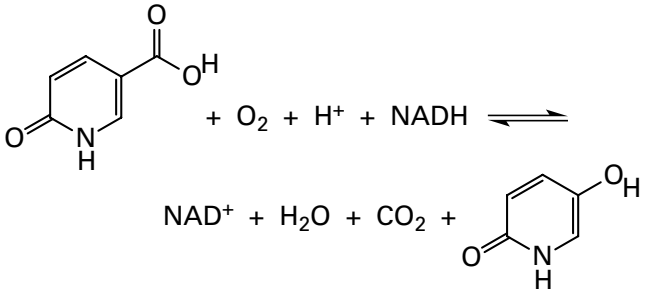
$$\text{4-hydroxybenzoate} + \text{NADPH} + H^+ + O_2 \rightleftharpoons \text{3,4-dihydroxybenzoate} + NADP^+ + H_2O \quad (2\text{–}212)$$

cyclohexanone monooxygenase[1319]



(2–213)

6-hydroxynicotinate 3-monooxygenase[1320]



(2–214)

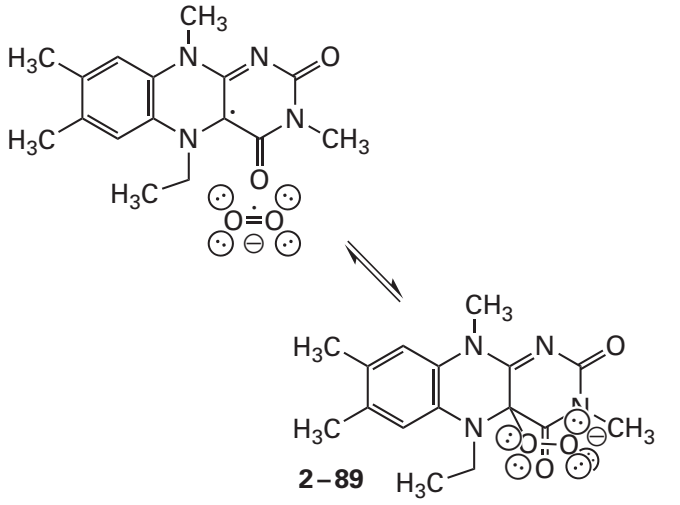
and the epoxidation of the carbon–carbon double bond in the center of fumitremorgin C catalyzed by a flavin monooxygenase from *Aspergillus fumigatus* that is related to 4-hydroxybenzoate 3-monooxygenase. In this last case, the epoxide produced then dissociates at one of the carbon–oxygen bonds, and the resulting carbenium ion undergoes an alkyl migration as in a pinacol rearrangement to form the spiro carbon in spirotryprostatin A.[1321] In the reaction catalyzed by a monooxygenase, by definition, one of the two oxygen atoms of molecular oxygen is incorporated into the product and the other into water.*

Melilotate 3-monooxygenase, 4-hydroxybenzoate 3-monooxygenase, and 6-hydroxynicotinate 3-monooxygenase are enzymes that catalyze **hydroxylations**. 6-Hydroxynicotinate 3-monooxygenase catalyzes an unusual hydroxylation in which a hydroxy group replaces a carboxy group rather than a hydrogen, a fact that reiterates the equivalence between carbon dioxide and a hydron. These three enzymes catalyze the hydroxylation of aromatic rings. Long-chain alkane monooxygenase from *Geobacillus thermodenitrificans*, however, is able to convert a linear alkane of up to 36 carbons into the corresponding primary alcohol.[1322,1323] The bond dissociation energy for a primary carbon–hydrogen bond (+410 kJ mol^{-1}), which seems to be the only logical first step in this reaction at an alkane, is quite large.

*Dioxygenases are enzymes that incorporate both atoms of molecular oxygen into their reactants.

In these hydroxylations and the reaction catalyzed by cyclohexanone monooxygenase, the species that reacts with the molecular oxygen is reduced flavin.[1317-1319] The flavin is usually reduced by either NADH or NADPH. The reduced flavin then reacts with molecular oxygen to produce an intermediate that performs the actual monooxygenation, after which the resulting oxidized flavin is again reduced by either NADH or NADPH.

The spectral characteristics of the **initial intermediate formed in one of these flavin monooxygenases** (Figure 2–46)[1319,1324-1327] from reduced flavin and molecular oxygen are indistinguishable from those of a 4a-peroxyflavin or its conjugate acid, a 4a-hydroperoxyflavin. 4a-Peroxyisoalloxazines or 4a-hydroperoxyisoalloxazines can be formed in solution nonenzymatically from an isoalloxazine and superoxide radical anion or hydrogen peroxide, respectively. For example, superoxide radical anion reacts in dimethylformamide with the neutral semiquinone radical of 5-ethyl-3,7,8,10-tetramethylisoalloxazine[1328] to produce its **4a-peroxyisoalloxazine anion** (**2–89**)



(2–215)

by a simple colligation.* The respective **4a-hydroperoxyisoalloxazine** (**2–90**) has been produced from the reaction between peroxide and an oxidized isoalloxazine in nonpolar solvents[1329]

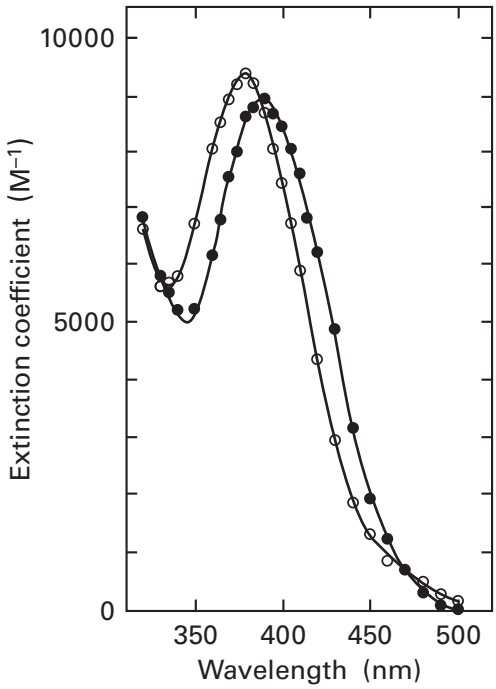


Figure 2–46: Absorption spectra of the two intermediates in the reaction of molecular oxygen with reduced flavin in the active site of 4-hydroxybenzoate 3-monooxygenase from *P. aeruginosa*.[1324] 4-Hydroxybenzoate 3-monooxygenase, the prosthetic flavin adenine dinucleotide of which was in the reduced state and to which the substrate 4-hydroxybenzoate was already bound, was mixed with a solution of O_2 so that the final concentrations of reactants would be 13 μM active sites, 1.1 mM oxygen, and 2.5 mM 4-hydroxybenzoate in a solution of 50 mM potassium phosphate at pH 6.55 at 3.5 °C. The absorbances of the solution at wavelengths separated by 5 or 10 nm were monitored as a function of time. Following the mixing of the reduced enzyme with oxygen, two sequential intermediates were observed. The first was formed in a bimolecular reaction between the enzyme and the O_2 with a rate constant of 2.6×10^5 M^{-1} s^{-1} (a pseudo-first-order rate constant of 280 s^{-1} at 1.1 mM O_2) and the second with a rate constant of 45 s^{-1}. The measurements were repeated at a series of wavelengths and the extinction coefficients of each of the two intermediates is plotted as a function of the wavelength. The intermediates were identified as 4a adducts of the reduced flavin (Figure 2–16) by comparison with spectra of model compounds. The intermediate that formed first (●) was identified as 4a-hydroperoxyflavin adenine dinucleotide. The intermediate that formed afterward (○) was identified as 4a-hydroxyflavin adenine dinucleotide.

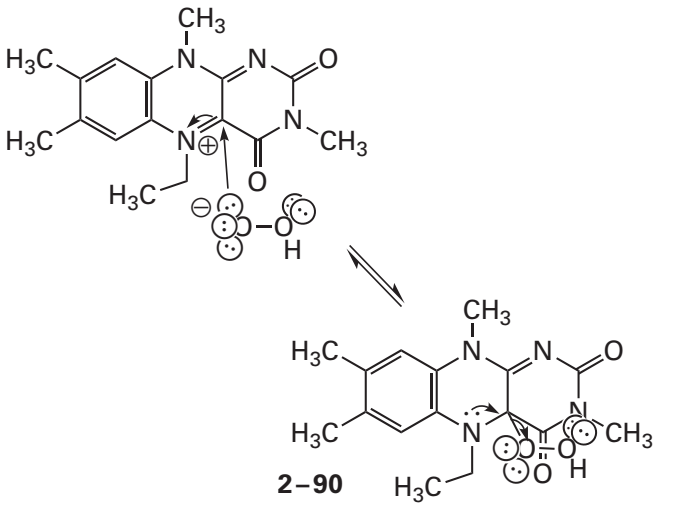
*A colligation is the combination of two radicals to form a covalent bond.

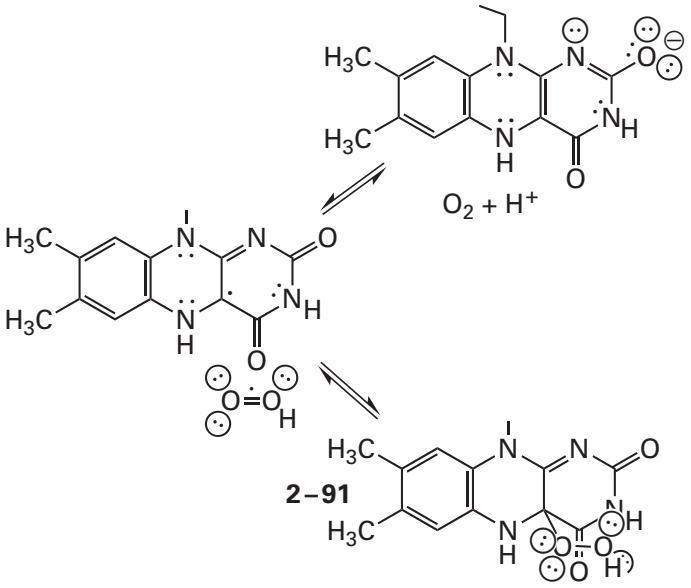


(2–216)

The neutral 4a-hydroperoxyflavin **2–90** reverts readily to reactants because the reaction is a simple addition of the conjugate base of hydrogen peroxide, HO_2^-, as a nucleophile, to the iminium ion in the oxidized 5-ethylflavin to produce the peroxy homologue of a hemiaminal.

A 4a-hydroperoxyflavin (see **2–90**) may be an intermediate in the nonenzymatic formation of hydrogen peroxide from oxygen by reduced flavins in solution.[286] In at least one flavoprotein oxidase, pyranose oxidase from *Trametes ochracea*, molecular oxygen oxidizes the reduced flavin, produced by oxidation of a pyranose, by forming a 4a-peroxyflavin anion (see **2–89**), which is then hydronated and dissociates into oxidized flavin and hydrogen peroxide (Equation 2–216),[1330] rather than transferring electrons one at a time to molecular oxygen. In this instance, the 4a-hydroperoxyflavin was identified spectroscopically (see Figure 2–46).

In the active sites of flavin monooxygenases, formation of the 4a-hydroperoxyflavin proceeds in a similar manner (Equations 2–207 and 2–215)



(2–217)

During its formation, **a hydron is provided by the active site**. In the active site of 4-hydroxyphenylacetate 3-monooxygenase from *Acinetobacter baumannii*, the molecule of oxygen is hydronated by the imidazolio group of Histidine 396 as the electron is transferred from the reduced flavin to molecular oxygen. Following transfer of the electron, the system is still in the triplet state, but it rapidly undergoes a nearly barrierless spin inversion to the singlet state before the hydronated superoxide radical anion, which is hydroperoxy radical (Equation 2–199), combines with the semiquinone of the flavin[1331] in a colligation. In the active site of L-ornithine N^5-monooxygenase [NAD(P)H] from *A. fumigatus*, the catalytic acid is the 2′-hydroxy group of the $NADP^+$ that has just provided the hydride to reduce the flavin.[1332] The 2′-hydroxy group relays a hydron from the δ-ammonio group of the substrate L-ornithine.[1333]

A 4a-hydroperoxyflavin or 4a-peroxyflavin that forms in an active site of a flavin monooxygenase either dissociates into hydrogen peroxide and oxidized flavin (a wasted reaction) or oxygenates the substrate.[1318] Two strategies are used to **prevent the production of hydrogen peroxide** under normal circumstances. In the first strategy, which has been adopted by monooxygenases that hydroxylate phenyl groups, the rate of reduction of the oxidized flavin by NADH or NADPH is usually hindered in the absence of the nominal reactant. For example, reduction of the oxidized flavin by NADPH in 4-hydroxybenzoate 3-monooxygenase [NAD(P)H] is 2×10^5 times slower in the absence of 4-hydroxybenzoate than in its presence.[1334] In the second strategy, which

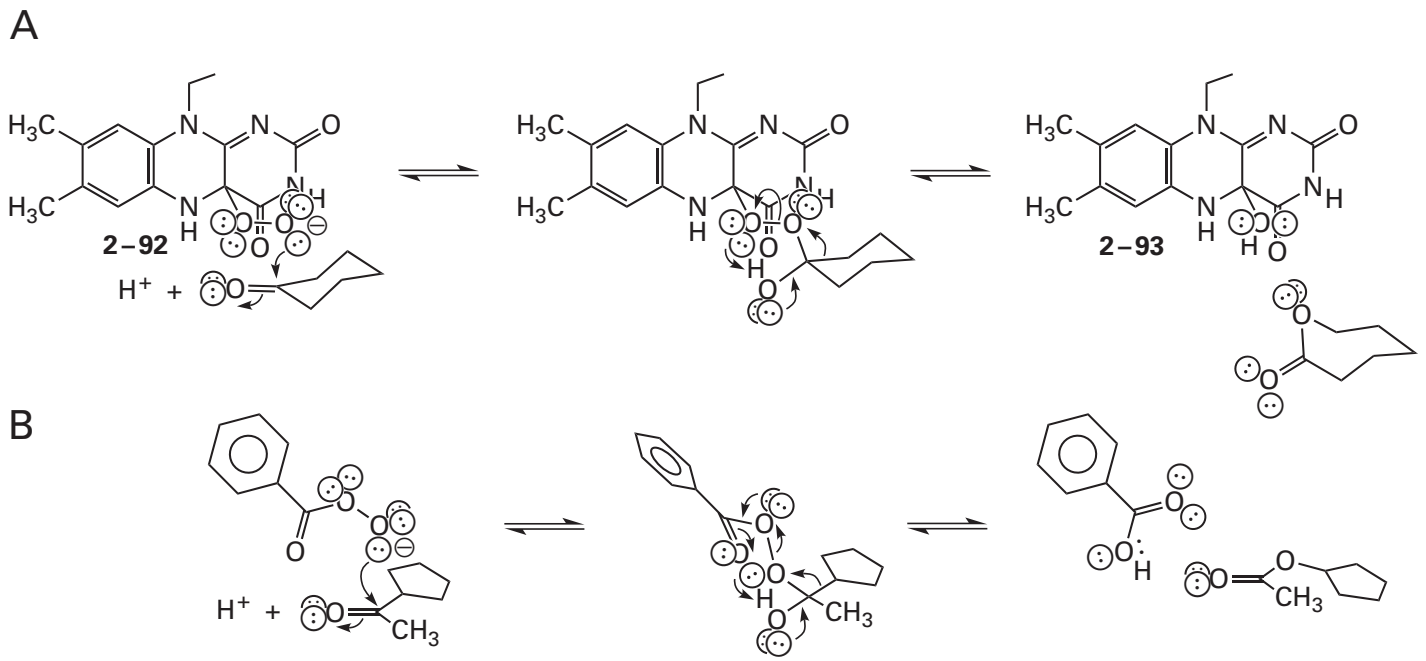


Figure 2–47: Mechanisms for **(A)** the Baeyer–Villiger monooxygenation catalyzed by cyclohexanone monooxygenase and **(B)** a nonenzymatic Baeyer–Villiger oxidation (Equation 2–219). **(A)** In the enzymatic reaction, the anionic distal oxygen of the 4a-peroxyflavin anion adds as a nucleophile to the electrophilic carbonyl carbon of the cyclohexanone. The resulting dialkyl peroxide cleaves heterolytically at the oxygen–oxygen bond, coincident with the migration of one of the alkyl carbons of the cyclohexanone to the adjacent oxygen. The migrating alkyl carbon is pushed by a lone pair of electrons on the alkoxide oxygen. The products of the rearrangement are the lactone and the 4a-hydroxyflavin. **(B)** In the nonenzymatic reaction, the anionic conjugate base of the peroxy acid adds as a nucleophile to the electrophilic carbonyl carbon of the acetylcyclopentane. The resulting dialkyl peroxide cleaves heterolytically at the oxygen–oxygen bond, coincident with the migration of the cyclopentyl group of the acetylcyclopentane to the adjacent oxygen. The migrating carbon of the cyclopentyl group is pushed by a lone pair of electrons on the oxygen of the hydroxy group. The migration of the carbon is coincident with the intramolecular transfer of the hydron on the hydroxy group to the acyl oxygen of the peroxy acid. The transfer of the hydron makes the benzoic acid a better leaving group and increases the push of the lone pair of electrons on the hydroxy group. The products of the rearrangement are cyclopentyl acetate and benzoic acid.

has been adopted by monooxygenases that hydroxylate other substrates and by the enzymes that catalyze Baeyer–Villiger oxidations, the flavin is reduced by NADPH in the absence of the nominal reactant, and after reduction of the flavin, the $NADP^+$ remains bound. The reduced flavin reacts with molecular oxygen to form the 4a-hydroperoxyflavin, which is quite stable as long as the $NADP^+$ remains bound. If the flavin is reduced with NADH or dithionite, no 4a-hydroperoxyflavin is observed. The 4a-hydroperoxyflavin lurks on the enzyme until an unsuspecting nominal reactant is bound and becomes oxygenated. If no reactant is bound, hydrogen peroxide is slowly formed and the reduction is wasted. Thus, inhibition of the production of hydrogen peroxide can occur either at the reduction step or at the step in which the nominal reactant is oxidized.

4a-Hydroperoxides of isoalloxazines in solution are as active as peroxycarboxylic acids [–C(O)OOH],[1335] which are routinely used as oxidants for Baeyer–Villiger oxidations (Figure 2–47B), for the monooxygenations of alkenes to epoxides, and for the oxidation of amines and sulfides to amine *N*-oxides and sulfoxides, respectively.[1336,1337] The oxygenated flavin in the active site of cyclohexanone monooxygenase from *Acinetobacter* has been shown to participate in a series of monooxygenations characteristic of a peroxy acid[1319] as well as the oxidation of sulfides to sulfoxides,[1338] a reaction that is also characteristic of a 4a-hydroperoxyisoalloxazine. It has been shown that the oxygenating species in the active site for all the various reactions catalyzed by cyclohexanone monooxygenase is the 4a-peroxyflavin itself (**2–92** in Figure 2–47A),[1339] or 4a-hydroperoxyflavin, its conjugate acid. These observations suggest that the enzymatic

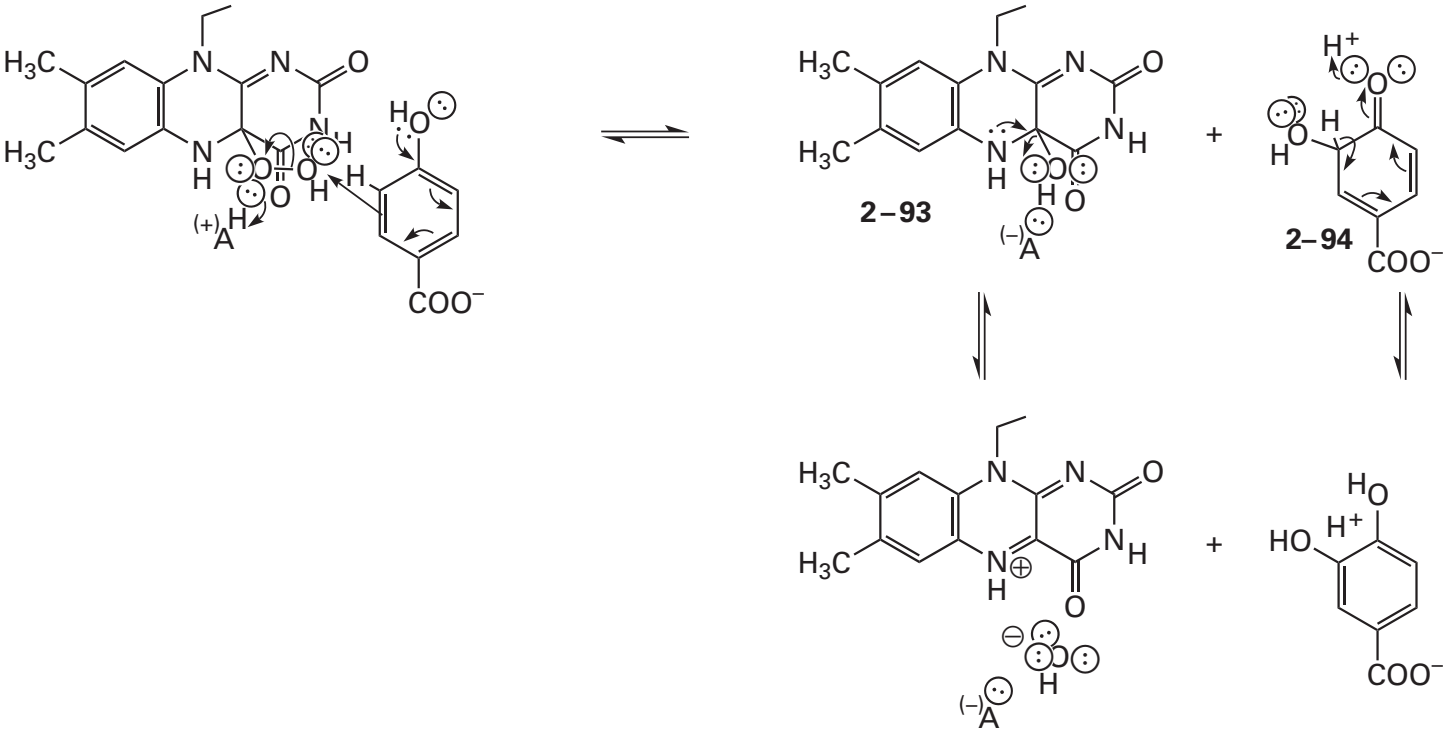

Figure 2–48: Mechanism for the hydroxylation of 4-hydroxybenzoate by 4a-hydroperoxyflavin in the reaction catalyzed by the flavoenzyme 4-hydroxybenzoate 3-monooxygenase (Equation 2–212). The electrophilic hydroperoxy group of the 4a-hydroperoxyflavin, formed by the reaction of molecular oxygen with reduced flavin, is attacked by a pair of the nucleophilic π electrons in the aromatic π molecular orbital system of the 4-hydroxyphenyl group of the 4-hydroxybenzoate at the same time that a catalytic acid hydronates the proximal oxygen of the hydroperoxy group to increase its electrophilicity. The resulting 4a-hydroxyflavin **2–93**, a hemiaminal, dehydrates to oxidized flavin. A hydrogen on the carbon adjacent to the 6-hydroxycyclohexa-2,4-dienone (**2–94**), which is the other product of the first step, dissociates as a hydron to restore the aromaticity of the phenyl group.

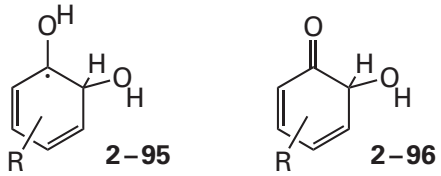
monooxygenations in which 4a-hydroperoxy-flavins and 4a-peroxyflavins are the oxidants have mechanisms similar to those for the oxidations performed by peroxycarboxylic acids and peroxycarboxylates.

The 4a-peroxyflavin in the active site of cyclohexanone monooxygenase is likely formed by the **colligation of the neutral flavin semiquinone and superoxide radical anion**, which in turn are formed by direct transfer of an electron from reduced flavin anion $H_2Fl_{red}^-$ (Figure 2–9) to molecular oxygen (Equation 2–217).[1339] In the enzymatic monooxygenations performed by melilotate 3-monooxygenase (Equation 2–211), 4-hydroxybenzoate 3-monooxygenase (Equation 2–212),[1340] or 6-hydroxynicotinate 3-monooxygenase (Equation 2–214), the 4a-hydroperoxyflavin performing the hydroxylation is also probably formed by this colligation of the flavin semiquinone and the superoxide radical anion, followed by a hydronation of the distal oxygen of the resulting 4a-peroxyflavin. This conclusion follows from the fact that hydrogen peroxide in solution cannot produce a 4a-hydroperoxyflavin from the flavin in the active sites of these former enzymes, so it is probably not hydroperoxy ion, HO_2^-, the conjugate base of hydrogen peroxide formed from molecular oxygen by two successive one-electron transfers from reduced flavin (Equations 2–207 and 2–208), that adds nucleophilically to oxidized flavin (Equation 2–216).

Melilotate 3-monooxygenase, 4-hydroxybenzoate 3-monooxygenase, and 6-hydroxynicotinate 3-monooxygenase catalyze the **hydroxylation of an aromatic ring**.[1327,1341,1342] The distal hydroxy group of the 4a-hydroperoxyflavin (**2–91**) is transferred to the aromatic ring, ortho or para to a hydroxy group or an amino group on that ring (Figure 2–48). An intermediate has been observed in transfer of the hydroxy group to various phenols by 4-hydroxybenzoate 3-monooxygenase from *P. fluorescens*[1318,1343,1344] and phenol 2-monooxygenase (NADPH) from *S. cerevisiae*[1345] that has an absorption spectrum similar

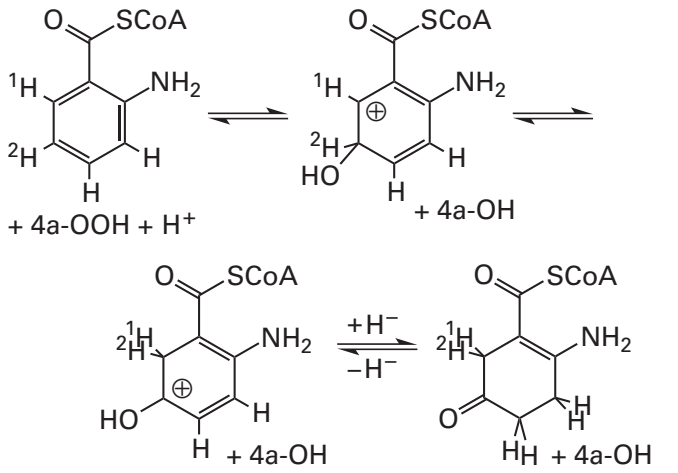
to the sum of the spectrum of enzyme-bound 4a-hydroxyflavin (Figure 2–46) and the spectrum of cyclic pentadienyl radical **2–95** of the respective aromatic ring.[1346,1347]



Consequently, it is possible that a cyclic pentadienyl radical is an intermediate in the formation of the usual cyclic pentadienyl cation in an electrophilic aromatic substitution. Because, however, no evidence for unpaired electrons in this spectral intermediate has been obtained,[1344] it seems more likely that the derivative of the aromatic reactant in this intermediate is actually the respective 2-hydroxycyclohexa-3,5-dieneone **2–96**.

The effects of electron-withdrawing groups in the 4-hydroxybenzoate on the rate of 4-hydroxybenzoate 3-monooxygenase,[1348] as well as the effects of electron-donating and electron-withdrawing substituents on the flavin,[1340] are most consistent with an **electrophilic aromatic substitution** in which the π molecular orbital system of the aromatic ring, as a nucleophile, attacks the distal oxygen of the 4a-hydroperoxyflavin, the electrophile, with the anionic conjugate base of the 4a-hemiaminal of the flavin, probably being hydronated in concert, as the leaving group (Figure 2–48).[1349] Certainly the facts that 4-hydroxybenzoate 3-monooxygenase and 6-hydroxynicotinate 3-monooxygenase are related to each other[1350] and that the former replaces a hydrogen with a hydroxy group while the latter replaces a carboxy group with a hydroxy group are consistent with a mechanism in which the hydrogen on carbon 3 of 4-hydroxybenzoate leaves as a hydron, as it would in an electrophilic aromatic substitution. There are also results from kinetic isotopic effects that are consistent with the conclusion that 6-hydroxynicotinate 3-monooxygenase from *Bordetella bronchiseptica* catalyzes the hydroxylation through an electrophilic aromatic substitution.[1320] In the crystallographic molecular model of 4-hydroxyphenylacetate 3-monooxygenase from *A. baumannii*, the imidazolyl group of a histidine is positioned to hydronate the proximal oxygen of the 4a-hydroperoxyflavin to improve its ability as a leaving group,[1342] and there is a molecule of water located in the active site of 4-hydroxybenzoate 3-monooxygenase (Equation 2–212) that can perform the same function.[1351]

That the conjugate base (**2–94**) of the usual cyclic pentadienyl cation in an electrophilic aromatic substitution is an intermediate in the reactions of these monooxygenases is demonstrated by a 1,2 sigmatropic rearrangement that is observed in some of them. When the hydroxy group is being added para to an electron-donating substituent, such as a hydroxy, alkyl, or amino group on the reactant, as in anthraniloyl-CoA monooxygenase

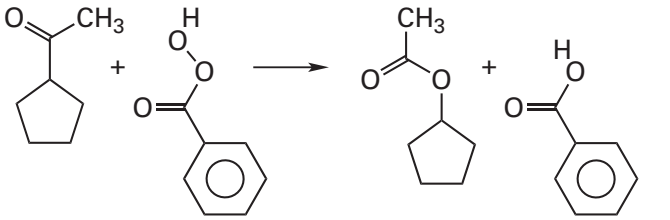


(2–218)

a deuterium located on the reactant at the site of the hydroxylation is found to migrate to the adjacent carbon.[1341] Such a 1,2-hydride migration is evidence for a carbocationic intermediate[1352] in an electrophilic aromatic substitution.

In these hydroxylations, the nucleophilic aromatic ring adds the distal hydroxy group of the **electrophilic 4a-hydroperoxyflavin**. In the active site of premalbrancheamide halogenase from *Malbranchea aurantiaca*, the distal hydroxy group of the prosthetic 4a-hydroperoxyflavin also acts as an electrophile that participates in a concerted nucleophilic substitution with a chloride as the nucleophile and the 4a-hydroxyflavin as the leaving group to produce hypochlorite (OCl^-). The hypochlorite chlorinates the 5-amino group of Lysine 108 to produce a chloramine that performs the actual halogenation of the anilino group in premalbrancheamide.[1353]

The **nucleophilic 4a-peroxyflavin** formed in the initial step in the enzymatic reaction of cyclohexanone monooxygenase (Equation 2–213) performs a **Baeyer–Villiger oxidation**. A nonenzymatic example of a Baeyer–Villiger oxidation[1354] in which the oxidant is a peroxycarboxylic acid would be

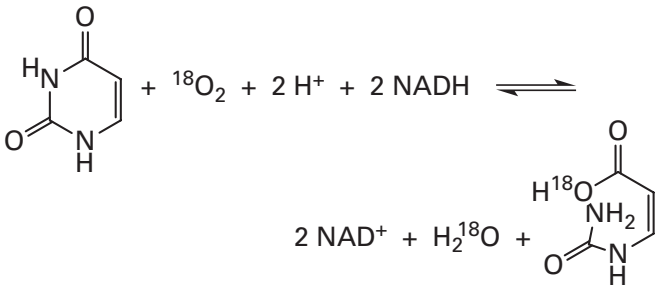


(2–219)

The step following the formation of the 4a-peroxyflavin in the active site of cyclohexanone monooxygenase (Figure 2–47A), by analogy with a Baeyer–Villiger reaction in solution (Figure 2–47B), is proposed to be the nucleophilic addition of the anionic oxygen in the 4a-peroxy group to the carbonyl of the cyclohexanone. In the crystallographic molecular model of the active site of cyclohexane monooxygenase from *Rhodococcus* occupied by $NADP^+$ and cyclohexanone, in which the flavin is in the oxidized state but not the 4a-peroxyflavin, the carbonyl carbon of the cyclohexanone is 0.39 nm from carbon 4a of the flavin, an appropriate distance for the two oxygens of a 4a-peroxy group to span.[1355]

The accepted mechanism for the Baeyer–Villiger oxidation performed in solution by a peroxy acid relies on the ability of the acyl oxygen of the peroxy acid to be **intramolecularly hydronated** and the resulting incipient carboxylic acid to function as the leaving group in a **1,2-alkyl migration**. The 4a-peroxy group of the 4a-peroxyflavin resides on a fully saturated carbon, but the proximal oxygen of the peroxy group could be hydronated by the hydoxy group of the hemiketal in a similar way to improve the ability of the **4a-hydroxyflavin (2–93)** as a leaving group (Figure 2–47A). In at least one Baeyer–Villiger monooxygenase,[1356] the guanidinio group of an arginine is stacked upon the π molecular orbital system of the flavin and its δ nitrogen could also act as the donor for a hydrogen bond to the proximal oxygen of the 4a-peroxyflavin, improving its ability to leave as a 4a-hydroxy group. The ring expansion concerted with the leaving of the 4a-hydroxyflavin results from a 1,2-alkyl migration.

In the Baeyer–Villiger oxidations, prosthetic 4a-peroxyflavin is formed by electron transfer from reduced flavin anion to molecular oxygen (Equation 2–207) followed by the colligation of the two radicals (Equation 2–215). The distal oxyanion of 4a-peroxyflavin then participates as a nucleophile that adds to the carbonyl group in the reactant (Figure 2–47A). Carbon 4 of uracil is an acyl carbon in an *N*-[(alkylamino)carbonyl]amide, and it also participates in nucleophilic substitutions. In the apparent hydrolysis of this amide catalyzed by pyrimidine oxygenase



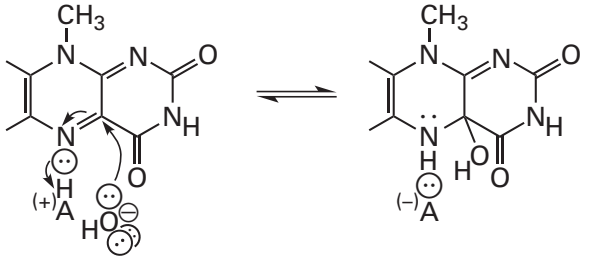
(2–220)

from *E. coli*, in which the *N*-acylurea is substituted by a hydroxy group, it has been concluded that rather than a hydroxide, which would usually be the reactant in a hydrolysis, the distal oxyanion of the 4a-peroxyflavin formed from molecular oxygen and the prosthetic flavin in the active site adds as a nucleophile to acyl carbon 4 in the first step in a nucleophilic substitution because one of the oxygens from oxygen-18 in enriched molecular oxygen ends up as one of the oxygens in the carboxy group of the product.[1357] The peroxy acid that results from this nucleophilic substitution by the hydroperoxy group then oxidizes the flavin to form an *N*-oxide on nitrogen 5 and the carboxylic acid that is the product of the enzymatic reaction (Equation 2–220). This flavin N^5-oxide has been isolated from an enzymatic reaction.[1358] The *N*-oxide is then reduced back to the reduced flavin by two successive hydride transfers from two NADH.

In the hydroxylation of nucleophilic aryl groups, a 4a-hydroperoxyflavin acts as an electrophile at the distal oxygen, but in the Baeyer–Villiger monooxygenations and the monooxygenation performed by pyrimidine oxygenase, a 4a-peroxyflavin acts as a nucleophile, also at the distal oxygen. The **only difference is a hydronation**. The hydronation of the distal oxygen is required to produce the electrophile, just as a hydronation of a carbonyl group significantly increases the electrophilicity of the carbonyl carbon, and the dehydronation of the distal oxygen is required to produce the nucleophile, just as the dehydronation of a molecule of water significantly increases the nucleophilicity of its oxygen. The identity of the other reactant, however, be it a nucleophile or an electrophile, respectively, dictates the course of the reaction, not the hydronation.

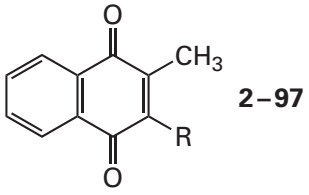
At the completion of either the hydroxylation of an aromatic ring (Figure 2–48) or a Baeyer–Villiger monooxygenation (Figure 2–47A), the other

oxygen atom of molecular oxygen remains at the 4a-position of the flavin on a carbonyl carbon, presumably as a hydroxy group. The resulting 4a-hydroxyflavin, a hemiaminal (Figures 2–47 and 2–48), loses hydroxide to the solution in a reaction that is the reverse of the addition of hydroxide to oxidized flavin



(2–221)

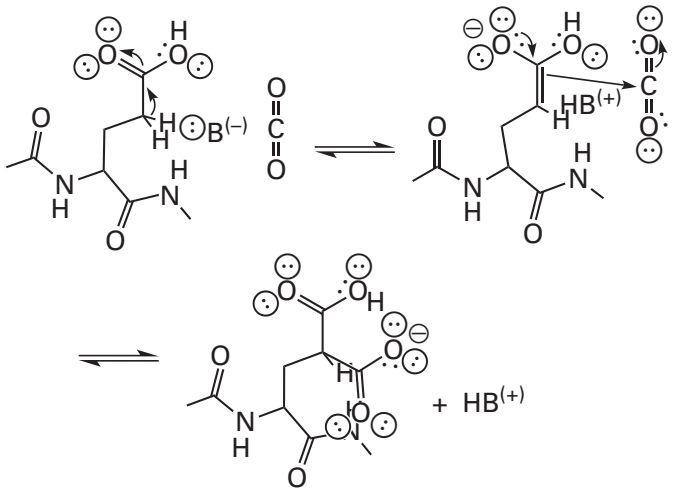
Menaquinones and phylloquinones are both 2-alkyl-3-methyl-1,4-naphthoquinones



2–97

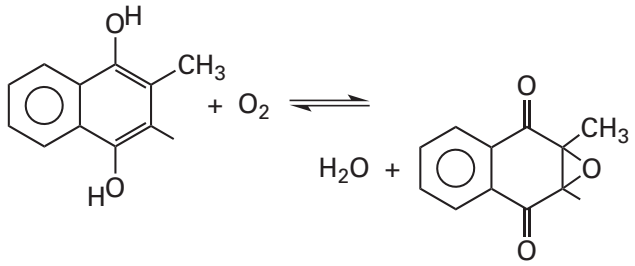
and 2-alkyl-3-methyl-1,4-naphthoquinones are vitamins K. Vitamins K are a group of coenzymes that differ only in their isoprenoid 2-alkyl groups, which are irrelevant to their function, and they are **used interchangeably and indistinguishably** in their enzymatically catalyzed reactions with molecular oxygen.

An enzyme that catalyzes the reaction of a vitamin K with molecular oxygen is peptidyl-glutamate 4-carboxylase. In the active site, molecular oxygen is combined with the reduced quinol of a vitamin K to produce a base ($:B^{(-)}$) strong enough to **remove a hydron from carbon 4 of a glutamate** in one of several proteins so that the resulting enolate can be carboxylated[1359]



(2–222)

in a posttranslational modification of the respective protein. Coincident with the **carboxylation**, which does not incorporate either oxygen of molecular oxygen into the γ-carboxyglutamate, the quinol of vitamin K is monooxygenated by one of the two atoms of molecular oxygen to form its 2,3-epoxyquinone[1360]

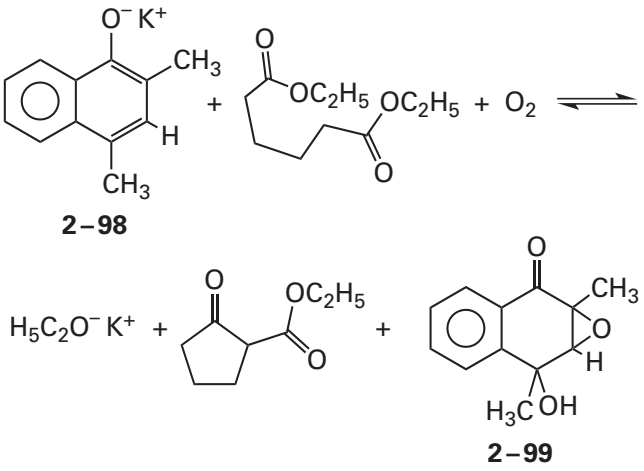


(2–223)

During this epoxidation of vitamin K, the necessary base is formed.[147]

When there is sufficient carbon dioxide present, one mole of the epoxide of vitamin K is produced for every mole of glutamic acid carboxylated.[1361] When there is insufficient carbon dioxide present, the enolate formed by the base eventually picks up a hydron from the solution to regenerate the glutamate,[1359] and the ratio of epoxide to peptidyl-4-carboxyglutamate increases accordingly. Both the carboxylation (Equation 2–222) and the epoxidation (Equation 2–223) are performed by peptidyl-glutamate 4-carboxylase.[1362] The 2,3-epoxide of vitamin K is reduced back to the quinol by a different enzyme or pair of enzymes to be used again.

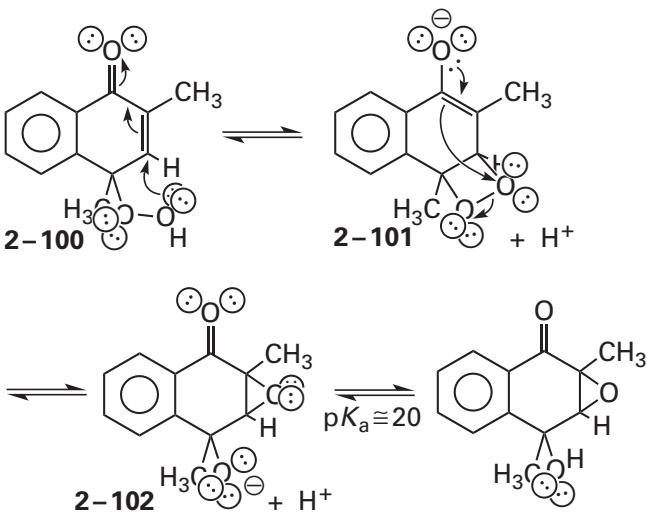
There is a nonenzymatic, intramolecular Claisen condensation that is a **model for the enzymatic reaction**



(2–224)

Under the conditions of the reaction, the initial 2,4-dimethyl-1-naphtholate **2–98** is too weak a base ($pK_a \cong 10$) to remove a hydron α to one of the esters in the diethyl 1,6-hexanedioate to form the required enolate, but it combines with molecular oxygen to produce a base that is strong enough to do so.[1363]

There are several other observations that provide an explanation for the mechanism of this reaction. The conjugate acid of naphtholate **2–98**, 2,4-dimethyl-1-naphthol, reacts with molecular oxygen in chloroform to give the stable 4-hydroperoxide (**2–100**)[1364]



(2–225)

In aqueous solution, the 4-hydroperoxide **2–100** turns into tertiary alcohol **2–99**, the product in the model reaction (Equation 2–224), in an intramolecular rearrangement.[1365] Both this rearrangement and the model reaction itself produce the two diastereoisomers of **2–99**, in each of which the oxygen of the epoxide is cis to the oxygen of the tertiary alcohol. It is proposed that an intermediate **dioxetane** (**2–101**) explains the cis stereochemistry of the product.[1364] When molecular oxygen reacts with the 2,4-dimethyl-1-naphtholate **2–98** to produce the tertiary alkoxide **2–102**, the standard enthalpy change of the reaction[1366] is around –200 kJ mol^{-1}, an observation demonstrating that there is more than enough energy released in the oxidation to convert a weak base, the naphtholate, into a strong base, the tertiary alkoxide ($pK_a \cong 20$),[1366] which is strong enough to produce the enolate responsible for the intramolecular condensation (Equation 2–224).

All these observations suggest a particular **mechanism for the enzymatic formation of a strong base** from the quinol of a vitamin K and molecular oxygen (Figure 2–49).[1367] As with the reaction of flavin with molecular oxygen, transfer of an electron from the quinol of vitamin K to oxygen under catalysis by a general base[1368] separates the electrons of the triplet state of molecular oxygen and permits rapid spin inversion. The two radicals then combine to form the 4-peroxynaphthoquinone, which converts to the anionic conjugate base of a 4-hydroxy group in the 2,3-epoxynaphthoquinone **2–103** through intermediate dioxetane **2–101**. The alkoxide ion **2–103** is not so strong a base as the tertiary alkoxide **2–102** because the electron-withdrawing hydroxy group in place of the electron-donating methyl group should lower the pK_a of its conjugate acid by about three or four units, but hydronation of the alkoxide by the hydron on carbon 4 of the glutamate can be concerted with dehydration of the hydrate of the 2,3-epoxynaphthoquinone, which is a significantly favorable reaction (Table 1–2).

When carboxylation of a glutamate by vitamin K is performed with $^{18}O_2$, about 15% of the 4-oxo group of the 2,3-epoxide of the vitamin K that is the product of the reaction[1369-1372] ends up as oxygen-18. This observation supports the mechanism (Figure 2–49) because it indicates that one of the oxygens of the molecular oxygen was attached at some point to carbon 4 of the vitamin K. It also indicates that dehydration of the hydrate is not completely stereospecific. When [4-^{3}H]-L-glutamate is used as a reactant, the enzyme exchanges the tritium at the *pro-S* position[1373] with a protium from the solution

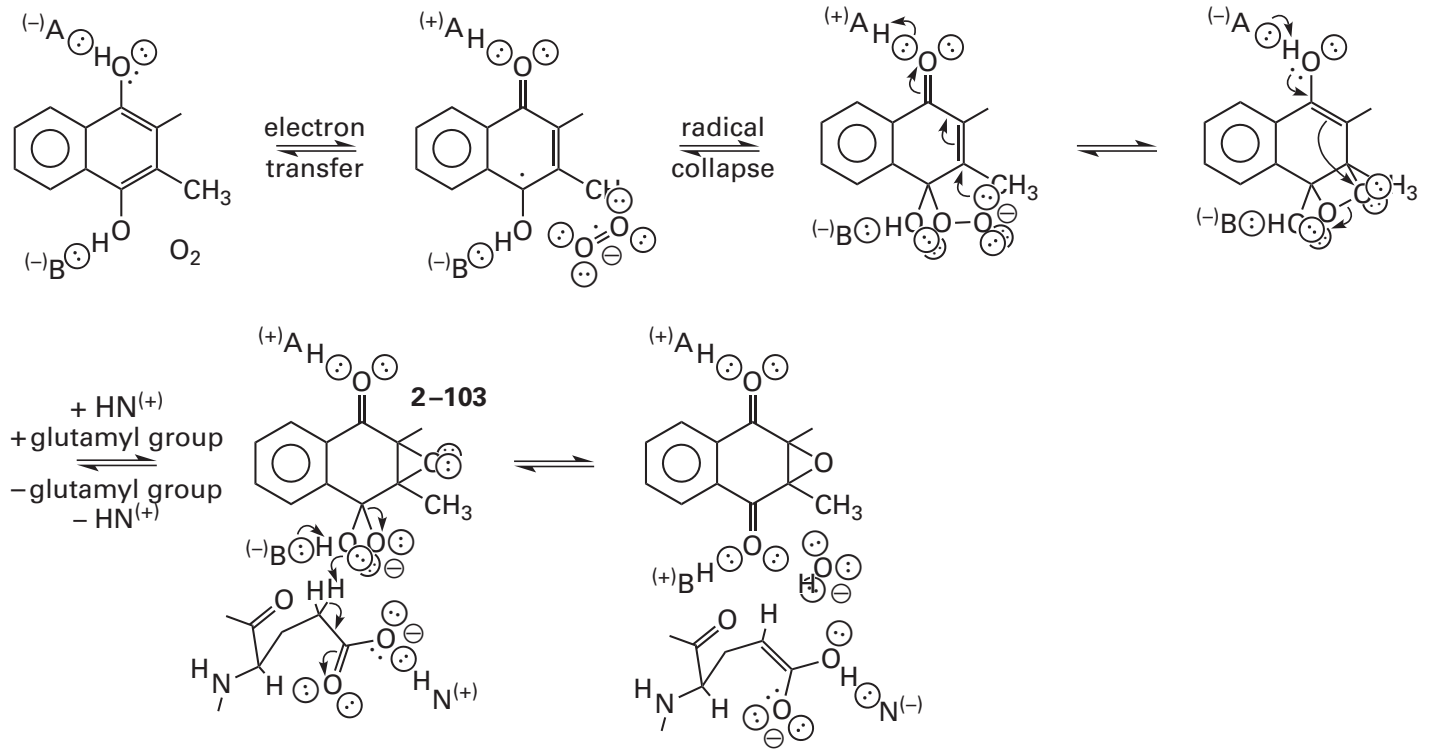


Figure 2–49: Mechanism for the formation of a glutamyl enolate by molecular oxygen and a vitamin K. Transfer of an electron from the vitamin K to molecular oxygen produces superoxide radical anion and the radical cation of the vitamin K, from the now oxo oxygen of which a hydron dissociates to produce the neutral radical. The separation of the unpaired electrons onto two molecules permits spin inversion to occur rapidly. Radical collapse forms a bond between the superoxide radical anion and the vitamin K radical, to form an adduct in which the superoxide has become a peroxy group. The anionic distal oxygen of the peroxy group participates as a nucleophile in an intramolecular conjugate addition to the *α,β*-unsaturated ketone to produce a dioxetane. The resulting enolate of the vitamin K adds nucleophilically and intramolecularly to the adjacent electrophilic oxygen of the dioxetane to produce the epoxide of the vitamin K. During the addition, the other oxygen is the leaving group from the dioxetane and becomes the oxyanion. This newly formed oxyanion removes the hydron from carbon 4 of the glutamatic acid to form its enolate. If, as is drawn, it uses the hydron that was on carbon 4 of the glutamatic acid as the acid required during its ejection as a hydroxide from the hydrate of the ketone, the free energy of the dehydration of the ketone is coupled to the removal of the hydron, a strategy that would increase its basicity even further.

2.5 times more rapidly than it catalyzes the carboxylation of the glutamate.[1374] Consequently, the hydroxide (Figure 2–49) bearing tritium must exchange with hydroxide ions in solution, which each bear a protium, rapidly and reversibly, a process that will also dilute the ^{18}O in the 4-hydrate of the 2,3-epoxide of the vitamin K. This consideration suggests that the dehydration of the hydrate is even less stereospecific than it seems to be. It is difficult to reconcile the high stereospecificity of the hydron abstraction with the low stereospecificity of the dehydration.

Aside from enzymes using flavin and vitamin K as prosthetic groups and coenzymes, almost all[1375-1377] of the enzymes that use molecular oxygen, molecular nitrogen, molecular hydrogen, superoxide radical anion, hydrogen peroxide, oxides of nitrogen, oxides of sulfur, and carbon monoxide as substrates have transition metals such as iron, copper, nickel, manganese, and molybdenum as prosthetic cations.* With the exception of peroxidases, the reactions catalyzed by these enzymes are oxidation–reductions that proceed by inner-sphere electron transfers during which the respective substrates occupy an open, exchangeable coordination site on the transition metallic ion.

*There is an oxidase in *Streptomyces wadayamensis* of unknown mechanism that uses only a prosthetic pyridoxal phosphate to catalyze a four-electron oxidation of L-arginine to 2-oxo-4(*S*)-hydroxy-5-guanidinovalerate and that uses two molecules of molecular oxygen only as general oxidants to accept the four electrons.[1378]

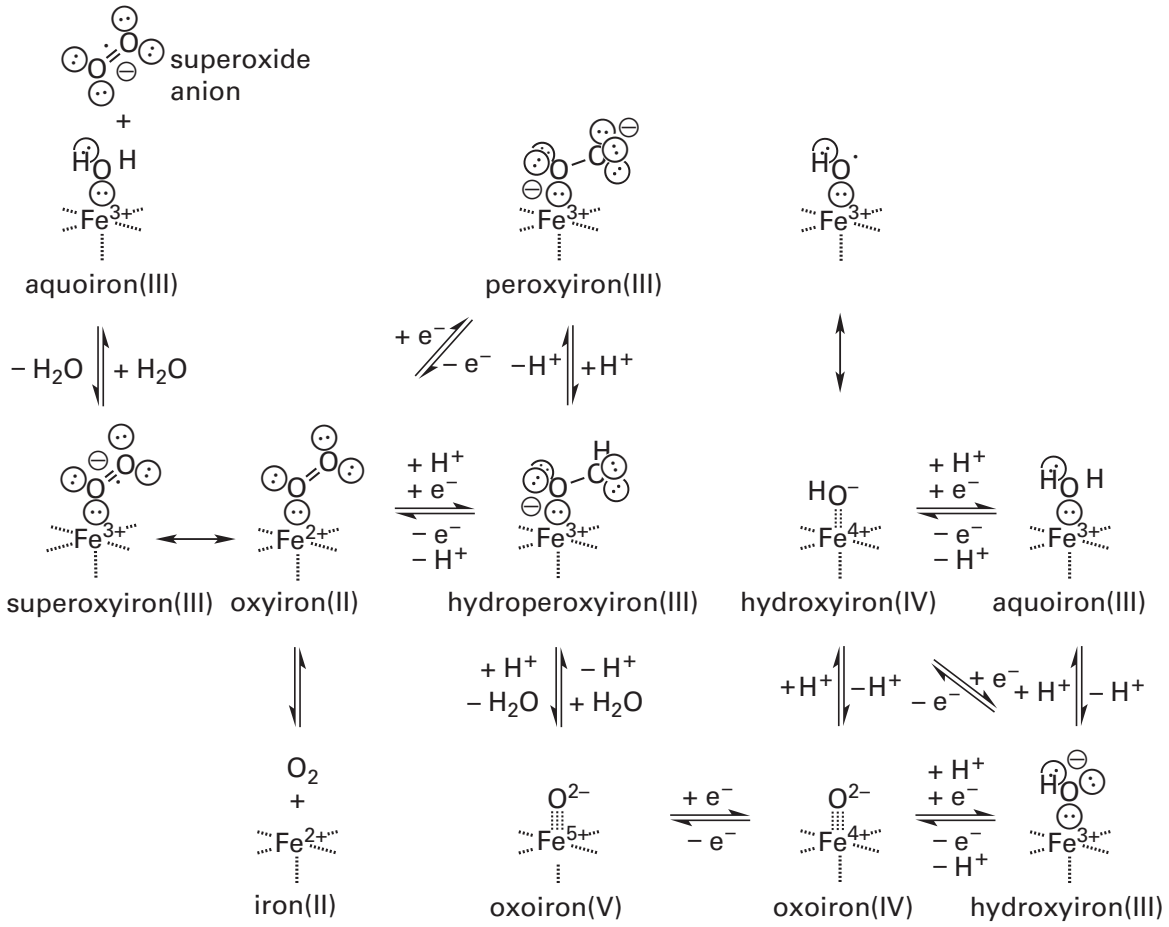

Figure 2–50: Complexes formed between iron ions and the different oxidation states of oxygen. Superoxide radical anion combines with Fe^{3+} (top) or molecular oxygen combines with Fe^{2+} (bottom) to produce the same complex, oxyiron(II), which stereochemically resembles a superoxide radical anion on Fe^{3+} but has the oxygen–oxygen bond length of molecular oxygen. The addition of a hydron and an electron to this complex produces hydroperoxyiron(III), identical to the complex resulting from the addition of hydroperoxide ion, the conjugate base of hydrogen peroxide, to Fe^{3+}. Hydroperoxyiron(III) is the conjugate acid of peroxyiron(III). The addition of a hydron to the distal oxygen in hydroperoxyiron(III) and the heterolytic loss of water produces oxoiron(V), which, if it is in a porphyrin, abstracts an electron from the aromatic π molecular orbital system of the porphyrin coincident with its formation to produce oxoiron(IV) porphyrin radical. The addition of an electron to oxoiron(V) produces oxoiron(IV). The hydronation of oxoiron(IV) produces hydroxyiron(IV), which is a resonance hybrid of hydroxide ion, OH^-, on Fe^{4+} and hydroxyl radical, ·OH, on Fe^{3+}. The addition of an electron to hydroxyiron(IV) produces hydroxyiron(III), the complex between hydroxide and Fe^{3+}, which is the conjugate base of aquoiron(III), the complex between water and Fe^{3+}.

One of the simplest examples of such a prosthetic metallic ion participating in such an **inner-sphere transfer of an electron** is the iron ion in superoxide reductase from *Pyrococcus furiosus*. In its ferric form, the Fe^{3+} is octahedrally coordinated, strongly by the imidazolyl groups of four histidines and the sulfido group of a cysteine and loosely by the carboxylate of a glutamate.[1379] In its ferrous form, the carboxylato group of the glutamate dissociates from the iron in response to the decrease in charge number of the iron ion, and a superoxide radical anion associates in a encounter-controlled second-order reaction at the open site on the Fe^{2+} made available by the dissociation. During the association of the superoxide radical anion, a hydron is transferred (Equation 2–199) to it, coincident with transfer of an electron from the Fe^{2+} to the superoxide in the inner sphere, to produce hydroperoxyiron(III), the equivalent of a complex between hydroperoxide (HO_2^-) and Fe^{3+} (Figure 2–50). After the rate-limiting transfer of a hydron to the hydroperoxide ion (Equation 2–202), the resulting hydrogen peroxide dissociates[1380] from the Fe^{3+}. With its open site again occupied by the carboxylato group of the glutamate, the Fe^{3+} is reduced by rubredoxin in the outer sphere back to Fe^{2+}, and the carboxylate

dissociates. The Fe^{2+} in a synthetic complex with 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane, to which a sulfanyl group has been appended so that it can act as one of the axial ligands to the iron, is able to reduce superoxide radical anion catalytically at the other axial location when it is supplied with a reductant able to supply electrons one at a time to the iron.[1381]

Superoxide dismutase catalyzes a reaction

$$2\,H^+ + O_2^{\cdot -} + O_2^{\cdot -} \rightleftharpoons O_2 + H_2O_2 \qquad (2\text{–}226)$$

in which superoxide radical anion is also a substrate. As in the case of superoxide reductase, an electron is again transferred in the inner sphere from a reduced prosthetic transition metallic ion to a bound superoxide radical anion (Equation 2–198), coincident with the necessary hydron transfers. After dissociation of the resulting hydrogen peroxide and association of a second superoxide radical anion with the now-oxidized transition metallic ion, the metallic ion is reduced by one electron transferred in the inner sphere from that superoxide radical anion, which becomes molecular oxygen (Equation 2–197).

In the different species of superoxide dismutase, different prosthetic metallic ions are used. Although the superoxide dismutases do not run the gamut of transition metallic ions, they come close. Depending on the species of superoxide dismutase, the prosthetic transition metallic ion is either a **copper ion**,[1382] which alternates between Cu^+ and Cu^{2+}; a **nickel ion**,[1383] which alternates between Ni^{2+} and Ni^{3+}; a **manganese ion**,[1384] which alternates between Mn^{2+} and Mn^{3+}; or an **iron ion**,[1385] which alternates between Fe^{2+} and Fe^{3+}. One superoxide dismutase may be closely related to another yet have a different prosthetic ion. For example, superoxide dismutase from *M. tuberculosis* is closely related to superoxide dismutase from *Mycobacterium leprae* (80 percent identity, 0 gap percent), but the former has an iron ion in its active site and the latter has a manganese ion.[1386] The superoxide dismutases containing a prosthetic nickel ion[1387] or a prosthetic copper ion,[1388] however, are unrelated to those that have an iron ion or a manganese ion.

