Chapter 5
Intermediates in Enzymatic Reactions

Almost all chemical reactions catalyzed by enzymes pass through two or more transition states and one or more intermediates after the complete set of substrates has been assembled in the active site. An intermediate in the mechanism of any chemical reaction can be distinguished from a transition state in that mechanism by the length of time it exists. A **transition state** lasts only as long as is necessary to pass over a maximum in the reaction coordinate (Figure 3–25). Because the movement over such a maximum resembles only half the stroke of an intramolecular vibration, the time required to pass over the top is less than the time required for a complete intramolecular vibration ($<10^{-12}$ s). Because the movement through the transition state is over a maximum of potential energy, a transition state does not have a finite lifetime. An **intermediate** in a reaction is an arrangement of atoms in the mechanism of a chemical reaction that has a lifetime longer than the time required for the intramolecular and intermolecular vibrations among those atoms to become established and that is formed from the reactants and reacts further to give the products. For any arrangement of atoms to persist for this length of time, the connections holding them together must be full covalent bonds or fully established noncovalent interactions, not partial bonds in the process of forming and unforming as is the case in a transition state. In this sense, an intermediate in any reaction must itself be either **one molecule or the noncovalent complex of two or more molecules**, even though the one molecule or these several noncovalently associated molecules together may be of higher energy than either reactants or products of the overall reaction.

Because intermediates have finite lifetimes, an intermediate in any reaction must have a potential energy that is less than the potential energy of the transition state immediately preceding it on the reaction coordinate leading from reactants and less than the potential energy of the transition state immediately following it on the reaction coordinate proceeding toward products. In other words, the constellation of atoms defining an intermediate is always an arrangement that occupies a potential well on the reaction coordinate (Figure 5–1). If the potential energy of an intermediate were not such a local minimum on the reaction coordinate, the intermediate would not have a finite lifetime.

Two examples of specific reactions will serve to illustrate the **distinction between transition states and intermediates**. An example of a reaction that proceeds without an intermediate is the transfer of the methyl group from the sulfur of *S*-adenosyl-L-methionine to the nitrogen of glycine in the concerted nucleophilic substitution catalyzed by glycine *N*-methyltransferase (Equation 1–19) after reactants have been gathered in the active site (see Figure 3–34). This reaction passes through a single transition state in which the past bond to the methyl carbon is being broken as the future bond to the methyl carbon is being formed. An example of a reaction in which there are intermediates is hydrolysis of an amide (Figure 1–10). In this reaction, the tetrahedral intermediate formed must exist for a period of time sufficient for hydronation of the nitrogen that is on the leaving group to occur. Otherwise, the leaving group would be an amide anion, which is 17 orders of magnitude more basic than the hydroxide anion that attacked the acyl carbon or 35 orders of magnitude more basic than the molecule of water that attacked the acyl carbon. The nitrogen of the amide cannot be hydronated before the nucleophilic addition occurs because it is not basic. Furthermore, if water was the initial nucleophile rather than hydroxide anion, as in the acid-catalyzed hydrolysis of an amide, the tetrahedral intermediate must also exist long enough for the hydron to be removed from the cationic oxygen that was derived from the oxygen in water. Each hydronation and dehydronation produces a new tetrahedral intermediate of unique structure, each a molecule in its own right, and each hydronation or dehydronation itself passes through a transition state, even though the respective free energies of activation for each transition state may be only slightly greater than the chemical potentials of the respective tetrahedral intermediates.

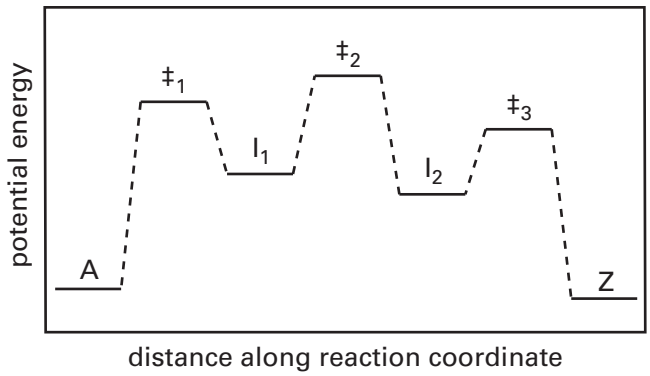

Figure 5–1: Diagrammatic representation of a reaction coordinate between reactant (A) and product (Z) that passes through three transition states ($\ddagger_1$, $\ddagger_2$, and $\ddagger_3$) and two intermediates (I_1 and I_2). Potential energies are presented as a function of distance along the reaction coordinate.

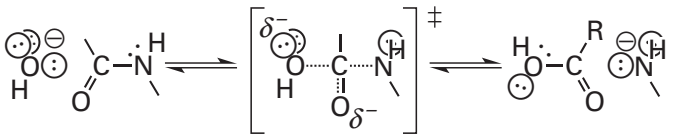
An alternative to the existence of the tetrahedral intermediate in hydrolysis of an amide, in which an intermediate would not be involved, would be a concerted nucleophilic substitution at the acyl carbon of the amide



(5–1)

For various reasons, such a reaction, although it does not immediately seem unreasonable, would have a significantly higher standard free energy of activation than the standard free energies of activation for formation of a tetrahedral intermediate, its tautomerizations, and its decomposition. Consequently, the chemical reaction in solution proceeds through the tetrahedral intermediates and their accompanying transition states rather than through only the one transition state.

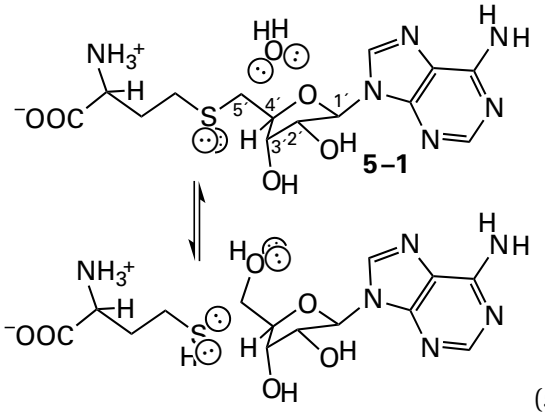
An enzymatic reaction involves intermediates for the same reason that a nonenzymatic reaction does. The reaction coordinate, passing through a series of successive intermediates, encounters a series of standard free energies of activation that are all smaller than the standard free energy of activation for even the least endergonic of the alternative reaction coordinates that have only one transition state. It should not be thought that in this way the enzyme divides up the larger free energy of activation associated with the one step. Rather, it happens that there is an alternative, but independent, reaction coordinate passing through the intermediates, and this reaction coordinate has **transition states that are all lower in free energy of activation** than that for any of the reaction coordinates with only a single transition state. This conclusion follows from the fact that the mechanism with intermediates is the one actually observed.

In reactions that occur in solution, an intermediate is usually described as if it were a single molecule—for example, a tetrahedral intermediate in hydrolysis of an amide. This description may be reasonable in other solvents; but in water, an intermediate in the mechanism for the usual reaction, in addition to a layer of hydration, has molecules of water or general acid–bases or both noncovalently bound to it through hydrogen bonds. These bound molecules are usually essential participants in the intermediate both structurally and energetically. For this reason, an intermediate in an enzymatic reaction can be viewed as a simpler structure than the analogous intermediate in a nonenzymatic, aqueous reaction because much or all of the layer of hydration, some or all of the necessary molecules of water, and all the molecules of general acid–bases have been replaced by the surrounding, well-structured protein, well-oriented donors and acceptors of hydrogen bonds, and catalytic acid–bases, respectively, from within the folded polypeptide and its associated prosthetic groups. An intermediate in an enzymatic reaction is the **complex between the catalytic functional groups in the active site and a particular covalent arrangement of the atoms** that had composed together the reactants that precede the intermediate and that will compose together the products that follow the intermediate in the enzymatic reaction. As is the case for the fully hydrated complex in aqueous solution, an intermediate in an enzymatic reaction is the entire complex between the rearranged atoms of the reactants and the protein surrounding the active site, as well as any adjacent fixed or unfixed molecules of water. To simplify matters, however, the intermediate in an enzymatic reaction is often discussed as if it were only the molecule or molecules formed from the atoms of reactants or products, and the active site itself is often not explicitly mentioned even though it is inescapably a participant.

The intermediates encountered in enzymatic reactions can be divided into two classes. On the one hand, an enzymatic reaction can pass through the **same series of intermediates** that the same chemical reaction would pass through in the same aqueous solution in the absence of enzyme. This situation is the basis for the paradigm of the enzyme associating with a transition state or an intermediate

of high energy in the reaction more tightly than the reactants. An example of such a reaction is hydrolysis of a peptide bond catalyzed by an aspartic endopeptidase, in which the carboxylato group of an aspartate removes a hydron from a molecule of water either before or as it attacks the acyl carbon of the amide to form the tetrahedral intermediate, and the carboxy group of the same aspartic acid hydronates the nitrogen of the tetrahedral intermediate to produce the leaving group (Equation 4–376). These two steps in hydrolysis of an amide would occur in solution under catalysis by acetate and acetic acid. On the other hand, because the active site of an enzyme resembles an aqueous solution only remotely, **unique intermediates**, which do not participate in the uncatalyzed reaction, may participate in the enzymatically catalyzed reaction. For example, although the serine endopeptidases in the family represented by trypsin and chymotrypsin catalyze a reaction identical to that catalyzed by an aspartic endopeptidase, these enzymes use a serine in the active site as the initial nucleophile to produce an ester between the enzyme and the acyl carbon of the original amide, and then the internal ester is hydrolyzed by water (Figure 3–6).[1,2] Both formation of the acyl enzyme and its hydrolysis must pass through the respective tetrahedral intermediates. It is not immediately obvious, however, that the reaction catalyzed by a serine endopeptidase can be described by the rule that an enzyme associates with a transition state that would normally exist in solution more tightly than it associates with the reactants. Why the seryl intermediate was chosen by natural selection to catalyze a reaction that other enzymes perform without one is, for obvious reasons, unknown.

The serine endopeptidases use an amino acid in the active site to form an intermediate unique to their enzymatic reactions relative to the mechanism of the reaction in solution, but adenosylhomocysteinase



(5–2)

uses a prosthetic group in the active site to form an intermediate unique to its enzymatic reaction. The reaction catalyzed by the enzyme is formally a nucleophilic substitution at a primary carbon. In solution, it would probably be concerted, but it would be a difficult reaction because the sulfido anion is a poor leaving group and hydronating the sulfide to cause the sulfanyl group to be the leaving group is difficult.

The following results, however, are consistent with a mechanism for the enzymatic reaction (Figure 5–2) in which 3′-oxo-4′,5′-dehydroadenosine is the central intermediate.[3,4] The enzyme contains NAD^+ bound tightly as a prosthetic group to its active site. When *S*-adenosyl-L-homocysteine (**5–1**) is added to bovine adenosylhomocysteinase, NADH is transiently formed. When the reaction is run in ^2H_2O, deuterium appears at carbon 4′ in the unreacted *S*-adenosyl-L-homocysteine. The hydrolysis of [4′-^{2}H]-*S*-adenosyl-L-homocysteine by the enzyme displays a deuterium kinetic isotope effect of 1.5. 4′,5′-Dehydroadenosine is oxidized by the enzyme and converted into adenosine. A crystallographic molecular model of the intermediate 3′-deoxy-3′-oxoadenosine occupying the active site of adenosylhomocysteinase from *Mycobacterium tuberculosis* (56% identity; 0.8 gap percent) with the prosthetic NAD^+—oxidant next to oxidant to prevent any reaction from occurring—places carbon 3′ of 3′-deoxy-3′-oxoadenosine immediately adjacent (0.39 nm) to carbon 4 of the nicotinamide and in the proper orientation to be reduced were the NAD^+ an NADH.[4]

If a mechanism in which 3′-oxo-4′,5′-dehydroadenosine is the central intermediate applies to adenosylhomocysteinase, the nucleophilic substitution occurs indirectly rather than directly, by an elimination–addition β to a carbonyl, a reaction in which thiols readily participate. This mechanism is reminiscent of the mechanism of cystathionine γ-synthase, in which a substitution of a succinyl group by the sulfanyl group of L-cysteine was accomplished by an even more complicated elimination–addition involving formation of the 1-carboxyprop-2-enimine of pyridoxal 5′-phosphate. In the case of adenosylhomocysteinase, the fact that the enzyme can catalyze hydrogen exchange at carbon 4′ of 5′-deoxyadenosine is consistent with the enzymatic reaction proceeding through the two respective enolates as intermediates in the elimination and addition, respectively, as shown, and this enzymatic reaction has at least five unique intermediates. Both

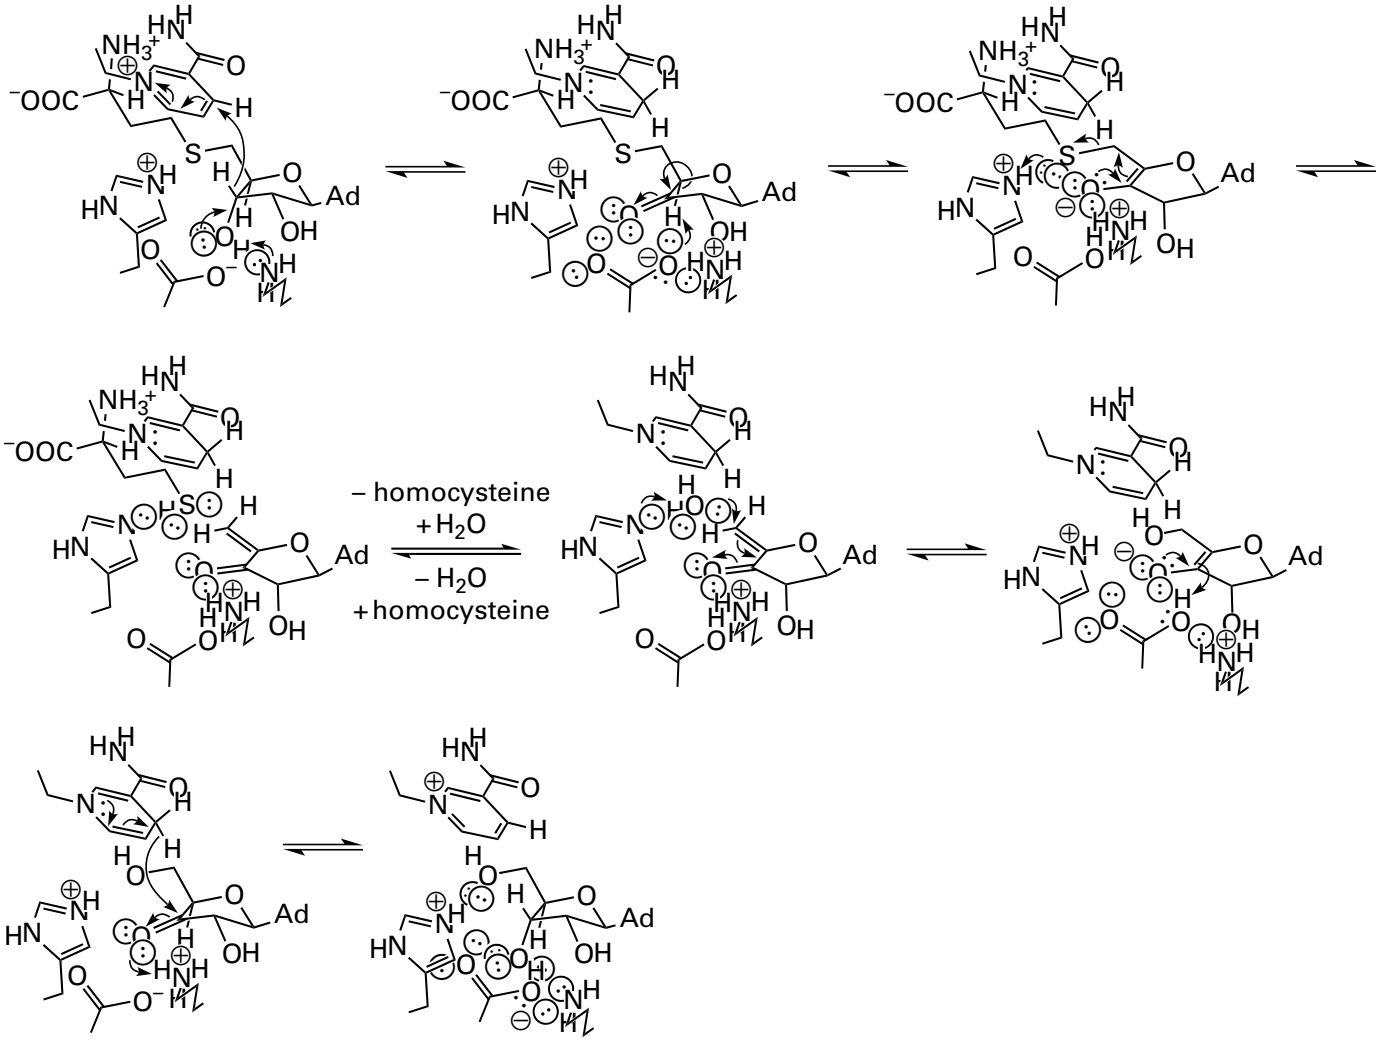


Figure 5–2: Mechanism proposed for adenosylhomocysteinase.[3,4] While a lysine removes a hydron from the 3′-hydroxy group, the prosthetic NAD^+ removes a hydride from carbon 3′ of adenosyl-L-homocysteine (Ad = adenosyl) to produce a 3′-deoxy-3′-oxoribosyl group that now has an acidic hydron at carbon 4′, which is then removed by an aspartate. Elimination from the resulting enolate of the sulfur of the homocysteinyl group, which is hydronated by a histidine, breaks the carbon–sulfur bond and produces 4′,5′-didehydro-3′,5′-dideoxy-3′-oxoadenosine as the central intermediate in the enzymatic reaction. After a molecule of water replaces the L-homocysteine, this α,β-unsaturated carbonyl compound is hydrated across the double bond, and the resulting ketone is reduced by hydride transfer from the NADH to produce adenosine as the other product of the enzymatic reaction.

the enzymatic reaction catalyzed by pyridoxine 5′-phosphate synthase (Figure 4–47) and that catalyzed by urocanate hydratase (Figure 4–49) also pass through at least five intermediates.

In the discussion so far, as it has proceeded in the earlier chapters, a number of intermediates in enzymatic reactions have been encountered. Together they have represented in turn different **classes of intermediates**. These classes can be distinguished by what is added or what is subtracted from the reactant or reactants to produce the intermediate.

A **covalent intermediate** is an intermediate in an enzymatic reaction in which the enzyme itself and the other atoms participating in the intermediate are covalently attached to each other. A covalent intermediate results when a functional group on the side chain of an amino acid in the active site or a functional group on a prosthetic group covalently attached to the active site is added to one reactant or to the product of the covalent association of two or more reactants. Often a portion of one of the original reactants departs as a leaving group as the covalent intermediate is formed. Examples of covalent intermediates are the acylseryl intermediates in serine endopeptidases (Figure 3–6) and acetyl-

cholinesterase (Equation 3–385), the acylcysteinyl intermediate in hydroxymethylglutaryl-CoA synthase (Equation 4–361), the phosphoaspartyl intermediate in the phosphatase encoded by the BT3141 gene of *Bacteroides thetaiotaomicron* (Figure 3–43), the phosphoseryl intermediates in phosphoglycerate mutase (Equation 3–421) and alkaline phosphatase (Equation 4–452), the phosphohistidinyl intermediates in pyruvate, phosphate dikinase (Equations 3–501 and 3–502), the adenylyl intermediate in sulfate adenylyltransferase (ADP) (Equation 3–161), and the lysylimines in fructose-bisphosphate aldolase (Figure 4–36 and Equations 4–304, 4–368, and 4–405) and 2-dehydro-3-deoxyphosphogluconate aldolase (Equation 4–325).

A **covalent prosthetic intermediate** is an intermediate in an enzymatic reaction in which the other atoms participating in the intermediate that are derived from the reactants are covalently attached to a prosthetic group that is itself covalently or noncovalently attached to the active site. In this class of intermediates, there is no covalent linkage formed between the substrate and the protein itself, only with the prosthetic group, which may or may not be covalently attached to the enzyme. Covalent prosthetic intermediates have already been discussed in detail in Chapters 1 and 2.

A **diamagnetic, noncovalent intermediate** is any intermediate in an enzymatic reaction that forms within the active site, that is noncovalently associated with the active site, and in which all electrons are paired in atomic and molecular orbitals. Examples of diamagnetic, noncovalent intermediates are the ketones produced by the prosthetic NAD^+ in UDP-glucose-4-epimerase (Equation 4–130) and adenosylhomocysteinase (Figure 5–2); the tetrahedral intermediates in aspartate—ammonia ligase (**3–75**), thermolysin (Figure 3–42 and Equation 4–445), glutamine synthetase (**3–98**), chloramphenicol *O*-acetyltransferase (**4–132**), endothiapepsin (Equation 4–376), urease (**4–175**), and leucyl aminopeptidase (**4–177**); the tetrahedral carbonyl adduct in the active site of fumarylacetoacetase (Equation 4–362); the tetrahedral adduct in the active site of 3-phosphoshikimate 1-carboxyvinyltransferase (**3–81** and Equation 4–414); the phosphorane in the active site of ribonuclease (**4–123**); and the carboxylated enolate in the active site of ribulose-bisphosphate carboxylase (Equation 3–424 and Figure 3–53).

Diamagnetic, noncovalent intermediates are independent molecules,* but because they are often unstable, they are usually bound tightly in the active site. For example, 3′-oxo-4′,5′-dehydroadenosine (Figure 5–2) is held so tightly in the active site of adenosylhomocysteinase by noncovalent forces that it cannot escape into the solution. If 3′-oxo-4′,5′-dehydroadenosine were to escape from the active site, the enzyme would be left in its reduced inactive form, incapable of reaction with the next homocysteinyladenosine, and 3′-oxo-4′,5′-dehydroadenosine would readily form Michael adducts with proteins in the cytoplasm. Both of these consequences would be unfortunate.

In the case of phosphoglucomutase (α-D-glucose-1,6-bisphosphate-dependent)

$$\alpha\text{-D-glucose 1-phosphate} \rightleftharpoons \text{D-glucose 6-phosphate} \qquad (5\text{–}3)$$

however, dissociation of the diamagnetic, noncovalent intermediate, α-D-glucose 1,6-bisphosphate, which does occur slowly, inactivates the enzyme but is not otherwise harmful. Nevertheless, a sufficient concentration of α-D-glucose 1,6-bisphosphate must always be present in the cytoplasm so that it can reassociate with the enzyme and continuously reactivate it. Consequently, another enzyme, glucose-1,6-bisphosphate synthase, is required to maintain proper levels of this **escaped intermediate**. Its only purpose is to service phosphoglucomutase.

In spite of the fact that it has provided the name for the enzyme and in spite of the fact that it is often included in the equation for the reaction (Equation 4–437), *cis*-aconitate, which is released into solution from the active site of aconitate hydratase, is not a product of the reaction but a diamagnetic, noncovalent intermediate that has escaped. Little if anything in the metabolism of a cell is produced from *cis*-aconitate, so its release from the active site is fortuitous rather than purposeful. Because *cis*-aconitate is unreactive and because the enzyme is not inactivated by its dissociation, its escape is harmless, and it is readily re-bound by the active site and converted into citrate or isocitrate. It is possible that some metabolites for which purposes have been found were once escaped intermediates.

*Diamagnetic, noncovalent intermediates are often ionic at the site of reaction, but since most biochemical molecules are ions, it would be meaningless to separate them into the categories of nonionic, diamagnetic, noncovalent intermediates and ionic, diamagnetic, noncovalent intermediates.

There are several classes of diamagnetic, noncovalent intermediates that are usually distinguished because of the special properties of their members.

A **carbanionic intermediate** is a diamagnetic, noncovalent intermediate that forms in an active site when a hydron or another electrophile dissociates heterolytically from a carbon in a reactant—usually a carbon adjacent to a carbonyl, imino, or acyl group—and that dissociation produces a carbanion or that forms when a nucleophile associates hetereolytically with a carbon in a reactant—usually a carbon conjugated to a carbonyl, imino, or acyl carbon—and that association produces a carbanion. Examples are the enolates and their conjugate acids in the active sites of 3-deoxy-8-phosphooctulonate synthase (**4–51**), L-fuconate dehydratase (Equation 4–268), malate synthase (Equation 4–272), pyruvate kinase (Equation 4–276), phospho*enol*pyruvate carboxykinase (Equation 4–419), 4-hydroxy-2-oxoheptanedioate aldolase (**4–166**), isocitrate dehydrogenase (**4–167**), and fumarylacetoacetase (**4–168**); the *cis*-enediolates in the active sites of triose-phosphate isomerase (Equations 4–46 and 4–55), fructose-bisphosphate aldolase (**4–170**), and D-psicose 3-epimerase (Equation 4–434); the *gem*-enediolates in the active sites of isocitrate lyase (Equation 4–310), chondroitin AC lyase (Figure 4–44), phosphopyruvate hydratase (**4–171**), and mandelate racemase (**4–172**); and the α,β-unsaturated enolates in the active sites of 4-chlorobenzoyl-CoA dehalogenase (**3–110**), steroid Δ-isomerase (Equation 4–416), and 2-hydroxymuconate tautomerase (**4–53**). It has already been noted that an enzyme may or may not stabilize an enolate by hydronating its oxyanion during or after its formation.

A **carbocationic intermediate** is a diamagnetic, noncovalent intermediate that forms in an active site when a leaving group dissociates heterolytically from a carbon in a reactant and that dissociation produces a carbocation or that forms when a hydron or another electrophile associates heterolytically with carbon in a reactant and that addition produces a carbocation. Examples are the carbenium ion in the active site of 3-deoxy-8-phosphooctulosonate synthase (**3–96**); the carbocationic intermediate in the electrophilic aromatic substitution catalyzed by tryptophan synthase (**4–122**); the oxocarbenium ions in the active sites of lysozyme (**3–26**), hypoxanthine phosphoribosyltransferase (**3–91**), and other glycosidases (Equation 4–400); and the carbenium ions that are intermediates in terpenoid synthesis (Figures 3–48 and 3–50 and Equation 3–368).

A **radical intermediate** is a paramagnetic noncovalent intermediate that possesses an unpaired electron and that forms in an active site when a hydrogen atom is abstracted from a reactant, when an electron is added or subtracted from a reactant, or when a reactant dissociates homolytically. Because they are so different from diamagnetic, noncovalent intermediates, radical intermediates can be treated separately. They are tightly held in an active site, unable to escape during their usually short lifetimes. Far fewer enzymes have radical intermediates than diamagnetic, noncovalent intermediates, but because of their unique peculiarities, these enzymes have received much attention. Examples that have been previously discussed are the radical intermediates in the active sites of enzymes that use cobalamin as a prosthetic group (**2–182** and Equations 2–369 through 2–373) and the radical intermediates in certain monooxygenases (**2–95**).

Chemical and Crystallographic Identification of Covalent Intermediates

If a covalent intermediate between an amino acid in the active site and a portion of a reactant or portions of two reactants is formed during the overall enzymatic reaction, the enzyme itself is transiently and covalently modified during its normal reaction. Chemical identification of this modification often involves the isolation of a peptide from the enzyme bearing the modification, as was the case for identification of an amino acid modified by an active-site label. **Chemical identification** of the modification can be used as evidence for involvement of the covalent intermediate in the enzymatic reaction. For example, when chymotrypsin catalyzes hydrolysis of 4-nitrophenyl acetate, the fast step in the overall reaction is formation of an intermediate *O*-acetylserine, which is the esterolytic homologue of the intermediate *O*-peptidylserine in the endopeptidolytic hydrolysis of a peptide bond normally catalyzed by the enzyme (Figure 3–6). The intermediate *O*-acetylserine accumulates because its hydrolysis, which is the second step in the esterolysis, is slow. When 4-nitrophenyl [^{14}C]acetate was used as a substrate, [^{14}C]acetyl-enzyme was formed, and the acetyl group was shown to be incorporated as an ester of Serine 195 by isolation of the acetylated peptide, GDS(acetyl)-GGPL,[1] where (acetyl) indicates modification of the serine. 4-Methylbenzenesulfonyl chloride inactivates chymotrypsin[5] by tosylating the same serine, and a crystallographic molecular model of the modified

enzyme could be obtained.[6] **Crystallographic molecular models** for the normal intermediate *O*-acylserine of other serine endopeptidases, such as those of trypsin[7,8] and pancreatic elastase,[9] have been reported.

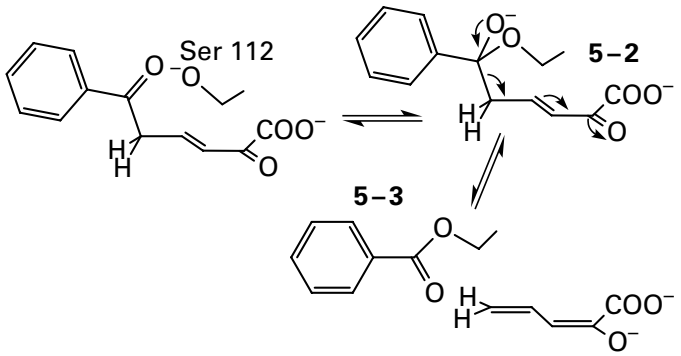
Covalent acyl intermediates in enzymatic nucleophilic substitutions are common. For example, in β-lactamase, an enzyme that catalyzes the hydrolysis of a strained cyclic amide rather than a linear amide, the intermediate ***O*-acylserine** in the enzymatic reaction was **identified spectrophotometrically** by its characteristic stretching frequency in the infrared at 1753 cm^{-1} for the carbon–oxygen double bond of the seryl ester. The intermediate was trapped by using a reactant that produces an intermediate *O*-acylserine that, like the intermediate *O*-acetylserine in chymotrypsin, is hydrolyzed much more slowly than it is formed.[10] The existence of this particular intermediate *O*-acylserine was also verified crystallographically.[11]

Crystallographic molecular models of serine endopeptidases complexed with inhibitors that are designed to react with the respective nucleophilic serines and form analogues of the **covalent tetrahedral intermediates** leading to and from the covalent intermediate *O*-acylserine have also been reported,[8,12-14] as well as a crystallographic molecular model of the actual tetrahedral intermediate produced during hydrolysis of a reactant for pancreatic elastase.[15] These latter results verify the complete mechanism of hydrolysis for serine endopeptidases (Figure 3–6). They also identify, in each case, the imidazolyl group of the homologous histidine that removes a hydron from the hydroxy group of serine, swings over to hydronate the leaving amino group, unhydronates the water that replaces that leaving amino group and that will hydrolyze the intermediate *O*-acylserine, and then swings back to hydronate the leaving hydroxy group of the serine. When the nucleophilic serine in the active site of subtilisin, another serine endopeptidase, is mutated to alanine, the value for $k_0\,K_m^{-1}$ decreases 3×10^6-fold.[16] All these results confirm the existence and importance of a covalent *O*-acylseryl intermediate in the reaction catalyzed by the various serine endopeptidases.

There are esterases that also proceed through intermediate *O*-acylserines during the hydrolyses of the particular esters that they catalyze. In the case of carboxylesterase from *Geobacillus stearothermophilus*, a covalent tetrahedral intermediate on the serine, again implicating a single imidazolyl group as the only catalytic acid–base, has been observed crystallographically.[17]

Intermediate *O*-acylserines, however, are often so transient that they cannot be identified either chemically or crystallographically. A method has been developed to incorporate 2,3-diaminopropionate in place of serine in an active site, in this way replacing a hydroxy group at a particular position with an amino group. The acyl intermediate that is formed in the resulting enzymatic reaction is an amide rather than an ester and is much more stable.[18]

2,6-Dioxo-6-phenylhexa-3-enoate hydrolase from *Paraburkholderia xenovorans* performs a retro-Claisen condensation on 2,6-dioxo-6-phenylhexa-3-enoate

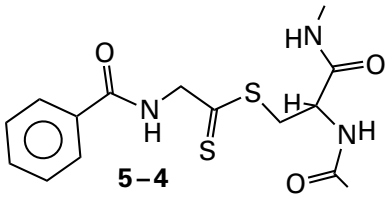


(5–4)

with benzoic acid and 2-oxopent-4-enoate, the more stable tautomer of the conjugate acid of the 2-oxidopenta-2,4-dienoate shown in the equation, as the two products. The thiohemiketal, homologous to the proposed hemiketal **5–2** between Serine 112 and 2,6-dioxo-6-phenylhexa-3-enoate in the normal enzymatic mechanism (Equation 5–4), has been observed in a crystallographic molecular model of a mutant in which Serine 112 was replaced by cysteine.[19] In this model, the bond between carbons 5 and 6 is parallel to the π molecular orbital system of the α,β-unsaturated carbonyl group from carbon 2 to carbon 4, as expected if the π molecular orbital system withdraws electron density from this carbon–carbon bond during the retro-Claisen condensation. Intermediate **benzoylserine 5–3** could be isolated in a peptic peptide purified from a digest of 2,6-dioxo-6-phenylhexa-3-enoate hydrolase mixed with 2,6-dioxo-6-phenylhexa-3-enoate. The modified Serine 112 was identified by mass spectrometry of the modified peptide. The same benzoylserine could be observed in the active site in a crystallographic molecular model of a mutant of the enzyme in which Histidine 265 had been mutated to glutamine to decrease the rate of hydrolysis of benzoylserine.[20]

2,6-Dioxo-6-phenylhexa-3-enoate hydrolase also catalyzes hydrolysis and methanolysis of 4-nitrophenyl benzoate with a catalytic constant identical, within experimental error, to the rate at which it catalyzes the retro-Claisen condensation, and the ratios of the products methyl benzoate and benzoic acid in mixtures of methanol in water for both reactions are the same. These latter results suggest that benzoylserine **5–3** is a common intermediate in both reactions and that hydrolysis of benzoylserine is the rate-limiting step, not the retro-Claisen condensation.[21] Using benzoylserine **5–3** as an intermediate in the reaction avoids the necessity for the less stable *gem*-dienolate as an intermediate. Esters are also the most common reactants chosen in nonenzymatic Claisen condensations for the same reason.

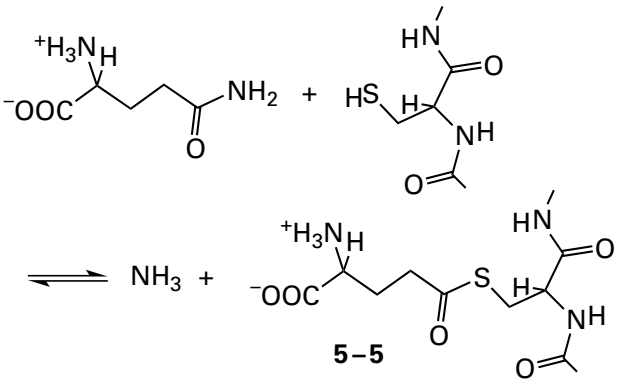
***S*-Acylcysteines** are also intermediates in hydrolyses catalyzed by enzymes. The intermediate *S*-acylcysteine in the endopeptidolytic hydrolysis catalyzed by papain was trapped by using the reactant methyl benzoylcarbamothioate, a methyl ester that produces an intermediate cysteinyl benzoylcarbamothioate



5–4

Again, intermediate **5–4** is formed on the active site more rapidly than it is hydrolyzed. Formation of this dithioester was demonstrated by its characteristic absorbance at 313 nm.[22] The cysteine that was thioacylated was later identified by modifying it with several chloromethyl ketones and identifying the products crystallographically.[23]

The homologous glutaminase domains[24] attached to various carbon–nitrogen ligases hydrolyze L-glutamine to provide the ammonia for the subsequent ligation. During hydrolysis, an *S*-(γ-L-glutamyl)-cysteine is formed as a covalent intermediate

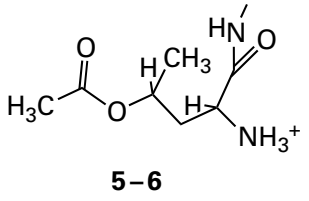


5–5

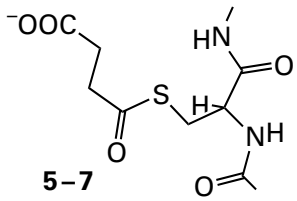
(5–5)

which is then hydrolyzed. A significant amount of this intermediate is present at steady state during catalysis by asparagine synthase (glutamine-hydrolysing) from *Escherichia coli*,[25] and the cysteine that is acylated is the same one modified by 6-diazo-5-oxo-L-2-aminohexanoic acid, which produced a covalent modification that could be identified crystallographically.[26] Intermediate *S*-(γ-L-glutamyl)cysteines (**5–5**) have been observed crystallographically in the active sites of some of these enzymes.[27,28]

There are a number of **acyltransferases** that transfer an acyl group from one reactant to another. Usually a covalent acylenzyme holds the acyl group. For example, glutamate *N*-acetyltransferase transfers an acetyl group from N^{α}-acetyl-L-ornithine to L-glutamate to produce N^{α}-acetyl-L-glutamate. When the enzyme from *Streptomyces clavuligerus* is mixed with only N^{α}-acetyl-L-glutamate, it becomes acetylated,[29] and the acetylated peptide TLLTFFATDAR is identified in a tryptic digest of the acetylated enzyme. A crystallographic molecular model of the acetylated enzyme identified Threonine 181, which is the amino-terminal threonine in this peptide, as the site of the acetylation (**5–6**)[30]



5–6



5–7

Consequently, it is inferred that during the overall acetyl transfer catalyzed by the enzyme, either N^{α}-acetyl-L-ornithine or N^{α}-acetyl-L-glutamate associates with the enzyme, the acetyl group is transferred to the threonine, and L-ornithine or L-glutamate dissociates. When L-glutamate or L-ornithine, respectively, associates and the acetyl group is transferred from ***O*-acetylthreonine** to its

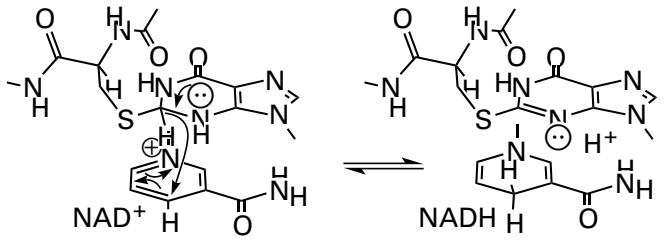
α-amino group, the net reaction is accomplished. The fact that glutamate *N*-acetyltransferase from *G. stearothermophilus* (38% identity; 1.5 gap percent) displays steady-state kinetics in which

$$v_0 = \frac{k_0 k_A k_B [E]_t [A]_0 [B]_0}{k_0 k_A [A]_0 + k_0 k_B [B]_0 + k_A k_B [A]_0 [B]_0} \quad (5\text{–}6)$$

when N^{α}-acetyl-L-ornithine and L-glutamate are reactants is consistent with a ping-pong mechanism (compare Equation 3–148) in which L-ornithine dissociates as a product before L-glutamate can associate as a reactant.[31] In a crystallographic molecular model of glutamate *N*-acetyltransferase from *M. tuberculosis* (31% identity; 1.7 gap percent), the active site seems to be designed to associate with either L-ornithine or L-glutamate in turn.[32]

There are acyltransferases that transfer an acetyl group between coenzyme A and the hydroxy group of L-homoserine, parking the acetyl group on the hydroxy group of a serine.[33-36] There are also acyltransferases that transfer a succinyl group between coenzyme A and the hydroxy group of L-homoserine, parking the succinyl group on the sulfanyl group of a cysteine as an ***S*-succinylcysteine** (**5–7**).[37-39] In addition, there are acyltranferases that transfer a γ-glutamyl group between the amino group of L-cysteinylglycine and the α-amino groups of other amino acids or peptides, parking the γ-glutamyl group on the hydroxy group of a threonine.[40,41]

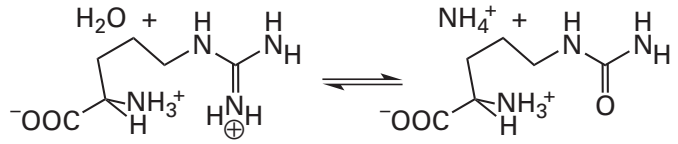
Covalent intermediates of derivatives of carbonic acid are also formed during enzymatic reactions. For example, addition of the sulfanyl group of a cysteine to the hypoxanthinyl group in inosine 5′-phosphate when it is bound in the active site of IMP dehydrogenase[42-45]



(5–7)

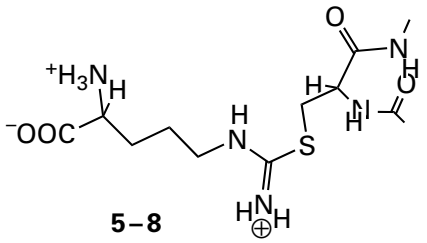
produces a tetrahedral covalent intermediate in the *N*-acyl-*N*′-alkylformamidine portion of the hypoxanthinyl group, a derivative of formic acid. Instead of one of the two nitrogens being expelled from the tetrahedral intermediate to form an acyl derivative, a hydride is expelled as a leaving group while being transferred to NAD^+. This expulsion of the hydride oxidizes the tetrahedral intermediate, which was an acyl derivative of formic acid, to an ***S*-alanyl-*N*-acyl-*N*′-alkylthiourea** (Equation 5–7), a derivative of carbonic acid that is the covalent intermediate in the reaction catalyzed by the enzyme. A peptide containing the covalent intermediate formed from [8-^{14}C]inosine 5′-phosphate was isolated from a digest of the enzyme from *Tritrichomonas foetus* that had been mixed with [8-^{14}C]inosine 5′-phosphate and NAD^+. Sequencing of the peptide showed that Cysteine 319 was the participant in the covalent intermediate.[43] The *S*-alanyl-*N*-acyl-*N*′-alkylthiourea (Equation 5–7) has also been observed crystallographically in the active site of IMP dehydrogenase from *Cricetulus griseus*.[45] In the enzymatic reaction, the *S*-alanyl-*N*-acyl-*N*′-alkylthiourea is then hydrolyzed to the *N*-acyl-*N*′-alkylurea in xanthosine 5′-phosphate, which is the final product in the direction written, and this hydrolysis also regenerates the cysteine.