The **coordinations of the metallic ions differ significantly** among the superoxide dismutases. Superoxide dismutases containing a prosthetic nickel ion coordinate the ion with the α-amino group of the protein, the amido nitrogen of a peptide bond, the sulfido groups of two cysteines, and the imidazolyl group of a histidine.[1387] Superoxide dismutases containing an iron ion and those containing a manganese ion coordinate the ion with the same side chains, the imidazolyl groups of three histidines and the carboxylato group of an aspartate, in the homologous positions in the sequences of amino acids.[1389-1394] The ligands around the manganese ion in the superoxide dismutase from *E. coli* are arranged octahedrally. The ligand position opposite one of the imidazolyl groups is occupied by a molecule of water, but the position opposite the single carboxylato group can be either vacant or occupied by a molecule of water. When a hydroperoxide associates with Mn^{3+}, it binds side-on and occupies the two positions occupied by molecules of water.[1395]

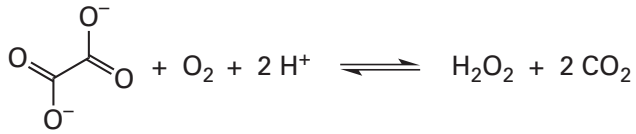
In the active site of a superoxide dismutase that contains a single mononuclear copper ion, the copper ion is coordinated in the reduced state by three imidazolyl groups from three histidines in an almost planar, trigonal array.[1396] In the reduced cuprous state of bovine superoxide dismutase, there are only these three ligands to the copper ion,[1397-1400] but there is a fourth imidazolyl group from another histidine nearby. This imidazolyl group is a ligand to a Zn^{2+} at its π nitrogen. In the reduced state, its τ nitrogen is 0.34 nm from the copper ion and therefore not a ligand.[1401] In the oxidized, cupric state of bovine superoxide dismutase, however, this **zinc-imidazolyl group**, in response to the change in charge number, has swung over and become a fourth ligand to the copper ion at its τ nitrogen, while the other three imidazolyl groups remain in the trigonal plane.[1388,1402]

The standard reduction potentials of aquo d^4 Mn^{3+} ($E^{\circ\prime}$ = +1510 mV) and aquo d^5 Fe^{3+} ($E^{\circ\prime}$ = +770 mV) are quite large, making them strong oxidants. Both the superoxide dismutases containing a prosthetic iron ion and the related superoxide dismutases containing a manganese ion have evolved to lower the **biochemical standard reduction potential of the respective metallic ion** into the range of −100 to +300 mV,[1403,1404] which is appropriate for the dismutation, being between the biochemical standard reduction potential of the redox couple of oxygen and the superoxide radical anion (–330 mV), the superoxide of which will reduce the oxidized metallic ion to form molecular oxygen, and the redox couple of superoxide radical anion and hydrogen peroxide (+940 mV), the superoxide radical anion of which will oxidize the reduced metallic ion to form hydrogen peroxide. When the correct metallic

ion, Fe^{2+} or Mn^{2+}, is replaced by the incorrect metallic ion, Mn^{2+} or Fe^{2+}, respectively, the respective environment still performs the same net shift in biochemical standard reduction potential, which brings the biochemical standard reduction potential for the wrong transition metallic ion to the wrong value, either too high or too low, respectively, to perform the dismutation.[1404] In contradistinction to this evolution of the protein to accommodate the properties of the metallic ions, there is a protein that binds either an iron ion or a nickel ion, and the respective metalloenzymes that result perform different oxygenations of the same reactant.[1405] The biochemical standard reduction potential of bovine superoxide dismutase containing a prosthetic copper ion is +120 mV,[1403] again appropriate to the task at hand.

A **detailed mechanism** has been presented for superoxide dismutases, such as those from *Bos taurus* and *S. cerevisiae*, containing a prosthetic copper ion in their active sites. A neutral, hydronated superoxide radical anion associates with Cu^{2+} at the axial coordination site and displaces the zinc-imidazolyl group. During this displacement, the τ nitrogen of the imidazolyl group removes the hydron from the hydrosuperoxide radical.[1406] Upon coordination, an inner-sphere transfer of an electron occurs instantaneously between the resulting superoxide radical anion and the Cu^{2+}, and the resulting molecule of molecular oxygen dissociates.[1407] A neutral hydrosuperoxide radical, which is a hydroperoxy radical (Equation 2–199), associates with the trigonally coordinated Cu^{+} at the open axial site. After the instantaneous inner-sphere transfer of an electron to the peroxy group, a hydroperoxy ion[1408] is sitting on a Cu^{2+}. The hydroperoxy ion is hydronated on its proximal oxygen by the adjacent zinc-imidazolium.[1406] The resulting unhydronated zinc-imidazolyl group recoordinates with the Cu^{2+} replacing the hydrogen peroxide and completing the catalytic cycle.

There is a manganese superoxide dismutase, with a manganese ion coordinated by the same ligands as those used by the enzymes in the family of iron and manganese superoxide dismutases,[1409] that can catalyze the reaction of oxalate oxidase

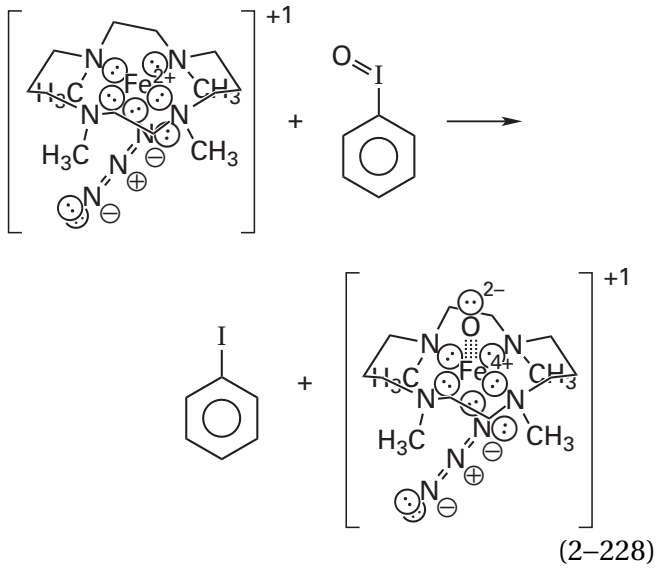


(2–227)

as well as the usual dismutation of superoxide radical anion. The oxidized Mn^{3+} form of the enzyme removes an electron from oxalate dianion, rather than from superoxide radical anion, and the resulting radical anion of oxalate decarboxylates almost immediately, as do most if not all radicals at the oxygens of carboxylic acids, to produce the first molecule of CO_2. The remains of the decarboxylation—a radical anion of carbon dioxide, a strong reductant, that is bound tightly by the now Mn^{2+}—reduces molecular oxygen to superoxide radical anion and becomes the second molecule of CO_2, which can no longer be a ligand to the Mn^{2+} and dissociates to be replaced as a ligand by the superoxide radical anion. The superoxide radical anion is reduced as usual to hydrogen peroxide by the Mn^{2+}, regenerating the Mn^{3+}.[1405]

There are a number of enzymatic reactions in which hydrogen peroxide is a substrate and a heme is the prosthetic group and in which the hydrogen peroxide oxidizes the iron in the heme to a high-valent state. The enzymes with hemes as prosthetic groups that have hydrogen peroxide as a substrate are hemoperoxidases.

There are synthetic examples of high-valent **oxoiron(IV)** (Figure 2–50).[1410-1414] One is the oxoiron(IV)

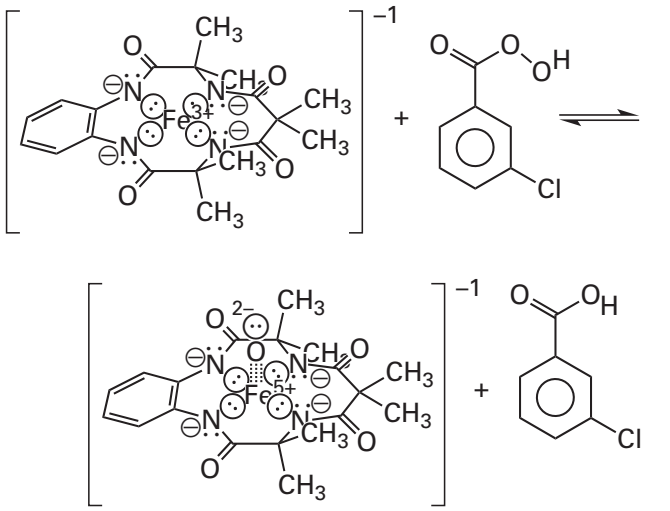


(2–228)

that is the product of two-electron oxidation of a pentacoordinated Fe^{2+} by iodosylbenzene.[1411] The neutral tertiary amino nitrogens in the cyclic tetraamine coordinating the iron ion in Equation 2–228 are basic and contribute sufficient electron density to the iron ion to permit it to achieve the +4 oxidation state. In the product of the oxidation, the formal oxidation state of the iron is +4 and that of the oxygen

from the iodosylbenzene that has become an axial ligand is –2. Similar oxoirons(IV) in cyclic tetraamines can be produced by using hydrogen peroxide[1410] or molecular oxygen itself[1414] as the oxidants.

A more extreme example of high-valent iron is the **oxoiron(V)** (Figure 2–50)[1415,1416]



(2–229)

that is the product of oxidation of a coordinated Fe^{3+} by *m*-chloroperoxybenzoic acid. In the product of the oxidation, the formal oxidation state of the iron is +5 and that of the oxygen is –2

$$\underset{(5e^-)}{Fe^{3+}} + \underset{(14e^-)}{ROOH} \longrightarrow \underset{(3e^-)}{Fe^{+5}}=\underset{(8e^-)}{O^{-2}} + \underset{(8e^-)}{ROH} \qquad (2\text{–}230)$$

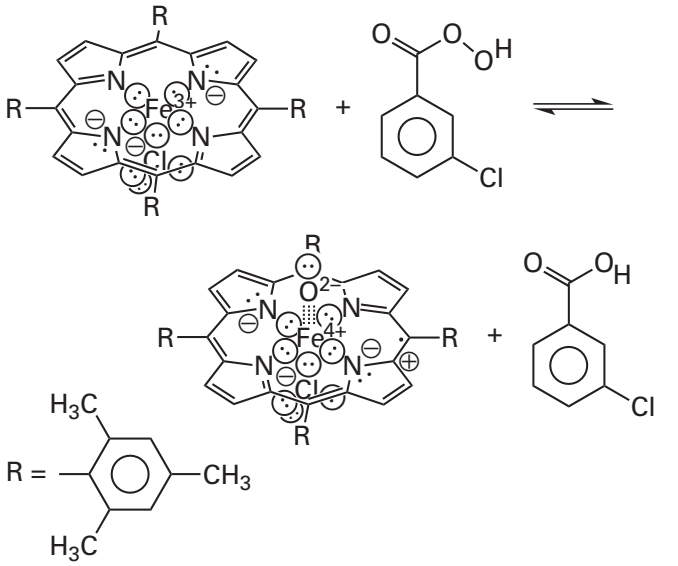
The strong electron donation of the four strongly basic, anionic amido nitrogens in the tetraamido macrocycle coordinating the Fe^{3+}, which are significantly more basic than four tertiary amino groups, is in part responsible for the capacity of the iron ion to achieve the +5 oxidation state when it is within this ligand.* The tetraamidooxoiron(V) in Equation 2–229 is in square pyramidal pentacoordination with the oxo group at the apex. When an iron(V) is generated in a more flexible ligand, again by the use of a peroxy acid, a complex between the peroxy acid and an iron(III) could be identified[1418] in which the acyl oxygen and the distal oxyanion of the peroxy acid had become the fifth and sixth ligand to a hexacoordinated, octahedral Fe^{3+}, a result that suggests that such an intermediate might be involved in the oxidation of Equation 2–229 and that the oxygen–oxygen bond of this intermediate dissociates to give the oxo group and the *m*-chloroperoxybenzoate, which then dissociates from the oxoiron(V).

The **porphyrin of a heme (2–69) is the biological equivalent** of the 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane in Equation 2–228 or the tetraamido macrocyclic ligand in Equation 2–229. The main difference among these three macrocyclic ligands is the values of pK_a for their respective nitrogens. In the cyclic tetraamide (Equation 2–229), each of the nitrogens is equivalent to the nitrogen in *N*-phenylacetamide (pK_a = 15) or the nitrogen in 2-methylpropionamide (pK_a = 17). In the cyclic tetraamine (Equation 2–228), each of the nitrogens is equivalent to the nitrogen in *N*-methyl-*N,N*-diethylamine (pK_a = 10.5). In the cyclic tetrapyrrole of protoporphyrin (**2–69**), the situation is complicated by the existence of two different types of nitrogen. A net of two of the nitrogens are similar to the nitrogen in pyrrole (pK_a = 17.5), and the net of two of the nitrogens are similar to the nitrogens in pyridine (pK_a = 5.2). These are net values because all four of the unhydronated nitrogens in a heme are essentially equivalent and have some hybrid of these two values of pK_a.

Hemes are one of the classes of prosthetic groups that form complexes directly with molecular oxygen, superoxide radical anion, hydrogen peroxide, and water. In the hemes that form these complexes, unlike in the hemes in proteins involved in electron transfer (Figure 2–22), the **sixth coordination site** on the iron ion, one of the two sites for an axial ligand in a heme transferring electrons, **is not occupied** by a basic amino acid from the protein but is occupied by ligands from the solution, or in a ferroheme, it is sometimes even unoccupied. The chemistry proceeds at the single open site on the iron, as in superoxide reductase.

Synthetic ferrihemes that are properly constructed to prevent destructive side reactions also react with peroxy acids

*When a bis[1-(2,4,6-trimethylphenyl)imidazol-2-ylidene], which is an even more basic, dicarbanionic ligand, coordinates an iron ion, an Fe^{6+} can be stabilized.[1417]



(2–231)

to produce a high-valent iron. The main difference between a porphyrin and the tetraamido macrocyclic ligand of Equation 2–229 is that because of its extensive, continuous, cyclic π molecular orbital system, the redox couple of dihydronated porphyrin radical cation and dihydronated neutral porphyrin has a much more negative reduction potential than the redox couple of dihydronated radical cation of the tetraamido macrocycle and dihydronated tetraamido macrocycle. Consequently, an electron is transferred from the highest occupied π molecular orbital of this π molecular orbital system of the porphyrin to the iron ion as the oxoiron(V) porphyrin is formed during the reaction with the peroxy acid, and the iron ends up in the +4 oxidation state and the porphyrin ends up as a π radical cation (porphyrin$^{\bullet+}$) to give **oxoiron(IV) porphyrin$^{\bullet+}$**. As the designation indicates, the electron deficiency, and hence the positive formal elementary charge of the hole, is in the π molecular orbital system of the radical cation* of the porphyrin.[1419,1420]

When an iron ion is inserted into a heme, the ligand field of the four nitrogens orients its five *d* orbitals (Figure 2–24) while affecting their energies (Figure 2–25). In the oxoiron(IV) porphyrin$^{\bullet+}$ (Equation 2–231), there are **four σ molecular orbitals and four *dp*π molecular orbitals among the iron and the oxygen**. These molecular orbitals resemble the molecular orbitals in a diatomic molecule (Figure 2–45 and **2–86**). The single **σ molecular orbital system** is formed by a combination of the $2s$ atomic orbital on the oxygen, the $4s$ atomic orbital on the iron, the $2p_z$ orbital on the oxygen, and the $3d_{z^2}$ orbital on the iron. These four atomic orbitals together combine to create four molecular orbitals: two bonding σ molecular orbitals and two antibonding σ molecular orbitals. Because all four of these atomic orbitals are cylindrically symmetric with the axis between the oxygen and the iron, the four molecular orbitals in the σ molecular orbital system that they create must also be, as are those in molecular oxygen. Unlike molecular oxygen, however, they are asymmetric about the two perpendicular rotational axes because the atoms are different. There are two perpendicular ***dp*π molecular orbital systems**. One *dp*π molecular orbital system is formed by overlap of the $2p_x$ orbital of the oxygen and the $3d_{xz}$ orbital of the iron ion, which creates a bonding *dp*π molecular orbital and an antibonding *dp*π molecular orbital, and the other is formed by overlap of the p_y orbital of the oxygen and the d_{yz} orbital of the iron, which also creates a bonding *dp*π molecular orbital and an antibonding *dp*π molecular orbital. Because the two *p* orbitals on the oxygen were orthogonal to each other and degenerate and the two *d* orbitals on the iron were also orthogonal to each other and degenerate, the two π molecular orbital systems they respectively create are perpendicular to each other, orthogonal, and degenerate. Except for the fact that these latter two overlaps are *dp*π overlaps rather than *pp*π overlaps, the two *dp*π molecular orbital systems are homologous to the two π molecular orbital systems in molecular oxygen itself.

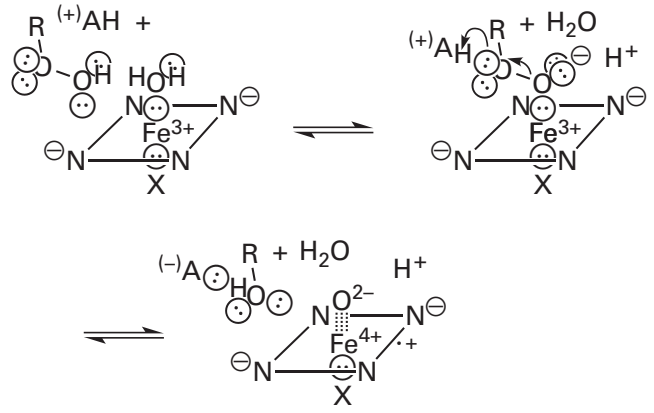
Upon dissociation of the *m*-chlorobenzoic acid with two electrons that were in the oxygen–oxygen bond, two electrons are required to complete the octet around the remaining oxygen. One is contributed by the iron and the other by the π molecular orbital system of the porphyrin. Formally, this creates an oxide dianion, O^{2-} (8 valence electrons), bonded to Fe^{4+} (4 valence electrons), which together account for **12 valence electrons**, the same number as in molecular oxygen. Six of these electrons occupy three of the σ molecular orbitals for a net of one σ bond; and the six remaining valence electrons occupy the two orthogonal, degenerate *dp*π molecular orbital systems, just as six valence electrons occupy the two orthogonal, degenerate π molecular

*Since the porphyrin in a heme is a dianion, when the radical forms, the charge on the entire porphyrin is –1. There is, however, a positive formal charge and an unpaired electron delocalized over the π molecular orbital system of the porphyrin, which make the π molecular orbital system a radical cation.

orbital systems of molecular oxygen (**2–87**). The same result occurs in the *dpπ* molecular orbital systems. Four of the electrons occupy the two bonding *dpπ* molecular orbitals, and two of the electrons are split between the two antibonding *dpπ* molecular orbitals to create a paramagnetic triplet state and a net of one *dpπ* bond.

Consequently, the oxygen–iron bond in an oxoiron(IV) porphyrin$^{\bullet+}$ is usually abbreviated Fe=O as if it were a double bond, one σ bond and one π bond; but another way of abbreviating it would be :Fe≒O:, which accounts for all 12 of the valence electrons (Equation 2–229). This latter formalism resembles the formalism that can be used for molecular oxygen. Unlike molecular oxygen, however, there is a significant difference in electronegativity between iron and oxygen, a difference of nuclear elementary charge, a difference in the type of atomic orbitals from the iron and the oxygen used to form the molecular orbitals, and the presence of the other axial ligand and the four lone pairs of electrons from the nitrogens of the heme that are ligands to the iron ion. All these factors affect the distribution of electrons between the iron and the oxygen. From here on, however, the bonding will simply be represented by three vertical dashed lines to indicate that there is a sigma bond and two *dpπ* overlaps, and the decision on covalency and distribution of electrons, as usual, will be left to the reader.

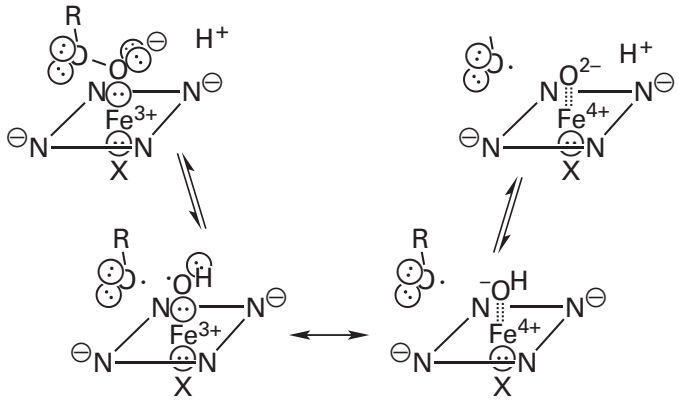
A **synthetic oxoiron(IV) porphyrin**$^{\bullet+}$ (Equation 2–231) can be produced with both hydrogen peroxide and alkyl hydroperoxides[1421,1422] as well as with peroxy acids. The former two reactions are most relevant to biochemical oxoiron(IV) porphyrins$^{\bullet+}$. The reactions proceed with general acid catalysis[1421,1423-1428] to promote the heterolysis of the respective oxygen–oxygen bond*



(2–232)

where R is a hydrogen (hydrogen peroxide), an alkyl group (a hydroperoxide), or an acyl group (a peroxy acid) and the leaving group (ROH) is a molecule of water, an alcohol, or a carboxylic acid, respectively.

In the absence of effective general acid catalysis, the oxygen–oxygen bond can also break homolytically[1424,1426,1429-1432]



(2–233)

to give a **synthetic hydroxyiron(IV) porphyrin** within an unoxidized heme. A hydroxyiron(IV) is formally equivalent to either a hydroxyl radical bound to Fe^{3+} or a hydroxide bound to Fe^{4+} (Figure 2–50). The conjugate base of a hydroxyiron(IV) is an **oxoiron(IV)** (Figure 2–50).

Alkyl hydroperoxides (R = alkyl) are more prone to homolysis than hydrogen peroxide (R = H), which is more prone to homolysis than peroxy acids (R = acyl).[1422,1429] Peroxy acids are more prone to heterolysis than hydrogen peroxide, which is more prone to heterolysis than alkyl hydroperoxides. The former sequence is that expected from the stability of the corresponding oxy radicals that are the homolytic leaving groups from the hydroxy group of the

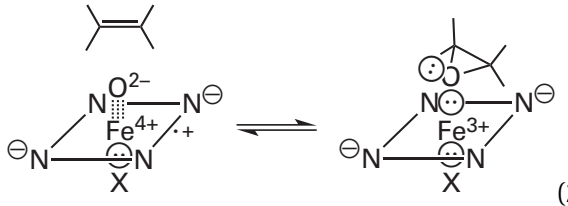
*From here on, a heme will be abbreviated by a square with nitrogens at its vertices.

peroxide or peroxy acid, and the latter sequence is that expected from the ability of the corresponding oxyanions to be heterolytic leaving groups from the hydroxy group of the peroxy acid or peroxide. Under appropriate conditions, the reaction with a peroxy acid, which provides the best leaving group for heterolysis, proceeds with no homolysis.[1421,1423]

The **hydroperoxyiron(III)** (Figure 2–50) in 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (see Equation 2–228) has been produced as a relatively stable compound and examined spectroscopically.[1413,1433] When a hydron and an electron, from triethylammonium and triethylamine, respectively, are then provided, the hydroperoxyiron(III) converts to oxoiron(IV). It is thought that the first step in this conversion is heterolytic dissociation of the oxygen–oxygen bond under acid catalysis by triethylammonium to give oxoiron(V), which, as a strong oxidant, then takes up an electron from triethylamine to become oxoiron(IV). This sequence of events suggests that when the nitrogens in the cyclic ligand are not strong anionic bases, as in Equation 2–229, a source of electrons is required to form oxoiron(IV). In the case of a heme, the **porphyrin is an intramolecular source of the necessary electron**. The same oxoiron(IV) can be formed from the complex between hydrogen peroxide and an Fe^{2+} in the same cyclic ligand by adding catalytic amounts of a base to catalyze the tautomerization in which a hydron dissociates from the proximal oxygen of the hydrogen peroxide and a hydron is added to the distal oxygen to permit heterolysis of the oxygen–oxygen bond. Because the iron begins as iron(II), no electron is needed to produce oxoiron(IV).

An oxoiron(IV) porphyrin$^{\bullet+}$ is so electrophilic that its oxygen is not basic enough to be hydronated at any pH. The oxygen atom in an oxoiron(IV) porphyrin, however, because an oxoiron(IV) porphyrin has one more electron than an oxoiron(IV) porphyrin$^{\bullet+}$, is a base. Its basicity depends on the identity of the proximal ligand on the other side of the heme.[1434] In the active site of an enzyme, the **pK_a of the oxygen atom in a hydroxyiron(IV) porphyrin** in which the proximal ligand is the imidazolyl group of a histidine[1435] is usually less than or equal to 3.5, so it is normally unhydronated.[1436] When the ligand is the sulfido group of a cysteine, which is a much stronger donor of electron density that an imidazolyl group, the pK_a of the oxygen atom[1434,1437] in a hydroxyiron(IV) porphyrin is between 10 and 12, so it is normally hydronated. The fact that the oxygen atom in an oxoiron(IV) porphyrin is basic indicates that, in its reactions, it should be susceptible to acid–base catalysis regardless of the identity of the proximal ligand.

A synthetic **oxoiron(IV) porphyrin$^{\bullet+}$ is able to convert an alkene into its epoxide**[1420,1438-1440]



(2–234)

The reaction proceeds with a kinetic intermediate, and the rearrangements of the alkene observed during its epoxidation suggest that this intermediate is a carbocation. The correlation between the rate constant of the epoxidation and the ionization potential of the carbon–carbon double bond suggests that the intermediate is a radical carbocation

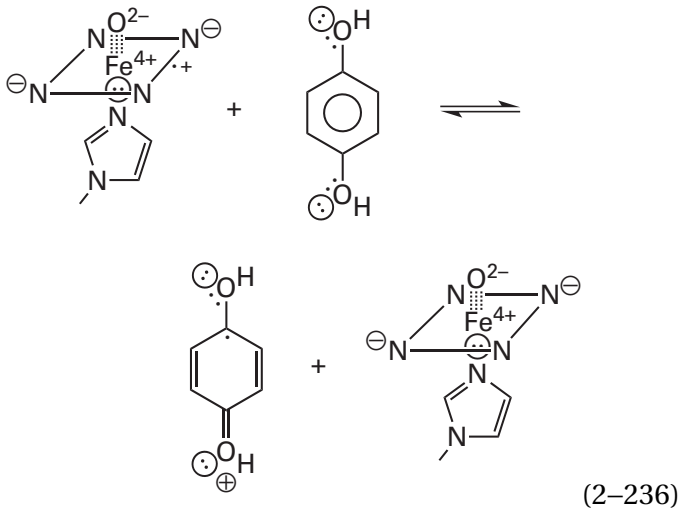
(2–235)

resulting from transfer of one electron from the π bond of the carbon–carbon double bond to the oxoiron(IV) porphyrin$^{\bullet+}$.[1441] If so, the intermediate is both a radical and a carbocation. The oxygen incorporated into the epoxide is that of the oxo group on the iron, but this fact was difficult to determine because the oxygen in a synthetic oxoiron(IV) porphyrin$^{\bullet+}$ is capable of rapid exchange with the oxygen in any water present in the solvent[1420,1426] before it performs the epoxidation. There has, however, been no evidence suggesting that the oxygen in an oxo group at a heme in an enzyme is capable of exchange with the water in the solution. A synthetic hydroxyiron(IV) porphyrin produced by homolysis (Equation 2–233) also performs epoxidation of olefins,[1426,1431,1442] but the distribution of products is quite different from that produced by oxoiron(IV) porphyrin$^{\bullet+}$, an observation suggesting that it proceeds by a different mechanism.

Both synthetic oxoiron(IV) porphyrins$^{\bullet+}$ and synthetic hydroxyiron(IV) porphyrins are **also able to hydroxylate alkanes to alcohols**,[1426,1443,1444] but the heme in the hydroxyiron(IV) porphyrin has to have substituents that withdraw electrons to make the hydroxyiron(IV) a strong enough oxidant. If a hydrocarbon chain is intramolecularly positioned over the iron in a heme model compound and the

heme is converted to oxoiron(IV) porphyrin$^{\bullet+}$, the closest methylene in the chain to the oxygen is converted into a secondary alcohol.[1445] If, however, there are several carbon–hydrogen bonds equally accessible to the oxygen of an oxoiron(IV) porphyrin$^{\bullet+}$, the carbon in the carbon–hydrogen bond with the smallest bond dissociation energy (BDE) is the one that is hydroxylated. This result suggests that the first step in the hydroxylation is abstraction of a hydrogen atom from the alkane. A synthetic oxoiron(IV) porphyrin is able to turn xanthene into xanthone,[1446] presumably by a hydrogen abstraction from the xanthene (BDE = 350 kJ mol^{-1}) followed by an electron transfer and then a hydrogen abstraction from the intermediate xanthydrol (BDE = 340 kJ mol^{-1}) followed by an electron transfer to give xanthone. The oxoiron(IV) in the cyclic ligand 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (Equation 2–228) is able to abstract hydrogens from the oxygen of a phenol.[1411] The bond dissociation energy (340 kJ mol^{-1}) for the hydroxy group of a phenol, however, is significantly less than that for an alkane (400 kJ mol^{-1}). A synthetic oxoiron(V), however, is a strong enough oxidant to hydroxylate alkanes.[1416] Providing an acidic donor for a hydrogen bond, in particular 2,6-dimethylpyridinium ($pK_a = 6.6$), to the oxygen of a synthetic hydroxyiron(IV) porphyrin increases its reactivity, both in rate and in the bond dissociation energies of its reactants,[1446] by increasing its electrophilicity. The active sites of enzymes often have one or two donors for hydrogen bonds to the oxygen of a prosthetic oxoiron.

A synthetic oxoiron(IV) porphyrin$^{\bullet+}$ is also able to **participate in one-electron transfer**[1432]



(2–236)

Hemoperoxidases use hydrogen peroxide or an alkyl hydroperoxide as a reactant to produce prosthetic oxoiron(IV) porphyrin$^{\bullet+}$ or oxoiron(IV) porphyrin from their ferric hemes. They use these high-valent intermediates either as a means to remove from the cytoplasm the hydrogen peroxide or the particular alkylperoxide that are the reactants

$$ROOH + 2\,H^+ + 2\,e^- \rightleftharpoons ROH + H_2O \qquad (2\text{–}237)$$

or use these intermediates to oxidize particular substrates. An uncomplicated example of the former purpose is L-ascorbate peroxidase, which reductively removes hydrogen peroxide from the cytoplasm and uses two molecules of the one-electron-transferring coenzyme L-ascorbate (Equation 2–163) to provide the necessary two electrons (Equation 2–237). An uncomplicated example of the latter purpose is myeloperoxidase

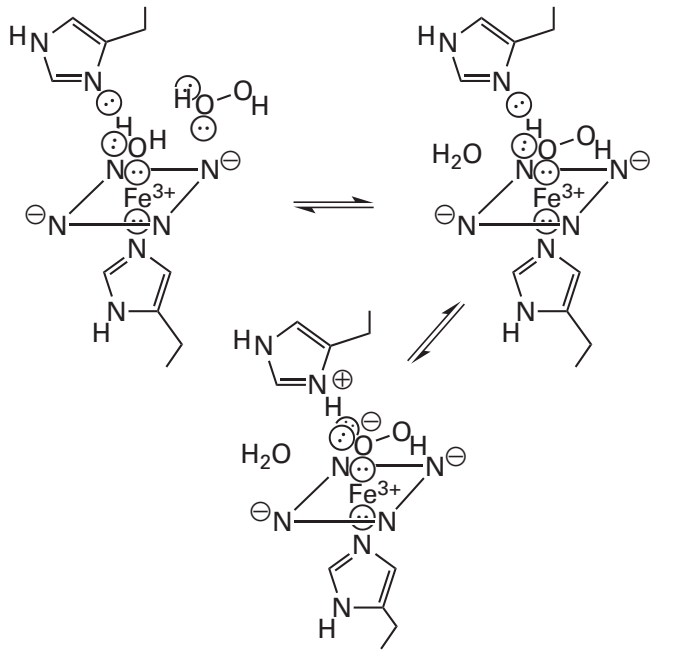
$$H^+ + H_2O_2 + Cl^- \rightleftharpoons HOCl + H_2O \qquad (2\text{–}238)$$

which produces oxoiron(IV) porphyrin$^{\bullet+}$ from hydrogen peroxide to oxidize chloride to hypochlorous acid[1447,1448]

$$H_2O + \text{oxoiron(IV) porphyrin}^{\bullet+} + Cl^- \rightleftharpoons HOCl + \text{hydroxyiron(III) porphyrin} \qquad (2\text{–}239)$$

where **hydroxyiron(III) porphyrin** (see Figure 2–50) is the complex between a hydroxide and the ferric heme. The same reaction is catalyzed by another peroxidase in mammalian tissue that oxidizes bromide to hypobromous acid but does not oxidize chloride.[1449]

In the resting state of a hemoperoxidase, the heme is usually an **aquoiron(III) porphyrin** (see Figure 2–50), the complex between a molecule of water and the ferric heme. In a few instances, however, the coordination site on the iron is not occupied by a molecule of water or any other ligand and is open to a strong enough ligand. The first step in the formation of oxoiron(IV) porphyrin$^{\bullet+}$ at the heme in a hemoperoxidase is replacement of the water on the open coordination site of the aquoiron(III) porphyrin by hydrogen peroxide or alkyl hydroperoxide

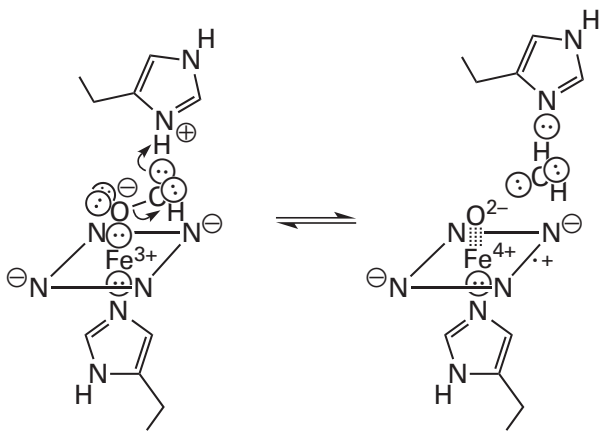


(2–240)

In the active site of most hemoperoxidases, there is the side chain of a histidine forming a hydrogen bond with the water initially on the Fe^{3+}.[1450,1451] This histidine must be both present and unhydronated[1452,1453] so that it can remove the hydron from the proximal oxygen of the hydrogen peroxide, either as the complex is forming or after it has formed.[1454]

The result of the replacement of the molecule of water and transfer of the hydron is a **hydroperoxyiron(III) porphyrin** (see Figure 2–50), the complex between a hydroperoxide ion and the ferric heme. A hydroperoxyiron(III) porphyrin has been observed transiently in the peroxidase from *Armoracia rusticana*[1455] and could be trapped as a stable species at low temperature.[1456] The bond formed between oxygen and iron is between a σ lone pair of electrons from the conjugate base of hydrogen peroxide and the empty, axial d_{z^2} atomic orbital on the iron.[1294]

In the next step of the reaction, heterolytic cleavage of the oxygen–oxygen bond occurs.[1457] The histidine that has just removed the hydron from the proximal oxygen of the hydrogen peroxide (Equation 2–240) hydronates its distal oxygen[1458,1459] to provide the necessary **acid catalysis**



(2–241)

for dissociation of the oxygen–oxygen bond and formation of the oxoiron(IV) porphyrin$^{\bullet+}$. The net of one double bond between iron and oxygen in the oxoiron(IV) porphyrin$^{\bullet+}$ in the active site of a hemoperoxidase that is the product of this sequence of steps has an infrared absorption band at a wavelength in the same range as the one for the net double bond in a synthetic oxoiron(IV) porphyrin$^{\bullet+}$.[1460,1461] The crystallographic molecular model of an oxoiron(IV) porphyrin$^{\bullet+}$ in catalase from *Penicillium janthinellum*, a hemoperoxidase, shows a single oxygen sitting on the iron in the heme (Figure 2–51).[1430,1457]

Chlorite O_2-lyase from *Dechloromonas aromatica* uses chlorite rather than hydrogen peroxide to produce an oxoiron(IV) porphyrin$^{\bullet+}$ in its active site. Chlorite ($OClO^-$) associates through one of its oxygens with the ferric heme in the active site to form an adduct homologous to a hydroperoxyiron(III) porphyrin. Instead of the distal oxygen being hydronated to create a leaving group, in this case the leaving group is hypochlorite (ClO^-) and its dissociation produces the oxoiron(IV) porphyrin$^{\bullet+}$. The hypochlorite reorients in the active site and the oxoiron(IV) porphyrin$^{\bullet+}$ then abstracts the oxygen atom from it. The final products of the reaction are Cl^-, molecular oxygen, which is formed from the two peripheral oxygens of the chlorite, and iron(III) porphyrin.[1462] In this case, an oxygen–oxygen bond is made rather than being broken.

In most of the peroxidases, the electron that reduces oxoiron(V) to oxoiron(IV) is provided by the porphyrin itself to produce oxoiron(IV) porphyrin$^{\bullet+}$. In cytochrome-*c* peroxidase from *S. cerevisiae*[1463,1464] and lignin peroxidase from *P. eryngii*,[1465,1466] however, the radical cation arising from transfer of the electron to oxoiron(V) during heterolysis of the oxygen–oxygen bond ends up located on the nearby indolyl group of a tryptophan in an oxoiron(IV) indolyl$^{\bullet+}$.

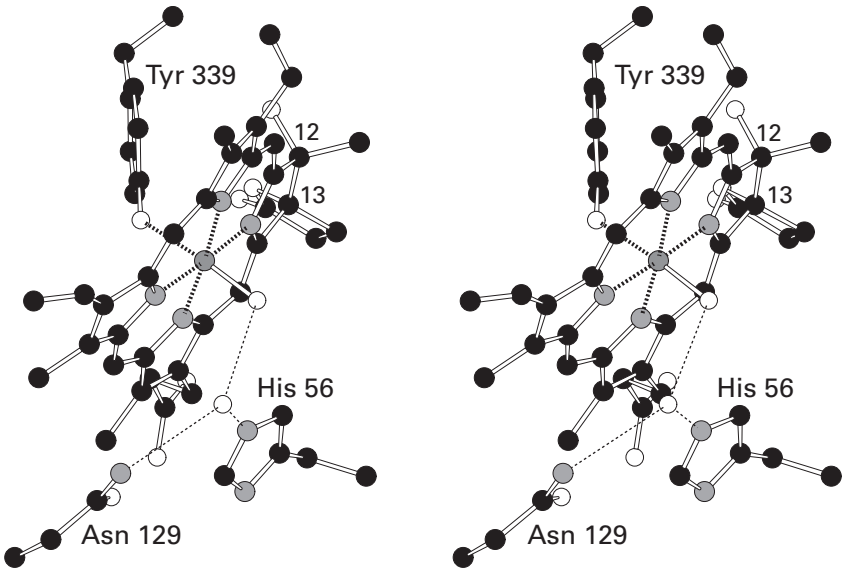


Figure 2–51: Stereodrawing[50] from the crystallographic molecular model of oxoiron(IV) porphyrin$^{\bullet+}$ in the active site of catalase from *P. janthinellum*.[1430] Black atoms are carbons, white atoms are oxygens, gray atoms are nitrogens, and the small dark gray sphere surrounded by ligands is an iron ion. A crystal of catalase from *P. janthinellum* was soaked for 2 min in 125 mM peroxyacetic acid, during which time its color turned from brown to green, suggesting that its heme had become oxoiron(IV) porphyrin$^{\bullet+}$. It was immediately brought to 100 K and stored at this temperature. In the crystallographic model derived from this crystal, there was a single atom of oxygen on the iron ion of the heme at a bond length expected for an iron–oxygen double bond (0.172 nm). The other axial ligand to the iron ion in the heme of this enzyme is the 4-oxido group of Tyrosine 339. The heme *b* (**2–69**) originally present in this catalase has been oxidatively modified during its lifetime of performing catalysis in the cell before it was purified. In addition to the methyl group at position 12, there is a hydroxy group (upper right corner in drawing) and the bond between carbon 12 and carbon 13 is a single bond instead of a double bond. In addition to the 2-carboxylatoethyl group on carbon 13, there is also a hydroxy group, and these two groups have formed a lactone (upper right corner in drawing). The oxygen of the oxo group is participating in a hydrogen bond with a molecule of water, which is held in place by the carbamoyl group of Asparagine 129 and the imidazolyl group of Histidine 56.

The tryptophan in cytochrome-*c* peroxidase is located in a pocket that stabilizes its radical cation,[1467] and when that tryptophan is mutated to a phenylalanine, the usual oxoiron(IV) porphyrin$^{\bullet+}$ forms instead.[1468] It has already been noted that, in cytochrome-*c* peroxidase, the two successive electrons transferred from two successive molecules of cytochrome *c* are both transferred to the **π radical cation of the tryptophan**. In the case of lignin peroxidase, the radical cation of the tryptophan actually oxidizes the lignin by abstracting electrons from it.[1469] In L-ascorbate peroxidase, however, which has a tryptophan in the homologous location, a normal oxoiron(IV) porphyrin$^{\bullet+}$ is formed[1470,1471] rather than an oxoiron(IV) indolyl$^{\bullet+}$.

In methylamine utilization protein, a peroxidase from *P. denitrificans*, there are two hemes: one at which the hydrogen peroxide is converted to an oxoiron(V) porphyrin and the other that provides the extra electron to convert the oxoiron(V) porphyrin to an oxoiron(IV) porphyrin. The iron ion in the other heme has a tyrosine and a histidine as axial ligands, and the Fe^{3+} is converted to the oxidation state of Fe^{+4} after providing the electron. The extra electron is transferred back and forth between the hemes by hopping through a tryptophan that serves as a relay station.[1472]

In many hemoperoxidases, in addition to the imidazolyl group that performs the acid catalysis, there is also the **guanidinio group of an arginine** located appropriately[1473,1474] to provide a hydrogen bond to a molecule of water that in turn forms a hydrogen bond to the distal oxygen of the hydrogen peroxide. This arrangement should polarize the oxygen–oxygen bond and hasten its cleavage.[1475] After the bond cleaves and the water leaves, this guanidinio group then swings over to form a hydrogen bond with the oxygen of oxoiron(IV) in the oxoiron(IV) porphyrin$^{\bullet+}$.[1451,1476] The fact that this hydrogen bond can form is an indication that there must be sufficient electron density on the oxygen to act as an acceptor.

In catalase

$$H_2O_2 + H_2O_2 \rightleftharpoons 2\,H_2O + O_2 \qquad (2\text{–}242)$$

the **proximal axial ligand to the iron in the heme, opposite its open site, is the 4-oxido group of a tyrosine** (Figure 2–51),[1458,1477,1478] rather than the more common imidazolyl group of a histidine (Equation 2–240).[1459] A portion of the spin density of the π radical cation in the oxoiron(IV) porphyrin$^{\bullet+}$ in catalase is delocalized into the tyrosinate ligand on the iron.[1479] An electron from the highest occupied π molecular orbital system of the tyrosinate is transferred into the highest occupied π molecular orbital of the porphyrin radical cation. It fills the hole left by the electron that was transferred to the oxoiron(V) and pairs with the electron in the highest occupied π molecular orbital of the porphyrin, and it leaves behind a hole and an unpaired electron in the highest occupied π molecular orbital of the tyrosinate. The degree to which the unpaired electron and the hole reside on the tyrosine varies among the catalases from different organisms,[1430] but in at least one case, the majority of the **spin density of the radical resides on the tyrosine**.[1480] In the catalase-peroxidase KatG from *M. tuberculosis*, the indolyl group of Tryptophan 107 is stacked against the heme. When the oxoiron(IV) porphyrin$^{\bullet+}$ is formed, as long as the radical cation remains on the heme, the enzyme is a peroxidase performing hydrogen abstraction from various reactants. When, however, the unpaired electron transfers to the indolyl group to form an indolyl radical cation, the resulting oxoiron(IV)porphyrin indolyl$^{\bullet+}$ becomes a catalase (Equation 2–242) and converts a molecule of hydrogen peroxide to a molecule of water. In the process it becomes a superoxyiron(III) porphyrin indolyl$^{\bullet+}$ that dissociates into a molecular oxygen and an iron(III)porphyrin, which again can act as either a catalase or a peroxidase.[1481]

The length of the iron–oxygen bond in the oxoiron(IV) within the cyclic ligand 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (Equation 2–228),[1410] is short (0.165 nm). When the radical cation remains localized to the porphyrin, the **length of the iron–oxygen bond** in the oxoiron(IV) porphyrin$^{\bullet+}$ in a crystallographic molecular model of a synthetic model compound is longer (0.172 nm),[1482] a fact indicating that there is less π bonding between iron and oxygen because the porphyrin radical cation, a weaker base, provides more electron density to the antibonding $dp\pi$ molecular orbitals of the oxoiron than the cyclic ligand. When the radical cation is localized on the tyrosinate or elsewhere in the protein, the length of the iron–oxygen bond in the oxoiron(IV) porphyrin that results is long (0.182 nm), a fact indicating that there is much less π bonding between iron and oxygen because the porphyrin, no longer the radical cation, provides even more electron density to the antibonding $dp\pi$ molecular orbitals. As a result, the σ lone pair of electrons is more localized on the oxygen so that it can be hydronated (right resonance structure in Equation 2-233).[1430]

Figure 2–52: Stereodrawing[50] of the crystallographic molecular model of a compound that serves as a model for the heme in an oxygen-binding hemoprotein in its oxygenated form.[1514] Black atoms are carbons, white atoms are oxygens, gray atoms are nitrogens, and the small dark gray sphere surrounded by ligands is an iron ion. The porphyrin in this model compound is a tetra(*o*-aminophenyl)porphyrin. Four molecules of pivalic acid [$(CH_3)_3CCOOH$] have been attached as amides, one to the anilino nitrogen in each of the four *o*-aminophenyl groups. These four pivalamides form a dome over one side of the heme. The axial position on the iron opposite the dome is occupied by a 2-methylimidazole to give the heme properties similar to the heme in hemoglobin or myoglobin. The ferrous model compound was recrystallized from refluxing ethanol in the absence of molecular oxygen. The resulting crystals were exposed to 1–2 atm of molecular oxygen saturated with ethanol vapor for several days and then prepared for crystallography. The map of electron density of the crystal that had been treated in this way showed that the iron of the heme in the crystals was occupied by molecular oxygen at its open axial position. In this complex between heme and molecular oxygen, the molecular oxygen assumes four different rotational isomers around the iron–oxygen bond because the heme has a fourfold rotational axis of pseudosymmetry coincident with the iron–oxygen bond. There are four orientations of equal energy, at rotational angles of 90° to each other, that are assumed by the molecule of oxygen. In the drawing only one of these four equally populated orientations is shown. Crystallographic molecular models were made for both the unoccupied heme and the heme occupied by oxygen. In the unoccupied heme, which is not shown, the iron is pulled 40 pm out of the plane of the porphyrin in the direction of the 2-methylimidazole by steric effects arising from the methyl group of 2-methylimidazole. When oxygen binds, as shown in the drawing, the iron returns almost to the plane of the porphyrin (final displacement of only 9 pm). In the heme occupied by molecular oxygen, the bond angle between the iron–oxygen bond and the oxygen–oxygen bond is 129°.

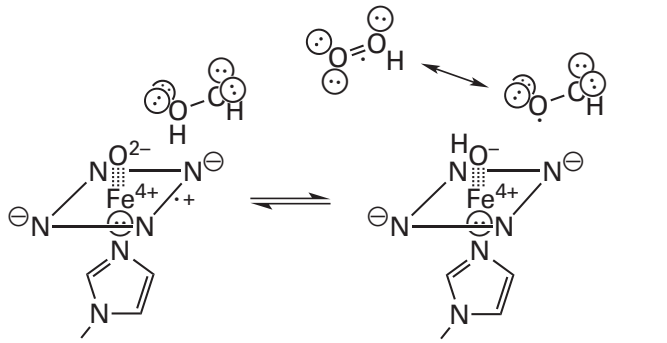
In many of the reactions catalyzed by hemoperoxidases, the oxoiron(IV) porphyrin$^{\bullet+}$, oxoiron(IV) phenoxy$^{\bullet}$, or oxoiron(IV) indolyl$^{\bullet+}$ **accepts a single electron during the oxidation of its natural substrate** or can accept a single electron from an appropriate unnatural substrate. Examples of the former case would be L-ascorbate peroxidase, cytochrome-*c* peroxidase, and manganese peroxidase, each of which accepts two successive single electrons in two separate outer-sphere transfers from two successive molecules of the one-electron donors that are their natural substrates: L-ascorbate (Equation 2–163), cytochrome *c*, and Mn^{2+}·oxalate^{2-}, respectively.[1483,1484] Examples of the latter case would be transfer of one electron from amines[1485] and sulfides[1486] to the oxoiron(IV) porphyrin$^{\bullet+}$ of the peroxidase from *A. rusticana*, which normally removes single electrons from phenols. When a single electron is transferred to oxoiron(IV) porphyrin$^{\bullet+}$, oxoiron(IV) porphyrin (Equation 2–233) is formed,[1487,1488] which in the cases of L-ascorbate peroxidase, cytochrome-*c* peroxidase, and manganese peroxidase then accepts the second electron.

Both oxoiron(IV) porphyrin$^{\bullet+}$ and oxoiron(IV) porphyrin in a hemoperoxidase are strong oxidants. In L-ascorbate peroxidase, the one-electron biochemical standard reduction potential for the redox couple of oxoiron(IV) porphyrin$^{\bullet+}$ and oxoiron(IV) porphyrin is +1160 mV and that for the redox couple of oxoiron(IV) porphyrin and aquoiron(III) porphyrin is +750 mV.[1489] In cytochrome-*c* peroxidase, the two-electron reduction potential at pH 6.1 for the redox couple of oxoiron(IV) indolyl$^{\bullet+}$ and aquoiron(III) indolyl is +740 mV.[1490] In a model compound in which an oxoiron(IV) is coordinated equatorially by the nitrogens of four pyridines and has a proximal axial ligand of a trialkylamine,[1491] a coordination similar to that of heme, the biochemical standard reduction potential for the redox couple of oxoiron(IV) and hydroxyiron(III) at pH 4 is +650 mV. These significantly **positive standard reduction potentials** permit such intermediates to participate as strong one-electron acceptors.

In an oxoiron(IV) porphyrin$^{\bullet+}$, the highest occupied molecular orbital of the porphyrin, which is occupied by the unpaired electron and the hole, has its **greatest spin density at the four meso positions** (carbons 5, 10, 15, and 20 in **2–69**),[1430] and these positions should be locations at which transfer of an electron can occur. In the peroxidase from *A. rusticana*, the channel that leads from the solution to the heme, in which the substrates are oxidized by the enzyme, is centered on one of these meso positions.[1492] During the oxidation of phenylhydrazine by the peroxidase from *C. cinerea*, which leads to inactivation of the enzyme, phenyl radical is produced within the active site by the successive abstraction by the enzyme of the equivalent of three hydrogen radicals from the two nitrogens of the phenylhydrazine, which leads to the production of molecular nitrogen and the phenyl radical. The phenyl radical then phenylates one of the meso positions of the heme.[1493] Because the phenyl radical (bond dissociation energy = 470 kJ mol^{-1}) is so reactive, its insertion at the meso carbon suggests that the meso carbon was immediately adjacent to it when it was formed.

In the reaction catalyzed by L-ascorbate peroxidase and cytochrome-*c* peroxidase, the hydrogen peroxide or alkyl hydroperoxide that produces the oxoiron(IV) porphyrin$^{\bullet+}$ associates with Fe^{3+} of the heme (Equation 2–240) and is turned into a molecule of water or alcohol, respectively, and the oxygen of the oxoiron(IV) porphyrin$^{\bullet+}$ (Equation 2–241). The oxygen of the oxoiron(IV) porphyrin$^{\bullet+}$ becomes a molecule of water following the formal transfer of two electrons and two hydrons. The net result is either that the hydrogen peroxide is turned into two molecules of water or that the alkyl hydroperoxide is turned into a molecule of alcohol and a molecule of water. Either result accomplishes the purpose of **removing peroxides**. In the process, two one-electron reductants, L-ascorbate and ferrocytochrome *c*, respectively, provide the required reducing equivalents.

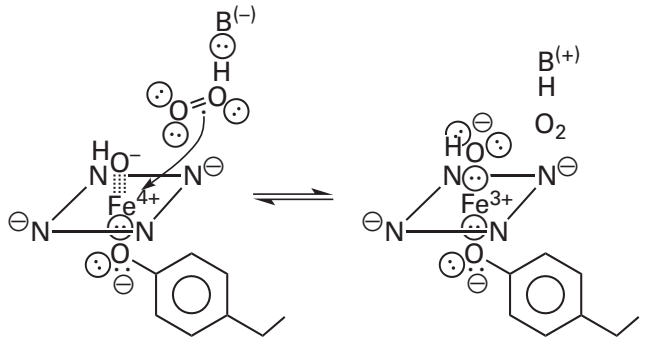
Catalase (Equation 2–242) uses the oxoiron(IV) porphyrin$^{\bullet+}$, or the oxoiron(IV) porphyrin phenoxy$^{\bullet}$, formed in its active site (Figure 2–51) from hydrogen peroxide to **oxidize a second molecule of hydrogen peroxide to molecular oxygen**, a reaction that is of course only appropriate to aerobic organisms and that serves twice over the role of removing hydrogen peroxide from the cytoplasm. It has been demonstrated that oxoiron(IV) porphyrin$^{\bullet+}$, formed nonenzymatically in a synthetic heme, can readily abstract a hydrogen atom from hydrogen peroxide[1432] to produce hydrogen superoxide radical



(2–243)

The bimolecular rate constant of this nonenzymatic reaction in solution at 25 °C is 10^7 M^{-1} s^{-1}, and the magnitude of this rate constant suggests that no catalysis is required at this step in the enzymatic reaction. The other product of this reaction is the hydroxyiron(IV) porphyrin,[1494] an intermediate formed stably when the oxoiron(IV) porphyrin$^{\bullet+}$ of catalase is reduced by a one-electron donor rather than a two-electron donor such as hydrogen peroxide.

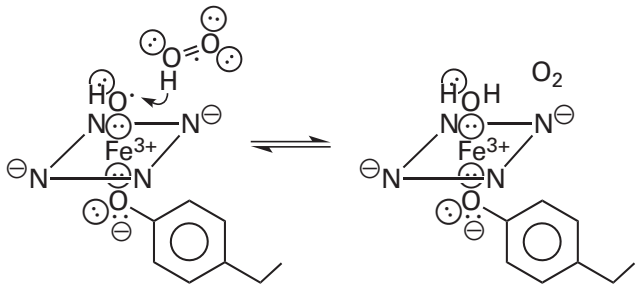
The last step in the enzymatic reaction of catalase could be transfer of an electron from hydrogen superoxide radical coupled to removal of a hydron



(2–244)

The imidazolyl group of the histidine, which removed the hydron from the proximal oxygen of hydrogen peroxide (Equation 2–240) and added the hydron to the distal oxygen (Equation 2–241), could remove a hydron from hydrogen superoxide radical while an electron is transferred from the superoxide radical anion to Fe^{4+}. In this case, the hydroxyiron(IV) porphyrin is acting as a hydroxide on Fe^{4+}, which is a strong oxidant. The imidazolium ion could then add a hydron to the hydroxide on hydroxyiron(III) porphyrin (Equation 2–244) to return the heme to aquoiron(III) porphyrin.

An alternative possibility for the last step is the abstraction of a second hydrogen atom by the hydroxyiron(IV) porphyrin from the hydrogen superoxide radical that has turned around within the active site of the enzyme[1432]



(2–245)

In this reaction the hydroxyiron(IV) porphyrin would be functioning as a hydroxyl radical on Fe^{3+}. A hydroxyl radical (bond dissociation energy = 497 kJ mol^{-1}) is capable of abstracting a hydrogen atom from almost anything. Either scenario is consistent with the fact that when a mixture of $H_2{}^{18}O_2$ and $H_2{}^{16}O_2$ is used as substrate for catalase, the molecular oxygen produced had the same percentage of doubly labeled $^{18}O_2$ as the percentage of doubly labeled $H_2{}^{18}O_2$ in the mixture,[1495] a result requiring that the σ oxygen–oxygen bond of the $H_2{}^{18}O_2$ remains intact during the enzymatic reaction.

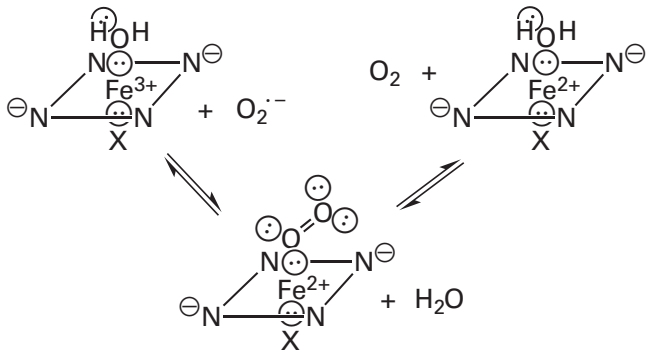
There are, however, as already noted, many **peroxidases that use the oxoiron(IV) porphyrin$^{\bullet+}$ to perform useful oxidations of particular substrates**, rather than just removing hydrogen peroxide from the cytoplasm. For example, manganese peroxidase uses its oxoiron(IV) porphyrin$^{\bullet+}$ in two successive removals of an electron from each of two Mn^{2+}·oxalate^{2-} ylides. Each Mn^{3+}·oxalate^{2-} ion it produces is a strong oxidant that is used to degrade lignin, one of the components of wood and one of the most difficult biological polymers to degrade. The inability to degrade lignin was responsible for the Carboniferous period. Lignin peroxidase also uses its oxoiron(IV) porphyrin$^{\bullet+}$ productively to remove two successive electrons from methoxyphenols in lignin by an outer-sphere electron transfer[1451] or an inner-sphere electron transfer[1496] to produce π radical cations in the lignin that lead to its fragmentation.[1497] In mammalian prostaglandin-endoperoxide synthase, there is a hemoperoxidase the only purpose of which is to regenerate the tyrosyl radical in the active site of the enzyme that is required for prostaglandin synthesis[1498] when that tyrosyl radical is occasionally lost by an adventitious reduction. This peroxidase uses its oxoiron(IV) porphyrin$^{\bullet+}$ to abstract either a

hydrogen or an electron from the tyrosine to regenerate the necessary tyrosyl radical.[1499,1500] The oxoiron(IV) porphyrin$^{\bullet+}$ in the active site of a dehaloperoxidase from *Amphitrite ornata* removes two electrons, one at a time, from a single molecule of chlorophenol to produce 4-benzoquinone and chloride.[1501]

During the oxidations of substrates catalyzed by hemoperoxidases, the hydrogen abstractions and electron transfers performed by oxoiron(IV) porphyrin$^{\bullet+}$ and hydroxyiron(IV) porphyrin often generate reactive oxidants in the vicinity of the heme. In many of these enzymes, these reactive oxidants adventitiously modify the heme itself or amino acids nearby. In catalase, the heme *b* in the active sites of the initially synthesized enzyme is often modified by oxidation to heme *d* (Figure 2–51);[653] in lactoperoxidase and iodide peroxidase, the hemes *b* are modified by oxidation to hemes *l*;[1502] and in myeloperoxidase, the heme *b* is modified by oxidation to heme *m*.[1503,1504] Such **adventitious oxidations** account for the existence of many if not most of these unusual hemes. In several of these instances, the oxoiron(IV) porphyrin$^{\bullet+}$ modifies amino acids in the protein as well. In a catalase, an adjacent sulfanyl group of a cysteine[1477] or the nitrogen of an adjacent imidazolyl group from a histidine[1478] is often oxidatively coupled to the β carbon of the tyrosinate that coordinates the iron ion. In catalase-peroxidase from *M. tuberculosis*, a methionine, a tryptophan, and a tyrosine have all been oxidatively coupled together.[1505,1506] Perhaps, originally, this coupling was adventitious, but presently this covalent complex is the location of a radical that forms during turnover of the enzyme and is essential for its enzymatic activity.[1507-1509] In cytochrome-*c* peroxidase from *S. cerevisiae*, an electron is removed adventitiously from each of two tyrosines in the protein during catalysis.[1510]

Hydrogen peroxide-dependent heme synthase from *G. stearothermophilus* is an enzyme that turns coproheme III, the complex between an iron ion and uroporphyrinogen III (**2–70**) and hence a precursor of heme *b*, into heme *b* (**2–69**), which is the precursor of almost all prosthetic hemes. Coproheme III has 2-carboxyethyl groups at positions 3 and 8 instead of vinyl groups, and the enzyme turns those two carboxyethyl groups into the vinyl groups that are in heme *b*. In the active site of the enzyme, the Fe^{3+} in coproheme that is a reactant is turned into an oxoiron(IV) tyrosine$^{\bullet}$ in the usual way with hydrogen peroxide.[1511] The tyrosine radical abstracts a hydrogen from carbon 1 of a 2-carboxyethyl group that then undergoes **oxidative decarboxylation** to become a vinyl group. The oxidative decarboxylation is then repeated at the other 2-carboxyethyl group. During the oxidative decarboxylation, an electron is transferred to the oxoiron(IV) porphyrin to regenerate the hydroxyiron(III) in the heme that was the reactant for the enzyme. This reaction resembles the adventitious reactions in which hemes in the active sites of peroxidases are oxidatively modified, but instead of a prosthetic heme being modified, it is a heme that is the reactant for the enzymatic oxidation.

A hemoperoxidase is usually inhibited by superoxide radical anion, which forms a complex with Fe^{3+} in the resting state of its heme (Figure 2–50). This complex is identical to the one that results when molecular oxygen binds to an Fe^{2+} in its heme[1512]



(2–246)

The complex between a ferrous heme and molecular oxygen is an **oxyiron(II) porphyrin** (see Figure 2–50).

Ferrous hemes in hemoproteins such as hemoglobin and myoglobin form reversible complexes with molecular oxygen. In these proteins, the proximal axial ligand to the iron, opposite the open site, is the imidazolyl group of a histidine in the protein and the open ligand position opposite this imidazolyl group is the one occupied by the molecular oxygen. Because an Fe^{2+} is less acidic when it is in a heme than when it is in solution, it forms complexes with bases such as water or hydrogen peroxide poorly. Consequently, when a ferrous heme is in aqueous solution in the absence of molecular oxygen, carbon monoxide, or similar ligands, the open site is vacant or fitfully occupied. The purpose of the complex between molecular oxygen and the Fe^{2+} in the heme in a hemoglobin at the open site is to carry the molecular oxygen from a location of high concentration to a location of low concentration: for example, from

the lungs to the skeletal muscles in a mammal. The heme in at least one hemoglobin, that from *A. ornata*, is able to double as a carrier of molecular oxygen and as a peroxidase. In its ferrous form it carries molecular oxygen, and in its ferric form it is a peroxidase.[1513]

There are several **facts that are known about the complex** between oxygen and a ferrous heme. It is diamagnetic.[1313] This fact states that all electrons in the complex are paired. The Fe–O–O angle in the oxygen complex of a heme model compound, the crystallographic molecular model for which can be constructed with high accuracy (Figure 2–52),[1514] is 129°. The Fe–O–O angles in crystallographic molecular models of oxymyoglobin from *P. macrocephalus* (123°)[1515-1518] and human oxyhemoglobin (125°)[1519] from data sets collected to Bragg spacings of 0.12 nm are almost the same as that in the model compound. Nuclear magnetic resonance spectra of $^{17}O_2$ bound to heme model compounds are in agreement with this bent ligation.[1520] In complexes between molecular oxygen and the hemes in hemoglobin[1519,1521] and myoglobin,[1517,1518,1522] a hydrogen bond forms between the distal oxygen of the molecular oxygen and the imidazolyl group of a histidine (Figure 2–53).[1523,1524] In a complex between molecular oxygen and the heme in the hemoglobin from *Ascaris suum*, there are hydrogen bonds between the distal oxygen and the 4-hydroxyphenyl group of a tyrosine and between the proximal oxygen and the carbamoyl group of a glutamine.[1525]

The Fe–O–O bond angle of 126° and the observed hydrogen bonds suggest that there are **two sp^2 lone pairs of electrons** on each oxygen (Equation 2–246) when it is bound by the iron. The **oxygen–oxygen bond length** in the complex (0.123 ± 0.01 nm),[1514,1516,1517,1519] however, is almost indistinguishable* from that of molecular oxygen itself (0.121 nm) and is much shorter than that of superoxide radical anion (0.133 nm)[1295] or hydrogen peroxide (0.148 nm). This fact only states that the bond order is the same as that in molecular oxygen and that the net of one π bond remains in the oxygen–oxygen bond. In other words, there are two more electrons in bonding π molecular orbitals than there are in antibonding π molecular orbitals. This conclusion does not mean, however, that the bound molecule of oxygen has the same π molecular orbital systems as an unbound molecule of oxygen.

Iron(II) has an even number of electrons (6 valence electrons and 18 core electrons); but it is paramagnetic in the high-spin state, as is molecular oxygen in the triplet state, because there are four unpaired electrons in the five $3d$ atomic orbitals (Figure 2–25). Upon the entry of Fe^{2+} into a heme, the high-spin state becomes less stable, but it is still more stable than the low-spin, diamagnetic state in which all electrons would be paired. Upon formation of the complex, the six formerly unpaired electrons, four from iron and two from oxygen, must become paired because the complex is diamagnetic.[1313] In the process of pairing these electrons, the proximal of the two oxygens becomes bonded to the iron.

Although there is little agreement on the details of the electronic structure, even though there is little ambiguity in the facts, several features of the bonding of molecular oxygen to the ferrous ion in a heme are commonly emphasized. Mixing between one or two d atomic orbitals on iron (d_{xz} and d_{yz} or both) and one or more of the four off-axial p atomic orbitals on the two oxygen atoms (p_x orbitals and p_y orbitals, or some set of both of these off-axial orbitals) creates one or two $dp\pi$ molecular orbital systems, each with a bonding and an antibonding molecular orbital. There is also the possibility of a third nonbonding molecular orbital formed from two p atomic orbitals, one from each oxygen, and a d atomic orbital from the iron ion. The occupied, bonding $dp\pi$ molecular orbitals provide energy to the bond. The **entry of d electrons from iron into antibonding π molecular orbitals** on molecular oxygen in turn enhances the basicity of one of the σ lone pairs of electrons on the proximal oxygen so that it can form a σ bond with the d_{z^2} orbital on iron.[1294] The atomic orbital on the oxygen that participates in the σ bond with iron must have gained sufficient p character to cause the oxygen atom in the bond to have almost sp^2 hybridization because the Fe–O–O bond has an angle of around 125° and the proximal oxygen that is bonded directly to the iron can also accept a hydrogen bond, presumably with the pair of electrons in the other sp^2 orbital. If the σ orbitals of the lone pairs of electrons on molecular oxygen had not gained extra p character, they would have remained

*This equivalence assumes that the oxygen–oxygen bond was unconstrained in the several refinements.

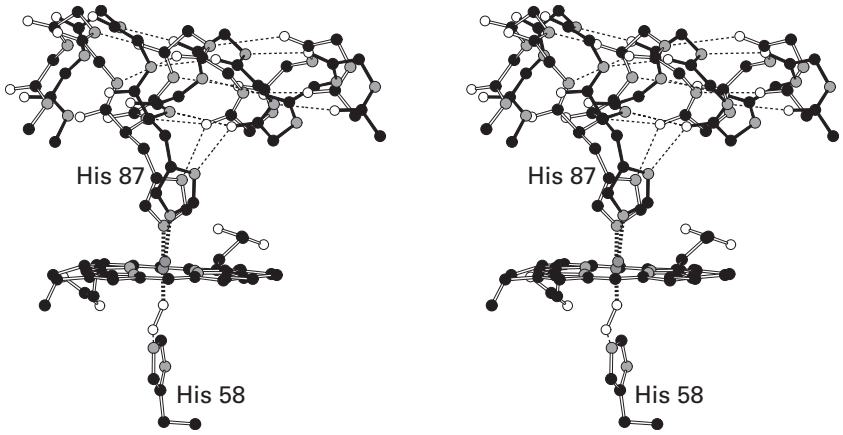


Figure 2–53: Stereodrawing[50] of portions of the superposed crystallographic molecular models of human oxyhemoglobin (white bonds) and human deoxyhemoglobin (black bonds) in the regions surrounding the histidine that is the fifth ligand to the iron in the heme from the α subunit.[1523,1524] Black atoms are carbons, white atoms are oxygens, gray atoms are nitrogens, and dark gray spheres surrounded by ligands are iron ions. The hemes in the two crystallographic molecular models have been superposed so that the changes demonstrated in the drawing between oxyhemoglobin and deoxyhemoglobin are relative to the fixed hemes. The α helices from both oxyhemoglobin and deoxyhemoglobin that contains the respective histidines (Histidines 87) are drawn as well as the iron ions in each heme, the molecule of oxygen bound to the iron in oxyhemoglobin, and the imidazolyl group of Histidine 58 that forms a hydrogen bond to the molecule of oxygen bound to the iron in oxyhemoglobin. For clarity, however, only the heme from oxyhemoglobin, viewed edge-on, is drawn because the two hemes, which have been purposely superposed, overlap each other throughout their structures, and this superposition would complicate the drawing. Aside from the side chains of the respective Histidines 87, only the peptide backbones of the two α helices are presented. The hydrogen bonds within each α helix and the hydrogen bond between the molecule of oxygen and Histidine 58 are drawn as thin dashed lines. The bonds between the respective iron ions and the imidazolyl groups of the coordinated histidines and the molecule of oxygen are drawn with thick dashed lines. In the deoxy conformation of the protein, the position of the imidazolyl group in Histidine 87 is such that it pulls the iron out of the plane of the heme. In the oxy conformation of the protein, the α helix shifts its position to the left, the imidazolyl group comes closer to the center of the heme, and the iron drops into the plane of the porphyrin. The binding of oxygen, because it is much stronger when the iron is in the plane of the porphyrin than when it is pulled away from the center, shifts the equilibrium between the deoxy conformation and the oxy conformation in favor of the oxy conformation.

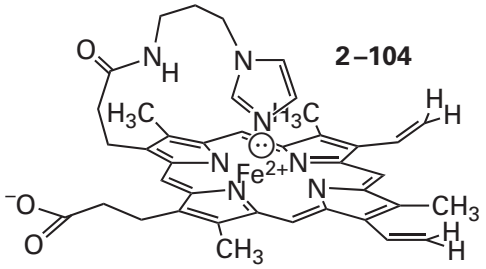
aligned with the axis of the two oxygen atoms, and the Fe–O–O bond angle would have been 180° because the σ molecular orbital system in molecular oxygen is required to be axially symmetric. Presumably, this extra p character in the σ bond to the iron results from occupation of antibonding π molecular orbitals on oxygen by electrons from the iron ion. This intrusion of electron density causes pairs of electrons in the delocalized π molecular orbitals to become localized, just as they are either during the production of superoxide radical anion or during the production of hydrogen peroxide. In each of these cases, an electron is added to an antibonding π molecular orbital during the respective reduction.

As electron density, entering what were formerly antibonding orbitals, is gained from iron in the π molecular orbitals on oxygen and all the valence electrons become paired, the net π bonding between the two oxygen atoms—the difference between occupation of bonding and antibonding orbitals—must not change because the oxygen–oxygen bond length remains the same. After these readjustments have taken place, there is excess electron density on the molecular oxygen, creating negative formal elementary charge on the distal oxygen.[1526] Therefore, iron, in the electron-rich, ferrous state, has contributed more electron density to the $dp\pi$ molecular orbital system than the oxygens, both more electronegative atoms, has contributed to the σ bond. The unique feature of Fe^{2+} in this reaction is the ability of its d orbitals to overlap with the π molecular orbital system of oxygen and donate sufficient electron density through the resulting π molecular orbital systems. This **back donation of π electron density to the π molecular orbital system of the molecular oxygen** is a common feature of the prosthetic cations of transition metals that interact directly with molecular oxygen.

The reversible association between hemoproteins and oxygen can be duplicated quite closely with the **synthetic heme**



2–104

and its homologues when they are dissolved in aqueous solutions of detergents.[1527,1528] The detergent provides micelles into which these hemes can dissolve. Properties of hemes in globins that are duplicated by the synthetic heme include changes in optical spectra upon ligation, dissociation constants, and on and off rates. These observations suggest that the protein of monomeric globins such as myoglobin simply provides a convenient way of simultaneously dissolving the otherwise insoluble heme in water, sterically preventing the formation of stable heme dimers held together by peroxide dianion, and providing the required axial ligand opposite the open site on the Fe^{2+}.

The **affinity for oxygen of the heme** in oligomeric globins such as hemoglobin, which contains four hemes, is further influenced by the structure of the protein. Depending on the conformation of the protein, the hemes in hemoglobin have either low or high affinity for oxygen. The Fe^{2+} is displaced in the direction of the imidazolyl group in the uncoordinated heme, which usually has no sixth ligand, by the electron repulsion between the four lone pairs of electrons on the pyrrole nitrogens and the lone pair of electrons on the nitrogen of the imidazolyl group. When molecular oxygen binds, the Fe^{2+} moves into the center of the heme[1514] because the σ bond and the $dp\pi$ bonds to the oxygen balance the electron repulsion on the two sides of the heme. Because the iron must move into the plane of the heme during the association of molecular oxygen, any steric constraint that hinders this movement should decrease the affinity of the heme for molecular oxygen. When alterations are made in the structure of heme model compound **2–104** that pull the imidazolyl group away from the plane of the porphyrin and consequently hinder the movement of the iron into the plane, the affinities for oxygen decrease.[1529]

It is also possible to compare crystallographic molecular models of hemoglobin in the conformations of high affinity and low affinity.[1530] In the conformation of low affinity, the α helix in which the histidine providing the axial ligand opposite the open site is located has moved relative to its position in the conformation of high affinity. This movement pulls the imidazolyl group farther away from the plane of the heme. Because the iron should respond to this tug, the movement of this α helix should be at least part of the explanation for the lower affinity

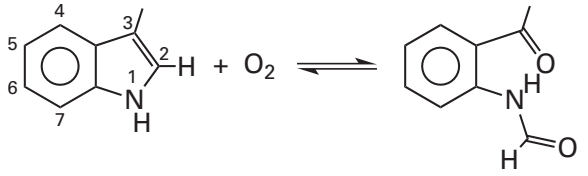
for molecular oxygen in this conformation (Figure 2–53).[1523,1524] In the conformation of high affinity, the imidazolyl group is not pulled away from its unconstrained position.

Occasionally the iron–oxygen bond in the complex between molecular oxygen and a ferroheme splits heterolytically to yield superoxide radical anion and iron(III) porphyrin

$$O_2{\cdot}Fe^{2+}{\cdot}\text{porphyrin} \longleftrightarrow O_2^{\cdot -}{\cdot}Fe^{3+}{\cdot}\text{porphyrin} \rightleftharpoons O_2^{\cdot -} + Fe^{3+}{\cdot}\text{porphyrin} \qquad (2\text{–}247)$$

The molecular oxygen bound reversibly to a heme in hemoglobin or myoglobin, however, is almost inert to this dissociation. It has already been pointed out that oxyiron(II) is not simply a molecule of oxygen associated through its σ molecular orbital system with an Fe^{2+}. Nor is it simply a superoxide radical anion associated by the bonding of one of its σ lone pairs of electrons with an Fe^{3+}. In some contexts, however, it is useful to assume that oxyiron(II) has properties expected of a superoxide radical anion associated with an Fe^{3+}, a superoxyiron(III). Some justification for this assumption is that in the active site of the TxtE protein from *Streptomyces scabiei*, which nitrates the phenyl ring of L-tryptophan, the prosthetic oxyiron(II) porphyrin participates in a colligation with the neutral radical nitric oxide to form peroxynitrite ion as the axial ligand to iron(III) porphyrin.[1531] This colligation acts as a detection of a radical.

The advantage of considering oxyiron(II) porphyrin as superoxyiron(III) porphyrin, which is similar to what is done when the properties of a molecule are considered to be the consequence of only one of its resonance forms, is illustrated by the indole dioxygenases. Tryptophan 2,3-dioxygenase[1532] and indoleamine 2,3-dioxygenase[1533] are two distantly related enzymes[1534] that both use hemes for the dioxygenation of the respective indolyl group

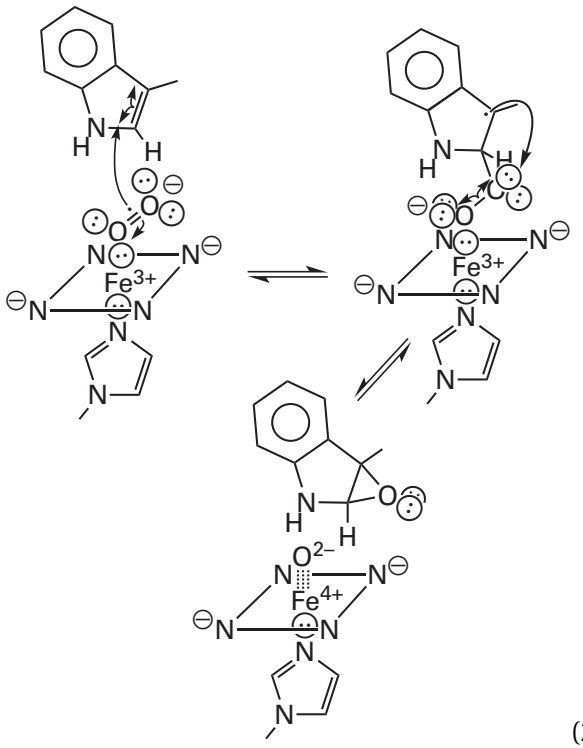


(2–248)

They are often present together in the same species, and they are assumed to have the same mechanism. In the reactions catalyzed by tryptophan 2,3-dioxygenase from *Pseudomonas*[1535] and by human tryptophan 2,3-dioxygenase,[1536] the respective products, each *N*-formyl-L-kynurenine, contain both oxygens from the molecular oxygen, a fact that causes tryptophan 2,3-dioxygenase to be designated a dioxygenase.

The first step in the mechanism of tryptophan 2,3-dioxygenase is the binding of molecular oxygen to the ferroheme adjacent to an already bound L-tryptophan to produce the usual oxyiron(II) porphyrin. The identical complex can be produced by association of superoxide radical anion with the ferric heme.[1537] Synthetic complexes between superoxide radical anion and several similarly coordinated Fe^{3+} are able to convert a number of indoles into the corresponding 2,3-dioxygenated products.[1538] In the crystallographic molecular model of the complex between L-tryptophan and tryptophan 2,3-dioxygenase from *Xanthomonas campestris*,[1534] the closest carbon of the indolyl group to the iron of the heme is carbon 2, and in the crystallographic molecular model of the complex between L-tryptophan, molecular oxygen, and human tryptophan 2,3-dioxygenase,[1539] the closest carbon to the distal oxygen is also carbon 2, which is 0.31 nm away, within the sum of the van der Waals radii (0.33 nm).

After the association of molecular oxygen with ferrous heme, the equivalent of a superoxide radical anion (Equation 2–247) on an iron(III) porphyrin is then thought to participate in a radical addition at carbon 2 of the indolyl group[1540,1541] to produce the equivalent of an alkylperoxyiron(III) porphyrin and a tertiary radical at carbon 3 of the indolyl group



(2–249)

significantly stabilized by delocalization into the phenyl ring. During **addition of the radical in the superoxide radical anion to the double bond,** π electron density is withdrawn onto the proximal oxygen as the bond between the distal oxygen and the carbon forms. When substituents that withdraw more and more of this π electron density into the heme are added to the porphyrin, the rate of disappearance of the oxyiron(II) porphyrin, a measure of formation of the σ bond, increases,[1542] and in the synthetic complexes, the most electron-deficient superoxyiron(III) complexes and the most electron-rich indoles are observed to form the oxygenated products with the greatest rates.[1538]

The alkylperoxyiron(III) then dissociates homolytically, rather than heterolytically, into the **2,3-epoxide of the indolyl group** and oxoiron(IV) porphyrin,[1541] rather than the oxoiron(IV) porphyrin$^{\bullet+}$. There is a side product of the enzymatic reaction catalyzed by both human tryptophan 2,3-dioxygenase and human indoleamine 2,3-dioxygenase that could reasonably arise from intramolecular nucleophilic addition of the α-amino group of L-tryptophan to carbon 2 of the 2,3-epoxide,[1536] and this side product is considered to be an indicator of the existence of the epoxide in the normal mechanism. The MarE protein from *Streptomyces* is a hemoprotein that is a distant relative of tryptophan 2,3-dioxygenase and indoleamine 2,3-dioxygenase. It catalyzes the monooxygenation of indole to 1,3-dihydroindol-2-one, a product that would result from dissociation of the 2,3-epoxide of indole at carbon 3 to form the tertiary carbenium ion, stabilized by delocalization into the phenyl ring, followed by a hydride migration[1543] from carbon 2 to the carbenium ion on carbon 3.

In the active sites of tryptophan 2,3-dioxygenase and indoleamine 2,3-dioxygenase, however, oxoiron(IV) porphyrin and the 2,3-epoxide are converted to the products, *N*-formyl-D-kynurenine and iron(II) porphyrin. All that is known about these latter steps is that the oxygen of oxoiron(IV) porphyrin, as well as the other oxygen from the original molecular oxygen, is incorporated into the products, but the results from the MarE protein suggests that dissociation of the epoxide at carbon 2 to form the iminium of nitrogen 1, rather than the tertiary carbenium ion at carbon 3, could initiate oxidative cleavage of the carbon–carbon bond.

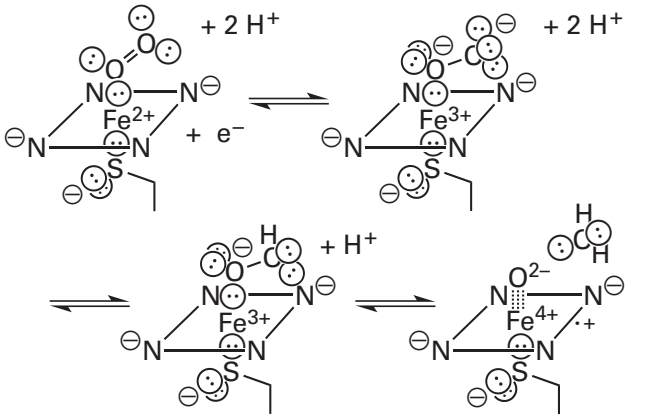
Proteins containing hemes P450 comprise a family of enzymes in which a complex between molecular oxygen and ferroheme can be reduced by one electron to peroxyiron(III) porphyrin or hydroperoxyiron(III) porphyrin. Historically, the members of this family have been referred to as cytochromes P450 even though they are not responsible for electron transfer. Each member of this family of enzymes has a heme in which the proximal axial ligand opposite its open site is the sulfido group of a cysteine.[662,1544,1545] This sulfido group is responsible for the absorption maximum of the heme at 450 nm, which gives this family the name cytochromes P450. Although the criterion for membership in this family of enzymes is only the possession of a heme with a sulfido group as the proximal axial ligand, most members of the family catalyze similar oxidations and have superposable tertiary structures.

The **resting state** of a prosthetic heme P450 is aquoiron(III) porphyrin (see Figure 2–50), the ferric heme with its open site occupied by a molecule of water. In most of these enzymes, reduction of the heme to the ferrous state by transfer of one electron is performed either by a [2Fe–2S] ferredoxin[1546,1547] or by flavoenzyme NADPH—hemoprotein reductase, which can be either a separate protein[1548] or a separate domain of the enzyme containing the heme P450 itself.[1152] Following production of the ferrous heme by transfer of one electron, oxygen binds to form a complex stereochemically indistinguishable from oxyiron(II) porphyrins in model compounds (Figure 2–52)[1514,1549,1550] except that, as in hemoglobin and

myoglobin, the dioxygen is confined to a single orientation by steric effects and by a hydrogen bond between a side chain from the protein and the distal oxygen.

Usually **reduction of the heme to the ferrous state**, which initiates the catalysis; the **association of the oxygen**; the eventual production of an unstable oxoiron(IV) porphyrin$^{\bullet+}$; and then its conversion to an unstable hydroxyiron(IV) porphyrin occur efficiently only after the reactant to be oxidized has bound to the active site of the enzyme so that it is prepared for the oxidation.[1551] Binding of the reactant also changes the spin state of Fe^{3+} in the aquoiron(III) porphyrin from low-spin to high-spin,[1552,1553] increases the biochemical standard reduction potential of the aquoiron(III) porphyrin, and stabilizes the subsequent complex between ferrous heme and molecular oxygen.[1554]

Following the binding of molecular oxygen to the iron(II) porphyrin, there is a second one-electron reduction. The second electron is provided by another molecule of the same ferredoxin or by the second electron from the flavin semiquinone of NADPH—hemoprotein reductase. The complex between molecular oxygen and Fe^{2+} in the heme is reduced by one electron to give **peroxyiron(III) porphyrin**[1555,1556]



(2–250)

where peroxyiron(III) is the complex (Figure 2–50) between peroxide dianion and Fe^{3+}. This intermediate has been produced in a stable form in solution with a synthetic heme by reducing the complex between its Fe^{2+} and molecular oxygen by one electron, and its spectroscopic properties have been documented.[1557]

The peroxyiron(III) porphyrin is then hydronated on its distal oxygen to form **hydroperoxyiron(III) porphyrin** (see Figure 2–50),[1555,1558,1559] which is the same as the complex between the ferriheme in a hemoperoxidase and hydroperoxide ion (Equation 2–240) except for the identity of the catalytic acid–bases that surround it. Again, this intermediate has been produced in a stable form in the same synthetic heme by hydronating the peroxyiron(III) porphyrin.[1557]

As in a peroxidase, the hydroperoxyiron(III) porphyrin is heterolytically cleaved under acid catalysis[1560] to give oxoiron(IV) porphyrin$^{\bullet+}$.[1549,1561,1562] The peroxyiron(III) porphyrin in the active site of chloride peroxidase from *Leptoxyphium fumago* can be trapped as a stable species at 77 K and converts first to the hydroperoxyiron(III) porphyrin, which is also stable until the temperature is raised further, at which point it then converts to the oxoiron(IV) porphyrin$^{\bullet+}$, but this intermediate can be observed only at temperatures below 220 K.[1456]

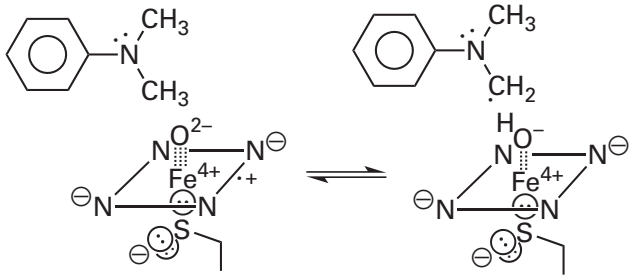
Because, in most cases, none of these transformations leading to the production of oxoiron(IV) porphyrin$^{\bullet+}$ in a heme P450 can occur until the reactant is bound and ready to be oxidized, most studies of the oxoiron(IV) porphyrin$^{\bullet+}$ in these enzymes have of necessity been of the evanescent intermediates in the enzymatic reaction, which almost immediately oxidize the substrate. For example, at 4 °C, the complex between iron(II) porphyrin, camphor, and molecular oxygen in the active site of camphor 5-monooxygenase from *P. putida* can be rapidly reduced by hydrated electrons to hydroperoxyiron(III) porphyrin, which then decays with a rate constant 96 ms^{-1} to iron(III) porphyrin, but no intermediates are observed.[1563] This observation demonstrates that the rate-limiting step, at least in this case, is heterolytic dissociation of the hydroperoxyiron(III) porphyrin and that all the steps in the reaction following formation of the resulting oxoiron(IV) porphyrin$^{\bullet+}$ are so fast that they are hidden from observation.

Stable forms of the oxoiron(IV) porphyrin$^{\bullet+}$, however, have been produced in chloride peroxidase from *L. fumago*[1564,1565]and in the peroxidase from *S. acidocaldarius*,[1566,1567] both of which contain hemes P450 by virtue of having sulfido groups as their proximal ligands. In chloride peroxidase, the **length of the iron–oxygen bond** (0.165 nm) is shorter than that in a hemoperoxidase (0.172 nm) that has an imidazolyl group as its proximal ligand rather than a sulfido group[1565] because electron donation from the sulfido group of the cysteine that is the axial ligand to the iron opposite the oxygen of the oxoiron(IV) fills in the π molecular orbitals and gives the

bond between the iron ion and the oxygen greater triple-bond character. When the oxoiron(IV) porphyrin$^{\bullet+}$ of the peroxidase from *S. acidocaldarius* is reduced unnaturally by one electron and spontaneously hydronates to become hydroxyiron(IV) porphyrin, the bond length of the iron–oxygen bond increases to 0.182 nm as more electron density is withdrawn onto the oxygen from the π molecular orbitals and the bond becomes more like a single σ bond.[1568]

Although most enzymes containing hemes P450 use molecular oxygen as the substrate to produce oxoiron(IV) porphyrin$^{\bullet+}$ coincident with two one-electron reductions, there are examples that use only hydrogen peroxide and no reductant to produce oxoiron(IV) porphyrin$^{\bullet+}$, just as a peroxidase would.[1569-1571] Regardless of how the enzyme containing a heme P450 produces the oxoiron(IV) porphyrin$^{\bullet+}$, however, it seems to have the same capabilities, as a result, in part, of the cysteine that is the ligand to the iron ion opposite the oxygen.[1562]

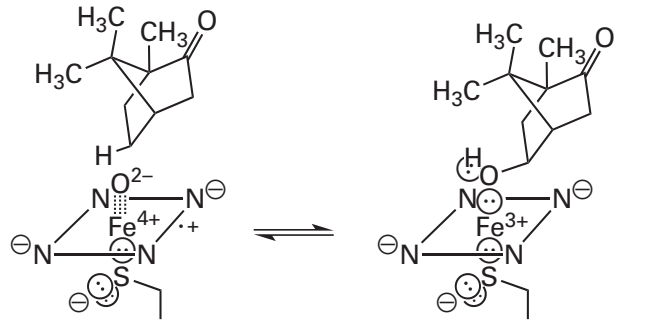
Enzymes containing hemes P450 catalyze several different types of oxidations. The oxoiron(IV) porphyrin$^{\bullet+}$ of a heme P450 can engage two successive **one-electron transfers**,[1572] as it does in a hemoperoxidase. It can **epoxidize olefins** (Equation 2–234),[1573,1574] just as it does in nonenzymatic reactions. It can **abstract a hydrogen atom** from a carbon adjacent to an amino nitrogen[1575]



(2–251)

And it can **remove the equivalent of a hydride** from a secondary alkane.[1576]

The most common oxidations catalyzed by hemes P450, however, are **hydroxylations of alkanes**. An example of the hydroxylation of an alkane is the stereospecific exo hydroxylation of camphor catalyzed by camphor 5-monooxygenase



(2–252)

To hydroxylate a saturated carbon requires a strong oxidant. It has been proposed that the advantage of a sulfido group as the proximal ligand is that it decreases the biochemical standard reduction potential of the oxoiron(IV) porphyrin$^{\bullet+}$, which is one of the intermediates in these reactions, into a range in which it is a strong enough oxidant to hydroxylate a saturated carbon but not strong enough to pull an electron irreversibly out of the tyrosines elsewhere in the protein.[1434]

Theoretical calculations[1577] have led to the suggestion that the **mechanism of hydroxylation** takes place in three steps. The oxoiron(IV) porphyrin$^{\bullet+}$ that is formed in the active site first abstracts the hydrogen atom of the carbon–hydrogen bond to be hydroxylated. The resulting hydroxy group on the hydroxyiron(IV) porphyrin (see Figure 2–50) and the alkyl radical reorient so that the orbital containing the unpaired electron on the hydroxyl radical of the hydroxyiron(IV) porphyrin and the orbital containing the unpaired electron of the alkyl radical can overlap. The two unpaired electrons in these two orbitals colligate to form a covalent bond between the carbon of the alkyl group and the oxygen of the hydroxy group.

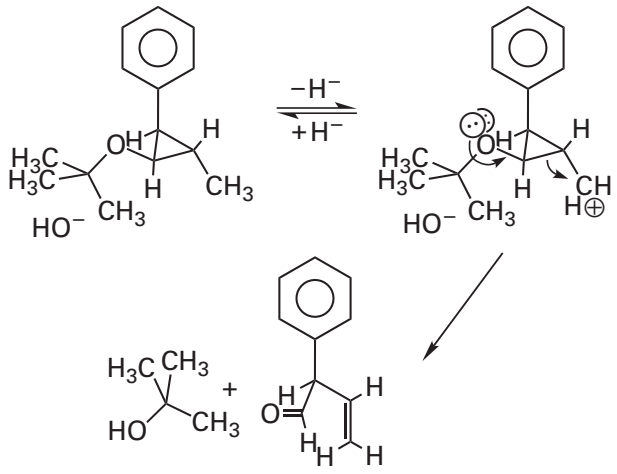
There are **a number of facts** that are consistent with this suggestion. When the hydrogen to be replaced by the hydroxy group is replaced by a deuterium, the rate of the enzymatic hydroxylation at that location decreases[1578] by a factor of as much as 10.[1579] Because the initial hydrogen abstraction is usually the rate-limiting step in a hydroxylation catalyzed by a heme P450 , the postulated hydroxyiron(IV) porphyrin has rarely been observed, but in the active site of terminal olefin-forming fatty acid decarboxylase from *Jeotgalicoccus*, an enzyme containing a heme P450, even though the rate of the reaction decreases by a factor of 8 when the hydrogen abstracted is replaced by a deuterium, the hydrogen abstraction is not completely rate-limiting, and hydroxyiron(IV) porphyrin has been observed as a

transient intermediate in the enzymatic reaction.[1580] The hydroxylation of an asymmetric carbon with a deuterium and a hydrogen, on which the hydrogen is replaced by a hydroxy group, proceeds with significant but not complete racemization.[1579,1581,2609] Both results suggest that a planar intermediate such as a carbenium ion or carbon radical is formed by removal of a hydride or a hydrogen atom, respectively, from the carbon to be hydroxylated. The rate constants for hydroxylation of a series of alkanes by the oxoiron(IV) porphyrin$^{\bullet+}$ in the active site of unspecific peroxygenase from *Agrocybe aegerita* decrease monotonically as the bond dissociation energies of the hydrogen that is replaced increase.[1582] This correlation is consistent with abstraction of the hydrogen being the rate-limiting step in the hydroxylation catalyzed by this heme P450.

When a complex between [5-$^2H_2$]camphor, oxygen, and iron(II) porphyrin in the active site of camphor 5-monooxygenase from *P. putida* at 74 K is reduced radiolytically and the temperature is raised to 190 K, the oxoiron(IV) porphyrin$^{\bullet+}$ forms and then hydroxylates the camphor at carbon 5. The product, (+)-*exo*-5-hydroxycamphor, remains as a ligand through its oxygen to the resulting iron(III) porphyrin, but the hydrogen of the hydroxy group is a deuteron,[1583] which could only have come from carbon 5 of the camphor. This observation is consistent with abstraction of a deuterium from carbon 5 of the camphor by the oxygen of the oxoiron(IV) porphyrin$^{\bullet+}$ to form deuterohydroxyiron(IV) porphyrin, the deuterohydroxy group of which colligates with the radical at carbon 5 of the camphor. Similar results were observed with the heme P450 in bovine cholesterol monooxygenase (side-chain-cleaving).[1584]

A number of compounds known as **radical clocks** have been submitted to hydroxylation.[1585] These compounds, such as methylcyclopropane or *trans*-2-methyl-1-phenylcyclopropane, rearrange rapidly when the respective radical is produced at the respective methyl group, and the rate constant of each rearrangement is known. The fact that rearranged products in these reactions are observed suggests that abstraction of a hydrogen atom is involved in the mechanism even if it is only occurring in a transition state with radical character. Also consistent with the conclusion that hydrogen abstraction is involved in the mechanism is that when the hydrogens that would be abstracted from the methyl group of *trans*-2-methyl-1-phenylcyclopropane are changed to deuteriums, the yield of oxidation of the phenyl ring increases.[1586] From the observed ratios of the alcohols with unrearranged and rearranged structures for a series of these radical clocks, the lifetime of a radical intermediate in the hydroxylation catalyzed by hemes P450 that are unspecific monooxygenases has been estimated to be around 100 fs[1587-1589] or around 50 ps.[1590,1591] The former seems too fast for a radical to be an intermediate, while the latter is consistent with a radical as an intermediate. One explanation of these discrepancies in the rates is that the active site of the enzyme may hinder sterically the rearrangements of the radicals of some of these molecular clocks, cause the lifetimes of the unrearranged radicals to increase, and lead to longer lifetimes of the radicals.[1589] This explanation, however, seems at odds with the rather large, hydrophobic pockets in crystallographic molecular models of these unspecific monooxygenases[1592] that arise from their need to hydroxylate an array of alkanes nonspecifically.

In contradistinction to these results from isotope effects, stereochemistry, and rearrangements of radical clocks, which are consistent with hydrogen abstraction as the first step, a high yield of products resulting from the rearrangements expected for an **oxocarbenium ion** and none of the products resulting from the rearrangements expected for a radical have been observed during the hydroxylation of (*trans*, *trans*-2-*tert*-butoxy-3-phenylcyclopropyl)methane by unspecific monooxygenase from *R. norvegicus*[1593]



(2–253)

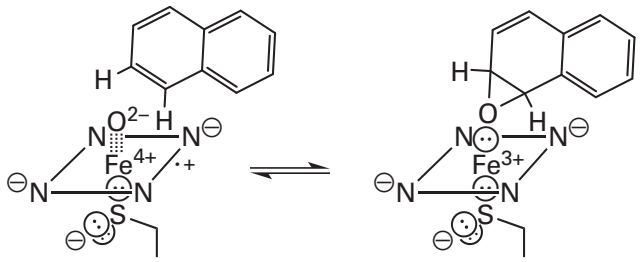
The radical would rearrange to the benzyl position rather than to the carbon with the *tert*-butoxy group.

There is little doubt about the fact that the oxoiron(IV) porphyrin$^{\bullet+}$ formed on an appropriate heme P450 is able to hydroxylate a saturated carbon.

For example, the stable oxoiron(IV) porphyrin$^{\bullet+}$ that can be produced in the active site of the epoxidase from *S. acidocaldarius* is able to hydroxylate dodecanoic acid at the fully saturated carbons at positions 9, 10, 11, and 12.[1567,1594] The oxoiron(IV) porphyrin$^{\bullet+}$ formed transiently in the active site of unspecific peroxygenase from *A. aegerita* is stable enough to be observed and has been shown to be able to hydroxylate alkyl carbons in a series of 10 carboxylic acids and ethers.[1595]

It is also possible, however, that in some situations the peroxyiron(III) porphyrin or hydroperoxyiron(III) porphyrin that is an intermediate preceding formation of the oxoiron(IV) porphyrin$^{\bullet+}$ can also perform hydroxylations. When the step in the mechanism in which hydroperoxyiron(III) porphyrin is converted to oxoiron(IV) porphyrin$^{\bullet+}$ by a nonspecific monooxygenase, cytochrome P450 2B4 from *R. norvegicus*, is inhibited by mutating a threonine serving as the required catalytic acid, the rates of hydroxylation of alkanes decrease but not so much as they should were the oxoiron(IV) porphyrin$^{\bullet+}$ the only species hydroxylating them, and the rates of epoxidations of alkanes actually increase.[1596] The homologous mutation in camphor 5-monooxygenase from *P. putida* eliminated hydroxylation completely while decreasing the rate of epoxidation by only about 80%.[1597] At the least, these results suggest that peroxyiron(III) porphyrin or hydroperoxyiron(III) porphyrin, the immediate precursors of oxoiron(IV) porphyrin$^{\bullet+}$, can perform the epoxidations and perhaps also the hydroxylations catalyzed by these enzymes, but not so effectively as the oxoiron(IV) porphyrin$^{\bullet+}$. In model reactions, a *m*-chlorobenzoylperoxyiron(III) porphyrin (Equation 2–232; R = *m*-chlorobenzoyl) is able to hydroxylate alkanes.[1443] There are results from various measurements of the effects of deuteration on the rates of hydroxylations catalyzed by enzymes containing hemes P450 that are interpreted to mean that oxoiron(IV) porphyrin$^{\bullet+}$ is responsible exclusively for the hydroxylation[1598] or that it is not.[1599,1600] Theoretical calculations, however, lead to the conclusion that peroxyiron(III) porphyrin is too weak an oxidant to perform a hydroxylation.[1577]

Enzymes containing hemes P450 also perform **monooxygenations of arenes**.[1601] For example, an unspecific peroxygenase from *A. aegerita* catalyzes the epoxidation of naphthalene



(2–254)

In this case, the oxoiron(IV) porphyrin$^{\bullet+}$ is formed by association of hydrogen peroxide with the prosthetic iron(III) porphyrin in the active site, followed by the usual heterolytic dissociation. The immediate product of this oxidation is the arene epoxide that undergoes an acid-catalyzed ring opening after its dissociation from the active site to give the ultimate product of the reaction, which is 1-hydroxynaphthalene,[1602] in addition to the water that dissociated during formation of the oxoiron(IV) porphyrin$^{\bullet+}$. A hydrogen on a carbon in an aromatic system is quite difficult to abstract (470 kJ mol^{-1}), so the monooxygenation of an arene proceeds by electrophilic aromatic substitution.

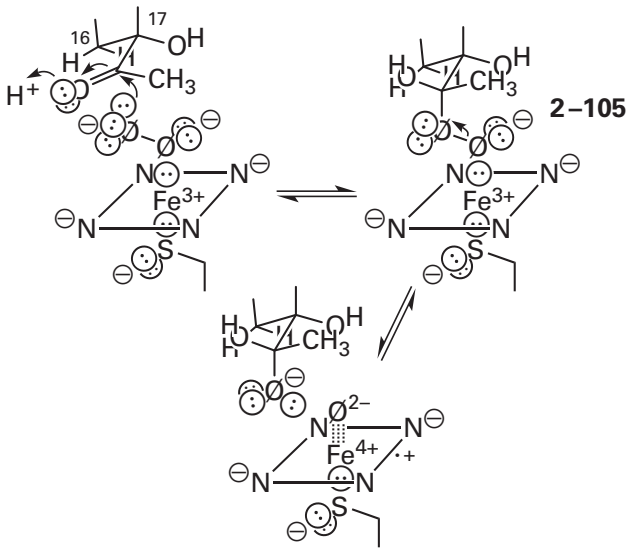
An analysis of the rates of aromatic monooxygenation by a synthetic oxoiron(IV) porphyrin$^{\bullet+}$ suggests that the first step in monooxygenation of an arene is electron transfer[1603] from the aromatic π molecular orbital system to the significantly electron-deficient oxoiron(IV) porphyrin$^{\bullet+}$. This electron transfer would be followed by a colligation to form a carbon–oxygen bond between the oxygen of the resulting oxoiron(IV) porphyrin and a carbon of the resulting radical cation of the arene. This colligation would form the usual intermediate in an electrophilic aromatic substitution. In the case of naphthalene, this intermediate would be a nonatetraenyl carbenium ion, with the oxygen of the now oxidoiron(III) and a hydrogen at the tetrahedral carbon at carbon 2 breaking the ring of *p* orbitals.[1604] Either the electrophilic aromatic substitution is completed as usual by dissociation of the hydron to give the hydroxylated arene as a product, or the oxido oxygen on the oxidoiron(III) porphyrin adds as a nucleophile to the carbocationic carbon immediately adjacent to it in the adduct to give the arene epoxide, as is the case in the nonspecific peroxygenase from *A. aegerita* (Equation 2–254).

In part because of the electron donation from the axial sulfido group (Equation 2–250), the **peroxyiron(III) porphyrin of a heme P450 is nucleophilic** at its distal oxygen[1556] and can add to a carbonyl.[1605-1609]

17α-Hydroxyprogesterone deacetylase is responsible for an oxidative cleavage

$$H_2Fl_{red}^- + O_2 + 17\alpha\text{-hydroxyprogesterone} \rightleftharpoons HFl_{ox} + \text{acetate} + \text{androstenedione} + H_2O \quad (2\text{–}255)$$

where $H_2Fl_{red}^-$ and HFl_{ox} are the reduced and oxidized flavin, respectively, in a separate enzyme, NADPH—hemoprotein reductase, that acts as an electron-transferring coenzyme for 17α-hydroxyprogesterone deacetylase. The acetyl group at carbon 17 of the 17α-hydroxyprogesterone becomes the acetate that is a product, and carbon 17 becomes a carbonyl group in the androstenedione that is the other product. The oxidation requires two electrons and breaks the bond between carbon 17 and the carbonyl carbon of the acetyl group. An intermediate in the reaction catalyzed by human 17α-hydroxyprogesterone deacetylase has been trapped at low temperature after adding O_2 to the complex between 17α-hydroxyprogesterone and human 17α-hydroxyprogesterone deacetylase in which the heme had already been reduced by NADPH—hemoprotein reductase. This intermediate had a resonance Raman infrared spectrum consistent with **ferric peroxy hemiketal 2–105**, which is the product of nucleophilic addition of a peroxyiron(III) porphyrin to the carbonyl in the acetyl group at carbon 17 of 17α-hydroxyprogesterone[1610]



(2–256)

In the crystallographic molecular model of the complex between human 17α-hydroxyprogesterone deacetylase and progesterone, the acetyl group is in the proper location and orientation[1611] for the nucleophilic addition.

In the normal enzymatic reaction, the peroxyiron(III) porphyrin that is the nucleophile is formed in the usual way from iron(III) porphyrin and an electron, molecular oxygen and the resulting iron(II) porphyrin, and a second electron. The normal complete cleavage (Equation 2–255) also occurs, however, when iodosylbenzene is substituted in the reaction catalyzed by human 17α-hydroxyprogesterone deacetylase for the molecular oxygen and the NADH that reduces the flavin.[1612] Iodosylbenzene produces oxoiron(IV) porphyrin$^{\bullet+}$ directly from iron(III) porphyrin in a two-electron oxidation (see Equation 2–228) requiring no other oxidant or reductant. This observation suggests that the only role of the initial addition of peroxyiron(III) porphyrin to the acetyl group to form **2–105** is that the electrophilic acyl carbon of the acetyl group acts in place of a hydron to permit heterolytic dissociation of the oxygen–oxygen bond to produce the *gem*-diol, which could otherwise form by a simple hydration, and oxoiron(IV) porphyrin$^{\bullet+}$ from peroxyiron(III) porphyrin (Equation 2–256). If this is the case, then the iodosylbenzene simply takes the place of the usual stratagem used by the enzyme to form an oxoiron(IV) porphyrin$^{\bullet+}$. One of the oxygens in the acetate produced from the conversion of 17α-hydroxypregnenolone by porcine 17α-hydroxyprogesterone deacetylase is an oxygen-18 that was the oxygen-18 of an [^{18}O]acetyl group on a reactant,[1605] and the other oxygen atom is an oxygen-18 from [$^{18}O_2$]molecular oxygen.[1612,1613] These two facts would require that the intact *gem*-diol proceed to the next steps in the reaction rather than dehydrating.

It is unclear, however, how the oxoiron(IV) porphyrin$^{\bullet+}$ and the *gem*-diol would proceed from this point to accomplish the cleavage. All, or almost all, of the most obvious mechanisms[1612] seem to be ruled out by the preceding and following observations. The other atom of oxygen-18 in [$^{18}O_2$]oxygen ends up as the oxygen in the carbonyl group at carbon 17 of the product, rather than the oxygen in the hydroxy group that was there in the reactant and already forming a covalent bond to carbon 17. The fact that both deuteriums in a 16,16-$^2H_2$-labeled reactant remain on carbon 16 in the product[1613] and the fact that all deuteriums in a $^2H_3$-labeled acetyl group at position 17 in the reactant also remain in the [$^2H_3$]acetate that is the product[1612,1613] together seem to rule out the abstraction of any hydrogen on a carbon by the oxoiron(IV) porphyrin$^{\bullet+}$. The fact that the bond dissociation energy of the oxygen–

hydrogen bond of a hydroxy group is quite large (445 kJ mol^{-1}) argues against the abstraction of a hydrogen from the hydroxy group at carbon 17 in the reactant, even though, in a crystallographic molecular model of a complex between 17α-hydroxyprogesterone and human 17α-hydroxyprogesterone deacetylase, the oxygen in the 17-hydroxy group is one of the closest (0.45 nm) atoms in the steroid to the iron ion in the heme. In this molecular model, the carbonyl carbon and the carbonyl oxygen of the 17-acetyl group and carbon 16 of the steroid are also all between 0.4 and 0.5 nm from the iron ion, so any one of them or all of them could be involved in the rearrangement leading to the cleavage.

All these considerations seem to rule out a heterolytic cleavage of the peroxy group (Equation 2–256) as a step in the oxidative deacetylation of 17α-hydroxyprogesterone deacetylase. Before the observation was made that iodosylbenzene could substitute for oxygen, the accepted mechanism for the oxidative cleavage performed by 17α-hydroxyprogesterone deacetylase was a homolytic one (Figure 2–54).[1556,1606-1609,1614] The homolytic proposal takes advantage of a spontaneous dissociation of the carbon–carbon bond adjacent to the radical of a *gem*-diol and the fact that a radical on carbon 17 of the steroid adjacent to the hydroxy group (BDE = 396 kJ mol^{-1}) is even more stable than a radical on a tertiary carbon (BDE = 400 kJ mol^{-1}). The fact that one of the oxygens in the molecular oxygen ends up in the carbonyl group of the androstenedione requires that the resulting hydroxyiron(IV), which is equivalent to a hydroxyl radical on Fe^{3+}, colligate with the radical on carbon 17 to form another, different *gem*-diol, but in the crystallographic molecular model, carbon 17 is 0.52 nm from the iron ion, albeit because it is a tetrahedral carbon in the 17α-hydroxyprogesterone, and it would have to move closer, presumably as the acetate that is the product of the reaction shifts away. The observation that iodosylbenzene can substitute for the molecular oxygen would require that the oxoiron(IV) porphyrin$^{\bullet+}$ formed by the iodosylbenzene remove the equivalent of a hydrogen atom from a *gem*-diol of the 17α-hydroxyprogesterone that is the reactant to produce the usual radical of the *gem*-diol and the oxoiron(IV)porphyrin. This abstraction would be difficult (BDE = 450 kJ mol^{-1}) unless a catalytic base

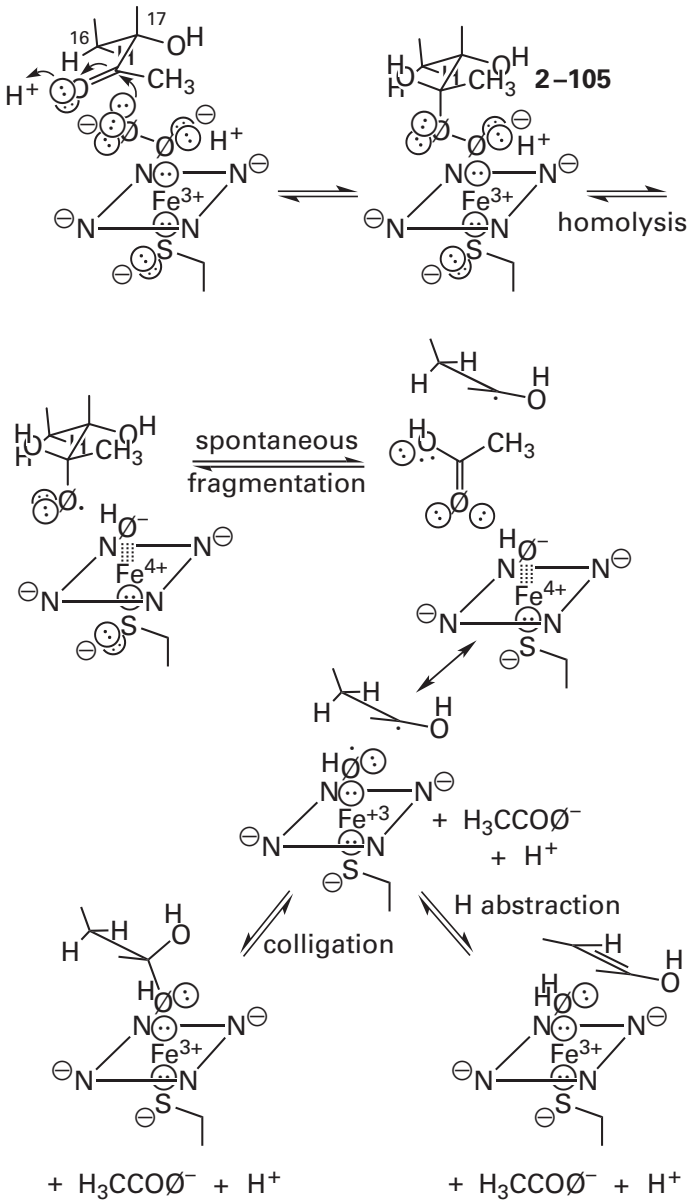


Figure 2–54: Homolytic deacetylation performed by the peroxyiron(III) porphyrin (Equation 2–250) in the active site of human 17α-hydroxyprogesterone deacetylase.[1606-1609] The nucleophilic[1556] peroxy group of the peroxyiron(III) porphyrin adds to the carbonyl of a methyl ketone to form peroxy hemiketal **2–105**. Upon hydronation of the oxygen proximal to the Fe^{3+}, the oxygen–oxygen bond of the peroxy group undergoes homolysis to produce hydroxyiron(IV) and the oxy radical of a geminal diol. The oxy radical of the geminal diol undergoes spontaneous fragmentation to produce acetate and the radical of the deacetylated hydroxyhydrocarbon. The radical of the hydroxyhydrocarbon ends up adjacent to the hydroxyiron(IV), which is the resonance hybrid of a hydroxyl radical on Fe^{3+}. The hydroxyl radical either reacts directly with the unpaired electron of the radical of the hydroxyhydrocarbon to produce the hydrate at carbon 17 of the final product, androstenedione, bound to the Fe^{3+} or abstracts a hydrogen immediately adjacent to the unpaired electron of the radical of the hydroxyhydrocarbon to produce the enol of androstenedione. The product that predominates in this last step depends upon the enzyme in which it occurs.[1606-1609]

removed the hydron from the hydroxy group first or the electron is removed from the oxyanion of the immediate product of the addition of hydroxide to the carbonyl.

A different enzyme containing a heme P450, cholest-4-en-3-one 26-monooxygenase [(25*S*)-3-oxocholest-4-en-26-oate forming] from *M. tuberculosis* turns the terminal *pro-S* methyl group in the linear 1,5-dimethylhexyl side chain of cholest-4-en-3-one into a carboxy group by three successive hydroxylations at that carbon. A significant portion (40%) of the products formed by the enzyme, however, when cholesterol, which has the same 1,5-dimethylhexyl side chain, is the reactant rather than cholest-4-en-3-one result from the deformylation of the (5*S*)-1,5-dimethyl-6-oxohexyl side chain. The (5*S*)-1,5-dimethyl-6-oxohexyl side chain is an intermediate in the overall reaction. It is formed by the first two hydroxylations and dehydration of the resulting *gem*-diol. In addition to the formic acid common to this deformylation of the side chain in cholesterol, the five other products making up this portion of the products of the reaction are those expected from various reactions between a hydroxyiron(IV) porphyrin in the active site and a radical at carbon 5 of the side chain resulting from dissociation of the formic acid. Both a hydroxyiron(IV) porphyrin and a radical at carbon 5 of the side chain should be produced by nucleophilic addition of the distal peroxy oxygen of peroxyiron(III) porphyrin to the 6-oxo group of the side chain that results from the first two hydroxylations followed by homolytic cleavage (see Figure 2–54). These five products are a fingerprint identifying the final oxidation of at least cholesterol as a homolytic process.

The oxoiron(IV) porphyrin$^{\bullet+}$ of a heme P450 can also function as a **strong electrophile.** Cholesterol monooxygenase (side-chain-cleaving), which is an enzyme containing a heme P450, is responsible for cleaving the bond between carbons 1 and 2 in the 1,5-dimethylhexyl side chain of cholesterol (carbons 20 and 22 of the cholesterol). The cleavage proceeds in three successive steps, each involving an oxoiron(IV) porphyrin$^{\bullet+}$ as a intermediate.[1615] The first two steps are simple hydroxylations at carbons 1 and 2 in the side chain, respectively. In the crystallographic molecular model of the complex between the human enzyme and 20,22-dihydroxycholesterol, which is the product of these first two hydroxylations of the side chain and the reactant for the final oxidation leading to cleavage of the carbon–carbon bond, the two hydroxy groups at carbon 1 and carbon 2 of the side chain sit astride the iron of the heme. When an oxygen atom is added to the heme in the molecular model to mimic the oxoiron(IV) porphyrin$^{\bullet+}$ that performs the cleavage of the carbon–carbon bond, the hydroxy group on carbon 2 of the side chain is only 0.23 nm from that oxygen.[1616] The conclusion drawn from this observation is that the 2-hydroxy group adds as a nucleophile to the electrophilic oxygen of the oxoiron(IV) porphyrin$^{\bullet+}$ to produce the peroxyiron(III) porphyrin with carbon 2 of the 1,2-dihydroxy side chain still attached to the distal oxygen of the peroxy group. The bonds in this intermediate then rearrange heterolytically, and the rearrangement produces hydroxyiron(III) porphyrin, pregnenolone, and 4-methylpentanal, the products of the side-chain cleavage.