Arginine deiminase from *Pseudomonas aeruginosa*



(5–8)

incorporates L-[1-^{14}C]-L-arginine covalently during its hydrolysis of L-arginine to L-citrulline; and when Cysteine 405 is mutated to serine, the enzyme no longer catalyzes the hydrolysis and no longer incorporates [1-^{14}C]-L-arginine.[46] A crystallographic molecular model has defined this intermediate as[47]



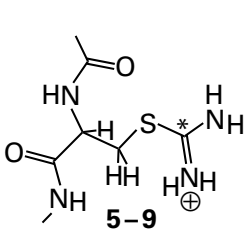
5–8

In the case of porcine glycine amidinotransferase

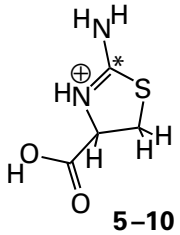
L-arginine + glycine $\rightleftharpoons$ L-ornithine + guanidinoacetate

(5–9)

mixing the enzyme with the amidino donor, [guanidinio-^{14}C]-L-arginine, in the absence of the acceptor, glycine, produces a covalent intermediate in which Cysteine 370[48] is amidinated (**5–9**)



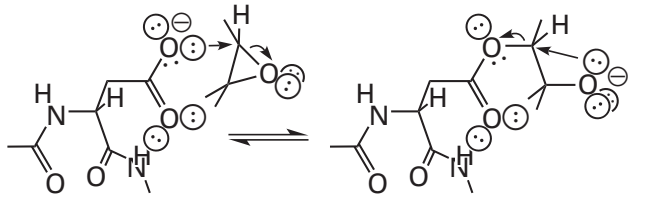
5–9



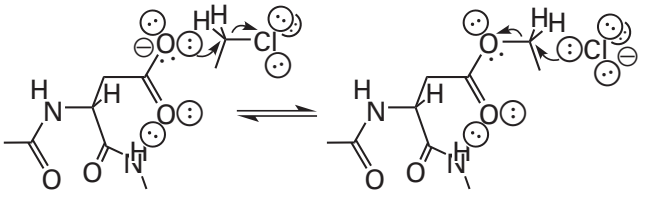
5–10

The ***S*-[^{14}C]amidinocysteine** (**5–9**; asterisk indicates carbon-14) in the [^{14}C]amidino enzyme cyclizes during acid hydrolysis of the protein to 2-amino-4-carboxy-[2-^{14}C]-4,5-dihydro-1,3-thiazole (**5–10**), a product that provided the initial identification of the intermediate.[49]

Esters of the carboxy groups on aspartates and glutamates in active sites are used as covalent intermediates in enzymatic nucleophilic substitutions. For example, in each active site of the related enzymes[50,51] epoxide hydrolase, haloalkane dehalogenase, and haloacid dehalogenase, there is an aspartate the carboxylato group of which performs a nucleophilic substitution on the electrophilic epoxide, haloalkane, or haloacid, respectively[52-54]

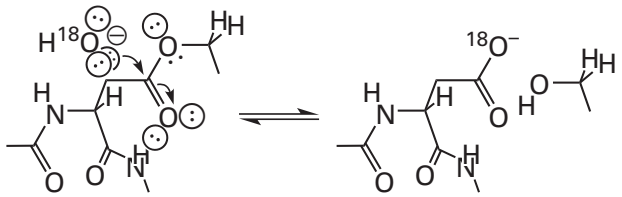


(5–10)



(5–11)

and the resulting covalent ***β*-aspartyl ester** is then hydrolyzed at its acyl carbon

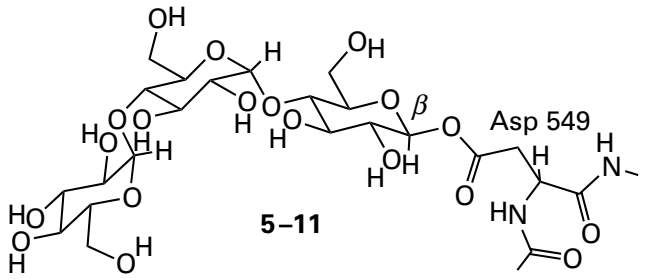


(5–12)

There is chemical evidence for this mechanism. Oxygen-18 from [^{18}O]H_2O is incorporated during the reaction into the aspartate in the active site of haloalkane dehalogenase from *Xanthobacter autotrophicus*. The [*β*-^{18}O]aspartate was isolated in a chymotryptic peptide to identify the particular aspartate that was labeled.[55] During the first turnover of epoxide hydrolase from *Rattus norvegicus* in [^{18}O]H_2O, no oxygen is incorporated into the product alcohol, but once the aspartate becomes isotopically labeled, it is incorporated into the product during later turnovers.[50] The crystallographic evidence for this mechanism is observation of the respective *β*-aspartyl esters (Equations 5–12) formed from the usual substrates in the active sites of haloalkane dehalogenase from *X. autotrophicus*[52] and haloacid dehalogenase from *Burkholderia cepacia*.[56]

Many, if not most, of the **glycosyltransferases** that retain the configuration of the glycosidic linkage in their product glycosides, as well as glycosidases that retain the configuration of the glycosidic linkage they hydrolyze, are thought to use mechanisms that pass through **covalent glycosyl intermediates**, which are *β*-aspartyl esters or *γ*-glutamyl esters formed between the respective glycosidic carbons and the carboxy groups of aspartates or glutamates in the active sites. For the overall nucleophilic substitution, a decision must be made: either a covalent glycosyl intermediate between two consecutive nucleophilic substitutions or an intermediate oxocarbenium ion and a single dissociative nucleophilic substitution.

An example of an active site that performs two successive nucleophilic substitutions with a covalent glycosyl intermediate is 4-*α*-glucanotransferase. The role of this enzyme is to transfer a maltotriose from the 4-hydroxy group of a D-glucose in a polysaccharide to the 4-hydroxy group of another D-glucose at the nonreducing end of another polysaccharide. The covalent glycosyl intermediate in the active site of 4-*α*-glucanotransferase from *Oryctolagus cuniculus* can be trapped, in the absence of an acceptor, with the covalent maltotriosyl intermediate[57]



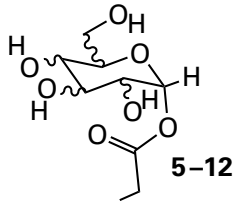
in its active site. When an acceptor is added, the enzyme transfers the maltotriosyl group to that acceptor in its normal reaction, but in the absence of acceptor, the maltotriosyl enzyme is stable. The glycosylated enzyme was digested with pepsin, and a peptide glycosylated on Aspartate 549 of the intact protein was isolated to identify the site of the modification.[58] Likewise, in the absence of an acceptor, cyclomaltodextrin glucanotransferase from *Niallia circulans* can be glycosylated with a 4-deoxymaltotriosyl group, and the resulting covalent glycosyl intermediate on Aspartate 229 can be observed crystallographically.[59]

Both 4-α-glucanotransferase and cyclomaltodextrin glucanotransferase are examples of glycosyltransferases in which the monosaccharide or oligosaccharide is transferred between a donor and an acceptor that are similar in structure—in these two examples, the nonreducing ends of polysaccharides. In such cases, the acceptor can associate with the same subsite as the donor, and the donor and acceptor can change places while the covalent intermediate holds on to the monosaccharide or oligosaccharide being transferred. There are, however, glycosyltransferases for which the donor and acceptor are structurally unrelated, so this strategy cannot be applied.

Just such an enzyme provides an example of an active site that performs a glycosyl transfer with an **oxocarbenium ion as an intermediate**. Lipopolysaccharide 4-α-galactosyltransferase from *Neisseria meningitidis* transfers the α anomer of D-galactose from UDP-α-D-galactose to the 4-hydroxy group of a D-galactosyl group in an elongating lipopolysaccharide with retention of configuration at D-galactose. The UDP in the UDP-α-D-galactose from which the α-D-galactosyl group is transferred and the lipopolysaccharide to which it is transferred are so dissimilar that there is no way they could occupy the same subsite in turn. Consequently, the active site of the enzyme binds both substrates simultaneously. In a crystallographic molecular model of the active site occupied by UDP-α-D-2-deoxy-2-fluoro-D-galactose and 4-deoxylactose, in which the 4-hydroxy group of the D-galactose, which would normally be the acceptor, is missing, carbon 4 of the D-galactosyl group in 4-deoxylactose is only 0.32 nm from carbon 1 of the α-D-galactosyl group in UDP-α-D-2-deoxy-2-fluoro-D-galactose,[60] not enough room to accommodate the missing 4-hydroxy group to which carbon 1 would normally be transferred. Even though the oxygen of the carbamoyl group of Glutamine 189, which is only 0.35 nm from carbon 1, has been proposed as a nucleophile that could form a covalent intermediate, in this glycosyltransferase, neither the carbamoyl nitrogen nor the carbamoyl oxygen is nucleophilic. Consequently, the α-D-galactosyl group is transferred directly to the 4-hydroxy group, with retention of configuration and probably without the intermediacy of a covalent intermediate. The intermediate in the **dissociative nucleophilic substitution** is probably an **oxocarbenium ion**.[61]

The issue in situations in which donor and acceptor are not simultaneously associated with an active site is whether or not an oxocarbenium ion can be an intermediate that lives long enough for the donor to leave and the acceptor to associate. An oxocarbenium ion in solution has a short half life (10^{-12} s).[62] Unless it is stabilized significantly by the enzyme both electronically, by providing a significant negative electric field such as that created by an adjacent carboxylato or carbamoyl group, and sterically, by preventing any nucleophile other than the intended one to approach it, including an adjacent carboxylato group, it would not exist long enough for the nonreducing monosaccharide to leave and be replaced by the intended nucleophile.[63] Both means of stabilization, however, are within the abilities of an active site, and it would not be unreasonable for the lifetime of the oxocarbenium ion to be extended long enough for the leaving hydroxy group of the donor to be replaced by the hydroxy group of the acceptor.

In contradistinction, for many if not all of the glycosidases that proceed by retention of configuration, including lysozyme,[64] it has been proposed that the usually present carboxylato group from an aspartate or glutamate, located on the opposite face of the glycosidic linkage from which the leaving group departs, adds to the oxocarbenium ion as the leaving group is departing to form an ester[65-67]

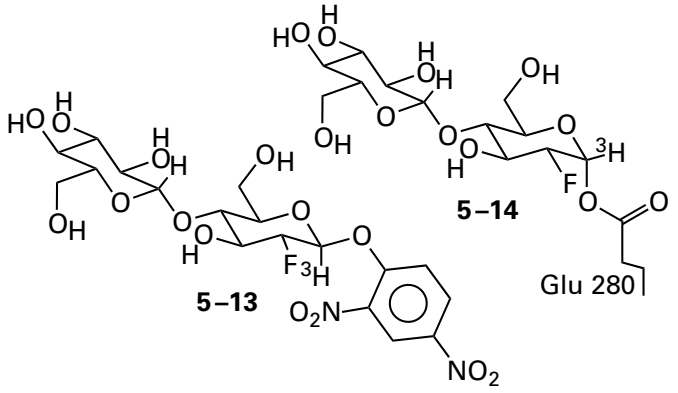


5–12

An ester is so stable that it can exist for as long as is necessary for the nucleophile intended to be the acceptor to arrive. After the nucleophile associates, the ester would then participate in a nucleophilic substitution as the glycosidic carbon during or immediately after the departure of the carboxylato group, which is a competent leaving group, from the glycosidic carbon. This proposal, however, would seem to require that, as is usually the case, a catalytic acid form a hydrogen bond with the ester oxygen of the carboxy group in the acyl intermediate to improve the ability of the carboxy group to leave during its dissociation from the intermediate. The presence of such a catalytic acid has not been mentioned, and in the active sites of many glycosidases that proceed with retention of configuration it seems not to be present. In the active site of lysozyme, there is none. Another drawback of this proposal is that the ester it requires has been observed only with unnatural substrates.

In the case of retaining **glycosidases**, as opposed to retaining glycosyltransferases, the nucleophile is water. In most of these enzymatic reactions, formation of the glycosyl intermediate, if it exists, is slower than its hydrolysis,[68] so even at equilibrium, little of the covalent intermediate should be present. One way to trap an intermediate is to discover a mutant in which hydrolysis of that intermediate is slow.[69] When Histidine 205 in cellulose 1,4-β-cellobiosidase from *Cellulomonas fimi*, a glycosidase that hydrolyzes cellobiose units from the nonreducing end of cellulose, is mutated to asparagine and Glutamate 127 to alanine, a covalent cellobiosyl intermediate at the carboxy group of Glutamate 233 can be trapped and observed crystallographically.[70]

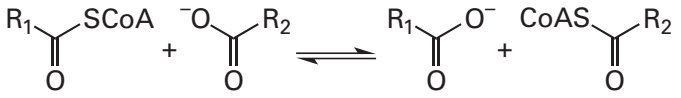
Another way to stabilize a covalent glycosyl intermediate might be to use a reactant in which a fluoro group has been synthetically introduced at the carbon next to the glycosidic carbon that participates in hydrolysis. For example, cellulase from *Acetivibrio thermocellus*[71] releases consecutively the cellobioses 4-(β-D-glucosido)-D-glucose from cellulose. When this enzyme is mixed with dinitrophenyl [^{3}H]fluorocellobioside **5–13**



a [^{3}H]fluorocellobiosyl derivative **5–14** of Glutamate 280 forms. This covalent intermediate can be isolated in a peptic peptide, which identifies the site of modification.[72] Fluorocellobioside **5–13** has also been used to form the homologous derivative (see **5–14**) with Glutamate 233 in the active site of cellulose 1,4-β-cellobiosidase from *C. fimi*, and a crystallographic molecular model of the modified active site has been reported.[73]

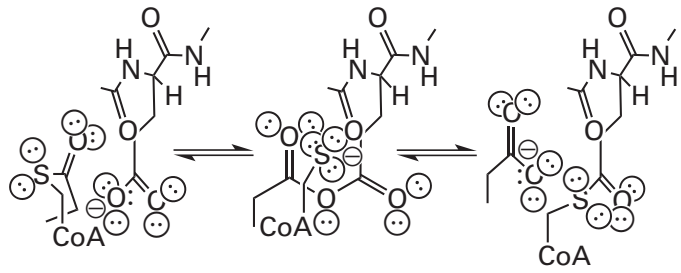
Covalent fluoroglycosyl derivatives of this type have been prepared from many glycosidases and characterized kinetically,[74,75] chemically,[76-80] and crystallographically.[75,81-86] The problem with these results is that the fluoroglycosides used to modify the carboxy groups in the active sites of these glycosidases are so different chemically from their usual substrates that they may simply be labeling the active site rather than producing an adduct homologous to an actual intermediate in the normal enzymatic reaction. For example, if the actual intermediate in one of these reactions were a glycosyloxocarbenium ion, a noncovalent intermediate, rather than a glycosylcarboxy group, a covalent intermediate, the fluoro substitution would destabilize that intermediate so drastically as to prevent its formation, and the increase in electrophilicity of a carbonyl carbon in the reagent would turn it into an active-site label. For example, when 2-acetamido-2-deoxy-D-glucopyranosyl-(β1,4)-2-deoxy-2-fluoro-β-D-glucopyranosyl fluoride was used to modify lysozyme, Aspartate 52 was modified by the glycoside,[64] but formation of a covalent glycosyl intermediate in the normal enzymatic reaction appears to be sterically precluded,[87] and the carboxylato group of Aspartate 52 probably serves as an anion to stabilize an oxocarbenium ion.

Carboxylic anhydrides of the carboxy groups of glutamates and aspartates are covalent intermediates for the common mechanism of the various CoA-transferases[88]



(5–13)

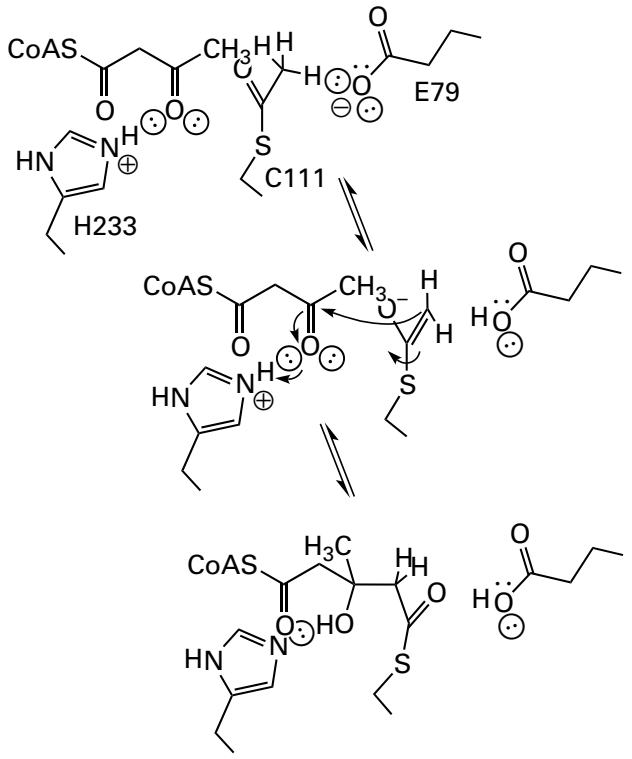
In the case of porcine 3-oxoacid CoA-transferase, chemical evidence for the existence of a **γ-glutamyl-SCoA thioester** at a glutamate in the protein, which participates in the mechanism of the enzymatic reaction as a covalent intermediate, has been presented.[89] A covalent γ-glutamyl-SCoA thioester in the active site of this enzyme[90] and the one in the active site of acetate CoA-transferase from *E. coli* have been observed crystallographically.[91] In the case of formyl CoA-transferase from *Oxalobacter formigenes*, both a covalent β-aspartyl-SCoA intermediate and a covalent β-aspartyl formyl anhydride have been observed crystallographically.[92] All these results are consistent with a general mechanism for coenzyme A transfer that includes a γ-glutamyl-SCoA



(5–14)

or a β-aspartyl-SCoA as a covalent intermediate, formation of either of which proceeds through the respective γ-glutamyl anhydride or β-aspartyl anhydride, also a covalent intermediate.

Because a hydron α to a thioester is significantly more acidic than a hydron α to an ester (Figure 1–23), covalent *S*-acylcysteinyl intermediates are often used as precursors to the respective α-enolates. An example is the intermediate in the reaction catalyzed by hydroxymethylglutaryl-CoA synthase, which catalyzes an aldol condensation (previously Equation 4–361)



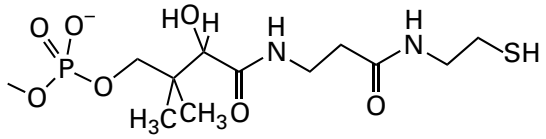
(5–15)

In the case of this enzyme, the covalent [1-^{13}C]acetylcysteinyl intermediate was first detected in a nuclear magnetic resonance spectrum of the enzyme from *Gallus gallus* that had been mixed with [1-^{13}C]acetyl-SCoA in the absence of the cosubstrate acetoacetyl-SCoA,[93] before it was observed crystallographically in the enzyme from *Staphylococcus aureus* (28 % identity; 3.1 gap percent).[94] Acetoacetyl-SCoA itself is produced by acetyl-CoA *C*-acetyltransferase, an enzyme that transfers an acetyl group from acetyl-SCoA to the sulfanyl of a cysteine and then adds the enolate of this acetyl group to a second acetyl-SCoA to produce acetoacetyl-SCoA in a Claisen condensation. A crystallographic molecular model of acetylated acetyl-CoA *C*-acetyltransferase from *Zoogloea ramigera* in a complex with acetyl-SCoA identifies acetylated Cysteine 89. In this complex, the α-carbon of the acetyl-SCoA, which becomes the enolate during the reaction, is immediately adjacent to the acyl carbon of the acetylcysteine, which is the electrophilic carbon in this Claisen condensation.[95]

Citrate (*pro*-3*S*)-lyase (see Problem 4–23) also catalyzes an aldol condensation

(5–16)

Following purification, the enzyme from *Klebsiella aerogenes* slowly loses activity in a process hastened by addition of citrate and Mg^{2+} or addition of hydroxylamine.[96] The inactive enzyme can be reactivated by exposure to acetic anhydride[96] or acetyl-SCoA.[97] During reactivation, the enzyme becomes acetylated on the sulfanyl group of the **4′-phosphopantetheinyl group**



5–15

in a molecule of coenzyme A covalently bound to a serine as a prosthetic group to the protein. This prosthetic coenzyme A is attached through a (β1,2)-glycosidic linkage between the 2′-hydroxy group on its ribosyl group and carbon 1 of a 5-phosphoribosyl group, which in turn is bound through its 5-phospho group in a phosphodiester to a serine of the polypeptide.[98] Only the enzyme acetylated on the sulfanyl group of this prosthetic coenzyme A is active as citrate lyase.

The enzyme lacking the covalently bound acetyl group, however, will carry out reactions in which it uses either extraneously added acetyl-SCoA or citryl-SCoA as if they were covalently bound to the protein.[99] Presumably this occurs because the extraneous acetyl-SCoA or citryl-SCoA displaces the covalently bound coenzyme A, which is only distantly tethered to the enzyme, from the active site. From products of these reactions of the unattached acyl-coenzymes A, it could be inferred that the normal enzymatic reaction proceeds through a covalent citryl intermediate in the sequence

$$\text{E·CoAS-acetyl} + \text{citrate} \rightleftharpoons \text{E·CoAS-citryl} + \text{acetate} \qquad (5\text{–}17)$$

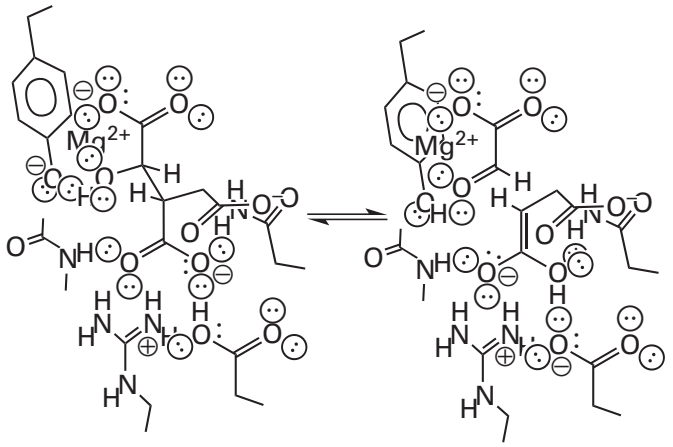
$$\text{E·CoAS-citryl} \rightleftharpoons \text{E·CoAS-acetyl} + \text{oxaloacetate} \qquad (5\text{–}18)$$

where E-CoASH is the prosthetic coenzyme A covalently attached to the enzyme. The advantage of forming the citryl thioester in Equation 5–17 is obvious because the carbon–carbon bond cleaved or formed during the retro-Claisen or Claisen condensation, respectively (Equation 5–18 in the respective direction), is weakened considerably (Figure 1–23).

In both the fatty-acid synthase system and citrate (*pro*-3*S*)-lyase, active sites that have covalently bound 4′-phosphopantetheinyl groups (**5–15**), the respective sulfanyl groups are used to provide the intermediate thioesters for the respective Claisen condensations. That this might be only marginally advantageous is suggested by the fact that isocitrate lyase, which also catalyzes a similar aldol condensation

$$\text{glyoxylate} + \text{succinate} \rightleftharpoons \text{isocitrate} \qquad (5\text{–}19)$$

proceeds without forming any thioesters.[100] In this instance, a *gem*-enediolate must be formed from the unesterified carboxy group of the isocitrate that is adjacent to the carbon–carbon bond to be cleaved. In the active site of isocitrate lyase from *M. tuberculosis* occupied by isocitrate, the incipient *gem*-enediolate is firmly hydronated by the carboxy group of a glutamate during the cleavage of that carbon–carbon bond. The two peripheral nitrogen–hydrogen bonds of the guanidinio group of an arginine and an amido nitrogen–hydrogen from the polypeptide form an oxyanion hole for the other oxygen. These groups, as well as the carbamoyl group of an asparagine, stabilize the *gem*-enediol, 4,4-dihydroxy-3-butenoate, that is the noncovalent intermediate in the reaction as its monoanionic *gem*-enediolate[101]



(5–20)

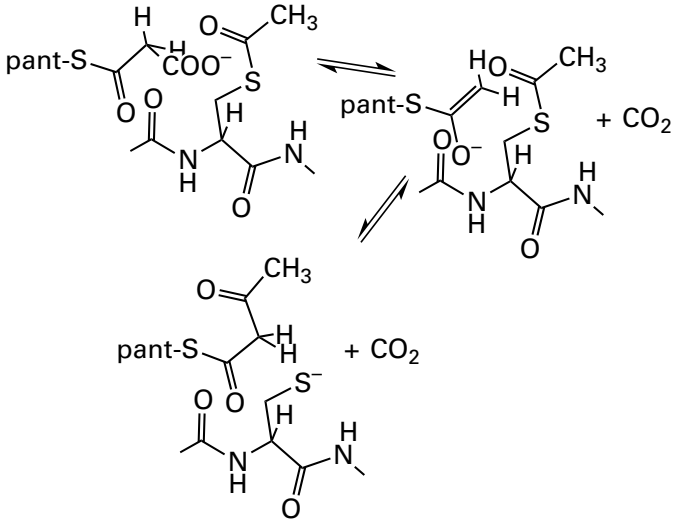
The hydroxy group of the isocitrate, which is a ligand to a Mg^{2+}, is dehydronated by a tyrosinate as the bond cleaves. Carbon 2 of the *gem*-enediolate is then hydronated by the hydroxy group of a serine (0.29 nm) that relays, through a molecule of water, a hydron from a histidine.[102] As with the endopeptidases, these two different examples of aldol condensations illustrate the fact that **different strategies**

involving different intermediates are often used by enzymes to catalyze the same reaction.

The fatty-acid synthase system (see Equations 3–492 through 3–499)

$$\text{acetyl-SCoA} + n\,\text{malonyl-SCoA} + 2n\,\text{NADPH} + (3n-1)\text{H}^+ \rightleftharpoons 2n\,\text{NADP}^+ + n\,\text{CO}_2 + (n+1)\text{HSCoA} + \text{CH}_3(\text{CH}_2\text{CH}_2)_n\text{COO}^- \quad (5\text{–}21)$$

is a multienzymatic complex, within which the active site of 3-oxoacyl-[acyl-carrier-protein] synthase catalyzes the Claisen condensation (see Equation 3–495)



(5–22)

that initiates the synthesis of a fatty acid. The malonyl group is a thioester of a 4′-phosphopantetheinyl group (HS-pant; **5–15**) covalently attached directly (rather than indirectly) through its 4′-phospho group in a phosphodiester to a serine located in the acyl-carrier domain of the multienzymatic complex, which is a homologue of the independent acyl-carrier proteins found in the cytoplasm of prokaryotes and plants.[103] The serine to which the 4′-phosphopantetheinyl group is attached was identified by isolating a [^{14}C]palmitoyl-4′-phosphopantetheinyl peptide from the fatty-acid synthase system from *Saccharomyces cerevisiae* that had been mixed with [^{14}C]palmitoyl-SCoA.[104] The acetyl group with which the enol is condensed during the first round in the synthesis of a fatty acid is also bound as a thioester, but it is bound to the sulfanyl group of a cysteine in the active site of 3-oxoacyl-[acyl-carrier-protein] synthase.

Both the acetyl group and the malonyl group, the enolate of which is the eventual nucleophile, arrive initially at the respective active sites of [acyl-carrier-protein] *S*-acetyltransferase (see Equation 3–492)

$$\text{CH}_3\text{CSCoA} + \text{HS-pant} \rightleftharpoons \text{HSCoA} + \text{CH}_3\text{CS-pant} \quad (5\text{–}23)$$

and [acyl-carrier-protein] *S*-malonyltransferase (see Equation 3–493)

$$^-\text{OOCCH}_2\text{CSCoA} + \text{HS-pant} \rightleftharpoons \text{HSCoA} + {}^-\text{OOCCH}_2\text{CS-pant} \quad (5\text{–}24)$$

in the fatty-acid synthase system as thioesters of coenzyme A. Again, HS-pant indicates a 4′-phosphopantetheinyl group in the same acyl-carrier domain.

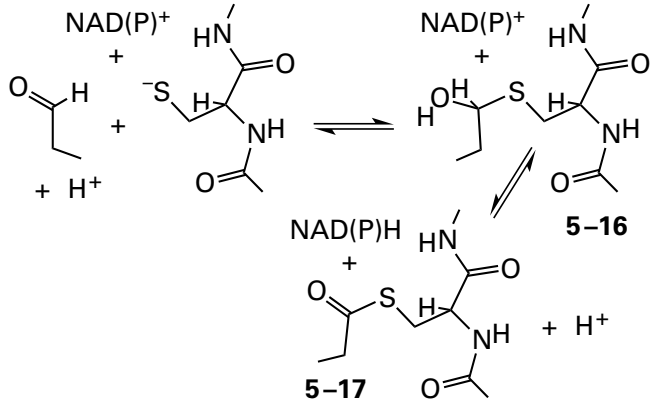
The transfer of the two groups to their respective locations for subsequent condensation within the active site of 3-oxoacyl-[acyl-carrier-protein] synthase (Equation 5–22) is not direct; the two groups pass through a sequence of other covalent intermediates, each formed by a nucleophilic substitution of one heteroatom for another heteroatom at an acyl group. In the fatty-acid synthase system from *S. cerevisiae*, the acetyl group of acetyl-SCoA is transferred first to a serine to form an *O*-acetylserine[105] in the active site of [acyl-carrier-protein] *S*-acetyltransferase (Equation 5–23), then to the sulfanyl group of the 4′-phosphopantetheinyl group in the acyl-carrier-protein domain to form a thioester again, and then from that sulfanyl group to the sulfanyl group of the cysteine in the active site of 3-oxoacyl-[acyl-carrier-protein] synthase to situate it for the Claisen condensation. The malonyl group of malonyl-SCoA is transferred first to a serine to form an ***O*-malonylserine**[106] in the active site of [acyl-carrier-protein] *S*-malonyltransferase (Equation 5–24) and then to the sulfanyl group of the 4′-phosphopantetheinyl group in the same acyl-carrier domain to form the necessary thioester that becomes the enolate within the active site of 3-oxoacyl-[acyl-carrier-protein] synthase that is the nucleophile in the Claisen condensation.

The two respective serines that pass on the acetyl group and the malonyl group to the sulfanyl group of the 4′-phosphopantetheinyl group in [acyl-

carrier-protein] *S*-acetyltransferase and [acyl-carrier-protein] *S*-malonyltransferase were identified by alkylating all accessible sulfanyl groups in the fatty-acid synthase system to prevent subsequent transfers, forming the esters with [^{14}C]acetyl-SCoA or [^{14}C]malonyl-SCoA, and isolating and sequencing the two unique peptides containing the respective esters.[105,106] The cysteine that holds the acetyl group during the condensation in the active site of 3-oxoacyl-[acyl-carrier-protein] synthase (Equation 5–22) was identified by its high reactivity to iodoacetamide and by subsequent isolation of the peptide modified by [^{14}C]iodoacetamide.[107]

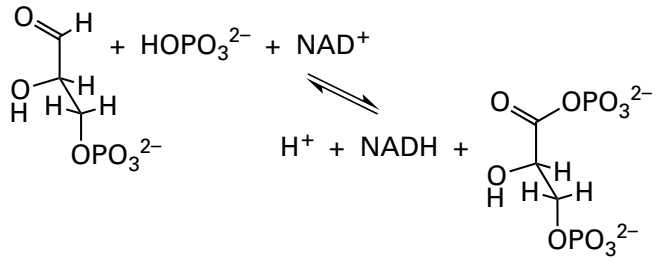
The sequence of events just described, however, has one drawback. If a malonyl group arrives first, its occupation of the sulfanyl group of the 4′-phosphopantetheinyl group on the sole acyl-carrier domain would block the transfer of the acetyl group to the sulfanyl group of the cysteine in the active site of 3-oxoacyl-[acyl-carrier-protein] synthase. For this reason, the presence of free coenzyme A is an absolute requirement for synthesis of a fatty acid by the fatty-acid synthase system. In its absence, the multienzymatic complex rapidly becomes occupied by malonyl groups, which cannot be removed because the reverse reaction is blocked, and the acetyl groups cannot be transferred onto the active site.[108] Consequently, the reversibility of the malonyl transfer and the presence of coenzyme A, the malonyl acceptor, permits the proper order of transfer to occur.

Thiohemiacetals are covalent intermediates in enzymatic oxidation–reductions. In such oxidation–reductions, thiohemiacetals are precursors to thioesters. For example, during the oxidation of aldehydes, *S*-(1-hydroxyalkyl)cysteines (**5–16**) are formed in an active site



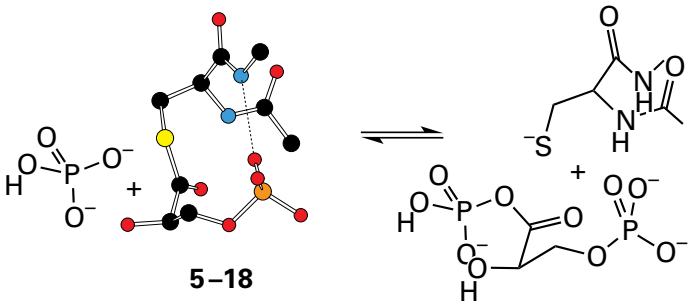
(5–25)

and their existence is inferred from the chemical or crystallographic identification of the more stable *S*-acylcysteine (**5–17**). In the oxidation–reduction (previously Equation 4–349)



(5–26)

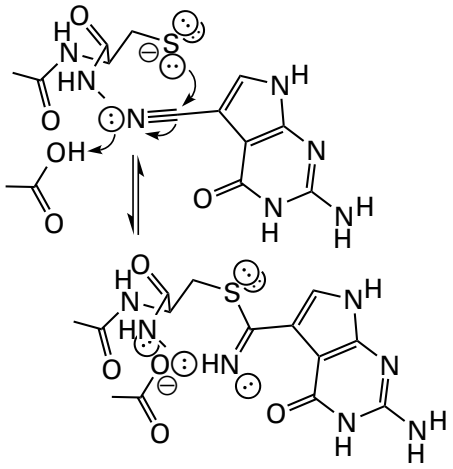
catalyzed by glyceraldehyde-3-phosphate dehydrogenase (phosphorylating), a 3-phospho-D-glyceroyl thioester[109] is phosphorylyzed to produce 3-phospho-D-glyceroyl phosphate



(5–27)

Acetylphosphate acetylates Cysteine 149 of the enzyme from *O. cuniculus* and is reduced by the enzyme to acetaldehyde, a reaction homologous to the normal reduction of 3-phospho-D-glyceroyl phosphate (reverse of Equation 5–26).[110,111] The peptide acetylated with [1-^{14}C]acetylphosphate was purified and sequenced to identify Cysteine 149 as the site of the modification. A crystallographic molecular model of the authentic 3-phospho-D-glyceroyl thioester intermediate (**5–18**) for glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) from *G. stearothermophilus* (54 % identity; 1.2 gap percent) demonstrated the existence of the thioacylation and identified the cysteine homologous to Cysteine 149 in the enzyme from *O. cuniculus* as the site of acylation.[109] In the case of aspartate-semialdehyde dehydrogenase from *E. coli*, an enzyme homologous to glyceraldehyde-3-phosphate dehydrogenase (phosphorylating),[112] the β-aspartyl thioester of the homologous cysteine has also been observed crystallographically.[113]

In reduction of the cyano group of 7-cyano-7-deazaguanine by preQ$_1$ synthase from *Bacillus subtilis*, a thioimidate is formed as a covalent intermediate by nucleophilic addition of the sulfido group of Cysteine 55 to the cyano group



(5–28)

The **thioimidate** is then reduced by NADPH to the thiohemiaminal in the usual addition of a hydride to its imino group. The resulting **thiohemiaminal** then dissociates from the sulfur of Cysteine 55 to give the imine, which is reduced to the amine by a second NADPH. The intermediate thioimidate (Equation 5–28) has been observed in a crystallographic molecular model of the enzyme that was crystallized in the presence of 7-cyano-7-deazaguanine but in the absence of NADPH.[114] The hydron required for the nucleophilic addition to avoid an anionic nitrogen is provided by Aspartate 62, which forms a hydrogen bond (0.31 nm) with the nitrogen of the thioimidate in the crystallographic molecular model. When reduction of 7-cyano-7-deazaguanine is being catalyzed by a mutant of preQ$_1$ synthase from *E. coli* (26% identity; 1.9 gap percent), the intermediate imine that results from reduction of the thioimidate and dissociation of the sulfido group from the thiohemiaminal and that is a noncovalent intermediate in the normal reaction is released into the solution, and the aldehyde that is the product of its hydrolysis could be identified by nuclear magnetic resonance spectroscopy.[115]

The active site of UDP-glucose dehydrogenase

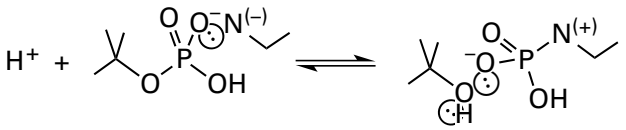
$$2\,NAD^+ + \text{UDP-}\alpha\text{-D-glucose} + H_2O \rightleftharpoons \text{UDP-}\alpha\text{-D-glucuronate} + 2\,NADH + 3\,H^+ \quad (5\text{–}29)$$

catalyzes two successive oxidations of carbon 6 of the glucosyl group in UDP-α-D-glucose. The first oxidation turns UDP-α-D-glucose into the aldehyde UDP-α-6-oxo-6-deoxy-D-glucose. The sulfanyl group of a cysteine in the active site then forms a thiohemiacetal with the carbonyl at carbon 6, which is oxidized to the thioester at carbon 6 of the glucuronyl group by the second NAD$^+$. The thioester is then hydrolyzed to give UDP-α-D-glucuronate. The nucleophilic cysteine that forms the thiohemiacetal and the subsequent thioester in the active site of UDP-glucose dehydrogenase from *Streptococcus pyogenes* was mutated to serine so that the seryl ester of UDP-α-D-glucuronic acid—rather than the cysteinyl ester, which was unstable—could be isolated in a peptic peptide from the UDP-α-D-glucuronyl enzyme.[116] The actual thiohemiacetal has also been observed crystallographically in a mutant of human UDP-glucose dehydrogenase, lacking its carboxy-terminal 27 amino acids, in which Glutamate 161 was mutated to glutamine to decrease the rate at which the thiohemiacetal of UDP-α-6-oxo-6-deoxy-D-glucose was oxidized to the thioester.[117] The intermediate thiohemiacetal of this mutant was also identified by mass spectrometry. The intact mutant enzymes—both unoccupied and containing the covalent intermediate thiohemiacetal in the active site—were in turn submitted to electrospray ionization mass spectrometry. The molecular mass of the unoccupied mutant was 52,019.3 Da, and the molecular mass of the covalent intermediate of the mutant enzyme was 52,581.6 Da. The molecular mass of UDP-α-6-oxo-6-deoxy-D-glucose, the intermediate aldehyde, is 564.3 Da, which should be equal to the increase in molecular mass upon formation of the hemiacetal.