Cytochrome-*c* oxidase catalyzes the complete reduction of molecular oxygen

$$4\,H^+ + 4\,e^- + O_2 \rightleftharpoons 2\,H_2O \qquad (2\text{–}257)$$

by a mechanism that is similar to the mechanism of an enzyme containing a heme P450. The four electrons required in the reaction are supplied to the enzyme by four molecules of the reduced form of the small electron-transferring coenzyme cytochrome *c*. The enzyme contains just enough prosthetic groups to store all four of these electrons at once. These prosthetic groups are a CuA dinuclear copper cluster (Figure 2–26F); a heme *a* or a heme *b*, depending on the species, in which the iron ion is fully coordinated and diamagnetic in its ferrous state and that acts as a one-electron donor; a heme *a*, heme *b*, or heme *o*, again depending on the species, that has an open site to which the molecular oxygen binds and that is high-spin and paramagnetic in its ferrous state; and a copper ion coordinated by three histidines that also has an open site.[932,1617-1621] One of the histidines that is a ligand to this mononuclear, prosthetic copper ion is the histidinyl group participating in the posttranslational modification that produces the 3-(N^{τ}-histidinyl)tyrosine (Figure 2–55), which is formed by a covalent crosslink between this histidine and a nearby tyrosine in the protein.[1047,1622-1624] The simultaneous presence of **four metallic electron donors** permits the fully reduced enzyme to reduce the molecular oxygen completely in one fell swoop without the

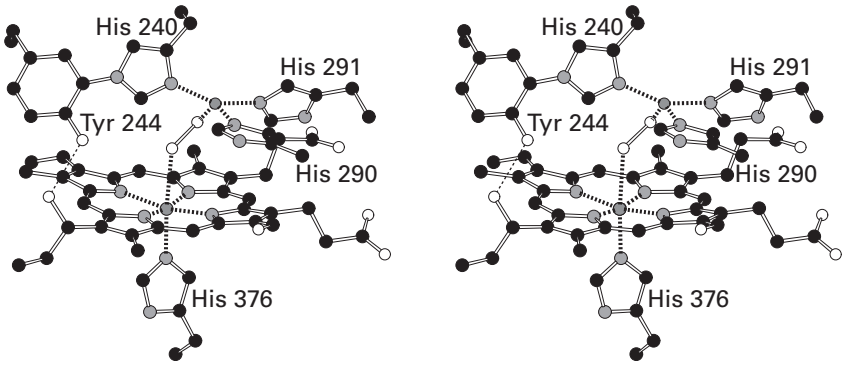

Figure 2–55: Stereodrawing[50] of one of the hemes *a* and one of the prosthetic copper ions complexed with a peroxide dianion in the crystallographic molecular model of bovine cytochrome-*c* oxidase.[1047] Black atoms are carbons, white atoms are oxygens, gray atoms are nitrogens, and the two dark gray spheres surrounded by ligands are an iron ion and a copper ion. Bovine cytochrome-*c* oxidase was purified from mitochondria under ambient aerobic conditions.[1624] The enzyme purified in this way and then recrystallized aerobically was fully oxidized, and six moles of electrons for every mole of enzyme were required to fully reduce its hemes and copper ions.[1623] This titration is consistent with the presence of the equivalent of a peroxide dianion in its active site. In the map of electron density from crystals of this enzyme, a feature of electron density equal in volume and shape to a peroxide dianion was observed spanning the iron ion of heme *a*, to which oxygen is known to bind, and the mononuclear copper ion adjacent to it. This feature of electron density was assumed to be a peroxide dianion and was modeled as such, in spite of the fact that the final oxygen–oxygen bond length following refinement was 0.17 nm,[1622] which is somewhat longer than the 0.14–0.15 nm of the usual peroxide dianion complexed by two metallic ions. The drawing is of the heme *a* and the side chain of Histidine 376 that is its axial ligand; the copper ion and the side chains of the three histidines, Histidines 240, 290, and 291, that are its ligands; and the peroxide dianion of the final crystallographic molecular model.[1047] One of the histidines, Histidine 240, is a 3-(N^{τ}-histidinyl)tyrosine with Tyrosine 244. The peroxide dianion is a ligand to Fe^{3+} in the heme *a* at one of its oxygens and a ligand to the copper ion at the other.

accumulation of intermediates that might release superoxide radical anion or hydrogen peroxide or, even worse, hydroxyl radical into the cytoplasm. During reduction of the fully oxidized bovine enzyme, the rate-limiting step is reduction of the iron in the heme with the open site with which the oxygen associates when it is in its reduced ferrous state (Figure 2–52) and at which the oxygen is reduced.[1625] Consequently, molecular oxygen usually does not bind to the enzyme nor does catalysis commence until the enzyme is fully reduced.

The iron ion in the fully coordinated heme that acts as the donor of a single electron in the bovine enzyme has as one of its axial ligands the imidazolyl group of a histidine that is only two positions in the sequence of amino acids away from the histidine providing the only axial ligand to the heme with the open site at which the reduction of the oxygen occurs.[1618] This connection provides a **continuous path for an electron** on which it can pass rapidly by outer-sphere electron transfer between the iron ions in these two hemes.[1626] The copper ion that is coordinated by the three histidines in bovine cytochrome-*c* oxidase is only 0.45 nm from the iron that has the open catalytic site, and there is nothing between these two metallic ions. This distance would be spanned by the two oxygen atoms in a peroxide dianion coordinated to the iron at one oxygen and the copper ion at the other (Figure 2–55). The dinuclear CuA cluster is coupled electronically to the iron of the fully coordinated heme participating in electron transfer, and a single electron equilibrates rapidly between their respective oxidized states.[1627,1628] The other copper ion, adjacent to the open site on the other heme, is coupled antiferromagnetically to the iron of that heme.[1629] All these arrangements guarantee the rapid arrival of four electrons at the site of reduction.

In the enzymes containing a heme P450 that hydroxylate alkanes, molecular oxygen is initially converted into water and an oxoiron(IV) porphyrin$^{\bullet+}$ (Equation 2–250). Occasionally, the oxoiron(IV) porphyrin$^{\bullet+}$ is converted by mistake in a two-electron reduction into a hydroxyiron(III) porphyrin (see Figure 2–50), and hence a second molecule of water, by absorbing two electrons from the reduced flavin of the NADPH—hemoprotein reductase[1630,1631] or by oxidizing the alkane, which normally is hydroxylated, to an alkene rather than an alcohol.[1632,1633] This abortive side reaction for a heme P450 mimics the actual reaction catalyzed by cytochrome-*c* oxidase.

When the reaction begins with fully reduced cytochrome-*c* oxidase, molecular oxygen is bound at the open site on the iron(II) porphyrin of the catalytic heme,[1634] perhaps by binding initially to the adjacent prosthetic Cu^+ and then moving to the iron[1635] to produce the prosthetic copper(I)oxyiron(II) porphyrin where the molecular oxygen is a ligand to both the Cu^+ and the Fe^{2+}. In several model compounds in which a ferroheme is properly positioned adjacent to a triply coordinated Cu^+, when oxygen binds between the two metallic ions, it is reduced in the inner sphere by an electron from the Fe^{2+} and an electron from the Cu^+ to give[1636-1640] the **complex between the ferriheme, a peroxide dianion, and the Cu^{2+}**, copper(II)peroxyiron(III) porphyrin. In bovine cytochrome-*c* oxidase, cytochrome-*c* oxidase from *P. denitrificans*, and cytochrome-*c* oxidase from *Columba livia*, the same reaction takes place following the binding of oxygen to produce a copper(II)peroxyiron(III) porphyrin[1641-1647] in which the prosthetic Cu^{2+} is coordinated by the distal oxygen of the peroxide dianion.[1629] The initial complex, copper(I)oxyiron(II) porphyrin, and the peroxy complex, copper(II)peroxyiron(III) porphyrin, must be in extremely rapid equilibrium because transfer of the electrons is in the inner sphere, but the question of which of the two complexes predominates at this stage of the reaction seems to be controversial.[1648] Either a copper(II)-peroxyiron(III) porphyrin or a copper(I)-oxyiron(II) porphyrin, which are isosteric and hence indistinguishable as well as being in equilibrium with each other, has been observed crystallographically in the bovine enzyme,[1648-1650] and in this crystallographic molecular model, the peroxide dianion or the molecule of oxygen is coordinated by both the iron ion at the proximal oxygen and the copper ion at the distal oxygen (Figure 2–55).[1047]

In the next step of the mechanism, the distal oxygen of the copper(II)peroxyiron(III) porphyrin is hydronated. The source of the hydron is unclear. It has been proposed that, because it is the closest catalytic acid to the bound oxygen, the source of the hydron is the hydroxy of the 4-hydroxyphenyl group of the adjacent 3-(N^{τ}-histidinyl)tyrosine, the histidinyl group of which is a ligand to the copper ion.[1047,1651-1653] The distance, however, from this hydroxy group to the distal oxygen[1650] in bovine cytochrome-*c* oxidase is 0.54 nm, and the orientations of these two groups are incompatible with such a hydron transfer (Figure 2–55). In one crystallographic molecular model of bovine cytochrome-*c* oxidase, however, there is a fixed molecule of water

forming a hydrogen bond to the hydroxy group of the 3-(N^{τ}-histidinyl)tyrosine, and it would be between the hydroxy group and the distal oxygen of the molecular oxygen. There are also thought to be other disordered molecules of water in the immediate vicinity.[1648] Consequently, one or two molecules of water could relay the hydron from the hydroxy group of the 3-(N^{τ}-histidinyl)tyrosine to the distal oxygen of the copper(II)peroxyiron(III) porphyrin. Nevertheless, the copper(II)hydroperoxyiron(III) porphyrin resulting from the hydronation dissociates heterolytically to produce **an oxoiron(IV) porphyrin and a hydroxide** bound[1643,1644,1654-1658] by the Cu^{2+}. The copper(II)-hydroperoxyiron(III) porphyrin that precedes the dissociation has been observed in a model compound that has a triply coordinated copper ion covalently attached to a heme positioned in the proper orientation.[1659]

Just as the tryptophan in cytochrome-*c* peroxidase provides an electron to the oxoiron(V) porphyrin formed initially by heterolysis of the hydroperoxyiron(III) porphyrin in its active site, in the active site of bovine cytochrome-*c* oxidase, the 3-(N^{τ}-histidinyl)tyrosine provides an electron from its electron-rich π molecular orbital system to the oxoiron(V) porphyrin formed initially by heterolysis of the copper(II)hydroperoxyiron(III) porphyrin so that, after a second hydronation, the intermediate at this step is a hydroxyiron(IV) porphyrin adjacent to a **neutral radical on the 3-(N^{τ}-histidinyl)tyrosine**,[1652,1660-1663] rather than the oxoiron(IV) porphyrin$^{\bullet+}$ that usually forms from an oxoiron(V) porphyrin. This hydroxyiron(IV) porphyrin with the adjacent imidazolyl-4-hydroxyphenyl radical has been reproduced in a model compound,[1664] which is able to catalyze the entire reduction of oxygen to water with electrons supplied by an electrode.[1665] In fact, another model compound in which a peroxyiron(III) porphyrin, the distal oxygen of which is a ligand to a Cu^{2+}, oxidizes 2,4,6-tri-*tert*-butylphenol to the neutral 2,4,6-tri-*tert*-butylphenoxy radical. In this reaction, the tri-*tert*-butylphenol hydronates the distal oxygen of the peroxyiron(III) porphyrin that is a ligand to the copper initiating the dissociation of the oxygen–oxygen bond, and the resulting oxoiron(V) porphyrin then removes an electron from the tri-*tert*-butylphenoxide.[1666] A complex between a different model compound also containing a peroxyiron(III) porphyrin, the distal oxygen of which is a ligand to a Cu^{2+}, forms a complex with 4-nitrophenol in which there is a hydrogen bond between the 1-hydroxy group and the distal oxygen of the peroxyiron(III) porphyrin.[1667]

The final steps in the reaction catalyzed by cytochrome-*c* oxidase are outer-sphere transfer of an electron from the other heme to the imidazoylphenoxy radical,[1647] rapid equilibration of the remaining electron between the CuA copper cluster and the other heme,[1668] and transfer of this second electron from the other heme to the hydroxyiron(IV) porphyrin to produce hydroxyiron(III) porphyrin.[1654]

In bovine cytochrome-*c* oxidase and cytochrome-*c* oxidase from *P. denitrificans*, this last transfer of an electron can be resolved into two steps. The first step is transfer of an electron from a nearby tryptophan to the hydroxyiron(IV) porphyrin to produce a tryptophan radical and the hydroxyiron(III) porphyrin, and the second step is transfer of the remaining electron from the other heme to the **tryptophan radical** to produce fully oxidized enzyme with one hydroxide ion on the Fe^{3+} and one on the Cu^{2+}, and the regenerated tryptophan.[1641,1669] The participation of this tryptophan is another example of an indolyl group acting as a relay station in the transfer of an electron.

The hydroxide that ends up on the ferric heme in bovine cytochrome-*c* oxidase can exchange rapidly with molecules of water in the solution.[1670] Nevertheless, the hydroxyiron(III) porphyrin is hydronated on its hydroxy oxygen, presumably the same hydronation permitting the exchange of the hydroxy group, to release water.[1671]

There is a model compound in which a copper ion is triply coordinated by two imidazolyl groups and a 2-(*N*-imidazolyl)phenol. These ligands are covalently attached to a heme in such a way that the copper and the iron are positioned at the proper orientation and distance to share a peroxide dianion. This model compound reduces molecular oxygen to two molecules of water, using electrons supplied by cytochrome *c*.[1672]

Oxides of nitrogen (Figure 2–56)[1673,1674] **are substrates for enzymes that use the same prosthetic groups that service the various oxides of oxygen.** Sulfite, an oxide of sulfur, also is a reactant for such enzymes. An example of a prosthetic group that is used in oxidation–reductions with either an oxide of nitrogen as a substrate or molecular oxygen as a

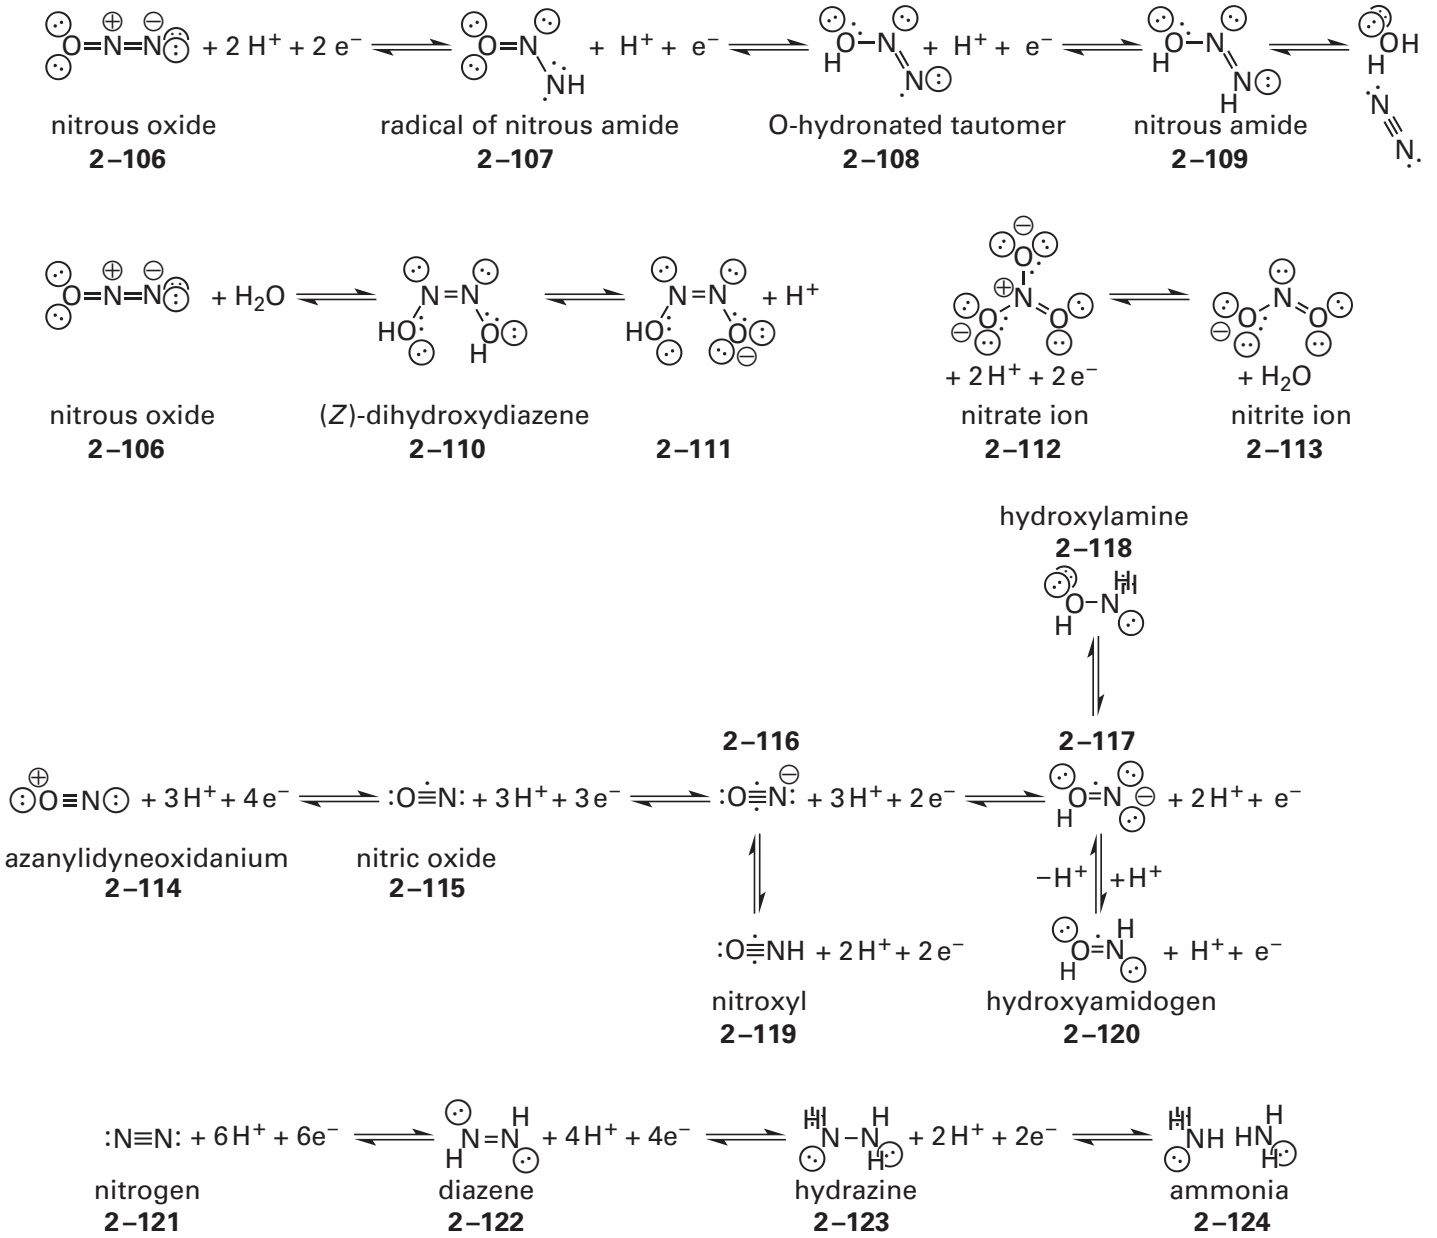

Figure 2–56: Oxides and hydrides of nitrogen and their interconversion by oxidation–reduction. Dihydroxydiazene and nitroxyl exist in the gas phase in equilibrium with each other, and dihydroxydiazene decomposes in water.[1673] Hydroxyamidogen has not been isolated, but its properties have been calculated.[1674] The remaining compounds and ions are relatively stable and can be purchased.

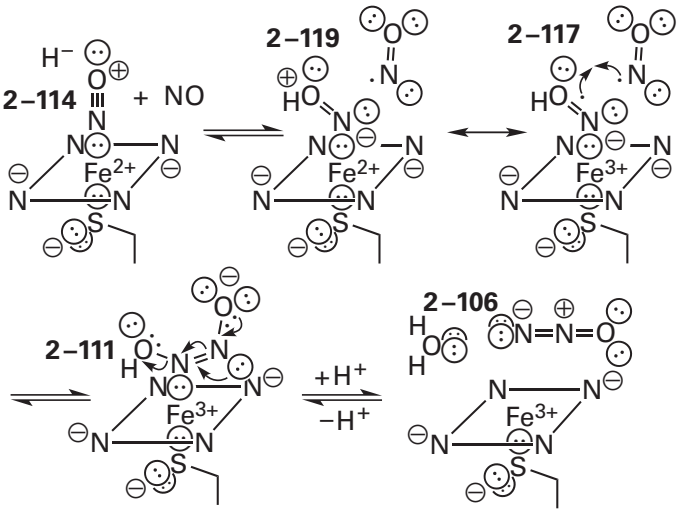
substrate would be a **heme P450.** Nitric oxide reductase [NAD(P)$^+$, nitrous oxide-forming] is an enzyme containing a heme P450 that performs a two-electron oxidation–reduction

$$H^+ + NADH + 2\,NO^{\cdot} \rightleftharpoons NNO + H_2O + NAD^+ \qquad (2\text{–}258)$$

Nitric oxide, NO$^{\cdot}$ (**2–115**), is molecular oxygen in which one of the oxygen atoms and its six valence electrons has been substituted by a nitrogen atom and its five valence electrons, so it has one fewer electron than molecular oxygen. As a result, nitric oxide is a stable radical. One of the two highest occupied π^* molecular orbitals of the diatomic molecular orbital system (Figure 2–45 and **2–86**) occupied by the unpaired electrons in molecular

oxygen (**2–87**) is unoccupied in nitric oxide, and the remaining unpaired electron occupies the other π^* molecular orbital. Unlike oxygen, which associates with only ferroheme, or the superoxide radical anion, which is isoelectronic with nitric oxide but associates with only ferriheme, **nitric oxide binds with almost equal affinity to both ferroheme and ferriheme**.[1675,1676] In these complexes, the nitrogen is on the iron.

The nitrogen of one of the two nitric oxides associates with the ferriheme of nitric oxide reductase [NAD(P)$^+$, nitrous oxide-forming] from *F. oxysporum*. During its association, the nitric oxide is oxidized by transfer of its unpaired electron to the Fe^{3+} to produce an Fe^{2+} coordinated by an **azanylidyneoxidanium ion** (**2–114**)



(2–259)

a cation that is diamagnetic because all its molecular orbitals are occupied by pairs of electrons. Because azanylidyneoxidanium is a cylindrical ion, it should associate as a coaxial ligand on the resulting Fe^{2+}, which is the case for a synthetic model complex that can be formed between an iron(III) porphyrin and nitric oxide. This synthetic model complex has been identified as that between azanylidyneoxidanium and iron(II) porphyrin.[1677] In the active site of nitric oxide reductase [NAD(P)$^+$, nitrous oxide-forming], NADH reduces this complex directly by formal transfer of a hydride to the electrophilic, cationic distal oxygen of the azanylidyneoxidanium,[1678-1680] just as a hydride from BH_4^- is able to reduce the synthetic model complex between the iron(II) porphyrin and azanylidyneoxidanium.[1677]

The resulting reduced intermediate[1681] is the complex between **nitroxyl** (**2–119**) and Fe^{2+}. Nitroxyl is isoelectronic with molecular oxygen and should be, as is molecular oxygen, a bent ligand to the Fe^{2+}. As in the case of the complex between a ferroheme and molecular oxygen, there is a resonance form of the complex, in which an electron is transferred from the Fe^{2+} to the nitroxyl to give the complex between Fe^{3+} and the anionic conjugate base (**2–117**) of **hydroxyamidogen** (**2–120**),[1674] which is isoelectronic with hydrosuperoxide radical (Equation 2–199). This resonance form illustrates how the nitroxyl on Fe^{2+} is able to participate in a colligation with a second molecule of nitric oxide to form the conjugate base (**2–111**) of **(*Z*)-dihydroxydiazene** (**2–110**). This colligation is followed by a heterolytic dissociation with water as the leaving group to give nitrous oxide, NNO (**2–106**), and H_2O.

An example of a set of prosthetic groups that is used both in oxidation–reductions with an oxide of nitrogen as a reactant and in oxidation–reductions with molecular oxygen as a reactant would be the set of prosthetic groups in cytochrome-*c* oxidase. In addition to nitric oxide reductase [NAD(P)$^+$, nitrous oxide-forming], which contains a heme P450 (Equations 2–258 and 2–259), there are also nitric oxide reductases

$$2\,H^+ + 2\,e^- + 2\,NO \rightleftharpoons NNO + H_2O \qquad (2\text{–}260)$$

namely nitric oxide reductase (cytochrome *c*) and nitric oxide reductase (menaquinol), from bacteria such as *Bradyrhizobium japonicum*, *P. aeruginosa*, *P. denitrificans*, and *Schinkia azotoformans* that are **evolutionarily related to cytochrome-*c* oxidases** and the homologous bacterial quinol oxidases.[1682,1683] As might be expected from this relationship, the two electrons needed for the reduction are provided by either a cytochrome *c*[1684,1685] or a quinol.[1686] Each of these related nitric oxide reductases contains a fully coordinated heme *b* acting as a one-electron donor and a heme *b* with an open site to which, in its ferrous state, the nitric oxide (**2–115**) binds. These two hemes are in homologous locations to the two in cytochrome-*c* oxidase, and as in cytochrome-*c* oxidase, an electron can be transferred rapidly (>1 ms^{-1}) between them.[1687] In place of the coordinated copper ion with an open site in the active site of cytochrome-*c* oxidase, however, there is a coordinated nonheme iron ion, also with an open site.[1684,1688]

In the active site of one of these nitric oxide reductases, unlike in the active site of nitric oxide

reductase [NAD(P)$^+$, nitrous oxide-forming], the nitric oxide associates when the iron ion in the catalytic heme and the nonheme iron ion are both Fe^{2+} ions. The nitric oxide binds with its nitrogen on the Fe^{2+} in the heme and its oxygen on the nonheme Fe^{2+}, just as the isosteric molecular oxygen binds between the iron and the copper ion in cytochrome-*c* oxidase (Figure 2–55). The nonheme Fe^{2+} provides one electron in the inner sphere to the nitric oxide to produce the intermediate, $[FeNOFe]^{4+}$, the complex between the anionic conjugate base (**2–116**) of nitroxyl and the Fe^{2+} in the heme and the nonheme Fe^{3+}. Because the conjugate base of nitroxyl is isoelectronic with molecular oxygen, the complex with the Fe^{2+} in the heme is isoelectronic with a molecule of oxygen on an Fe^{2+} in a heme. This intermediate is also homologous with the intermediate, $[FeNOH]^{2+}$, the complex between the conjugate acid of nitroxyl (**2–119**) and the Fe^{2+} in the heme after the first step in Equation 2–259 with the nonheme Fe^{3+} replacing the hydron, H^+.

The second nitric oxide then participates in a colligation as it does in Equation 2–259 to produce again the conjugate base (**2–111**) of (*Z*)-dihydroxydiazene. Computations[1689] suggest that, following the colligation, both oxygens of the conjugate base or the dianionic dibase of (*Z*)-dihydroxydiazene are ligands to the nonheme Fe^{3+} to form a pentacyclic metallacycle of the two nitrogens, the two oxygens, and the Fe^{3+}. Consequently, it is probably the case that the oxygen of the second nitric oxide, after it enters the active site, also becomes a ligand to the nonheme Fe^{3+} before the colligation occurs. The heterolytic dissociation then proceeds as before (Equation 2–259). The NNO then dissociates from the active site and leaves behind an oxido oxygen held between the two now Fe^{3+} ions but somewhat closer (0.04 nm) to the nonheme Fe^{3+}, which is the substitute for a hydron.[1688] A synthetic heme with a nonheme Fe^{2+} held in the proper location relative to the Fe^{2+} in the heme is able to convert two molecules of nitric oxide nonenzymatically to NNO.[1690]

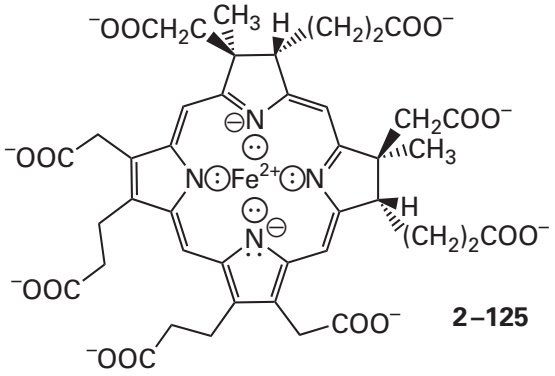
The two electrons from the reduced heme *b* within the enzyme and a molecule of reduced cytochrome *c* or a quinol then successively reduce the two Fe^{3+} ions, the one in the heme and the nonheme Fe^{3+}, to Fe^{2+} ions, and the oxido oxygen picks up two hydrons and dissociates as a molecule of water.[1690] As the diferric oxide is unreactive, there is no need for the two electrons to arrive simultaneously as there is in cytochrome-*c* oxidase. These nitric oxide reductases are another, quite different, example of the **ability of the same arrangements of prosthetic groups to process both an oxide of oxygen and an oxide of nitrogen.**

Oxides of nitrogen can also be oxidized or reduced by the **removal or addition of only one electron** instead of two. In the active site of nitrite reductase (NO-forming) from bacteria such as *Pseudomonas stutzeri*, *P. pantotrophus*, and *P. denitrificans*, the Fe^{2+} in a heme d_1[654,1691] with the imidazolyl group of a histidine as the proximal axial ligand is responsible for the reduction of nitrite ion, ONO^- (**2–113**), the central nitrogen of which reversibly associates with the iron as its sixth ligand.[1692] The nitrite ion is reduced by one electron to nitric oxide (NO) and a molecule of water. During the reaction, two hydronated imidazolio groups from two histidines provide the two hydrons to one of the two oxygen atoms of the nitrite ion that leaves as a molecule of water. The Fe^{2+} in the heme provides the single electron. Following dissociation of the molecule of water from the nitrogen, the resulting complex between nitrous oxide (**2–106**) and the Fe^{3+} has the properties of a complex between Fe^{2+} and azanylidyneoxidanium ion (Equation 2-259).[1693] The Fe^{3+} in the heme d_1, either with the nitric oxide still bound or after its dissociation, is reduced by an electron from a heme *c*[1149] covalently attached as a prosthetic group to a separate structural domain in the protein.[1050,1691] The heme *c* in turn is reduced with an electron from the small dissociable electron-transferring coenzyme cytochrome c_{550}.

Ferredoxin—nitrite reductase from plants such as *S. oleracea*[1694] catalyzes the complete reduction of nitrite ion to ammonium ion, a **reduction requiring six electrons**

$$8\,H^+ + 6\,e^- + ONO^- \rightleftharpoons NH_4^+ + 2\,H_2O \qquad (2\text{–}261)$$

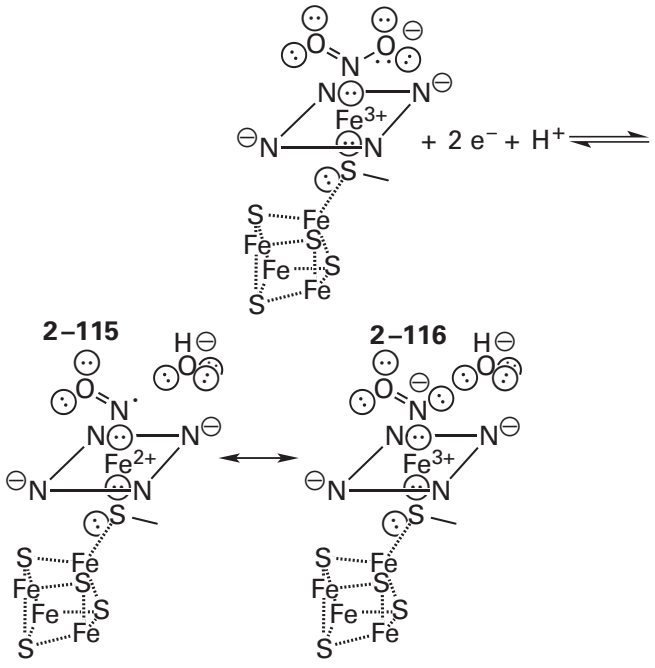
The enzyme uses a heme for the reduction, but the heme is a siroheme



2–125

The ligand to the iron at the axial position is the sulfido sulfur of a cysteine, as in a heme P450, but what disqualifies the enzyme from being an enzyme containing a heme P450 is that the same sulfido sulfur is also the ligand to one of the irons in a **[4Fe–4S] iron–sulfur cluster**.[1695] The two redox couples, the siroheme and the [4Fe–4S] iron–sulfur cluster, act as independent electron-transferring prosthetic groups,[1696] but they are strongly coupled in the inner sphere by the bridging sulfur of the cysteine that they share.[671] The reductants providing the six electrons are six [2Fe–2S] ferredoxins in a sequence of outer-sphere, one-electron steps involving association of the reduced form and dissociation of the oxidized form of each of these small electron-transferring coenzymes. When a reduced ferredoxin is bound to the enzyme and the prosthetic [4Fe–4S] iron–sulfur cluster has already been reduced, two electrons are available to be simultaneously transferred to the siroheme.

The lone pair of electrons on the central nitrogen of the nitrite ion (**2–113**) associates with the open site on the ferric siroheme to become a sixth ligand,[1695,1697] and the two electrons passing through the prosthetic [4Fe–4S] iron–sulfur cluster and a hydron perform a **reductive heterolytic dissociation** of a nitrogen–oxygen bond of the nitrite ion to produce the complex between nitric oxide (**2–115**) and ferrous siroheme[1698] and a hydroxide ion[1699]



(2–262)

In the active site of the enzyme from *S. oleracea*, the hydron is provided by the ammonio group of Lysine 224.[1695] A complex between nitric oxide and ferrous heme has been stabilized in the unrelated, pentaheme nitrite reductase (cytochrome; ammonia-forming) from *S. oneidensis*, which catalyzes the same reduction (Equation 2–261), by controlling the reduction potential of the solution to prevent the later steps in the overall reaction.[1700]

In the active site of ferredoxin—nitrite reductase, the reductive heterolytic dissociation is accomplished by transfer of one of the arriving electrons from the reduced ferredoxin and the reduced prosthetic [4Fe–4S] iron–sulfur cluster through a d_{xz} or d_{yz} orbital on the iron ion (Figure 2–24) into a vacant antibonding π molecular orbital in the allyl π molecular orbital system on the nitrite ion. The **push of the electron density** arriving on the nitrogen and the fact that it is entering an antibonding π molecular orbital of the nitrite ion weaken the nitrogen–oxygen bond for heterolysis.[1701]

The resulting complex between nitric oxide (**2–115**) and iron(II) porphyrin is equivalent to the complex between nitroxyl ion (**2–116**) and iron(III) porphyrin. Nitroxyl ion is the conjugate base of nitroxyl (**2–119**), a fact that explains how the nitrogen is then hydronated. Following hydronation of the nitrogen, the next two electrons are transferred to the resulting complex between nitroxyl and iron(III) porphyrin, while a hydron is transferred to the oxygen and another hydron is transferred to the nitrogen to produce the complex between hydroxylamine, $HONH_2$ (**2–118**), and ferric siroheme.[1698] This complex is then reduced by two electrons, and two hydrons are added to produce a molecule of water, ammonia, and uncoordinated ferrisiroheme. In this final reduction, the electrons have to arrive two at a time to avoid the formation of hydroxyl radical, hence the prosthetic [4Fe–4S] iron–sulfur cluster in ferredoxin—nitrite reductase.

Assimilatory sulfite reductase (NADPH)

$$8\,H^+ + 6\,e^- + SO_3^{2-} \rightleftharpoons H_2S + 3\,H_2O \qquad (2\text{–}263)$$

from bacteria such as *E. coli* and *D. vulgaris* is an enzyme evolutionarily related (22% identity; 2.3 gap percent) to ferredoxin—nitrite reductase (Equation 2–261). In fact, many sulfite reductases also catalyze the reduction of nitrite ion to ammonia. Sulfite reductases contain a subunit homologous to ferredoxin—nitrite reductase[1695] in which there is the same inner-sphere complex[1697] of an [4Fe–4S] iron–sulfur cluster and a siroheme.[661,1702]

The main difference between assimilatory sulfite reductase (NADPH) and ferredoxin—nitrite reductase is the presence in the former of an additional subunit containing sites at which two flavins are bound as prosthetic groups.[1703] One of the flavins is reduced by successive hydride transfers from molecules of NADPH; and the other, by transfer of two electrons from the first. When the enzyme is fully reduced, there are **six electrons immediately available for each turnover**, two on each of the flavins, one on the[4Fe–4S] iron–sulfur cluster, and one on the siroheme. All six of these electrons are ultimately derived from NADPH. Having them all immediately available ensures that sulfite can be fully reduced in one blast without the need for additional associations and dissociations of molecules of NADPH.

The nucleophilic lone pair of electrons on the central sulfur of the sulfite ion (see Equation 2–124) associates with the Fe^{2+} of the reduced siroheme, and its three oxygens form hydrogen bonds with the guanidinio nitrogens of two arginines, two ammonio nitrogens of lysines, and two molecules of water.[1697] These **catalytic acids** successively provide the eight hydrons needed for hydronation of the oxygens and the sulfur so that the hydrons are all immediately available as well. Overlap between the vacant *d* orbitals on the sulfur of the sulfite and the occupied d_{xz} and d_{yz} orbitals on the Fe^{2+} in the electron-rich siroheme permits efficient transfer of electron density onto sulfur, and the push of this electron density weakens each of the sulfur–oxygen bonds in turn to permit their successive reductive heterolytic dissociation,[1699] as happens to nitrite ion in the active site of ferredoxin—nitrite reductase. The rate-limiting step in the reaction is the reductive heterolytic dissociation of the first molecule of water to give a hydrosulfinate ion associated with the iron ion of the heme, and the further reduction by four electrons and the consumption of six hydrons proceeds so rapidly that no intermediates that could dissociate are allowed to accumulate, nor have any intermediates been observed.

As with assimilatory sulfite reductase (NADPH), nitrite reductase (cytochrome; ammonia-forming) from bacteria such as *Sulfurospirillum deleyianum* and *Wolinella succinogenes*, which catalyzes the same reaction as ferredoxin—nitrite reductase (Equation 2–261), contains enough prosthetic groups, which in this case are five prosthetic hemes *c*, to provide simultaneously, along with its small electron-transferring coenzyme cytochrome *c*, the six electrons needed to accomplish the reduction and **avoid the problem of having intermediates accumulate**. Four of the prosthetic hemes *c* have as their two axial ligands imidazolyl groups from histidines and transfer electrons, and the fifth, at which the reaction proceeds, has nitrogen 7 of a lysine as its proximal axial ligand opposite the open site.[1704,1705] The reaction also requires eight hydrons (Equation 2–261). In the active site of nitrite reductase (cytochrome; ammonia-forming) from *W. succinogenes* with a nitrite ion bound to the iron of the heme, the imidazolyl group of a histidine forms a hydrogen bond with one of the oxygens of the nitrite ion. There is a cluster of eight molecules of water and the 4-hydroxyphenyl group of a tyrosine that are all held together by hydrogen bonds, and two of the molecules of water in this cluster form hydrogen bonds with the other oxygen of the nitrite ion. This cluster is continuous with the surrounding solution and is responsible for shuttling the necessary hydrons into the active site, rather than having all the hydrons immediately at hand.[1701,1706] Other than the immediate availability of at least six electrons in the fully reduced enzyme, the mechanism of the reaction and the intermediates are the same as those of ferredoxin—nitrite reductase (Equation 2–262).[1701] Nitrite reductase (cytochrome; ammonia-forming) from *W. succinogenes* also reduces sulfite to hydrogen sulfide, a reaction also requiring six electrons and eight hydrons (Equation 2–263), at a rate that is actually faster than assimilatory sulfite reductases (NADPH).[1707]

Hydroxylamine dehydrogenase from *N. europaea*, however, contains **more than enough prosthetic groups**, seven hemes *c* in addition to the heme with the open site at which the oxidation occurs, to absorb all four of the electrons produced during the oxidation of hydroxylamine (**2–118**)[1042]

$$H_2O + H_2NOH \rightleftharpoons NO_2^- + 5\,H^+ + 4\,e^- \qquad (2\text{–}264)$$

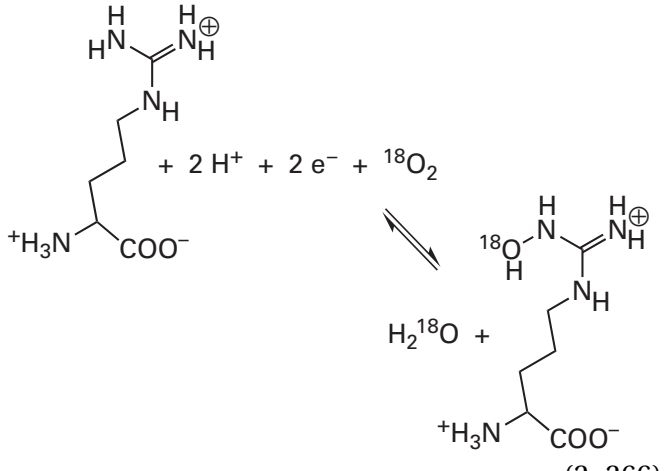
The hemes *c* are grouped in pairs, a fact suggesting that the electrons are removed two at a time during the oxidation

$$H_2O + H_2NOH \rightleftharpoons H_2O + NO^- + 3\,H^+ + 2\,e^- \rightleftharpoons NO_2^- + 5\,H^+ + 4\,e^- \qquad (2\text{–}265)$$

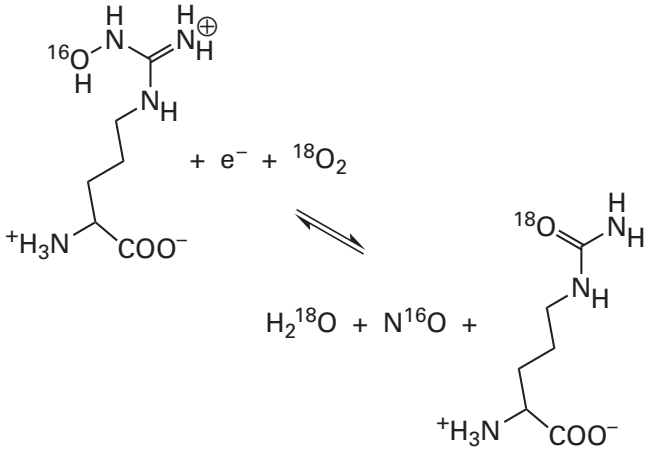
while the intermediate conjugate base of nitroxyl, NO^- (**2–116**), remains tightly bound to the iron ion of the heme. Nitrite reductase (cytochrome; ammonia-forming) from *Thioalkalivibrio nitratireducens*, which only uses six electrons for its enzymatic reaction (Equation 2–261), contains eight hemes *c*,[1708] again more than enough.

In all the reactions involving a prosthetic heme that have been discussed so far, the axial ligand opposite the open site on the prosthetic heme usually does not involve itself directly in the oxidation–reduction performed by the heme other than to tune the iron ion to a reduction potential appropriate to the oxidation–reduction. The axial ligand to the iron ion in the prosthetic heme in ferredoxin—nitrite reductase (Equation 2–262) is an exception to this general rule because of its coordination of the prosthetic [4Fe–4S] iron–sulfur cluster. Another exception is the sulfido group of Cysteine 123, which is the axial ligand to the prosthetic heme in thiosulfate dehydrogenase from *A. vinosum*, which oxidizes two thiosulfates to tetrathionate, the disulfide between two thiosulfates. In this instance, the sulfido group of Cysteine 123 participates in a mixed disulfide between itself and one of the thiosulfates that is the result of a two-electron oxidation mediated by the heme. The second thiosulfate participates in a thiol–disulfide exchange with the mixed disulfide to regenerate the sulfido group of the axial ligand and tetrathionate.[1709]

Nitric-oxide synthase[1710,1711] contains a heme P450 that catalyzes two successive monooxygenations, one at a guanidinio nitrogen and the next at the carbonate carbon of the hydroxylated guanidinio group[1712-1715]



(2–266)



(2–267)

The consequential product of the reaction, as the name implies, is NO, nitric oxide (**2–115**).

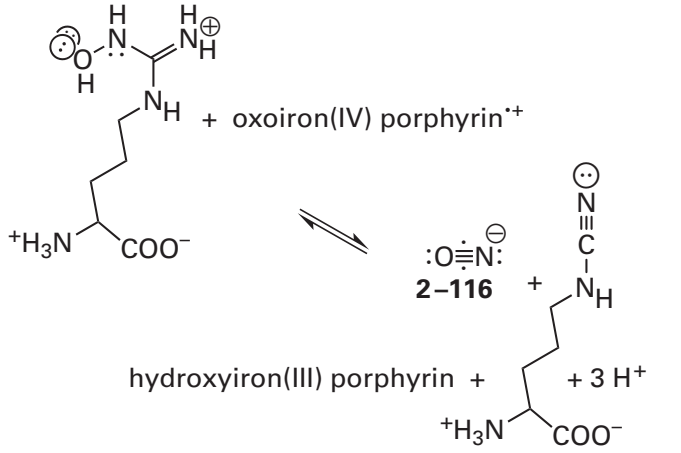
The first reaction catalyzed by nitric-oxide synthase, the hydroxylation of a guanidinio nitrogen (Equation 2–266), has the usual stoichiometry of an enzyme containing a heme P450 and a mechanism that proceeds through the usual oxoiron(IV) porphyrin$^{\bullet+}$. Although **the second of the successive reactions catalyzed by nitric-oxide synthase (Equation 2–267) requires only one electron**, the ultimate source of that single electron is nevertheless the flavin of the NADPH—hemoprotein reductase that is a domain of nitric oxide synthase in animals and that is homologous (31% identity; 4 gap percent) with the aforementioned, detached independent NADPH—hemoprotein reductase that provides electrons to hemes P450.[1716,1717] Because NADPH can supply electrons only two at a time, the **overall stoichiometric reaction** catalyzed by the enzyme is

$$3\,\text{NADPH} + \text{H}^+ + 4\,\text{O}_2 + 2\,\text{L-arginine} \rightleftharpoons 2\,\text{L-citrulline} + 2\,\text{NO} + 3\,\text{NADP}^+ + 4\,\text{H}_2\text{O} \quad (2\text{–}268)$$

and a single electron or a hole has to be stored on the enzyme between the production of the first nitric oxide and the production of the second.

In addition to the stoichiometric fact that the conversion of N^{ω}-hydroxy-L-arginine to citrulline and nitric oxide requires only one electron, this reaction is unusual because an oxygen atom from molecular oxygen ends up where the oxygen atom of a molecule of water would end up were there a hydrolysis at the guanidinio carbon of the N^{ω}-hydroxy-L-arginine that ends up as citrulline. The second monooxygenation **does not involve an oxoiron(IV)**

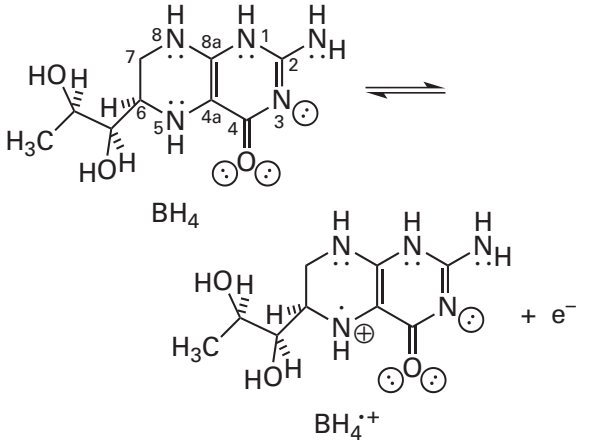
porphyrin$^{\bullet+}$ because when an oxoiron(IV) porphyrin$^{\bullet+}$ is formed at the heme in the enzyme from *R. norvegicus* by using hydrogen peroxide as the oxidant rather than molecular oxygen, N^{ω}-hydroxy-L-arginine is converted by that oxoiron(IV) porphyrin$^{\bullet+}$ to N^{δ}-cyano-L-ornithine and nitroxyl ion, ON^- (**2–116**)[1718-1720]



(2–269)

a two-electron oxidation, instead of the normal L-ornithine and nitric oxide (Equation 2–267), a one-electron oxidation.

In addition to the heme, the active site of nitric-oxide synthase contains a prosthetic **(6*R*)-L-*erythro*-5,6,7,8-tetrahydrobiopterin,**[1721-1723] a homologue of flavin. The (6*R*)-L-*erythro*-5,6,7,8-tetrahydrobiopterin (BH_4) participates in the enzymatic reaction by providing a single electron and becoming the **radical cation** ($BH_4^{\bullet+}$)

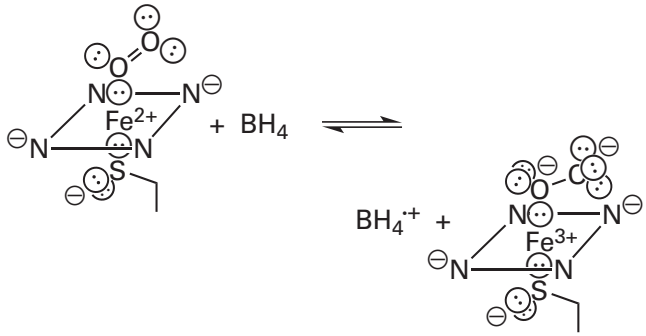


(2–270)

The radical cation participates in the enzymatic reaction by taking up a single electron.[1724-1727] The BH_4 is located in the crystallographic molecular model of the murine and the human enzymes with its 2-imino group forming a hydrogen bond to the carboxy group of the 17-(2-carboxyethyl) group of the heme (see **2–69**)[1728,1729] but directed 180° away from the heme and far from the open site on the iron. Consequently, it can participate only in outer-sphere electron transfer, albeit over a short distance and through a hydrogen bond.

During catalysis, the $BH_4^{\bullet+}$ that is a required intermediate in the enzymatic reaction is slowly and inescapably converted by adventitious oxidation to 6(*R*)-L-*erythro*-6,7-dihydrobiopterin,[1730] which dissociates from the enzyme and must be replaced by free BH_4 either from the cytoplasm or from the solution of the enzymatic assay. Depending on how rapidly the enzyme is turning over, many cycles of oxygenation are completed before this replacement is necessary. Consequently, the BH_4 does not appear in the overall equation (Equation 2–268).

The BH_4 **participates during the hydroxylation of L-arginine**. When a form of murine nitric-oxide synthase lacking the domain for NADPH—hemoprotein reductase and its flavin and having a ferroheme and L-arginine in its active site is mixed with molecular oxygen, oxyiron(II) porphyrin is formed immediately by association of the oxygen with the ferroheme and then decays coincident with both the appearance of $BH_4^{\bullet+}$ and the hydroxylation of the L-arginine to N^{ω}-hydroxy-L-arginine.[1725,1731,1732] This observation indicates that the BH_4 is responsible for the outer-sphere electron transfer necessary to produce the peroxyiron(III) porphyrin[1726,1733-1735] that precedes the formation of oxoiron(IV) porphyrin$^{\bullet+}$, which is required to hydroxylate the guanidinio nitrogen of L-arginine[1727]



(2–271)

Unlike in the foregoing reaction in which the heme was chemically reduced, in the intact nitric-oxide synthase from *R. norvegicus*, the reduced flavin in the active site of the attached NADPH—hemoprotein reductase is responsible for one-electron reduction of the heme from aquoiron(III) porphyrin

to iron(II) porphyrin, and as a result, the reduced flavin becomes the semiquinone. The production of nitric oxide and L-citrulline from L-arginine and molecular oxygen depends on the ability of the flavin in the NADPH—hemoprotein reductase domain to form a stable semiquinone.[1736]

Consequently, in the **reaction in which L-arginine is hydroxylated**, reduced flavin reduces the heme from iron(III) porphyrin to iron(II) porphyrin and becomes the semiquinone, molecular oxygen binds to the Fe^{2+}, and BH_4 provides the electron necessary to produce peroxyiron(III) porphyrin and becomes $BH_4^{\bullet+}$. The kinetics of these two steps have been followed by using hydrated electrons to reduce the iron(III) porphyrin and rapidly initiate the reaction.[1737] Molecular oxygen associates with the iron(II) porphyrin with a rate constant of $3 \times 10^8\ M^{-1}\ s^{-1}$, and the BH_4 then transfers the necessary electron with a rate constant of $2\ ms^{-1}$. The hydron required to hydronate the peroxyiron(III) porphyrin to form the oxoiron(IV) porphyrin$^{\bullet+}$ (Equation 2–250) is provided by the L-arginine itself.[1738] Following hydronation, the hydroperoxyiron(III) porphyrin becomes oxoiron(IV) porphyrin$^{\bullet+}$, which hydroxylates the ω nitrogen of the L-arginine in the usual manner.

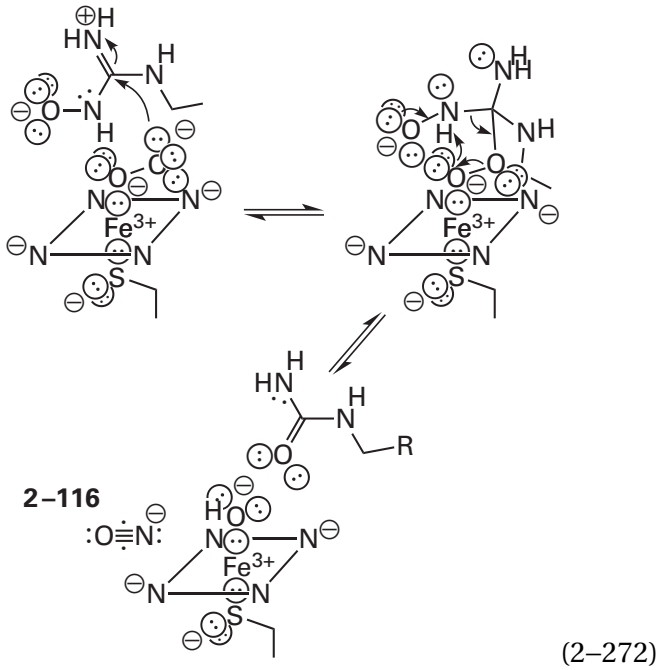
At the end of these steps, the flavin is the semiquinone, the BH_4 is the radical cation,[1725] the heme is the iron(III) porphyrin, and the L-arginine has become N^{ω}-hydroxy-L-arginine. The $BH_4^{\bullet+}$ is then reduced to BH_4 by the flavin semiquinone[1725] with the heme serving as a relay station.[1730,1734] When it is fully reduced, the flavin is able to reduce by one electron the iron(III) porphyrin to iron(II) porphyrin, so it must be the case that the semiquinone can also do so. The reduced heme in turn is able to reduce $BH_4^{\bullet+}$ to BH_4. The oxidized flavin is then reduced by an NADPH.

In the **conversion of N^{ω}-hydroxy-L-arginine to nitric oxide and L-citrulline** (Equation 2–267) by nitric-oxide synthase from *B. subtilis*,* in which N^{ω}-hydroxy-L-arginine occupies the active site instead of L-arginine, the now-reduced flavin reduces iron(III) porphyrin to iron(II) porphyrin, and the BH_4 provides the electron necessary to form peroxyiron(III) porphyrin (Equation 2–271), just as both of these prosthetic groups did before. The peroxyiron(III) porphyrin, however, is only slowly hydronated because there is no catalytic acid, which in the first step was the guanidinio group of the L-arginine, in its vicinity.[1739] As a result, in the bovine enzyme, the peroxyiron(III) porphyrin becomes a detectable intermediate that immediately precedes the formation of nitric oxide and L-citrulline.[1740] Because peroxyiron(III) porphyrin is a nucleophile (see Figure 2–54),[1556] because it is the intermediate that immediately precedes formation of the products, and because one of its oxygen atoms ends up at the acyl oxygen of L-citrulline,[1719,1741] it must be the distal oxyanion of the peroxide in the **peroxyiron(III) porphyrin that is the nucleophile** that adds to the carbonate carbon in the nucleophilic substitution that occurs at that carbon of the N^{ω}-hydroxy-L-arginine and that ultimately produces L-citrulline, just as the distal oxygen of 4a-peroxyflavin adds to the acyl carbon in uracil during the analogous nucleophilic substitution catalyzed by pyrimidine oxygenase (Equation 2–220).

In crystallographic molecular models of the complexes of both N^{ω}-hydroxy-L-arginine and nitric oxide with nitric-oxide synthases from *B. subtilis*[1739] and *R. norvegicus*,[1742] the nitrogen of the nitric oxide occupies the open coordination site on the iron. In this instance, nitric oxide was bound to the active site not as a product of the reaction but as an inert analogue of a peroxide dianion in peroxyiron(III) porphyrin. This complex between the heme and nitric oxide is isosteric with a peroxyiron(III) porphyrin, but the nitric oxide is not a nucleophile. In the crystallographic molecular models, the oxygen of the nitric oxide, taking the place of the nucleophilic distal oxygen of peroxyiron(III) porphyrin (see Figure 2–54), is 0.36 nm from the carbonate carbon of the *N*-hydroxyguanidino group. If, however, the peroxy group in place of the nitric oxide were to rotate around the iron–oxygen bond, a rotation for which there is no hindrance, it would be in the proper location to add nucleophilically to the carbonate carbon of the *N*-hydroxyguanidino group. In these crystallographic molecular models, the hydroxylated nitrogen on the N^{ω}-hydroxy-L-arginine forms a hydrogen bond (0.28 nm) with the nitrogen of the nitric oxide that sits upon the iron ion.

When all these dispositions are considered, the following **nucleophilic substitution**

*Although murine nitric-oxide synthase and nitric-oxide synthase from *B. subtilis* are quite different in size (1144 aa and 363 aa, respectively), the catalytic domain (365 aa) in murine nitric-oxide synthase is essentially the same (44% identity; 0.5 gap percent) as the entire enzyme (363 aa) from *B. subtilis*, and the two enzymes share the same mechanism.



(2–272)

should be a part of the mechanism for the production of nitric oxide. The fact that the hydroxide produced in the reaction ends up on the Fe^{3+} at the end of the reaction catalyzed by murine nitric-oxide synthase[1743] is consistent with this proposal. The nucleophilic substitution as written, however, yields nitroxyl ion, ON^- (**2–116**), instead of nitric oxide, ON (**2–115**). Nitroxyl ion has one more electron than nitric oxide (Figure 2–56), hence the negative charge number, and it is isoelectronic with molecular oxygen, with the additional electron occupying the other π^* molecular orbital (**2–87**). The negative charge number can be explained by the fact that the nucleus of a nitrogen atom has one fewer proton than the nucleus of an oxygen atom.

If the BH_4 in the active site of murine nitric-oxide synthase is present as the radical cation, the heme is in the ferric state, and N^{ω}-hydroxy-L-arginine is added along with hydrogen peroxide to form the hydroperoxyiron(III) porphyrin by direct association with iron(III) porphyrin, the active site, in a single turnover, produces nitric oxide and L-citrulline and ends up containing BH_4 rather than $BH_4^{\bullet+}$.[1744] If, however, the active site contains BH_4 instead of $BH_4^{\bullet+}$, the products are L-citrulline and nitroxyl, ONH (**2–119**), the conjugate acid of nitroxyl ion, ON^- (**2–116**), as in Equation 2–272. When the enzyme from *R. norvegicus* is depleted of BH_4, L-arginine is turned into N^6-cyano-L-ornithine and nitroxyl ion (Equation 2–269), the anionic conjugate base of nitroxyl, rather than L-citrulline and NO.[1733,1745]

In other words, the presence of $BH_4^{\bullet+}$ is essential to the production of nitric oxide (**2–115**) instead of nitroxyl ion (**2–116**), two oxides of nitrogen that differ by only one electron (Figure 2–56). It is essential because **$BH_4^{\bullet+}$ is the acceptor for the electron on nitroxyl ion**. It has been shown that when nitroxyl ion is generated in solution, it associates with the ferric heme of murine nitric-oxide synthase in which the tetrahydrobiopterin is $BH_4^{\bullet+}$, and the nitroxyl ion is oxidized to nitric oxide while the $BH_4^{\bullet+}$ is reduced to BH_4.[1744] It is not surprising that a complex between ferric heme and nitroxyl ion is able to reduce $BH_4^{\bullet+}$ because nitroxyl ion is a strong reductant (–810 mV). The fact that it can, however, provides a role for $BH_4^{\bullet+}$ and explains why nitroxyl is the product when $BH_4^{\bullet+}$ is not present.

In the crystallographic molecular model of nitric-oxide synthase in the complex with nitric oxide, replacing the peroxide ion, and N^{ω}-hydroxy-L-arginine, the π molecular orbital system of the *N*-hydroxyguanidino group is stacked flat against the π molecular orbital system of the porphyrin, and the hydroxyamino group is immediately adjacent to the nitrogen of one of the pyrrolyl groups in the porphyrin, and both the nitrogen and the oxygen are in van der Waals contact (0.36 nm) with that nitrogen. Consequently, the nitroxyl ion released in the nucleophilic substitution (Equation 2–272) would be right up against this nitrogen of the pyrrolyl group, and the nitroxyl ion, as a strong reductant, should be able to reduce $BH_4^{\bullet+}$ easily by injecting an electron into the π molecular orbital system of the heme, through which it would transfer directly to $BH_4^{\bullet+}$ through the hydrogen bond between the heme and the $BH_4^{\bullet+}$. Because the $BH_4^{\bullet+}$ is electronically coupled to the heme, it probably withdraws electron density from the highest occupied molecular orbital of the porphyrin, which has a lobe over the nitrogen of the pyrrolyl group. This **electron transfer from nitroxyl ion to $BH_4^{\bullet+}$** immediately following the nucleophilic substitution (Equation 2–272) completes the reaction.

When all these observations are considered, the overall enzymatic reaction (Equation 2–268), which is a **three-electron reduction**, can be divided into **two cycles**.

Before **the first cycle**, the initial enzyme contains as its prosthetic groups reduced flavin, BH_4, and aquoiron(III) porphyrin, which together have an odd number of valence electrons. The first L-arginine then associates, and at the end of the first cycle, the enzyme from which the first nitric oxide and the first L-citrulline have dissociated and which has

consumed one NADPH contains, as its prosthetic groups, the semiquinone of flavin, BH_4, and aquoiron(III) porphyrin, which together have an even number of valence electrons because the single electron required in the second half of the first cycle has departed with the products (Equation 2–267). After the first cycle, there is probably an equilibrium mixture of reduced flavin, flavin semiquinone, oxidized flavin, iron(III) porphyrin, iron(II) porphyrin, BH_4, and $BH_4^{\bullet+}$, as well as radicals at any relay stations between the flavin and the heme.

In the **second cycle**, this collection of prosthetic groups with an even number of electrons binds L-arginine, and the electrons distribute in such a way that the heme is iron(II) porphyrin, the flavin is oxidized, and the pterin is BH_4, a configuration with an even number of electrons in the proper distribution to hydroxylate L-arginine (Equation 2–271). The hydroxylation is a reaction that requiries two electrons and that leaves the prosthetic groups with again an even number of electrons. At some point, before the intermediate N^{ω}-hydroxy-L-arginine is converted to nitric oxide and L-citrulline during the second half of the second cycle, the oxidized flavin is reduced by a second molecule of NADPH. The flavin then reduces, by the transfer of one electron, the $BH_4^{\bullet+}$ formed during the conversion of L-arginine to N^{ω}-hydroxy-L-arginine, and the resulting flavin semiquinone reduces the aquoiron(III) porphyrin to iron(II) porphyrin. The oxidized flavin is then reduced by a third molecule of NADPH. After the N^{ω}-hydroxy-L-arginine has been oxidized in the second half of this second cycle (Equations 2–271 and 2–272) and the second nitric oxide and the second L-citrulline have dissociated, the flavin is reduced, the heme is aquoiron(III) porphyrin, and the pterin is BH_4. The prosthetic groups with an odd number of valence electrons are ready to repeat the first cycle, and the overall reaction (Equation 2–268) has been accomplished.

In each cycle, at the point at which nitroxyl ion dissociates from the tetrahedral intermediate during the nucleophilic substitution (Equation 2–272), the BH_4 is the radical cation ready to accept the undesired electron. The difference in the active sites at this point in the two cycles is whether or not the flavin is the semiquinone.

During the first cycle, N^{ω}-hydroxy-L-arginine can dissociate from the active site to leave it with $BH_4^{\bullet+}$, aquoiron(III) porphyrin, and flavin semiquinone. The flavin semiquinone then reduces the $BH_4^{\bullet+}$ to BH_4 using the heme as a relay station, the flavin is reduced by a molecule of NADPH, and the active site is returned to the state that precedes the first cycle. During the second cycle, N^{ω}-hydroxy-L-arginine can dissociate from the active site to leave it with BH_4, aquoiron(III) porphyrin, and flavin semiquinone, the state in which the enzyme exists after the full first cycle and before the second. Eventually, any N^{ω}-hydroxy-L-arginine that has dissociated into the solution reassociates with one of these two forms of the enzyme to be converted to nitric oxide and L-citrulline.

There are hemoproteins the purpose of which is to bind nitric oxide.[1746] One property of its binding to a heme is that, unlike oxygen, nitric oxide significantly weakens the affinity of the iron ion for the axial ligand opposite the open site to which it binds—for example, the affinity of the iron for the imidazolyl group of a histidine. This weakening of the bond to the proximal axial ligand may trigger the conformational changes that these hemoproteins undergo upon binding nitric oxide[1675] and that are responsible for their function.

Hemes, because of the rigid, sterically defined arrangement of their ligands, provide the clearest introduction to high-valent iron and to the complexes between iron ions and the oxides of oxygen, sulfur, and nitrogen. A number of enzymes that react with the oxides of oxygen, however, have nonheme iron ions as prosthetic groups (Figure 2–57). The nonheme iron ion in *all-trans*-8′-apo-β-carotenal 15,15′-oxygenase from *Synechocystis* (Figure 2–57A)[1747] is the most similar to the iron ion in a heme, as it is octahedrally coordinated with four sp^2 nitrogens from the imidazolyl groups of four histidines at four of the octahedral positions. In the resting ferrous enzyme, one open position is occupied by a molecule of water and the other is vacant. The two open positions, however, are adjacent to each other rather than opposite each other as in a heme, so the comparison with a heme would be that three of the nitrogens from three of the imidazolyl groups take the place of three of the nitrogens in the heme, the octahedral position occupied by the fourth nitrogen of the heme is vacant, the axial ligand to the iron ion is the fourth imidazolyl group, and the other axial ligand is the molecule of water.

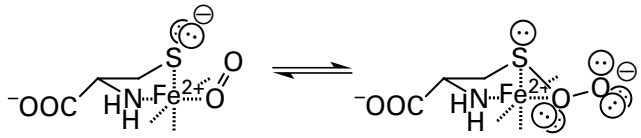
Figure 2–57: Drawings[50] of the ligands to prosthetic nonheme iron ions in the crystallographic molecular models of **(A)** *all-trans*-8′-apo-β-carotenal 15,15′-oxygenase from *Synechocystis*,[1747] **(B)** protocatechuate 3,4-dioxygenase from *P. putida*,[1758] **(C)** linoleate 13*S*-lipoxygenase from *G. max*,[1763] **(D)** cephalosporin synthase from *S. clavuligerus*,[1780] **(E)** naphthalene 1,2-dioxygenase from *P. putida*,[1790] **(F)** hemerythrin from *Themiste dyscritum*,[1876] **(G)** murine inositol oxygenase,[1883] **(H)** rubredoxin:oxygen oxidoreductase from *D. gigas*,[1893] and **(I)** methane monooxygenase (soluble) from *M. capsulatus*.[1904] Black atoms are carbons, red atoms are oxygens, and blue atoms are nitrogens. Iron ions are the rusty brown spheres surrounded by their ligands. In most cases, there are six ligands to each iron ion, sometimes in undistorted and sometimes in distorted octahedral array. The side chains acting as ligands are labeled. The lone red spherical ligands in Panels A, B, D, H, and I are molecules of water or hydroxide ions. Often the coordinated molecule of water or the hydroxide forms a hydrogen bond to the carboxy group of an aspartate (D) or a glutamate (I). In Panel C, a portion of the alkyl hydroperoxide that is the product of the lipoxygenase reaction, which was coordinated to the iron ion in the enzyme in the crystal submitted to diffraction, is drawn; and in Panel G, a complete molecule of *myo*-inositol, which was coordinated to the one of the iron ions in the inositol oxygenase in the crystal, is drawn. In Panels E, F, and H, the complex between the respective enzyme and molecular oxygen was present in the crystal and the molecule of oxygen is drawn. In naphthalene 1,2-dioxygenase (E), the molecule of oxygen forms two bonds to the iron ion; in hemerythrin (F), one oxygen forms a bond to an iron ion and the other forms a hydrogen bond with a μ-oxo group; and in rubredoxin:oxygen oxidoreductase (H), one oxygen forms a bond to an iron ion and the other forms a hydrogen bond with the carboxy group of a glutamate. In prosthetic clusters of more than one iron ion, there are often μ-oxo groups between two of the irons. In the drawings (F, G, H, and I), they are the white spheres that connect two iron ions. Often a μ-oxo group will form a hydrogen bond to the side chain of an amino acid (G, H, and I) or an oxygen in a molecule of oxygen (F). A single iron ion can be coordinated by the two oxygens of the same carboxylate (E). In prosthetic clusters of more than one iron ion, two of the iron ions are often coordinated by the same carboxylate of an aspartate (F, G, and H) or a glutamate (F, H) with each of its oxygens coordinating a different iron ion.

There are three related enzymes: *all-trans*-8′-apo-β-carotenal 15,15′-oxygenase (Figure 2–57A), carotenoid oxygenase 1 from *Neurospora crassa* (27% identity; 3.1 gap percent), and β-carotene 15,15′-dioxygenase from *G. gallus* (26% identity; 3.7 gap percent).[1749] The first oxidatively cleaves *all-trans*-8′-apo-β-carotenal at the central carbon–carbon double bond to *all-trans*-retinal (**2–85**) and (2*E*,4*E*,6*E*)-2,6-dimethylocta-2,4,6-trienedial, the second oxidatively cleaves stilbenoids at the central carbon–carbon double bond to two substituted benzaldehydes, and the third oxidatively cleaves β,β-carotene (**2–78**) at the central carbon–carbon double bond to two molecules of retinal (**2–85**). In each case, a carbon–carbon double bond is cleaved and the two carbons end up as the carbonyls of the two aldehydes that are the products. No electrons other than those in the respective reactants and those in the molecular oxygen are required. The two atoms in molecular oxygen end up as the two atoms of oxygen in the carbonyl groups of the two aldehydes, so these enzymes are dioxygenases.[1748]

The first steps in the respective oxidative cleavages are the association of the respective reactant with the active site followed by the association of molecular oxygen with Fe^{2+}.[1749] In a crystallographic molecular model of the active site of carotenoid oxygenase 1 occupied by a reactant for the enzyme, the position on the iron ion occupied by the molecule of water homologous to the one in the active site of *all-trans*-8′-apo-β-carotenal 15,15′-oxygenase (Figure 2–57A) is pointed at the reactant and only 0.31 nm from the double bond that will be oxidatively cleaved, an orientation and proximity stating that the position on the prosthetic Fe^{2+} at which the molecular oxygen binds is the position occupied by the molecule of water. The vacant position is pointed away from the reactant. It is unclear how the oxidative cleavage proceeds, but the fact that the products are aldehydes and the fact that oxygen in the carbonyl group of each aldehyde was one of the oxygens in molecular oxygen suggests that a dioxetane (see **2–101**) is an intermediate in the reaction.[1748]

In cysteine dioxygenase from *R. norvegicus*, the Fe^{2+} in the resting active site is coordinated by three imidazolyl groups from only three histidines.[1750-1752] L-Cysteine, as a reactant, associates with the active site by coordinating the Fe^{2+} with its sulfido group and its α-amino group,[1753] which provides the fourth nitrogen in the coordination of the Fe^{2+}, so that the complex then resembles the coordination in *all-trans*-8′-apo-β-carotenal 15,15′-oxygenase (Figure 2–57A). Molecular oxygen binds to the remaining open site on the octahedral Fe^{2+}, which is only partially occupied by loosely bound water,[1754] and the sulfido sulfur then forms a covalent bond with the proximal oxygen atom, which is adjacent to it in the complex, to form the adduct



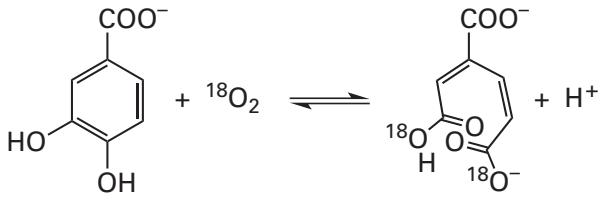
(2–273)

through a colligation between a thiyl radical and a superoxyiron(III).[1755] This adduct has been observed crystallographically.[1756,1757] The colligation does not result in any change in the oxidation state of the Fe^{2+}, which in this instance is approximating the sulfido group and the proximal oxygen, but the ability of Fe^{2+} to form superoxyiron(III), the ability of the Fe^{3+} in superoxyiron(III) to promote a radical on sulfur, and the ability of the iron to catalyze intersystem crossing are all exploited. Whether or not this adduct is an intermediate in the normal enzymatic reaction, however, is controversial, but it does result in the formation of a covalent bond between the sulfur and the oxygen, which would be one of the two covalent bonds between sulfur and oxygen in L-3-sulfinoalanine, which is the final product of the enzymatic reaction.

Unlike the preceding examples, most prosthetic nonheme iron ions are **coordinated both by the nitrogens of the imidazolyl groups of histidines and by the oxygens in the 4-oxido groups of tyrosines, in the carboxylates of aspartates or glutamates, or in the acyl oxygens of the carbamoyl groups of asparagines or glutamines**. For example, in protocatechuate 3,4-dioxygenase from *P. putida*,[1758,1759] two of the four imidazolyl groups found in *all-trans*-8′-apo-β-carotenal 15,15′-oxygenase (Figure 2–57A) have been replaced by two tyrosinates and the coordination is roughly bipyramidal, with one of the tyrosines and one of the histidines at the axial positions of the bipyramid (Figure 2–57B).[1758,1760] In this active site, the **basic oxyanions of the 4-oxido groups of two tyrosines stabilize the Fe^{3+} oxidation state.** In human persulfide dioxygenase, which, although unrelated, has a mechanism analogous to that of cysteine dioxygenase (Equation 2–273),[1761] the prosthetic Fe^{3+} is coordinated by two imidazolyl groups and the carboxylato group of an aspartate[1762] rather than three imidazolyl groups.

In linoleate 13*S*-lipoxygenase from *Glycine max*, the two oxygens in the coordination sphere of the iron ion are provided by the carboxylate of the carboxy terminus of the protein and the carbamoyl group of an asparagine (Figure 2–57C),[1763] but there are three imidazolyl groups instead of two, which together produce an octahedrally coordinated iron ion with only one open site.[1764,1765] Nevertheless, the two oxygens stabilize the ferric state. The 12*Z* double bond in the linoleate [(9*Z*,12*Z*)-9,12-octadecadienoate)] that is a reactant for linoleate 13*S*-lipoxygenase associates with the open site on the Fe^{3+}. Transfer of an electron from that double bond, probably concerted with the dissociation of a hydron from the methylene carbon between what were the 12*Z* double bond and the 9*Z* double bond on the linoleate, produces a stable, neutral **pentadienyl radical** delocalized over carbons 9 through 13. The pentadienyl radical has been defined by electron paramagnetic resonance spectroscopy.[1766] Transfer of the electron to the Fe^{3+} reduces it to Fe^{2+}.[1767,1768] The unpaired electron density at carbon 13 in the highest occupied molecular orbital of the pentadienyl radical then adds to the distal oxygen of a molecule of oxygen that has associated as usual at the now open octahedral site on the now Fe^{2+}. This radical addition to the molecular oxygen forms an acyclic lipid peroxy radical, (9*Z*,11*E*,13*S*)-13-peroxyoctadeca-9,11-dienoate. The ability of molecular oxygen to add rapidly to an alkyl radical and form the more stable alkylperoxy radical is a well-known reaction. A common example of such a radical addition is the use of molecular oxygen to terminate radical polymerizations. The electron needed to turn the resulting peroxy radical into the peroxy ion is provided by the Fe^{2+}, so at the end of the reaction, the anionic conjugate base of (9*Z*,11*E*,13*S*)-13-hydroperoxyoctadeca-9,11-dienoate ends up as a ligand to the octahedrally coordinated Fe^{3+} (Figure 2–57C) The conjugate base of the alkylperoxide is then hydronated on its peroxy oxygen by the carboxy-terminal carboxy group[1763,1769] to form the product of the enzymatic reaction, (9*Z*,11*E*,13*S*)-13-hydroperoxyoctadeca-9,11-dienoate.

Protocatechuate 3,4-dioxygenase is a member of the family of **intradiol dioxygenases**. A member of this family dioxygenates a vicinal dihydroxyphenyl group and turns it into a (2*Z*,4*Z*)-hexa-2,4-dienedioate. For example, protocatechuate 3,4-dioxygenase turns protocatechuate (3,4-dihydroxybenzoate) into (2*Z*,4*Z*)-3-carboxyhexa-2,4-dienedioate

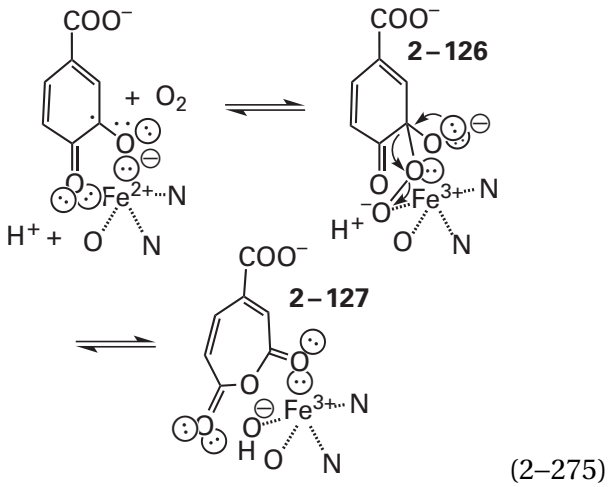


(2–274)

In the active site of protocatechuate 3,4-dioxygenase, one of the hydroxyls of the dihydroxyphenyl group in the reactant displaces the 4-hydroxyphenyl group of the axial tyrosine (Figure 2–57B) from the Fe^{3+}, and the adjacent hydroxy group of the catechol displaces the equatorial molecule of water, so the diol

becomes a bidentate ligand[1770] to the Fe^{3+}. When the axial tyrosine in protocatechuate 3,4-dioxygenase from *P. putida* is replaced by a histidine, the anionic imidazolio group of which is a much stronger ligand to Fe^{3+}, the rate of association of protocatechuate with the Fe^{3+} is decreased by at least 600-fold.[1771]

Following the association of the diol, the Fe^{3+} withdraws electron density from the phenyl ring and creates a partial radical at carbon 3 of the protocatechuate.[1772] The resulting partial radical of Fe^{2+} associates with a molecule of oxygen to approximate it to the radical. The radical of protocatechuate at carbon 3 then reacts as an alkyl radical with the bound molecular oxygen.[1773] In the case of protocatechuate 3,4-dioxygenase, the partial radical at carbon 3 of protocatechuate enters one of the half-occupied, antibonding π molecular orbitals of the molecule of oxygen, and this molecular orbital and an atomic orbital of carbon 3 form a bond between the carbon and the distal oxygen atom. An electron from the now Fe^{2+} enters the other half-occupied, antibonding π molecular orbital of the molecular oxygen, and the two electrons in this latter orbital become a pair of σ electrons sitting between the distal oxygen atom and the now Fe^{3+},[1774,1775] coordinating the Fe^{3+} and forming a **metallacyclic peroxide** (**2–126**)

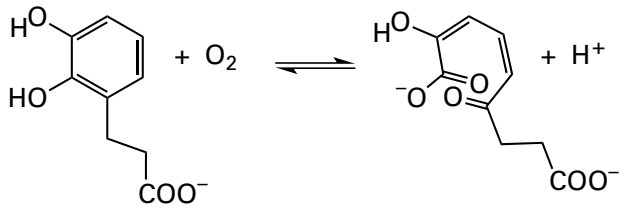


(2–275)

The cyclic peroxide rearranges to the anhydride (**2–127**) of the product[1775-1777] in a ring expansion analogous to a Baeyer–Villiger reaction (Figure 2–47). There are crystallographic molecular models of metallacyclic peroxide **2–126** and ring-expanded anhydride **2–127** formed from 4-fluoro-2-hydroxyphenol in the active site of protocatechuate 3,4-dioxygenase from *P. putida*.[1778] The anhydride is hydrolyzed by the adjacent hydroxide on the Fe^{3+}, which was originally derived from molecular oxygen,[1759,1770] and both atoms from the molecular oxygen are incorporated into the product (Equation 2–274).

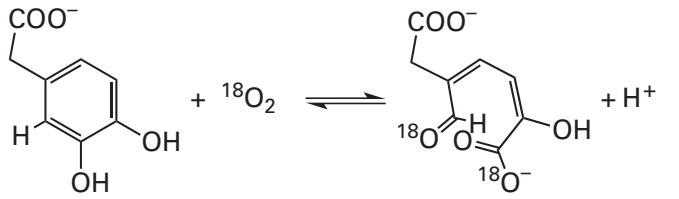
The **most prevalent coordination of a mononuclear, prosthetic, nonheme iron ion** is one in which the nitrogens of **two imidazolyl groups** and one or both[1779] of the oxygens from **one carboxy group**, either an aspartate or a glutamate, provide three or four of the octahedral ligands to the iron ion and, in the resting unoccupied enzyme, the oxygens of three or two waters, respectively, provide the remaining octahedral ligands (Figure 2–57D).[1780] When only one of the oxygens of the carboxylate is a ligand, the other can form a hydrogen bond to one of the waters on the iron ion and is available as a catalytic acid–base. Any one of the molecules of water can be replaced by an oxygen, nitrogen, or sulfur in one of the substrates or, when the iron ion is Fe^{2+}, by molecular oxygen. This coordination is capable of several different types of oxygenation.

The **extradiol dioxygenases** are a family of enzymes that, by and large, use this coordination of an iron ion by two imidazolyl groups and the carboxy group of a glutamate. The reactants for these dioxygenases are dihydroxyphenyl or aminohydroxyphenyl groups. The two hydroxy groups or the hydroxy group and the amino group on the phenyl group can be either ortho to each other or para to each other. A member of this family converts a dihydroxyphenyl group or an aminohydroxyphenyl group into the respective 6-oxohexa-2,4-dienoate by oxidatively cleaving the carbon–carbon bond adjacent to one of the hydroxy groups but not the carbon–carbon bond between two vicinal ortho hydroxy groups. For example, 3-carboxyethylcatechol 2,3-dioxygenase



(2–276)

converts 3-(2,3-dihydroxyphenyl)propanoate to (2*E*,4*Z*)-2-hydroxy-6-oxonona-2,4-diene-1,9-dioate. 3,4-Dihydroxyphenylacetate 2,3-dioxygenase



(2–277)

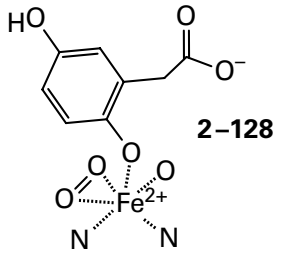
from *Brevibacterium fuscum*[1781] converts 3,4-dihydroxyphenylacetate to (2*E*,4*Z*)-2-hydroxy-5-carboxymethyl-6-oxohexa-2,4-dienoate, and biphenyl-2,3-diol 1,2-dioxygenase from *Pseudomonas*[1782] converts biphenyl-2,3-diol to (2*E*,4*Z*)-2-hydroxy-6-oxo-6-phenylhexa-2,4-dienoate.

Unlike the intradiol dioxygenases, **in the resting state, the iron in the active site of an extradiol dioxygenase is an Fe^{2+}**, in part because there is only one weakly basic anionic oxygen coordinating the iron ion. The Fe^{2+} in the active site of gentisate 1,2-dioxygenase from *Pseudaminobacter salicylatoxidans*, however, which is a member of a separate family of extradiol dioxygenases, is coordinated by three histidines and no carboxylate.[1783] When the Fe^{2+} in 3,4-dihydroxyphenylacetate 2,3-dioxygenase (Equation 2–277) from *B. fuscum* is changed to a Mn^{2+}, there is almost no change in the rate of the enzymatic reaction.[1784] Consequently, because the biochemical standard reduction potentials of Mn^{2+} and Fe^{2+} differ by 700 mV, the oxidation state of the metallic ion probably is not required to change during the enzymatic reaction and its role is to assemble the reactants.

The mechanism of the extradiol dioxygenases begins when the hydroxy group of the substrate that is adjacent to the site of cleavage associates with the Fe^{2+} in the active site. In a crystallographic molecular model of the complex between the Fe^{2+} and the reactant 3,4-dihydroxy-L-phenylalanine in the active site of 3,4-dihydroxyphenylalanine 2,3-dioxygenase (see Equation 2–277) from *Streptomyces sclerotialus*, both the 3-hydroxy group, adjacent to the site of cleavage, and the 4-hydroxy group become ligands to the Fe^{2+}, and the 2-imidazolyl groups and the carboxy oxygen fill three of the other octahedral positions around the Fe^{2+}, an arrangement that leaves an open site.[1785] A molecule of oxygen then binds to the open site—or when the reactant does not have vicinal diols, to one of the two open sites—on the Fe^{2+} to form an oxyiron(II). The oxyiron(II) withdraws an electron from the phenyl ring to form a **radical on the carbon adjacent to the hydroxy group** next to the site of cleavage, just as in the intradiol dioxygenases (see Equation 2–275).

The conclusion that this radical exists is based on results from **radical probes**. The 3-carboxyethylcatechol 2,3-dioxygenases (Equation 2–276) from both *E. coli* and *C. necator* catalyze the isomerization of the radical probe *cis*-2-(2,3-dihydroxyphenyl)-cyclopropane-1-carboxylate to *trans*-2-(2,3-dihydroxyphenyl)cyclopropane-1-carboxylate, an isomerization that requires that the 2,3-dihydroxyphenyl group in these radical probes be converted in the active site to the 2,3-dihydroxyphenyl radical.[1786] Two different complexes between 2-hydroxy-4-nitrophenol and the oxyiron(II) in the active site of 3,4-dihydroxyphenylacetate 2,3-dioxygenase from *B. fuscum* (Equation 2–277) have been examined spectroscopically.[1787] The various spectra of the first complex identify it as 2-hydroxy-4-nitrophenol associated through its 2-hydroxy group to oxyiron(II), and those of the second complex are consistent with it being 2-hydroxy-4-nitrophenol radical bound to superoxyiron(II). In the second complex, an electron from the 2-hydroxy-4-nitrophenol has been withdrawn onto the molecular oxygen to form the superoxide radical anion.

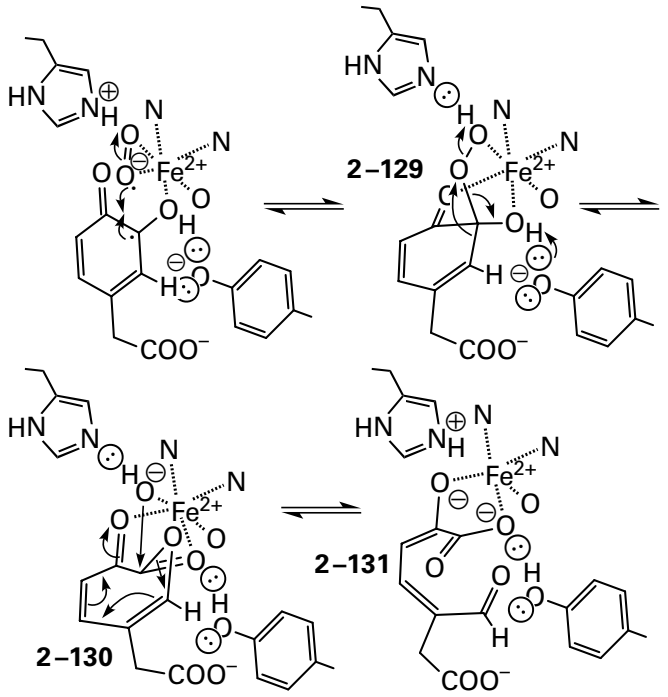
Because the oxidation state of the Fe^{2+} probably does not change during formation of the initial radical, it must be the molecule of oxygen on the Fe^{2+} that forms this initial radical. Either the complex between homogentisate and oxyiron(II) or homogentisate radical and superoxyiron(II), which are indistinguishable, has been observed crystallographically in the active site of homogentisate 1,2-dioxygenase from *P. putida*,[1788] and either the complex between 3,4-dihydroxynitrobenzene and oxyiron(II) or 3,4-dihydroxynitrobenzene radical and superoxyiron(II), which are indistinguishable, has been observed crystallographically in the active site of 3,4-dihydroxyphenylacetate 2,3-dioxygenase from *B. fuscum*.[1789] In these complexes, either the molecule of oxygen or the superoxide radical anion is **bound sideways** to the iron ion (see Figure 2–57E),[1790] and the homogentisate (2,5-dihydroxyphenylacetate), or its radical, is coordinated to the iron ion by the 2-hydroxy group



2–128

or the 3,4-dihydroxynitrobenzene, or its radical, is coordinated to the iron ion by both the 3-hydroxy group and the 4-hydroxy group. In the crystallographic molecular model of the occupied active site of homogentisate 1,2-dioxygenase (**2–128**), the closest oxygen atom in the molecular oxygen is 0.26 nm from carbon 2; and in the crystallographic molecular model of the occupied active site of 3,4-dihydroxyphenylacetate 2,3-dioxygenase, the closest oxygen atom in the molecular oxygen is 0.24 nm from carbon 3. In both of these cases, the distances are well within the sum of the van der Waals radii. This disposition suggests that the radical at the respective carbon in each of these two active sites is the result of an inner-sphere electron transfer from the highest occupied π molecular orbital for the aromatic π molecular orbital system of the respective phenyl group to one of the half-occupied π^* molecular orbitals on the oxygen molecule. A model compound that mimics this complex between a hydroxyphenyl radical and an Fe^{2+} has been synthesized.[1791]

The next step in the reaction of an extradiol dioxygenase, for example, 3,4-dihydroxyphenylacetate 2,3-dioxygenase



(2–278)

is the addition of the radical at the carbon on which the coordinated hydroxy group is located to the closest oxygen of the superoxide radical anion in a colligation to form **metallacyclic peroxide 2–129**, analogous to the one in protocatechuate 3,4-dioxygenase (**2–126**) but on an Fe^{2+} rather than a Fe^{3+}. This intermediate metallacyclic peroxide has been observed crystallographically in the active sites of 3,4-dihydroxyphenylacetate 2,3-dioxygenase from *B. fuscum*[1789] and homogentisate 1,2-dioxygenase from *P. putida*[1788] and has been identified spectroscopically in the active site of 3,4-dihydroxyphenylacetate 2,3-dioxygenase from *B. fuscum*.[1787]

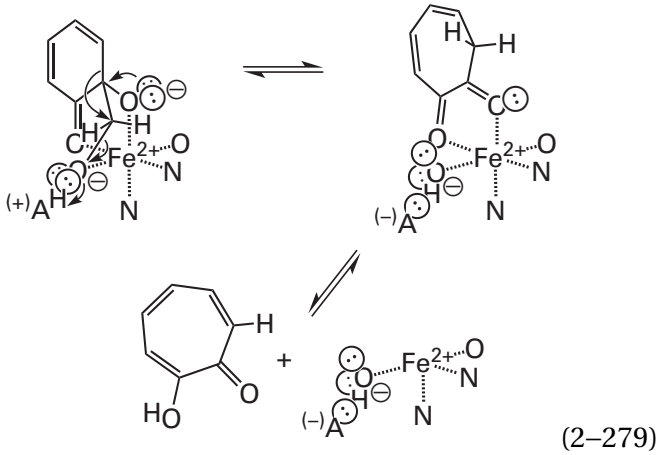
Given that the distance between the carbon and the oxygen is only 0.24–0.26 nm, it seems odd that formation of the bond producing the peroxide is not coincident with formation of the radical, and that the radical and the superoxide radical anion are identifiable intermediates. Because molecular oxygen is a triplet molecule and the peroxide is a singlet molecule, however, the existence of these intermediates may result from the fact that intersystem crossing must occur before the peroxide can form and that separation of the two electrons into the two reactants and coordination to the Fe^{2+} hastens but does not eliminate this usually slow process. It may also be slow because the spin density on the carbon is meager.

The cyclic peroxide then rearranges to form the lactone of the product (Equation 2–278), which in the case of 3,4-dihydroxyphenylacetate 2,3-dioxygenase would be **2–130**. This ring expansion is again an analogue of a **Baeyer–Villiger rearrangement** (Figure 2–47B) with the leaving group being a hydroxyiron(II) instead of a carboxylate. The 4-oxidophenyl group of a tyrosine in the active site of 3,4-dihydroxyphenylacetate 2,3-dioxygenase from *B. fuscum* (0.25 nm) removes a hydron from the hydroxy group that becomes one of the acyl oxygens during this rearrangement.[1789]

In the crystallographic molecular model of the complex between the active site of 3,4-dihydroxyphenylacetate 2,3-dioxygenase from *B. fuscum* and 2-hydroxy-4-nitrophenol, which is a slow substrate for the enzyme, the respective metallacyclic peroxide (see **2–129**) that precedes the ring expansion is observed.[1789] In this intermediate, the imidazolyl group of a histidine forms a hydrogen bond (0.30 nm) to the oxygen of the peroxy group that is on the iron ion. 2,2-Hydroxy-4-sulfonatocyclohexa-2,4-dienone is isosteric and isoatomic but not isoelectronic with the product of only a heterolysis of the oxygen–oxygen bond in the respective metallacyclic peroxide (see **2–129**) but not a rearrangement. In a complex of the same enzyme with this analogue, the imidazolyl group of the same histidine forms a hydrogen bond (0.28 nm) to a hydroxide on the Fe^{2+}.[1792] It can be concluded that this imidazolyl group **hydronates the proximal oxygen** of the peroxy

group in **2–129** during the actual rearrangement (Equation 2–278) so that the leaving group in the heterolysis of the oxygen–oxygen bond that occurs during the rearrangement is ferrous hydroxide.

2-Hydroxy-2-hydroxymethylcyclohexa-3,5-dien-1-one is an analogue of peroxy intermediate **2–127** that is missing the carboxymethyl group and the other hydroxy group and in which the oxygen atom of the peroxy group on carbon 2 has been replaced with a methylene carbon. When 2-hydroxy-2-hydroxymethylcyclohexa-3,5-dien-1-one is mixed with 3-carboxyethylcatechol 2,3-dioxygenase from *E. coli*, 2-hydroxy-1-oxocyclohepta-2,4,6-triene is produced by the enzyme[1793]



(2–279)

The cycloheptatriene ring in this rearranged intermediate is a carbon analogue of the lactone of the product (**2–130**) in which the oxa group in the ring of the latter is a methylene carbon in the former. This ring expansion is analogous to a pinacol rearrangement with neighboring group participation. This rearrangement catalyzed by this extradiol dioxygenase is the homologue of the usual ring expansion that occurs in the active site of an extradiol dioxygenase (Equation 2–278).

In the crystallographic molecular model of the active site of 3,4-dihydroxyphenylacetate 2,3-dioxygenase from *B. fuscum* occupied by the respective metallacyclic peroxy intermediate (**2–129**) of 2-hydroxy-4-nitrophenol, the hydroxy oxygen of a tyrosine side chain distorts the ring of the intermediate 2-hydroxy-4-nitro-1-oxo-2-peroxycyclohexa-3,5-diene by pushing the bond between carbon 2 and carbon 3 of the phenyl ring toward the oxygen of the peroxy group.[1794] Such a distortion in the normal enzymatic reaction would encourage the migration of the bond between carbon 2 and carbon 3 of the phenyl ring to that oxygen (Equation 2–278).

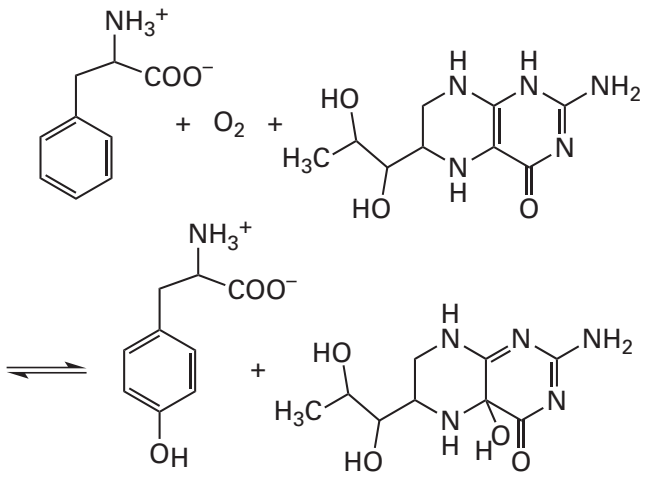
Following the migration of the σ bond during ring expansion, the resulting **lactone is hydrolyzed** by the hydroxide on the Fe^{2+} that was the leaving group in dissociation of the peroxyiron(II). The imidazolyl group of the histidine dehydronates the oxygen of the hydroxy group on the Fe^{2+}, itself a Lewis acid, during the nucleophilic addition to increase its nucleophilicity. The hydrolyzed lactone has been observed in crystallographic molecular models of the active site of homogentisate 1,2-dioxygenase from *P. putida*[1788] and the active site of 3,4-dihydroxyphenylacetate 2,3-di-oxygenase from *B. fuscum*.[1789]

So far the prosthetic nonheme iron ions that have been discussed have either remained in the same oxidation state throughout the respective reactions or changed back and forth from Fe^{2+} to Fe^{3+}, but no high-valent intermediates have been evoked or have been needed. There are a collection of enzymes in the active sites of which there are prosthetic, nonheme iron ions that do pass through high-valent intermediates.

The same coordination of an iron ion by two imidazolyl groups and a carboxylate oxygen (Figure 2–57D) is used by oxidases and oxygenases that require two electrons from the electron-transferring coenzymes, L-ascorbate or (6*R*)-5,6,7,8-tetrahydrobiopterin (Equation 2–270), or 2-oxoglutarate, a cosubstrate, to accomplish the oxidation or oxygenation of their respective nominal substrates through high-valent intermediates.[1780,1795-1800] An example of an oxidase that uses L-ascorbate (Equation 2–163) as a reductant is aminocyclopropanecarboxylate oxidase[1801]

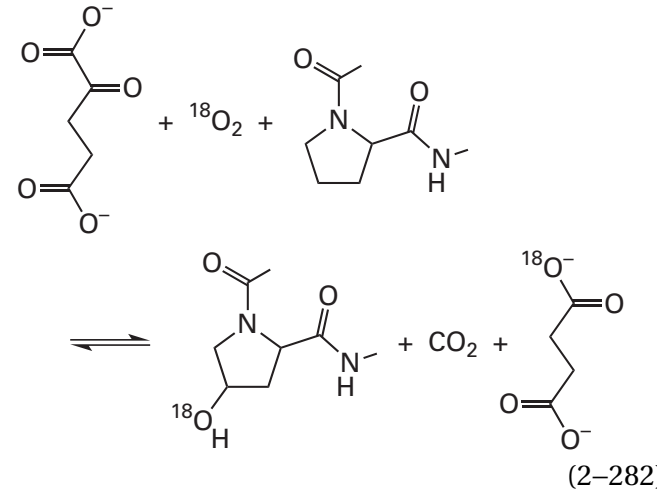
$$\begin{aligned}&\text{1-aminocyclopropane-1-carboxylate} + O_2 + \\ &2\ \text{L-ascorbate} \rightleftharpoons 2\ \text{L-monodehydroascorbate} \\ &+ 2\,H_2O + H^+ + \text{cyanide} + \text{ethylene} + CO_2\end{aligned} \qquad (2\text{–}280)$$

The two L-monodehydroascorbates then disproportionate to an L-dehydroascorbate (Equation 2–163) and an L-ascorbate. An example of a monooxygenase that uses BH_4 as a reductant is phenylalanine 4-monooxygenase



(2–281)

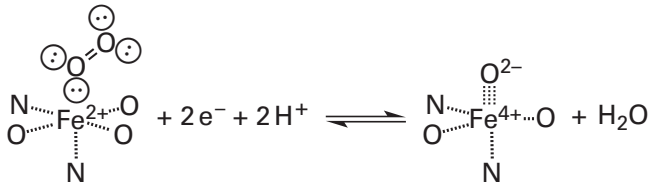
In this latter reaction (Equation 2–281), the 4a-hydroxyhemiaminal of 6,7-dihydrobiopterin,[1802] which, as shown, is the actual product of the enzymatic reaction,[1803,1804] is dehydrated to 6,7-dihydrobiopterin by 4a-hydroxytetrahydrobiopterin dehydratase,[1805] and the resulting 6,7-dihydrobiopterin is enzymatically reduced back to BH_4 by 6,7-dihydropteridine reductase. An example of an oxygenase that uses 2-oxoglutarate as a reductant is procollagen-proline 4-dioxygenase



(2–282)

The product of this reaction is succinate, which is a common metabolite in the citric acid cycle, as is 2-oxoglutarate. Bovine procollagen-proline 4-dioxygenase incorporates one oxygen-18 from $^{18}O_2$ into the hydroxy group on the proline in the procollagen and the other oxygen-18 from $^{18}O_2$ into the carboxylate of the succinate.[1806]

The conversion of two L-ascorbates to two L-monodehydroascorbates, the conversion of tetrahydrobiopterin to 4a-hydroxytetrahydrobiopterin, and the conversion of 2-oxoglutarate to carbon dioxide and succinate in each case provides the **two electrons needed to convert an oxyiron(II) to an oxoiron(IV)**



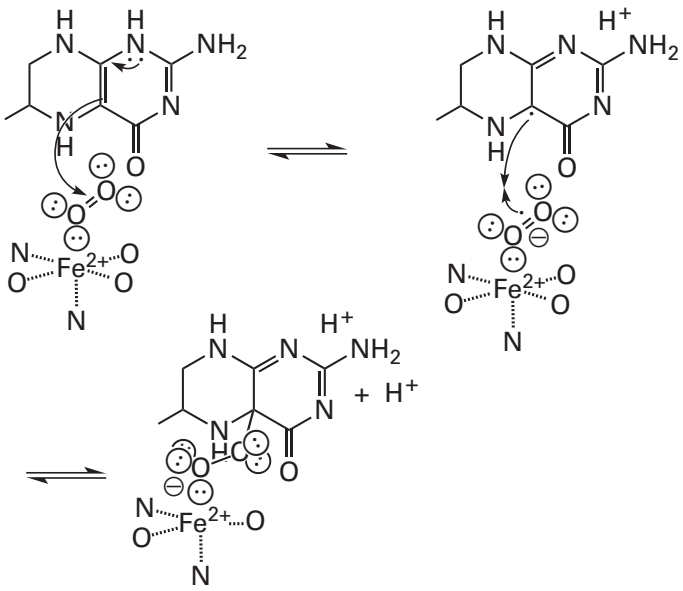
(2–283)

within the respective active sites,[1796,1807-1812] and this prosthetic high-valent iron oxide participates in the observed oxygenations.[1813] Nuclear resonance vibrational spectra of the oxoiron(IV) in such an active site are consistent with pentacoordination with the two imidazolyl groups and the carboxylato group as three of the ligands, the oxo group as the fourth ligand, and an oxygen atom from a molecule of water or a reactant as the fifth ligand.[1814]

L-Ascorbate provides two electrons to the active site, one at a time as required, in outer-sphere transfers. The first electron converts the nonheme oxyiron(II) to peroxyiron(III) (see Equation 2–250). A hydron and the second electron, in place of an electron from a surrounding porphyrin (Equation 2–241), are needed to convert the peroxyiron(III) to an oxoiron(IV).

In contrast to L-ascorbate, BH_4 and 2-oxoglutarate engage in **covalent intermediates** while providing the two electrons needed for the respective oxygenations.

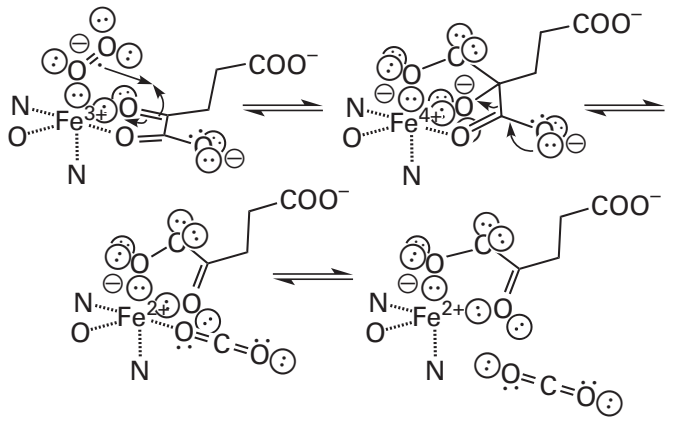
Tetrahydrobiopterin converts oxyiron(II) to the **hemiaminal of a peroxyiron(II)**[1815]



(2–284)

Although formation of this 4a-[peroxyiron(II)]-dihydrobiopterin is formally a nucleophilic addition of a pair of electrons in the electron-rich BH_4 to the molecular oxygen, the actual reaction probably involves two steps. The first is the transfer of an electron from BH_4 to the molecular oxygen of the oxyiron(II) to form superoxyiron(II). The second is the colligation of the two radicals, as in the active site of 3,4-dihydroxyphenylacetate 2,3-dioxygenase (Equation 2–278). These two steps permit rapid intersystem crossing. In this instance, the two radicals that colligate are the semiquinone of tetrahydrobiopterin, $BH_3^{\bullet}$, and superoxyiron(II).[1816]

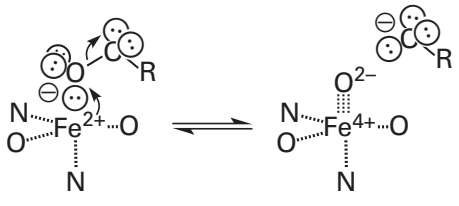
2-Oxoglutarate converts oxyiron(II) that is formed between molecular oxygen and the Fe^{2+} of the active enzyme,[1817] and which is equivalent (Figure 2–50) to superoxyiron(III), to a **succinylperoxyiron(II)**[1780,1818-1822]



(2–285)

which is the complex between monoperoxysuccinic acid and Fe^{2+}. This complex has been observed in a crystallographic molecular model of L-arginine hydroxylase from *Streptomyces vinaceus*.[1821]

From both the hemiaminal of a peroxyiron(II) (Equation 2–284) and the acylperoxyiron(II) (Equation 2–285), upon the usual heterolytic cleavage, an **oxoiron(IV)** is formed



(2–286)

with the respective oxygens, those of 4a-hydroxydihydrobiopterin and succinate, respectively, as leaving groups. This oxoiron(IV) intermediate has been detected spectroscopically in several of these enzymes.[1823-1827] In the case of the oxoiron(IV) formed by 2-oxoglutarate, the succinate that is one of the products remains a ligand to the iron ion until the oxygenation catalyzed by the enzyme has been completed, when both the oxidized product and the succinate dissociate.[1821]

The only purpose of formal nucleophilic addition to BH_4 (Equation 2–284) or decarboxylation of 2-oxoglutarate (Equation 2–285) is to provide the two electrons necessary during the conversion of oxyiron(II) to oxoiron(IV). Phenylalanine 4-monooxygenase from *R. norvegicus*, stripped of BH_4, is able to hydroxylate L-phenylalanine if hydrogen peroxide is used to produce oxoiron(IV) from the iron(II) in its active site, bypassing the normal route in the cytoplasm that relies on BH_4.[1828]

There is a **model compound for a nonheme oxoiron(IV)** in which the iron ion is coordinated by three guanidino nitrogens and an amino nitrogen and the iron–oxygen bond is of the appropriate length (0.165 nm). The arrangement of the five ligands in this model compound is a trigonal bipyramid.[1829] In a similar model compound, the four ligands to the iron are three pyrimidinyl nitrogens and an amino nitrogen and the iron is in the ferric state. The Fe^{3+} in this model compound is able to associate with hydrogen peroxide, and the ferric hydroperoxide dissociates to form oxoiron(V) rather than oxoiron(IV).[1830] This observation demonstrates that with the proper ligands a nonheme oxoiron(V) can be a stable product, but it may not be attainable in the active site of an enzyme.

The two nonheme oxoirons in these synthetic models for high-valent, nonheme iron ions in enzymes illustrate an **important distinction between an iron ion in a heme and an iron ion that is not in a heme**. When a hydroperoxyiron(III) porphyrin in a heme is provided with a hydron by an acid, the oxygen–oxygen bond dissociates heterolytically to form initially an oxoiron(V) porphyrin, which immediately or coincidently removes an electron from the highest occupied π molecular orbital of the porphyrin and becomes an oxoiron(IV) porphyrin$^{\bullet+}$. This latter option is not available to a nonheme iron ion. A nonheme hydroperoxyiron(III) can dissociate in solution under acid catalysis to produce a nonheme oxoiron(V), but because an oxoiron(V) is so unstable in most instances, it is difficult to form, and an oxoiron(V) has not yet been observed in the active site of an enzyme. If an electron is provided along with the hydron, as occurs in a heme, a hydroperoxyiron(III) dissociates to form an oxoiron(IV). A

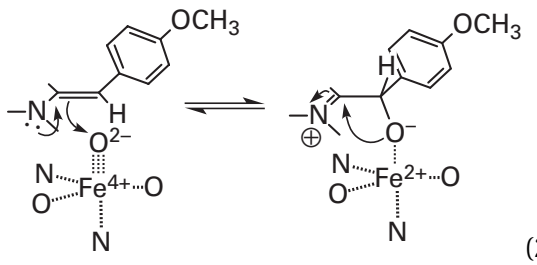
nonheme oxyiron(II), however, which is formed by the association of molecular oxygen with a nonheme Fe^{2+}, upon two-electron reduction and the addition of a hydron becomes the equivalent of a hydroperoxyiron(II) which dissociates heterolytically to form an oxoiron(IV). In this case, the electron required is provided before the dissociation of the peroxide rather than during its dissociation.

Depending on the specificity of the particular oxidase, monooxygenase, or dioxygenase, the oxoiron(IV) formed on the prosthetic nonheme iron ion (Equation 2–286) in an active site that obtains the necessary two electrons from ascorbate, BH_4, or 2-oxoglutarate can perform **one of several different types of oxidation**. The oxoiron(IV) can **hydroxylate an aliphatic carbon**;[1799,1819,1831,1832] hydroxylate the carbon adjacent to either a sulfonato group[1831,1833] or a carbamoyl nitrogen[1834] to produce ultimately a carbonyl group from that carbon upon hydrolysis of the resulting 1-hydroxy-1-sulfonate or the resulting hemiaminal, respectively, hydroxylate a methyl group to a hydroxymethyl group, hydroxylate the resulting hydroxymethyl group to the formyl group, and hydroxylate the resulting formyl group to the carboxy group in three separate steps.[1835]

The first step in the hydroxylation of an aliphatic carbon–hydrogen bond by oxoiron(IV) is the **abstraction of hydrogen from the carbon**. In the hydroxylation of L-arginine by 2-oxoglutarate dioxygenase (ethene-forming) from *P. savastanoi*, when the hydrogen on the L-arginine that is replaced by the hydroxy group is substituted with a deuterium, the rate at which the oxoiron(IV) formed in the active site decays during the enzymatic reaction decreases[1836] by a factor of greater than 16. In the hydroxylation of the normal substrate 2-amino-ethanesulfonate by taurine dioxygenase from *E. coli*, a hydroxyiron(III) is the intermediate that is formed directly from oxoiron(IV), the result expected (Figure 2–50) for abstraction of a hydrogen atom as the first step in the actual hydroxylation.[1837] In a crystallographic molecular model of the active site of the enzyme in which the oxoiron(IV) has been replaced by an inert oxovanadium(IV) and 2-aminoethanesulfonate is bound, the nearest hydrogen on carbon 1 of the 2-aminoethanesulfonate is only 0.20 nm from the oxo group on the vanadium ion, well within van der Waals contact (0.26 nm), and its carbon–hydrogen bond is pointed at the oxo group.[1838] In the reaction catalyzed by deacetoxycephalosporin-C synthase from *S. clavuligerus*, the role of the oxoiron(IV) formed in its active site is only that of abstracting a hydrogen from a methyl group to initiate a ring expansion.[1839] In verruculogen synthase from *A. fumigatus*, the radical produced on the substrate by abstraction of a hydrogen atom by oxoiron(IV), instead of becoming an alcohol, reacts with a second molecule of molecular oxygen to form the peroxy radical (see Equation 2–275).[1840]

If the first step in hydroxylation of an aliphatic carbon is the abstraction of a hydrogen by oxoiron(IV), then the result at the iron ion would be hydroxyiron(III), and the next step should be the **combination of the carbon radical with the hydroxyiron(III)** to produce the hydroxy group in the product coordinated to iron(II).[1837] In the aliphatic halogenase SyrB2 from *Pseudomonas syringae*, the oxoiron(IV) abstracts a hydrogen from a saturated carbon, and the resulting aliphatic radical reacts with a chloride, which is a ligand to the hydroxyiron(III), rather than its hydroxy group, to give a chloro group on the product rather than a hydroxy group.[1841] There is a synthetic model compound containing a hydroxyiron(III) pentacoordinated by two pyrimidino nitrogens, a tertiary amino group, and a hydroxy group in addition to the hydroxy group of hydroxyiron(III). The hydroxy group on Fe^{3+} in this model compound adds to a carbon radical to give the alcohol as the product.[1842] Consequently, just as hydroxyiron(IV) is equivalent to a hydroxyl radical on an Fe^{3+} (Figure 2–50), hydroxyiron(III), although formally a simple ferric hydroxide, is also equivalent to a hydroxyl radical on an Fe^{2+}, or a chloride as a ligand on a hydroxyiron(III) is equivalent to a chlorine radical on hydroxyiron(II).

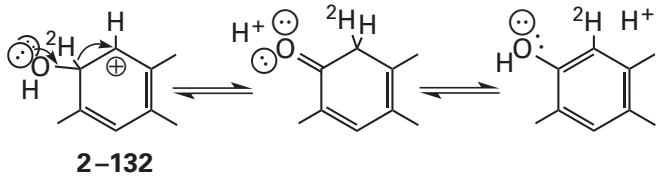
There are epoxidases in this family of enzymes that use oxoiron(IV) to **convert a carbon–carbon double bond into an epoxide**[1822] or produce the diol from a carbon–carbon double bond,[1834] presumably by an intermediate epoxidation. For example, the epoxidase AsqJ, which is involved in a step in the biosynthesis of aspoquinolone mycotoxin by *Emericella nidulans*, monooxygenates the electron-rich carbon–carbon bond of an enamine adjacent to a 4-methoxyphenyl group. In the active site of the 2-oxoglutarate-dependent enzyme, the prosthetic oxoiron(IV) acts as an electrophile to which the nucleophilic α position of the enamine adds, and during the addition the iminium is formed



(2–287)

This intermediate has been observed in a crystallographic molecular model of the enzyme.[1822] In the intermediate, the oxygen–carbon bond of the oxido group is normal to the plane of the enamine and parallel to its π molecular orbital system as expected, but the 4-methoxyphenyl ring is rotated so that in the reactant it would have been out of conjugation with the enamine. Following the nucleophilic addition, the oxyanion of the oxido group on the resulting Fe^{2+} then nucleophilically adds intramolecularly to the iminio carbon to form the epoxide that is the product of the reaction. The initial addition of the carbon–carbon double bond to the oxoiron(IV) is only marginally affected by the substitution of the 4-methoxy group, a strong electron-donating group, with strong electron-withdrawing groups. This result is consistent with weak conjugation of the 4-methoxyphenyl ring with the enamine.

In the enzymes that use BH_4 as a coenzyme and that **hydroxylate an aryl carbon–hydrogen bond**, such as in the hydroxylation of L-phenyl-alanine at carbon 4 (Equation 2–281), L-tyrosine at carbon 3, and L-tryptophan at carbon 5, oxoiron(IV) forms an intermediate that is chemically equivalent to pentadienyl carbenium ion **2–132**



2–132

(2–288)

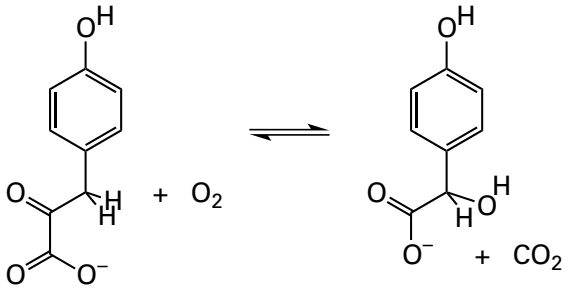
A fact that is consistent with the existence of this carbenium ion is the observation of a **1,2-hydride migration** (Equation 2–288) or a 1,2-methyl migration from the carbon that is hydroxylated to an adjacent carbon when deuterated or methylated substrates, respectively, are used.[1352,1843-1847] In the crystallographic molecular model of the complex between L-tryptophan and tryptophan 5-monooxygenase from *G. gallus*, carbon 5 of the L-tryptophan is 0.39 nm from the iron ion, but carbon 4 is only 0.43 nm from the iron ion.[1779] These are appropriate distances if the oxygen of oxoiron(IV) is sitting between the iron and the double bond between carbon 4 and carbon 5 during an epoxidation to produce, perhaps,[1848] an intermediate arene epoxide,[1849] which would then dissociate to pentadienyl carbenium ion **2–132**.

In addition to hydroxylation and epoxidation, oxoiron(IV) in one of the enzymes in this family can also **remove a hydride**[1850] or aggressively **withdraw, in the inner sphere, two electrons** from 1-aminocyclopropane-1-carboxylate also bound to iron(IV) to produce ethene, carbon dioxide, and hydrogen cyanide.[1851] Each of these reactions regenerates iron(II) ready to begin again.

With many of the enzymes that activate molecular oxygen by using a nonheme Fe^{2+}, in particular the 2-oxoglutarate dioxygenases, a serious flaw arises in practice. When molecular oxygen is bound to an Fe^{2+}, there is always a significant probability that the complex will **dissociate to produce superoxide radical anion and Fe^{3+}** (Equation 2–246). As superoxide radical anion is rapidly disproportionated in the cytoplasm by superoxide dismutase (Equation 2–226), it does not accumulate sufficiently to reduce the Fe^{3+} back to Fe^{2+}, and the enzyme is inactivated by its own reaction. In most oxygenases, especially those using nonheme iron, the usual mechanism for reducing the iron back to the ferrous form and reactivating the enzyme is to use L-ascorbate (Equation 2–163) as a one-electron reductant. When one of these leaky oxygenases, such as procollagen-proline 4-dioxygenase (Equation 2–282), is operating, **L-ascorbate** must be present continuously. Even at its maximum rate, a molecule of procollagen-proline 4-dioxygenase can oxygenate only about 50–200 molecules of substrate in the absence of L-ascorbate before the iron becomes adventitiously oxidized. Procollagen-proline 4-dioxygenase can be rereduced only at the expense of one electron from L-ascorbate (Equation 2–163).[1852,1853] A failure to hydroxylate collagen causes scurvy, a result of ascorbic acid deficiency. In other oxygenases, however, reductants other than L-ascorbate, and even superoxide radical anion itself, can substitute in this role.[1854]

There are a number of enzymes in the nonheme, iron-dependent dioxygenase family that have Fe^{2+} ions in their active sites also coordinated by two imidazolyl groups from two histidines and one or two of the oxygens of a carboxylate from aspartate or glutamate (Figure 2–57D) but that obtain electrons

for their oxygenations from sources other than L-ascorbate, 2-oxoglutarate, or BH_4. In 4-hydroxymandelate synthase

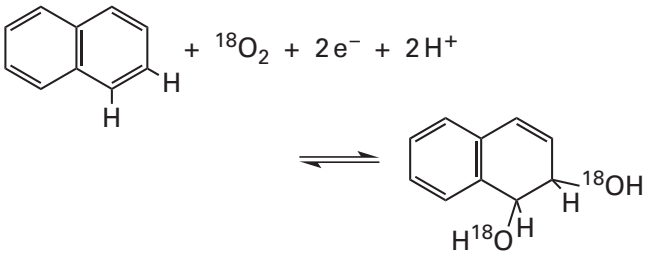


(2–289)

from *Amycolatopsis orientalis*, the substrate 4-hydroxyphenylpyruvate has within itself a 2-oxo carboxylic acid that forms oxoiron(IV) just as 2-oxoglutarate does by decarboxylation. The oxoiron(IV) then hydroxylates the methylene carbon of the intermediate 2-(4-hydroxyphenyl)acetate.[1855]

In (*S*)-2-hydroxypropylphosphonic acid epoxidase from *Streptomyces wedmorensis*,[1855,1856] 2-hydroxyethylphosphonate dioxygenase from *Streptomyces viridochromogenes*,[1857-1860] and isopenicillin-N synthase from *E. nidulans*,[1861,1862] the respective prosthetic iron ion coordinated by two imidazolyl groups and a carboxylato oxygen begins the respective oxygenation in the ferrous state; binds molecular oxygen to form the usual oxyiron(II), which as always is equivalent to superoxy-iron(III). The superoxyiron(III) then converts to hydroperoxyiron(III) upon the transfer of an electron and a hydron or hydrogen atom from the respective reactant. A subsequent, transient intermediate oxoiron(IV) has been identified spectroscopically in the oxidation catalyzed by 2-hydroxyethylphosphonate dioxygenase.[1863] This oxoiron(IV) would result from the homolytic dissociation of a hydroxyl radical from hydroperoxyiron(III). A computationally reasonable proposal for the epoxidation catalyzed by (*S*)-2-hydroxypropylphosphonic acid epoxidase is that the resulting **hydroxyl radical**, which is reactive enough (BDE = 497 kJ mol^{-1}) to abstract a hydrogen from any carbon atom, then abstracts a hydrogen from carbon 1 of 2-hydroxypropylphosphonic acid to initiate its epoxidation.[1864] In the case of 2-hydroxyethylphosphonate dioxygenase, however, the hydroxyl radical would participate in a colligation with the radical at carbon 2 of the 2-hydroxyethylphosphonate that, in this case, results from the abstraction of hydrogen from carbon 2 by superoxyiron(III), which becomes hydroperoxyiron(III).[1860]

There are a number of oxygenases that obtain the two electrons necessary for their oxygenations one at a time from a reduced Rieske [2Fe–2S] iron–sulfur cluster,[1865-1868] rather than from ascorbate, BH_4, or 2-oxoglutarate. The Rieske [2Fe–2S] iron–sulfur cluster is ultimately reduced one electron at a time by flavin. In naphthalene 1,2-dioxygenase



(2–290)

from *P. putida*, the prosthetic iron ion is coordinated by two imidazolyl groups from two histidines and two oxygens from the same bidentate carboxylato group of an aspartate (Figure 2–57E). The flavin that provides the electrons to the Rieske [2Fe–2S] iron–sulfur cluster is reduced by NADH.[1790] Naphthalene 1,2-dioxygenase with only a reduced nonheme Fe^{2+} and a reduced Rieske [2Fe–2S] iron–sulfur cluster catalyzes one dioxygenation of a naphthalene in the absence of any further source of electrons[1869] to give the diolate monoanion of the product tightly bound to the resulting Fe^{3+}.[1870] The diol, however, is released only upon reduction of the Fe^{3+}. These observations demonstrate that the actual oxygenation performed by the nonheme Fe^{2+} requires only one electron from the Rieske [2Fe–2S] iron–sulfur cluster and that the role of the second electron is to reduce the Fe^{3+} formed during oxygenation back to Fe^{2+}.