What happens to the structure of a protein such as UDP-glucose dehydrogenase upon atomization in the gas phase of the mass spectrometer is unknown. The fact that the molecular mass of the unmodified protein observed in the mass spectrometer was 52,019.3 Da, together with the fact that the molecular mass of the protein calculated from its sequence of amino acids is 52,019.6 Da, confirms that all the water associated with the native protein definitely does dissociate in the vacuum. It has always been assumed that other noncovalently associated ligands, including inorganic ions, dissociate in the vacuum as well, which also seems to be confirmed in this case. That UDP-glucose dehydrogenase in the gas phase is dehydrated and unliganded also suggests that it no longer assumes its native tertiary structure because if it did, buried molecules of water and

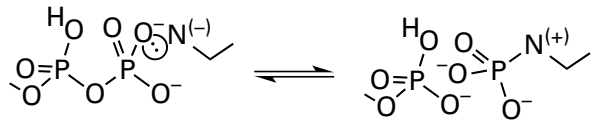
buried adventitious ions would probably remain. The fact that the molecular mass observed for the covalent thiohemiacetal is within the molecular mass of two hydrons of that expected seems to confirm that the covalent intermediate is the actual vaporized molecule being detected by the spectrometer. It also demonstrates that the thiohemiacetal, which would rapidly hydrolyze were the molecule of protein to unfold while still in an aqueous solution, nevertheless does not hydrolyze upon atomization in the electrospray.

Phosphate esters, phosphoanhydrides, or phosphoramidates of amino acids are covalent intermediates in the active sites of enzymes that perform nucleophilic substitutions at phosphorus. These are usually formed by a nucleophilic substitution of the bridging oxygen in a phosphoric ester



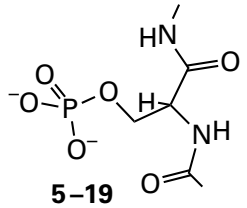
(5–30)

or the bridging oxygen in a phosphoanhydride

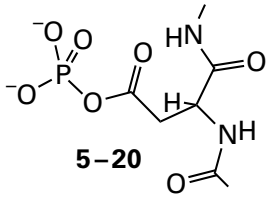


(5–31)

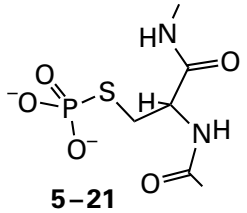
by a nucleophile, ⊙N$^{(-)}$–, in the active site to form a **phosphorylated intermediate**. Examples of such phosphorylated intermediates are ***O*$^{\beta}$-phosphoserine (5–19), *O*$^{\beta}$-phosphoaspartate (5–20), *O*$^{\gamma}$-phosphoglutamate, *S*-phosphocysteine (5–21) *N*$^{\tau}$-phosphohistidine, or *N*$^{\pi}$-phosphohistidine (5–22)**



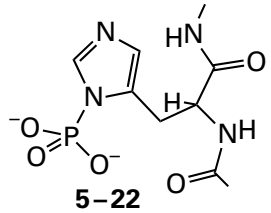
5–19



5–20



5–21



5–22

One advantage of such a phosphorylated intermediate is that the same catalytic groups in the active site that are used to activate the phospho donor by acid–base catalysis can serve to activate the phospho acceptor in an identical, but reciprocal, manner. For example, in the reaction catalyzed by nucleoside-diphosphate kinase (previously Equation 4–286)

$$MgXTP^{2-} + MgYDP^{-} \rightleftharpoons MgXDP^{-} + MgYTP^{2-} \qquad (5–32)$$

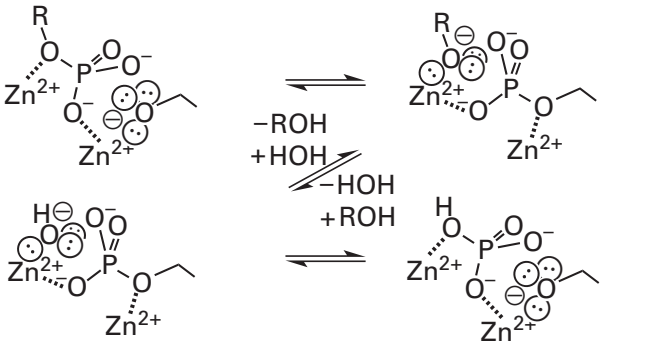
in which X and Y represent different nitrogenous bases, the oxygens acting as phosphate donor and phosphate acceptor are chemically identical because both are the most distal oxygens in a nucleoside diphosphate. As a result, the enzymatic reaction can proceed through a phosphorylated intermediate,[118] formed by transfer of a phosphate from a nucleoside triphosphate to an amino acid in the active site to produce its nucleoside diphosphate and unformed by transfer of the phosphate to the other nucleoside diphosphate to produce the other nucleoside triphosphate. By remaining in the active site as the phosphorylated intermediate, the free energy of hydrolysis of the phosphoanhydride of the nucleoside triphosphate can be retained to facilitate transfer to the acceptor.

Because nucleoside-diphosphate kinase is only marginally selective as to the nucleotide, it must recognize mainly the complex between magnesium and the triphosphate (see Figure 4–52) and carbons 3′ through 5′ of the ribose or deoxyribose. This intuition is validated in crystallographic molecular models[119,120] of the enzyme from *Dictyostelium discoideum* in complexes with MgADP^{-} and MgTDP^{-}. The ribose rings and the $Mg(H_2O)_4$ diphospho groups in the two complexes are caught firmly in a web of hydrogen bonds deep in the active site. The web is formed from the same donors and acceptors, which donate and accept at the same locations in the substrates. The adenine and thymine bases, however, are near the opening of the active site with their π systems stacked against the π system of the same phenylalanine, but they participate in no hydrogen bonds with the enzyme that might distinguish between them.

If the mechanism for nucleoside-diphosphate kinase is the one just described, then the donor of the phospho group must dissociate from the active site as MgXDP^{-}, an irreversible step during measurement of the initial rate for the enzymatic reaction, before the acceptor is bound as MgYDP^{-}. This

sequence of events is consistent with the fact that steady-state kinetics of the enzymatic reaction display the behavior of Equation 5–6, which is that expected for a ping-pong mechanism.[121] The steady-state kinetics are chemical evidence consistent with a phosphorylated intermediate.

In the reaction catalyzed by alkaline phosphatase (previously Equation 4–452)



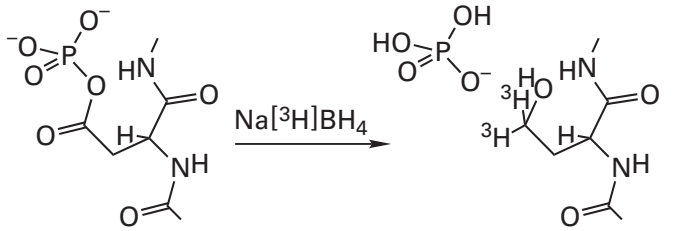
(5–33)

the various donors of the phospho group that can be substrates for the enzyme and the water that is the usual acceptor may not resemble each other at first glance, but they are all alcohols. The crystallographic molecular model suggests that only the phospho ester itself forms contacts with the active site to be activated by catalytic acids and bases.[122] For this reason, the enzyme has a broad specificity for phosphate monoesters, and it is not surprising that there is a phosphorylated intermediate in this enzymatic reaction. The fact that the reaction proceeds with retention of configuration at phosphorus is consistent with the existence of a phosphorylated intermediate.[123]

Demonstration of the existence of phosphorylated intermediates in enzymatic reactions usually begins with the observation that [^{32}P]phosphate is transferred from the substrate that is a phospho donor in the reaction to the enzyme itself to form a **covalently [^{32}P]phosphorylated protein**. The phosphoamino acid formed in this transfer can sometimes be identified directly by hydrolyzing the modified protein and isolating the covalently modified amino acid. For example, succinate-CoA ligase (ADP-forming) from *E. coli* proceeds through a phosphorylated intermediate,[124] and the [^{32}P]phosphate incorporated during this reaction into the bovine enzyme was isolated as N^{τ}-phospho-L-histidine after alkaline hydrolysis or enzymatic digestion of the protein.[125] The phosphorylated intermediate in the reaction catalyzed by nucleoside-diphosphate kinases (Equation 5–32) from both *Bos taurus* and *S. cerevisiae* has been identified in the same way as N^{π}-phospho-L-histidine (**5–22**).[118,126] In these two instances, the phosphorylation occurred exclusively at the τ nitrogen and the π nitrogen, respectively, as would be expected from the regioselectivity usually displayed by active sites.

The phosphorylated protein formed as an intermediate in the reaction catalyzed by alkaline phosphatase from *E. coli* has been digested with pepsin at low pH, to prevent alkaline hydrolysis, and an analysis of the resulting peptides showed that the phosphate is covalently attached to Serine 102, the first serine in the sequence TGKPDYVTDSAASA.[127] When Serine 102 is mutated to alanine, the enzymatic activity decreases by a factor of 100,000.[128]

The phosphorylated intermediate in the enzymatic reaction catalyzed by P-type Ca^{2+} transporter [129] from *O. cuniculus* has been identified indirectly as O^{γ}-phosphoaspartate (**5–20**) by reducing it to [^{3}H]homoserine with sodium [^{3}H]borohydride



(5–34)

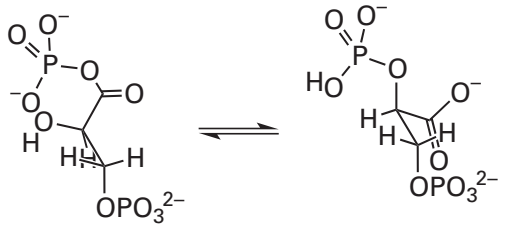
and isolating the [^{3}H]homoserine produced upon hydrolysis of the polypeptide in acid.[130]

The phosphorylated intermediate in the enzymatic reaction catalyzed by enzyme II of the phosphotransferase system from *E. coli* has been identified as an *S*-phosphocysteine (**5–21**) both by isolation of the phosphopeptide and by analysis with nuclear magnetic resonance spectroscopy.[131]

Phosphorylated intermediates have also been **observed crystallographically**. For example, N^{τ}-phosphohistidine in the active site of succinate-CoA ligase (ADP-forming) from *E. coli*,[132] N^{π}-phosphohistidine (**5–22**) in the active sites of the nucleoside-diphosphate kinases from *D. discoideum* and *Drosophila melanogaster*,[133] N^{τ}-phosphohistidine in phospholipase D from *Streptomyces*,[134] N^{τ}-phosphohistidine in fructose-2,6-bisphosphate 2-phosphatase from *R. norvegicus*,[135] and N^{τ}-phosphohistidine in human bisphosphoglycerate mutase[136] have all been captured crystallographically. The O^{β}-phosphoseryl intermediate (**5–19**) in alkaline phosphatase from *E. coli* has been observed in the active site of a crystallographic molecular model of a mutant in

which Histidine 331 has been mutated to glutamine to decrease the rate of its dephosphorylation.[137] The O^{γ}-phosphoaspartyl intermediate in histidinol-phosphatase from *E. coli* has been observed crystallographically in the active site of the enzyme in which Ca^{2+} replaces the required Mg^{2+} to decrease its rate of dephosphorylation.[138] The *S*-phospho-cysteinyl intermediate[139] in human protein-tyrosine-phosphatase has been observed crystallographically in a mutant in which Glutamine 262 has been mutated to alanine to decrease the rate of its dephosphorylation.[140]

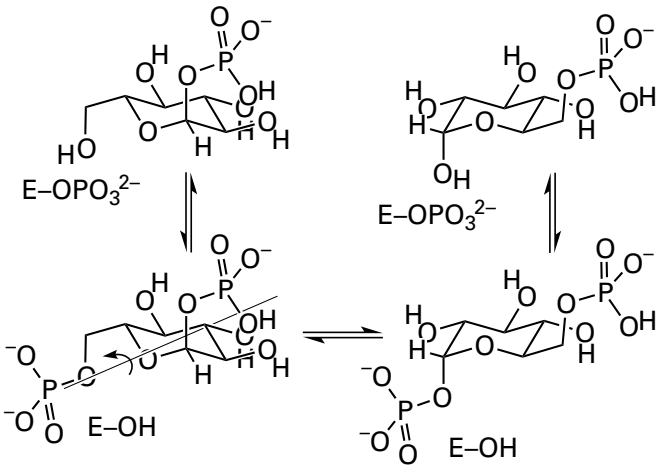
Bisphosphoglycerate mutase catalyzes the transfer of the 1-phospho group of 3-phospho-D-glyceroyl phosphate to its 2-hydroxy group



(5–35)

The phosphorylated intermediate in the reaction is an N^{τ}-phosphohistidine. Either substrate, 3-phospho-D-glyceroyl phosphate or 2,3-diphospho-D-glycerate, can phosphorylate the imidazolyl group.[141] Within the active site, the 3-phospho group of the intermediate 3-phospho-D-glycerate that results from either nucleophilic substitution is anchored firmly in a cup of seven donors of hydrogen bonds.[136] The carboxyhydroxymethyl group of the 3-phospho-D-glycerate can pivot around this anchor along the bond between carbons 2 and 3 (as in Equation 5–35) so that the phospho group can be transferred from the N^{τ}-phosphohistidine to the carboxy group or the hydroxy group to complete the reaction.

Phosphoglucomutase (α-D-glucose-1,6-bisphosphate-dependent) catalyzes the transfer of the 1-phospho group of α-D-glucose 1-phosphate to its 6-hydroxy group[142]



(5–36)

The phosphorylated intermediate ($E–OPO_3^{2-}$) is an O^{β}-phosphoserine (**5–19**) in the active site, which is roughly isoergonic with the phospho groups on carbons 1 and 6. The same phosphorylated enzyme[143] acts on the two monophospho substrates, turning each into the intermediate, α-D-glucose 1,6-bisphosphate, by transferring its phospho group to either the unphosphorylated 6-hydroxy group of α-D-glucose 1-phosphate or the unphosphorylated 1-hydroxy group of D-glucose 6-phosphate, respectively.[144] The intermediate α-D-glucose 1,6-bisphosphate, although occasionally dissociating, usually flips over (around the axis indicated in Equation 5–36) while enclosed tightly within the active site, and then it transfers the other phospho group back to the enzyme, after which the respective monophospho product dissociates.[145]

β-Phosphoglucomutase catalyzes the transfer of the 1-phospho group of β-D-glucose-1-phosphate to its 6-hydroxy group, rather than the 1-phospho group of α-D-glucose 1-phosphate, as was the case with phosphoglucomutase (α-D-glucose-1,6-bisphosphate-dependent). The phosphorylated intermediate in this instance is an O^{γ}-phosphoaspartate even though there seems to be little difference in the enzymatic reaction catalyzed by it and the one catalyzed by phosphoglucomutase (α-D-glucose-1,6-bisphosphate-dependent). β-D-Glucose 1,6-bisphosphate is produced from either β-D-glucose 1-phosphate or D-glucose 6-bisphosphate by the phosphorylated enzyme, but because the active site is open to the solution,[146] the β-D-glucose 1,6-bisphosphate usually dissociates completely and rebinds in the opposite orientation rather than flipping over in the active site to transfer the other phosphate back to the enzyme to complete the reaction.[147]

In the case of phosphoglucomutase (α-D-glucose-1,6-bisphosphate-dependent), the intermediate α-D-glucose 1,6-bisphosphate slowly dissociates from the active site as the reaction progresses, inactivating the enzyme, so a reliable concentration of α-D-glucose 1,6-bisphosphate in the solution is maintained by glucose-1,6-bisphosphate synthase. Because β-D-glucose 1,6-bisphosphate normally dissociates from the active site of β-phosphoglucomutase, the enzyme itself maintains an equilibrium concentration of the intermediate in the solution.

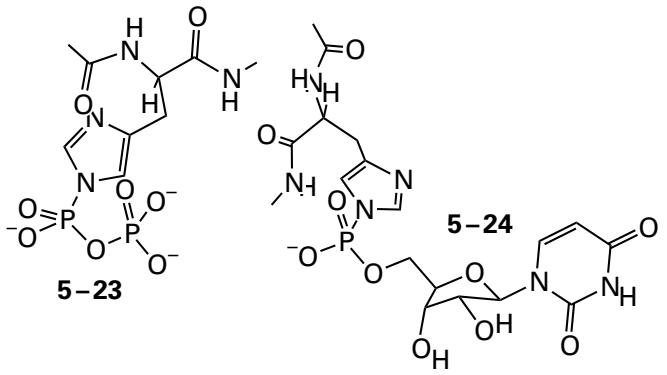
The N^{τ}-phosphohistidinyl intermediate in equine bisphosphoglycerate mutase was identified by isolating a tryptic [^{32}P]phosphorylated peptide.[148] The O^{β}-phosphoseryl intermediate[149] in phosphoglucomutase from *O. cuniculus* was identified by isolating a [^{32}P]phosphorylated peptide from a partial acid hydrolysis of the enzyme.[150] The O^{γ}-phosphoaspartyl intermediate in β-phosphoglucomutase from *Lactococcus lactis* was observed in a crystallographic molecular model of the enzyme.[146]

As was noted earlier, the **stereochemistry** of an enzymatic reaction can also be consistent with the existence of a covalent phosphorylated intermediate.[151] If the overall enzymatic reaction is observed to proceed with inversion of configuration at the phosphorus that is transferred, this observation is consistent with direct in-line transfer between donor and acceptor without the involvement of a phosphorylated intermediate. If the overall reaction is observed to proceed with **retention of configuration at phosphorus**, this is consistent with two successive phosphotransfers both taking place with inversion, one from donor to enzyme and the other from enzyme to acceptor.

There are also phosphorylated intermediates formed from substituted phospho groups. A phosphorylated intermediate[152] in the reaction catalyzed by pyruvate, phosphate dikinase from *Clostridium symbiosum* (previously Equation 3–500)

$$\text{phospho}\textit{enol}\text{pyruvate} + MgOPO_3PO_3^{2-} + 2\,H^+ + AMP^{2-} \rightleftharpoons MgATP^{2-} + HOPO_3^{2-} + \text{pyruvate} \quad (5\text{–}37)$$

is an ***N*$^{\tau}$-diphosphohistidine** (**5–23**)[153,154]

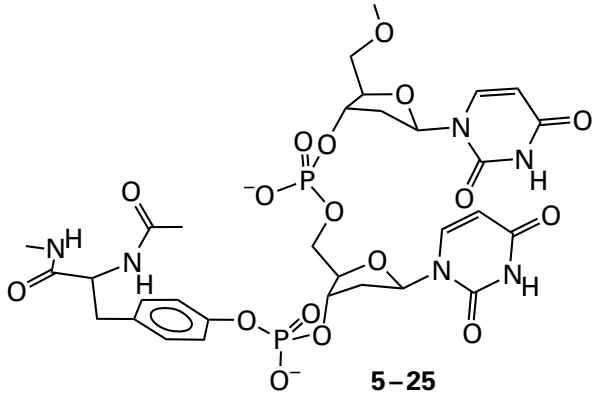


The phosphorylated intermediate in UDP-glucose—hexose-1-phosphate uridylyltransferase

$$\text{UDP-}\alpha\text{-D-glucose} + \alpha\text{-D-galactose 1-phosphate} \rightleftharpoons \alpha\text{-D-glucose 1-phosphate} + \text{UDP-}\alpha\text{-D-galactose} \quad (5\text{–}38)$$

from *E. coli* is an ***N*$^{\tau}$-uridylylhistidine** (**5–24**), the existence of which was confirmed crystallographically[155] after the modified histidine had been identified chemically.[156,157] There is an ***N*$^{\tau}$-adenylylhistidinyl intermediate**, which was identified crystallographically, in the reaction catalyzed by ADP-glucose phosphorylase from *Arabidopsis thaliana*.[158] The existence of the **guanylylhistidinyl intermediate** in the reaction catalyzed by GDP-L-galactose phosphorylase from *A. thaliana*[159] was inferred from electrospray ionization mass spectrometry. In this case, the observed molecular mass of the enzyme increased from 53,107 Da to 53,451 Da upon formation of the intermediate, a difference (345 Da) that is within a hydron of the molecular mass of guanosine monophosphate minus the molecular mass of a molecule of water.

When a type I topoisomerase cleaves one of the two strands of double-helical DNA to permit supercoiling to be relieved, the 3′-phospho group on the 5′ end produced by the cleavage remains as a covalent ***O*^{4}-(3′-phosphopolynucleotidyl)tyrosinyl intermediate**[160]



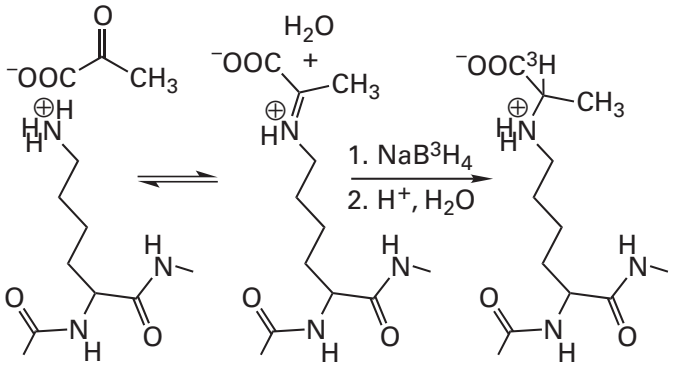
5–25

which has been isolated in a peptide containing the modified tyrosine from topoisomerase I from *S. cerevisiae*[161] and observed crystallographically in a complex between DNA and the active site of human topoisomerase I.[162] This covalent intermediate preserves the free energy of the phospho ester that was in the DNA so that the 3′-phospho group can be rejoined to the 5′-hydroxy group on the 3′ fragment to reconstruct the intact DNA after the supercoiling has been relaxed.

Type II topoisomerase relieves or promotes supercoiling by breaking the two strands of the DNA simultaneously, leaving the two broken strands as O^4-(3′-phosphopolynucleotidyl)tyrosinyl intermediates. The enzyme from *S. cerevisiae* is an α_2 homodimer, so each strand that has been broken ends up with its 5′ end covalently attached to one of the two Tyrosines 782 from the two subunits. The O^4-(3′-phosphopolynucleotidyl)tyrosinyl intermediate has been isolated on a peptide derived from trypsin digestion of topoisomerase II from *S. cerevisiae*,[163] and it has also been observed in a crystallographic molecular model of a complex of topoisomerase II from *S. cerevisiae* and DNA.[164] The two sites of single-strand cleavages on opposite strands of the DNA are immediately adjacent to the crystallographic twofold rotational axis of symmetry in the α_2 homodimer so that there are only four base pairs in the DNA between them.[165] After both covalent intermediates are formed to create the two nearby breaks, there is a conformational change in the protein that dissociates the interface in the α_2 homodimer at which the cleavage has occurred, separating the two ends of the broken DNA and creating a space between them large enough for a portion of the intact, double-helical DNA distant from the site of cleavage to pass through the vacancy.[166-168] The two strands are then rejoined, again taking advantage of the fact that the covalent intermediate has preserved the free energy of the phospho ester.

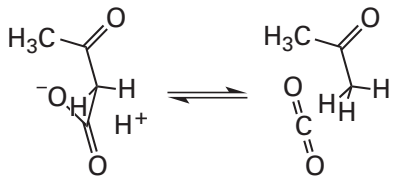
In the recombinases, there are also covalent phosphotyrosyl intermediates that conserve the free energy of the cleaved phosphodiester after each strand of DNA is severed, but they are formed with phospho groups on the 3′ ends of the strands rather than the 5′ ends.[169]

Lysyliminiums are covalent intermediates in enzymatic aldol condensations, Claisen condensations, dehydrations,[170] and decarboxylations. Covalent ester, thioester, and phosphorylated intermediates are usually stable enough to be identified directly, but lysyliminiums are covalent intermediates that must be **trapped by chemical conversion to a stable species**. Lysyliminiums are usually trapped by reduction. For example, tritium is incorporated into 2-dehydro-3-deoxyphosphogluconate aldolase from *Pseudomonas fluorescens* upon reduction of the intermediate lysyliminium of pyruvate[171] with $Na[^3H]BH_4$ (previously Equation 4–325)



(5–39)

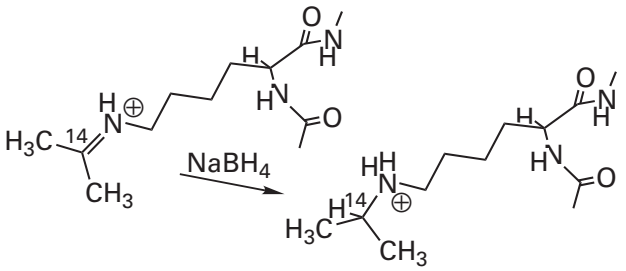
Acetoacetate decarboxylase catalyzes the exchange of one electrophile for another, carbon dioxide for a hydron, at an acidic carbon[172]



(5–40)

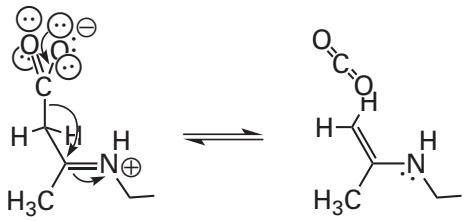
When [3-^{14}C]acetoacetate was mixed with the enzyme from *Clostridium acetobutylicum* in the presence of $NaBH_4$, radioactivity was incorporated into the protein in a reduction analogous to that of the intermediate in 2-dehydro-3-deoxyphosphogluconate aldolase (Equation 5–39). The radioactively modified acetoacetate decarboxylase was digested with trypsin, and the radioactive peptide ELSAYPK([^{14}C]isopropyl)K, in which the radioactive modification was

N^6-[^{14}C]isopropyllysine, was isolated and sequenced.[173] From this observation, it was concluded that the covalent intermediate trapped by **reduction with sodium borohydride** was the lysyliminium between Lysine 115 and acetone



(5–41)

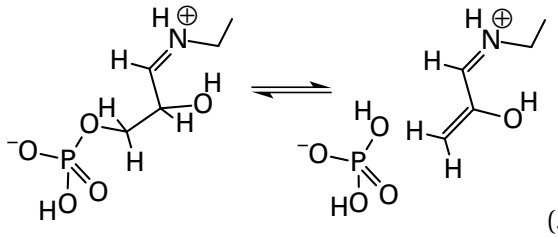
This conclusion is consistent with a mechanism in which the lysyliminium of acetoacetate is formed in the active site to expedite the decarboxylation



(5–42)

In a crystallographic molecular model of the complex between the enzyme and pentane-2,4-dione, a homologue of acetoacetate in which the carboxy group that would be decarboxylated is replaced by a methyl group, the carbon–carbon bond homologous to the one broken in the normal reaction is positioned by the active site parallel to the π molecular orbital system of the lysyliminium.[172] The enzyme uses the π system of the iminium cation to withdraw electron density from the carbon–carbon σ bond (Equation 5–42).

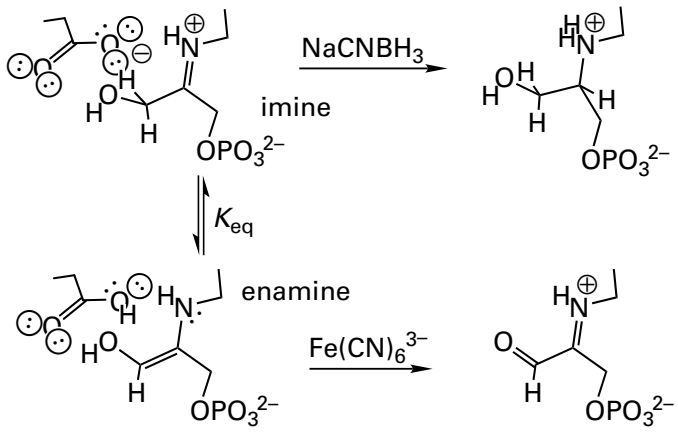
Mutants of (5-formylfuran-3-yl)methyl phosphate synthase from *Methanocaldococcus jannaschii* that decrease its overall activity, so that intermediates accumulate, were mixed with its substrate, D-glyceraldehyde 3-phosphate. The mixture was reduced with $NaBH_4$ and digested with trypsin, and the resulting **peptides** were submitted to mass spectrometry. In the mass spectrum, there was a peptide that had the mass expected of the tryptic peptide containing Lysine 27 of the enzyme that had been covalently modified at its 6-amino group so that the trypsin was unable to hydrolyze the peptide bond at that location. The modification increased the mass of this peptide and fragments of the peptide containing Lysine 27 by 58 Da, which is the mass of an additional C_3OH_6. This increase is the additional mass expected for the product of reduction by borohydride of the lysyliminium resulting from the α,β-elimination of a phosphate from the lysyliminium of glyceraldehyde 3-phosphate



(5–43)

These results from **mass spectrometry** are evidence for the lysyliminium being the initial covalent intermediate in the enzymatic reaction.[174] The lysyliminium accelerates elimination of phosphate to form the enol, which then adds to the carbonyl of the glycerone phosphate that is the second substrate in the reaction that eventually produces (5-formylfuran-3-yl)methyl phosphate.

Both reduction of the lysyliminium in 2-dehydro-3-deoxyphosphogluconate aldolase (Equation 5–39) and reduction of the lysyliminium in acetoacetate decarboxylase (Equation 5–41) were based on earlier observations with fructose-bisphosphate aldolase in which a very similar lysyliminium between a lysine in the active site and glycerone phosphate (Figure 4–36) had been trapped with sodium borohydride.[175,176] When fructose-bisphosphate aldolase from *O. cuniculus* is mixed with glycerone phosphate, a tautomeric equilibrium is established on the active site between the lysyliminium and the lysylenamine that are both covalent intermediates in the enzymatic reaction[176]



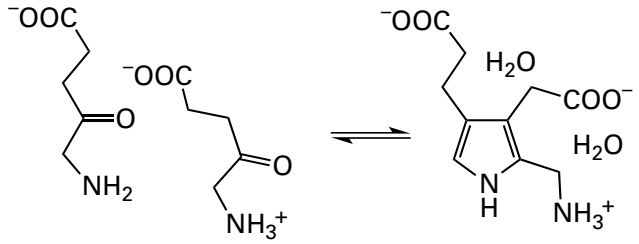
(5–44)

The enzyme could be denatured rapidly in acid, and the **lysylenamine could be trapped by oxidation**,

either with tetranitromethane[177] or with ferricyanide, or the lysyliminium could be trapped with sodium cyanoborohydride.[178] In this way, the equilibrium constant for the tautomerization within the active site ($K_{eq} = 3$) could be ascertained.

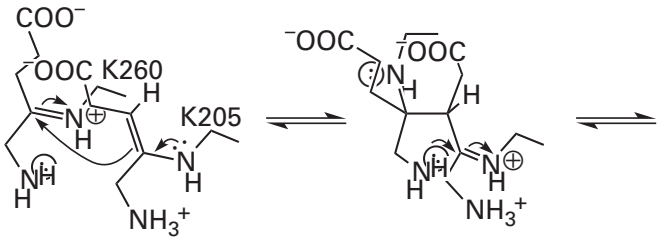
Crystallographic molecular models of the lysyliminium intermediates in fructose-bisphosphate aldolase have been presented. When crystals of the enzyme from *O. cuniculus* were suspended in 10 mM D-fructose 1,6-bisphosphate for 3 min and then rapidly frozen, the iminium intermediate of D-fructose 1,6-bisphosphate was captured at equilibrium in the active site (Figure 5–3).[179-182] The carbon–carbon bond weakened by the iminium is held by the active site so that it is parallel to its π system. When Lysine 146, which shuttles a hydron from the 4-hydroxy group of D-fructose 1,6-bisphosphate to carbon 3 of the enamine of glycerone phosphate, was mutated to alanine, the turnover number of the enzyme decreased 30,000-fold.[183] When crystals of the enzyme were suspended for 2 min in 1 mM glycerone phosphate and then rapidly frozen, the lysylenamine of glycerone phosphate (Equation 5–44) was observed in the active site of the crystallographic molecular model.[179] When a similar experiment, however, was performed with crystals of 2-dehydro-3-deoxyphosphogluconate aldolase from *E. coli*, an equilibrium mixture of the lysylhemiaminal and the lysyliminium and water was observed in the active site.[184]

Porphobilinogen synthase catalyzes the condensation of two α-amino ketones to form a pyrrole



(5–45)

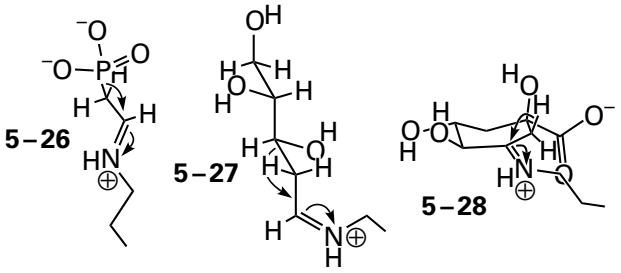
In the active site of the enzyme from *P. aeruginosa*, Lysines 205 and 260 are adjacent to each other,[185] and in a crystallographic molecular model of a mutant in which Aspartate 139 has been changed to asparagine to decrease the catalytic constant of the enzyme, the two reactants, both 5-aminolevulinates, occupy these two lysines as the respective lysyliminiums.[186] The enamine of the lysyliminium of Lysine 205 condenses with the iminium carbon of the lysyliminium of Lysine 260, followed by addition of the amino group of the lysyliminium of Lysine 260 to the lysyliminium of Lysine 205



(5–46)

to form the 2,4-diaminopyrrolidine in which the amino groups at carbons 2 and 4 are the amino groups of the two lysines. Two successive eliminations of the amino groups of these two lysines end up aromatizing the pyrrolidine to the pyrrole and simultaneously releasing the ring from the two lysines.

As was the case with (5-formylfuran-3-yl)methyl phosphate synthase, lysyliminium **5–26** that weakens the carbon–phosphorus bond



in the active site of phosphonoacetaldehyde hydrolase from *Bacillus cereus* has been trapped by reduction with [^{3}H]$NaBH_4$, and a tryptic peptide has been isolated that contains the resulting N^6-[^{3}H]ethyllysine, which is the product of reduction by [^{3}H]BH_4^- of the N^6-vinyllysine formed by dissociation of the monomeric metaphosphate.[187] This same *N*-ethyllysine has also been observed crystallographically.[188] Both lysyliminium **5–27,** which weakens the carbon–carbon bond in 2-deoxy-D-ribose 5-phosphate in the active site of deoxyribose-phosphate aldolase from *E. coli*, and the hemiaminal that precedes lysyliminium **5–27** in the mechanism of the reaction have been observed crystallographically.[189]

Lysyliminium **5–28**,[190] which results from the nucleophilic substitution of the amino group of a lysine in the active site of 3-dehydroquinate dehydratase for the carbonyl oxygen at carbon 3 of the substrate 3-dehydroquinate, weakens the adjacent carbon–hydrogen bond so that it can be removed as a

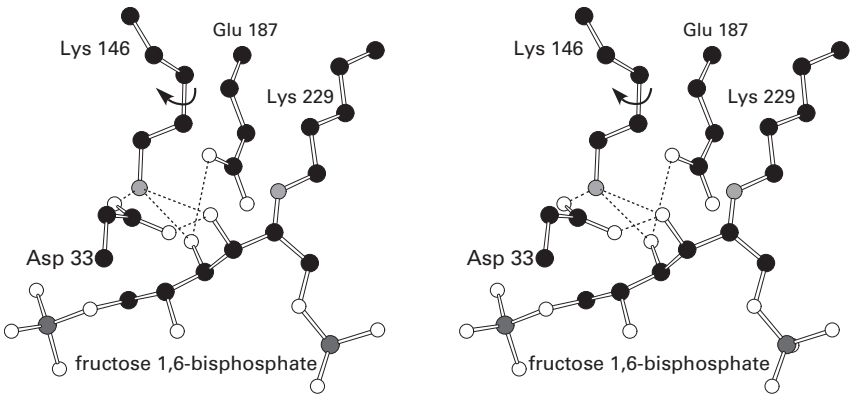


Figure 5–3: Stereodrawing[181] of a crystallographic molecular model of the active site of fructose-bisphosphate aldolase from *O. cuniculus* occupied by D-fructose 1,6-bisphosphate.[179] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large dark gray atoms are atoms of phosphorus. Crystals of fructose-bisphosphate aldolase from *O. cuniculus*, which had been expressed in *E. coli*, were soaked for 3 min in a solution containing 10 mM D-fructose 1,6-bisphosphate and then quickly frozen. In the map of electron density, there was a feature that could unambiguously be accounted for as the iminium adduct between a molecule of D-fructose 1,6-bisphosphate and the 6-amino group of Lysine 229. The bond between carbons 3 and 4 of D-fructose 1,6-bisphosphate in this adduct is held by the active site so that it is parallel to the π system of the iminium cation that is withdrawing its electron density. The 3-hydroxy and 4-hydroxy groups of D-fructose 1,6-bisphosphate form a network of hydrogen bonds with the side chains of Aspartate 33, Lysine 146, and Glutamate 187. During the reaction, the 6-amino group of Lysine 146 removes the hydron from the 4-hydroxy group as it becomes the carbonyl of glyceraldehyde 3-phosphate while the bond between carbons 3 and 4 is broken. Lysine 146 then pivots about the bond between its γ and δ carbons to align its now 6-ammonio group to hydronate carbon 3 of the enamine that eventually becomes glycerone phosphate. The enzymatic reaction proceeds with retention of configuration at carbon 3 of D-fructose 1,6-bisphosphate.[182]

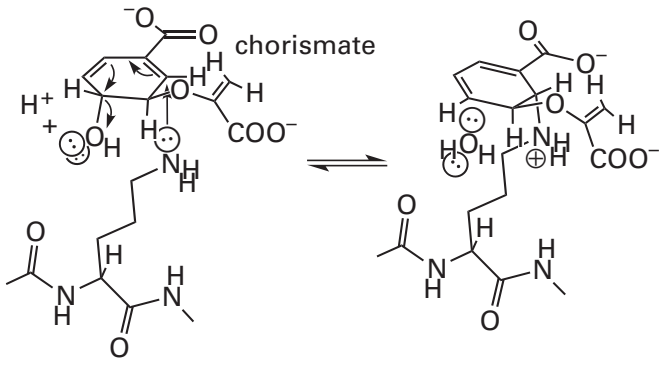
hydron to initiate the dehydration of 3-dehydroquinate. Evidence for the existence of lysyliminium **5–28** was provided by mass spectrometry. 3-Dehydroquinate dehydratase from *E. coli* was mixed with the reactant 3-dehydroquinate and then immediately injected into an electrospray mass spectrometer. A component with a mass of 27,618 mass units, which is 151 mass units greater than the observed mass of the unliganded enzyme (27,467 mass units), was detected in the mass spectrum.[191] This increase is within two hydrons of the mass expected for the lysyliminium of the product of dehydration, 3-dehydroshikimate (molar mass 171 g mol^{-1}). When the lysyliminium forms, the other product is a molecule of water (molar mass 18 g mol^{-1}) containing the oxygen of the original carbonyl group of 3-dehydroshikimate. The lysyliminium with the lysine before the dehydration has been observed in the active site of a crystallographic molecular model of 3-dehydroquinate dehydratase from *Salmonella enterica* in a complex with the substrate 3-dehydroquinate, and the lysyliminium with the lysine in the active site following the dehydration has been observed in the crystallographic molecular model of 3-dehydroquinate dehydratase from *Clostridioides difficile* in a complex with 3-dehydroshikimate.[192] In the crystallographic molecular models of the complexes between the active site of 3-dehydroquinate dehydratase from *E. coli* and either quinate or shikimate,[193] the analogues of the respective substrates that have hydroxy groups at carbon 3, rather than carbonyl groups at which addition of the amino group of the lysine would occur, the distances between the respective carbons 3 and the amino groups of the same lysines in each model are each only 0.36 nm.

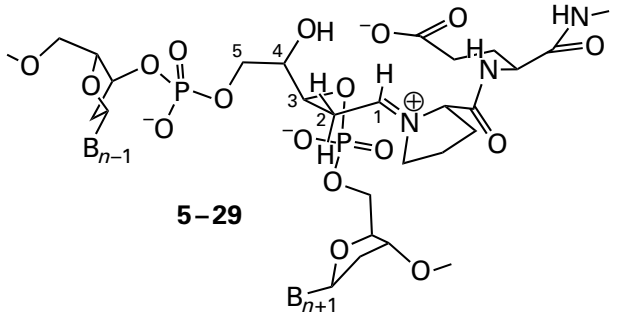
Mass spectrometry was also used to identify a covalent intermediate in the nucleophilic substitution catalyzed by aminodeoxychorismate synthase from *E. coli* (52,984 mass units) When the enzyme was mixed with the substrate chorismate (225 g mol^{-1}) in the absence of L-glutamine, the source of the ammonia in the nucleophilic substitution of an amino group for a hydroxy group catalyzed by the enzyme, a new peak of 53,192 mass units was observed in the mass spectrum of the enzyme,[194] consistent with the existence of the covalent intermediate formed between chorismate and Lysine 274 in the active site



(5–47)

Nucleophilic addition of ammonia to carbon 4 of this adduct from which a molecule of water has just left would give, in reverse, 4-amino-4-deoxychorismate, the normal product in this enzymatic reaction.