The first step in the reaction catalyzed by naphthalene 1,2-dioxygenase is the association of molecular oxygen with the prosthetic nonheme Fe^{2+}. In a crystallographic molecular model of fully reduced naphthalene 1,2-dioxygenase exposed to molecular oxygen, either a peroxide dianion or **molecular oxygen is bound sideways to the Fe^{2+}**, occupying both of its open positions (Figure 2–57E).[1790] Kinetic studies of the electron transfer from the prosthetic Rieske [2Fe–2S] iron–sulfur cluster during the dioxygenation of a series of reactants by benzoate 1,2-dioxygenase,[1868] a related enzyme (25% identity; 3.6 gap percent) also from *P. putida*, and during the monooxygenation of a series of reactants by the related enzyme, salicylate 5-hydroxylase[1871] from *Ralstonia* (23% identity;

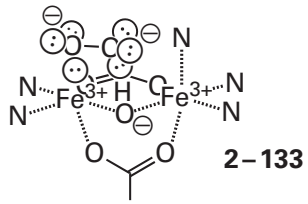
3.3 gap percent), are consistent with an adduct forming between the reactant and the oxyiron(II) prior to transfer of an electron from the Rieske [2Fe–2S] iron–sulfur cluster, which would require that the distal oxygen of the equivalent of a superoxyiron(III) add to the phenyl ring of a reactant to form a pentadienyl radical within the ring. This conclusion would identify the complex observed in the crystallographic molecular model as the complex between molecular oxygen and Fe^{2+}. The products formed by naphthalene 1,2-dioxygenase when radical probes are used as reactants instead of naphthalene are consistent with a radical of the naphthalene[1872] being an intermediate in the enzymatic reaction.

The fact that fully oxidized benzoate 1,2-dioxygenase, in the absence of any reductant, catalyzes the same 1,2-dioxygenation of benzoate that it normally does when hydrogen peroxide is substituted for molecular oxygen[1873] and the fact that during this unnatural reaction a hydroperoxyiron(III) is an intermediate[1874] at first suggested that, following the association of molecular oxygen with Fe^{2+} in the active site, an electron is transferred from the reduced Rieske [2Fe–2S] iron–sulfur cluster to the complex and a peroxyiron(III) is formed, as would be formed directly from hydroperoxide ion and Fe^{3+}, and that peroxyiron(III) is the species accomplishing the rest of the reaction. It has been concluded, however, that this unnatural oxidation with hydrogen peroxide follows a different mechanism from the natural reaction up to a point at which the two mechanisms converge.[1874]

Once the radical of the substrate is formed by **radical addition of the superoxyiron(III) to the aromatic ring**, how the rest of the reaction proceeds is unclear. There are computations that favor a particular mechanism.[1874] In a model compound containing peroxyiron(III) in which the Fe^{3+} is coordinated with ligands homologous to the two imidazolyl groups and the carboxylato group, the carboxylato group ends up as a peroxy acid. Spectroscopic observations indicate that the distal oxygen of the peroxy acid and the acyl oxygen of the peroxy acid are ligands to an octahedral Fe^{3+}. This observation implies that a peroxy acid could be involved in the enzymatic reaction.[1418,1875]

There are also dinuclear clusters of prosthetic iron ions that bind molecular oxygen and use it to perform oxidations. Hemerythrin is an example of a dinuclear prosthetic iron cluster that binds molecular oxygen. One of the Fe^{2+} ions of its dinuclear cluster is coordinated by three histidines from the protein, and the other Fe^{2+} is coordinated by two histidines (Figure 2–57F).[1876-1878] Two of the other ligands to each of the Fe^{2+} ions are provided by the respective oxygens of the same aspartate and the same glutamate. Finally, the two Fe^{2+} ions are bridged by a μ-oxo group. A ***μ*-oxo group** is an oxide dianion or a hydroxide that coordinates simultaneously two metallic ions.[1879] The μ-oxo oxide or μ-hydroxo hydroxide in a ***μ*-oxo diiron cluster** or a μ-hydroxo diiron cluster couples the Fe^{2+} ions ferromagnetically in the inner sphere.

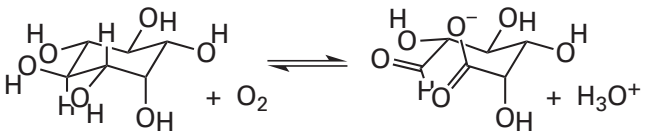
Hemerythrin, like hemoglobin, is responsible for binding molecular oxygen and transporting it in the circulation. In its deoxygenated, diferrous state, one Fe^{2+} is octahedrally and fully coordinated, but the other, although it is also octahedrally coordinated, has an open site. When molecular oxygen is bound by diferrous hemerythrin, it occupies this open site (Figure 2–57F) to saturate the octahedral coordination of this Fe^{2+}. When molecular oxygen is bound to the Fe^{2+} in the heme of a hemoprotein such as hemoglobin or myoglobin, the resulting complex has properties expected of both a complex between molecular oxygen and Fe^{2+} and a complex between superoxide radical anion and Fe^{3+} (Equation 2–246). When molecular oxygen is bound to the Fe^{2+} with the open site in diferrous hemerythrin, however, both iron ions are reversibly oxidized to Fe^{3+} ions.[1880,1881] The molecular oxygen in turn is reversibly reduced by the two electrons from the two Fe^{2+} ions and hydronated by the adjacent μ-hydroxo group on its distal oxygen through a hydrogen bond that remains in the final complex between the diferric cluster and a hydroperoxide ion (Figure 2–57F).[1882] This **ability of a dinuclear, diferrous cluster to convert molecular oxygen on an open Fe^{2+} spontaneously to a peroxyiron(III)**



2 – 133

is one of the novel features of this type of prosthetic group. Hemerythrin performs no further chemistry with the peroxyiron(III), using it only as a stable form of molecular oxygen while carrying it from regions of high concentrations of molecular oxygen to regions of low concentrations of molecular oxygen.

In the μ-oxodiiron cluster (Figure 2–57G)[1883] of murine and human[1884] inositol oxygenase



(2–291)

one of the iron ions is coordinated by the oxygen of a carboxylate and two nitrogens from imidazolyl groups and the other by two nitrogens from imidazolyl groups, and the iron ions are bridged by a μ-oxo group but only one carboxylato group. Because the other bridging carboxylato group is missing, one of the octahedral sites on the former iron ion (to the right in the drawing) is open, and two of the octahedral sites on the latter iron ion (to the left in the drawing) are open. The μ-oxodiiron cluster in inositol oxygenase oxidatively cleaves a carbon–carbon bond between two carbons, each with a hydroxy group trans to each other but equatorial (Equation 2–291). The distantly related[1885] 2-amino-1-hydroxyethylphosphonate dioxygenase (glycine-forming) from an unassigned species of bacterium has the same μ-oxodiiron cluster with the same ligands in the same orientation. It cleaves a bond between a carbon with a hydroxy group and a phosphorus with two hydroxy groups.[1886]

The active form of inositol oxygenase is not the diferrous state but a **mixed-valent state**[1887] in which one electron is delocalized between two Fe^{3+}. There is a completely symmetric, synthetic dinuclear cluster of prosthetic iron ions[1888] that is also able to support a similar mixed-valent state.[1889] Because this synthetic complex is symmetric, the two iron ions are in identical coordination, and the electron is delocalized equally between them.

myo-Inositol associates with the two open sites on the one iron ion in the active site of inositol oxygenase (Figure 2–57G), and upon its association, the affinity of the other iron ion for the molecule of water in its open, axial coordination site decreases measurably.[1890] This decrease in affinity for water suggests that this iron ion is now a localized Fe^{2+} while the other iron ion has become a localized Fe^{3+}. The decrease in affinity for water as the iron ion becomes a localized Fe^{2+} promotes the exchange of the molecule of water with a molecule of oxygen. The two hydroxy groups of the *myo*-inositol that have associated with the now Fe^{3+} are the two hydroxy groups between which the oxidative cleavage of the ring by the oxygenation catalyzed by the enzyme occurs (Equation 2–291 and Figure 2–57G), and the hydroxy group on carbon 1 and the hydroxy group on the phosphorus that associate with the iron ion in the active site of 2-amino-1-hydroxyethylphosphonate dioxygenase (glycine-forming) are the two hydroxy groups between which the oxidative cleavage occurs.[1886] The dioxygen of the oxyiron(II) at the iron ion to which the *myo*-inositol is not bound has the properties of a superoxide radical anion bound to Fe^{3+} and is in position to abstract the hydrogen from carbon 1 of the bound *myo*-inositol (Figure 2–57G).[1891] Following abstraction of the hydrogen atom, the oxyiron(II) has become a hydroperoxyiron(III), which is then converted into a species of high-valent iron that performs the oxygenation. No reductant is required in the stoichiometry reaction, so at the end for the oxygenation, the diiron cluster has necessarily returned to the mixed-valent state. Abstraction of the hydrogen on carbon 1 in 2-amino-1-hydroxyethylphosphonate also initiates the oxidative cleavage performed by 2-amino-1-hydroxyethylphosphonate dioxygenase (glycine-forming) from *Gimesia maris*.[1892]

In the μ-oxodiiron cluster (Figure 2–57H)[1893] of rubredoxin:oxygen oxidoreductase

$$4\ \text{rubredoxin}_{\text{red}} + 4\ H^+ + O_2 \rightleftharpoons 4\ \text{rubredoxin}_{\text{ox}} + 2\ H_2O \qquad (2\text{–}292)$$

from *D. gigas*, one of the iron ions is coordinated by the imidazolyl groups of two histidines and the carboxylato group of a glutamate and the other by the imidazolyl group of one histidine and the carboxylato group of an aspartate, and they are bridged by a μ-oxo group and the carboxylato group of another aspartate. The carboxylato group of the nonbridging aspartate forms a hydrogen bond with the μ-oxo hydroxide, as did one of the carboxylato groups of an aspartate in inositol oxygenase (Figure 2–57G).

In the first step in the four-electron reduction catalyzed by rubredoxin:oxygen oxidoreductase, molecular oxygen binds to the diiron(II) cluster in the resting enzyme at an open site on one of the two Fe^{2+} ions in the cluster (Figure 2–57H), and it is converted to hydroperoxydiiron(III). In 4-aminobenzoate *N*-oxygenase from *Streptomyces thioluteus*, which has the same distribution of ligands in its diiron cluster as rubredoxin:oxygen oxidoreductase, nuclear resonance vibrational spectra of this intermediate are consistent with an arrangement in

which each oxygen of the hydroperoxide is a ligand to a different iron ion in the cluster,[1894] and the hydron on the hydroperoxy group forms a hydrogen bond with the carboxylato group of the glutamate the carboxy group of which was a donor in the hydrogen bond with molecular oxygen (Figure 2–57H) and must have hydronated that oxygen. In the active site of rubredoxin:oxygen oxidoreductase, one of the oxygens of the hydroperoxydiiron(III), presumably the one already hydronated, becomes a molecule of water and and the other either becomes a higher-valent iron ion, which is then reduced to aquoiron(III) to complete the conversion of the molecular oxygen to two molecules of water, or it is reduced to aquoiron(III) in concert with the dissociation of the oxygen–oxygen bond. It is thought, however, that an oxoiron(IV) is formed during the dissociation of the oxygen–oxygen bond in 4-aminobenzoate *N*-oxygenase and that oxoiron(IV) is responsible for the oxygenation of the 4-amino group to the *N*-oxide as the first step in oxidizing it to the 4-nitro group.

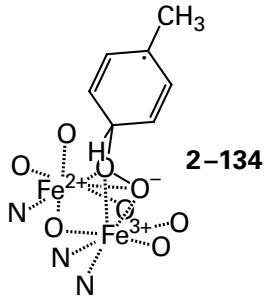
In the μ-oxodiiron cluster in rubrerythrin from *D. vulgaris* in its diferric state, one Fe^{3+} is coordinated by the imidazolyl group of a histidine and by both oxygens of the carboxylato group of a glutamate and the other Fe^{3+} is coordinated by one of the oxygens of the carboxylato group of a glutamate and both oxygens of the carboxylato group of another glutamate. The carboxylato groups of two glutamates bridge the two Fe^{3+}, as do the aspartate and the glutamate in hemerythrin (Figure 2–57F), and there is one μ-oxo group.[1895] This coordination has the fewest imidazolyl groups and the most carboxylato groups and other oxyanions of any diiron cluster. Ruberythrin is a peroxidase (Equation 2–237) that uses two rubredoxins as the source of the necessary two electrons.[1896] The diferrous form of the prosthetic group binds hydrogen peroxide with one of its oxygens on each of the Fe^{2+} ions, reduces the hydrogen peroxide with the two electrons from the two Fe^{2+} ions to a molecule of water and a hydroxide that ends up as that μ-oxo group between the two now Fe^{3+} ions. The dinuclear cluster then releases the μ-oxo hydroxide as a molecule of water, but only after both Fe^{3+} ions have been reduced back to Fe^{2+} ions.[1897] As a result, the diferrous cluster has no μ-oxo group and each Fe^{2+} has an open site because the μ-oxo group of the diferric cluster has been released as the second molecule of water derived from the hydrogen peroxide. This sequence of events demonstrates that **a μ-oxo group is nothing more than an oxide ion,** which is the conjugate base of a hydroxide ion, which is the conjugate base of a molecule of water.

The **most common diiron cluster**,[1895,1898-1903] however, is one in which each of the two iron ions is coordinated by the imidazolyl group of a histidine and the carboxylato group of a glutamate, and they are bridged by a third carboxylato group from a glutamate (Figure 2–57I).[1904,1905] This arrangement of these five ligands is bilaterally pseudosymmetric rather than rotationally pseudosymmetric and hence the symmetry is serendipitous. The other participants coordinating the diferric cluster in methane monooxygenase (soluble) from *Methylococcus capsulatus* are a fourth carboxylato group from a glutamate (the upper glutamate in Figure 2–57I) and two μ-oxo groups.

In these clusters, **the coordination of the two irons varies noticeably between the diferric state and the diferrous state** and from one enzyme to the next. For example, in the diferric cluster in methane monooxygenase (soluble) from *M. capsulatus* (Figure 2–57I) there are two μ-oxo groups, one of which forms a hydrogen bond to the other oxygen of the carboxylato group of the upper glutamate in the drawing; but in the diferrous cluster in the same enzyme, there is only one μ-oxo group. The other μ-oxo group has been replaced completely by the now bidentate anionic oxygen of the carboxylato group of the upper glutamate, which swings in to replace the μ-oxo group and bridge the two Fe^{2+}.[1905] In its mixed-valent state, the diiron cluster in methane monooxygenase (soluble) has a structure intermediate between the diferrous and the diferric structures.[1906] In yet other enzymes in particular oxidation states, the carboxylato group of the glutamate in the front of the drawing bridges the two iron ions to form an arrangement like that of the two carboxylato groups in hemerythrin (Figure 2–57F) except that there is no μ-oxo group.[1907] In the diferrous state of the cluster in the active site of benzoyl-CoA 2,3-epoxidase from *Aromatoleum evansii*, only one oxygen from the carboxylato group of a glutamate coordinates one of the Fe^{2+} ions, in addition to the imidazolyl group of a histidine and the single oxygen from the carboxylato group of a glutamate coordinating each of the Fe^{2+} ions, respectively.[1908] In general, the diferric form of one of these diiron clusters has one or two μ-oxo groups as well as additional carboxylato oxygens coordinating the two Fe^{3+} ions while the diferrous form of the same cluster usually has no μ-oxo group or μ-hydroxo group bridging the Fe^{2+} ions or one μ-hydroxo group bridging them.[1905,1908-1910] The imidazolyl group and the

single carboxylato oxygen at each iron ion and the bridging carboxylato group, however, are the constant ligands from species to species, remain unchanged by reduction or oxidation, and form **the core of the dinuclear cluster**.

This most common μ-oxodiiron cluster performs **several different oxidation–reductions**. For example, the diferrous diiron cluster in toluene 4-monooxygenase[1911] catalyzes the hydroxylation of toluene at carbon 4 (the para position). Several intermediates in the monooxygenation catalyzed by toluene 4-monooxygenase from *Pseudomonas mendocina* have been observed crystallographically.[1912] In the initial complex between molecular oxygen and the dinuclear diiron(II) complex, one of the two oxygens is coordinated by both of the Fe^{2+} as if it were a μ-oxo group. In an intermediate 4-peroxytolyl complex and an unnatural complex between hydrogen peroxide and the prosthetic diiron(III) in the oxidized enzyme, the two oxygens of the peroxy group are both ligands to both of the iron ions. It was concluded from these observations that in the initial complex between toluene and oxydiiron(II), the superoxyiron(II)iron(III), which is a resonance hybrid of the oxydiiron(II), adds homolytically to carbon 4 of the toluene to form the 4-peroxytolyl radical, in which the other carbons in the ring are participants in a delocalized pentadienyl radical and the two oxygens of the peroxy group are both ligands to both of the iron ions



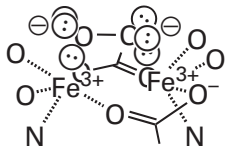
2–134

How this intermediate proceeds through the necessary aromatization and dissociation of the oxygen–oxygen bond of the peroxide is unclear. It does not, however, seem to proceed through a high-valent intermediate. A nearly quantitative hydride migration of the hydrogen from carbon 4 of the toluene to carbon 3 of the product 4-hydroxytoluene (see Equation 2–288) requires that the hydride migration be a step in the overall mechanism and consequently that the pentadienyl radical in the intermediate become a pentadienyl carbenium ion by losing its unpaired electron.[1913] This transformation of the radical to the carbenium ion would require an outer-sphere electron transfer because there is a saturated carbon between the pentadienyl radical and the rest of the complex that would act as an acceptor of the electron. The weakest bond in the intermediate is the oxygen–oxygen bond, but the point at which it dissociates has not been established. One possibility is that the electron is transferred, the hydride migrates, and the resulting carbenium ion withdraws the electrons in the oxygen-oxygen bond. The final step in the reaction is reduction of the two Fe^{3+} by two electrons to two Fe^{2+} and the release of the now loosely bound 4-hydroxytoluene and the μ-hydroxy group as a water.

The diferrous diiron cluster in stearoyl-[acyl-carrier-protein] 9-desaturase from *Ricinus communis*

$$2\,H^+ + 2\,e^- + \text{stearoyl-SACP} + O_2 \rightleftharpoons \text{oleoyl-SACP} + 2\,H_2O \qquad (2\text{–}293)$$

also has all the same ligands as the diferrous diiron cluster in methane monooxygenase (soluble). It performs the **conversion of an alkane to an alkene**. In the resting diferrous state, there are no μ-oxo groups and the two iron ions are bridged by the carboxylato groups of the two glutamates.[1910] There is one vacant position on each of the two Fe^{2+} ions. The diferrous cluster binds molecular oxygen, and during the association, the molecular oxygen is reduced by the two Fe^{2+} ions to a peroxide dianion that bridges the two now Fe^{3+} ions with one of its oxyanions bound by each of the irons[1914]



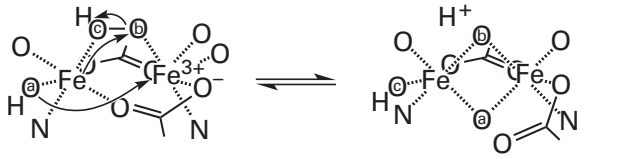
2–135

A **peroxydiiron(III)** with this structure has been chemically synthesized. This model compound, unlike the clusters in the various enzymes, is two-fold rotationally symmetric around the oxygen–oxygen bond, and the bonding between the one Fe^{3+}, the one oxygen, the other oxygen, and the other Fe^{3+}, Fe–O–O–Fe, is twisted so that the dihedral angle for the two Fe^{3+} down the oxygen–oxygen bond is 52° to accommodate, within the steric constraints, the usual 90° dihedral angle along the oxygen–oxygen bond in a peroxide.[1915] There is also a crystallographic molecular model of the peroxy-

diiron(III) intermediate in stearoyl-[acyl-carrier-protein] 9-desaturase.[1916] In this molecular model, the same dihedral angle for the four atoms, Fe–O–O–Fe, is only 30°, presumably because the crystallographic molecular model is not so accurate as that for the model compound and because there are different steric constraints.

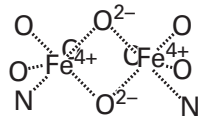
In aldehyde oxygenase (deformylating) from *Nostoc punctiforme*, the peroxydiiron(III) itself is the species accomplishing the enzymatic reaction, in which the peroxyanion first adds as a nucleophile to the carbonyl of an aldehyde.[1917] In stearoyl-[acyl-carrier-protein] 9-desaturase, however, and most other enzymes that have this type of nonheme diiron(II) cluster, the peroxydiiron(III) (**2–135**), upon heterolysis, becomes a **high-valent intermediate**. In the active site of stearoyl-[acyl-carrier-protein] 9-desaturase, this high-valent intermediate is electrophilic enough to remove the formal equivalent of a hydride from the saturated alkane of the reactant to desaturate it.[1918] The two electrons supplied by two [2Fe–2S]-ferredoxins during this reaction (Equation 2–293) are required to convert the diiron(III) that is formed during the oxidation of the alkane to the alkene back to diiron(II). In the diiron(III) state, there is at least one μ-oxo group bridging the iron, which one might think comes from the molecular oxygen, but when the diiron(III) cluster is formed using $^{18}O_2$, there is no μ-oxo oxygen that is an oxygen-18,[1898] perhaps because it exchanges with water in the solution too rapidly to be observed.

The chemical **identity of the high-valent intermediate** formed from one of these peroxydiirons(III) (**2–135**) has been elucidated in methane monooxygenase (soluble) from bacteria such as *Methylosinus trichosporium* and *M. capsulatus*. The peroxydiiron(III) in one of these enzymes, which is the same whether it is formed from molecular oxygen bound to the diferrous cluster[1919] or hydrogen peroxide bound to the diferric cluster,[1920] is hydronated and cleaves heterolytically to produce a cyclic **2,4-dioxo-1,3-diiron(IV)***[1921-1924]



(2–294)

This cyclic 2,4-dioxo-1,3-diiron(IV), in which each iron is iron(IV), has solved the problem of the source of the electron that is usually transferred from a porphyrin, a tryptophan, a tyrosine, or an L-ascorbate to the oxoiron(V) formed by heterolysis of a hydroperoxyiron(III) by taking that electron from the other Fe^{3+}



2–136

Its structure is homologous to a [2Fe–2S] iron–sulfur cluster, but the bonding is more ionic and the two iron ions are octahedrally rather than tetrahedrally coordinated because the ligands are oxygens instead of sulfurs. The more electronegative oxygens stabilize the Fe^{+4} oxidation states as opposed to the Fe^{+3} oxidation states of an oxidized [2Fe–2S] iron–sulfur cluster. A model compound containing this 2,4-dioxo-1,3-diiron(IV) has been synthesized. In the model compound, the lengths of the iron–oxygen bonds are 0.177 nm,[1925] similar to the iron–oxygen bond (0.172 nm) in the oxoiron(IV) porphyrin$^{\bullet+}$ of a hemoperoxidase. A mixed-valent, cyclic dioxoiron(IV)iron(III) has also been synthesized,[1926] and its crystallographic molecular model is also available.[1927]

In addition to being able to turn an alkyl group into an alkenyl group as it does in stearoyl-[acyl-carrier-protein] 9-desaturase, a cyclic 2,4-dioxo-1,3-diiron(IV) also can **hydroxylate methane** as it does in the reaction catalyzed by methane monooxygenase[1928,1929]

$$H^+ + NADH + CH_4 + O_2 \rightleftharpoons CH_3OH + NAD^+ + H_2O$$

(2–295)

The hydroxylation of methane is the most difficult hydroxylation of an alkane because methane has the greatest bond dissociation energy (440 kJ mol^{-1}) for its carbon–hydrogen bonds. Another synthetic

*The three oxygens involved in the rearrangement are labeled with the letters a, b, and c to distinguish them one from the others, and their disposition before and after the rearrangement has been determined experimentally with isotopes of oxygen.

version of cyclic 2,4-dioxo-1,3-diiron(IV) (**2–136**) is capable of hydroxylating a hydrocarbon.[1930]

As with the hydroxylations of alkyl carbons performed by enzymes containing hemes P450, which proceed by the same stoichiometry, the mechanism of these hydroxylations has not been settled.[1931-1933] Several aspects of the reaction catalyzed by methane monooxygenase (soluble), however, have been established. It is known that the oxygen of the hydroxy group of the methanol is one of the oxygen atoms that was in the molecular oxygen[1934,1935] and that, at the completion of the reaction catalyzed by methane monooxygenase from *M. capsulatus*, the oxygen of the methanol that is the product of the monooxygenation is in one of the μ-oxo positions in the cyclic di-μ-oxo-diiron(III) that is the product of the oxygenation performed by the cyclic 2,4-dioxo-1,3-diiron(IV).[1936] These results suggest that the 2,4-dioxo-1,3-diiron(IV) abstracts a hydrogen from the methane, and the resulting methyl radical colligates with the hydroxyl radical that is a μ-oxo group in the resulting hydroxyl-oxodiiron(III) to give methanol with its oxygen at that μ-oxo position.

Two electrons are required at the end of the hydroxylation to return the dioxodiiron(III) to the diiron(II) state, so the cluster is ready to go again, and also able to release the methanol. In methane monooxygenase (soluble) from *M. trichosporium*, these two electrons are ultimately from NADH reducing a flavin, and in the membrane-embedded methane monooxygenase (particulate) from *M. capsulatus*, these two electrons are from a quinol.

When the electrons are required in one of these reactions is in part determined by the reactants and the products. Because the stoichiometry of the reaction of molecular oxygen with *myo*-inositol to produce D-glucuronate (Equation 2–291) does not involve any electrons, none have to be supplied. When molecular oxygen and methane are turned into methanol and water (Equation 2–295), or molecular oxygen and stearoyl-[acyl-carrier protein] are turned into oleoyl-[acyl-carrier protein] (Equation 2–293), two electrons are required, but these are used only at the end of the reaction to regenerate the dioxo-diiron(II). When molecular oxygen is turned into water (Equation 2–292), however, four electrons are required and at least some of them must be supplied during the oxidation.

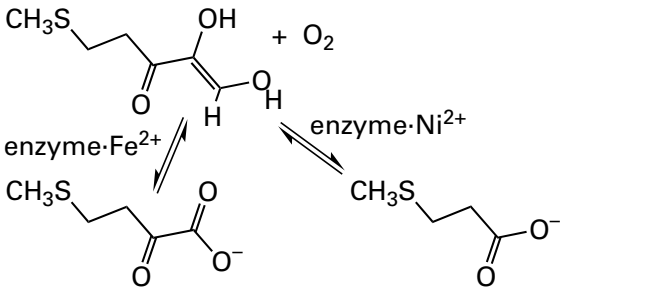
Although the cyclic 2,4-dioxo-1,3-diiron(IV) in methane monooxygenase (soluble) from *M. capsulatus* is required to hydroxylate methane, methyl groups adjacent to a functional group such as a cyano group or a nitro group, which can withdraw electron density effectively, can be hydroxylated by the initial peroxydiiron(III) (**2–135**). The rate of this hydroxylation decreases as the bond dissociation energy of the carbon–hydrogen bond in such substituted methyl groups increases,[1937] a result suggesting that the first step in such a hydroxylation is also the abstraction of a hydrogen atom. The same enzyme, however, hydroxylates a set of radical clocks without significant rearrangement,[1938] a result suggesting that a radical intermediate, which would result from the abstraction of a hydrogen atom, is not involved in these hydroxylations, The hydroxylations of these radical clocks, however, are probably accomplished by the 2,4-dioxo-1,3-diiron(IV) rather than the peroxydiiron(III) because these substrates are electron-rich rather than electron-poor. Significant rearrangement of 1,1-dimethylcyclopropane, however, which is another radical clock, occurs when it is hydroxylated by the methane monooxygenase (soluble) from *M. trichosporium*, but the products of the rearrangements that occur during this particular hydroxylation are consistent with the formation of both a methyl radical and a methyl carbenium ion.[1935]

In murine ribonucleoside-diphosphate reductase, a cyclic 2,4-dioxo-1,3-diiron(IV) formed in the usual way is first reduced by one electron,[1939] perhaps from a neighboring tryptophan.[1940] This reduction forms a mixed-valent species in which the ring in **2–136** has been broken and the iron(III) that is the product of the reduction has a hydroxide, which was a μ-oxo group, as a ligand but is still connected by the remaining μ-oxo group to the remaining iron(IV), which now has an open site, the site from which the hydroxide on the iron(III) left.[1941,1942] This species removes the formal equivalent of a hydrogen atom, perhaps as an electron and a hydron, from the hydroxy group of a tyrosine in the protein[1943] to **produce the neutral tyrosyl radical** required for the enzymatic reaction. The role of the diiron cluster is to create this tyrosyl radical initially, and presumably to maintain it over the lifetime of the enzyme, but the diiron cluster does not participate in the reduction of the ribonucleoside diphosphate that is the enzymatic reaction catalyzed by ribonucleoside-diphosphate reductase.

A diiron(II) cluster can also have **an oxide of nitrogen rather than an oxide of oxygen as its substrate**. Nitric oxide reductase [NAD(P)$^+$, nitrous oxide-forming] (Equation 2–258) from *Thermotoga maritima* has a diiron(II) cluster. Two molecules of nitric oxide, NO (**2–115**), bind to the cluster, one nitric oxide on each Fe^{2+}. The two Fe^{2+} ions provide the two

electrons needed for the production of one molecule of nitrous oxide, NNO (**2–106**), from the two nitric oxides in the process forming a double bond between the two nitrogens, and one of the oxygen atoms from one of the two nitric oxides leaves as a molecule of water.[1944] The resulting diiron(III) cluster is then reduced back to the diiron(II) cluster by a reduced flavin.

There are also oxygenases in which the non-heme metallic ion is a nickel ion rather than an iron ion. Acireductone dioxygenase (Ni^{2+}-requiring) from *K. pneumoniae* uses molecular oxygen to perform an oxidative cleavage



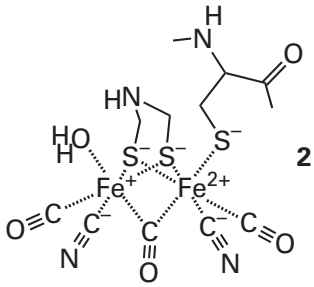
(2–296)

When acireductone dioxygenase from *K. pneumonia* is expressed in *E. coli*, it retains both Fe^{2+} and Ni^{2+} upon purification. Both metallic dications are in the respective high-spin states.[1945,1946] The enzyme with Fe^{2+} in the active site and the enzyme with Ni^{2+} in the active site can be separated and shown to produce, from the same reactant, 1,2-dihydroxy-5-thiomethylpent-1-ene-3-one, the product 2-oxo-4-thiomethylbutanoate in the former case and the product 3-thiomethylpropanoate in the latter.[1947] The difference in the products results from a difference in the electronic properties in the two metallic ions.[1948] There are also two different groups of hydrogenases, diiron hydrogenases and nickel–iron hydrogenases.

Unlike those in diiron oxygenases, the diiron clusters found in hydrogenases have two μ-sulfido groups instead of μ-oxo groups. A hydrogenase reduces the equivalent of two hydrons to form molecular hydrogen in one direction and oxidizes molecular hydrogen in the other

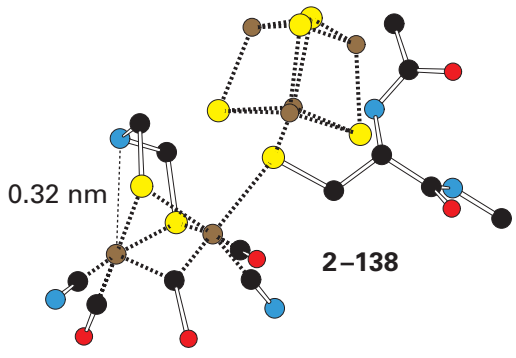
(2–297)

rather than reducing molecular oxygen. The two electrons participating in the reaction are provided or taken up, respectively, by various electron-transferring coenzymes, such as ferredoxins, cytochromes *c*, and menaquinones, depending on the species in which the hydrogenase is found. The cluster in the crystallographic molecular model of the diiron hydrogenase from *C. pasteurianum*



2–137

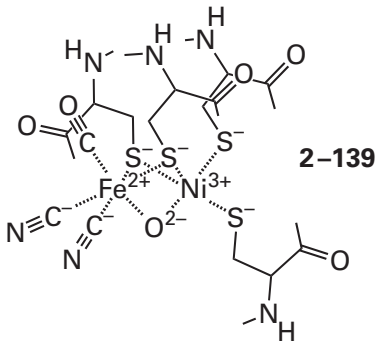
has only one ligand from the protein itself, the sulfido group of a cysteine,[1949] but it is surrounded and enclosed by the folded polypeptide. Two of the ligands to the iron ions are cyanide ions and three are isoelectronic, but neutral, carbon monoxides.[1950] In the resting state of the enzyme, one of the carbon monoxides bridges the two iron ions as a **μ-carbonmonoxy group**. There is some disagreement in the crystallographic molecular models as to whether or not the bridging carbon monoxide is present in all the diiron clusters, but Fourier-transform infrared spectra of diiron hydrogenases from *C. acetobutylicum*[1951] and *Chlamydomonas reinhardtii*[1952,1953] demonstrate that when the cluster is enzymatically active, the bridging carbon monoxide is present throughout the reaction. The two μ-sulfido groups are the two sulfido groups from the dithiodihemiaminal, 2-aza-1,3-disulfanylpropane,[1954-1957] which would not be a stable compound in free aqueous solution. The sulfido group of the lone cysteine is also one of the four cysteines that attach the four iron ions of a separate prosthetic [4Fe–4S] iron–sulfur cluster to the protein[1954,1958,1959]



2–138

and thus the sulfido group of this cysteine electronically couples the two prosthetic groups, the diiron cluster **2–137** and the [4Fe–4S] iron–sulfur cluster, in the inner sphere. There are three other [4Fe–4S] iron–sulfur clusters in the diiron hydrogenase from *C. pasteurianum* to remove or provide electrons during the oxidation of molecular hydrogen or the reduction of hydrons, respectively.

There are also **hydrogenases with a nickel–iron dinuclear cluster**. These hydrogenases are apparently unrelated to the diiron hydrogenases.[591,1949] The cluster itself



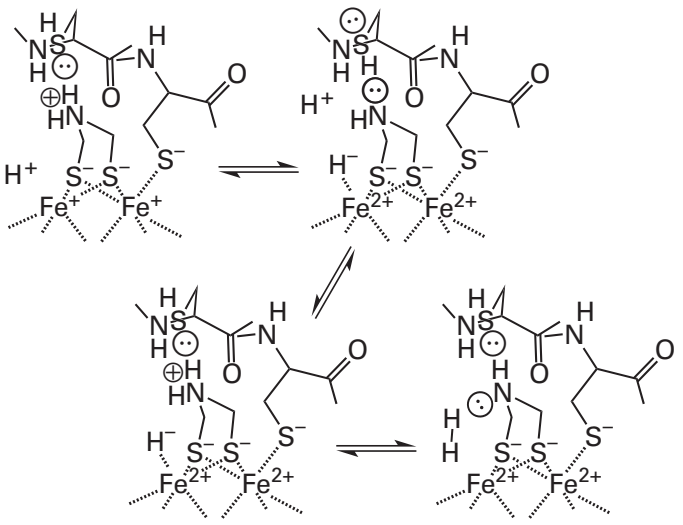
2–139

however, can be viewed as homologous to a diiron cluster in the family of diiron hydrogenases in which some of the ligands have been changed. First and foremost, the iron ion on the right in **2–137** is replaced by a nickel ion. There is no bridging carbon monoxide, and in its place in the fully oxidized but inactive nickel–iron hydrogenase from *A. vinosum* is a μ-oxo group,[1960] which dissociates as a hydroxide upon activation of the enzyme by reduction.[1961,1962] This dissociation leaves an open site on the iron ion and an open site on the nickel ion, both of which probably participate in the oxidation–reduction. The two bridging sulfido groups from the 2-aza-1,3-disulfanylpropane are replaced by the sulfido groups of two cysteines, the carbon monoxide on the iron ion is replaced by a cyanide, and the water on the iron ion is replaced by a carbon monoxide. The nickel ion has the sulfido group of a fourth cysteine and a open site instead of a carbon monoxide and a cyanide, respectively. The replacement of a carbon monoxide by a sulfido group makes sense because nickel is a softer metal than iron,[1963,1964] the bond dissociation energy of a nickel–sulfur bond ($+360 \pm 20$ kJ mol^{-1}) is greater than that of an iron–sulfur bond ($+340 \pm 20$ kJ mol^{-1}), and the bond dissociation energy of a nickel–carbonyl bond ($+100$ kJ mol^{-1}) is less than that of an iron–carbonyl bond ($+170$ kJ mol^{-1}).[1965]

In a subunit of nickel–iron hydrogenase from *A. vinosum*, in addition to the nickel–iron dinuclear cluster, there are three [4Fe–4S] iron–sulfur clusters evenly spaced in a chain leading away from the nickel–iron dinuclear cluster to remove electrons or provide electrons as needed.

The details of the **catalytic cycle of diiron hydrogenases** are well understood. Because the [4Fe–4S] iron–sulfur cluster is electronically coupled to the diiron cluster in its inner sphere, it is difficult to distinguish spectroscopic absorptions based on unpaired spins arising from an unpaired electron in the [4Fe–4S] iron–sulfur cluster from those arising from an unpaired electron in the diiron cluster. It has been found, however, that the distribution of electrons between the [4Fe–4S] iron–sulfur cluster and the diiron cluster can be distinguished by Fourier-transform infrared spectroscopy, and this has allowed potentiometric titrations of diiron hydrogenase from *C. reinhardtii* to be dissected.[1966] In the **oxidized paramagnetic resting state**, one of the iron ions in the diiron cluster is an Fe^{+} and the other is an Fe^{2+},[1967] and the [4Fe–4S] iron–sulfur cluster is in the $[(Fe^{2+})_2(Fe^{3+})_2\,(^{2-}S)_4(^{-}S-)_4]^{2-}$ state. After reduction by one electron, there is a pH-dependent electronic equilibrium[1966] between [iron(I)iron(II)]·$[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4]^{3-}$ and [diiron(I)]·$[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4]^{2-}$. Below a p$K_a$ of 7.2, the equilibrium is between [iron(I)iron(II)]·$[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4]^{3-}$ and [H^{+}diiron(I)]·$[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4]^{2-}$ with a reduction potential of greater than –250 mV.* Above the pK_a of 7.2, the equilibrium is between [iron(I)iron(II)]·$[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4]^{3-}$ and [diiron(I)]·$[(Fe^{2+})_2(Fe^{3+})_2\,(^{2-}S)_4(^{-}S-)_4]^{2-}$ with a reduction potential of –530 mV. Consequently, as might be expected, hydronation of the diiron cluster makes it significantly easier for the [4Fe–4S] iron–sulfur cluster to reduce the diiron cluster to diiron(I). Because of the value of the pK_a, it has been concluded that the nitrogen in the 2-aza-1,3-disulfanylpropane is the acid–base responsible for easing the reduction when hydronated. The two Fe^{+} in either the [diiron(I)]·$[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4]^{2-}$ state or the [H^{+}diiron(I)]·$[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4]^{2-}$ state are able to reduce a hydron to a hydride.[1951,1953,1968-1970]

*The notation [H^{x}iron(X)iron(X)]·$[(Fe^{x+})_3Fe^{x+}(^{2-}S)_4(^{-}S\text{-})_4]^{3-}$ refers to the distribution of electrons in the complete cluster **2–138**. The two irons in the hydrogenase cluster are designated as iron rather than Fe to distinguish them from the four irons in the [4Fe–4S] iron–sulfur cluster.

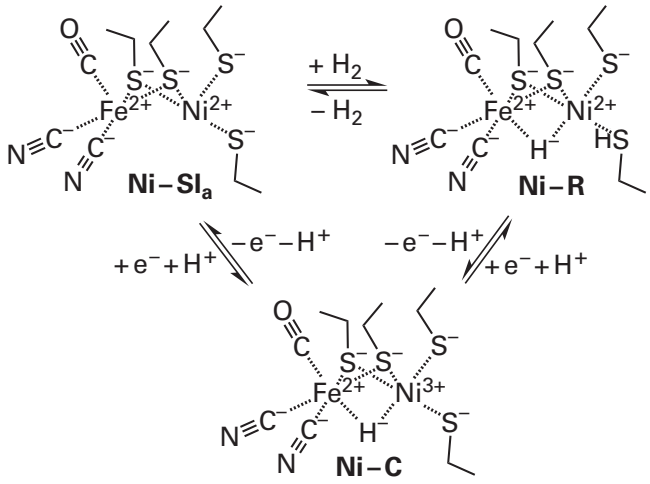


(2–298)

Nuclear magnetic resonance,[1971] Mössbauer,[1972] Fourier-transform infrared, and nuclear resonance vibrational[1973] spectra are those expected if the hydride ends up occupying the open site on the iron ion to the left in **2–137** as a terminal iron hydride. During reduction of the hydron, an electron is transferred from the other iron–sulfur clusters in the enzyme to the coupled [4Fe–4S] iron–sulfur cluster, so the final state of the active site is $[H^{-}\text{diiron(II)}]\cdot[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4]^{3-}$. The conversion of $[H^{+}\text{diiron(I)}]\cdot[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4]^{2-}$ to $[H^{-}\text{diiron(II)}]\cdot[(Fe^{2+})_3Fe^{3+}(^{2-}S)_4(^{-}S-)_4]^{3-}$ can be followed by Fourier-transform infrared spectroscopy at cryogenic temperatures.[1951]

During reduction of the hydron to the hydride, because the diiron cluster ends up after reduction as diiron(II) rather than diiron(I), Fourier-transform infrared spectra gathered at cryogenic temperatures demonstrate that the hydron on the nitrogen in the 2-aza-1,3-disulfanylpropane has dissociated.[1953] Presumably, the increase in charge on the iron ions has lowered the pK_a for the nitrogen. In the active sites of diiron hydrogenases from *C. reinhardtii* and *Desulfovibrio desulfuricans,* the hydronation state of this nitrogen at this stage can be monitored by ^{57}Fe nuclear resonance vibrational spectroscopy.[1974] There is a hydrogen bond between the sulfanyl group of a cysteine in the active site and the amino nitrogen in the 2-aza-1,3-disulfanylpropane (Equation 2–298). Because the amino nitrogen and the iron ion on which the hydride is located are only 0.32 nm apart,[1950,1954] when the sulfanyl group is a donor to the amino nitrogen and the hydron on the amino nitrogen is pointed at the hydride, the two van der Waals circumferences of the hydrogen on the ammonium and the hydrogen in the iron hydride are only separated by around 0.05 nm. The sole hydron on the amino nitrogen, however, is not acidic enough to react with the hydride, but when there is a hydrogen bond between the lone pair of electrons on the sulfanyl group of the cysteine rather than the hydrogen and one of the hydrons on the hydronated ammonio group of the 2-aza-1,3-disulfanylpropane, the hydron pointed at the hydride has become acidic enough to hydronate the hydride.* This hydronation forms H_2, the product of the reaction, which probably dissociates immediately. The hydronation and the dissociation of the H_2 return the clusters to the resting oxidized $[\text{iron(I)iron(II)}]\cdot[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_4]^{2-}$ state.

The **catalytic cycle of the nickel–iron hydrogenases** seems to differ significantly from that of the diiron hydrogenases. During the oxidation of molecular hydrogen, the nickel–iron cluster in the hydrogenase from *D. vulgaris* passes through three major intermediates, Ni-SI_a, Ni-R, and Ni-C, that have been identified spectroscopically.[1975] By microscopic reversibility it must pass through through the same three intermediates in the reverse direction when it is reducing two hydrons. In the resting, reduced, activated Ni-SI_a state, the metallic ions are Ni^{2+} and Fe^{2+}, and the two respective sites on the metallic ions that were coordinated by the μ-oxo group in the inactive, oxidized state **2–139** are open. Upon the association of molecular hydrogen from the solution to form the fully reduced Ni-R intermediate, a hydride, as a ***μ*-hydrido group**, bridges the two formerly open sites on the metallic ions



(2–299)

*One should recall that there is no such thing as a bare hydron in aqueous solution.

This Ni-R intermediate has been crystallized under an atmosphere of molecular hydrogen, and reflections from the resulting crystal could be collected to Bragg spacing of 0.089 nm. At this level of resolution, **hydrogen atoms could be observed** in the map of electron density.[1964] There was clear electron density for the μ-hydrido group between the Ni^{2+} and the Fe^{2+} as well as for a hydron on the sulfido group coordinating the nickel ion that is closest to the μ-hydrido group.[1976] The distance from the bridging hydride to this hydron is 0.245 nm, so the two are almost within van der Waals contact (0.23 nm). It has been concluded that a molecule of hydrogen from the solution has been dissociated heterolytically by the cluster into the μ-hydrido group and this hydron.

Because there is a channel[1977] from the solution to the Ni^{2+}, it has been suggested that the hydrogen associates first with it. Calculations of dissociation energies between Ni^{2+} and molecular hydrogen and between Fe^{2+} and molecular hydrogen are consistent with this conclusion.[1978] This conclusion is also consistent with the fact that the **hydron ends up on one of the sulfido groups** coordinating the Ni^{2+}. If the molecular hydrogen associates initially with the open site on the Ni^{2+}, this would bring the hydrogen that is to become the hydron immediately adjacent to the sulfido group.

The next intermediate in the direction of the oxidation of molecular hydrogen, the Ni-C state, is normally formed upon the transfer of an electron from the Ni-R intermediate (Equation 2–299). Spectra of this intermediate with a bridging atom of protium and a bridging atom of deuterium provided the first unambiguous evidence for the existence of an atom of hydrogen bridging the two metallic ions in the mechanism of the enzyme.[1979,1980] In the Ni-C state, which is one electron more oxidized than the Ni-R state in which a hydride bridged the two metallic ions, the two metallic ions are Ni^{3+} and Fe^{2+},[1975] so the atom of hydrogen bridging the two metallic ions that was observed spectroscopically in the Ni-C intermediate must still be a hydride. Because the nickel ion is so electropositive, the hydron has dissociated from the sulfanyl group.

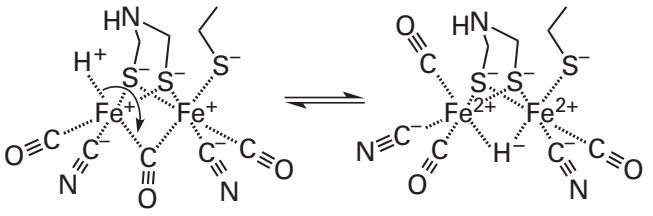
Even though, in the usual steps that occur during the oxidation of molecular hydrogen, the Ni-C intermediate is produced by oxidizing the Ni-R intermediate by the removal of one electron, in the spectroscopic experiments, the Ni-C intermediate was formed by reducing the resting, activated Ni-SI_a state with an external reductant. It follows that the reductive conversion of the Ni-SI_a state to the Ni-C intermediate, which is the first step in the reduction of two hydrons (Equation 2–299), requires that the addition of an electron to the resting, activated Ni-SI_a state causes a hydron to be converted into a bridging μ-hydrido group, since no molecular hydrogen was present. Presumably, in the reverse direction, the removal of an electron from the intermediate Ni-C state state **oxidizes the bridging μ-hydrido group to a hydron** that dissociates during the oxidation returning the enzyme to the resting, activated Ni-SI_a state. One way to explain the oxidation in this step that occurs during the oxidation of molecular hydrogen is that during the transition from the Ni-C state with a bridging hydride to the resting Ni-SI_a state (Equation 2–299), an electron is removed from the Fe^{2+}, and the resulting Fe^{3+} and the Ni^{3+} then each remove an electron from the hydride to convert it into a hydron that is forced to dissociate immediately from the cluster. This step would resemble the reverse of the step in which a hydron is converted to a hydride by the transfer of one electron from each of the Fe^{+} in a diiron hydrogenase (Equation 2–298).

In Equation 2–299, the conversion of two hydrons and two electrons to molecular hydrogen proceeds in a counterclockwise direction; and the conversion of molecular hydrogen to two hydrons and two electrons, in a clockwise direction.

There are model compounds for intermediates in the oxidation–reduction catalyzed by the nickel–iron cluster in a hydrogenase. There are synthetic nickel–iron clusters in which a hydride bridges the two metallic ions.[1981-1983] A model compound that mimics the nickel–iron cluster in hydrogenase is hydronated by HBF_4 ($pK_a = -4.9$) preferentially on one of the alkanethiolates coordinating the nickel ion rather than an equivalent alkanethiolate coordinating the iron ion.[1984] In a different model compound in which there are only two μ-sulfido groups, the hydronation occurs on one of these sulfurs, but generation of molecular hydrogen from this hydronated complex requires the addition of both an electron and an external hydron.[1983] A mononuclear nickel(I) complex, in which one of the ligands to the nickel is a tertiary amine, is able to dissociate a molecule of hydrogen heterolytically; the hydride ends up on the nickel and the hydron ends up on the amino nitrogen.[1981,1982]

There are synthetic model compounds for the diiron cluster in a hydrogenase that have a carbon monoxide as well as two sulfido groups, bridging two Fe^{+} ions in their resting state. Kinetic and spectroscopic observations of these model diiron clusters

have led to the conclusion that a hydron, transferred from a nearby ammonio nitrogen, associates with an open site on one of these Fe^{+} ions. The resulting complex then rearranges by a concerted ligand exchange



(2–300)

so that the hydron ends up as a bridging hydride[1985] between the two now Fe^{2+} ions and the carbon monoxide ends up at the position at which an open site was located before the rearrangement.[1986-1988] These four ligands are not attached covalently to the iron ion and are free to move across its surface. The result would be a bridging hydride in place of the former bridging carbon monoxide, which would become a nonbridging carbon monoxide. It is possible to accomplish such a ligand exchange in the active site of diiron hydrogenase from *C. reinhardtii*, the product of which has been identified as containing a bridging hydride by infrared spectroelectrochemistry. It was concluded, however, that this arrangement is not involved in the normal equilibration of two hydrons and two electrons with molecular hydrogen catalyzed by the enzyme.[1951,1952]

The diiron hydrogenases complete the **panoply of the oxidation states of iron, from iron(I) to iron(V)**, that are achieved in enzymatic reactions.

The ligands to the iron ions in a diiron hydrogenase and the ligands to the iron ion in a nickel–iron hydrogenase are cyanide ions and carbon monoxides. These diatomic ions and molecules are **isoelectronic with a molecule of nitrogen** (**2–140**)

2–140

2–141 **2–142** **2–114**

The ten electrons in molecular nitrogen are distributed into the five molecular orbitals of a symmetric, diatomic molecular orbital system (**2–86**). The two pairs of electrons indicated in **2–140** and the pair of electrons in the σ bond are delocalized into the three cylindrically symmetric σ molecular orbitals—bonding σ_s, antibonding σ_s^*, and bonding σ_p—and there are two orthogonal π bonds, each occupied by two electrons.

When the nucleus of a nitrogen atom is replaced by the nucleus of a carbon atom, the same molecular orbital system remains in the resulting **cyanide** (**2–141**) with the following exceptions. The electric field of a carbon nucleus with only six protons is less than that of a nitrogen nucleus that has seven protons, so the atomic orbitals from carbon that are mixing are of higher energy than those from nitrogen. As a result, there is more mixing between the p_z orbital on nitrogen and the *s* orbital on carbon. The carbon atom, because its nucleus has one fewer proton, has a negative formal elementary charge.

When the nucleus of a nitrogen atom is replaced by the nucleus of an oxygen atom, the same molecular orbital system remains in the resulting **azanylidyneoxidanium ion** (**2–114**) with the following exceptions. The electric field of an oxygen nucleus with eight protons is greater than that of a nitrogen nucleus that has only seven protons, so the atomic orbitals from oxygen that are mixing are of lower energy than those from nitrogen. As a result, there is more mixing between the p_z orbital on oxygen and the *s* orbital on nitrogen. The oxygen atom, because its nucleus has one more proton, has a positive formal elementary charge.

In **carbon monoxide** (**2–142**), the difference in the energies of the atomic orbitals that are mixing is even more extreme, but for the same reasons, the carbon atom has a negative formal elementary charge and the oxygen has a positive formal elementary charge, which is the reverse of their differences in electronegativity. The negative formal elementary charges on the carbon atoms in the cyanide and carbon monoxide cause their lone pairs of electrons to be the ligands to a metallic ion rather than the lone pairs on the oxygens, which in most other Lewis bases would be the ligands to a metallic ion.

Certain anaerobic bacteria, such as *Carboxydothermus hydrogenoformans*, *M. thermoacetica*, *Methanosarcina barkeri*, and *M. thermophila*, convert carbon monoxide into carbon dioxide and use the reducing equivalents obtained from this oxidation as a source of energy as well as for reducing metabolites, much as carbon monoxide used to be burned in households for heat. These bacteria also convert carbon monoxide into acetyl-SCoA, from which they

can produce all the carbon in their metabolites[1989,1990] by the Wood–Ljungdahl metabolic pathway.[1991] In a sense this is a strategy similar to photosynthesis, in which reducing equivalents are obtained from light and all the fixed carbon is obtained from carbon dioxide. Any excess reducing equivalents that arise during metabolism in these bacteria are excreted as molecular hydrogen, which is produced by a ferredoxin hydrogenase with the usual nickel–iron cluster.

The enzyme responsible for oxidizing carbon monoxide to carbon dioxide is anaerobic carbon monoxide dehydrogenase

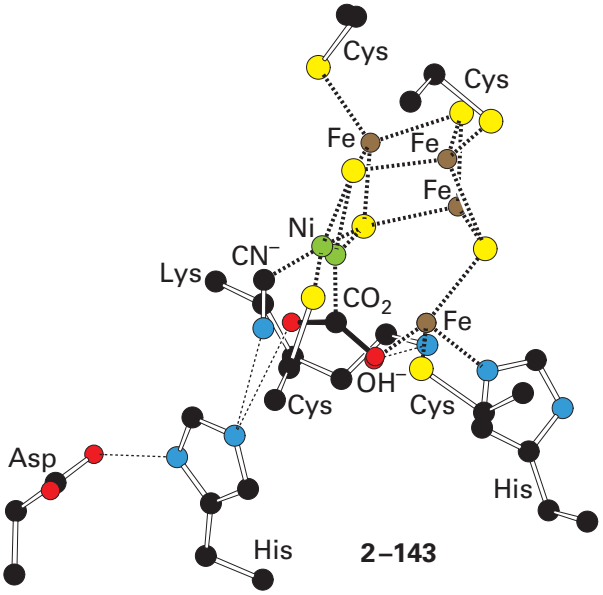
$$2\,H^+ + CO_2 + 2\,\text{reduced ferredoxin} \rightleftharpoons CO + H_2O + 2\,\text{oxidized ferredoxin} \qquad (2\text{–}301)$$

The standard reduction potential for the half-reaction[1992,1993]

$$CO_2(g) + 2\,e^- + 2\,H^+ \rightleftharpoons CO(g) + H_2O \qquad (2\text{–}302)$$

is –560 mV, which is why a [4Fe–4S] ferredoxin (Figure 2–19) is the carrier of electrons that has been matched with the enzyme, just as a [4Fe–4S] ferredoxin is matched with photosystem I.

Carbon dioxide, bound to the nickel ion in the crystallographic molecular model of the complex between carbon dioxide and the **[4Fe–4S–Ni] iron–sulfur–nickel cluster** in the active site of anaerobic carbon monoxide dehydrogenase from *C. hydrogenoformans*,[1994] can be superposed on the crystallographic molecular model of the complex between cyanide, hydroxide, and the [4Fe–4S–Ni] iron–sulfur–nickel cluster and its surrounding catalytic amino acids in active site of the enzyme from *M. thermoacetica*[1995]



In the drawing, only the carbon dioxide and one of the nickel ions are from the former crystallographic molecular model while the cyanide and the hydroxide, as well as the entire cluster and the surrounding amino acids, are from the latter. Because the complex between carbon dioxide (CO_2) and the [4Fe–4S–Ni] iron–sulfur–nickel cluster in the former active site is assumed to be the complex between the cluster and the substrate carbon dioxide, the complex between a cyanide (CN^-), a hydroxide (OH^-), and the [4Fe–4S–Ni] iron–sulfur–nickel cluster is assumed to mimic the complex between the cluster and the substrates carbon monoxide and hydroxide ion in the latter active site. Electron-paramagnetic spectra of the [4Fe–4S–Ni] iron–sulfur–nickel clusters in the enzymes from *M. thermoacetica* and *M. thermophila* change as either carbon monoxide or carbon dioxide associates with the respective enzyme.[1996,1997]

In the anaerobic carbon monoxide dehydrogenases from both *C. hydrogenoformans* and *M. thermoacetica*, the [4Fe–4S–Ni] iron–sulfur–nickel cluster (**2–143**) is a [4Fe–4S] iron–sulfur cluster from which one of the iron ions has pulled away and its former location in the cluster has become occupied by a nickel ion. Both the nickel ion and the iron ion that has been pulled away are tetracoordinate. The iron ion that has pulled away is still coordinated by one of the sulfides in the cluster, the sulfido group of the usual cysteine, and the imidazolyl group of a histidine while the nickel ion is coordinated by two sulfides within the cluster (large light gray atoms) and the sulfido group of another cysteine. In both the complex with cyanide and hydroxide and the complex with carbon dioxide, the nickel ion is in a

slightly distorted square planar coordination, which is one of its usual dispositions, with the cyanide or the carbon of the carbon dioxide as its fourth ligand, and the detached iron ion is in a somewhat more distorted tetrahedral coordination with the oxygen of the hydroxide or an oxygen of the carbon dioxide as its fourth ligand.