The central covalent intermediate in the enzymatic reaction catalyzed by DNA-formamidopyrimidine glycosylase, which has been observed crystallographically within the active site of the enzyme from *Thermus thermophilus*,[195] is a **prolyliminium** formed with the amino-terminal proline of the protein

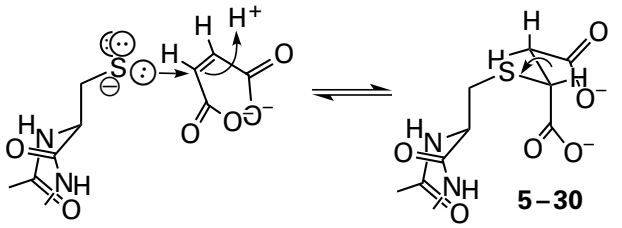


5–29

where B_{n+1} and B_{n-1} are the bases in the DNA on the deoxyriboses that precede and follow the deoxyribose at which the enzyme cleaves the strand of DNA, and the carbons in that deoxyribose are numbered.* The advantage of a prolyliminium is that it does not need to retain a hydron to be cationic and hence more electrophilic. This intermediate then participates in a β-elimination of the 5′-phospho group at carbon 3, followed by a δ-elimination of the 3′-phospho group at carbon 5. The two eliminations cleave the strand of DNA, and they leave clean 5′ and 3′ phosphorylated ends. The other product is the prolylimine of 2,4-hydroxypenta-2,4-dienal.

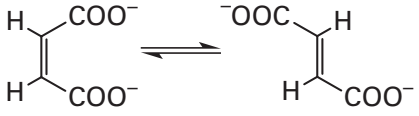
*The central deoxyribose ring has been opened at the glycosidic carbon during the formation of the imine.

Addition of the sulfido group of a cysteine to the β carbon in an α,β-unsaturated carbonyl or acyl derivative produces in one step a covalently bound enolate. A covalent intermediate, **2-(cysteinyl)-butanedioate** (**5–30**), is formed between Cysteine 76 and maleate



(5–48)

in the active site of maleate isomerase



(5–49)

from *Nocardia farcinica*. The initial step in formation of adduct **5–30** is the direct formation of the *gem*-enediolate at the carbon adjacent to the one to which the sulfido group adds. The *gem*-enediolate would then be hydronated on the α carbon either during or after its formation. The resulting 2-(cysteinyl)-butanedioate (**5–30**), an unprecedented intermediate, was discovered in the crystallographic map of electron density (Figure 5–4)[196] for a mutant of the enzyme in which Cysteine 194, a catalytic acid in the enzymatic reaction, was converted to an alanine and that had been crystallized in a solution of 50 mM maleate. It is formed in a Michael addition of the sulfanyl group of Cysteine 76 to one or the other of the α,β-unsaturated carboxylic acids that are substrates for the enzyme. The purpose of the adduct is to break the double bond in either maleate or fumarate and permit a rotation about the now single bond (indicated by the arrow in covalent intermediate **5–30**). Consequently, when the sulfanyl group of the cysteine leaves in a retro-Michael addition, either maleate [(*Z*)-but-2-enedioate] or fumarate [(*E*)-but-2-enedioate] is produced on the active site. In the Michael adduct observed in the crystallographic molecular model (Figure 5–4), the dihedral angle along the central carbon–carbon bond is almost exactly halfway between the dihedral angle for the *Z*-configuration and the one for the *E*-configuration of the respective substrates.

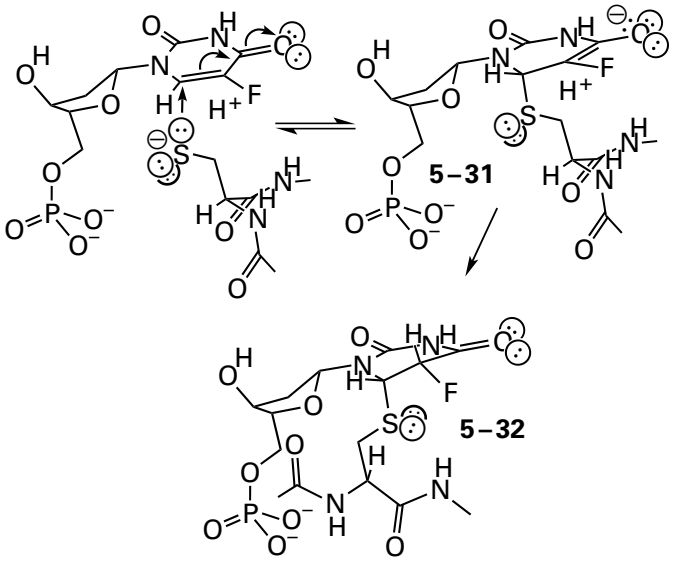
Thymidylate synthase is responsible for providing the methyl group on thymidine (previously Equation 3–535)

5,10-methylenetetrahydrofolate + dUMP $\rightleftharpoons$ dTMP + 7,8-dihydrofolate

(5–50)

where dUMP is 2′-deoxyuridine 5′-monophosphate and dTMP is thymidine 5′-monophosphate. During this reaction, the methylene carbon of 5,10-methylenetetrahydrofolate, an electrophile, becomes the methyl group of dTMP, in a substitution for the hydron at carbon 5 of the uracil in dUMP, which is also an electrophile. Thymidylate synthase is an excellent example of the array of chemical transformations that an active site can apply consecutively to the same covalent intermediate and the **evidence that can be assembled to validate such a multistep mechanism**. Support for the existence of each of the several covalent intermediates in the reaction has been provided either chemically or crystallographically or by both procedures.

Thymidylate synthase is covalently inactivated[197,198] by 2′-deoxy-5-fluorouridine 5′-monophosphate in a reaction involving nucleophilic addition of the sulfido group of a cysteine in the active site of the enzyme to carbon 6 in the α,β-unsaturated *N*-carbamoylcarbamoyl group of 2′-deoxy-5-fluorouridine 5′-monophosphate[199]



(5–51)

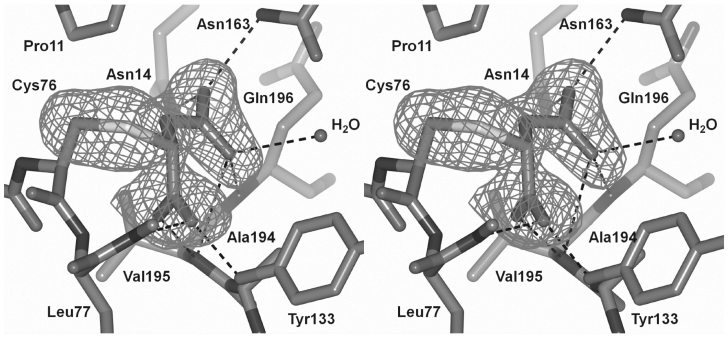


Figure 5–4: Crystallographic molecular model of the active site of maleate isomerase from *N. farcinica* occupied by the covalent intermediate that results from nucleophilic addition of the sulfanyl group of Cysteine 76.[196] An almost completely inactive mutant of the enzyme, in which Cysteine 194 had been mutated to alanine, was crystallized from a solution containing 50 mM maleate. In the resulting map of electron density, there was a feature immediately adjacent to the sulfanyl group of Cysteine 76 that was consistent with the nucleophilic adduct of that sulfanyl group with the carbon–carbon double bond of maleate. Because the 4-carboxy group of the adduct was held in the active site in the same plane as the bond between carbons 2 and 3, the adduct could have been the *gem*-enediolate or the hydronated *gem*-enediolate. A model of *S*-[(2*R*)-succinyl]cysteine was inserted into the map of electron density in place of Cysteine 76, and the resulting crystallographic molecular model was submitted to refinement. As the refinement converged, the succinyl group and the side chain of Cysteine 76 were removed from the model, and the final rounds of refinement were performed to produce the omit map of electron density drawn in the figure. The omit map of electron density is superposed on the refined structure from which the succinate and the side chain were not removed. Reprinted with permission from reference 196. The cysteine that forms covalently bound enolate **5–31**, Cysteine 198 in the enzyme from *Lactobacillus casei*, was identified by isolating and sequencing a cyanogen bromide fragment from a sample of the enzyme that had been covalently modified by 2′-deoxy-[2-^{14}C]-5-fluorouridine 5′-monophosphate.[200] In the process of digestion and isolation of the peptide, enolate **5–31** is hydronated and stabilized as adduct **5–32**, which is the product of a Michael addition of the sulfanyl group of the cysteine to the α,β-unsaturated acyl group in the substrate. It is assumed that, during the normal reaction, the same cysteine also adds in the same manner to carbon 6 of the natural reactant, dUMP, to produce the homologous enolate (**5–31** with H in place of F) of the homologous *N*-carbamoylamide. The normal reaction, however, immediately proceeds to completion for two reasons: first, there is not a fluorine at carbon 5 in dUMP strongly withdrawing electron density, as there is in enolate **5–31**, and second, in the 2′-deoxyuridine 5′-monophosphate there is not a fluorine taking the place of the hydrogen on carbon 5, which is removed as a hydron in the later steps of the reaction.

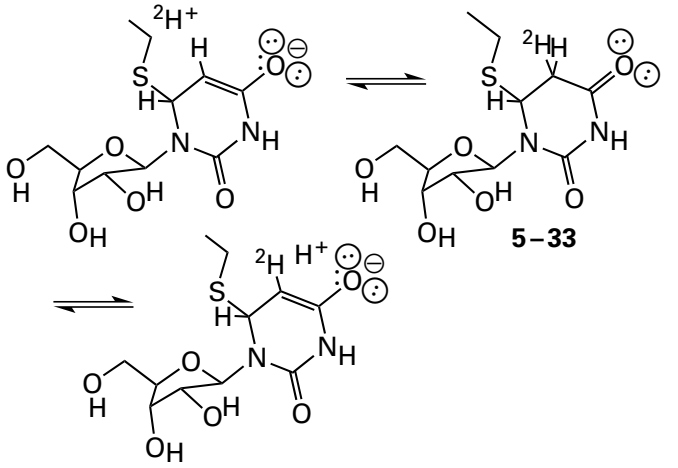
The advantage of this nucleophilic addition in the normal reaction is to turn carbon 5 in the uracil in one step into the carbanionic carbon of an enolate. This enolate is the conjugate base of an *N*-carbamoylamide (see Equation 5–51). That formation of the covalent intermediate leads to a dramatic increase in the basicity of carbon 5 has been demonstrated in a model system by noting the appearance of hydrogen exchange at carbon 5 of uridine upon addition of thiols[201]



(5–52)

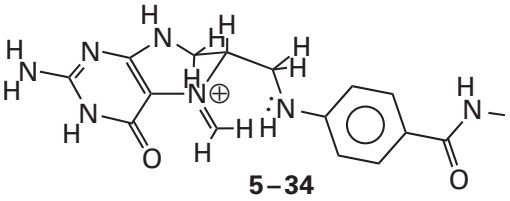
as would be expected for the α-position of saturated *N*-carbamoylamide **5–33**.

The enolate of the normal substrate, dUMP, has been observed in several crystallographic molecular models of the active site of thymidylate synthase from *E. coli* (60% identity; 0.4 gap percent) in which either inactive analogues of 5,10-methylenetetrahydrofolate are also occupying the active site or the enzyme had been mutated to decrease its catalytic constant.[202-204]

On the basis of all these observations, it can be concluded that addition of the cysteine to carbon 6 of dUMP produces the respective enolate (**5–31** with H in place of F or Equation 5–52 with deoxyribose in place of ribose) in the active site as the **first covalent intermediate** in the normal mechanism.

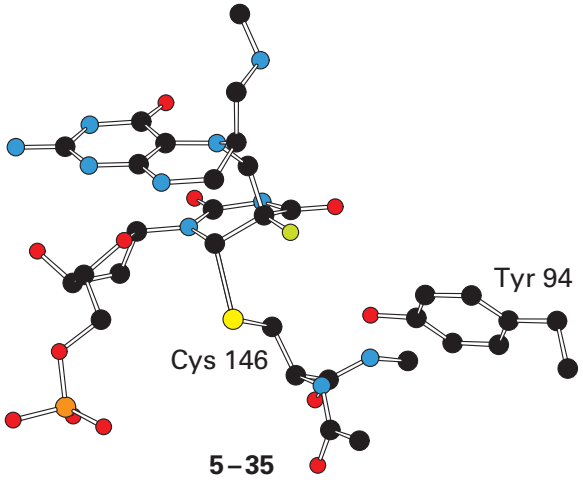
In crystallographic molecular models, this enolate, formed by addition of the sulfanyl group of the homologous Cysteine 146 to dUMP in the active site of the enzyme from *E. coli*, is stabilized in an oxyanion hole formed by an amido nitrogen–hydrogen of the side chain of Asparagine 177 and a molecule of water relaying the acidity of Glutamic Acid 58.[202-208] When the homologous asparagine in the enzyme from *L. casei* is mutated to serine,[199] the rate constant $k_0\,(K_{m,dUMP})^{-1}\,(K_{m,mTHF})^{-1}$ for the enzyme, where mTHF is 5,10-methylenetetrahydrofolate, decreases by a factor of 4000, and when the homologous glutamate in the enzyme from *L . casei* is mutated to alanine, the rate constant $k_0\,(K_{m,dUMP})^{-1}\,(K_{m,mTHF})^{-1}$ decreases by a factor of 10^6. The exchange of tritium at carbon 5 of dUMP, however, relative to the rate of thymidylate synthesis increases by a factor of 20.[209] This last observation suggests that the enzymatic reaction has been blocked because the enolate is not properly stabilized so that it cannot rapidly participate in the next step of the reaction and so that the resulting *N*-carbamoylamide (**5–32** with H replacing F or **5–33** with deoxyribose in place of ribose) can participate only in hydrogen exchange (Equation 5–52). Consistent with this explanation is the fact that one of the main effects of mutation of the glutamate is a decrease in the rate of the nucleophilic addition of this enolate that occurs in the next step of the enzymatic reaction.[210]

In the crystallographic map of electron density[208,211] for the complex formed between thymidylate synthase of *E. coli* and 2′-deoxy-5-fluorouridine 5′-monophosphate and 5,10-methylenetetrahydrofolate, both the covalent bond formed between Cysteine 146 from the active site and carbon 6 of 5-fluorouracil (**5–31**) and a new covalent bond between the methylene carbon of N^5-methylenetetrahydrofolate (previously **1–82**)



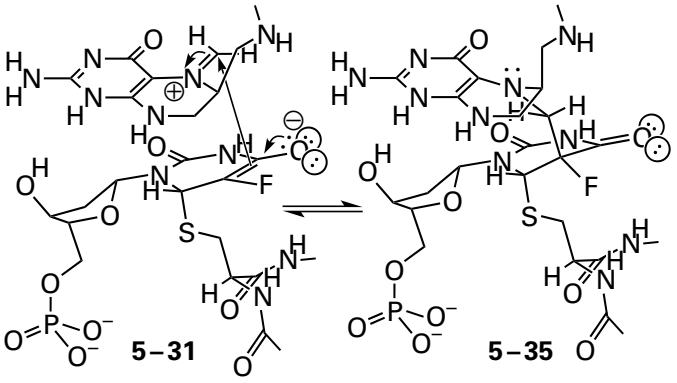
5–34

and carbon 5 of 5-fluorouracil are observed



5–35

This **second covalent intermediate** is formed by nucleophilic addition of enolate **5–31** to the electrophilic methylene carbon in N^5-methylenetetrahydrofolate

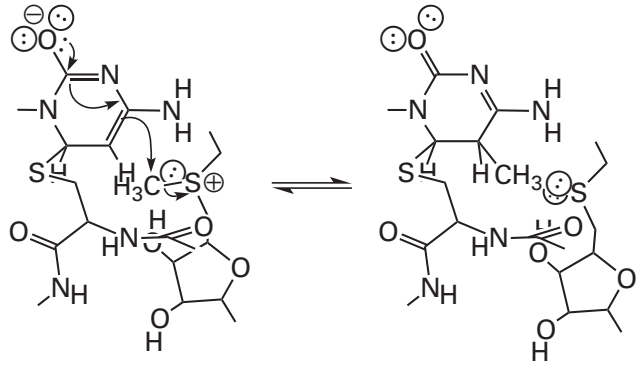


5–31 **5–35**

(5–53)

which is formed from 5,10-methylenetetrahydrofolate by the usual dissociation of nitrogen 10. This crystallographic molecular model of the unnatural intermediate **5–35** verifies the capacity of the normal covalent, intermediate enolate (**5–31** with H in place of F) formed from the cysteine and 2′-deoxyuridine 5′-monophosphate to function as an enolate, as well as the ability of that enolate in the active site to add to the 5-methyleneiminium in N^5-methylenetetrahydrofolate to form adduct **5–36** (Figure 5–5) during the normal enzymatic reaction. If anything, the substitution of that hydrogen with a fluorine should hinder this nucleophilic addition because of the electron withdrawal from the enolate caused by fluorine, yet it does not.

A covalent, intermediate enolate, analogous to enolate **5–31**, the first covalent intermediate of the reaction catalyzed by thymidylate synthase, forms between a cytosine in DNA and a cysteine in the active site of DNA (cytosine-5-)-methyltransferase from *Haemophilus parahaemolyticus*.[212] In this case, however, the covalent, intermediate enolate is methylated in a concerted nucleophilic substitution at carbanionic carbon 5 of this adduct of cytosine by *S*-adenosyl-L-methionine



(5–54)

rather than indirectly by 5,10-methylenetetrahydrofolate. This reaction illustrates the nucleophilicity of the intermediate enolate.

An analogous enolate is also formed between carbon 6 in a uracil in tRNA and a cysteine in the active site of methylenetetrahydrofolate—tRNA-(uracil^{54}-C^5)-methyltransferase [NAD(P)H-oxidizing] from *B. subtilis*. The ultimate source of the methyl group in this case is N^5-methylenetetrahydrofolate, but the methylene at carbon 5 of N^5-methylenetetrahydrofolate is first transferred to nitrogen 5 of the prosthetic flavin in the active site of the enzyme, a transfer of a methylene group from one anilino nitrogen to another, where it ends up as a methylene group between nitrogen 5 of the flavin and the sulfanyl group of a cysteine in the active site, before being transferred to carbon 5 of the uracil in the tRNA.[213]

The **fourth covalent intermediate*** in the normal reaction of thymidylate synthase is the exocyclic methylene at carbon 5 of the original uracil in dUMP (**5–38**), which is formed by an elimination (Figure 5–5) in the first step of which the hydrogen on

*This intermediate, the fourth, is presented before the third because its existence, which has been proven, is evidence for the existence of **5–37**, the third intermediate.

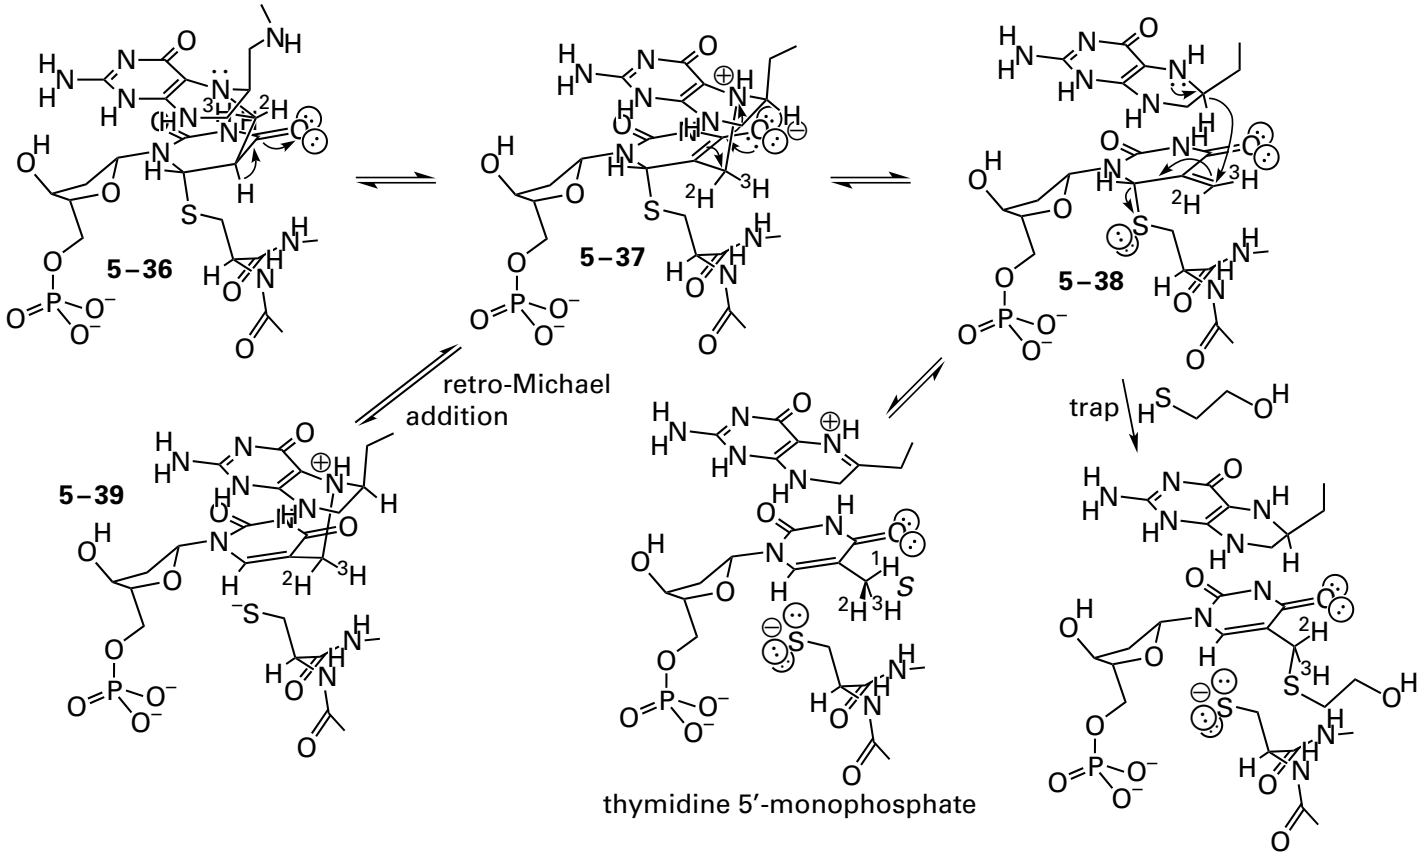


Figure 5–5: Final steps in the mechanism of the reaction catalyzed by thymidylate synthase. The ternary complex **5–36** formed from Cysteine 146, 2′-deoxyuridine 5′-phosphate, and 5,10-methylenetetrahydrofolate is dehydronated at carbon 5 of the former uracil, which is adjacent to the carbamoyl group at carbon 4, and nitrogen 5 of the tetrahydrofolate is hydronated to produce enolate **5–37**. This tautomerization producing enolate **5–37** sets up the elimination that produces exocyclic olefin **5–38** of the uracil. A hydride is transferred from tetrahydrofolate to this exocyclic olefin to produce the enolate, which then undergoes a elimination of cysteine in a step producing the 5-methyluracil (thymine) in the product, thymidine 5′-phosphate. There are two side reactions along the main path. First, thioether **5–37** may dissociate in a retro-Michael addition into the thiolate and adduct **5–39**, but that would decrease dramatically the elimination of the tetrahydrofolate from adduct **5–39** because the enolate would be lost. Second, α,β-unsaturated ketone **5–38** can be trapped with 2-sulfanylethanol.

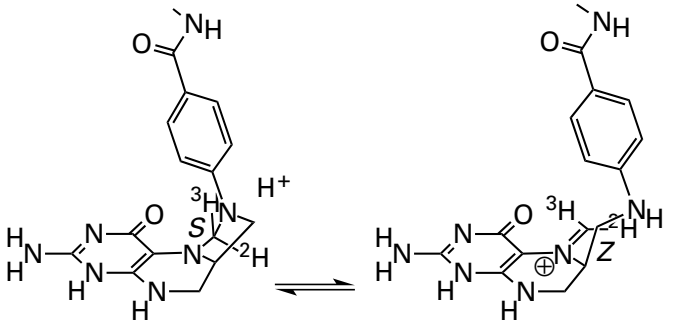
carbon 5 is removed as a hydron by the 4-hydroxyphenyl group of Tyrosine 94 (see **5–35**). In the crystallographic molecular models[208,211] of the ternary complex **5–35** formed between Cysteine 146 in the active site of thymidylate synthase from *E. coli* and 2′-deoxy-5-fluorouridine 5′-phosphate and N^5-methylenetetrahydrofolate, the complex has the stereochemistry expected for the immediate product of addition of the enolate (Equation 5–53).* The bond just formed between the methylene carbon and carbon 5 of the uracil in dUMP is parallel to the π system of the acyl group at carbon 4 of the uracil, and the new carbon–carbon bond is antiperiplanar to the lone pair of electrons on nitrogen 5 of tetrahydrofolate. For removal of the hydron, however, from carbon 5 by the 4-hydroxyphenyl group of Tyrosine 94 that initiates the elimination leading to the exocyclic methylene (Figure 5–5), the bond to the hydrogen on carbon 5 of the original uracil (the bond to the fluorine in **5–35**) must be parallel to the π system of the acyl group at carbon 4 of the intermediate.[211] This orientation can be achieved in the boat conformation of the ring of the original uracil (compare the conformation of the ring of the original uracil at carbon 5 in **5–35** with its conformation in **5–36**). Following removal of the hydron

*The carbon–sulfur bond (0.216 nm rather than 0.19 nm) is stretched in the crystallographic molecular model of adduct **5–35,** perhaps because of a steric effect resulting from the fact that the hydroxy group of Tyrosine 94 is pushing up on the fluorine (van der Waals radius of 0.15 nm) of **5–35** (0.32 nm). This steric effect is probably much less in the actual intermediate in which there is a hydron (van der Waals radius of 0.115 nm) rather than a fluorine on carbon 5, so in the actual intermediate in the active site, the carbon–sulfur bond could well be unstretched.

on carbon 5 by Tyrosine 194, the bond to nitrogen 5 of tetrahydrofolate, which is now parallel to the π system of enolate **5–37**, which is the **third covalent intermediate** in the reaction, is broken in the elimination* to give the exocyclic methylene in **5–38**.

Aside from these electronic considerations, the intermediacy of enolate **5–37**, which has not been observed crystallographically, is also consistent with the known stereochemistry of the reaction. (6*R*,11*S*)-[11-^{3}H,11-^{2}H]-5,10-Methylenetetrahydrofolate produces (5*S*)-[5-^{3}H,5-^{2}H]thymidine monophosphate.[214,215] Because (6*R*,11*S*)-[11-^{3}H,11-^{2}H]-5,10-methylenetetrahydrofolate has the 11*S* conformation, when the 5-methyleneiminium cation is formed from (6*R*,11*S*)-[11-^{3}H,11-^{2}H]-5,10-methylenetetrahydrofolate, it will be the *Z* isomer[215]



(5–55)

This isomer would produce (Equation 5–53) adduct **5–36** with the noted stereochemistry (Figure 5–5).[211] Upon isomerization, elimination, and direct intramolecular hydride transfer[216,217] from carbon 6 of tetrahydrofolate, which must occur from above in orientation **5–38**, the (*S*)-[^{3}H,^{2}H]methyl group would be generated.

Further evidence for existence of covalent intermediate **5–37** has been provided by chemical synthesis. In intermediate enolate **5–37**, the sulfur of the sulfanyl group of the cysteine in the active site is situated in an electronically equivalent location to nitrogen 5 of tetrahydrofolate because the bond between the original carbon 6 of the uracil in dUMP and this sulfur is parallel to the π molecular orbital system of the enolate, as is the bond between the exocyclic methylene and nitrogen 5 of tetrahydrofolate. Consequently, it would be surprising if the sulfur were not also prone to elimination, just as is nitrogen 5 of tetrahydrofolate, to give intermediate **5–39**. Intermediate **5–39** is no longer a covalent intermediate, and it should be able to leave and enter the active site from the solution. In fact, intermediate **5–39** has been synthesized and shown to be a kinetically competent precursor to 5,10-methylenetetrahydrofolate and dUMP and to tetrahydrofolate and dTMP.[218] Intermediate **5–39** has a catalytic constant that is twice that for the reactants 5,10-methylenetetrahydrofolate and dUMP.

When thymidylate synthase from *E. coli* is in the process of catalyzing the methylation of dUMP, the reaction is quenched with hydrochloric acid, and the quenched solution is submitted to chromatography, intermediate **5–39** is one product of the quench.[219] It has been proposed that intermediate **5–39** is an actual intermediate in the overall reaction, formed by elimination of the sulfido group and a hydron from intermediate **5–36,** and that the readdition of the sulfido group to carbon 6 in intermediate **5–39,** coincident with dissociation of the anilino nitrogen of tetrahydrofolate, then gives intermediate **5–38**. Elimination of the sulfido group of the cysteine, however, from covalent intermediate **5–36**, which is a retro-Michael addition, would require that intermediate **5–37** be formed in any case, so the advantage of forming noncovalent intermediate intermediate **5–39** is far from obvious. In addition, the fact that synthetic intermediate **5–39** is able to enter and presumably escape from the active site with ease, while covalent intermediate **5–37** cannot, seems to mitigate against this proposal.

During the elimination from intermediate **5–36** that produces covalent intermediate **5–38** (Figure 5–5), an elimination which has the enolate **5–37** as an intermediate, the hydron on carbon 5 of what was the uracil in dUMP, because it is acidic as a result of addition of the sulfido group to the uracil, can be removed by Tyrosine 94 of the enzyme from *E. coli*.[205,207,208] When the homologous tyrosine, Tyrosine 146, in the enzyme from *L. casei* is mutated to phenylalanine, the rate constant $k_0\,(K_{m,dUMP})^{-1}$ $(K_{m,mTHF})^{-1}$ decreases by a factor of 10,000. When it is replaced by 2-fluorotyrosine, 3-fluorotyrosine, or 3,5-difluorotyrosine, the pK_a observed in the pH–rate profile for the steady-state Michaelis constant $K_{m,mTHF}$ for 5,10-methylenetetrahydrofolate decreased proportionally to the decrease in pK_a for the respective fluorotyrosine.[220]

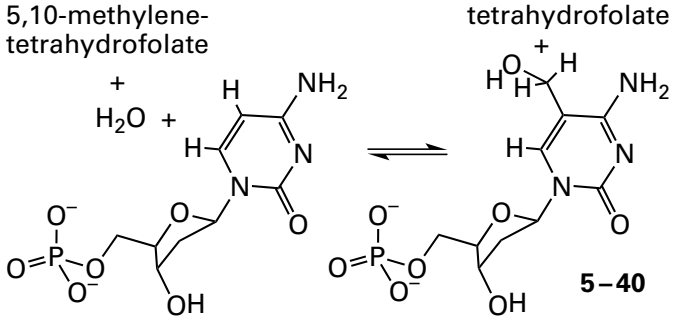
The product of the elimination in the mechanism of thymidylate synthase described in the first two steps of Figure 5–5 is the covalent intermediate

*Nitrogen 5 of tetrahydrofolate must be hydronated in the usual inescapable requirement before the elimination can occur. The closest acid (0.41 nm) in the crystallographic molecular model[208] of adduct **5–35** is another molecule of water forming a hydrogen bond to the carboxy group of Glutamate 58 of the enzyme from *E. coli*, and this water could relay the acidity of Glutamate 58 to nitrogen 5.

2′-deoxy-6-cysteinyl-5-methyleneuridine 5′-monophosphate (**5–38**). The exocyclic methylene in the 2′-deoxy-6-cysteinyl-5-methyleneuridine is in a carbon–carbon double bond α,β to an acyl carbon and should be susceptible to nucleophilic additions. In fact, intermediate **5–38** has been trapped in a Michael addition with 2-sulfanylethanol (Figure 5–5) in a mutant of the enzyme from *E. coli* in which Tryptophan 82 has been mutated to tyrosine to decrease the rate of steps that follow its formation in the mechanism of the enzyme. The resulting product of this nucleophilic addition was isolated and identified by nuclear magnetic resonance spectroscopy and mass spectrometry.[221]

The final step in the reaction catalyzed by thymidylate synthase is the transfer of a hydride from carbon 6 of the coenzyme tetrahydrofolate to the 5-methylene group of intermediate **5–38** (Figure 5–5). This transfer is concerted with the leaving of sulfur in the sulfanyl group of cysteine in the active site[222] to give thymidine 5′-monophosphate, the **final product** of the methylation. This reduction is required because the original carbon in 5,10-methylenetetrahydrofolate is at the carbonyl oxidation state and the methyl group in thymidine 5′-monophosphate is the vinylogous *N*-methylurea. In the active site of methylenetetrahydrofolate—tRNA-(uracil^{54}-C^5)-methyltransferase [NAD(P)H-oxidizing] from *B. subtilis*, the reduced flavin that transferred the methylene group to carbon 5 of the uracil provides the hydride.[213] There is a significant kinetic isotope effect for transfer of the hydride in the active site of thymidylate synthase.[223,224] This kinetic isotope effect is independent of temperature,[222] which distinguishes it from the kinetic isotope effect for removal of the hydron by Tyrosine 94 in the elimination that produces intermediate **5–38**.[225] The fact that the decrease in Michaelis constant $K_{m,mTHF}$ for 5,10-methylenetetrahydrofolate as the pH is lowered has been assigned to the pK_a of Tyrosine 94, the fact that there is a kinetic isotope effect for removal of the hydron from carbon 5 by Tyrosine 94, and the fact that there is a kinetic isotope effect for transfer of the hydride all suggest that the rate-limiting step in the enzymatic reaction is transfer of the hydride but that removal of the hydron from carbon 5 is significantly rate-affecting.

Addition of a hydride, formally a nucleophile, to intermediate **5–38** is analogous to addition of a hydroxide ion, actually a nucleophile, to 2′-deoxy-6-cysteinyl-2-methylenecytosine, the homologous covalent intermediate in the reaction catalyzed by deoxycytidylate 5-hydroxymethyltransferase[226]



(5–56)

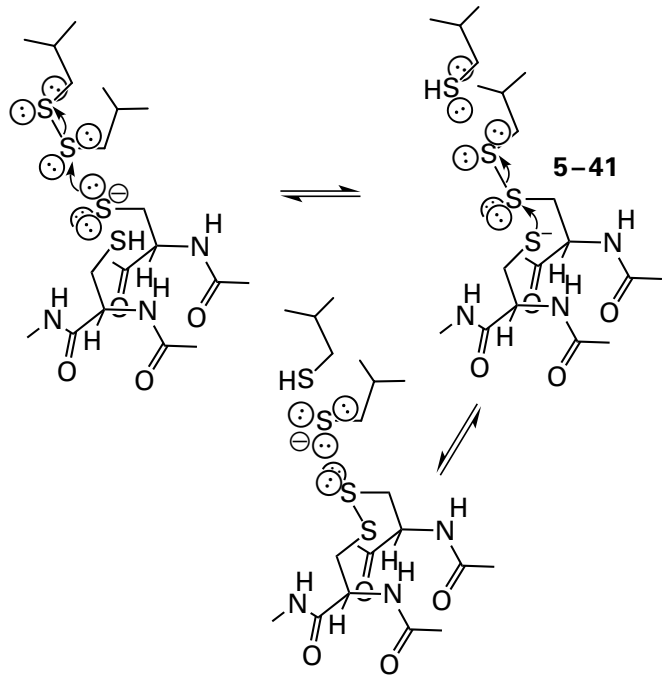
encoded by the genome of Enterobacteria phage T4. In this latter instance, addition of the hydroxide instead of a hydride, which is also analogous to the nucleophilic addition of 2-sulfanylethanol to intermediate **5–38** (Figure 5–5), produces the hydroxymethyl group in the product 5-hydroxymethyldeoxycytidylate (**5–40**) rather than a methyl group.

In the latter steps of the reaction catalyzed by thymidylate synthase (Figure 5–5), following nucleophilic addition of carbon 5 of the enolate that is the first covalent intermediate to the methyleneiminium cation of N^5-methylenetetrahydrofolate, the continued necessity for the covalent intermediate between the uracil in dUMP and the cysteine is evident. This adduct continues to permit carbons 4 and 5 to act as an acyl carbon and a carbon α to an acyl carbon, respectively, so that the necessary enolates and α,β-unsaturated acyl compounds can be formed. Such chemistry at the position α to an acyl carbon would not be possible if the double bond between carbons 5 and 6 of the uracil were intact because the hydron on that carbon is orthogonal to the π molecular orbital system of the acyl group at carbon 4 and hence, unreactive.

There is no cysteine in the active site of the unrelated thymidylate synthase (FAD) from Enterobacteria phage T4 that can participate in a nucleophilic addition to carbon 5 of the uracil in dUMP,[227] even though it catalyzes the same reaction. Thymidylate synthase (FAD), as its name implies, is a flavoenzyme with a prosthetic flavin adenine dinucleotide in its active site, which must be in its reduced form before the methylation can proceed.[228] Even though there is no cysteine in the active site, there are several results that are consistent with formation of an enolate at oxygen 4, carbon 4, and carbon 5, as occurs in the active site of thymidylate synthase. The reduced enzyme catalyzes exchange of the hydron at carbon 5 of dUMP with deuterons in ^2H_2O in the absence of 5,10-methylenetetrahydrofolate, as would be expected if the active site is able to create the enolate.[229] If the enzymatic reaction is quenched

while it is proceeding, 2′-deoxy-5-hydroxymethyluridine 5′-monophosphate can be isolated,[230] which is the product expected from addition of water to the α,β-unsaturated acyl intermediate homologous to intermediate **5-38** (Figure 5–5), as occurs in the active site of deoxycytidylate 5-hydroxymethyltransferase (Equation 5–56). These observations have led to the proposal that the reduced flavin reversibly adds a hydride to carbon 6 of dUMP to produce directly the enolate as the first step in the reaction, which would accomplish the same function as the nucleophilic addition of the sulfanyl group of the cysteine in the active site of thymidylate synthase.[229] Consistent with this explanation is the fact that, in the crystallographic molecular model of the complex between the oxidized enzyme and dUMP, the dUMP stacks upon the isoalloxazine of the flavin, and carbon 6 of the dUMP sits directly on top of nitrogen 5 of the flavin,[227] which would be poised to transfer a hydride if it were reduced flavin. The stacking of the two rings against each other is reminiscent of the complexes between NAD^+ and reduced flavin in active sites in which the NAD^+ is reduced by flavin.

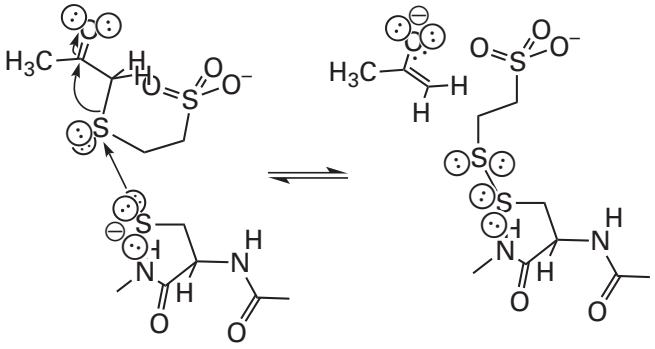
There are several enzymes that have mixed disulfides between cysteines in their active sites and sulfanyl groups in their respective substrates as covalent intermediates in their reactions. For example, in the active site of human glutathione-disulfide reductase, reduced flavin reduces a disulfide between Cysteines 58 and 63 (Figure 2–11). The sulfido group of Cysteine 58 then engages in thiol–disulfide exchange with the disulfide in glutathione disulfide (see Equation 2–136)



(5–57)

to produce one reduced glutathione and a mixed disulfide (**5–41**) between Cysteine 58 and the other molecule of glutathione. This mixed disulfide has been observed crystallographically.[231] A second thiol–disulfide exchange with the sulfido group of Cysteine 63 then produces the second molecule of reduced glutathione and regenerates the disulfide between Cysteines 58 and 63 awaiting reduction in the next round.

A thiol–disulfide exchange is a **nucleophilic substitution at sulfur**. Nucleophilic substitutions at sulfur also occur in active sites with leaving groups other than a sulfanyl group. For example, in the reaction catalyzed by 2-oxopropyl-CoM reductase (carboxylating), an enolate is the leaving group in a nucleophilic substitution

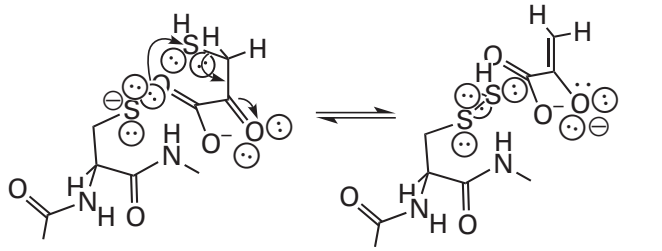


(5–58)

that produces a mixed disulfide between a cysteine in the active site and 2-sulfanylethanesulfonate

(coenzyme M), which is one product of the reaction in the direction written. This covalent intermediate has also been observed crystallographically in the active site of 2-oxopropyl-CoM reductase (carboxylating) from *X. autotrophicus*.[232] The sulfido group of a second cysteine in the active site then releases the 2-sulfanylethanesulfonate in a thiol–disulfide exchange (see Equation 5–57). The enolate of acetone that is the leaving group in the nucleophilic substitution is carboxylated with carbon dioxide within the active site to produce acetoacetate, the other product of the enzymatic reaction in the direction written.

Mixed disulfides between hydrogen sulfide and cysteines form in the active sites of sulfurtransferases. For example, in 3-mercaptopyruvate sulfurtransferase from *E. coli*, a hydrogen sulfide is transferred from 3-sulfanylpyruvate to Cysteine 237 in the active site of the enzyme



(5–59)

with the enolate of pyruvate as the leaving group. The resulting cysteine persulfide has been observed crystallographically.[233,234] The first persulfide of this type was observed in the crystallographic molecular model of thiosulfate sulfurtransferase (rhodanese).[235,236] Sulfenic acids (RS–OH) are oxygen analogues of these persulfides, and they are covalent intermediates in the active sites of peroxidases.[237,238]

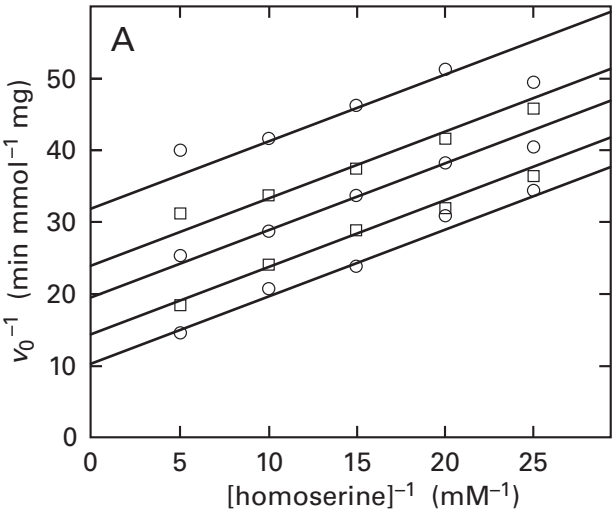
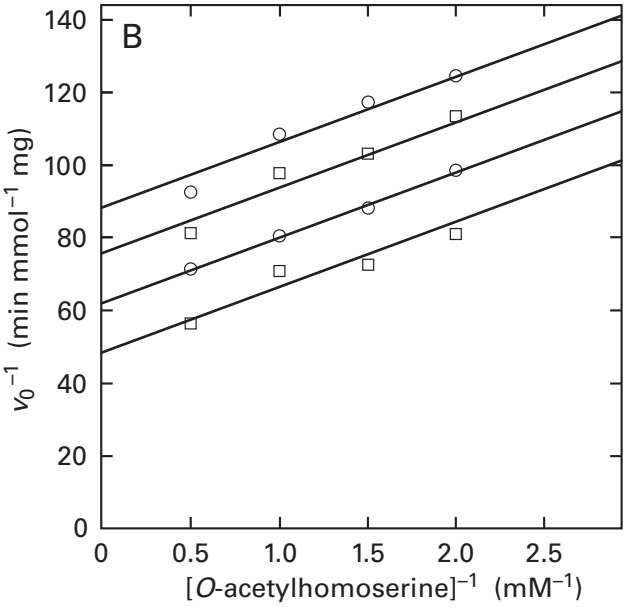
Problem 5–1: Homoserine *O*-acetyltransferase from *Haemophilus influenzae*

$$\text{acetyl-SCoA} + \text{L-homoserine} \rightleftharpoons \text{HSCoA} + \textit{O}\text{-acetyl-L-homoserine}$$

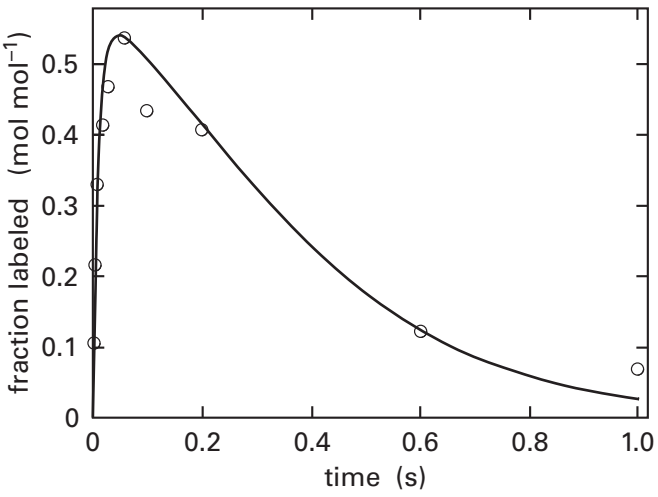
displays the following steady-state kinetics.[33]





Reciprocals (minutes millimole^{-1} milligram) of the initial rates plotted against the reciprocals (millimolar^{-1}) of the initial concentrations of reactants for the enzymatic reaction catalyzed by homoserine *O*-acetyltransferase from *H. influenzae*. (A) Varying concentrations of L-homoserine at constant concentrations of acetyl-SCoA, in descending order, of 0.042, 0.056, 0.083, 0.143, and 0.33 mM. (B) Varying concentrations of *O*-acetyl-L-homoserine at constant concentrations of coenzyme A, in descending order, of 0.20, 0.25, 0.33, and 0.50 mM.

When the enzyme (0.28 mM) was mixed with [^{3}H]acetyl-SCoA (0.40 mM) for various times and then mixed with 25% trichloroacetic acid to denature and precipitate the protein, and the precipitate was then collected, washed, and submitted to scintillation counting, the following results were observed.



Covalent incorporation of tritium into homoserine *O*-acetyltransferase. The incorporation of radioactivity into the precipitated protein is expressed in terms of moles (mole of active sites)$^{-1}$.

When Serine 163 in the enzyme from *Schizosaccharomyces pombe* was mutated to alanine, no acetylation of the protein occurred.[34]

(A) Write a mechanism for the transacetylation. Include arbitrary but suitable side chains from amino acids in the active site in your mechanism.
(B) What feature of your mechanism is consistent with the steady-state kinetics?
(C) What feature of your mechanism is consistent with the acetylation of the enzyme?
(D) What feature of your mechanism is consistent with the results of the mutation?

Problem 5–2: Aspartate-semialdehyde dehydrogenase catalyzes the reaction

$$\text{NADPH} + \text{L-4-aspartylphosphate} + \text{H}^+ \rightleftharpoons \text{L-aspartate 4-semialdehyde} + \text{HOPO}_3^{2-} + \text{NADP}^+$$

Write a mechanism for the reaction involving a covalent intermediate at a cysteine.

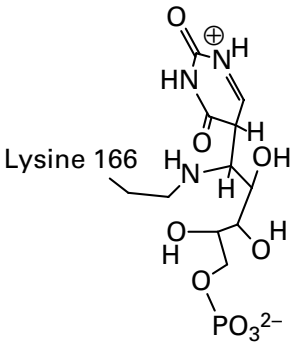
Problem 5–3: Methanol in water reacts about 100-fold more rapidly with the acyl intermediate in the reaction catalyzed by chymotrypsin (Figure 3–6) than does water itself.

(A) If this is the case, explain why the catalytic constant k_0 for the combined hydrolysis and methanolysis of 4-nitrophenyl acetate by chymotrypsin is markedly increased in methanol–water solutions, but that for *N*-acetyl-L-tryptophan amide is unchanged from the value in water alone.
(B) Estimate the value of the catalytic constant k_0 for the combined hydrolysis and methanolysis of 4-nitrophenyl acetate in 1 M methanol in water relative to k_0 in water alone and the fraction of the product that would be methyl acetate.

Problem 5–4: When pseudouridylate synthase

$$\text{pseudouridine 5′-phosphate} + \text{H}_2\text{O} \rightleftharpoons \text{uracil} + \text{D-ribose 5-phosphate}$$

from *E. coli* was crystallized from a solution of D-ribose 5′-phosphate and uracil, the covalent intermediate



was observed in the map of electron density in its active site.[239] Write a mechanism for the reaction catalyzed by the enzyme that involves this covalent intermediate. Hint: Find the correct enolate in uracil.

Problem 5–5: UDP-Glucose—hexose-1-phosphate uridylyltransferase catalyzes the reaction

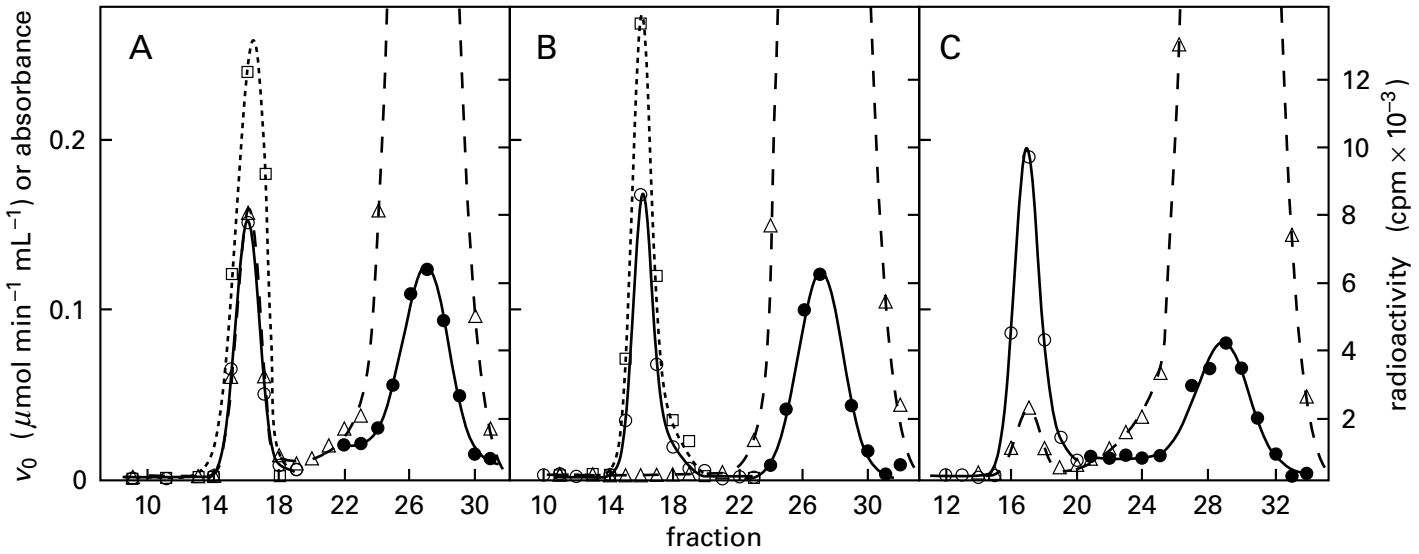
$$\text{UDP-}\alpha\text{-D-glucose} + \alpha\text{-D-galactose 1-phosphate} \rightleftharpoons \alpha\text{-D-glucose 1-phosphate} + \text{UDP-}\alpha\text{-D-galactose}$$

(A) Suppose that the reaction proceeded through the two ternary complexes

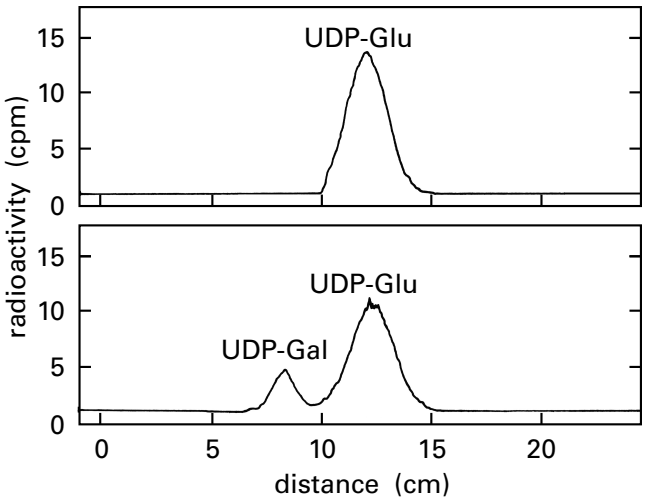
$$\text{E·UDP-glucose·galactose 1-phosphate} \rightleftharpoons \text{E·glucose 1-phosphate·UDP-galactose}$$

and draw the structure of the pentavalent intermediate at phosphorus that would have to be bound tightly by the active site. Indicate the entering oxygen and the leaving oxygen.

The following results have been observed.[240]



Distribution of (○) A_{280} (protein), (●) A_{260} (nucleotides), (△) radioactivity (counts per minute milliliter^{-1}), and (□) catalytic activity (micromoles minute^{-1} milliliter^{-1}) following chromatography of several mixtures. (A) The mixture of reactants contained initially 8 nmol of active sites for UDP-glucose—hexose-1-phosphate uridylyltransferase from *E. coli* and 32 nmol of [*uracil*-5,6-$^3H_2$] UDP-D-glucose (specific radioactivity 2.0×10^7 cpm μmol^{-1}) in 0.2 mL of 50 μM L-cysteine and 5 mM potassium phosphate, pH 7.5. After 5 min at room temperature, the solution was passed thorough a column (1 × 41 cm) of Sephadex G-25 equilibrated and eluted with the same buffer at 4 °C. Fractions of approximately 1 mL were collected at intervals of 5 min. (B) The mixture of reactants was identical with that of Panel A except that the tritiated UDP-D-glucose was replaced with 34 nmol of UDP-[U-^{14}C]-D-glucose (specific radioactivity 5.8×10^6 cpm μmol^{-1}). (C) The mixture of reactants was identical with that of Panel A except that it also contained 32 nmol of D-glucose 1-phosphate. [240]



Distribution of radioactivity upon chromatography of two mixtures of reactants. The complete mixture of reactants contained initially 32 nmol of [*uracil*-5,6-$^3H_2$]UDP-D-glucose (6.3×10^5 cpm), 36 nmol of UDP-D-galactose, and UDP-glucose—hexose-1-phosphate uridylyltransferase (0.56 micromolar minute^{-1}) in 25 μL of buffer consisting of 0.5 mM L-cysteine and 5 mM potassium phosphate, pH 7.5. After 25 min at 25 °C, half of the solution was subjected to descending paper chromatography for 92 h with ethanol–methyl ethyl ketone–0.5 M morpholinium tetraborate, pH 8.6 (7:2:3), as the mobile phase. The upper panel is the control without enzyme, and the lower is the complete mixture of reactants.[240]

(B) On the basis of these results, write a mechanism for the enzymatic reaction involving a covalent uridylyl-enzyme intermediate.

(C) On the basis of the mechanism you wrote in part B, explain the uridylyl exchange observed in Figure B.

(D) Draw the complete structure of the covalent uridylyl intermediate formed between a portion of the substrate and a histidine in the active site of the enzyme.[156]

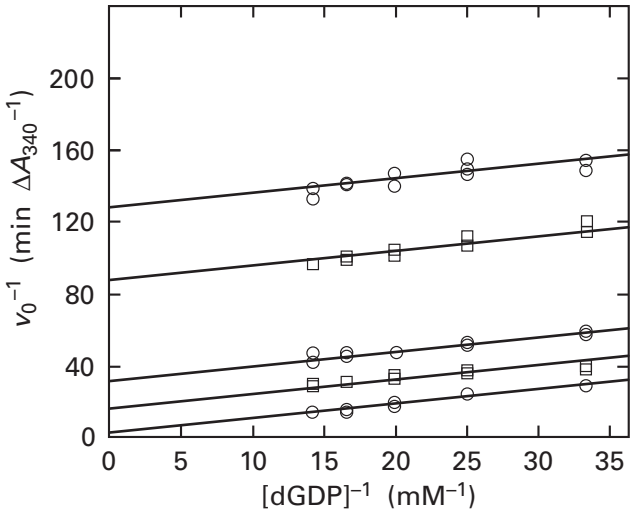
(E) The overall enzymatic reaction proceeds with retention of configuration of phosphorus.[151] To which of the two phosphorus atoms in a uridylyl substrate must this statement refer?

(F) Draw a structure of UDP-D-glucose and indicate the phosphorus with an arrow. Show how this observation rules out a mechanism in which this phosphorus is transferred directly in a ternary complex as in part A and is consistent with formation of the covalent intermediate you drew in part C. Show this by drawing structures of the intermediates in the key steps.

(G) Explain why the mechanism of part B that passes through a covalent intermediate is more economical than the mechanism of part A that passes through a ternary complex.

(H) Consider the amino acids in the active site that must form hydrogen bonds to the UDP monosaccharides and those that activate the phosphate for transfer. Which can be called upon to perform twice the work?

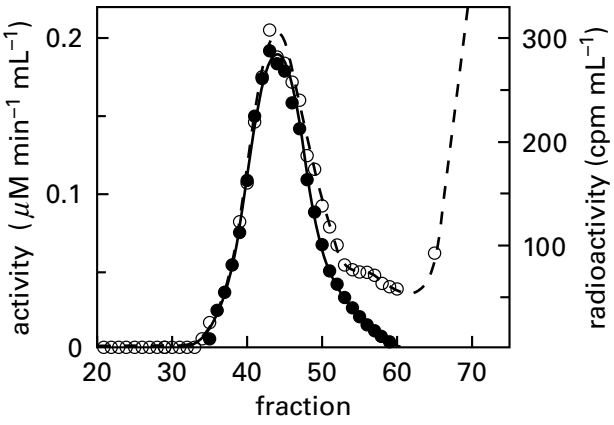
Problem 5–6: Nucleoside-diphosphate kinase catalyzes Equation 5–32. When MgATP^{2-} is used as the phosphate donor (MgXTP^{2-}) and MgdGDP$^-$ as the phosphate acceptor (MgYDP$^-$) in the enzymatic reaction, the following kinetic behavior is observed.



Plot of the reciprocal [minutes (change in A_{340})$^{-1}$] of the initial rate for the enzymatic assay, which is coupled to oxidation of NADH, against the reciprocal (millimolar^{-1}) of the concentration of MgdGDP$^-$ for human nucleoside-diphosphate kinase at concentrations, from top to bottom, of MgATP^{2-} of 15, 25, 50, 100, and 800 μM.[241]

(A) Write a kinetic mechanism that is consistent with these observations. In your mechanism, explicitly name substrates and products as MgATP^{2-}, MgdGDP$^-$, MgADP$^-$, and MgdGTP^{2-}. Abbreviate the enzyme as E.

When human nucleoside-diphosphate kinase was mixed with Mg[^{32}P]ATP^{2-} for 1 min at 30 °C and then the mixture was added to a column of Sephadex G-100, the following elution profile was obtained.

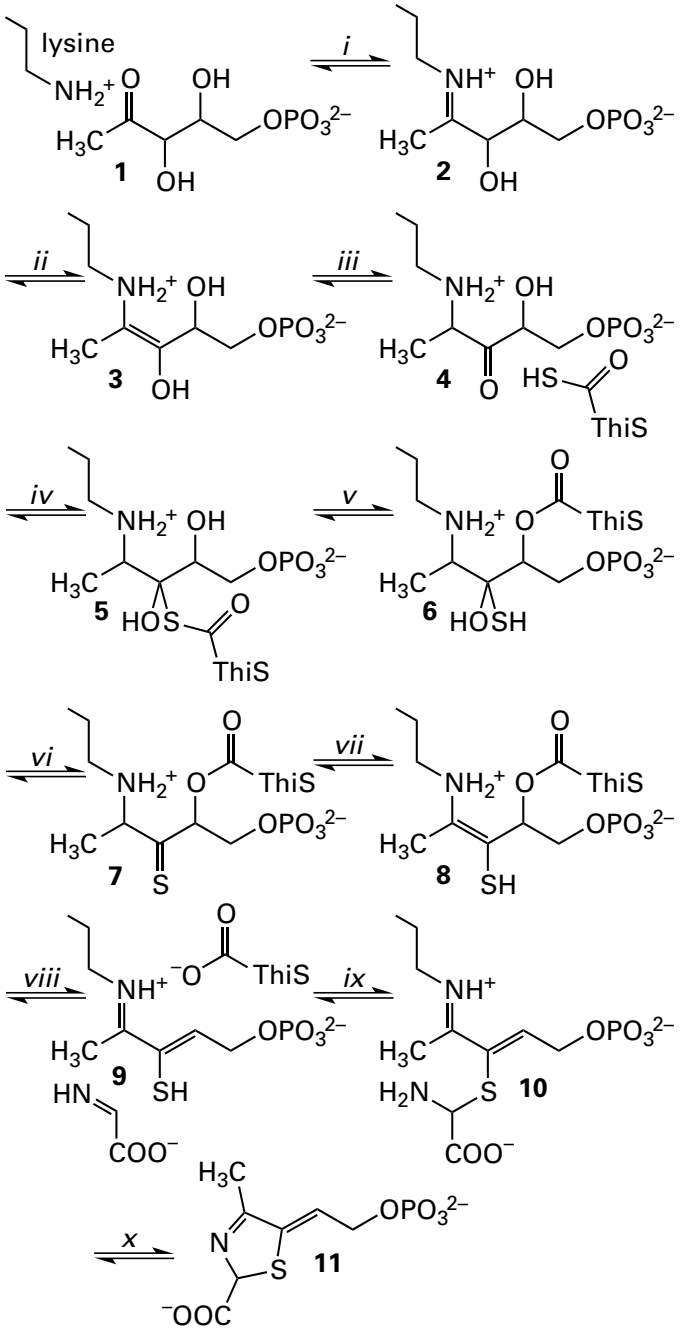


Separation of [^{32}P]nucleoside-diphosphate kinase from Mg[^{32}P]ATP^{2-} on a column of Sephadex G-100.[242] Enzymatic activity (micromolar minute^{-1} milliliter^{-1}) and radioactivity (counts per minute milliliter^{-1}) are plotted as a function of the number of the fraction.

The authors point out in the publication that nucleoside-diphosphate kinase elutes from Sephadex G-100 at a position where the stationary phase for the molecular exclusion is separating proteins on the basis of their size.

(B) How do these results rule out the possibility that ^{32}P is associated with proteins other than nucleoside-diphosphate kinase?
(C) Which phosphate of Mg[^{32}P]ATP^{2-} was certainly radioactive?
(D) Write a chemical mechanism for the reaction of nucleoside-diphosphate kinase that incorporates both your kinetic mechanism and an explicit explanation of the results in Figure B.
(E) When enzyme from fractions 40–45 from the Sephadex G-100 column was mixed with MgGDP^{-}, what radioactive nucleotide was subsequently isolated from the mixture? Indicate precisely where the radioactive phosphorus resides on that nucleotide.

Problem 5–7: Thiazole synthase converts 1-deoxy-D-xylulose 5-phosphate and 2-iminoacetate into 2-[(2*R*,5*Z*)-2-carboxy-4-methylthiazol-5(2*H*)-ylidene]-ethyl phosphate. It has been proposed that the enzymatic mechanism proceeds through the following sequence of covalent intermediates

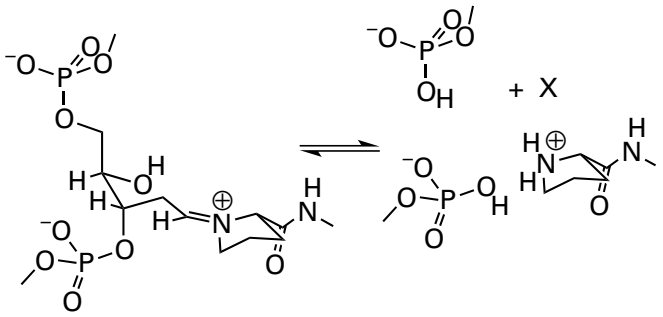


where the primary alkylamino group is the 6-amino group of a lysine in the active site of the enzyme and ThiS is a small protein that carries a sulfide as a monothiocarboxy group at its carboxy terminus. Intermediate **5** has been observed in a crystallographic molecular model.[243]

(A) Using the lowercase Roman numbers for each step, identify the type of chemical reaction and describe what is occurring in each step.
(B) Using the boldface numbers for particular intermediates, identify any reactants or products that do not appear at that point in the chemical equations as written.

(C) Write out the mechanism of each step in detail. Show all removals and additions of hydrons and any reactants or products not shown in the diagram.

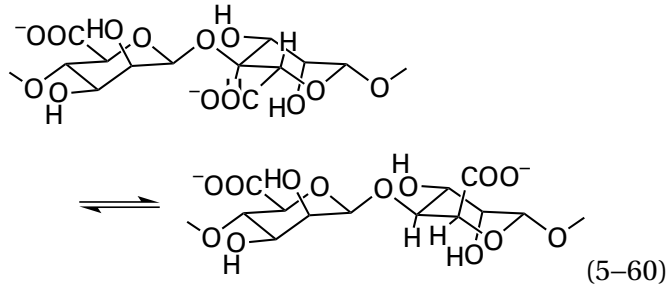
Problem 5–8: Write a mechanism for the reaction



catalyzed by DNA-formamidopyrimidine glycosylase.[195] What is X?

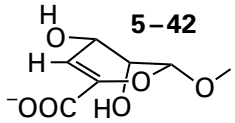
Chemical and Crystallographic Identification of Diamagnetic, Noncovalent Intermediates

There are instances in which a stable noncovalent intermediate is present in an active site at a high enough concentration to be isolated directly and identified chemically or crystallographically. In such cases, there is no need to perform chemical analysis of the protein. For example, poly(*β*-D-mannuronate) C5 epimerase from *P. aeruginosa* catalyzes the epimerization



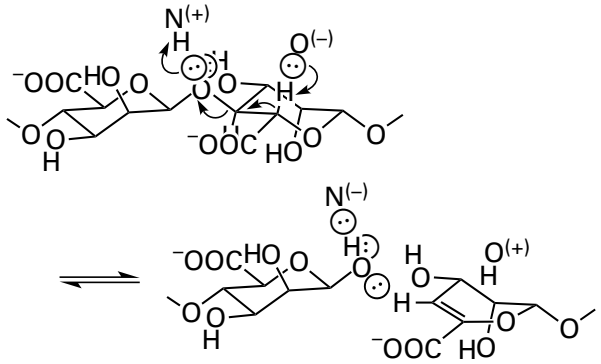
(5–60)

When the enzymatic reaction was quenched 5 s after the enzyme was mixed with a polymer of 34 D-mannurates, fragments of the polymer of various lengths could be isolated from the enzyme in 25% yield based on the concentration of active sites, and each fragment was shown by a colorimetric assay to end in a glycal of mannurate[244]



5–42

Consequently, it was concluded that these glycals were noncovalent intermediates in the enzymatic reaction. Each is formed by an elimination at the respective glycosidic linkage (see Equation 4–358)



(5–61)

To accomplish the overall epimerization for which the enzyme is responsible, during the readdition of the 1-hydroxy group of the adjacent mannuronate (reverse of Equation 5–61), the hydron is added to carbon 5 of the glycal from the opposite face of the double bond from which it was removed during the initial elimination. In a crystallographic molecular model of the active site of the enzyme from *Azotobacter vinelandii*, Tyrosine 149 is in the proper position to remove the hydron on carbon 5 on the *β*-D-mannuronyl group being epimerized and add the hydron to oxygen 1 of the leaving *β*-D-mannuronate, just as Tyrosine 242 does in the active site of chondroitin AC lyase (Figure 4–44), and Histidine 154 is in the proper position to add a hydron to the other side of the double bond in the glycal to produce the *α*-L-guluronyl group during the readdition of the hydroxy group.[245] The identification of the intermediate led to the rather unexpected conclusion that the polymer is cleaved and then reformed to perform the epimerization, presumably as a way to stabilize the *gem*-dienolate.

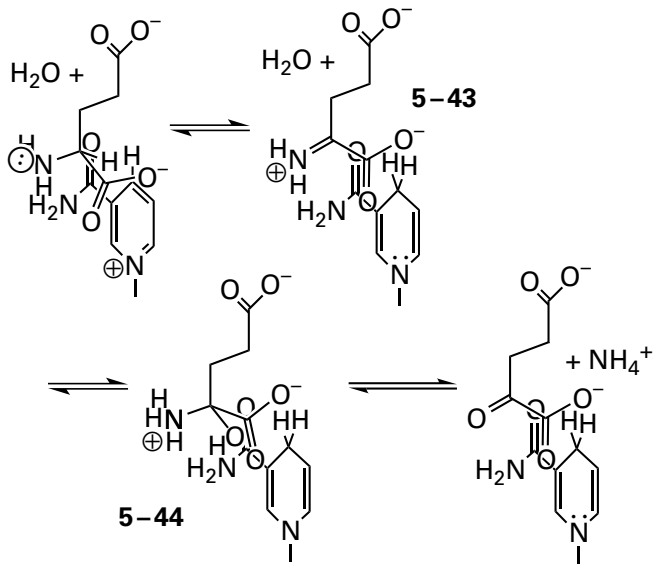
In the case of RNA polymerase (see Figure 3–73B) from *E. coli*, samples were removed and quenched at various intervals from 0.5 to 150 s from reaction mixtures in which the synthesis of RNA under the control of the double-stranded DNA of the λP_R promoter had been initiated. Each intermediate

segment of single-stranded RNA 3–16 bases long that was a noncovalent intermediate in the enzymatic reaction could be separated electrophoretically and quantified. The rates of the individual, consecutive steps in which an additional base was added to the elongating strand of RNA could be derived from these observations.[246]

One way to improve the chances of having measurable concentrations of a noncovalent intermediate in the active site is to have all substrates for the enzyme present in the solution at their equilibrium ratios and at concentrations high enough to saturate the active sites. Under these conditions, an **equilibrium between reactants, intermediates, and products** is established in all active sites in the solution. When such an equilibrium was established in the active site[247] of bovine glutamate dehydrogenase [NAD(P)$^+$] (previously Equation 3–319)

$$\text{L-glutamate} + H_2O + NAD(P)^+ \rightleftharpoons 2\text{-oxoglutarate} + NH_4^+ + NAD(P)H \quad (5\text{–}62)$$

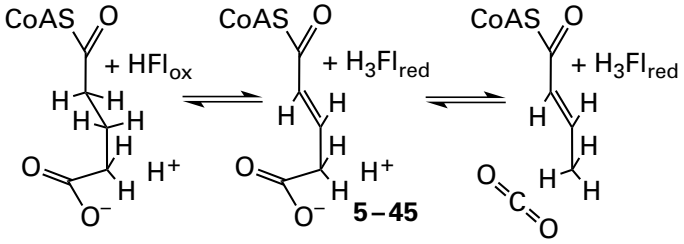
imine **5–43** (10%) and hemiaminal **5–44** (60%)



(5–63)

identified spectrophotometrically in the ultraviolet range, were present in the active site at equilibrium.[248]

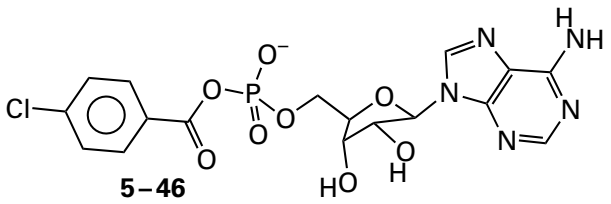
Noncovalent intermediates sometimes accumulate in an active site when **one reactant is omitted from the solution**. For example, when an electron acceptor, which normally would be oxidized electron-transfer flavoprotein, is omitted from an anaerobic solution of the oxidized flavoenzyme human glutaryl-CoA dehydrogenase (ETF), glutaconyl-SCoA (**5–45**) accumulated (25%) in the active site[249] as a noncovalent intermediate[250]



(5–64)

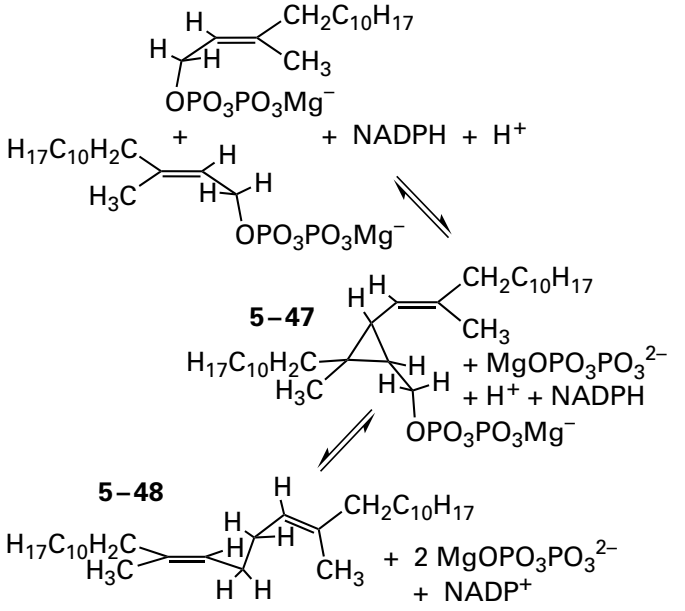
where HFl_{ox} is the oxidized prosthetic flavin and H_3Fl_{red} is the reduced prosthetic flavin. The glutaconyl-SCoA present in the active site as a noncovalent intermediate was identified by high-pressure liquid chromatography and mass spectrometry after inactivation and precipitation of the protein.

The mixed anhydride **5–46**



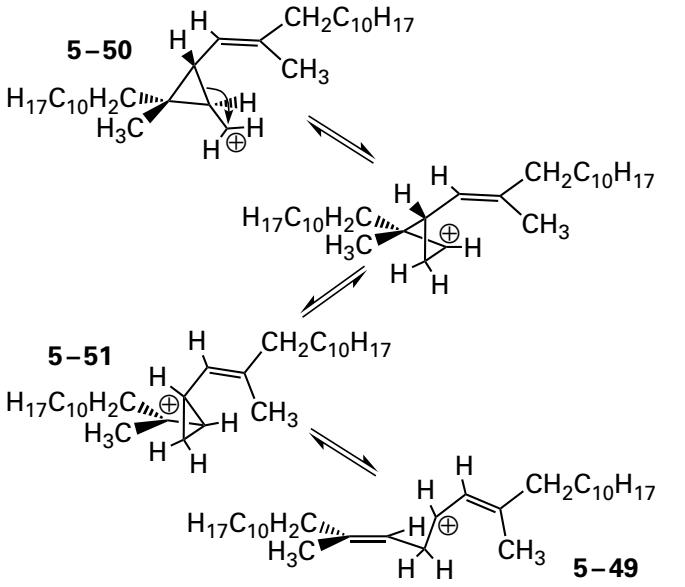
could be isolated from the active site of 4-chlorobenzoate—CoA ligase from *Pseudomonas* when the enzyme was mixed with 4-chlorobenzoate and $MgATP^{2-}$ in the absence of its third reactant, coenzyme A. It was identified by nuclear magnetic resonance spectroscopy.[251] This observation is consistent with the transfer of an adenylyl group from $MgATP^{2-}$ to the carboxy group of 4-chlorobenzoate to form mixed anhydride **5–46** with diphosphate as the leaving group. This nucleophilic substitution at phosphorus activates the carboxy group for a nucleophilic substitution of the sulfanyl group of coenzyme A for the adenylyl group in the intermediate to form the product 4-chlorobenzoate-SCoA.

In the case of squalene synthase from *S. cerevisiae*, the noncovalent intermediate, (+)-presqualene diphosphate (**5–47**),[252-255] is formed in an initial step from two molecules of (2*E*,6*E*)-farnesyl diphosphate



(5–65)

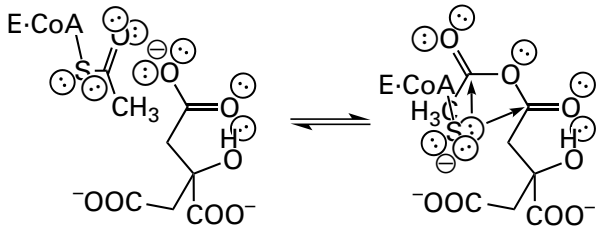
upon dissociation of diphosphate from one of them to form the allyl carbenium ion, which adds to the carbon–carbon double bond of the other to form the cyclopropane. Then, following dissociation of the second diphosphate and a sequence of carbocationic rearrangements (previously Equation 3–368)



(5–66)

the final carbenium ion (**5–49**) is reduced by a hydride from NADPH to the final product squalene (**5–48**). In the absence of NADPH, the steps in the enzymatic mechanism beyond (+)-presqualene diphosphate (**5–47**) are blocked, and (+)-presqualene diphosphate slowly dissociates as a stable compound from the active site.[256] Under normal circumstances, sufficient NADPH is available to prevent the release of the intermediate. In this instance, the intermediate in the enzymatic reaction was sufficiently complex that total organic synthesis was required to define its structure unambiguously.[253,254]

If a noncovalent intermediate in an enzymatic reaction is **too unstable to isolate**, other approaches are applied. For example, **mixed anhydrides of two carboxylic acids** that are substrates for the enzyme are noncovalent intermediates in acyl exchanges, and these mixed anhydrides are too unstable to isolate. During each turnover, citrate (*pro*-3*S*)-lyase accomplishes the exchange of a citryl group for the initial acetyl group in the thioester of the prosthetic coenzyme A in the active site (Equation 5–17).[257] The most likely noncovalent intermediate in this partial reaction is a mixed anhydride formed between citrate and acetate[258]



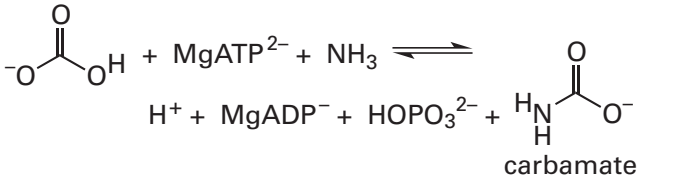
(5–67)

The sulfido group of the prosthetic coenzyme A (as shown), or the sulfido group of a cysteine known to be located nearby in the active site,[259] then adds to the acyl carbon of the citryl group in the mixed anhydride intermediate to complete the substitution of the citryl group for the acetyl group and give the acetate that is one product of the enzymatic retro-Claisen condensation. In reverse, the sulfido group would add to the acyl carbon of the acetyl group in the mixed anhydride to re-form the acetyl intermediate. The existence of this mixed anhydride as an intermediate was demonstrated by the fact that oxygen-18 in the carboxy group of citrate is transferred to the acetate that is the product during a single turnover of the enzyme.

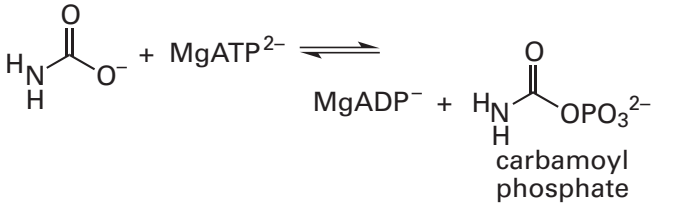
Another approach to identification is to **trap an unstable noncovalent intermediate** by a chemical reaction that produces a stable derivative of it. Carbamoyl-phosphate synthase (glutamine-hydro-lysing) catalyzes three separate reactions (previously Equations 3–531 to 3–533)

$$H_2O + \text{L-glutamine} \rightleftharpoons \text{L-glutamate} + NH_3 + H^+$$

(5–68)

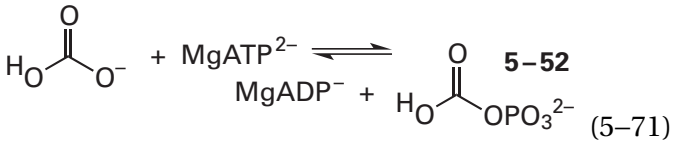


(5–69)

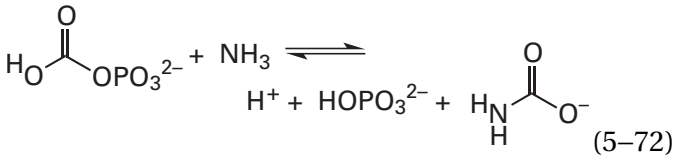


(5–70)

in three separate active sites connected by two tunnels. The phosphocarbonate **5–52**, formed as a noncovalent intermediate at the active site in the enzyme from *E. coli* that is responsible for producing carbamate (Equation 5–69)

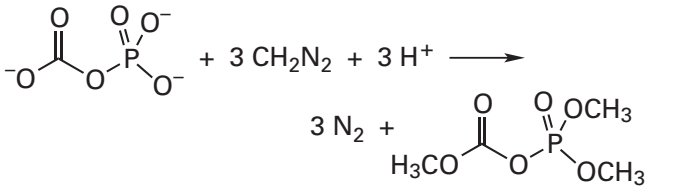


(5–71)



(5–72)

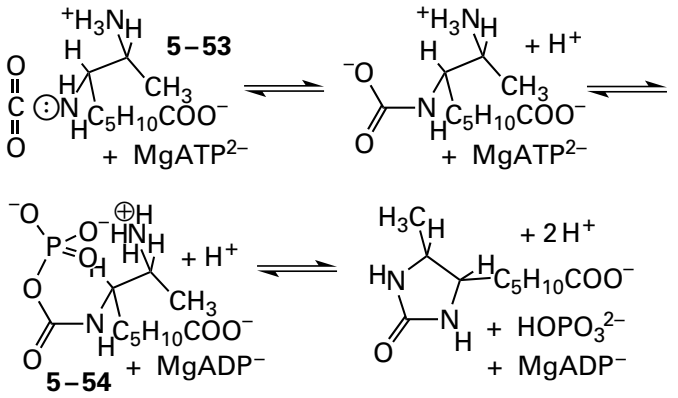
can be trapped by mixing a solution of the enzyme, $MgATP^{2-}$, and bicarbonate with diazomethane[260]



(5–73)

The resulting trimethyl phosphocarbonate is a stable compound, unlike the phosphocarbonate itself, because it has no oxyanions to provide push.