In addition to this [4Fe–4S–Ni] iron–sulfur–nickel cluster, in each of these enzymes there is a standard [4Fe–4S] iron–sulfur cluster 1.1 nm away, and another standard [4Fe–4S] iron–sulfur cluster 1.0 nm further away.[1996-1999] These clusters **shuttle electrons** from the [4Fe–4S–Ni] iron–sulfur–nickel cluster to the oxidized ferredoxin that is a substrate for the enzyme and that carries each of the electrons away from the enzyme. In the reverse direction, these clusters shuttle electrons to the [4Fe–4S–Ni] iron–sulfur–nickel cluster from the reduced ferredoxin that brings each of the electrons to the enzyme.

In the crystallographic molecular model (**2–143**) of the complex between the cluster and carbon dioxide,[2000] the **bond length** between the nickel ion and the carbon of the carbon dioxide is 0.181 nm, and the three **bond angles** around the carbon are all within 5° of 120°. The bond length between nickel and carbon is quite short for a bond of this type.[2001] Both this short bond length and the bond angles suggest that this complex can be considered to be the **nickel ester of carbonic acid**. In fact, the carbon–oxygen bond lengths (0.130 ± 0.003 nm) are indistinguishable from those (0.128 nm) in a carbonate ion.[2002]

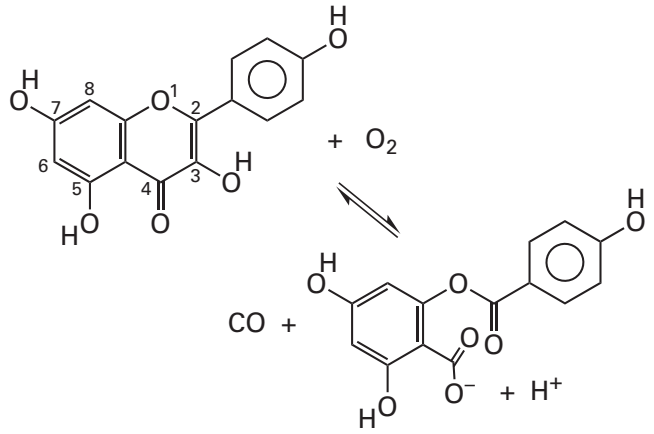
The biochemical standard reduction potential of the [4Fe–4S–Ni] iron–sulfur–nickel cluster in anaerobic carbon monoxide dehydrogenase from *M. thermoacetica*[2003,2004] is –530 mV, and this value is for a two-electron reduction. Because the biochemical standard reduction potential of a [3Fe–4S] iron–sulfur cluster is in the range of +65 to −400 mV (Figure 2–19), because the reduced form of a [3Fe–4S] iron–sulfur cluster is $[Fe^{2+}(Fe^{3+})_2(^{2-}S)_4(^{-}S-)_3]$ (Equation 2–171), and because the reduced [4Fe–4S–Ni] iron–sulfur–nickel cluster in anaerobic carbon monoxide dehydrogenase is paramagnetic, the most likely **form of the reduced** [4Fe–4S–Ni] **iron–sulfur–nickel cluster** is equivalent to $[(Fe^{2+})_2(Fe^{3+})_2Ni^{+}(^{2-}S)_4(^{-}S-)_2]$. The nickel ion in such an oxidation state would be Ni^{+1}, which is nucleophilic, and the peripheral iron ion could be Fe^{3+}, which is a strong Lewis acid. The reduced state of the [4Fe–4S–Ni] iron–sulfur–nickel cluster binds carbon dioxide,[2005] and the crystal of anaerobic carbon monoxide dehydrogenase from *C. hydrogenoformans* was poised in the reduced state before the carbon dioxide that formed the complex with the [4Fe–4S–Ni] iron–sulfur–nickel cluster (**2–143**) was diffused into the crystal.[1994]

From all these considerations, a reasonable mechanism for the reduction of carbon dioxide can be formulated.[2004] One of the oxygen atoms of the carbon dioxide associates with the peripheral Fe^{3+} as a coordinated ligand and forms a hydrogen bond to the ammonio group of a lysine, and the other oxygen forms a hydrogen bond with the imidazolyl group of a histidine. The **nucleophilic Ni^{+}** adds to the carbon atom to form the nickel analogue of an ester of carbonic acid observed in the one crystallographic molecular model (**2–143**). The ammonio group of the lysine hydronates the oxygen of the carbonate, the hydronated oxygen leaves the carbon as a ferric hydroxide,[2005] and the carbon of the resulting carbon monoxide rotates away from the hydroxide into the position of the carbon of the cyanide in the other crystallographic molecular model, while the hydrogen bond between the oxygen atom and the imidazolyl group remains intact. The cluster has been oxidized by the removal of two electrons during this transformation, and the carbon monoxide leaves the oxidized form of the cluster, which is the equivalent of $[Fe^{2+}(Fe^{3+})_3Ni^{2+}(^{2-}S)_4(^{-}S-)_2]$. Two ferredoxins bind in sequence and their single electrons are passed in the outer sphere through the [4Fe–4S] iron–sulfur clusters to rereduce the [4Fe–4S–Ni] iron–sulfur–nickel cluster.[2005] In the reverse reaction, as one or two electrons are removed from the carbon monoxide by the nickel and the iron ions of the $[Fe^{2+}(Fe^{3+})_3Ni^{2+}(^{2-}S)_4(^{-}S-)_2]$ cluster, the carbon of the carbon monoxide becomes electrophilic enough for the hydroxide on the adjacent iron ion in the cluster (**2–143**) to accomplish a nucleophilic addition to produce carbon dioxide.

It has been proposed,[2004] however, that the reduced state of the cluster is actually paramagnetic $[(Fe^{2+})_4Ni^{+}(^{2-}S)_4(^{-}S-)_2]$ rather than paramagnetic $[(Fe^{2+})_2(Fe^{3+})_2Ni^{+}(^{2-}S)_4(^{-}S-)_2]$, and the oxidized state is, therefore, $[(Fe^{2+})_3Fe^{3+}Ni^{2+}(^{2-}S)_4(^{-}S-)_2]$. If this is the case, the ferrous hydroxide rather than a ferric hydroxide is the leaving group, albeit a poorer one, during the reduction of carbon dioxide, but the nickel ion would still be nucleophilic because the cluster would have two additional electrons. The hydroxide, on an Fe^{2+}, would exchange more rapidly with the next molecule of CO_2, but in the oxidation

of carbon monoxide, the electron withdrawal from the carbon monoxide by the oxidized cluster would be significantly weaker, making it less electrophilic.

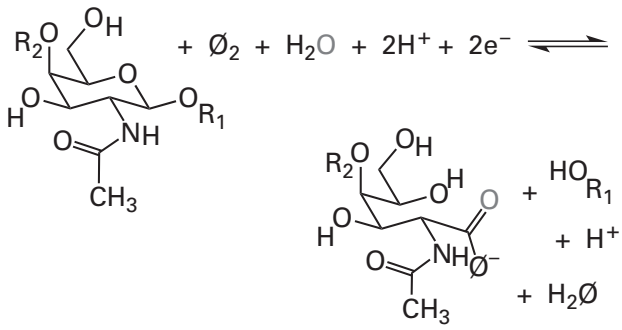
There are also mononuclear, prosthetic copper ions and dinuclear, trinuclear, and tetranuclear clusters of prosthetic copper ions that catalyze reactions in which the oxides of oxygen and the oxides of nitrogen are substrates. For example, quercetin 2,3-dioxygenase*



(2–303)

from *Aspergillus japonicus* oxidatively cleaves two adjacent carbon–carbon bonds, between carbons 2 and 3 and between carbons 3 and 4, while turning the central carbon into carbon monoxide. The prosthetic, **mononuclear Cu^{2+}** in its active site is coordinated by three imidazolyl groups from three histidines as well as the carboxylato group of a glutamate, which stabilizes the cupric state. In the crystallographic molecular model of the anaerobic complex between the reactant kaempferol (Equation 2–303), and this Cu^{2+} in the enzyme (Figure 2–58A),[2006] the 3-hydroxy group of the kaempferol, which will become the oxygen of the carbon monoxide (Equation 2–303), is coordinated[2007] to the Cu^{2+}. In this complex, the Cu^{2+} withdraws electron density from carbon 3 of the kaempferol (Equation 2–303) to create a partial radical cation at carbon 3. The positive elementary charge of the radical cation, which resides mostly on carbon 2, is stabilized by π electron donation from both the 4-hydroxyphenyl group and oxygen 1. Oxygen reacts with this partial radical as it does with the partial radical in protocatechuate 3,4-dioxygenase (Equation 2–275), and the resulting 3-hydroxy-3-peroxy intermediate rearranges to the products by a mechanism that has yet to be determined. The actual mechanism may involve[1775] a Baeyer–Villiger rearrangement similar to the one thought to occur in the mechanism for an extradiol dioxygenase (Equation 2–278).

The prosthetic, mononuclear copper ion in lytic chitin monooxygenase



(2–304)

which is a polysaccharide monooxygenase from *Serratia marcescens*, oxidatively cleaves chitin, poly-(β1,4)-2-acetamido-2-deoxy-D-glucose. From isotopic distributions it has been determined that one of the oxygens in the new carboxylate comes from molecular oxygen (denoted Ø) and the other from water (denoted with a gray O).[2008] In a crystallographic molecular model of the related (45% identity; 2.0 gap percent) polysaccharide monooxygenase from *Bacillus amyloliquefaciens*, the copper ion is coordinated by the imidazolyl group of a histidine and both the imidazolyl group and the amino group of the amino-terminal histidine.[2009] In the crystallographic molecular model of the complex between molecular oxygen and the active site of the yet again related (29% identity; 3 gap percent) lytic chitin monooxygenase from *Jonesia denitrificans*, the oxygen associated with the prosthetic Cu^{+} is bound in a bent configuration to the now mononuclear Cu^{2+} and has been identified as a peroxide. In a crystallographic molecular model by neutron diffraction of the same complex, the amino-terminal amino group coordinating the Cu^{2+} has been observed to be the highly unusual anionic conjugate base of the amino group,[2010] which might stabilize a higher-valent form of the copper ion that could be responsible for the monooxygenation. Hydroxylation of carbon 1 of a 2-acetamido-2-deoxy-D-glucose (bond dissociation energy = 380 kJ mol^{-1}) would create a tetrahedral intermediate.

*In Equation 2–303, the enzyme is shown oxidizing kaempferol, 2-(4-hydroxyphenyl)-3,5,7-trihydroxy-4*H*-chromen-4-one, which is a close relative of quercetin, 2-(3,4-di-hydroxyphenyl)-3,5,7-trihydroxy-4*H*-chromen-4-one.

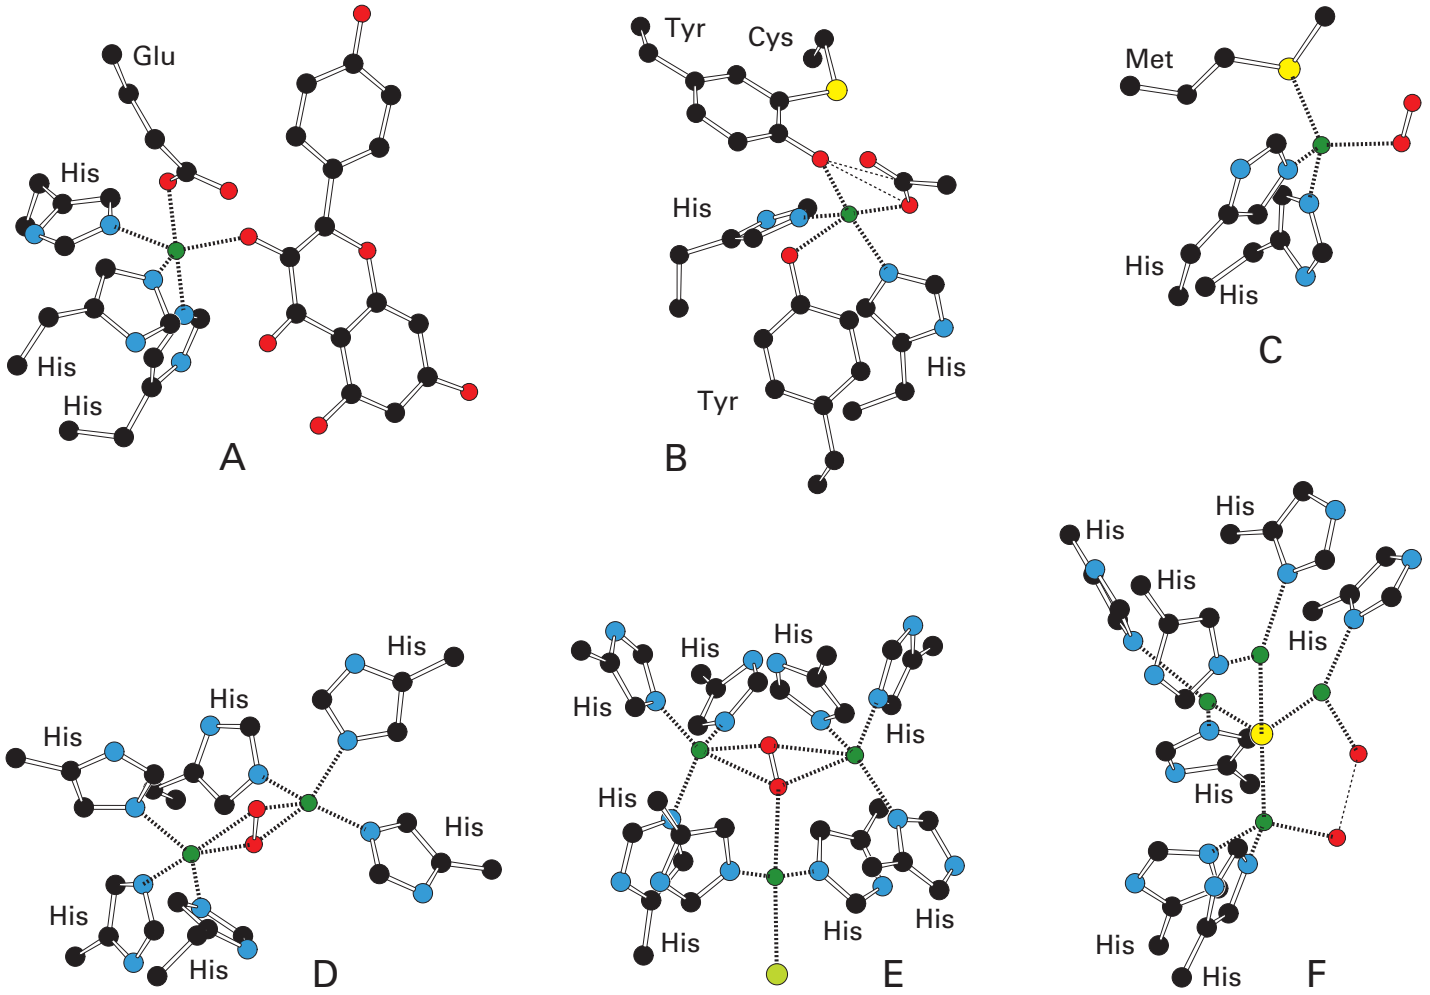


Figure 2–58: Drawings[50] of the ligands to prosthetic copper ions in the crystallographic molecular models of **(A)** quercetin 2,3-dioxygenase from *A. japonicus*,[2006] **(B)** galactose oxidase from *H. rosellus*,[1314,2013] **(C)** peptidylglycine monooxygenase from *R. norvegicus*,[2055] **(D)** hemocyanin from *L. polyphemus*,[2026,2027] **(E)** laccase from *M. albomyces*,[2065] and **(F)** nitrous-oxide reductase from *A. cycloclastes*.[2073] Black atoms are carbons, red atoms are oxygens, and blue atoms are nitrogens. Copper ions are the dark green spheres surrounded by their ligands. Each copper ion has three, four, or five ligands and, unlike in most inorganic copper complexes, there are no regular geometries to the arrangements of the ligands. The side chains acting as ligands are labeled. The open site on the copper in galactose oxidase in Panel B is occupied by a molecule of acetate. The two lone red spherical ligands in Panel F are molecules of water or hydroxide ions that form a hydrogen bond with each other. In Panel A, a molecule of kaempferol, a substrate for quercetin 2,3-dioxygenase, which was coordinated to the copper ion in the enzyme in the crystal submitted to diffraction, is drawn. In Panels C, D, and E, the complex between the respective enzyme and molecular oxygen was present in the crystal, and the molecule of oxygen is drawn. In peptidylglycine monooxygenase (C), the molecule of oxygen forms one bond to the copper ion. In hemocyanin (D) and laccase (E), however, the molecule of oxygen is found between two copper ions; one oxygen forms two bonds, one to each copper ion, and the other oxygen also forms two bonds, one to each copper ion. In laccase (E), one of the oxygens forms a third bond, to a third copper ion. This third copper ion has a chloride (lone, large, light green sphere at very bottom of the drawing) as its fourth ligand. The four copper ions in nitrous-oxide reductase (F) are each coordinated by a single central sulfide dianion (lone, large, light yellow sphere in the center of the drawing).

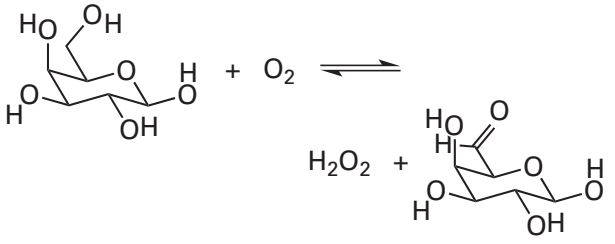
There is a methane monooxygenase (particulate) embedded in the plasma membranes of *Methylocystis, M. trichosporium*, and *M. capsulatus* that uses a copper ion, similarly coordinated to two imidazolyl groups and both the imidazolyl group and the amino group of the amino-terminal histidine, to hydroxylate methane (bond dissociation energy = 439 kJ mol^{-1}).[2011,2012]

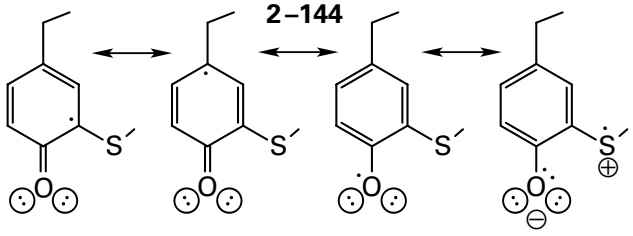
In the active site of galactose oxidase



(2–305)

from *Hypomyces rosellus*, the mononuclear Cu^{2+} is coordinated by the imidazolyl groups of two histidines, the 4-oxidophenyl group of a tyrosine, and the 4-oxidophenyl group of the conjugate base of a 3-(*S*-cysteinyl)tyrosine (Figure 2–58B).[1314,2013] In the active form of the oxidized cupric galactose oxidase from *H. rosellus*, the 3-(*S*-cysteinyl)-4-oxidophenyl ion has been converted into the fairly stable, neutral **3-(*S*-cysteinyl)phen-4-oxi radical**

2–144



by removal of an electron.[1316,2014,2015] In this radical, the unpaired spin is distributed evenly among the oxygen, the sulfur, and carbons 1 and 3 of the phenyl group,[536] as expected from the resonance structures. To exploit the last resonance form that defines the delocalization of the unpaired electron onto the sulfur, the alkylsulfanyl group must be in an orientation that brings one of its lone pairs of electrons parallel to the π molecular orbital system of the phenyl group so that it can be conjugated with it. Aligning this lone pair of electrons decreases the standard reduction potential of the phenolato oxygen by as much as 150 mV.[2016]

The 6-hydroxy group of the D-galactose that is to be oxidized associates with the Cu^{2+} at its open site, which is occupied by a molecule of water in the resting state, located at the same ligand position as acetate in the crystallographic molecular model (Figure 2–58B). The hydron is removed from the 6-hydroxy group, and the equivalent of a hydride is removed from carbon 6 of the D-galactose to convert it to the product D-*galacto*-hexodialdose. The hydron and the two electrons equivalent to a hydride are removed in such a way that one of the electrons converts the Cu^{2+} to a Cu^{+} and the other electron converts 3-(*S*-cysteinyl)tyrosinyl radical to 3-(*S*-cysteinyl)tyrosine,[2017] which remains associated[2018] with the Cu^{+}. Following dissociation of the product, molecular oxygen associates with the Cu^{+}, an electron is transferred from the Cu^{+} to the molecular oxygen to produce the equivalent of superoxide radical anion coordinated to Cu^{2+}, and the cupric superoxide removes an electron from the 3-(*S*-cysteinyl)tyrosine and is hydronated to produce **cupric hydroperoxide**.[2019] The hydroperoxide ion dissociates from the now regenerated, oxidized, cupric resting state. The most likely candidate for the catalytic base that removes the two hydrons from D-galactose and adds the hydron to the superoxide radical anion is the 4-oxido group of the 3-(*S*-cysteinyl)tyrosine itself. In the crystallographic molecular model, the active site is occupied by acetate (an analogue of the reactant), various intermediates, and the product at carbon 6 as well as a stand-in for the superoxide radical anion. In this model, the acyl carbon of the acetate and the acyl oxygen of the acetate coordinating the copper ion are only 0.29 and 0.28 nm, respectively, from this 4-oxido group (thin dashed lines in Figure 2–58B).[1314]

Mononuclear copper ions also catalyze **reductions of nitrogen oxides** as well as oxygen oxides. Nitrite reductase (NO-forming) reduces nitrite ion, ONO^{-} (**2–113**), to nitric oxide, NO (**2–115**), and a molecule of water, a one-electron reduction. The prosthetic group in nitrite reductase (NO-forming) from *A. faecalis*[2020] and nitrite reductase (NO-forming) from *A. xylosoxidans*[703] is a copper ion coordinated by three imidazolyl groups from three histidines as ligands. The Cu^{+} provides the one electron needed for the reduction of the nitrite ion.[2021] The electron-transferring coenzyme that ultimately provides the electron is pseudoazurin. There is a second mononuclear, prosthetic copper ion in the enzyme—coordinated by a sulfanyl group, two imidazolyl groups, and a sulfide from a methionine (Figure 2–26D)—that relays the electron from the pseudoazurin to the catalytic copper ion. Nitrite ion reversibly associates with the reduced catalytic Cu^{+} as a fourth ligand.[1061,2020,2022] A model compound, in which a Cu^{+} is coordinated by the three nitrogens in 1,4,7-triisopropyl-1,4,7-triazacyclononane, with nitrite ion as its fourth ligand, is able to reduce the nitrite ion to nitrous oxide (**2–106**) upon addition of acetic acid.[2023] The acid is necessary for hydronation of the oxygen that leaves the nitrogen of the nitrite ion as a molecule of water during the reduction (see Equation 2–262). In the active site of nitrite reductase (NO-forming) from *A. xylosoxidans*, there

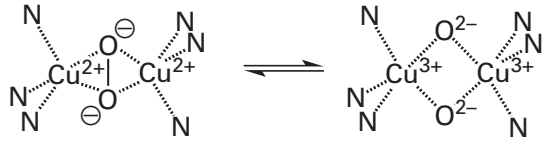
are both a carboxy group from an aspartic acid and an imidazolyl group from a histidine, properly positioned to supply together two hydrons to ensure that a molecule of water is the leaving group.[2024] When each of these amino acids in nitrite reductase (NO-forming) from *A. faecalis* is mutated in turn to an asparagine, the enzymatic activity decreases by factors of 100 and 1500, respectively.[2025] In the enzymatic reaction, following the reduction of nitrite ion to nitric oxide, the resulting Cu^{2+} is then reduced by an electron from a typical prosthetic copper, with two sulfurs from a cysteine and a methionine and two nitrogens from two histidines as ligands (Figure 2–26D),[703,711] which relays the electron[2021] from the Cu^{+} in the small dissociable electron-transferring coenzyme pseudoazurin or the heme in cytochrome c_{551}.[1168]

Enzymes that have oxides of oxygen and oxides of nitrogen as substrates also contain **dinuclear clusters of prosthetic copper ions** in their active sites. The paradigm of such a dinuclear cluster of prosthetic copper ions is the one in hemocyanin (Figure 2–58D).[2026,2027] The protein surrounding the dinuclear cluster in the crystallographic molecular model of hemocyanin from *Limulus polyphemus* is superposable on the protein surrounding the dinuclear cluster of prosthetic iron ions in the crystallographic molecular models of hemerythrins (Figure 2–57F),[2027] and this observation demonstrates that these two proteins, hemocyanin and hemerythrin, share a common ancestor. In a hemocyanin, histidines are found at positions both in the sequence of amino acids and in the crystallographic molecular model equivalent to those of Histidines 25, 54, 73, 77, and 106 in the hemerythrin from *Themiste hennahi*, and as they do to the iron ions in hemerythrin, they all provide ligands to the two copper ions. In the hemocyanins, however, Glutamate 58 and Aspartate 11, which are bidentate ligands to the iron ions in hemerythrin from *T. hennahi*, are replaced by a threonine and an asparagine, neither of which is coordinated to either copper ion.[2028] This change removes two negative elementary charges from the constellation around the metallic ions, consistent with the difference in charge number between two Fe^{2+} and two Cu^{+}. There is, however, one additional ligand in the hemocyanins to compensate partially for the loss of the four carboxylato oxygens. Phenylalanine 29 in the sequence of amino acids for the hemerythrin from *T. hennahi* is replaced by a histidine in the hemocyanins that provides a third ligand to the one copper ion. This replacement causes the two copper ions in hemocyanin to be equivalent in their coordination, as each has three imidazolyl groups from three histidines surrounding it arranged in roughly the same orientations (Figure 2–58D).

In the hemocyanins in the active deoxygenated state, the two copper ions are in the cuprous state. When molecular oxygen binds, they are both oxidized reversibly[2029] to Cu^{2+} and the dioxygen is reduced to the peroxide dianion, O_2^{2-}, just as it is in a hemerythrin, but it is then not hydronated. The **peroxide dianion is bound between the two Cu^{2+}** with each of its oxygens coordinated to each of them (Figure 2–58D).

For the hemocyanins, the oxygen–oxygen bond of the peroxide dianion remains intact in this reversible complex between the dinuclear cluster of copper ions and molecular oxygen.[2030] There are synthetic dinuclear clusters of cuprous ions, in each of which the Cu^{+} is also coordinated by three diazoles as in hemocyanin. These clusters bind molecular oxygen in a complex with the same spectroscopic signatures and the same structures as those for hemocyanins and in which the oxygen–oxygen bond of the bound peroxide dianion definitely remains intact.[2031-2033]

When, however, the ligands coordinating the two copper ions in a synthetic dinuclear cluster are more basic than diazoles, an equilibrium can be observed[2034,2035] in which the bond between the two oxygens is broken

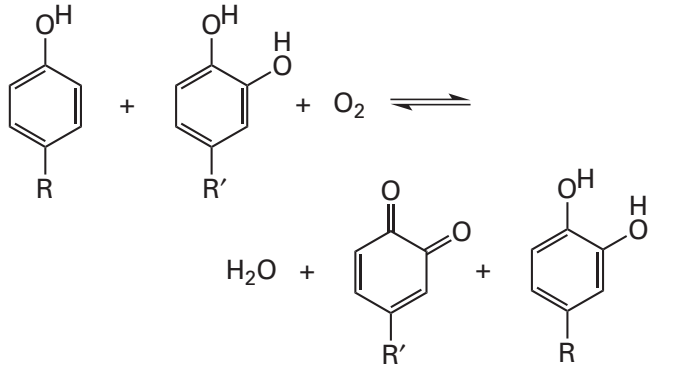


(2–306)

and a **cyclic 1,3-dioxo-2,4-dicopper(III)** is produced.[2036-2040] These synthetic, cyclic, high-valent oxocopper complexes are able to remove hydrogen atoms from aromatic rings,[2041] hydroxylate benzylic carbons,[2038,2040] oxidize a sulfide to a sulfoxide,[2040] perform a Baeyer–Villiger oxidation,[2040] and hydroxylate a *m*-dialkylphenyl group between its two alkyl substituents[2042] as well as **hydroxylate a phenol ortho to its hydroxy group**.[2043-2045]

This last reaction, performed by a synthetic, high-valent 1,3-dioxo-2,4-dicopper(III), is the same one catalyzed by monophenol monooxygenase*

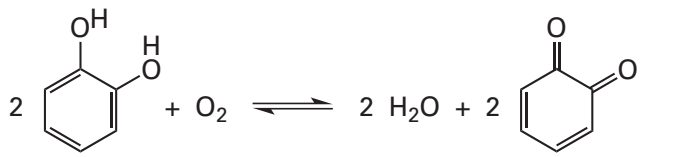
*This enzyme is also widely referred to as "tyrosinase".



(2–307)

where R can be the same as R′. Monophenol monooxygenase from *Streptomyces castaneoglobisporus* has a dinuclear cluster of copper ions that is the same as that of hemocyanin within a protein structurally and functionally homologous to hemocyanin.[2046,2047] The most significant difference between monophenol monooxygenase and hemocyanin is that monophenol monooxygenase has the 4-hydroxy group of a tyrosine in a position from which it can form a hydrogen bond or transfer a hydron to one of the oxygen atoms of the molecular oxygen when it is bound as a peroxide dianion to the dinuclear cluster (Figure 2–58D). This catalytic acid may promote the cleavage of the oxygen–oxygen bond in the dicupric peroxide to produce cyclic 1,3-dioxo-2,4-dicopper(III) (Equation 2–306), in which one of the μ-oxo groups is a μ-hydroxo group. Such a cyclic 1-oxo-3-hydroxo-2,4-dicopper(III) may be responsible for the hydroxylation catalyzed by this enzyme. It is also possible, however, that the species responsible for the observed monooxygenation is the dicupric peroxide itself.[2048] The two electrons required to regenerate the dicuprous cluster from the dicupric cluster that remains after the hydroxylation has occurred are provided by the catechol that is a cosubstrate for the enzymatic reaction (follow R′ in Equation 2–307). This catechol acts as if it were a quinol. Once the remaining μ-oxo is hydronated and dissociates as a molecule of water, the dicuprous cluster is then ready to bind the next molecule of oxygen.

In catechol oxidase

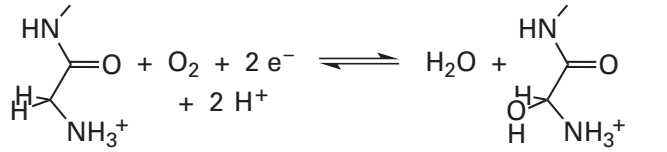


(2–308)

from *Ipomoea batatas*, which is also homologous to hemocyanin,[2046,2049] there is no catalytic base adjacent to the usual dicupric peroxide. Nor does the enzyme catalyze a hydroxylation, only an oxidation by electron transfer, so in this case, the **dicupric peroxide itself may be the oxidant** receiving the two pairs of electrons sequentially from the two catechols that are the reactants and that associate one after the other with the active site.[2049] The result, however, is the same: upon hydronation, the two μ-oxo groups between the two now cuprous copper ions become two molecules of water. In catechol oxidase, one of the six histidines coordinating the two copper ions (see Figure 2–58D) is a 2-(*S*-cysteinyl)histidine.

A cyclic 1,3-dioxo-2,4-dicopper(III) is homologous to the cyclic 2,4-dioxo-1,3-diiron(IV) that is the oxidant formed in the active site of methane monooxygenase (particulate) (**2-136**). In fact, methane monooxygenase (particulate) from *M. capsulatus* has a dinuclear cluster of prosthetic copper ions rather than a dinuclear cluster of prosthetic iron ions. In this cluster, one of the copper ions is coordinated by two imidazolyl groups from two histidines, and the other copper is coordinated by one imidazolyl group from the amino-terminal histidine and the free α-amino group of that histidine. There is a symmetric synthetic 1,3-dioxo-2,4-dicopper(III) in which each copper ion is coordinated by an imidazolyl group and a primary amine.[2050] Spectral properties of this synthetic 1,3-dioxo-2,4-dicopper(III) are similar to those of a high-valent intermediate in the reaction catalyzed by the methane monooxygenase (particulate) that uses copper ions as prosthetic groups.[2051]

Peptidylglycine monooxygenase performs the hydroxylation of the secondary α carbon of an amino-terminal glycine



(2–309)

A related enzyme,[730] dopamine β-monooxygenase, hydroxylates the benzylic carbon in 4-(2-aminoethyl)benzene-1,2-diol. Both enzymes use L-ascorbate (Equation 2–163) as the source of the two electrons. In both enzymes there are two prosthetic copper ions in coordinations that are analogous to those of the two copper ions in nitrite reductase (NO-forming). One is coordinated by the imidazolyl

groups of two histidines and the sulfide of a methionine,[730] reminiscent of the widely distributed type of mononuclear copper ion in plastocyanin (Figure 2–26D) except that the usual cysteine is missing, which is not the case in nitrite reductase (NO-forming). This absence leaves an open site[536] on the Cu^+ in the active form of the enzyme. The other copper ion is trigonally coordinated by three imidazolyl groups, just as is the catalytic copper ion in nitrite reductase (NO-forming).

It was always thought that, just like the two mononuclear copper ions in nitrite reductase (NO-forming), the two prosthetic copper ions in peptidylglycine monooxygenase and dopamine β-monooxygenase operated independently, except that their roles were exchanged. The open site on the prosthetic copper ion coordinated by the two imidazolyl groups and the sulfide was the catalytic site in these two latter enzymes, and the copper ion coordinated by the three imidazolyl groups relayed the electrons consecutively from the two ascorbates.[535]

There is what may well be a critical difference, however, between nitrite reductase (NO-forming) and peptidylglycine monooxygenase. In the former case, the cysteine coordinating the one copper ion is from the cysteine that follows one of the histidines coordinating the other copper ion in the sequence of amino acids for the enzyme,[703,2022] so all the intervening atoms are rigidly holding the two copper ions apart. In peptidylglycine monooxygenase and dopamine β-monooxygenase the cysteine is no longer there, and although the two copper ions are 1.1 nm apart in the unoccupied enzymes,[730] as they are in nitrite reductase (NO-forming),[2020] there is nothing between them. In a crystallographic molecular model of human dopamine β-monooxygenase, there is a closed conformation in which two hinged domains, coordinating one of the copper ions, have closed upon each other to bring the two copper ions to within 0.5 nm of each other,[2052] in an orientation in which they can share either a molecule of oxygen or a hydroperoxide.[2053]

Consequently, peptidylglycine monooxygenase and dopamine β-monooxygenase and their relatives could well be considered to have a dinuclear cluster of prosthetic copper ions in their active sites. One hint that this may well be the case is that in the resting state of peptidylglycine monooxygenase the two copper ions have different reduction potentials (+270 and −15 mV), but upon association of a peptide that is a reactant for the enzyme the two copper ions have the same reduction potential (+80 mV) as if they were participants in an electronically coupled cluster.[535]

A complex forms between molecular oxygen and the Cu^+ that is coordinated by the two imidazolyl groups and the sulfide (Figure 2–58C),[2054,2055] but this occurs only when the active site is in a complex with a peptide substrate containing an amino-terminal glycine.[2054] Molecular oxygen binds at a location immediately adjacent to the hydrogen that is to be replaced by a hydroxy group (Equation 2–309). The **association of molecular oxygen with the Cu^+** is analogous to the binding of molecular oxygen to a prosthetic Fe^{2+} or ferroheme both because it ends up in a bent configuration (Figure 2–58C) and because carbon monoxide is able to associate[2056] with the Cu^+. The Cu^+ provides one of the electrons required by the reaction.

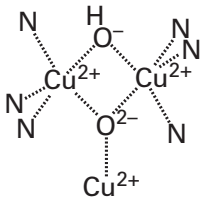
Following this initial association between molecular oxygen and the Cu^+, the mechanism of the monooxygenation is less clear. The initial complex is equivalent to a superoxycopper(II), which would be a weak oxidant.[2057-2060] It seems likely, however, that the active species is the dinuclear cluster of copper ions that forms when the domains close. In this case, the initial complex between Cu^+ and molecular oxygen could be first hydronated[2061] and then reduced by the second electron in the dinuclear cluster to the dicupric hydroperoxide,[2053] which could be either the active oxidant or a precursor to the active oxidant,[2057,2060] as is the case with a peroxyiron(III).

The multicopper oxidases are a family of related enzymes[695,696,706,2062-2064] that each contain a **trinuclear cluster of prosthetic copper ions**. A representative of these clusters is the trinuclear cluster in laccase from *M. albomyces* (Figure 2–58E).[2065] In a laccase, this cluster in its fully reduced tricuprous state reduces molecular oxygen to two molecules of water. The four electrons required for this reduction, depending on the laccase, are derived from the oxidation of four quinols, four catechols, four aminophenols, or four phenylenediamines that are oxidized, each by one electron, to their semiquinones. These one-electron oxidations are the purpose of the respective laccase.

Following the association of a molecule of oxygen with the trinuclear cluster of three Cu^+ in the active site of a laccase, the **molecular oxygen is reduced to two molecules of water**. The molecule of oxygen coordinates all three Cu^+ ions (Figure 2–58E). As the molecular oxygen associates with the trinuclear cluster, the molecule of oxygen is reduced to a peroxide dianion by two of the three Cu^+ among which

it is bound.[2066-2068] The peroxide dianion is then hydronated at one of its two oxygens by the carboxy group of an aspartic acid[2067] and reduced by one electron from the third Cu^+ as the oxygen–oxygen bond dissociates.[2069] Finally, an electron is transferred from a fourth, nearby (1.2 nm), mononuclear Cu^+ (Figure 2–26A) by outer-sphere electron transfer.

The product of the reductions and the heterolytic cleavage of the peroxide is a complex in which the hydroxide resulting from hydronation of one oxygen atom has become a μ-hydroxy group between two of the Cu^{2+} and the oxide dianion that was the other oxygen is now sitting in the plane of and equidistant from all three Cu^{2+}, coordinating all three of them[2070]



2–145

In this form of the cluster, all the copper ions have been oxidized, and in the active site of the laccase from *T. vernicifluum*, it is only after its formation that three successive electron transfers from the nearby mononuclear copper ion occur, passing the electrons one at a time from three of the aromatic coreactants to rereduce[2071] the three Cu^{2+}. Hydronations of the oxide dianion and the hydroxide, concerted with rereduction of the three Cu^{2+} to three Cu^+, are necessary to regenerate the fully reduced form of the cluster in the active site of laccase and two molecules of water.[2072] The electron removed from the fourth aromatic coreactant reduces the mononuclear copper itself to Cu^+ ready to provide the fourth electron needed to reduce the next molecular oxygen to water. As in cytochrome oxidase, all the electrons necessary to reduce molecular oxygen to the equivalent of two molecules of water are present in the enzyme itself so that no intermediates have a chance to dissociate into the solution.

The nearby mononuclear copper ion in one of these multicopper oxidases, of which laccase is an example, is reduced from Cu^{2+} to Cu^+ by removing an electron from the **particular reactant that is oxidized by that particular multicopper oxidase**. It has already been noted that the mononuclear copper ion in laccase (Figure 2–26A) consecutively removes one electron from each of four quinols, four catechols, four aminophenols, or four phenylenediamines to produce their semiquinones, and these four electrons consecutively reduce the completely cupric cluster (**2–145**) to the completely cuprous cluster as the μ-hydroxide and the μ-oxide dianion are hydronated and eventually leave the enzyme as hydroxide ions or molecules of water.

Each of the other enzymes in the family of multicopper oxidases has, in addition to the trinuclear cluster, a mononuclear cluster responsible for the consecutive oxidations of its particular reactants. For example, L-ascorbate oxidase uses a mononuclear copper ion, coordinated as is the one in plastocyanin (Figure 2–26D), to oxidize consecutively four molecules of L-ascorbate to four L-monodehydroascorbates by four separate outer-sphere electron transfers.[696] After rereduction of the enzyme, the tricuprous cluster is ready to bind the next molecule of oxygen (Figure 2–58E) and the cuprous mononuclear cluster is ready to provide the fourth electron. Because the reduction of oxygen to water oxidizes a particular multicopper oxidase, the mononuclear Cu^{2+} that it then uses to perform its particular oxidation is a **particularly strong oxidant**. The purpose of L-ascorbate oxidase, an enzyme that seems to oxidize a coenzyme that is only used as a reductant by converting molecular oxygen to water, is unknown.

Nitrous-oxide reductase

$$2\,H^+ + 2\,e^- + NNO \rightleftharpoons N_2 + H_2O \qquad (2\text{–}310)$$

contains a **tetranuclear cluster of prosthetic copper ions** (Figure 2–58F).[747,2073] In the crystallographic molecular models of nitrous-oxide reductase from *P. denitrificans*[2074] and from *Achromobacter cycloclastes*,[2073] three of the copper ions are coordinated by the imidazolyl groups of two histidines and one of them by the imidazolyl group of only one histidine, and each of the four copper ions forms a bond with the same tetrahedrally coordinated sulfide dianion in the center of the cluster.[2075,2076] This form of the cluster is responsible for the enzymatic activity.[2077,2078] The **nitrous oxide**, $N{\equiv}N^+{-}O^-$ (**2–106**), is thought to bind to the reduced tetracopper(I) cluster in the active site of the enzyme at the position occupied by the two molecules of water in the crystallographic molecular model of the oxidized enzyme (Figure 2–58F),[2079] with its peripheral nitrogen taking the place of one of the waters and its peripheral oxygen taking the place of the other[2080] to form

a six-membered ring composed of the two nitrogens and the oxygen of nitrous oxide, the two copper ions with open sites, and the sulfide dianion. The fully reduced tetracuprous cluster is responsible for the reduction,[2078,2080] and it performs successive inner-sphere transfers of the two electrons to the bound nitrous oxide while its oxygen is hydronated twice by a catalytic acid base.[2079] In the paramagnetic tricopper(I)copper(II) intermediate, there is an unpaired electron shared between the two copper ions coordinated by the resulting O-hydronated tautomer, $^{\bullet}$N=N–OH (**2–108**), of the radical (**2–107**) of nitrous amide (**2–109**).[2081] Transfer of the next electron and a hydron produces molecular nitrogen and a molecule of water. There is a CuA dinuclear cluster of copper ions (Figure 2–26F) 1.0 nm away from the tetranuclear cluster of prosthetic copper ions, and this CuA cluster is the point of entry for the electrons from the natural donor that rereduces the enzyme.[747] It is unclear why six Cu^{+} are needed for a two-electron reduction (Equation 2–310).

Manganese ions are also found in enzymes that perform oxidation–reductions of the oxides and hydrides of hydrogen, oxygen, nitrogen, carbon, and sulfur. In these enzymes, the prosthetic manganese ions can assume the oxidation states **Mn^{+2}, Mn^{+3}, Mn^{+4}, and possibly Mn^{+5}**.

There are several enzymes that have a prosthetic, **mononuclear manganese ion** in their active sites and use it to catalyze reactions similar to those catalyzed by mononuclear iron ions. For example, 3,4-dihydroxyphenylacetate 2,3-dioxygenase from *Arthrobacter globiformis* has a manganese ion in its active site even though it catalyzes the same reaction (Equation 2–277) passing through the same intermediates (Equation 2–278) as a 3,4-dihydroxyphenylacetate 2,3-dioxygenase that has a mononuclear iron ion in its active site.[2082] Toxoflavin lyase from *Paenibacillus polymyxa* has a mononuclear manganese ion in its active site that is coordinated by two carboxylato groups and an imidazolyl group,[2083] a coordination that ensures that the manganese ion remains Mn^{2+} during the reaction. The enzyme catalyzes a reaction analogous to a Baeyer–Villiger rearrangement[2084] like the one catalyzed by the Fe^{2+} in 3,4-dihydroxyphenylacetate 2,3-dioxygenase (Equation 2–278).

There are also enzymes that have mononuclear manganese ions in their active sites that are unlike enzymes with iron ions in their active sites. Oxalate decarboxylase

$$\text{oxalate} + H^{+} \rightleftharpoons CO_2 + \text{formate} \qquad (2\text{–}311)$$

from *B. subtilis*[2085] has a mononuclear Mn^{2+} in its active site octahedrally coordinated by three imidazolyl groups, a carboxylato group, and two molecules of water.[2086] Although it catalyzes a reaction that does not involve molecular oxygen, molecular oxygen must be present for the enzymatic reaction to occur. It is believed that the two open sites on the Mn^{2+} are occupied at the same time by oxalate and molecular oxygen, and that the molecular oxygen removes an electron from the carboxylato group of the oxalate that is a ligand to the Mn^{2+} and becomes a superoxide radical anion.[2085] The electron transfer produces the carboxy radical of oxalate ($^{-}OOCCOO^{\bullet}$) that decomposes into carbon dioxide and a formyl radical anion ($^{-}OOC^{\bullet}$). The existence of the formyl radical anion as an intermediate in the enzymatic reaction has been demonstrated by trapping it with *N-tert*-butyl-1-phenylmethanimine oxide, a stable radical that adds to the formyl radical anion released adventitiously into the solution as a side product by a mutant of the enzyme.[2087] In the unmutated enzyme this intermediate is presumably held tightly in the active site. Hydronation of the carbon of the formyl radical anion coincident with transfer of an electron from the superoxide radical anion back to the resulting formate radical completes the reaction and regenerates the molecular oxygen. In one sense, the molecular oxygen is an electron-transferring coenzyme, accepting an electron and then donating it back, much as the electron-transferring coenzyme for ribonucleoside-diphosphate reductase containing the stable tyrosyl radical removes an electron from the sulfido group in the active site and then donates it back at the end of the reaction.

The decomposition of the carboxy radical of oxalate is an example of the rapid and **spontaneous decarboxylation of any carboxy radical**. During decarboxylation, the carbon dioxide leaves behind the radical of the carbon to which it was attached

$$RCO_2^{\bullet} \longrightarrow R^{\bullet} + CO_2 \qquad (2\text{–}312)$$

In the case of oxalate decarboxylase, this is the formyl radical anion. The bond dissociation energies of most carbon–carbon bonds between a carboxy radical and an adjacent carbon are actually negative (–30 to –110 kJ mol^{-1}),[2088] unlike those for almost every other type of carbon–carbon bond, because

carbon dioxide is such a stable molecule. The first-order rate constants for the decarboxylations of most carboxy radicals[2089-2091] at 20 °C are in the range between 1 and 800 ns^{-1}. The decarboxylation of the carboxy radical formed upon dissociation of the oxygen–oxygen bond of the peroxy group in the *tert*-butyl peroxy ester of ethyl oxalate occurs so rapidly that it was concluded that it was indistinguishable from being concerted with dissociation of the oxygen–oxygen bond.[2092]

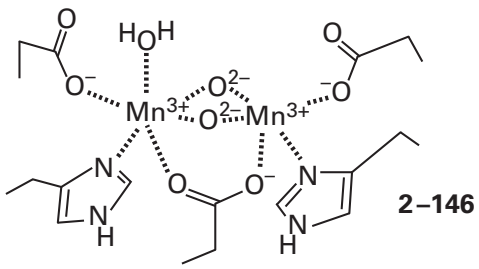
Oxalate oxidase

$$\text{oxalate} + O_2 + 2\,H^+ \rightleftharpoons 2\,CO_2 + H_2O_2 \qquad (2\text{–}313)$$

from *Hordeum vulgare* has a mononuclear manganese ion also coordinated by three imidazolyl groups and a carboxylato group.[1409] The manganese ion, however, must be Mn^{3+} or Mn^{4+} rather than Mn^{2+} for the enzyme to be active. In oxalate oxidase, the **Mn^{3+}**, rather than the complex between molecular oxygen and Mn^{2+}, **removes an electron** from the oxalate to produce carbon dioxide and the same formyl radical anion, which is then converted into carbon dioxide rather than formate when the molecular oxygen removes the unpaired electron from it. The resulting superoxide radical anion is hydronated, and transfer of a hydron from an acid and an electron from the Mn^{2+} to the hydroperoxy radical completes the reaction.[2093]

There is also a dinuclear cluster of prosthetic manganese ions in an oxidase in *S. thioluteus* that has a structure similar to those of dinuclear clusters of prosthetic iron ions (Figure 2–57F to 2–57I) in that it has two bidentate bridging carboxylato groups. One of the manganese ions is coordinated by two imidazolyl groups and a monodentate carboxylato group, and the other manganese ion is coordinated by an imidazolyl group and another monodentate carboxylato group. This dinuclear cluster of prosthetic manganese ions catalyzes the *N*-hydroxylation of arylamines.[2094]

Catalase from *L. plantarum* (Equation 2–242) has a **dinuclear cluster of prosthetic manganese ions**[2095,2096]



2–146

that resembles closely the dinuclear cluster of prosthetic iron ions (Figure 2–57I) in methane monooxygenase (soluble). The dinuclear cluster cycles between the $Mn^{+3}\,Mn^{+3}$ oxidation state and the $Mn^{+2}\,Mn^{+2}$ oxidation state.[2097,2098] The former oxidizes hydrogen peroxide to oxygen; the latter reduces hydrogen peroxide to water. It is thought that, in the oxidized cluster, hydrogen peroxide replaces water as a ligand on the exocyclic open site of one of the manganese ions in **2–146,** and after the reduction and the removal of the hydrons, the resulting molecular oxygen leaves from the resulting Mn^{2+}. In the reduced enzyme, however, hydrogen peroxide is able to replace a μ-hydroxy group, the conjugate acid of one of the μ-oxo groups in **2–146**, because it is not held that tightly by the Mn^{2+} ions.[2095]

There is a synthetic dinuclear cluster of manganese ions that is able to catalyze the same dismutation of hydrogen peroxide performed by the catalase, albeit at a much slower rate.[2099] It is possible to oxidize manganese catalase from *L. plantarum* to a superoxymanganese(IV)manganese(III)[2100] state, which is not an intermediate in the normal enzymatic reaction but displays some of the properties[2101] of the cluster of four manganese ions in photosytem II.

The prosthetic cluster of four manganese ions in photosytem II of green plants and cyanobacteria is responsible for producing molecular oxygen from two molecules of water. The random choice of water as the source of electrons for photosynthesis, and the production of molecular oxygen as a by-product of this choice, is one of the most influential events in the history of life on earth. The oxidation of water is performed by a pentanuclear cluster of four manganese ions, a calcium dication, and five μ-oxo ions.[1009,1028,2102,2103] During the conversion of two molecules of water to a molecule of oxygen, a four-electron oxidation, the four hydrons that are also products are released to the positive, acidic solution because electrons are transferred from the cluster that performs the oxidation to the hole in the special pair, which is on the positive, acidic side of the membrane (Figure 2–34).

In the crystallographic molecular model of photosystem II from *Thermosynechococcus vulcanus*, **each of the four manganese ions in the cluster is octahedrally coordinated** by six ligands (Figure 2–59).[1011,1012,2104-2106] The ligands are μ-oxo ions, carboxylato groups, molecules of water, and imidazolyl groups, typical ligands for manganese ions (see **2–146**). The calcium dication has seven oxygens, anionic and neutral, as ligands pushing and shoving around it, which is one of the typical coordinations for Ca^{2+}. Three of the seven external faces of the cluster have bidentate carboxylato groups coordinating the two metallic ions on that face. Each μ-oxo ion has four ligands. By convention the manganese ions, the μ-oxo groups, and the molecules of water in the vicinity are numbered as in the figure to ease discussion of their roles.

In a synthetic cubane of three Mn^{4+}, four μ-oxo groups, and a Ca^{2+}, for which a crystallographic molecular model of high resolution is available, all nine of the oxygen–manganese distance are between 0.183 and 0.192 nm.[2107,2108] Six of the distances between manganese ions and oxo groups in the crystallographic molecular model of the cluster in photosystem II from *T. vulcanus*[2106] are between 0.18 and 0.19 nm. The distance, however, between Oxo 5 and Manganese 1 is 0.27 nm and the distance between Oxo 5 and Manganese 4 is 0.22 nm, and these dispositions significantly widen the gap between Manganese 4 and Manganese 1. **Within this gap, the molecule of oxygen is produced** from two oxygen atoms that were originally in two molecules of water.[2109,2110] This widening is presumably a steric effect produced by the side chains of the amino acids that are ligands to these manganese ions, and it is essential to provide the room necessary for the oxidation. In response to this steric widening of the gap between Manganese 1 and Manganese 4, the distance between Manganese 3 and Oxo 3 increases to 0.23 nm, the distance between Manganese 3 and Oxo 5 increases to 0.21 nm, and the distance between Manganese 2 and Oxo 3 increases to 0.21 nm.

Because Ca^{2+} is incapable of being oxidized or reduced at normal biochemical potentials, the **manganese ions in the cluster provide four electrons**, one at a time in a sequence of steps, to the successive holes that develop in the special pair during the absorption of four successive quanta of light by the reaction center within photosystem II. As has already been noted, transfer of each of these four electrons from the cluster of manganese ions (Figure 2–59) to the hole in the special pair (Figure 2–35) passes through a tyrosine—Tyrosine 161 in the active site of photosystem II from *T. vulcanus* (Figure 2–59)—which donates an electron to the hole in the special pair to become the tyrosyl radical, which then removes an electron from the cluster.

The **four separate removals from the cluster, each of one electron,** by the special pair in the reaction center can be coordinated over a population of photosystems II by sitting a suspension of chloroplasts in the dark until the majority of the tetranuclear clusters of prosthetic manganese ions are reduced by endogenous reductants to the resting S_1 or $(Mn^{3+})_2(Mn^{4+})_2$ oxidation state, the state of the crystallographic molecular model in Figure 2–59, and then exposing them to a regular sequence of short flashes of light intense enough to excite almost all photosystems II in the sample on each flash.[2111-2113] The same result can be achieved by poising purified photosystem II electrochemically in the S_1 state and then exposing the preparation to successive flashes of light.

If it is intense enough, the **first flash** creates holes in almost all the special pairs, and each hole then accepts an electron through the tyrosine from its associated cluster to take the majority of the clusters to the S_2 or $\mathbf{Mn^{3+}(Mn^{4+})_3}$ oxidation state ($t_{½}$ = 100 μs).[2114-2116] The distribution of absorbances in the electron–nuclear double resonance spectrum for this S_2 oxidation state of photosystem II of *Thermosynechococcus elongatus* indicates that the electron, and hence the hole, is shared almost equally among the four manganese ions and that none of the manganese ions can be Mn^{2+}.[2117]

Up to this point, the two molecules of water or μ-oxo bridges within each cluster that will become the molecule of oxygen are still molecules of water, μ-hydroxy bridges, or μ-oxo bridges, and they exchange with molecules of water in the solution, albeit slowly.[2118-2120] Oxo 5 has been identified as one of these exchangeable oxygens by W-band oxygen-17 electron–electron double resonance-detected nuclear magnetic resonance spectra[2121] after rapid dilution of samples poised in the S_2 oxidation state into $H_2{}^{17}O$. This μ-oxo bridge is the most likely to be one of the two **oxygens destined to become molecular oxygen** because it is the only μ-oxo bridge that is coordinated by the Ca^{2+} and two of the four manganese ions, is adjacent to a third manganese ion, and sits in the widened gap between Manganese 1 and Manganese 4. Furthermore, the geometry of its coordination is strained because it is farther from

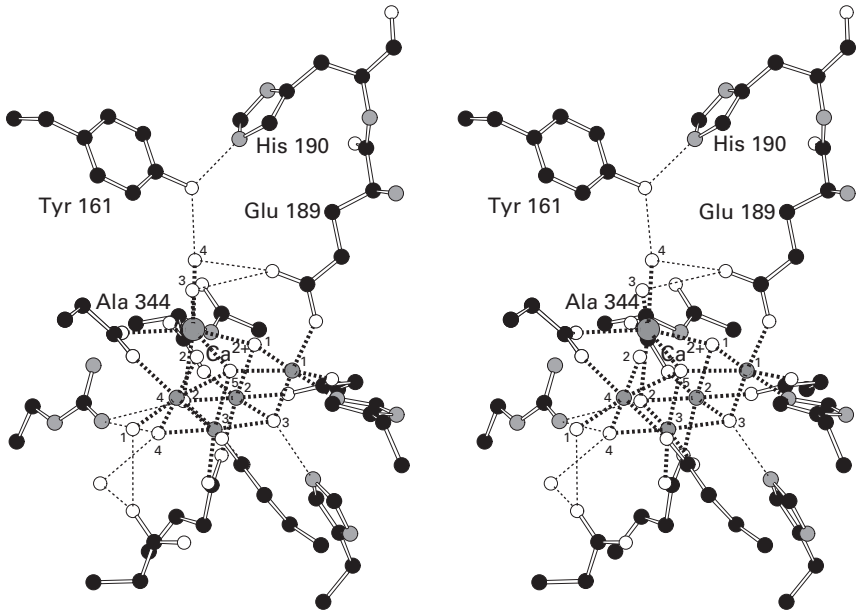


Figure 2–59: Stereodrawing[50] of the cluster of four manganese ions and a calcium dication responsible for the conversion of two molecules of water into a molecule of oxygen.[1011] Black atoms are carbons, white atoms are oxygens, and gray atoms are nitrogens. The calcium dication is the large labeled dark gray sphere, and the four manganese ions are the smaller dark gray spheres surrounded by their ligands. By convention, the manganese ions, the μ-oxo groups, and the molecules of water in the vicinity are numbered as in the figure to ease discussion of their roles. The μ-oxo groups among the metallic ions and several molecules of water are the small white spheres. Crude particles containing photosystem II were extracted from thylakoids of *T. vulcanus* with the detergent lauryldimethylamine *N*-oxide. These crude particles were dissolved in a solution of 2.0% *n*-dodecyl β-D-maltoside, 20 mM NaCl, and 25% glycerol at pH 6.0, and purified by stepwise elution from a chromatographic medium to which quaternary amines are covalently attached.[2105] The intact photosystem II with all its components still associated was then further purified by recrystallization with poly(ethylene glycol) from 40 mM $MgSO_4$, 20 mM $CaCl_2$, 20 mM NaCl, and 0.02% *n*-dodecyl β-D-maltoside at pH 6.5.[2104] The final crystals were submitted to X-ray crystallography, and data were collected to Bragg spacing of 0.19 nm.[1011] The cluster and the side chains of the aspartates, glutamates, histidines, and an arginine that attach it to the protein are drawn. The free carboxylate of the carboxy-terminal alanine (Alanine 344) of one of the folded polypeptides in the complex is also a bidentate ligand to the cluster.

tetrahedral than any of the other μ-oxo bridges in the cluster. There is evidence from crystallography performed with short pulses of X-rays that one of the bonds between this μ-oxo group and either Manganese 1 or Manganese 4 lengthens further during the transition between S_1 and S_2.[2123]

In the next step, the **second flash** takes the cluster to the S_3 oxidation state ($t_{½} = 250\ \mu s$).[2114] Magnetic resonance spectroscopy of this oxidation state[2124] and determinations of its spin state[2125] demonstrate that **all four of the manganese ions are Mn^{4+}**.

A crystallographic molecular model of the cluster in the S_3 oxidation state, derived from a data set with reflections to Bragg spacing of 0.215 nm that was assembled from reflections collected with short pulses of X-radiation (10 fs) impinged on the crystals after two flashes of light, clearly shows that **two oxo groups are now between Manganese 4 and Manganese 1**.[2110] The distances from Manganese 4 to the first oxo group, from the first oxo group to the second oxo group, and from the second oxo group to Manganese 1 are 0.22, 0.19, and 0.17 nm, and the distance between Manganese 4 and Manganese 1 has expanded from 0.49 nm in the S_1 oxidation state to 0.52 nm. This disposition of oxygen atoms is consistent with other crystallographic observations performed with short pulses of X-rays[2126] and extended X-ray absorption fine structure,[2127] which are consistent with a structure for the complex in which the bond between Oxo 5 and either Manganese 1 or Manganese 4 has been broken, and the open coordination site on that Mn^{4+} has become occupied by a hydroxide. The van der Waals radius of an oxygen atom is 0.15 nm, the oxygen–oxygen bond length in hydrogen peroxide is 0.149 nm, and the oxygen–oxygen bond length in a molecule of oxygen is 0.121 nm. Consequently, because the distance between the two oxo groups is 0.19 nm, the two oxo groups are forced into a disposition in which their van der Waals circumferences overlap significantly, but they are not yet either a hydroperoxide or a molecule of oxygen.