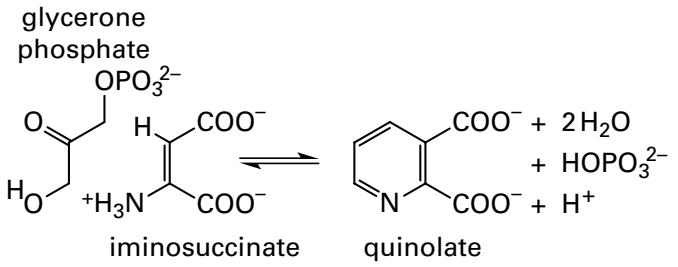
Noncovalent intermediates in enzymatic reactions are often **identified crystallographically**.[261] For example, when a crystal of dethiobiotin synthase from *E. coli*



(5–74)

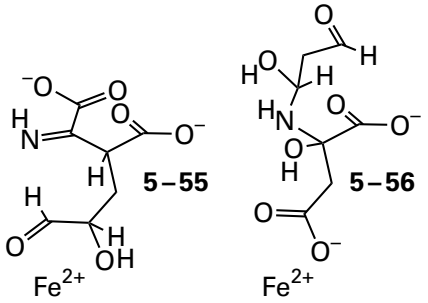
was soaked with $MgATP^{2-}$ and 7,8-diaminononanoate (**5–53**) for 1 h and then $NaHCO_3^{2-}$ was added to the solution for 80 s before the crystal was frozen, carbamic phosphoanhydride **5–54**, an analogue of carbamoyl phosphate, was observed occupying the active site of the enzyme in the map of electron density for this crystal.[262] This noncovalent intermediate had already been isolated from enzyme dissolved in solution that was mixed with these same reactants for 100 s at pH 7.5 and then acidified to pH 4.[263]

The observation of a potential intermediate in a map of electron density **can be deceptive**. The active site of quinolinate synthase[264]



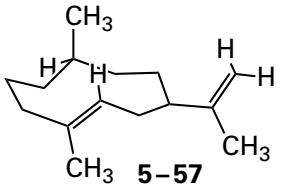
(5–75)

contains a tetranuclear [4Fe–4S] iron–sulfur cluster with an open site[265] on one of the Fe^{2+}, as does aconitate hydratase. Two distinct crystallographic maps of electron density for crystals of quinolinate synthase from *Thermotoga maritima* and *Pyrococcus horikoshii*, respectively, have been reported, each of which is consistent with a different noncovalent intermediate



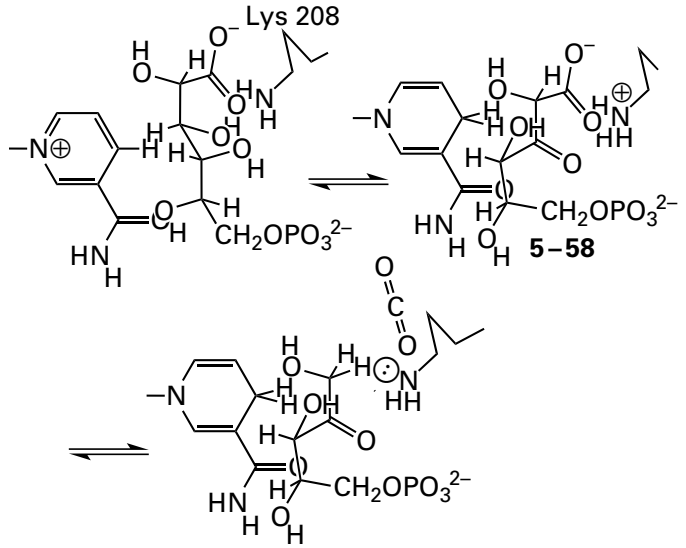
Because of the two carboxylato groups, the two maps of electron density of the potential intermediates are distinct enough that they cannot both be of the same noncovalent intermediate. In the condensation catalyzed by the enzyme, a carbon–carbon bond and a nitrogen–carbon bond are formed between the two reactants. In intermediate **5–55**, the carbon–carbon bond has formed[266,267] and in intermediate **5–56** the nitrogen–carbon bond has formed,[268] so at least one of them cannot be a normal intermediate in the enzymatic reaction. There are two different chemically defensible mechanisms that can include the respective intermediate and convert glycerone phosphate and iminosuccinate into quinolinate, so a decision cannot be made by appeal to mechanism. The active site forms a complex with glycerone phosphate[266,269] in which the hydroxy group and the carbonyl oxygen are ligands to the Fe^{2+}, which would lead to **5–55** in which this ligation is retained. The active site, however, also forms a complex with iminosuccinate in which the 4-carboxy group is a ligand to the Fe^{2+}, which is more similar to the ligation in **5–56**, and it also forms a complex with the nitrogen and the 3-carboxy group of quinolinate.[266,269,270] In its favor, dicarboxylic acid **5–55** associates with the active site with the two oxygens that will eventually leave during the production of quinolinate as ligands to the Fe^{2+}, which would be consistent with the role of such tetranuclear [4Fe–4S] iron–sulfur clusters in other dehydrations.

If the equilibrium in the active site is such that insignificant concentrations of a noncovalent intermediate accumulate or can be caused to accumulate, other strategies must be applied. One of these strategies is to **use an analogue of one substrate as an alternative reactant** that is mistaken by the enzyme for the actual substrate and from which the usual intermediate is formed; but the intermediate formed from the analogue is stable. For example, germacrene A is a noncovalent intermediate in the reaction catalyzed by aristolochene synthase (Figure 3–48) from (2*E*,6*E*)-farnesyl diphosphate. It is never present, however, in sufficient quantities to be isolated. When the enzyme from *Aspergillus terreus* was mixed with (7*R*)-6,7-dihydrofarnesyl diphosphate, which is (2*E*,6*E*)-farnesyl diphosphate reduced at the 6,7 carbon–carbon double bond, the resulting analogue, 1,2-dihydrogermacrene



accumulated in the active site at 1.3% of the rate of the normal reaction and was identified by gas chromatography and mass spectrometry.[271] 1,2-Dihydrogermacrene **5–57** lacks the 1,2-double bond present in germacrene that is needed to complete the enzymatic reaction.

In the enzymatic reaction catalyzed by phosphogluconate dehydrogenase ($NADP^+$-dependent, decarboxylating), 6-phospho-D-*ribo*-3-hexulosonate (**5–58**) is the central, noncovalent intermediate formed in the active site[272] from the substrate, 6-phospho-D-gluconate, during the oxidative decarboxylation



(5–76)

producing D-ribulose 5-phosphate. It had not been trapped chemically, in part because the rate of the initial dehydrogenation that produces it is slower than the rate of the subsequent decarboxylation of the 3-oxo carboxylic acid that eliminates it, so little of the intermediate can accumulate on the active site during the normal reaction.[273] Fortuitously, it was discovered that an analogue of the substrate, 2-deoxy-6-phospho-D-gluconate, is converted by

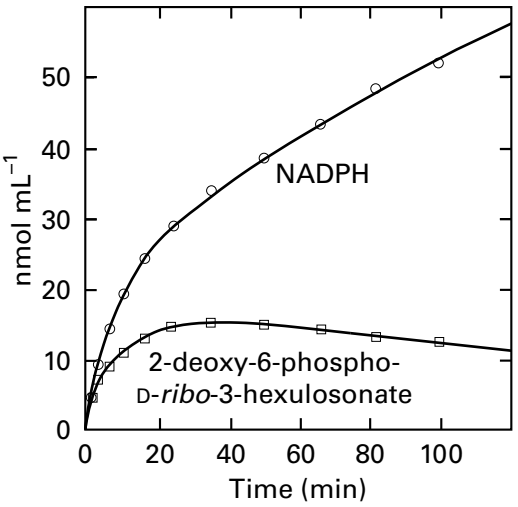


Figure 5–6: Kinetics of formation of 2-deoxy-6-phospho-D-*ribo*-3-hexulosonate and NADPH in the unnatural reaction catalyzed by phosphogluconate dehydrogenase (NADP$^+$-dependent, decarboxylating).[273] To the reaction mixture at 20 °C (final volume of 1 mL buffered at pH 8.0) were added 1.0 μmol of 2-deoxy-6-phospho-D-gluconate, 1.2 μmol of NADP$^+$, and 0.68 unit of phosphogluconate dehydrogenase. (○) The increases in the concentration of NADPH (nanomoles milliliter^{-1}) were followed as a function of the respective intervals (minutes) by the absorbance of the solution at 340 nm. (□) The concentrations of 2-deoxy-6-phospho-D-*ribo*-3-hexulosonate (nanomoles milliliter^{-1}) were assessed at intervals (minutes) by withdrawing samples and forming a formazan derivative from the β-oxo carboxylic acid by reaction with diazotized 4-nitroaniline.

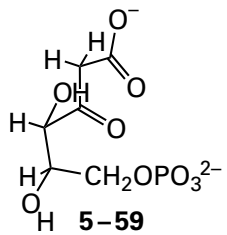
phosphogluconate dehydrogenase (NADP$^+$-dependent, decarboxylating) from *Cyberlindnera jadinii* into 2-deoxy-6-phospho-D-*ribo*-3-hexulosonate



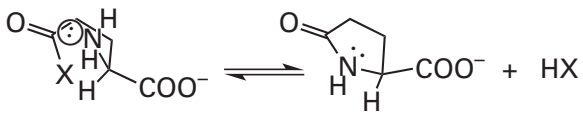
5–59

Unlike the natural intermediate, which remains tightly bound in the active site, the rate at which 2-deoxy-6-phospho-D-*ribo*-3-hexulosonate dissociates from the active site is almost the same as the rate at which it is decarboxylated while on the active site. Consequently, 2-deoxy-6-phospho-D-*ribo*-3-hexulosonate appears in the solution as the reaction progresses (Figure 5–6).[273] This 2-deoxy-6-phospho-D-*ribo*-3-hexulosonate is eventually re-bound at the active site and decarboxylated to 2-deoxy-D-ribulose 5-phosphate, another observation consistent with 6-phospho-D-*ribo*-3-hexulosonic acid (**5–58**) being the normal intermediate. Simply by replacing the hydroxy group at carbon 2 with a hydrogen, an analogue of an otherwise undetectable intermediate was produced and even released into the solution in significant yield by the enzyme.

As with phosphogluconate dehydrogenase (NADP$^+$-dependent, decarboxylating), an alternative reactant has been used with glutamine synthetase (previously Equation 4–453)

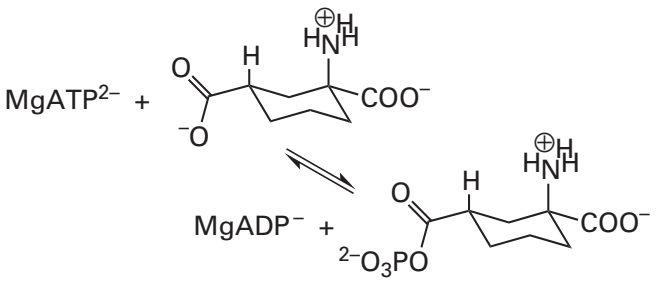
$$\text{L-glutamate} + NH_3 + MgATP^{2-} \rightleftharpoons MgADP^- + HOPO_3^{2-} + \text{L-glutamine} \quad (5\text{–}77)$$

to identify an intermediate in the enzymatic reaction. When the enzyme from *E. coli* is mixed with L-glutamate and MgATP^{2-} in the absence of ammonia, a large change in fluorescence of the protein occurs that is consistent with formation of an intermediate.[274] If this intermediate sits in the active site for any length of time in the absence of ammonia, 5-carboxy-2-pyrrolidone is formed by cyclization of an activated L-glutamate



(5–78)

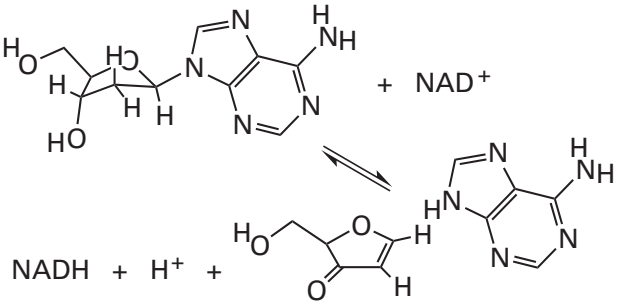
where X is a good leaving group, presumably phosphate. Attempts to isolate directly the expected intermediate, 5-phospho-L-glutamate, usually have been unsuccessful, owing to the spontaneous formation of 5-carboxy-2-pyrrolidone in solution after denaturation of the enzyme. *cis*-1-Amino-1,3-dicarboxycyclohexane, however, is a reactant for glutamine synthetase that resembles L-glutamate[275] but cannot cyclize as L-glutamate can. When *cis*-1-amino-1,3-dicarboxycyclohexane is incubated with ovine glutamine synthetase, in the absence of ammonia, the analogous acyl phosphate is formed, and it can be isolated and identified chemically[276]



(5–79)

These results demonstrate the ability of the enzyme to form an acyl phosphate at the proper position in a reactant.

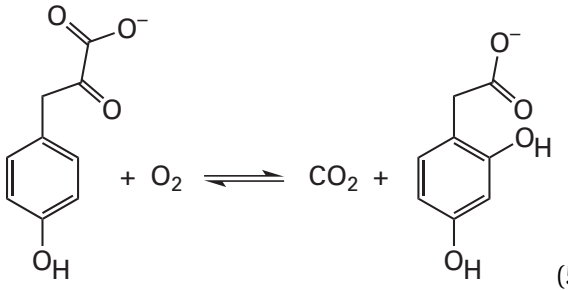
If an alternative reactant is used, the intermediate formed by the enzyme can also be unstable but nevertheless **disintegrate in such a way as to implicate the existence of a particular intermediate.** For example, bovine adenosylhomocysteinase, in addition to catalyzing its normal reaction (Equation 5–2), also catalyzes the unnatural oxidative elimination of adenine from 2′-deoxyadenosine



(5–80)

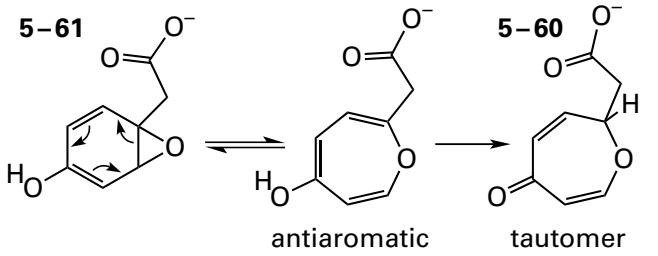
concomitant with reduction of the prosthetic NAD^+ to NADH.[277] This elimination is consistent with the initial formation of 2′-deoxy-3′-oxoadenosine during a reaction analogous to the first step in the normal enzymatic reaction (Figure 5–2).

Another strategy is to **mutate the enzyme** to block the enzymatic reaction in such a way that a noncovalent intermediate will accumulate. For example, when Phenylalanine 337 in 4-hydroxyphenylpyruvate dioxygenase



(5–81)

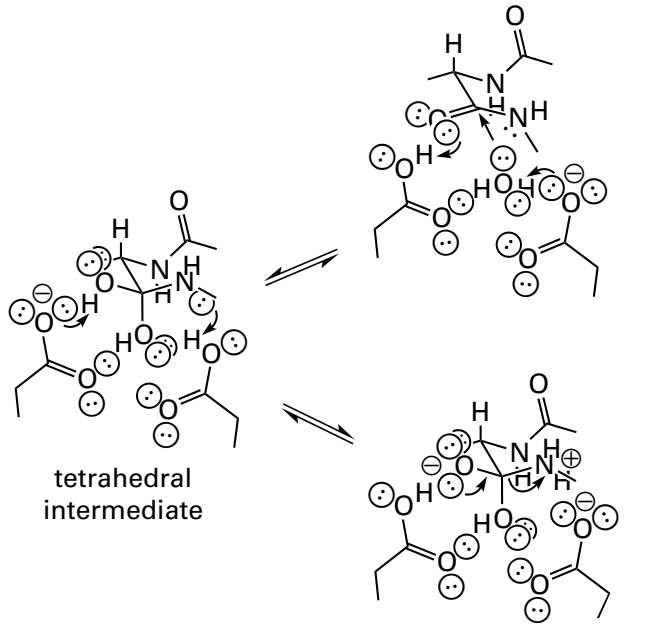
from *Streptomyces avermitilis* was mutated to isoleucine, the enzyme still converted 4-hydroxyphenylpyruvate into homogentisate but also produced oxepinone **5–60**[278]



(5–82)

which is the product expected from the rapid, nonenzymatic rearrangement of benzene oxide **5–61** believed to be the noncovalent intermediate in the normal enzymatic reaction.

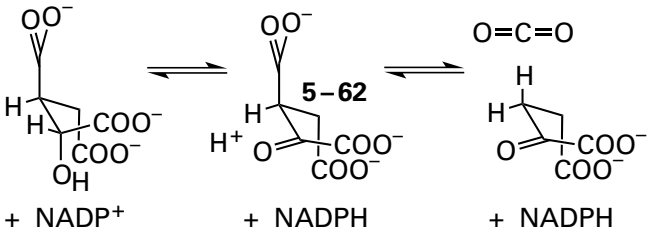
A noncovalent intermediate can also be accumulated in an active site for crystallographic observation by decreasing the rate of the enzymatic reaction in such a way that the **steps following formation of the intermediate are inhibited**. When crystals of the aspartic endopeptidase HIV-1 retropepsin from human immunodeficiency virus type 1 were soaked in a solution of the peptide AETFYVDGAA at pH 2.5, a pH at which the enzyme has little enzymatic activity, the tetrahedral intermediate in the enzymatic reaction (previously Equation 4–376)



(5–83)

could be observed occupying the active site in the resulting map of electron density.[279] The tetrahedral intermediate for hydrolysis of the peptide NLLTQI was observed crystallographically in the active site of the same enzyme in which Isoleucine 54 had been mutated to valine to decrease enzymatic activity.[280]

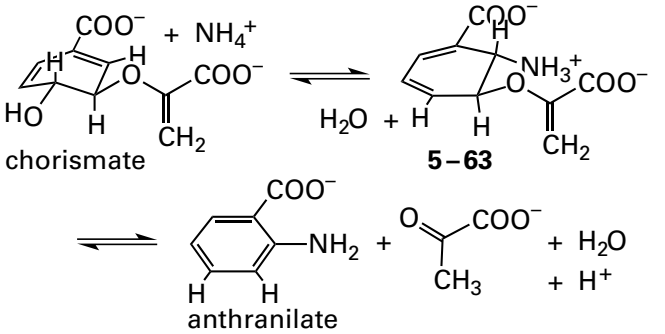
Isocitrate dehydrogenase ($NADP^+$) catalyzes the oxidative decarboxylation of isocitrate



(5–84)

by passing through the noncovalent intermediate oxalosuccinate (**5–62**), an α-oxo acid. A mutant of the enzyme from *E. coli* in which Lysine 230 was changed to methionine was shown to be inhibited in the decarboxylation step of the mechanism.[281] When crystals of the mutant enzyme were soaked in 0.5 M isocitrate, 0.5 M Mg^{2+}, and 0.5 M $NADP^+$ for 60 s and then submitted to diffraction, electron density corresponding to oxalosuccinate was observed in the active site of the resulting crystallographic molecular model.[282] In the map of electron density, the carbon–carbon bond to the carboxylato group that dissociates as CO_2 is held parallel to the π molecular orbital system of the carbonyl by the active site, as one might expect.

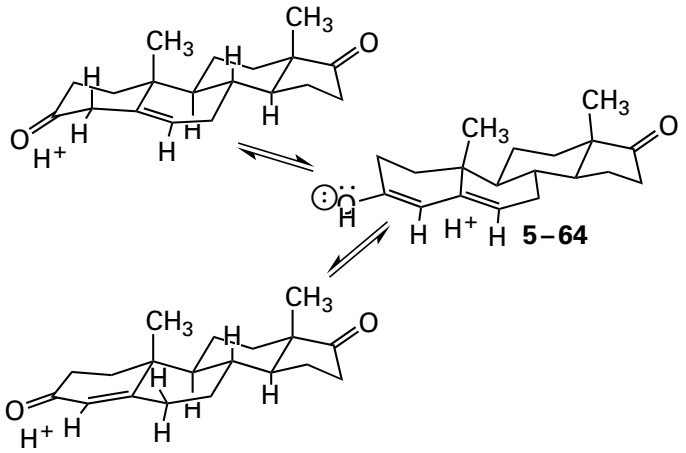
Another approach to its chemical identification is to synthesize a noncovalent intermediate, if it is stable enough to be synthesized, and show that the synthetic compound is converted by the enzyme into its usual substrates. For example, enol ether **5–63** is an intermediate in the addition–elimination catalyzed by anthranilate synthase



(5–85)

It is stable enough to be synthesized chemically,[283] and when it was mixed with NH_4^+ and anthranilate synthase from *Serratia marcescens*, the enzyme could convert the synthetic compound to anthranilate in an elimination that displayed a limiting rate of 600 nmol min^{-1} mg^{-1} and a Michaelis constant for chorismate of 0.1 mM. The corresponding rate constants for chorismate at saturating NH_4^+ were 500 nmol min^{-1} mg^{-1} and 0.1 mM. These observations demonstrated that the **synthetic intermediate is kinetically competent**. Furthermore, when a mutant of the enzyme from *S. enterica*, in which Histidine 398 had been changed to methionine to decrease the rate of the elimination in the second step of the enzymatic reaction (Equation 5–85), was mixed with chorismate for 3 h, enol ether **5–63** could be isolated from the solution,[284] and at 0 °C, the wild-type enzyme produces enol ether **5–63** and releases a portion of it into the solution.[285]

Unsaturated enol **5–64** (see Equations 4–416 and 4–417)



(5–86)

that is the intermediate in the reaction catalyzed by steroid Δ-isomerase has been synthesized.[286] The enzyme from *Comamonas testosteroni* converts the synthetic intermediate (Int) to a mixture of the two steroids that are substrates for the enzyme with a specificity constant, k_{Int}, of 230 μM^{-1} s^{-1} which is indistinguishable from the specificity constant, $k_{\Delta 5}$, of 210 μM^{-1} s^{-1} for the conversion of androst-5-ene-3,17-dione (Δ5) to androst-4-ene-3,17-dione. Again, the synthetic intermediate is kinetically competent.

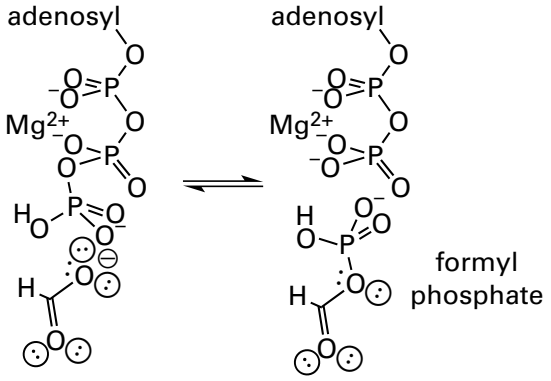
In many instances, however, a synthetic compound that is identical to an actual **noncovalent intermediate is not kinetically competent** when added to the enzyme and the remainder of the substrates required for enzymatic activity. One reason for this failure is that, to protect the normally formed intermediate from hydrolysis, dissociation, or another alteration that would occur in a partially aqueous environment, the active site of the enzyme closes around the substrates to shield them almost

completely from the solution before the intermediate is formed. Another reason is that, to prevent its undesired rearrangement or decomposition, the intermediate, after it is formed, is tightly circumscribed by the active site. In such instances, it can be difficult for the intermediate, when it is present in the solution, necessarily without a complete set of reactants, to effect the same rearrangements of the active site that occur in the normal sequence of events when a complete set of reactants binds to the active site.

Formate—tetrahydrofolate ligase

$$MgATP^{2-} + \text{formate} + \text{tetrahydrofolate} \rightleftharpoons MgADP^{-} + HOPO_3^{2-} + \text{10-formyltetrahydrofolate} \quad (5\text{–}87)$$

has formyl phosphate as an intermediate in its reaction

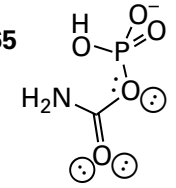


(5–88)

Formyl phosphate is unstable and is rapidly hydrolyzed in solution at neutral pH. Presumably this unstable intermediate is protected from counterproductive hydrolysis by the active site. Electron density for formyl phosphate and $MgADP^-$ has been observed in the active site of the enzyme from *Moorella thermoacetica* crystallized in the presence of $MgATP^{2-}$ and formate but in the absence of tetrahydrofolate.[287] In the absence of tetrahydrofolate, the enzyme from *Clostridium cylindrosporum* slowly releases formyl phosphate, formed at its active site, into the solution.[288] These observations are evidence that formyl phosphate is a genuine noncovalent intermediate.

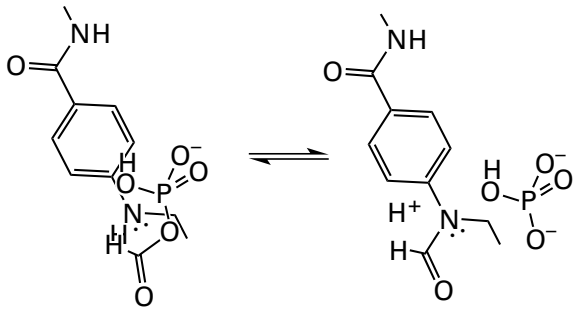
When synthetic formyl phosphate, however, is mixed with the enzyme in the presence of $MgADP^-$ and tetrahydrofolate, both 10-formyltetrahydrofolate (Equation 5–87 in the forward direction) and $MgATP^{2-}$ (Equation 5–87 in the reverse direction) are produced, but the catalytic constants k_0 for the respective rates of their production from formyl phosphate were only 3% and 1% of the catalytic constants for their rates of production from the usual substrates for the enzyme.[289] Carbamoyl phosphate

5–65



resembles formyl phosphate and is mistaken by the enzyme for formyl phosphate. The enzyme catalyzes phosphotransfer from carbamoyl phosphate to $MgADP^-$ to form $MgATP^{2-}$ (the reverse of Equation 5–88), consistent with the role of formyl phosphate as an intermediate in the enzymatic reaction,[290] but again the rate of the unnatural reaction is only about 1% that of the reaction of $HOPO_3^{2-}$ and 10-formyltetrahydrofolate with $MgADP^-$ to form $MgATP^{2-}$.

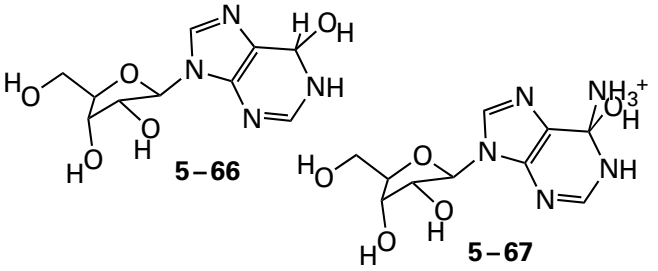
The purpose for producing formyl phosphate as an intermediate is to activate the carboxy group by providing an excellent leaving group. This activation permits formate to form the anilide in a nucleophilic substitution with a poor nucleophile



(5–89)

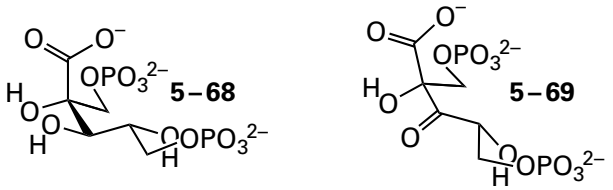
The nucleophile is a poor one ($pK_a = -1.25$) because the pair of electrons on the exocyclic nitrogen of the anilino group is withdrawn into the π system of the phenyl group. This delocalization positions the pair of electrons in a molecular orbital perpendicular to the plane of the phenyl ring rather than residing in an sp^3 atomic orbital on the nitrogen as it would in an amino group.

Analogues for intermediates of high energy can be used as evidence for the existence of that intermediate in an enzymatic reaction. It has already been noted that analogues for intermediates of high energy (Table 3–7) are often competitive inhibitors with high affinity for the active sites of enzymes, and several examples of such analogues have already been presented and discussed at length. The earlier discussion focused on these inhibitors as evidence for the proposal that the active sites of enzymes are constructed to bind intermediates of high energy tightly and thereby lower the free energy required to produce these intermediates at the active site. Another view of such observations is that if a particular compound has been designed to mimic a postulated intermediate in a proposed mechanism for the enzymatic reaction, the fact that it binds tightly to the active site is evidence for the existence of that intermediate. For example, the inhibition of bovine adenosine deaminase by (6*S*)-6-hydroxy-1,6-dihydropurine ribonucleoside (**5–66**)

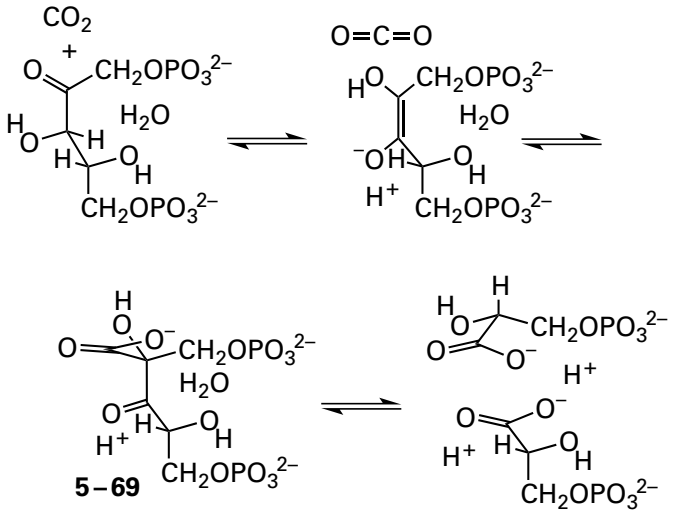


with competitive inhibition constant of 0.2 pM, is strong evidence that the noncovalent intermediate in the enzymatic reaction (see Figure 3–36) is tetrahedral intermediate **5–67**.[291-293]

2-Carboxy-D-arabinitol 1,5-bisphosphate (**5–68**)



is an inhibitor of ribulose-bisphosphate carboxylase from *Spinacia oleracea* with a dissociation constant around 0.2 pM.[294,295] This observation is one fact providing evidence for the existence of 2-carboxy-3-oxo-D-arabinitol 1,5-bisphosphate (**5–69**) as the noncovalent intermediate[296] preceding the retro-Claisen condensation catalyzed by ribulose-bisphosphate carboxylase (previously Equation 4–173)



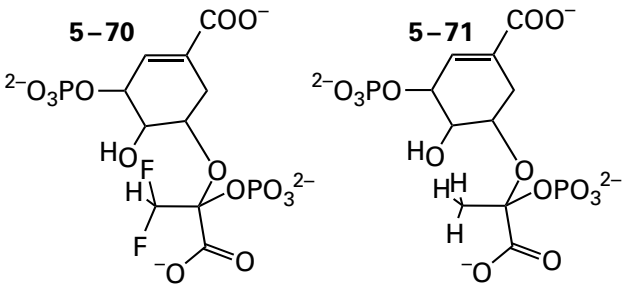
(5–90)

that produces two molecules of 3-phospho-D-glycerate. Intermediate **5–69** is formed from D-ribulose 1,5-bisphosphate at the active site by an isomerization analogous to the one catalyzed by triose-phosphate isomerase, followed by a nucleophilic addition of the resulting *cis*-enediolate to carbon dioxide. When the enzyme from *S. oleracea* was mixed with CO_2 and D-ribulose 1,5-bisphosphate and then denatured with acid after 0.3 s and the resulting solution was reduced immediately with $NaBH_4$, both 2-carboxy-D-arabinitol 1,5-bisphosphate (**5–68**) and 4-carboxy-D-arabinitol 1,5-bisphosphate, the two products expected from nonstereospecific reduction of intermediate **5–69** at the central carbonyl group, were identified as products in 7% yield relative to the concentration of active sites.[297] The reduction produces the diastereomeric mixture because it occurs nonstereospecifically after intermediate **5–69** has been ejected from the active site by acidic denaturation, so the fact that both diastereomers are present is evidence for the existence of the noncovalent intermediate. There are crystallographic molecular models of analogue **5–68** of the noncovalent intermediate, in the active sites of ribulose-bisphosphate carboxylases from *S. oleracea* (Figure 3–53),[298,299] *Rhodospirillum rubrum*,[300] and *Synechococcus*.[301]

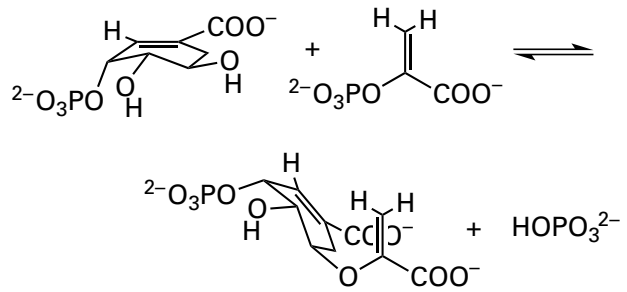
Analogue **5–68** is a far more potent inhibitor (K_d = 0.2 pM) of the enzyme than its epimer 2-carboxy-D-ribitol 1,5-bisphosphate (K_d = 1 μM).[294,302] Both inhibitors have the same stereochemistry at carbons 3 and 4 as D-ribulose 1,5-bisphosphate. The only difference between them is the stereochemistry at carbon 2, and the large difference in their dissociation constants, as well as the stereochemistry of the products of reduction of the ejected intermediate,

identifies the stereochemistry of the nucleophilic addition of the *cis*-enediolate to CO_2 (Equation 5–90) during the enzymatic reaction.

The fact that (*R*)-difluoromethylketal phosphate **5–70**

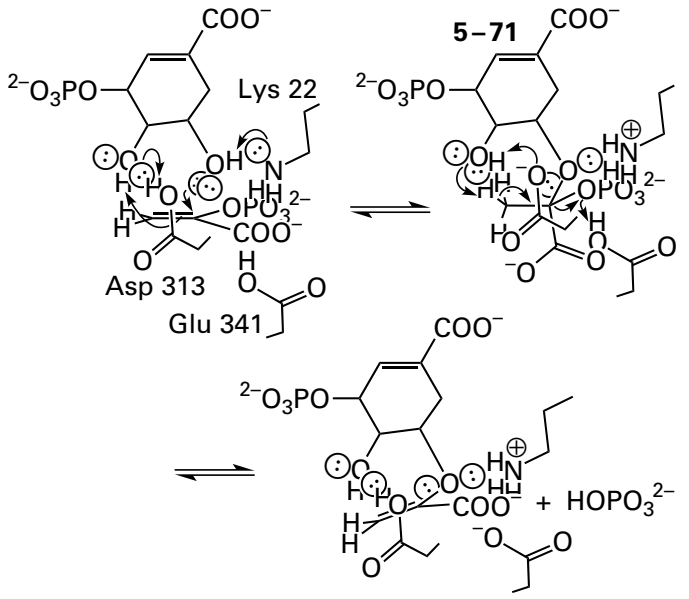


is a competitive inhibitor with a high affinity (K_i = 4 nM)[303] for the active site of 3-phosphoshikimate 1-carboxyvinyltransferase (see Equation 4–321; previously Problem 4–26)



(5–91)

from *Petunia hybrida* has been presented as evidence that (*S*)-methylketal phosphate **5–71*** is an intermediate in the reaction catalyzed by the enzyme (previously Equation 4–414)



(5–92)

(*S*)-Methylketal phosphate **5–71** has been synthesized; and when it was mixed with the enzyme, it was converted to a 3:1:1 mixture of the substrates 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate (product of Equation 5–91) and phospho*enol*pyruvate and 3-phosphoshikimate (reactants in Equation 5–91), as expected for a noncovalent intermediate in the reaction.[304]

The facts that (*S*)-difluoromethylketal phosphate is a weaker competitive inhibitor (K_i = 75 nm)[303] and that (*R*)-methylketal phosphate is not converted to substrates by the enzyme[304] verify the stereochemistry of the actual intermediate in the enzymatic reaction.

There is a crystallographic molecular model of (*R*)-difluoromethylketal phosphate **5–70** occupying the active site of 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli*,[305] and noncovalent intermediate **5–71** has been observed crystallographically in the active site of an inactive mutant of the enzyme from *E. coli*—in which the catalytic acid, Aspartate 313, had been changed to alanine—when it was crystallized in the presence of 3-phosphoshikimate and phospho*enol*pyruvate,[306] When the enzyme from *Streptococcus pneumoniae* was crystallized from a solution containing 3-phosphoshikimate and (*Z*)-3-fluorophospho*enol*pyruvate, electron density for the monofluoromethylketal phosphate analogue of **5–70** was found in the active site of the enzyme.[307]

When 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli* was mixed at high concentration with an equimolar amount of shikimate 3-phosphate and 2 mM phospho*enol*pyruvate and 5 mM phos-

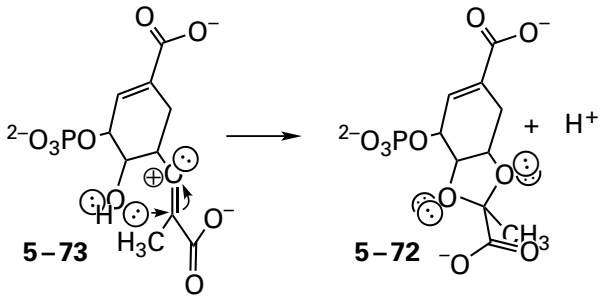
*The two fluorines invert the stereochemical designation.

phate, an equilibrium was established on the active site in which intermediate **5–71** comprised 30% of the several bound reactants[308] and from which, upon alkaline denaturation of the protein, ketal phosphate **5–71** could be isolated and identified by nuclear magnetic resonance spectroscopy.[309] When a solution (450 μL) containing 12 mM shikimate 3-phosphate and a 3.4 mM concentration of active sites for 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli* was mixed with a solution (21 μL) containing 267 mM [2-^{13}C]phospho*enol*pyruvate (final concentration 12.5 mM) or a solution (450 μL) containing 4 mM shikimate 3-phosphate and a 1.1 mM concentration of active sites was mixed with a solution (8 μL) containing 244 mM [3-^{13}C]phospho*enol*pyruvate (final concentration 4.3 mM), additional absorptions appeared in the nuclear magnetic resonance spectra that were assigned to the respective carbons-13 in intermediate **5–71**, bound at equilibrium in the respective active sites.[310]

When ketal phosphate **5–71,** isolated from the active site of 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli* by alkaline denaturation, was mixed with fresh enzyme, it was converted to substrates at a rate (120 s^{-1})[311] close to the rate (420 s^{-1}) at which the intermediate was calculated to decompose to substrates of the enzymatic reaction.[308]

From all these observations, it has been concluded that the first step of the reaction catalyzed by 3-phosphoshikimate 1-carboxyvinyltransferase (Equation 5–91) is nucleophilic addition of the 5-hydroxy group of 3-phosphoshikimate to carbon 2 of phospho*enol*pyruvate to produce ketal phosphate **5–71**. This rather unusual nucleophilic addition, which is not stabilized in any usual manner, appears to be an inescapable conclusion. The concerted addition of a hydron to carbon 3 of phospho*enol*pyruvate during nucleophilic addition of the 5-hydroxy group or the initial hydronation of carbon 3 to produce a carbenium ion at carbon 2 must be required to avoid formation of a primary carbanion at carbon 3, which would result from unassisted addition of the 5-oxido group of the conjugate base of 3-phosphoshikimate.

The fact that a minor side product of the enzymatic reaction is ketal **5–72**



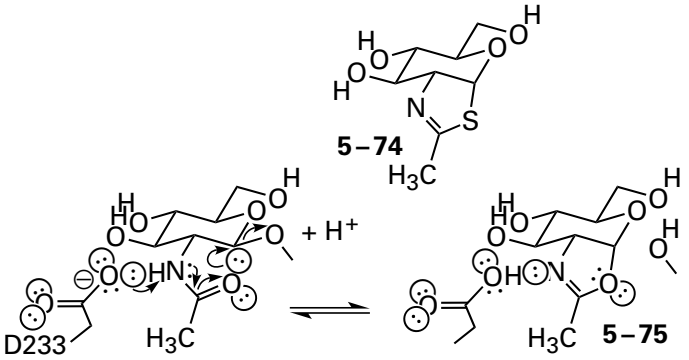
(5–93)

suggests that phosphate leaves from intermediate **5–71** to produce oxocarbenium ion **5–73** as an intermediate before a hydron is removed from the methyl group to form the desired product.[312,313] It is possible, however, that ketal **5–72** is the result of an intramolecular concerted nucleophilic substitution at the tertiary carbon of intermediate **5–71**.

The related enzyme[314] UDP-*N*-acetylglucosamine 1-carboxyvinyltransferase (20% identity; 2.6 gap percent) catalyzes addition of the 3-hydroxy group of UDP-*N*-acetylglucosamine to phospho*enol*pyruvate and the subsequent elimination of phosphate. Chemical and crystallographic evidence has been presented for an intermediate in this enzymatic reaction that is analogous to methylketal phosphate **5–71**.[315-317]

Noncovalent intermediates are also formed by substrate-assisted catalysis. Enzymes such as chymotrypsin (Figure 3–6), 4-α-glucanotransferase (**5–11**), cellulase (**5–14**), and alkaline phosphatase (Equation 5–33) have covalent intermediates in their enzymatic reactions. Each of these covalent intermediates is formed by a nucleophilic substitution in which the electrophile is an atom in a substrate and the nucleophile is a heteroatom in the side chain of an amino acid in the active site. In other instances, however, the nucleophile used in analogous enzymatic reactions is a functional group in the substrate itself rather than in the enzyme, such as the 2′-hydroxy group on the substrate for ribonuclease (Figure 4–46). A noncovalent intermediate, such as 2′,3′-cyclic phosphate in the cleavage of RNA by ribonuclease, results from this intramolecular substrate-assisted catalysis.

β-*N*-Acetylhexosaminidase catalyzes hydrolysis of an *N*-acetylgalactosamine or *N*-acetylglucosamine from the nonreducing end of an oligosaccharide. The fact that thiazoline **5–74**[318]



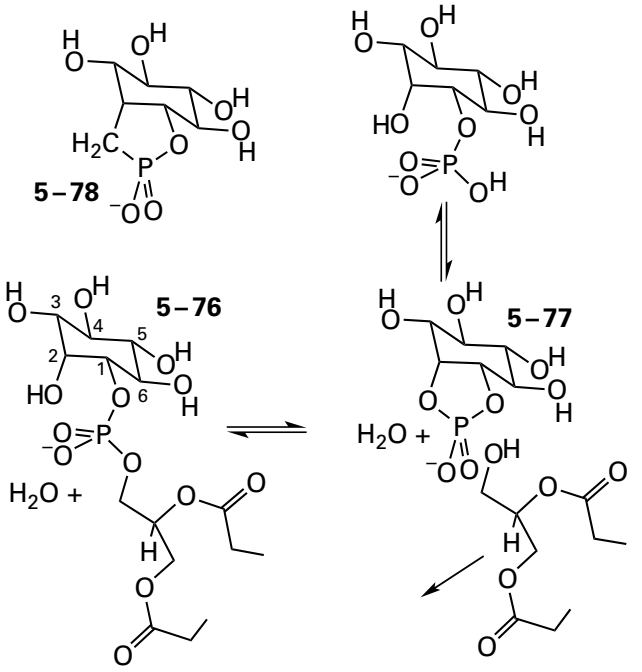
(5–94)

is a competitive inhibitor (K_i = 70 nM) of the human enzyme[319] is evidence that *β*-*N*-acetylhexosaminidase catalyzes its reaction by intramolecular concerted nucleophilic substitution of the hydroxy group of the adjacent saccharide at the reducing end of *N*-acetylgalactosamine or *N*-acetylglucosamine by the acyl oxygen of its *N*-acetyl group (Equation 5–94) with oxazoline **5–75** as a noncovalent intermediate.

In crystallographic molecular models of thiazoline **5–74** in the active sites of isoenzymes of human *β*-*N*-acetylhexosaminidase and a bacterial homologue, the carboxy groups homologous to that of Aspartate 233 in the human A isoenzyme form hydrogen bonds to the respective imino nitrogens of the inhibitor.[320-322] These facts identify that carboxy group as the one performing two roles. First, it acts as the catalytic base required to remove the hydron from the 2-imino nitrogen of the substrate (pK_a = 17) to increase sufficiently the nucleophilicity of the acyl oxygen in the nucleophilic substitution. Second, it acts as a catalytic acid (right side of Equation 5–94) to hydronate the imino nitrogen to make the oxygen a better leaving group in the second concerted nucleophilic substitution of the hydroxy group of a molecule of water for the acyl oxygen of the acetyl group to complete the hydrolysis.

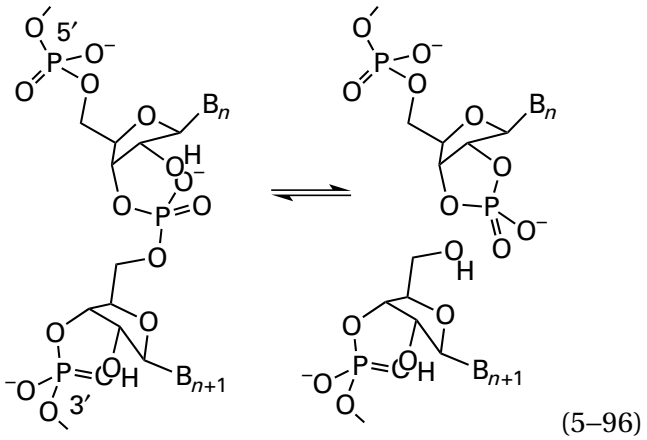
Protein O-GlcNAcase from *B. thetaiotaomicron* is an enzyme that hydrolyzes an *N*-acetylglucosamine from a serine in a glycoprotein by substrate-assisted catalysis through the same oxazoline (**5–75**) as the one formed in the active site of *β*-*N*-acetylhexosaminidase.[319] When Aspartate 242, the aspartate that acts as a catalytic base and then a catalytic acid at the imino group of *N*-acetylglucosamine in the active site of this enzyme, is mutated to asparagine, oxazoline **5–75** can be seen in the map of electron density for the active site computed from the diffraction of a crystal of the enzyme that had been mixed with an *N*-acetylglucoside with a good leaving group.[323] The fact that oxazoline **5–75** is observed in the active site in the mutant but not in the wild type implies that the importance of hydronation of its nitrogen to create a leaving group capable enough to participate in a nucleophilic substitution that breaks the oxazoline, which should be quite stable, is significantly greater than the need to dehydronate the imino group during formation of the oxazoline.

Phosphoinositide phospholipase C hydrolyzes the phosphodiester in 1-phosphatidyl-1D-*myo*-inositol.[324] The enzyme from *B. cereus* converts 1-phosphatidyl-1D-*myo*-inositol (**5–76**) to 1,2-diacyl-*sn*-glycerol and 1D-*myo*-inositol 1,2-cyclic phosphate (**5–77**), which are both released from the active site, and then the enzyme slowly hydrolyzes the 1D-*myo*-inositol 1,2-cyclic phosphate to 1D-*myo*-inositol 1-phosphate



(5–95)

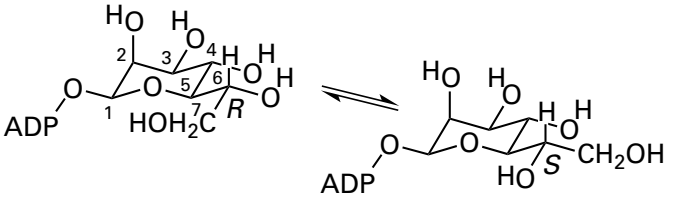
This behavior is analogous to the reaction catalyzed by ribonuclease (previously Equation 4–364)



(5–96)

Bovine phosphoinositide phospholipase C, however, produces 90% 1D-*myo*-inositol 1-phosphate and 10% 1D-*myo*-inositol 1,2-cyclic phosphate, and it does not hydrolyze the 1D-*myo*-inositol 1,2-cyclic phosphate once it has been released into the solution.[325] Electron density for the inhibitor 1D-*myo*-inositol-2-methylene-1,2-cyclic phosphonate (**5–78**), a stable analogue of 1D-*myo*-inositol 1,2-cyclic phosphate, has been located in the active site of a crystallographic molecular model of phosphoinositide phospholipase C from *R. norvegicus*.[324] All these results suggest that, in the active site of the enzyme from mammals such as *B. taurus* and *R. norvegicus*, 1D-*myo*-inositol 1,2-cyclic phosphate (**5–77**) is a noncovalent intermediate in the enzymatic reaction that remains bound in the active site and that is converted, almost exclusively, into 1D-*myo*-inositol 1-phosphate, the major product of the enzymatic reaction (Equation 5–95).

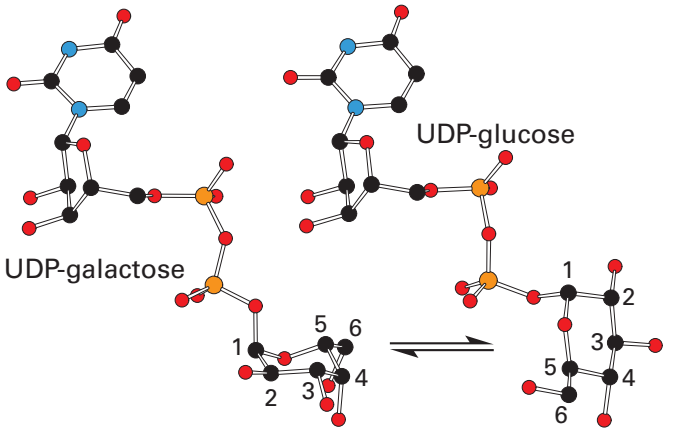
Ketones or ketimines transiently formed from alcohols or amines, respectively, are noncovalent intermediates in a number of enzymatic reactions. In most of these instances, a prosthetic NAD^+, tightly bound at the active site, oxidizes a secondary alcohol or internal primary amine that is the reactant to produce the respective ketone or ketimine as an intermediate. This intermediate then undergoes a transformation, and the resulting, transformed ketone or ketimine is then reduced by NADH to a secondary alcohol or primary amine on the same carbon on which it was in the reactant. In the process, the prosthetic NAD^+ is regenerated. For example, in the active site of ADP-*glyceromanno*-heptose 6-epimerase



(5–97)

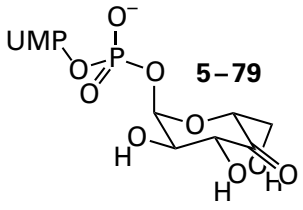
the prosthetic NAD^+ removes the hydride from the secondary alcohol at carbon 6 of the *β*-L-*glycero*-*manno*-heptosyl group, oxidizing it to the ketone, and then the prosthetic NADH reduces the ketone by adding a hydride to the face opposite from the one from which the hydride was removed.[326] The ketone formed by the oxidation leaks slowly from the active site, while ADP-*glyceromanno*-heptose 6-epimerase from *E. coli* is turning over, and the ketone can be trapped with phenylhydrazine.[327] In the active site of the enzyme, however, there seems to be enough room for the ketone at carbon 6 to flip over as a result of rotation about the bond between carbons 5 and 6, dragging along the hydroxymethyl group, and the ketone then can be reduced from the other face to complete the epimerization most of the time before the intermediate ketone can escape from the active site.[328,329]

In the active site of UDP-glucose 4-epimerase (previously Equation 3–422)[330]



(5–98)

the tightly bound NAD^+ oxidizes UDP-D-galactose to UDP-4-oxo-D-glucopyranoside



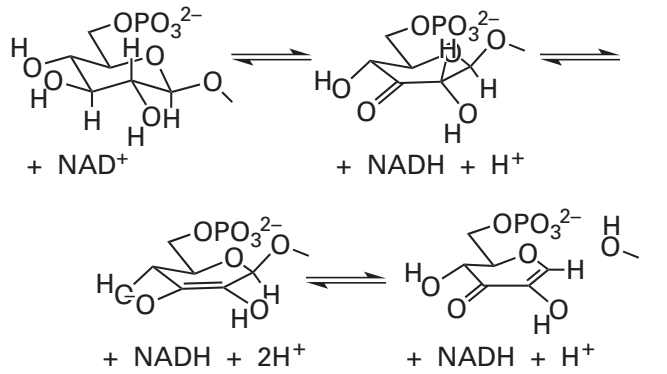
UDP-4-Oxoglucopyranoside **5–79** pivots in the active site,[331] and then the NADH reduces it to UDP-D-glucose.

There are several observations consistent with the existence of UDP-4-oxoglucopyranoside **5–79** as a noncovalent intermediate in the enzymatic reaction. When either UDP-D-glucose or UDP-D-galactose is mixed with the enzyme from *E. coli*, a portion of the bound NAD^+ is reduced to NADH.[332] When TDP-4-oxo-6-deoxy-D-glucose is mixed with enzyme, the prosthetic group of which has been reduced to NADH, TDP-4-oxo-6-deoxy-D-glucose is reduced to a mixture of TDP-6-deoxy-D-glucose and TDP-6-deoxy-D-galactose.[333] When high concentrations of the enzyme are mixed with UDP-D-galactose and $Na[^3H]BH_4$ is subsequently added, the intermediate UDP-4-oxo-D-hexose **5–79** can be trapped as a mixture of UDP-[4-^{3}H]-D-glucose and UDP-[4-^{3}H]-D-galactose.[334,335] Crystallographic molecular models of the NADH form of the enzyme from *E. coli* in a mismatched, inactive complex with UDP-D-glucose[336] and in a mismatched, inactive complex with UDP-D-galactose[331] define the flip that the intermediate UDP-4-oxo-D-hexose **5–79** performs (Equation 5–98). This conformational change is the only transformation the intermediate undergoes between the oxidation and the subsequent reduction, as is the conformational change on a much smaller scale in the epimerization catalyzed by ADP-*glyceromanno*-heptose 6-epimerase (Equation 5–97).

A related enzyme (25% identify, 2.7 gap per cent), CDP-paratose 2-epimerase from *Yersinia pseudotuberculosis*, catalyzes the epimerization of CDP-D-paratose (CDP-3,6-dideoxy-D-glucose) at carbon 2 instead of carbon 4. It does so, however, by oxidizing carbon 4 to the ketone, as might be expected from its similarity, but then performing a retroaldol condensation between carbons 2 and 3 followed by an aldol condensation, after the aldehyde at carbon 2 has flipped over, to produce the other epimer at carbon 2.[337] Oxidation to the ketone permits the retroaldol and aldol condensations to occur.

The reaction catalyzed by CDP-paratose 2-epimerase illustrates the fact that the production of a ketone as an intermediate by a prosthetic NAD^+ **opens up all the chemistry available to a carbonyl group**, such as the acidity of its α carbon, elimination from its β carbon, nucleophilic addition, aldol and retroaldol condensations, and Claisen and retro-Claisen condensations. For example, adenosylhomocysteinase exploits the acidity of the α carbon of the ketone produced as an intermediate in its enzymatic mechanism to set up elimination of a poor leaving group (Figure 5–2).

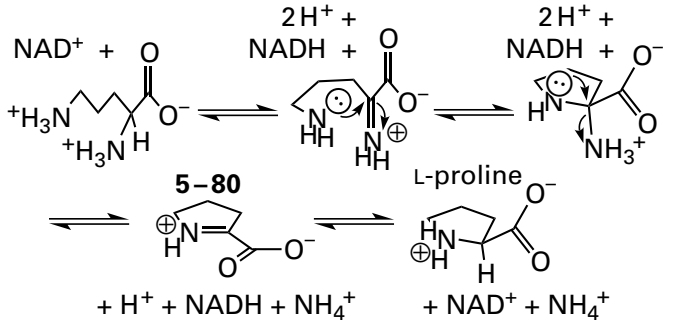
6-Phospho-β-glucosidase from *T. maritima*[338] uses a similar β-elimination



(5–99)

in which a molecule of water substitutes in reverse for the hydroxy group on the alcohol that is the leaving group. This mechanism is an alternative to the usual mechanisms for hydrolysis of a glycoside. The chemical evidence for this alternative mechanism includes a requirement for catalytic amounts of NAD^+ (1 μM) for catalysis; the appearance of deuterium at carbon 2 of the product when the reaction is run in D_2O; the ability of the enzyme to exchange a deuterium for a hydrogen at carbon 2 of 1,5-anhydroglucitol 6-phosphate, an analogue of the product D-glucose 6-phosphate; and a kinetic isotope effect for the substrate 4-nitrophenyl 6-phospho-β-D-[3-^{2}H]glucoside.[339] None of these observations would result from the usual mechanisms for hydrolyzing glycosides in which the leaving group is hydronated, and a covalent intermediate with a carboxylato group from the active site at carbon 1 may or may not form.

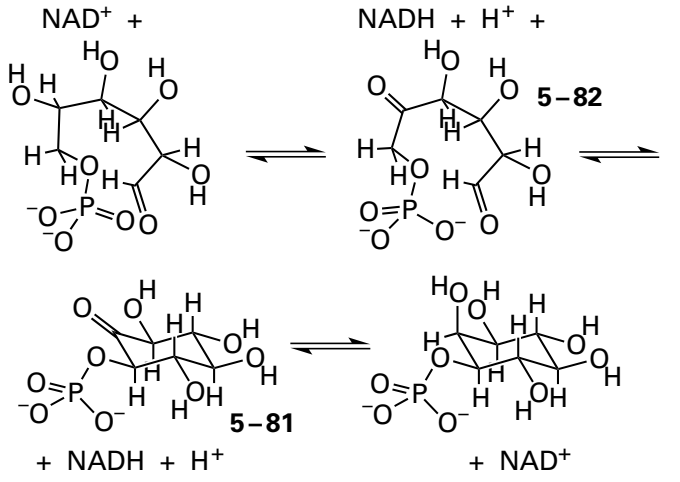
Ornithine cyclodeaminase, which catalyzes a formal nucleophilic substitution of an amino group for ammonia at the α carbon of L-ornithine, proceeds through **nucleophilic substitution at an iminium ion**



(5–100)

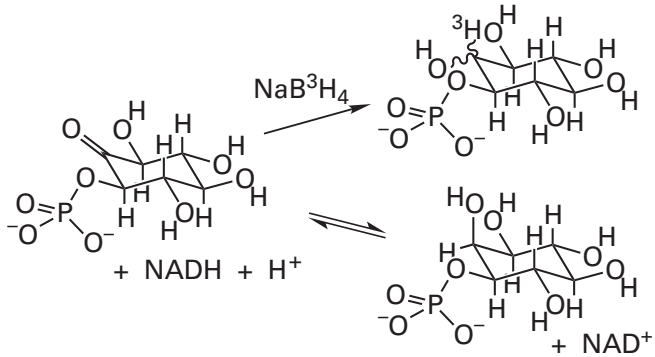
The enzyme contains a tightly bound, prosthetic NAD^+. Upon addition of L-ornithine to ornithine cyclodeaminase from *Clostridium sporogenes*, a portion of the NAD^+ is reduced to NADH.[340] In the crystallographic molecular model of the mismatched complex between the enzyme from *Pseudomonas putida* and NADH and L-ornithine, carbon 2 of L-ornithine and carbon 4 of nicotinamide are in the proper orientation for transfer of a hydride, and they are only 0.38 nm apart.[341] In the reaction catalyzed by the enzyme, the δ nitrogen of L-ornithine is retained in L-proline.[340] All these results are consistent with formation of 3,4-dihydro-2*H*-pyrrole-5-carboxylic acid (**5–80**) as a noncovalent intermediate in the enzymatic reaction (Equation 5–100) by nucleophilic addition to the intermediate imine. In this reaction, a hydride is removed from and returned to the same carbon with the same stereochemistry, so the only role of the oxidation is to produce the imine and exploit its capabilities.

The 2-dehydro-1D-*myo*-inositol 3-phosphate (**5–81**), produced as a noncovalent intermediate in the conversion of D-glucose 6-phosphate to 1D-*myo*-inositol 3-phosphate catalyzed by inositol-3-phosphate synthase (see Equation 4–179)



(5–101)

is the product of carbon–carbon bond formation by an **aldol condensation** enabled by the initial oxidation of D-glucose 6-phosphate at carbon 5 by the prosthetic NAD^+. Noncovalent intermediate **5–81** can be trapped nonstereospecifically[342] from the active site of the enzyme from *R. norvegicus* with NaB^3H_4 before it can be reduced stereospecifically in the normal reaction to 1D-*myo*-inositol 3-phosphate by the prosthetic NADH



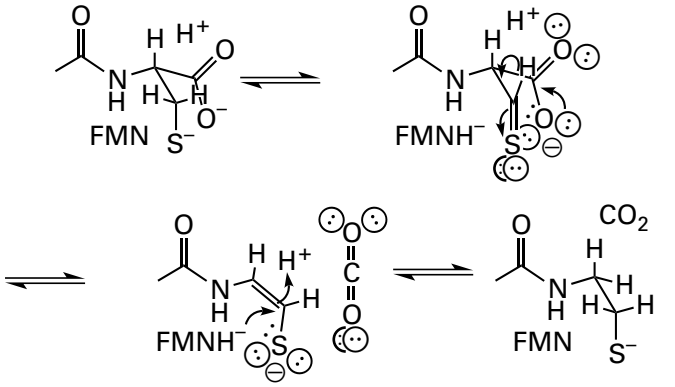
(5–102)

that is the product of the initial oxidation of D-glucose 6-phosphate (Equation 5–101). The lack of stereospecificity in the reaction with NaB^3H_4 demonstrates that it was noncovalent intermediate **5–81** that was reduced because, as usual, the product of the enzymatic reduction is stereospecific.

2-Dehydro-1D-*myo*-inositol 3-phosphate (**5–81**) has been synthesized. It is a competitive inhibitor ($K_i = 4\ \mu M$) of the enzyme from *S. cerevisiae* when the prosthetic group is NAD^+, but it is converted to the product of the enzymatic reaction, 1D-*myo*-inositol 3-phosphate, when the prosthetic group in the active site is NADH.[343] When crystals of the enzyme from *Archaeoglobus fulgidus* are mixed with the substrate D-glucose 6-phosphate and NAD^+ and heated at 80 °C for 15 min in the absence of Mg^{2+}, electron density corresponding to NADH and the ketone 5-dehydro-D-glucose 6-phosphate (**5–82**) could be observed in the active site of the enzyme.[344] In this instance, the absence of Mg^{2+}, a cofactor for the enzyme, prevents the aldol condensation from occurring. In the crystallographic molecular model, carbon 4 of nicotinamide and carbonyl carbon 5 of 5-dehydro-D-glucose 6-phosphate are in the proper orientation for hydride transfer, and they are only 0.35 nm apart, so the ketone and NADH must represent the more favored participants in that particular equilibrium.

Instead of using NAD^+ to oxidize an alcohol or amine to a ketone or ketimine, respectively, phosphopantothenoylcysteine decarboxylase uses a prosthetic

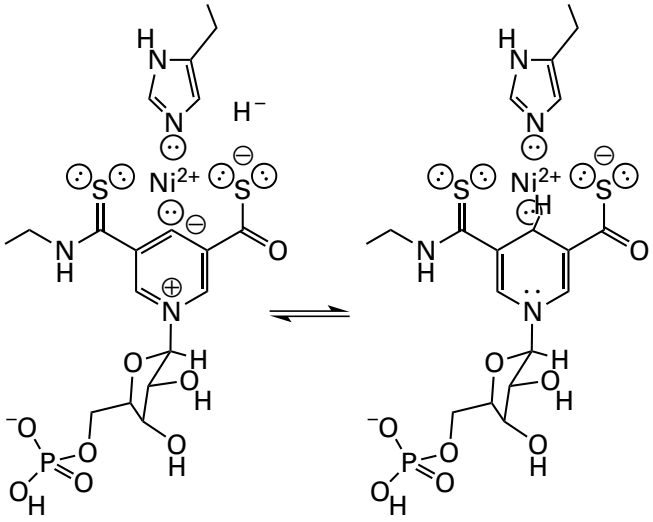
flavin mononucleotide[345] to oxidize a thiol to a thioaldehyde[346]



(5–103)

The 1-carboxythioaldehyde is easily decarboxylated, in contrast to the thiol. A hydron then replaces the carboxy group, and the decarboxylated thioaldehyde is reduced back to the thiol to produce pantotheine 4′-phosphate. One piece of evidence for this mechanism is that the analogue of the substrate with a cyclopropyl group at carbon 2 of the cysteinyl group is an active-site label for human phosphopantothenoylcysteine decarboxylase. This ability requires that the thiol be oxidized to the thioaldehyde to make the cyclopropyl group an effective electrophile.[347]

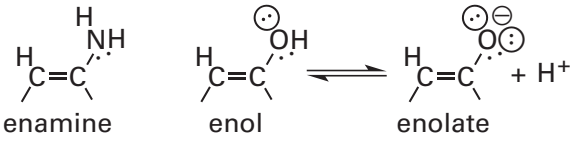
Lactate racemase from *Lactiplantibacillus plantarum* equilibrates (*S*)-lactate and (*R*)-lactate. The active site contains a prosthetic Ni^{2+} that is coordinated by a derivative of nicotinamide mononucleotide. One ligand to the Ni^{2+} is carbon 4 of the nicotinamide ring.[348] The nicotinamide is still reduced by a hydride, and it seems as though the nickel is simply a rather complex substitute for the usual hydrogen atom at carbon 4 of nicotinamide



(5–104)

The active site racemizes lactate by using the derivative of nicotinamide mononucleotide to remove a hydride to form pyruvate as an intermediate and then add the hydride to the opposite side of the carbonyl carbon in the pyruvate. Pyruvate (in a constant ratio of greater than 0.30 mole fraction relative to competent active sites) has been isolated upon quenching a solution in which (*S*)-lactate and (*R*)-lactate were being equilibrated.[348] As might be expected, regardless of the mechanism of racemization, a deuterium kinetic isotope effect (2.2) was observed for the racemization of either (*S*)-[2-^{2}H]lactate or (*R*)-[2-^{2}H]lactate.

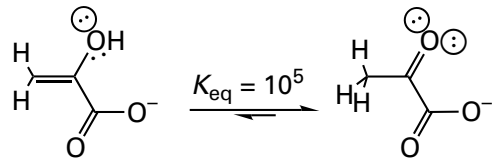
Enamines, enols, and enolates, the conjugate bases of enols, are common noncovalent heterolytic intermediates in enzymatic reactions.



(5–105)

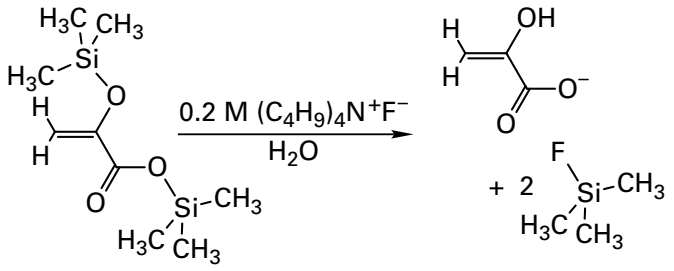
This widespread behavior has already been discussed from a mechanistic standpoint. Several strategies have been used to provide **chemical evidence for their existence**.

In some instances, the enol that is the intermediate can be **synthesized**. For example, *enol*pyruvate, the enol of pyruvate, is unstable in solution relative to the ketone (Figure 1–23)



(5–106)

but the enol can be generated rapidly by treatment of phospho*enol*pyruvate with alkaline phosphatase[349] or by fluorolysis of 2-[(trimethylsilyl)oxy]propenoic acid trimethylsilyl ester[350]



(5–107)

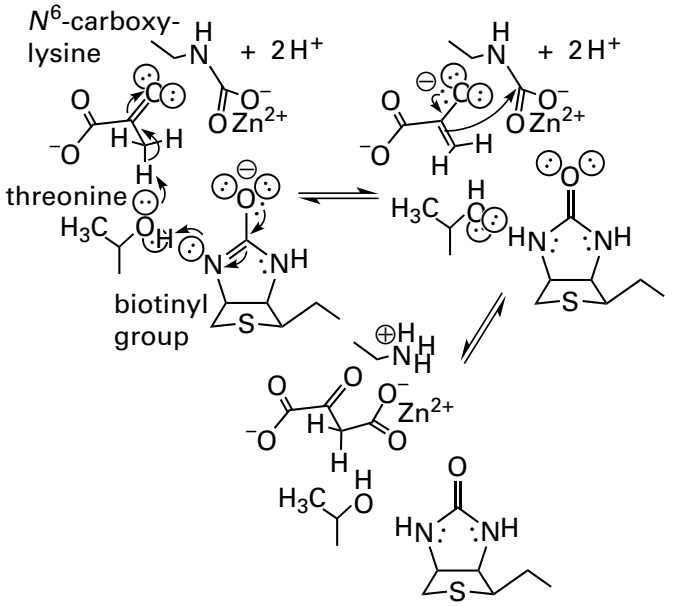
The lifetime of *enol*pyruvate (4 min at pH 6.4 and 20 °C) is long enough that it can be examined as an intermediate in an enzymatic reaction.

The biotinyl enzyme methylmalonyl-CoA carboxytransferase

(*S*)-methylmalonyl-SCoA + pyruvate ⇌ propanoyl-SCoA + oxaloacetate

(5–108)

transfers a carboxy group from (*S*)-methylmalonyl-SCoA to pyruvate by using a prosthetic biotinyl group as the carrier between the active site responsible for decarboxylating (*S*)-methylmalonyl-SCoA and the active site responsible for carboxylating pyruvate, and vice versa. When methylmalonyl-CoA carboxytransferase from *Propionibacterium freudenreichii* is present in a solution made from ^2H_2O, in which either (*Z*)-[3-^{3}H]*enol*pyruvate or (*E*)-[3-^{3}H]*enol*pyruvate is then generated rapidly, the enzyme catalyzes the stereospecific conversion of the respective *enol*pyruvate to [3-^{3}H,3-^{2}H]pyruvate by deuteronating its 2-*Si* face in a reaction requiring the presence of (*S*)-methylmalonyl-SCoA, which itself does not participate in the deuteronation.[351] This ability of the enzyme to accept *enol*pyruvate as a reactant and stereospecifically add a deuteron is consistent with the participation of *enol*pyruvate as an intermediate in the enzymatic reaction occurring at the active site in the enzyme responsible for carboxylating the pyruvate*



(5–109)

Crystallographic molecular models of the same active site, occupied in turn by pyruvate and oxaloacetate, suggest that the carboxy group is transferred from the biotinyl group to the amino group of Lysine 184 to produce an N^6-carboxylysine, which becomes a ligand to a prosthetic Zn^{2+}, before the carboxy group is transferred to the *enol*pyruvate.[352]

A related (31% identity; 1.5 gap percent) enzyme, pyruvate carboxylase from *Rhizobium etli*, performs the same carboxylation in an almost identical active site. Crystallographic molecular models of two active sites, one occupied by pyruvate and the other by biotin, suggest that the anionic conjugate base of the nitrogen in the ureylene of the biotin, the same one from which the carboxy group was just transferred to Lysine 184, provides the base that removes the hydron from pyruvate to form the enolate of *enol*pyruvate.[353] Its basicity is relayed through a threonine that is at the same location in the active sites of both pyruvate carboxylase and methylmalonyl-CoA carboxytransferase. There is also an N^6-carboxylysine at the same location in the active site of pyruvate carboxylase from *R. etli* as that occupied by the one in methylmalonyl-CoA carboxytransferase.

*The mechanism, as written, does not involve a deuterium, but if it were proceeding in ^2H_2O with phospho*enol*pyruvate as the reactant, deuterium would be added stereospecifically to phospho*enol*pyruvate by reversal of the first step because there would be a deuterium in the active site on threonine.

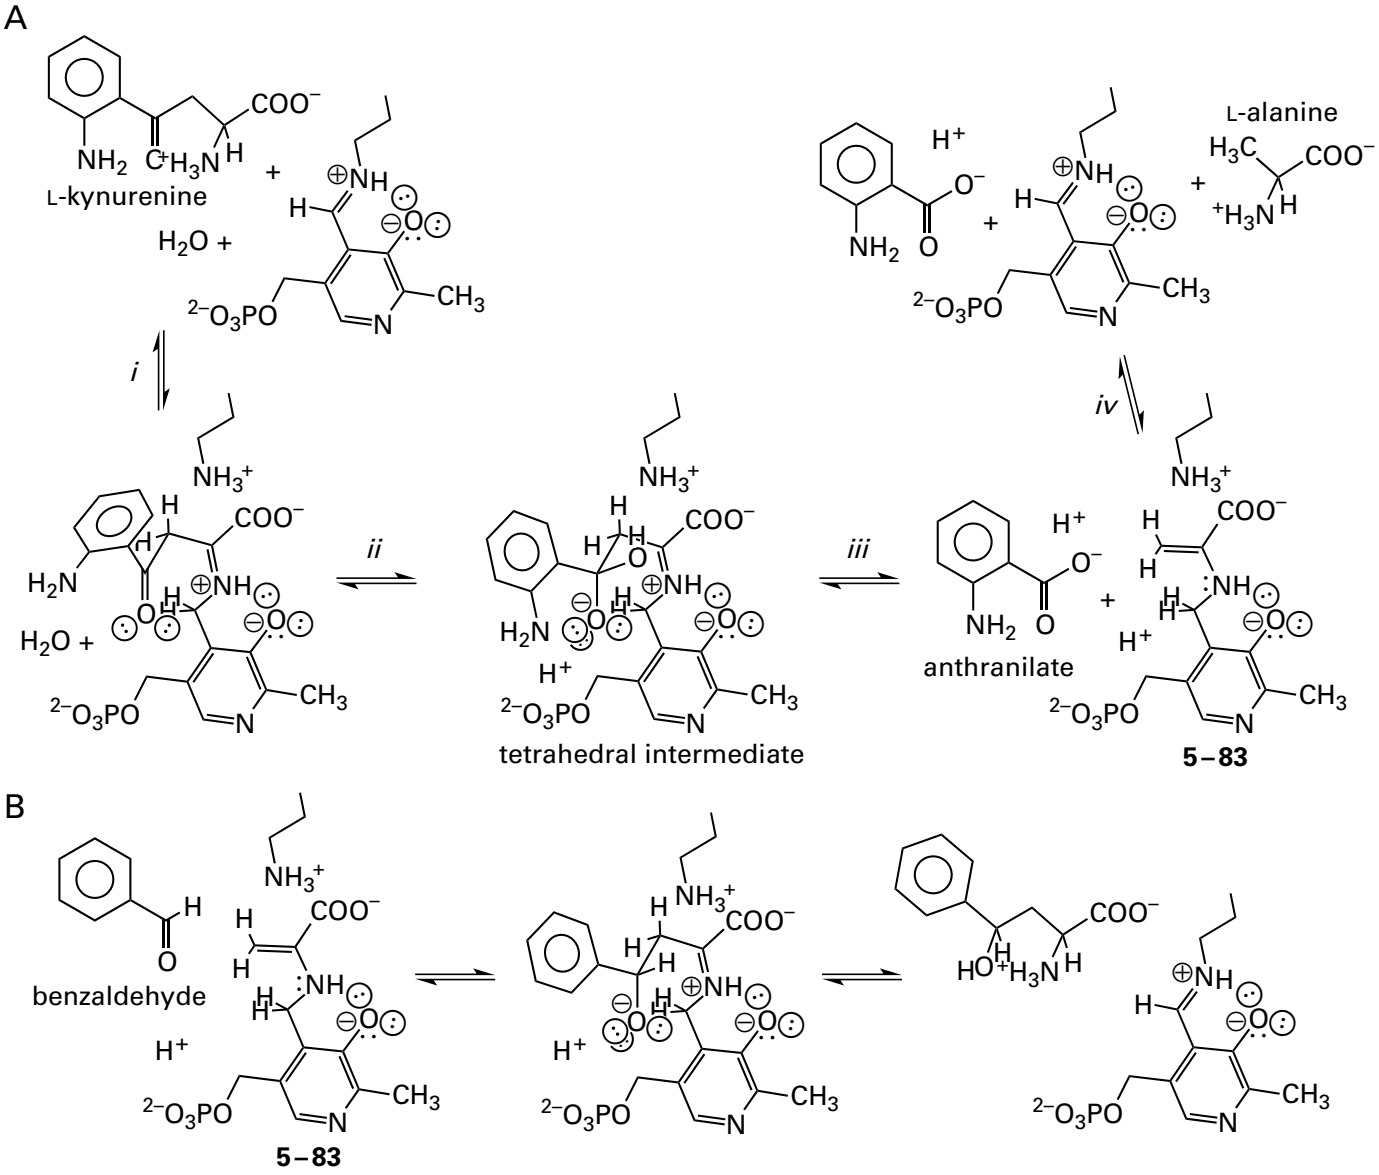


Figure 5–7: Intermediates in the reaction catalyzed by kynureninase. (**A**) Steps in the mechanism. (*i*) The external pyridoximine of L-kynurenine is formed from an internal pyridoximine of the prosthetic pyridoxal 5′-phosphate by transimination (Figure 2–2), and the imine of pyridoxamine 5′-phosphate and 2,4-dioxo-4-(*o*-aminophenyl)butanoic acid is then produced by tautomerization (Equations 2–4 and 2–21). (*ii*) A molecule of water then adds nucleophilically to the former carbonyl of L-kynurenine, and a hydron is removed from the resulting hydronated hydroxy group to yield the tetrahedral intermediate. (*iii*) *N*-Pyridoxylenamine **5–83** then leaves from the tetrahedral intermediate to produce anthranilate. (*iv*) Upon hydronation of the methylene carbon of *N*-pyridoxylenamine **5–83** (not shown), the imine of pyridoxamine 5′-phosphate and pyruvate is produced; the external imine of pyridoxal 5′-phosphate and L-alanine is then formed by the usual tautomerization; and L-alanine is released by transimination. (**B**) *N*-Pyridoxylenamine **5–83** can be trapped by its addition to the carbonyl of benzaldehyde added to the solution to produce the secondary alcohol. 2-Amino-4-hydroxy-4-phenylbutanate is released from the adduct by transimination. The production of 2-amino-4-hydroxy-4-phenylbutanate is a signature of the intermediacy of *N*-pyridoxylenamine **5–83** in the enzymatic reaction.

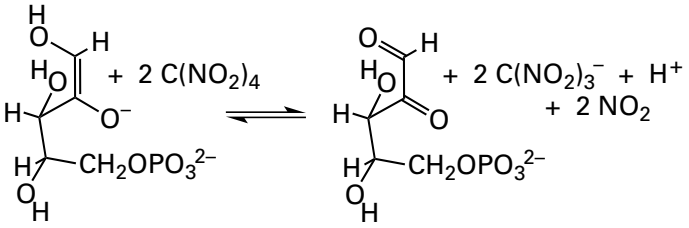
When phospho*enol*pyruvate carboxylase from *Zea mays*, which is neither a biotinyl enzyme nor related to biotinyl carboxylases, is reconstituted with unphysiological, prosthetic metallic cations such as Ni^{2+} and Co^{2+} that stabilize the intermediate *enol*pyruvate and decrease the rate of carboxylation, *enol*pyruvate leaks out of the active site and can be trapped as pyruvate.[354]

Enamines and enolates are electron-rich nucleophiles, and when one is an intermediate in an enzymatic reaction, it can be **trapped by an electrophile**. For example, *N*-pyridoxylenamine **5–83**, formed from L-kynurenine following the dissociation of anthranilate during the retro-Claisen condensation catalyzed by kynureninase (Figure 5–7) from *Pseudomonas marginalis*, can be trapped with benzalde-

hyde[355] before it is converted to L-alanine, the other usual product of the enzymatic reaction, and the prosthetic pyridoxal 5′-phosphate. The *enol*pyruvate that is an intermediate in the reaction catalyzed by pyruvate kinase (Figure 4–52) could be trapped as bromopyruvate in 2–30% yield, based on the concentration of active sites, when the enzyme from *O. cuniculus* is rapidly mixed with 2 M $HClO_4$ saturated with Br_2, a strong electrophile.[356] Pyruvate itself is not brominated under the same conditions.