In the S_1 oxidation state, the distances from Manganese 4 to Oxo 5 and from Oxo 5 to Manganese 1 are 0.22 and 0.27 nm, so at first glance it seems as though an oxo group has been inserted between Oxo 5 and Manganese 1, but there is obviously no way to tell one of the oxo groups from the other crystallographically. The closest molecule of water to the bonds between Manganese 4, Oxo 5, and Manganese 1 at the S_1 oxidation state (Figure 2–59) is Water 3 on the Ca^{2+}, but it lies immediately adjacent to the bond between Manganese 4 and Oxo 5. If this molecule of water becomes the second oxo group, it probably inserts into the space between Manganese 4 and Oxo 1, and the two resulting oxo groups simply shift in location to the orientations of lowest energy. Studies of the effect of external pH on the rate lead to the conclusion that the transition from the S_2 to the S_3 oxidation state proceeds with the release of a hydron into the solution,[2128] perhaps one of the hydrons on the molecule of water or the hydroxide that is removed before it enters the gap. If indeed Water 3 has entered the gap, it is probably the carboxylato group of Glutamate 189 that removes the hydron.

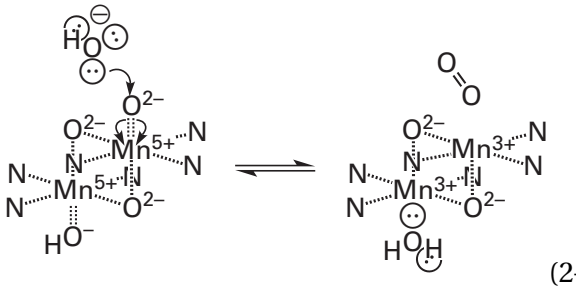
There are a number of observations consistent with the conclusion that the molecule of water that becomes the second oxo group during the transition to the S_3 oxidation state is Water 5, the **closest molecule of water on the Ca^{2+}**. In the presence of ammonia, Water 1 and Water 2 on Manganese 4, respectively, are replaced by two molecules of ammonia, but ammonia has no effect on the ability of photosystem II to turn molecules of water into molecules of oxygen.[2129] Because these are the only other observed molecules of water near the space between Manganese 4 and Manganese 1, this observation supports the conclusion that the new oxo group between them in the S_3 oxidation state was Water 3 before it inserted. In addition, Fourier-transform infrared spectra of the molecule of water destined to enter the gap are significantly affected by the substitution of Ca^{2+} by Sr^{2+}, an observation that indicates that Water 3 is that molecule of water.[2130] There are also arguments,[2109,2131-2133] however, that the molecule of water that fills the gap is actually Water 2 on Manganese 4, but the fact that the replacement of this molecule of water by ammonia has no effect on the conversion of water to molecular oxygen would seem to rule out this possibility.

It is only after the **third flash**[2111] takes the cluster to the S_4 oxidation state by removing one more electron from it that four electrons in the two oxo groups in the gap between Manganese 1 and Manganese 4 are removed by the surrounding manganese ions and a molecule of oxygen is produced. The transfer is so rapid that no intermediates, not even S_4 itself, have been observed while the molecule of oxygen is being produced.[2111,2113,2134] During this transition between S_3 and S_4, the exchange of oxygens in the cluster destined to become molecular oxygen with molecules of water in the solution slows dramatically,[2134] a fact suggesting that at this point an

almost irreversible commitment to **forming an oxygen–oxygen bond** has been made. During this transition between S_3 and S_4, a transient intermediate has been observed that is produced by the dissociation of a hydron from the cluster, perhaps from a hydroxy group, before the four electrons are removed essentially simultaneously from the two oxo groups.[2135]

In S_3, all four manganese ions are Mn^{4+}, and the cluster itself contains an even number of electrons. The removal of an electron from the cluster in which the two oxo groups are in position between Manganese 1 and Manganese 4 initiates the immediate formation of molecular oxygen. Upon removal of the electron, the cluster has an odd number of electrons. Formally, because one electron has been removed from a cluster of four Mn^{4+}, one of the manganese ions on which an oxo group is located has become an **oxomanganese(V)**. Just as in S_2, however, the unpaired electron in the cluster in photosystem II could well be distributed over the entire complex, so it is not clear whether the formation of molecular oxygen is the expression of the capacity of an oxomanganese(V) or the expression of the capacity of the unpaired electron itself. Synthetic oxomanganese(V) complexes, however, have been proposed to be models of an oxomanganese(V) in the S_4 oxidation state.[2136]

In isolation, surrounded by singlet ligands such as nitrogens, oxygens, or sulfurs, an oxomanganese(V) has an even number of electrons and is a strong electrophile, which would be expected to react instantaneously with an immediately adjacent formal oxide or hydroxide. In fact, oxomanganese(V) in a binuclear dioxodimanganese(V) is known to be able to act as an electrophile in a nucleophilic addition of hydroxide to produce molecular oxygen[2137]

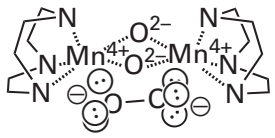


(2–314)

When, however, a mononuclear oxomanganese(V) in 5,10,15-tri(4-nitrophenyl)porphyrin was synthesized, it also reacted as an electrophile with hydroxide, but the product was peroxymanganese(III) rather than molecular oxygen.[2138] Consequently, the other oxomanganese(V) in the dinuclear complex (Equation 2–314), an excellent oxidant, is required to remove two electrons from the initial peroxymanganese(III) formed from the oxomanganese(V) to which the hydroxide added to produce the molecular oxygen. If there is a transient oxomanganese(V) in the cluster at the S_4 oxidation state, it must be formed from either Manganese 1 or Manganese 4 and the respective, adjacent oxo group in the space between them. The other oxo group would be equivalent to a hydroxide and would immediately add nucleophilically to the oxygen of the oxomanganese(V). It is possible that the other three Mn^{4+} in the cluster together would constitute a strong enough oxidant to convert the resulting hydroperoxymanganese(III) to molecular oxygen and Mn^{3+}, as well as a hydron.

If, however, the unpaired electron in S_4 is distributed over the cluster, including the oxygen atoms in the cluster, it is possible that the equivalent of an oxy radical initiates a sequence of radical intermediates in the production of molecular oxygen.[2120,2139] In one of the steps in this sequence, a single bond would be formed between the two oxo groups between Manganese 1 and Manganese 4 in the cluster to produce again a peroxide dianion shared by the two Mn^{4+}.

In both the mechanism involving a nucleophilic addition and the mechanism involving a colligation, a peroxide or hydroperoxide between two Mn^{4+} is an intermediate. A binuclear peroxydimanganese(IV)



2–147

has been synthesized in which two Mn^{4+} are complexed with a bridging peroxide dianion. Upon acidification (pH 3) in 0.5 M NaCl, the peroxide is released as molecular oxygen[2140] and the manganese ions end up as the chlorides of Mn^{3+}. In this reaction, each manganese has oxidized each atom of oxygen in the final molecular oxygen by one electron.

There is also precedence, in a synthetic cluster of manganese ions that can convert water to molecular oxygen, for the oxygen to be produced from two μ-oxo oxides.[2141] In this case, however, both μ-oxo groups that combine to form oxygen are ligands to the same manganese ion. It has been proposed that such an intermediate could be involved in the

formation of molecular oxygen in the S_4 oxidation state,[2142] but it is hard to see how the two oxo groups between Manganese 1 and Manganese 4 could end up on just one manganese ion because both manganese ions are coordinated by five other ligands, and Mn^{4+} holds its ligands tightly. Another synthetic cluster of manganese ions can convert two molecules of water to molecular oxygen, but again, the two molecules of water must occupy two open sites on the single manganese ion in the cluster.[2137]

During the hidden formation of molecular oxygen in the S_4 oxidation state in photosystem II, four electrons are transferred to the manganese ions from the two oxygens that begin at the oxidation state of water and end up at the oxidation state of molecular oxygen. Consequently, the manganese ions that consumed the four electrons have been reduced to the S_0 or $(Mn^{3+})_3Mn^{4+}$ oxidation state.[2115] Magnetic multiresonance electron paramagnetic spectra[2122] following rapid dilution into $H_2{}^{17}O$ and surface-enhanced Raman infrared spectra[2143] of photosystem II poised electrochemically in the S_0 oxidation state identify a hydroxy group, presumably derived from a molecule of water that has filled the empty space between Manganese 4 and Manganese 1 left behind after dissociation of the molecular oxygen. This hydroxy group then becomes Oxo 5 in the S_1 oxidation state after the removal of an electron from the cluster at the S_0 oxidation state.[2122]

The **fourth flash** returns the majority of the photosystems II to the S_1 or $(Mn^{3+})_2(Mn^{4+})_2$ oxidation state, where we began.[2115] Consequently, four successive flashes, which provide four successive quanta of light to each photosystem II and which absorb one electron from the cluster for each quantum of light, complete the cycle.

At this point in the discussion, the role of the Ca^{2+} and why it is suitable to fill this role become obvious. Water 3 on the Ca^{2+} lies immediately adjacent to the gap between Manganese 4 and Manganese 1, and its role seems to be to feed molecules of water or hydroxide ions into the gap.[2144,2145] It is also immediately adjacent to Water 4 on the Ca^{2+} that participates in an extended cluster of molecules of water* that are held together by hydrogen bonds and that ultimately blend into the positive, acidic solution.[2110] The two oxo groups in the gap between Manganese 1 and Manganese 4 in the S_3 oxidation state immediately become a molecule of oxygen on reaching the S_4 oxidation state. The molecule of oxygen immediately dissociates because the Manganese 4 and Manganese 1 are both Mn^{3+}, neither of which has any affinity for molecular oxygen. The empty gap is filled by Water 3 in the S_0 oxidation state, Water 4 moves over to the position previously occupied by Water 3, and Water 4 is replaced by a molecule of water from the extended cluster of molecules of water. Upon again reaching the S_3 oxidation state, the single oxo group between Manganese 4 and Manganese 1 is shoved over to Manganese 1 as a molecule of water or a hydroxide is pulled into the gap, and Water 4 again moves over and is replaced by a molecule of water in the chain.

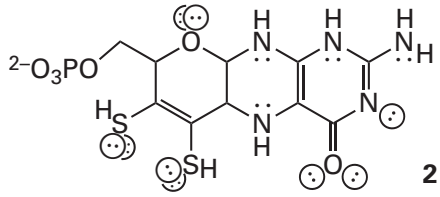
Water 3 and Water 4 seem to be at the center of the action (Figure 2–59). The 4-hydroxy group of Tyrosine 161, the tyrosine from which electrons are removed consecutively during photosynthesis, forms a hydrogen bond to Water 4. There is a hydrogen bond between the 4-hydroxy group of Tyrosine 161 and the imidazolyl group of Histidine 190, which along with the carboxy group of Glutamate 189 (a ligand to Manganese 1) can be a catalytic acid shuttling hydrons away from Water 3 and Water 4. The most reasonable path along which an electron can pass out of the cluster upon the successful capture of a photon would be through Histidine 190 and Glutamate 189. The carboxy group of Glutamate 189 can form a hydrogen bond with either Water 3 or Water 4, and there are crystallographic maps of difference electron density suggesting that this carboxy group is planted by one of its oxygens on Manganese 1 while its other oxygen pivots as the consecutive oxidations proceed.[2110,2144,2145] When Glutamate 189 is mutated to a serine or a glycine, the progression from the S_2 to the S_3 oxidation state is prevented.[2132]

Manganese(III) is the paradigmatic octahedrally coordinated transition metallic ion. Its ionic radius (0.075 nm) is quite small, and it is a hard metallic ion that holds its ligands tightly and closely because of the high field strength. As a result, the rate constant for the exchange of a molecule of water[2146] from a Mn^{3+} is in the range of 10 μs^{-1}. Calcium dication is an even harder metallic ion that is almost exclusively coordinated by oxygens from its ligands, but it has a large ionic radius (0.11 nm). As a result, it holds its ligands farther from its nucleus, and, because they are held farther away and its charge number is only +2, it holds its ligands less tightly. As a result, the rate constant for the exchange of a molecule of water from Ca^{2+} is 200 μs^{-1}. Because it

*There is also a chain of water molecules, albeit far less extensive, connecting the waters on Manganese 4 to the positive, acidic solution.[2110]

is so large and holds its ligands so loosely, its coordination is haphazard, varying from four oxygens to seven oxygens oriented unpredictably, presumably in a configuration dictated only by steric forces and electron repulsion within the ligands themselves. Consequently, molecules of water can move over the surface of a Ca^{2+} readily, the perfect situation for feeding molecules of water into the breach between Manganese 1 and Manganese 4 one after the other as molecules of oxygen are made and rapidly dissociate.

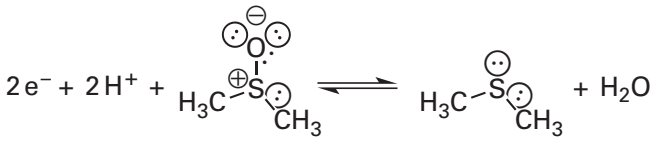
Molybdenum ions are used prosthetically in active sites to perform oxidation–reductions in which single atoms of oxygen are reduced or oxidized, while coreactants are oxidized or reduced. In these reactions the prosthetic molybdenum ion can assume the oxidation states **Mo^{4+}, Mo^{5+}, and Mo^{6+}**. A mononuclear, prosthetic molybdenum ion is almost always coordinated by one or two **molybdopterins**



2–148

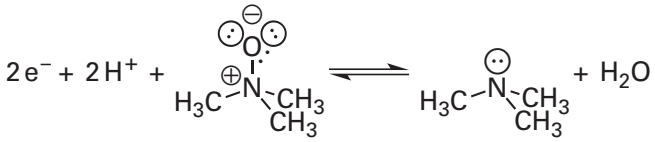
or one or two of its derivatives.[2147-2153] Eukaryotic molybdoenzymes usually contain the unmodified molybdopterin (**2–148**) while prokaryotic molybdoenzymes almost always contain modified molybdopterins that are dinucleotides in which a GMP, a CMP, an AMP, or an IMP is attached to the phosphate group of the molybdopterin* in a diphosphate linkage,[2154] but there is at least one bacterial molybdoenzyme in which the molybdenum ion is coordinated by two unmodified molybdopterins.[2155] Eukaryotic **molybdoenzymes** always have a molybdenum ion coordinated by only one unmodified molybdopterin while bacterial and archael molybdoenzymes can have molybdenum ion coordinated by one or two modified molybdopterins. The oxomolybdenum(VI) bismolybdopterin prosthetic group in respiratory dimethylsulfoxide reductase from *R. sphaeroides* (Figure 2–60)[2148,2156] is an example of a prosthetic molybdenum ion coordinated by two molybdopterins. In the figure, the 5′-guanidyl groups on the phospho groups of the two molybdopterins in this bacterial molybdoenzyme have been omitted.

Most, but not all,[2157] of the enzymes containing molybdenum ions coordinated by one or two molybdopterins **convert the oxygen atom in an oxo group or hydroxy group on a reactant into a molecule of water**, a conversion involving no oxidation or reduction of the atom of oxygen, coincident with the reduction of the reactant by two electrons supplied by an electron-transferring coenzyme. In the reverse direction, they convert the atom of oxygen in a molecule of water into an oxo group or hydroxy group on a reactant, again a conversion involving no oxidation or reduction of the atom of oxygen, coincident with the oxidation of the substrate by two electrons that are accepted by the same electron-transferring coenzyme. Examples of molybdoenzymes are respiratory dimethylsulfoxide reductase



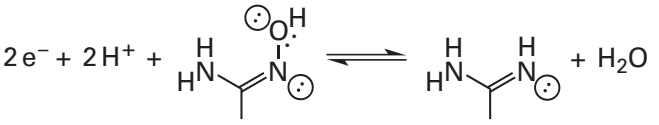
(2–315)

trimethylamine-*N*-oxide reductase[2149]



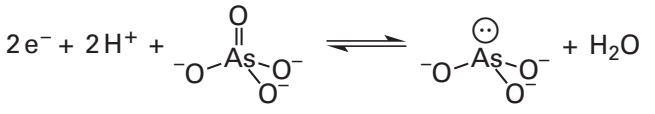
(2–316)

amidoxime reductase[2158,2159]



(2–317)

arsenate reductase (azurin)[2160]



(2–318)

*From here on, no distinction will be made between molybdopterin itself and a molybdopterin to which a nucleotide is attached. They will both be called "molybdopterin".

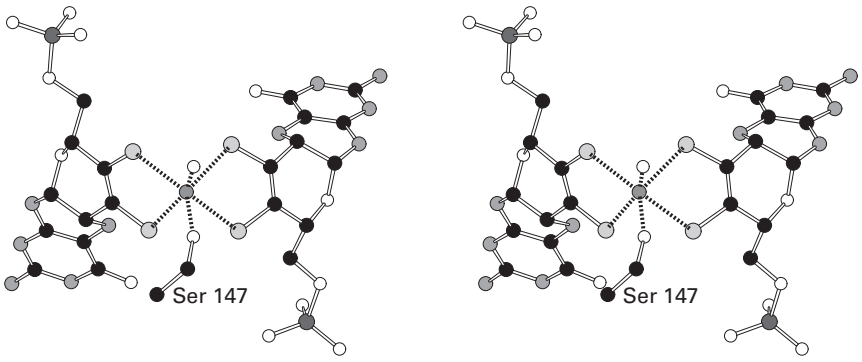


Figure 2–60: Stereodrawing[50] of the enzymatically active oxomolybdenum(VI) bismolybdopterin in the crystallographic molecular model of fully oxidized respiratory dimethylsulfoxide reductase from *R. sphaeroides*.[2156] Black atoms are carbons, white atoms are oxygens, and gray atoms are nitrogens. The molybdenum ion is the smaller dark gray sphere surrounded by its ligands in the center of the drawing. The two molybdopterins (**2–148**), to the right and to the left in the drawing, provide four sulfido groups as ligands to the Mo^{6+}. The two molybdopterins are related by a twofold rotational axis of pseudosymmetry passing through the molybdenum. The hydroxy group of Serine 147 provides a sixth ligand to the molybdenum ion. The axis of pseudosymmetry roughly bisects the angle between the oxo group and the hydroxy group.

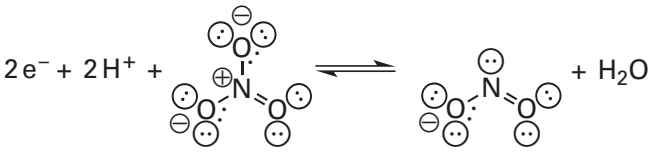
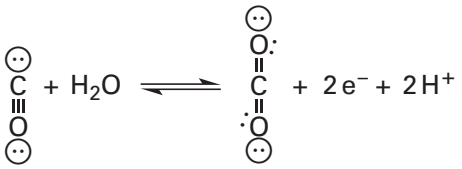
nitrate reductase (quinone)[883]



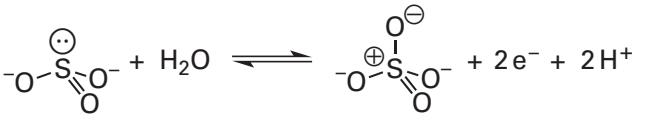
(2–319)

aerobic carbon monoxide dehydrogenase[2161,2162]



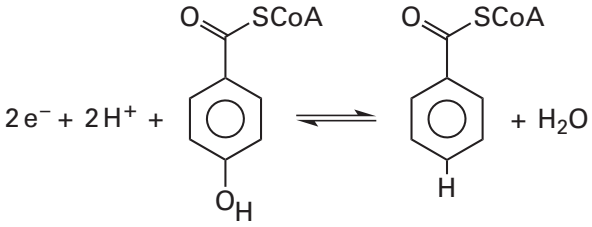
(2–320)

sulfite oxidase



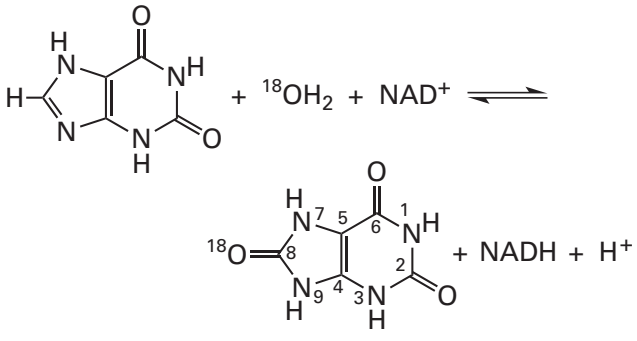
(2–321)

4-hydroxybenzoyl-CoA reductase[2163]



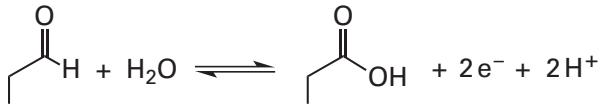
(2–322)

xanthine dehydrogenase[2164]



(2–323)

and aldehyde dehydrogenase (FAD-independent)



(2–324)

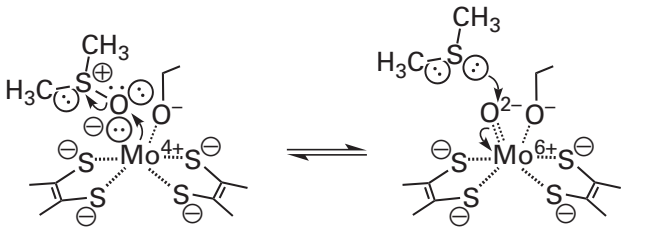
These examples illustrate the fact that these enzymes containing molybdenum ions coordinated by one or two molybdopterins are able to transfer an oxo group or hydroxy group to or remove an oxo group or a hydroxy group from an atom of sulfur, nitrogen, arsenic, or carbon. In the case of carbon, a hydrogen on the carbon is usually replaced by a hydroxy group or, in reverse, a hydroxy group is replaced by a hydrogen. These reactions at carbon, however, should be distinguished from the hydroxylations catalyzed by prosthetic groups such as oxoiron(IV) porphyrin$^{\bullet+}$ because the carbons hydroxylated are not aliphatic carbons.

In the crystallographic molecular model of the enzymatically active[2156,2165,2166] oxidized form of respiratory dimethylsulfoxide reductase from *R. sphaeroides*, the hexacoordinate molybdenum ion in the oxomolybdenum(VI) bismolybdopterin is **coordinated by the four sulfido groups from the two molybdopterins** and the oxido group of a serine in addition to an oxo group (Figure 2–60). In the oxomolybdenum(VI) bismolybdopterin in the enzyme, the molybdenum ion is stable in the **Mo^{+6} oxidation state** because at this level of oxidation it is isoelectronic with the noble gas krypton. The ion, however, because of its large positive charge number, must be coordinated by several ligands of nominally negative charge number, such as oxide ions and sulfido groups. Again, the degree of covalency between these ligands and the metallic ion is left to the preferences of the reader.

The first step in the enzymatic reaction of respiratory dimethylsulfoxide reductase in the direction of reduction is the **reduction of the oxomolybdenum(VI) bismolybdopterin to aquomolybdenum(IV) bismolybdopterin.** The oxomolybdenum(VI) bismolybdopterin in the active site of respiratory dimethylsulfoxide reductase from *E. coli*, which is embedded in the plasma membrane of the bacterium, is reduced by two successive electrons from two of the four prosthetic [4Fe–4S] iron–sulfur clusters situated in the enzyme.[2167] These [4Fe–4S] iron–sulfur clusters are in turn reduced by two molecules of menaquinol dissolved in the membrane that associate one after the other with the enzyme. The oxomolybdenum(VI) bismolybdopterin in the

active site of the soluble, cytoplasmic respiratory dimethylsulfoxide reductase from *R. sphaeroides* contains no prosthetic groups that transfer electrons, but it is reduced by two successive electrons[2168] from the reduced form of a single molecule of pentaheme cytochrome *c* that associates with the enzyme,[2169] so there are two electrons available at the same time to the oxomolybdenum(VI) bismolybdopterin in the reduced hemes of the cytochrome *c*. During the reduction, because the electrons are transferred from the [4Fe–4S] iron–sulfur clusters or the cytochrome one at a time, an intermediate oxomolybdenum(V) bismolybdopterin can be observed. For the enzyme from *R. sphaeroides*, the biochemical standard reduction potential for the redox couple of oxomolybdenum(VI) bismolybdopterin and oxomolybdenum(V) bismolybdopterin is +200 mV, and that for the redox couple of oxomolybdenum(V) bismolybdopterin and oxomolybdenum(IV) bismolybdopterin is +140 mV, which is appropriate for the biochemical standard reduction potential (+160 mV) for the redox couple dimethyl sulfoxide and dimethyl sulfide. The successive biochemical standard reduction potentials, however, for the enzyme from *E. coli* are –15 mV and –174 mV.[2170,2171]

In the respiratory dimethylsulfoxide reductase from *R. sphaeroides*, the molecule of water in the aquomolybdenum(IV) bismolybdopterin that was the oxo group is replaced by the oxygen of the dimethyl sulfoxide. In the next step, dimethyl sulfide dissociates, completing **transfer of the oxygen to the molybdenum ion**



(2–325)

and in the process reoxidizing it from Mo^{4+} to Mo^{6+}. In a sense, the Mo^{4+} provides a nucleophilic pair of electrons that nucleophilically adds to the electrophilic oxygen of the dimethyl sulfoxide, and dimethyl sulfide is the leaving group in an associative nucleophilic substitution. The oxygen of the dimethyl sulfoxide becomes the oxygen of the now-regenerated oxomolybdenum(VI) bismolybdopterin.[2172]

The dissociation of dimethyl sulfide from the oxomolybdenum(VI) bismolybdopterin (Equation 2–325) in the enzyme from from *R. sphaeroides* is reversible (K_d = 120 μM), and if high concentrations of dimethyl sulfide are present, dimethyl sulfoxide bound to molybdenum(IV) bismolybdopterin becomes the dominant species of the enzyme,[2168,2173] inhibiting catalysis.

A **synthetic complex** of a molybdenum ion coordinated by two molecules of bis-(4-*tert*-butylphenyl)-2-pyridylmethanethiolate, which together provide two sulfido groups and two pyridinium nitrogens as ligands to the metallic ion, has in addition two identical oxo groups (molybdenum–oxygen bond lengths of 0.1696 nm) on the oxidized Mo^{+6} and one oxo group (bond length of 0.1681 nm) on its reduced Mo^{+4}. The reduced form of this synthetic complex can be transformed into the oxidized form by transfer of an oxygen atom from dimethyl sulfoxide or trimethylamine *N*-oxide to the molybdenum in reactions producing dimethyl sulfide or trimethylamine, respectively. Another synthetic complex of a molybdenum ion coordinated by a phenolate and two 2,3-disulfanylbut-2-enes, which mimics structurally the more elaborate complex of molybdenum, two molybdopterins, and a serine[2174] in respiratory dimethylsulfoxide reductase, is also able to reduce dimethyl sulfoxide to dimethyl sulfide[2175] and trimethylamine *N*-oxide to trimethylamine (Equation 2–319),[2176] but at much slower rates than the reductions catalyzed by the enzymes. In this nonenzymatic reaction, an intermediate complex between molybdenum(IV) and the oxygen of the sulfoxide (Equation 2–325) forms before the bond between sulfur and oxygen in the sulfoxide dissociates,[2177] just as it does in the enzymes. Neither of these synthetic complexes, however, can perform the reductions catalytically; the reactions that they catalyze are merely stoichiometric. There is, however, a synthetic complex of a molybdenum ion coordinated with two molecules of 2,2-diphenyl-2-sulfanylacetate, each of which coordinates the metallic ion with its sulfido group and its carboxylato group, that is able to catalyze the dehydration of nitrobenzene ($C_6H_5NO_2$) to nitrosobenzene (C_6H_5NO) and water using benzenethiol as a reducing agent.[2178]

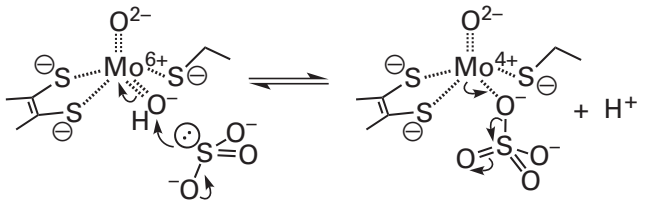
Both trimethylamine-*N*-oxide reductases (Equation 2–316) and bacterial nitrate reductases (quinone) (Equation 2–319) share a common ancestor with respiratory dimethylsulfoxide reductases[2179] and presumably proceed by the same mechanism. In fact, in some organisms the same protein cata-

lyzes the activities of both respiratory dimethylsulfoxide reductase and trimethylamine-*N*-oxide reductase. Bacterial nitrate reductases (quinone), however, have variations on the coordination found in respiratory dimethylsulfoxide reductase. The oxidized form of nitrate reductase (quinone) from *E. coli* has, as usual, an oxomolybdenum(VI) bismolybdopterin, but it uses the carboxylate of an aspartate rather than the alkoxide of a serine as the sixth ligand to the oxomolybdenum(VI) bismolybdopterin.[883] Otherwise, reduction of nitrate ion, NO_3^- (**2–112**), to nitrite ion, ONO^- (**2–113**), proceeds as does the reduction of dimethyl sulfoxide by respiratory dimethylsulfoxide reductase. One of the oxygens in the nitrate ion exchanges with the molecule of water on the reduced aquomolybdenum(IV) bismolybdopterin, and the nitrite ion leaves to give the oxomolybdenum(VI) bismolybdopterin, which is then reduced by two electrons back to aquomolybdenum(IV) bismolybdopterin. The two necessary electrons are provided by a quinol acting as an electron-transferring coenzyme.

The resting oxidized forms of the nitrate reductases (quinone) from *D. desulfuricans* and *C. necator*, however, have a molybdenum(VI) bismolybdopterin, but they have thioxo groups instead of oxo groups and the serines have been replaced by cysteines.[2180,2181] Upon addition of nitrate, the sulfido group of the cysteine adds to the electrophilic thioxo group in a nucleophilic addition with molybdenum(IV) bismolybdopterin as a leaving group. The nucleophilic addition turns the sulfanyl group of the cysteine into a dithio group and coincidentally reduces the molybdenum(VI) bismolybdopterin to molybdenum(IV) bismolybdopterin. The site on molybdenum(IV) bismolybdopterin that was formerly occupied by the thioxo group is now open for the nitrate, and the resulting anionic dithio group of the modified cysteine, as a monodentate ligand, occupies the site on molybdenum(IV) bismolybdopterin formerly occupied by the sulfido group of the cysteine. The reduction of nitrate then proceeds, as does the reduction of dimethyl sulfoxide (Equation 2–325) and the reduction of the nitrate in the active site of nitrate reductase (quinone) from *E. coli*, with an oxomolybdenum(VI) bismolybdopterin intermediate alternating with an aquomolybdenum(IV) bismolybdopterin intermediate while the dithio group remains unchanged as a ligand to the molybdenum now uninvolved in the reduction of nitrate,[2182-2184] just as the oxido group of the serine remains uninvolved in the reduction of dimethyl sulfoxide. The nitrate reductases (quinone) from *D. desulfuricans* and *C. necator* obtain the necessary electrons from a cytochrome *c* that acts as an electron-transferring coenzyme.

In sulfite oxidase (Equation 2–321) from *G. gallus*, the molybdenum ion in the oxomolybdenum(VI) is pentacoordinate. It is **coordinated by only one molybdopterin**, and the remainder of the coordination of Mo^{6+} is completed by the sulfido group of a cysteine, a hydroxide, and an oxo group.[2151] Both in sulfite oxidase from *G. gallus* and in a synthetic model of its prosthetic group,[2185] the distribution of the ligands around the molybdenum is **square pyramidyl**, with the oxo group at the apex of the pyramid and the two sulfido groups of the molybdopterin, the sulfido group of the cysteine, and the hydroxide at the four equatorial positions at the base of the pyramid.

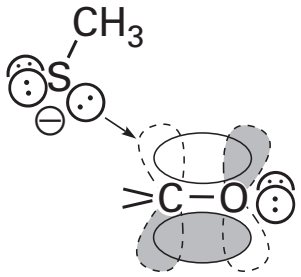
In sulfite oxidase from *G. gallus*, the **equatorial hydroxy group is the electrophile** (Equation 2–326),[2151,2186] not the apical oxo group as in respiratory dimethylsulfoxide reductase from *R. sphaeroides*. The oxomolybdenum(VI) bismolybdopterin in the active site of respiratory dimethylsulfoxide reductase from *R. sphaeroides* is electrophilic at its oxo oxygen, and the dimethyl sulfoxide is a nucleophile that adds to this electrophile (reverse of Equation 2–325). In sulfite oxidase (Equation 2–321) from *G. gallus*,[2151] in the direction of reduction, the oxygen of the sulfate exchanges with the equatorial hydroxy group (molybdenum–oxygen bond of 0.22 nm) in the oxohydroxymolybdenum(IV) molybdopterin rather than the oxo group (molybdenum–oxygen bonds of 0.17 nm). Consequently, in the reverse reaction, the sulfite must add to a hydroxymolybdenum(VI) molybdopterin rather than an oxomolybdenum(VI) molybdopterin



(2–326)

which seems counterintuitive.

Sulfite is definitely a nucleophile. In the addition to hydroxymolybdenum(VI) molybdopterin, as in the addition of a nucleophile such as methyl sulfide to a carbonyl carbon (previously**1–17**)



2–149

the σ lone pair of electrons on the sulfur in sulfite adds to the lowest unoccupied molecular orbital of the π molecular orbital system of the electrophile, in this case hydroxyoxomolybdenum(VI) molybdopterin. The main difference is that in a carbonyl group the more electronegative atom is the oxygen, and in a hydroxyoxomolybdenum(VI) molybdopterin it is the Mo^{6+}. It also turns out that, at least in the case of sulfite oxidase, the **lowest unoccupied π molecular orbital**, spread over the complete oxohydroxymolybdenum(VI) molybdopterin, is much more extensive over the hydroxy group than over the oxo group.[2186] Consequently, it seems to make sense that the enzyme has directed the nucleophile toward this oxygen, in addition to the fact that it is far easier for the sulfate to exchange with a hydroxide on hydroxyoxomolybdenum(VI) than an oxo group.

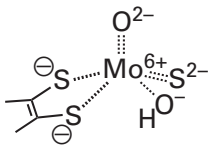
Following the addition of sulfite ion to the hydroxy group of the oxohydroxymolybdenum(VI) molybdopterin in sulfite oxidase from *A. thaliana* (Equation 2–326), the sulfate remains coordinated to oxomolybdenum(IV) molybdopterin for a while and can be trapped on the molybdenum by oxidizing it to oxomolybdenum(V) molybdopterin,[2187] which exchanges anions more slowly because of its higher positive charge.

Following dissociation of sulfate from the usual oxomolybdenum(IV) molybdopterin and its replacement by a molecule of water, **oxoaquomolybdenum(IV) molybdopterin is oxidized back to oxohydroxymolybdenum(VI) molybdopterin**. In sulfite oxidase from *A. thaliana*, two molecules of oxygen remove one electron at a time from the molybdenum ion as they are reduced to two superoxide radical anions, which then disproportionate, while in sulfite oxidase from *G. gallus*, in spite of its name, hemes in the enzyme shuttle electrons to and from cytochrome *c*.[2188]

In respiratory dimethylsulfoxide reductase, the oxomolybdenum(VI) bismolybdopterin produced by reduction of dimethyl sulfoxide (Equation 2–325) is rereduced by the addition of two electrons, and the oxygen of the resulting hydroxy group, which was the oxygen of the dimethyl sulfoxide, is hydronated and dissociates as a molecule of water,[2189] the other product of the reaction. In sulfite oxidase, aquooxomolybdenum(IV) molybdopterin, which forms upon the exchange of sulfate (Equation 2–326) with the molecule of water that is the other reactant in the oxidation of sulfite (Equation 2–321), is oxidized by the removal of two electrons with the concomitant dehydronation of the molecule of water to give a hydroxy group on Mo^{6+}. The equatorial hydroxy group of the resulting dioxohydroxymolybdenum(VI) molybdopterin, which was the molecule of water, becomes the oxygen in the next sulfate (Equation 2–326).

Xanthine dehydrogenase (Equation 2–323) is altered by oxidation upon purification and becomes a xanthine oxidase, but the enzyme in the cytoplasm, which has a reducing environment, is xanthine dehydrogenase.[2190] The alteration of the dehydrogenase to the oxidase can also be accomplished by digestion of the enzyme with endopeptidases.[2150] The two electrons removed from xanthine during its oxidation to urate at the prosthetic molybdenum ion in the active site pass one at a time through two [2Fe–2S] iron–sulfur clusters to a flavin adenine dinucleotide.[2191] In the unmodified enzyme in cytoplasm, the electrons are conjoined by the flavin and passed to NAD^+. In the enzyme after it is oxidized adventitiously during purification or altered by digestion, the flavin passes the two electrons to molecular oxygen in the usual way (Equations 2–207 and 2–208).

In the active site of bovine xanthine dehydrogenase, as in sulfite oxidase from *G. gallus* (Equation 2–326), the prosthetic molybdenum ion is coordinated by only one molybdopterin[2150]



2–150

The ligands are again arrayed roughly at the vertices of a square pyramid (Figure 2–61).[2192-2194] The equatorial sulfido group of the cysteine in sulfite oxidase is replaced by an **equatorial thioxo group** in the fully oxidized enzyme. In this oxohydroxythioxomolybdenum(VI) molybdopterin, the length of the bond between the molybdenum and the sulfur identifies it as a formal double bond and identifies the sulfur as a thioxo group (**2–150**).[2195] An oxo group

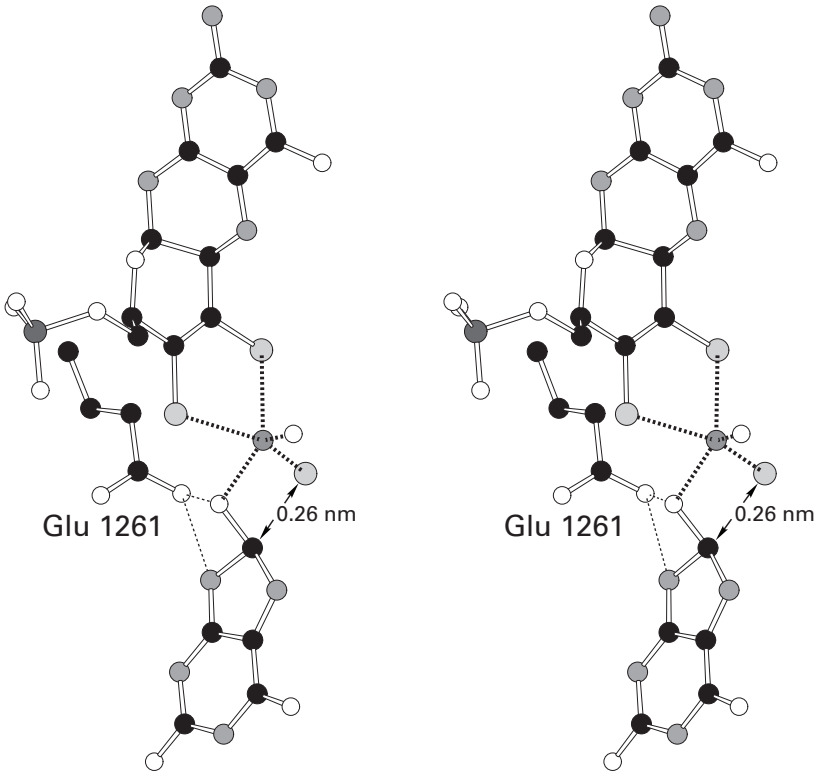


Figure 2–61: Stereodrawing[50] from the crystallographic molecular model of bovine xanthine dehydrogenase complexed with urate.[2194] Black atoms are carbons, white atoms are oxygens, and gray atoms are nitrogens. A crystal of bovine xanthine dehydrogenase was soaked in a large excess of NADH under strictly anaerobic conditions in order to reduce both flavin and the iron–sulfur clusters in the protein and to block any electron transfer from the molybdenum ion. Then the molybdenum ions in the crystal were fully reduced by soaking the crystal in 4 mM titanium citrate. The resulting crystal of fully reduced enzyme was then soaked in 250 μM urate. The molybdenum ion is the dark gray sphere in the right-center of the drawing surrounded by its ligands: the two sulfanyl groups of one molybdopterin (upper portion of the drawing), an oxo group (to the right of the molybdenum ion), the oxygen on carbon 2 of the urate (Equation 2–323), and a hydrosulfide (large light gray sphere to the lower right of the molybdenum). One of the oxygens of the carboxy group of Glutamate 1261 is equidistant (0.29 nm) from nitrogen 1 and the oxygen on carbon 2 of the urate. Carbon 2 of the urate is essentially tetrahedral. The place in the tetrahedron that would be occupied by a hydrogen points directly to the hydrosulfide, and carbon 2 is only 0.26 nm away from the sulfur.

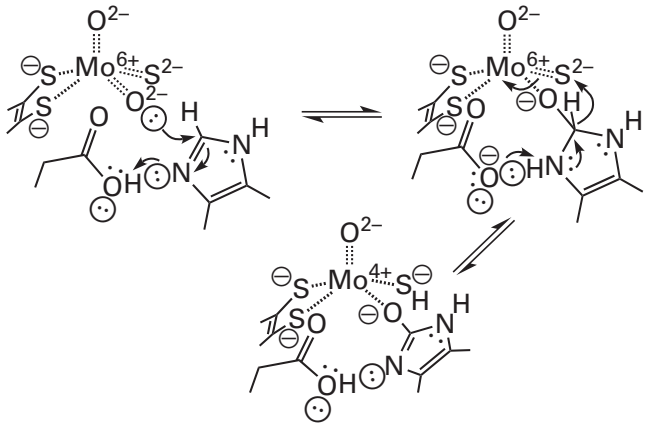
again occupies the apical position, and a hydroxy group occupies one of the equatorial positions (oxygen–molybdenum bond lengths of 0.17 and 0.20 nm, respectively).[2195,2196]

The first transfer of an electron from the molybdenum ion takes the Mo^{4+} to Mo^{5+}, which can be monitored because it is paramagnetic,[2197] and the next transfer of an electron takes the Mo^{5+} to Mo^{6+}. In the active site of bovine xanthine oxidase these steps have biochemical standard reduction potentials of −410 and −380 mV, respectively.[2198] The **ability of molybdenum to assume the Mo^{+5} oxidation state**[2197] and flavin to form the semiquinone permits these transfers of single electrons through the iron–sulfur clusters connecting them.

In the crystallographic molecular model of the complex that forms between urate and the fully reduced prosthetic group in the active site of bovine xanthine dehydrogenase (Figure 2–61), the equatorial position occupied by the hydroxy group in the fully oxidized enzyme is occupied by the oxygen that is removed from urate during its reduction (reverse of Equation 2–323). Consequently, during the oxidation of xanthine, the **oxygen of the equatorial hydroxy group must be transferred to the xanthine** to become the oxygen of the urate, just as the equatorial hydroxy group in sulfite oxidase becomes the oxygen of the sulfate (Equation 2–326).

The **oxygen atom can be followed** over short intervals of time from a molecule of water in the solution to the hydroxy group on the molybdenum ion and then to the ureylene group in the urate by monitoring oxygen-18 by mass spectrometry and by following the effects of oxygen-17 on the electron paramagnetic spectrum of the molybdenum ion in oxohydroxythioxomolybdenum(V) in the active site of bovine xanthine oxidase.[2199-2202] These observations demonstrate that a molecule of water first occupies the open site on oxothioxomolybdenum(IV) molybdopterin; then becomes, upon the removal of two electrons through the iron–sulfur clusters to the flavin, the equatorial hydroxy group on oxohydroxythioxomolybdenum(VI) molybdopterin; and is then transferred to carbon 8 of the xanthine.

The equatorial hydroxy group in the fully oxidized oxohydroxythioxomolybdenum(VI) molybdopterin (**2–150**) of bovine xanthine oxidase has a pK_a somewhere above 8.5,[2195] but that of the equatorial thioxo group is much lower, as would be expected of a thioxo group in an environment identical to that of the hydroxy group, because sulfur is a less electronegative element than oxygen. Upon dehydronation of the hydroxy group by a glutamate in the active site (Figure 2–61) that acts as a catalytic base, the resulting **equatorial oxide adds nucleophilically** to carbon 8 of the xanthine,[2164,2193,2202] which is the carbon hydroxylated in the course of the enzymatic reaction



(2–327)

In two crystallographic molecular models, one of the complex between xanthine and bovine xanthine oxidase in which the thioxo group has been replaced by an oxo group[2203] and one of the complex between hypoxanthine and unadulterated bovine xanthine oxidase,[2204] carbon 8 of the xanthine and carbon 8 of the hypoxanthine, respectively, are in each case the closest atom (0.27 and 0.28 nm) and well within van der Waals contact (0.32 nm) with the equatorial hydroxy group that should be the nucleophile in the initial addition, and in each case this equatorial hydroxy group is the closest atom to carbon 8.

The now hydronated carboxy group of the glutamate **hydronates the nitrogen** of the xanthine (Equation 2–327), thereby increasing the electrophilicity of its aromatic ring and susceptibility to the nucleophilic aromatic addition of the oxide. In the crystallographic molecular model of the complex in the active site of bovine xanthine dehydrogenase (Figure 2–61)[2194] between the fully reduced enzyme and urate, one of the oxygens of this glutamate, Glutamate 1261, is equidistant (0.285 nm) from both the oxygen that was the hydroxy group on the molybdenum ion and nitrogen 1 of the urate.

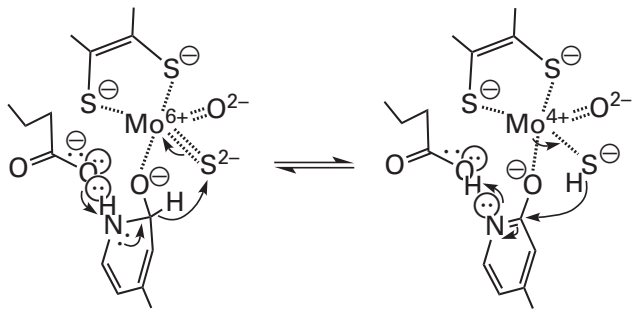
A crystallographic molecular model of fully oxidized bovine xanthine oxidase has been obtained from crystals soaked in a solution containing 2-hydroxy-6-methylpurine, a slow substrate for the enzyme.[2205] In this molecular model, there is a bond (0.16 nm) between the oxygen of the equatorial hydroxy group of the oxohydroxythioxomolybdenum(VI) molybdopterin and carbon 8 of the

2-hydroxy-6-methylpurine, indicating that the hydroxy group has added nucleophilically to carbon 8 in the imidazolyl ring of the substrate (Equation 2–327). In the crystallographic molecular model of the complex between the conjugate base of urate and the fully reduced oxosulfidomolybdenum(IV) in the active site of bovine xanthine dehydrogenase (Figure 2–61),[2194] an almost identical complex is also observed with the oxygen on carbon 8 of the urate as a ligand to the molybdenum ion at the same location as that occupied by the hydroxy group in the unoccupied oxidized enzyme. Consequently, this particular complex can be formed between the oxidized enzyme and a reduced substrate and between the reduced enzyme and an oxidized substrate, a fact demonstrating that it represents a **central intermediate in the enzymatic reaction**.

In the crystallographic molecular model of the complex between the conjugate base of urate and the fully reduced oxosulfidomolybdenum(IV) molybdopterin, the length of the bond between the oxygen and the molybdenum ion is 0.22 nm, the usual length between a hydroxide and molybdenum. The length of the bond between the oxygen and the carbon is 0.14 nm, the usual length of a single carbon–oxygen bond, and the bond angle between these two bonds is 116°. Both the bond lengths and the bond angle are consistent with a simple **complex between a molybdenum ion and an alkoxy group** participating in a single bond with a carbon. The lengths of the bond between the molybdenum and the sulfur in this complex and the one in the complex between the oxidized enzyme and another slow unnatural substrate, 4-[5-pyri-din-4-yl-1*H*-[1,2,4]triazol-3-yl]pyridine-2-carbonitrile, are both 0.23 nm, a bond length consistent with coordination between a hydrosulfide ion and a molybdenum ion rather than a thioxo group.

The next step in the enzymatic reaction (second step in Equation 2–327) is **transfer of a hydride** from carbon 8 of the tetrahedral intermediate to the thioxo group on the molybdenum. In the crystallographic molecular model of the reduced enzyme and urate, carbon 2 of the urate has become essentially tetrahedral, and the position in the tetrahedron that would be occupied by a hydrogen is pointed directly at the sulfur (Figure 2–61) of what is apparently a hydrosulfide, based on the length of its bond to the molybdenum ion. The distance between this carbon and the sulfur is 0.26 nm, a distance significantly less than the sum (0.29 nm) of a carbon–hydrogen bond length (0.11 nm) and the van der Waals radius for sulfur (0.18 nm). This short distance and the orientation implies that there is an intimate association between this carbon and the sulfur. It is almost as if this complex is halfway between that in which the hydride has been removed by the thioxo group, which becomes a hydrosulfide as a result, and that in which the hydride is still on carbon 2 and the sulfur of the thioxo group has not yet removed it. This consideration implies that in the active site in the crystal there is an equilibrium between the two locations for the hydrogen atom, on sulfur and on carbon. In any case, the crystallographic structure is completely consistent with the participation of this transfer of the hydride in the enzymatic reaction, and in effect, the molecular model portrays the transfer of the hydride. When the protium on carbon 8 of the xanthine is replaced by a tritium, the enzymatic reaction decreases by a factor of 3.5, a fact demonstrating that transfer of the hydride is a slow and therefore difficult step in the reaction.[2206]

The crystallographic molecular model of the complex between the oxidized prosthetic group in the active site of bovine xanthine dehydrogenase and the slow unnatural substrate 4-[5-pyridin-4-yl-1*H*-[1,2,4]triazol-3-yl]pyridine-2-carbonitrile[2193] also manifests the features of this central intermediate in Equation 2–327. The reaction in the active site with this unnatural substrate proceeds to the step at which the bond between oxygen and carbon is formed (first step in Equation 2–327) but continues further only very slowly. Again, the carbon that has been attacked nucleophilically by the oxygen on the molybdenum is not planar as it will be in the product but slightly puckered, with the apex of its pucker again pointing toward the sulfur, which is only 0.35 nm from the carbon. The overall structure of the complex with the inhibitor in the crystallographic molecular model suggests again that the following equilibrium has been established in the active site



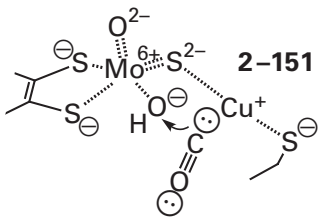
(2–328)

A **thioxo group on an oxothioxomolybdenum(VI) molybdopterin is electrophilic before the hydride is transferred** because it is the equivalent of the oxo group in an oxomolybdenum(VI) molybdopterin (Equation 2–326).[2195] In the active site of aldehyde dehydrogenase (FAD-independent) (Equation 2–324), an enzyme that shares a common ancestor with xanthine dehydrogenase,[2153] the basic equatorial oxide on its dioxothioxomolybdenum(VI) molybdopterin, also formed by dehydronation of the equatorial hydroxy group, adds nucleophilically to the electrophilic carbonyl carbon of an aldehyde, and the hydrogen of the aldehyde is transferred as a hydride to the thioxo group on its Mo^{6+}. The oxo oxygen of an oxomolybdenum(VI) bismolybdopterin in ethylbenzene dehydrogenase is also able to remove a hydride from a benzylic carbon to produce a benzylcarbenium ion,[2207] so there is nothing special about a thioxo group in this regard. In the active sites of the formate dehydrogenases from *E. coli*,[2208] *C. necator*,[2209] and *D. desulfuricans*,[2210] the thioxo group on the prosthetic thioxomolybdenum(VI) dimolybdopterin also accepts a hydride from a formate either bound noncovalently in the active site, immediately adjacent to the thioxo group, or coordinated to the molybdenum ion by its carboxylato group.

In the normal enzymatic reaction catalyzed by xanthine dehydrogenase (Equation 2–327), as well as the reaction with the unnatural substrate (Equation 2–328), even though neither of the final products is significantly aromatic in the respective locations, transfer of the formal equivalent of a hydride from carbon to the electrophilic thioxo group is driven by **restoration of the aromaticity** of the 2-oxidopyridyl group or of the 2-oxidoimidazolyl group in the conjugate base of the urate, respectively. In addition, the hydride is pushed off the carbon by the lone pairs of electrons on the three heteroatoms or the two heteroatoms, respectively, of the tetrahedral intermediate. Following this transfer of a hydride, the conjugate base of urate, the product of the reaction catalyzed by xanthine dehydrogenase and xanthine oxidase, ends up as a ligand to the Mo^{4+} and exchanges with a molecule of water to complete the cycle.

One of the more peculiar aspects of a hydroxymolybdenum(VI) molybdopterin, which is illustrated by the dramatic difference between its use in sulfite oxidase (Equation 2–326) and its use in xanthine dehydrogenase (Equation 2–327), is that in the former case it is used as an electrophile and in the latter case it is used as a nucleophile. One might argue that the difference is in its hydronation or dehydronation, but more likely it is whether the reactant is a nucleophile or an electrophile that determines its eventual role in the reaction.

There are aerobic carbon monoxide dehydrogenases (Equation 2–320) that use a molybdenum ion coordinated by a single molybdopterin rather than a nickel ion (**2–143**). In aerobic carbon monoxide dehydrogenase from *Afipia carboxidovorans*, the molybdenum ion is coordinated in equatorial positions by the two sulfido groups of the sole molybdopterin and a hydroxy group and in the axial position by an oxo group. When the molybdenum ion is Mo^{6+}, the remaining equatorial position is occupied by a thioxo group (0.23 nm) that becomes a sulfido group (0.29 nm) when it is Mo^{4+}. This thioxo group or sulfido group is also a ligand[2162,2211] for a prosthetic Cu^{+}. The Cu^{+} is in turn coordinated by the sulfido group of a cysteine and the nitrogen of one of the amido groups in the backbone of the polypeptide. At the open site on Cu^{+} in both oxidized and reduced active sites, there is a molecule of water that forms a hydrogen bond with the equatorial hydroxy group on the molybdenum ion. The function of the Cu^{+} is believed to be the provision of an open site at which the carbon of the carbon monoxide can associate



2–151

displacing this molecule of water. The distance between the Cu^{+} and the hydroxy group in the equatorial position on the Mo^{6+} is 0.34 nm, so the association of the carbon monoxide with the Cu^{+} would bring the carbon immediately adjacent to the hydroxy group on the molybdenum. Although there are several mechanisms that have been proposed to explain the remainder of the reaction,[2161,2211,2212] the simplest and the one most consistent with the usual mechanism of an active site containing a prosthetic molybdenum is one in which the carbon of the carbon monoxide, as a nucleophile, adds to the electrophilic hydroxide while the carboxylato group forming a hydrogen bond with the hydroxide removes the hydron. This nucleophilic addition would produce carbon dioxide directly, which would then dissociate from the cluster.[2213]

All the transition metallic ions of the fourth row from vanadium to zinc, with the possible exception of chromium, play enzymatic roles. Ironically, molybdenum, the transition metal below chromium, is the only one from the fifth row that does. It turns out that tungsten, the transition metal below molybdenum, is the only one in the sixth row that plays a role enzymatically, but almost exclusively as a congener of molybdenum. **Tungstoenzymes** contain one or two molybdopterins[2214-2216] that coordinate the respective tungsten ion in the same way that molybdenum is coordinated in molybdoenzymes,[2152] and the tungsten in these tungstoenzymes[2217] assumes the same oxidation states as molybdenum: W^{+4}, W^{+5}, and W^{+6}. In fact, when the molybdenum ion in respiratory dimethylsulfoxide reductase from *R. capsulatus* is replaced by a tungsten ion, the enzyme catalyzes the reduction of dimethyl sulfoxide even more rapidly.[2218] The tungsten ion in the active site of aldehyde ferredoxin oxidoreductase from *P. furiosus*, the surrounding side chains, and the site at which the substrates associate are superposable on those in the active site of the molybdoenzyme aldehyde ferredoxin oxidoreductase from *D. gigas*.[2219]

There are, however, tungstoenzymes that catalyze reactions that are unusual. In the active site of benzoyl-CoA reductase, a tungstoenzyme in *Geobacter metallireducens*, the reduced aquotungsten(IV) bismolybdopterin provides two electrons and perhaps a hydron to reduce the phenyl group in benzoyl-SCoA to a cyclohexa-1,5-dienyl group by the formal addition of two hydrogen atoms to carbon 3 and carbon 4 in a difficult reduction* that breaks the aromaticity of the phenyl ring.[2220,2221] In the active site of acetylene hydratase from *Pelobacter acetylenicus*, a tungsten ion coordinated by two molybdopterins and the sulfido group of a cysteine[2222] catalyzes the simple hydration of acetylene to acetaldehyde, a reaction that involves no formal oxidation or reduction.

It has been pointed out that, in the early anaerobic world, ionic tungsten was much more available to living organisms than ionic molybdenum.[2223] Consequently, the respective tungstoenzymes were probably the **ancestors of the present-day molybdoenzymes**. In *Methanothermobacter wolfeii* there are two formylmethanofuran dehydrogenases, one with a molybdenum ion in its active site and the other with a tungsten ion in its active site, that share a common ancestor but are only distantly related.[2224,2225] The enzyme containing a tungsten ion is constitutively active, but the enzyme containing molybdenum is only present when molybdenum ion is available in the environment. This fact and the fact that the tungsto version of respiratory dimethylsulfoxide reductase is more effective raise the question of why the tungstoenzymes became molybdoenzymes.[2223]

Nitrogenase catalyzes a reduction that converts molecular nitrogen to two ammonium ions (Figure 2–56). So far, the discussion has centered on reactions in which one or more oxygen atoms are participants. In the case of nitrogenase, there are no oxygen atoms involved as participants in the reduction performed by the prosthetic metallic ions.

Nitrogenase occurs in both aerobic bacteria and anaerobic bacteria, but the proteins catalyzing the reaction in each case are closely related and presumably all operate by the same mechanism. One of the two stoichiometric equations for the enzymatic reaction in the aerobic bacterium *A. vinelandii* is[2226,2227]

$$\begin{aligned} &8\ \text{reduced ferredoxin} + 16\ MgATP^{2-} + 16\ H_2O \\ &+ N_2 \rightleftharpoons H_2 + 2\ NH_4^+ + 6\ H^+ + \\ &8\ \text{oxidized ferredoxin} + 16\ MgADP^- + 16\ HOPO_3^{2-} \end{aligned} \qquad (2\text{–}329)$$

In the second stoichiometric reaction, the nitrogenase from *A. vinelandii* uses its indigenous flavodoxin rather than its indigenous ferredoxin as a source of the necessary electrons.[2228,2229] Nitrogenase is also able to reduce acetylene, the conjugate acid of carbide ($C{\equiv}C^{2-}$), to ethylene,[2230] a two-electron reduction, and hydrogen cyanide to methane and NH_4^+,[2231,2232] a six-electron reduction. The substrates in these two reductions are isoelectronic with N_2, and are presumably mistaken for it. Neither of these reductions, however, is as difficult as the reduction of N_2.

Two proteins together are responsible for reduction of N_2 to NH_4^+. They are dinitrogenase, the molybdenum–iron protein, in the active site of which the actual reduction