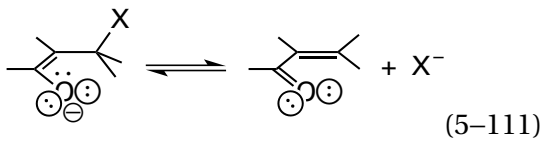
Because they are electron-rich, intermediate enolates and enamines in enzymatic reactions have also been identified by their susceptibility to **oxidation**. It has already been noted that the electron-rich 1,2-enaminol produced between fructose-bisphosphate aldolase and glycerone phosphate (Figure 4–36) can be oxidized to the imino aldehyde (Equation 5–44) with $Fe^{III}(CN)_6^{3-}$ as well as other oxidants.[357] Reduction of tetranitromethane in the presence of phosphogluconate dehydrogenase ($NADP^+$-dependent, decarboxylating) from *S. cerevisiae*, ribulose 5-phosphate, and NADPH is thought to represent oxidation of the electron-rich *cis*-enediolate that is an intermediate in the reaction catalyzed by the enzyme (Equation 5–76)[357,358]



(5–110)

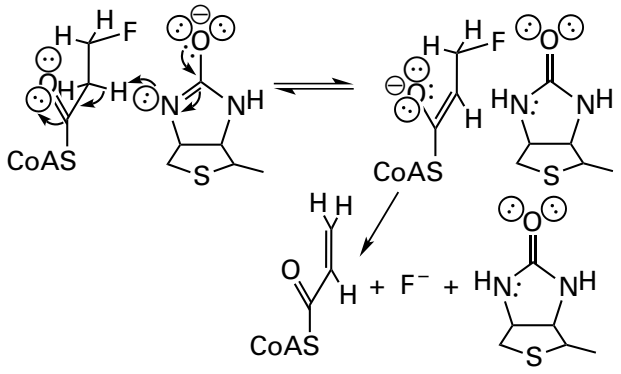
In these oxidations, the reagents used are one-electron oxidants that must remove electrons one at a time from the electron-rich enols or enamines.

If an **analogue of a reactant** is synthesized to incorporate a **good leaving group**, such as a halogen on the β carbon in the enolate formed as an intermediate in the reaction, and if the active site will recognize the analogue as a reactant, then when the enolate forms, the leaving group next to the carbanionic α carbon will leave in a β-elimination



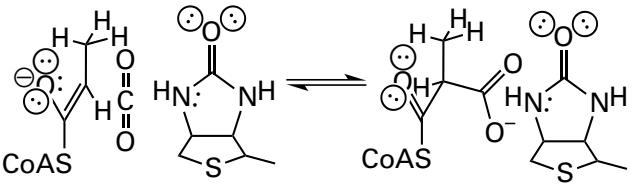
(5–111)

The product of this elimination will identify the carbanionic carbon of the enol. Porcine propionyl-CoA carboxylase* converts 3-fluoropropionyl-SCoA to acrylyl-SCoA[359]



(5–112)

a product that arises from elimination of fluoride from an intermediate enolate.[360] In the absence of a good leaving group, the conjugate base of the substrate propionyl-SCoA, which is the intermediate enolate in the normal reaction catalyzed by the enzyme, is carboxylated by carbon dioxide that has been released from the *N*-carboxybiotin bound at the active site as a prosthetic group



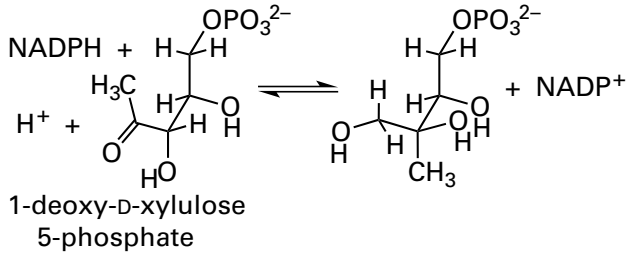
(5–113)

As was the case with the active site responsible for carboxylating pyruvate in methylmalonyl-CoA carboxytransferase (Equation 5–109), following dissociation of carbon dioxide, the anionic nitrogen from which carbon dioxide has just dissociated in the conjugate base of the biotinyl group performs the role of the catalytic base that removes the hydron

*Three different enzymes, methylmalonyl-CoA carboxytransferase, propionyl-CoA carboxylase, and pyruvate carboxylase, contain domains that are related to each other. The domains responsible for the same reaction—carboxylating propionyl-SCoA and decarboxylating methylmalonyl-SCoA—within methylmalonyl-CoA carboxytransferase from *P. freudenreichii* and porcine propionyl-CoA carboxylase are closely related (52% identity; 1.0 gap percent); less so are the domains in porcine pyruvate carboxylase and methylmalonyl-CoA carboxytransferase from *P. freudenreichii* responsible for carboxylating and decarboxylating pyruvate (31% identity; 1.4 gap percent). Both propionyl-CoA carboxylase and pyruvate carboxylase contain a domain responsible for carboxylating biotin (44% identity; 0.9 gap percent), a domain that does not exist in methylmalonyl-CoA carboxytransferase because it is not required to. These three enzymes are examples of subunit swapping and domain swapping.

from carbon during formation of the enolate (Equation 5–112), but in this instance it seems to remove the hydron directly rather than indirectly.[360]

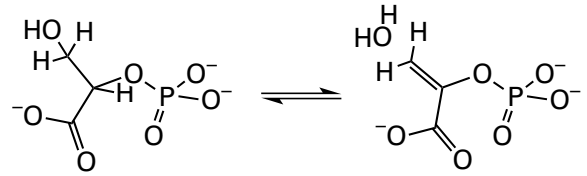
In some instances, placing a group capable of electron withdrawal on its carbanionic α carbon, rather than the β carbon, stabilizes an enolate, and this **stabilization of the enolate** is evidence for its existence as a noncovalent intermediate. For example, 1-deoxy-D-xylulose-5-phosphate reductoisomerase from *E. coli* catalyzes an isomerization[361]



(5–114)

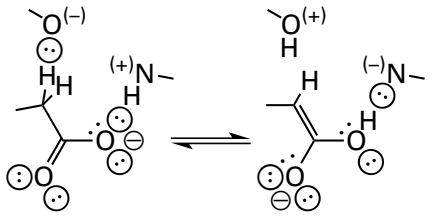
that requires the enolate of 2-hydroxypropanal as an intermediate in an aldol condensation that produces 2-*C*-methyl-D-erythritol 4-phosphate. The enolate of 2-hydroxypropanal in turn is derived from carbons 1 through 3 of 1-deoxy-D-xylulose 5-phosphate in a retroaldol condensation. When 1-fluoro-1-deoxy-D-xylulose 5-phosphate is used as a reactant, which places a fluoromethyl group on the α carbon of the enolate of 2-hydroxypropanal in place of its methyl group, the rate of this isomerization increases. This increase in rate was presented as evidence that the enolate of 2-hydroxypropanal, which would be stabilized by the fluoromethyl group on its carbanionic α carbon, is an intermediate in the reaction.[362]

The **inhibition of an enzyme by an analogue of an enolate** thought to be an intermediate in the reaction (**3–53**, **3–55**, **3–57**, **3–59**, and **3–61** in Table 3–7) is often cited as evidence of its existence. For example, enzymatic addition–eliminations that occur adjacent to carboxylato groups, as in the case of phosphopyruvate hydratase (previously Equation 4–128 and see Figures 3–35 and 4–43)



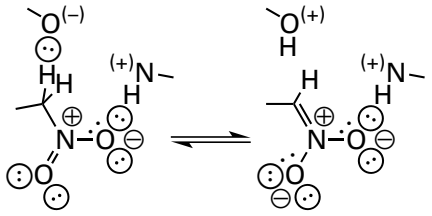
(5–115)

have been observed uniformly to proceed through the intermediate *gem*-enediolates[363]



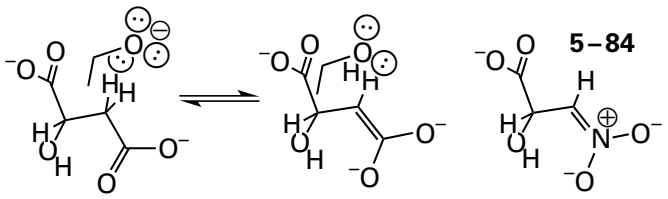
(5–116)

that are the tautomers of the carboxylates rather than through intermediate carbocations. A simple demonstration of this generalization is that these enzymes are strongly and competitively inhibited by the conjugate bases of nitro analogues of the respective enolates



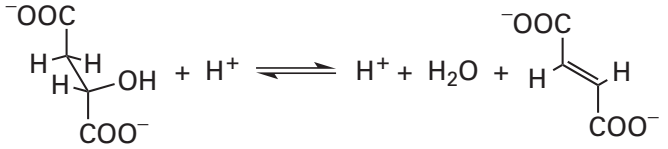
(5–117)

For example, the intermediate *gem*-enediolate



(5–118)

formed during the dehydration of (*S*)-malate and the hydration of fumarate catalyzed by fumarate hydratase (previously Equation 4–226 and see Figure 4–27)[364]



(5–119)

can be mimicked by the conjugate base of 3-nitro-2-hydroxypropionate (**5–84**).[365] The conjugate base of 3-nitro-2-hydroxypropionate is a competitive inhibitor of porcine fumarate hydratase with a dissociation constant (K_i) 10,000 times smaller than the dissociation constant ($K_{d,succ}$) for succinate (succ), also a simple competitive inhibitor of the enzyme, and 1000 times smaller than the Michaelis constant ($K_{m,mal}$) for (*S*)-malate (mal) as a reactant.

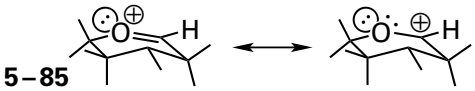
Table 5–1: Ratio of Products for the Solvolysis of β-Galactosides by β-Galactosidase[368]

β-galactoside	limiting rate[a] (μmol min^{-1} mg^{-1})	ratio of products[b]
2-nitrophenyl	360	1.97 ± 0.05
3-nitrophenyl	327	1.96 ± 0.13
3-chlorophenyl	180	2.08 ± 0.24
4-nitrophenyl	69	1.99 ± 0.05
phenyl	40	1.94 ± 0.20
4-methoxyphenyl	33	2.14 ± 0.13
4-chlorophenyl	7.5	2.02 ± 0.16
4-bromophenyl	7.0	2.03 ± 0.08

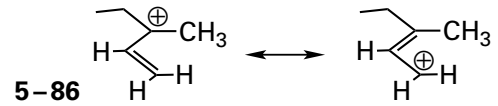
[a]Limiting rate in the absence of methanol. All reactions were run at 25 °C at pH 7.5. [b]Ratio of methyl β-D-galactoside to D-galactose for reactions run in 0.25 M methanol.

Similarly, the conjugate base of 2-amino-3-nitropropionate is a potent competitive inhibitor ($K_{mAsp}\,K_i^{-1} = 200$) of aspartate ammonia-lyase from *Clostridium budayi*;[365] the conjugate base of (3-hydroxy-2-nitropropyl)phosphonate is a potent competitive inhibitor ($K_{m,PGA}\,K_i^{-1} = 1000$) of phosphopyruvate hydratase from *S. cerevisiae*;[363] and the conjugate base of 2-hydroxy-3-nitro-1,2-propanedicarboxylate is a potent competitive inhibitor ($K_{m,cit}\,K_i^{-1} = 3000$) with respect to citrate (cit) for bovine aconitate hydratase.[366]

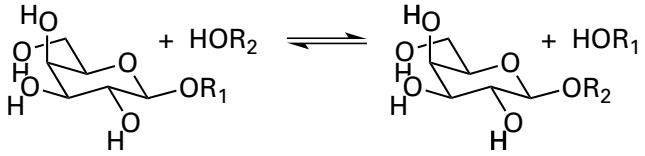
Although carbocationic intermediates are common in organic reactions under acidic conditions, they are usually encountered in enzymatic reactions only in glycosyl transfer and the biosynthesis of polyisoprenoids.[367] In a glycosyl transfer reaction, carbocationic intermediates are stabilized as oxocarbenium ions



Carbocationic intermediates involved in polyisoprenoid biosynthesis usually begin as allylic carbenium ions

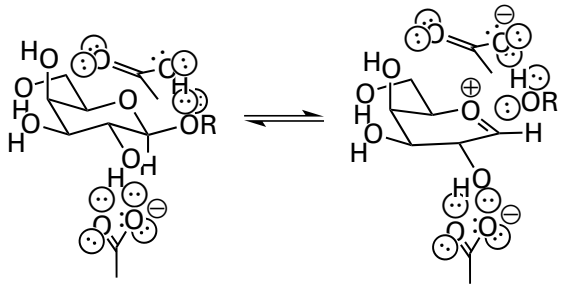


β-Galactosidase is a retaining **glycosyltransferase** that displays little specificity for the alcohols between which the galactosyl group is transferred



(5–120)

When the enzyme processed any one of a series of β-galactosides in a solution of 0.25 M methanol in water, the products were methyl β-galactoside, arising from transfer to methanol ($R_2 = CH_3$), and D-galactose, arising from transfer to water ($R_2 = H$), in a molar ratio of 2:1, even though the ratio of methanol to water in the solution was 1:220.[368] The molar ratio between the two products remained 2:1 within the experimental error of the measurements when the catalytic constant k_0 of the enzyme was varied over a 50-fold range by choosing a set of reactants that differed in the properties of the leaving group, HOR_1 (Table 5–1).[368] The most reasonable explanation for this observation is that either acceptor, water or methanol, reacts with the galactosyl group only after the leaving group has departed from the active site. The production of an oxocarbenium ion as an intermediate in the reaction

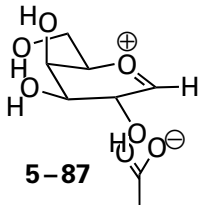


(5–121)

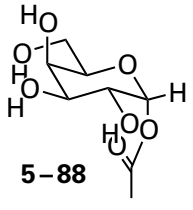
would explain these observations, as would a covalent galactosyl-enzyme intermediate.[81] In either case, the acceptor, methanol or water, would be reacting with the same intermediate left behind by the departing alcohol, regardless of the particular galactoside used to produce that intermediate.

This observation with β-galactosidase again raises the question of whether retaining glycosyl-

transferases such as β-galactosidase have **an oxocarbenium ion or an ester as an intermediate**



5–87



5–88

It has already been mentioned, for example, that there is significant controversy over whether there is an oxocarbenium ion as a stabilized noncovalent intermediate or a ester as a covalent intermediate in the nucleophilic substitutions catalyzed by lysozyme (Figure 3–27).[64] The extreme instability of an oxocarbenium ion in aqueous solution[369] is a point often mentioned in favor of the ester as a covalent intermediate. It is, however, also a point in favor of a stabilized oxocarbenium ion. The advantage of such a oxocarbenium ion as an intermediate is the fact that it would be far more reactive than ester **5–88**. Most glycosyltransferases display behavior consistent with an almost fully dissociative nucleophilic substitution.[367] Formation of a covalent intermediate can have only a small advantageous effect on the departure of the alcohol that is the leaving group while forming the covalent intermediate from a dramatically reactive intermediate that is formed anyway in the enzymatic reaction would be significantly disadvantageous for catalysis. In almost every glycosyltransferase, the rate of dissociation of the alcohol from the reactant is much slower than formation of the glycoside from the intermediate that is left behind during that dissociation. This almost universal observation would be consistent with an intermediate that is far more reactive than an ester.

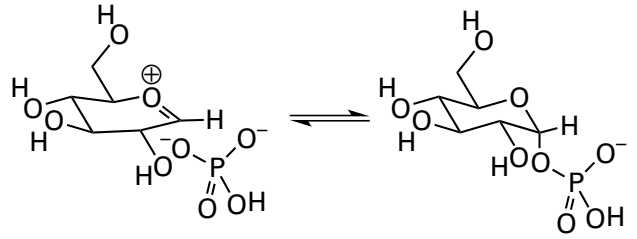
In the active sites of retaining glycosyltransferases, there is almost always the carboxylato group of a glutamate or aspartate adjacent to the carbonyl carbon that becomes the oxocarbenium ion (bottom carboxylato group in Equation 5–121). Consequently, the question becomes whether the carboxylato group stabilizes an oxocarbenium ion by the effect of its electric field or captures it by forming a covalent bond with the carbonyl carbon in a dissociative nucleophilic substitution. These alternatives differ sterically. Unless the active site is constructed in such a way that the carboxylato oxygen is sterically prevented from forming a covalent bond with the oxocarbenium ion, it will almost certainly do so.

During intramolecular catalysis of the hydrolysis of an enol ether or 4-nitrophenyl riboside by carboxylato groups, oxocarbenium ions are intermediates in the absence of an adjacent carboxylato group. Results from observations of such reactions have reached different conclusions about the possibility of electrostatic stabilization of an oxocarbenium ion. In both cases, a rigid superstructure was designed that held the carboxylato group near the carbon on which the oxocarbenium ion develops but not close enough to form an unstrained ester with the carbon. In both instances, there was no evidence indicating that the adjacent carboxylato group was catalyzing the reaction nucleophilically by adding to the carbon to form an ester as a covalent intermediate in the reaction. In the case of intramolecular catalysis of the 4-nitrophenyl riboside, the carboxylato group was held rigidly by the superstructure at a distance and orientation that stringently precluded formation of an ester. The acceleration of hydrolysis of the enol ether by the nearby carboxylato group was 20-fold, but it was attributed to intramolecular acid catalysis in which the carboxy group added a hydron to the α carbon of the enol ether rather than to electrostatic catalysis.[370] The acceleration of hydrolysis of the 4-nitrophenyl riboside was 900-fold relative to the same superstructure in which the carboxylato group was replaced by a hydrogen, and it was proposed that at least a portion of this acceleration could be attributed to electrostatic catalysis.[371] A problem with these observations is that both hydrolyses were followed in aqueous solution, a situation in which electrostatic interactions are minimized by the high relative permittivity of the solvent. In the active site of an enzyme, however, the relative permittivity is much less, a fact that would increase the effectiveness of electrostatic catalysis.

Chemical evidence to support the existence of oxocarbenium ions in the mechanisms of glycosyltransferases has been presented. For example, in the reaction catalyzed by glycogen phosphorylase, a retaining glycosyltransferase

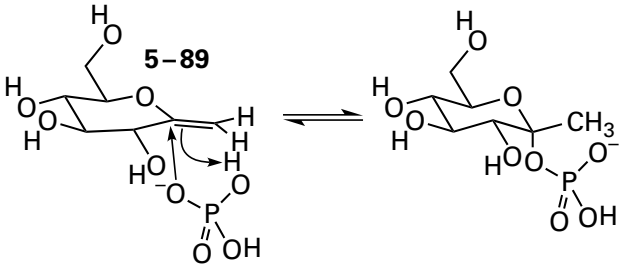
$$[(1\rightarrow4)\text{-}\alpha\text{-D-glucosyl}]_n + HOPO_3^{2-} \rightleftharpoons [(1\rightarrow4)\text{-}\alpha\text{-D-glucosyl}]_{n-1} + \alpha\text{-D-glucose 1-phosphate} \quad (5\text{–}122)$$

the phosphate could act as the enforced acceptor for an oxocarbenium ion



(5–123)

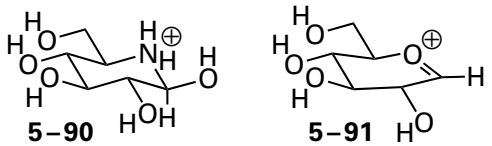
from the same side to which the leaving group in the reaction dissociates. 2,6-Anhydro-1-deoxy-D-*gluco*-hept-1-enitol (**5–89**) and phosphate are converted to 1-deoxy-α-D-*gluco*-heptulose 2-phosphate by phosphorylase from *O. cuniculus* in an addition in which the planar carbon–carbon double bond seems to be mistaken for the planar oxocarbenium ion[372,373]



(5–124)

The existence of this reaction is consistent with the existence of oxocarbenium ion in the normal reaction.

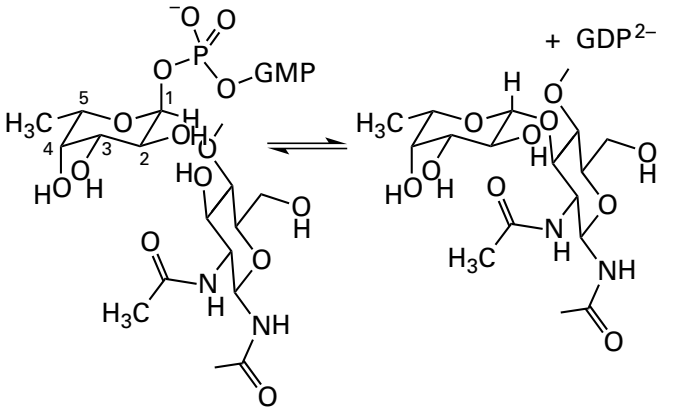
5-Deoxy-5-amino-D-glucose (**5–90**, nojirimycin)



is an antibiotic produced by *Streptomyces* that is a potent competitive inhibitor of glucosidases[374,375] at concentrations of 1–10 μM. It is thought that the ability of nojirimycin to inhibit glucosidases results from its resemblance to the oxocarbenium ion **5–91** that is the common intermediate in these reactions. 1,5-Dideoxy-5-aminoglucopyranose, a stable cyclic amine, also inhibits glucosidases[376] at concentrations of 1–10 μM, and it has been used as an analogue of an oxocarbenium ion in crystallographic studies of the active sites of glucosidases.[377]

Cyclic amines that mimic the oxocarbenium ions that would be intermediates in other glycosidases have also been synthesized and shown to be potent inhibitors.[378]

Fluoro derivatives of substrates for glycosidases have also been synthesized. If a fluoro group occupies a position adjacent to the carbon of an oxocarbenium ion that is an intermediate in an enzymatic reaction, its ability to withdraw electron density strongly should destabilize that intermediate. For example, the fact that GDP-2-deoxy-2-fluoro-β-L-fucose is a reversible, competitive inhibitor of the substrate GDP-β-L-fucose for human glycoprotein 3-α-L-fucosyltransferase, with an inhibition constant of 4 μM, rather than being a substrate itself, suggests that an oxocarbenium ion, which should be destabilized by the adjacent fluorine, is an intermediate in this inverting glycosyltransferase[379]

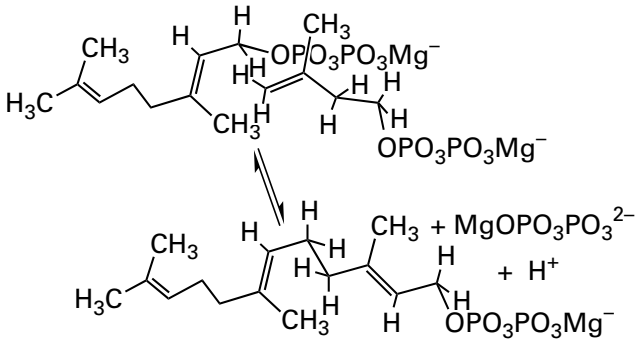


(5–125)

Values of the steady-state rate constants $k_0\,(K_{\mathrm{mUDPX}})^{-1}$ for UDP-α-D-galactofuranose, UDP-α-D-3-deoxy-3-fluorogalactofuranose, and UDP-α-D-2-deoxy-2-fluorogalactofuranose (where UDPX is the respective UDP monosaccharide) in the reaction catalyzed by UDP-galactopyranose mutase from *E. coli* are 1200, 6.6, and 0.51 $\mathrm{nM^{-1}\,s^{-1}}$, respectively. As the 3-hydroxy group is replaced by a fluorine and then the substitution is made closer to the glycosidic carbon of the galactofuranose, the rate of the enzymatic reaction decreases. This trend is consistent with the existence of an oxocarbenium ion as a carbocationic intermediate in the enzymatic reaction.[380]

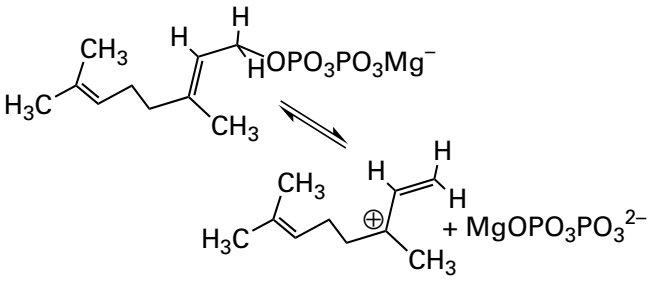
Although all these results have been interpreted as evidence for the existence of oxocarbenium ions as noncovalent carbocationic intermediates in these glycosyltransferases and the mutase, they are also consistent with the existence of an expanded transition state with oxocarbenium character in which the acceptor, in inverting glycosyltransferases, or the carboxylato group of an aspartate or glutamate, in retaining glycosyltransferases, is adding as the leaving group is departing.

Carbocationic intermediates are definitely produced in the active sites of enzymes catalyzing the biosynthesis of polyisoprenoids. For example, an initial enzyme in all these biosynthetic pathways is (2*E*,6*E*)-farnesyl diphosphate synthase[381-383]



(5–126)

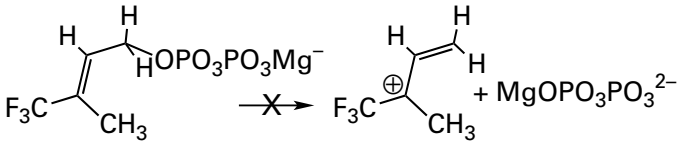
The reaction can be formulated as a dissociative nucleophilic substitution (see Figure 1–26) resembling that for the nonenzymatic cationic polymerization of alkenes at low pH. In this mechanism, a tertiary allylic carbenium ion is formed in the first step by dissociation of diphosphate, a good leaving group, from geranyl diphosphate



(5–127)

which is an allylic diphosphate. Because the diphosphate in geranyl diphosphate is on a primary carbon and because addition of the alkene proceeds with inversion of configuration at the allylic carbon bearing the diphosphate, it was also possible that a concerted nucleophilic substitution with inversion of configuration could occur at the allylic carbon rather than a dissociative nucleophilic substitution with an allylic carbenium ion as an intermediate.[384]

A decision has been made between these two possibilities by replacing one methyl group of dimethylallyl diphosphate, which is also a substrate for the enzyme in place of geranyl diphosphate, with a trifluoromethyl group.[385] In model studies, it was shown that such a replacement would increase the rate of a concerted nucleophilic substitution by a factor of 10 but would decrease the rate of a dissociative nucleophilic substitution with an allylic carbenium ion as an intermediate by a factor of 10^6 because of the difficulty of forming the carbenium ion next to an electron-withdrawing substituent



(5–128)

In the reaction catalyzed by porcine (2*E*,6*E*)-farnesyl diphosphate synthase, (trifluoromethyl)methylallyl diphosphate, although it is a competitive inhibitor, shows no reaction ($k_{0,CF3} < 10^{-6} k_{0,CH3}$). These results rule out a concerted nucleophilic substitution and are consistent with the existence of an allylic carbenium ion in the normal reaction.

A series of other **fluorinated derivatives** of geranyl diphosphate were also synthesized, and it was shown that the rate constants for their nonenzymatic solvolysis at low pH, a reaction definitely proceeding by dissociative nucleophilic substitution with an allyl carbenium ion as an intermediate, correlated closely with the catalytic constants, k_0, of the same compounds as reactants in the reaction catalyzed by (2*E*,6*E*)-farnesyl diphosphate synthase from *G. gallus*. These results also support the existence of an allyl carbenium ion as a carbocationic intermediate in this enzymatic reaction.[386]

The other carbocationic intermediate in the reaction catalyzed by (2*E*,6*E*)-farnesyl diphosphate synthase is the tertiary carbenium ion formed upon addition of the initial allylic carbenium ion to the carbon–carbon double bond (see Figure 1–26). A hydron is removed from this other carbenium ion to yield the other double bond in the product. Evidence for the existence of this other carbocationic intermediate was obtained similarly by showing that 2,2-difluoroisopentenyl diphosphate was not utilized as an acceptor in the enzymatic reaction, even when it was incubated for a period of 3 days with the enzyme and geranyl diphosphate serving as the donor of the initially formed carbenium ion.[387] Again, fluorination prevented the reaction from occurring by hindering formation of the tertiary carbenium ion on the acceptor.

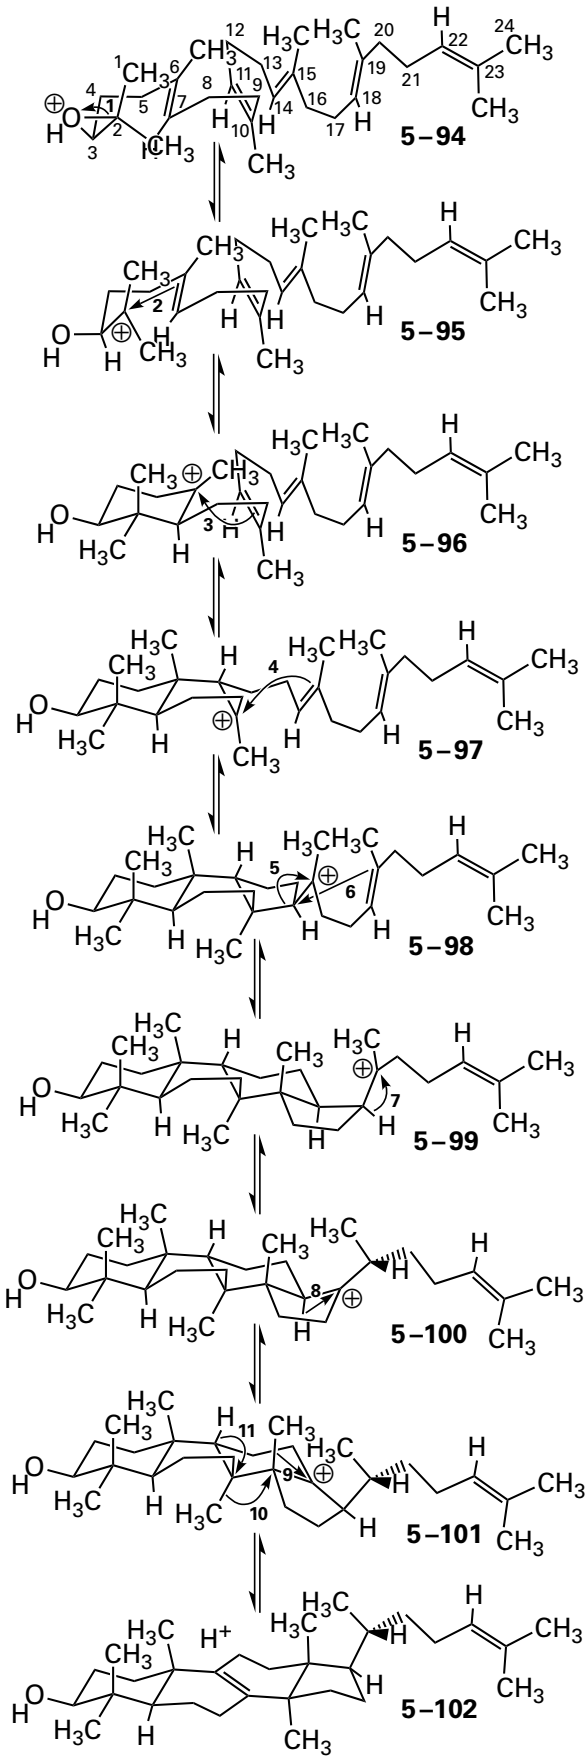


Figure 5–8: Intermediates in the reaction converting (3*S*)-2,3-epoxy-2,3-dihydrosqualene (**5–94**) into lanosterol (**5–102**) catalyzed by lanosterol synthase.[392,393] Each dissociation, ring closure, and 1,2-migration of σ bonds, hydrogens, and methyl groups that consecutively form the ten intermediate carbenium ions is numbered in bold. Seven of the intermediate carbenium ions (**5–95** through **5–101**) are drawn. The undrawn carbenium ions are those produced by 1,2-migrations numbered **5**, **9**, and **10**.

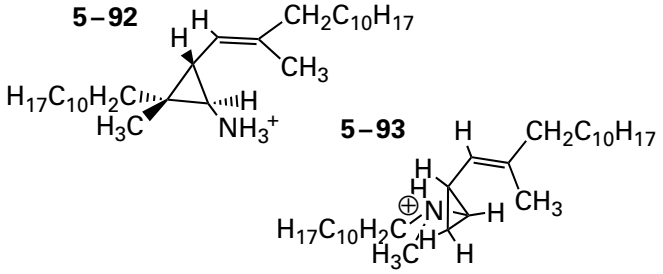
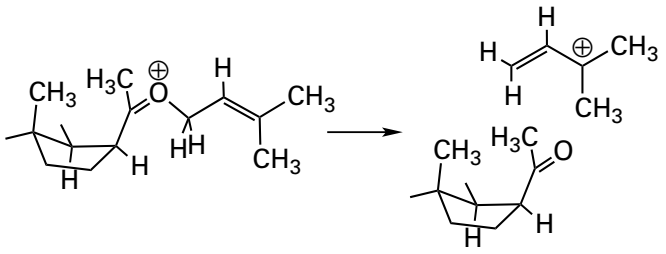
(+)-Presqualene diphosphate (**5–47**) is converted by squalene synthase to squalene (**5–48** in Equation 5–65) through two cyclopropyl carbenium ions **5–50** and **5–51** (Equation 5–66). One set of observations consistent with their existence as carbocationic intermediates is the fact that analogues **5–92** and **5–93**



in which a primary ammonio group and a tertiary **ammonio group respectively replaces the carbocationic carbon**, are effective inhibitors of squalene synthase from *S. cerevisiae*.[388] Another observation consistent with the role of carbenium ion **5–51** as an intermediate is that when an inert analogue of NADPH is added to a solution containing the enzyme from *S. cerevisiae* and farnesyl diphosphate, so that the final carbenium ion **5–49** cannot be reduced to squalene, the tertiary alcohol arising from addition of water to carbenium ion **5–51** was produced by the enzyme in 17% yield.[389,390] In the absence of NADPH, the enzyme converts (+)-presqualene diphosphate into a mixture of alcohols, which are products of addition of water to carbenium ion **5–49**, and a carbenium ion, which is the product of the immediate rearrangement of carbenium ion **5–50**.[390,391]

Lanosterol synthase produces lanosterol (**5–102**), the precursor to cholesterol, by cyclizing (3*S*)-2,3-epoxy-2,3-dihydrosqualene (**5–94**). The cyclization and rearrangement passes through ten carbenium ions (Figure 5–8).[392-394] Chemical evidence supports the existence of most of these carbocationic intermediates in the enzymatic reaction. When Histidine 234 in lanosterol synthase from

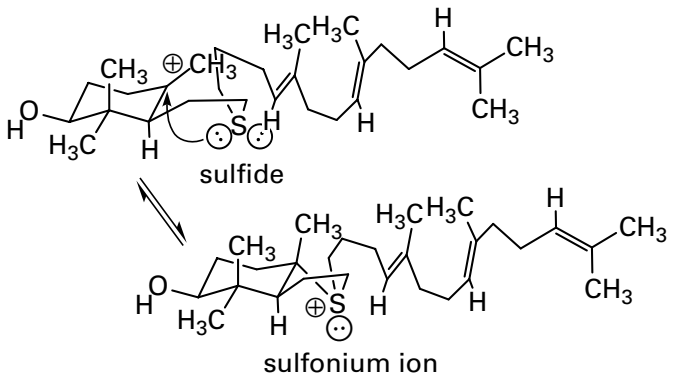
S. cerevisiae is mutated to each of the other 19 amino acids, one at a time, the various **mutants of the enzyme** produce, from (*S*)-2,3-epoxy-2,3-dihydrosqualene, in addition to lanosterol, steroids that result from the loss of a hydron adjacent to each of the carbenium ions **5–96**, **5–98**, **5–99**, and **5–101**.[395,396] When the electrophilicity of carbenium ion **5–99** is decreased dramatically by **mutating the substrate synthetically** to (20*E*)-20,21-dehydro-2,3-epoxy-2,3-dihydrosqualene, which places a double bond allylic to the carbocation, further rearrangement ceases at this point because of the stability of the allylic carbenium ion, and the alcohol resulting from addition of water to this allylic carbenium ion is produced by lanosterol synthase from *S. cerevisiae* rather than lanosterol.[397] When carbon 20 of (*S*)-2,3-epoxy-2,3-dihydrosqualene is replaced with an oxygen, the resulting oxocarbenium ion, homologous to carbenium ion **5–99**, loses an allyl carbenium ion in the active site[398]



(5–129)

and the production of the ketone by the enzyme from *S. cerevisiae* is evidence for the existence of carbenium ion **5–99**.[399] In the same enzymatic reaction, a minor product that results from a direct rearrangement of the carbenium ion arising from the (*S*)-2,3-epoxy-2,3-dihydro-20-oxasqualene that is analogous to carbenium ion **5–98** is also isolated.[400] This minor product has a cyclopentyl ring at the same location as the unexpanded cyclopentyl ring in carbenium ion **5–98**. The rearrangement of the carbenium ions in the active site probably pauses at carbenium ion **5–98** and its analogues because the next step turns a tertiary carbenium ion into a secondary carbenium ion.

Analogues of (3*S*)-2,3-epoxy-2,3-dihydrosqualene (**5–94**) in which a sulfur replaces either a carbon or a carbon and its attached methyl group have also been synthesized. Analogues, in which carbons 6, 10, 18, and 19 (see Figure 5–8) are replaced by sulfur and the double bonds in which they participate are not present, are potent inhibitors of lanosterol synthase from *Candida albicans* and *R. norvegicus*.[401-403] During the rearrangements of these analogues, following the normal sequence (Figure 5–8), these inhibitors place **sulfur in a sulfide** immediately adjacent to and four atoms away from the carbocationic carbon in carbenium ions **5–95**, **5–96**, ring expanded **5–98**, and **5–98** itself, respectively. The sulfur can add to the respective carbenium ion nucleophilically to produce a five-membered ring containing a sulfonium cation

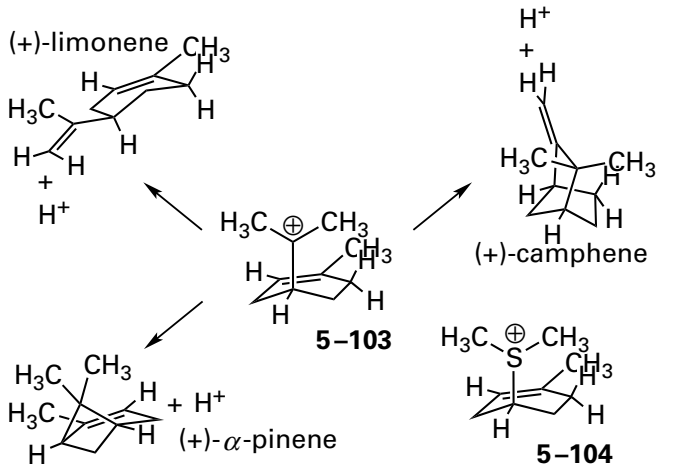


(5–130)

which is far more stable than a carbenium ion[404] and prevents any further rearrangement. The cationic sulfonium observed in each case also ends up at the same location as a carbenium ion in the normal sequence of rearrangements, so in this case, the active site itself produces the positive charge at a location in which it normally would stabilize a positively charged carbenium ion, just as the ammonio inhibitors of squalene synthase (**5–92** and **5–93**) do without the assistance of the active site. Because the active site of the enzyme creates the cation, these sulfides are **mechanism-based inhibitors**. Substitutions at carbons 5, 8, and 13 of (3*S*)-2,3-epoxy-2,3-dihydrosqualene, positions that are sterically prevented from adding nucleophilically (Equation 5–130) to any of the carbocationic carbons in the sequence (see Figure 5–8), produced weak inhibitors of the enzyme.[401,405] Analogues of carbenium ions **5–95**, **5–96**, and **5–97**, in which a nitrogen has been replaced by the carbocationic carbon to produce the ammonium cation, are also strong inhibitors of lanosterol cyclase from *R. norvegicus*.[406]

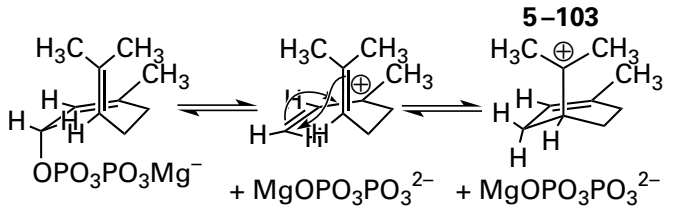
As has already been discussed, linear head-to-tail polyisoprenoids with an allylic diphosphate at one end, such as geranyl diphosphate, (2*E*,6*E*)-farnesyl diphosphate (Equation 5–126), and geranylgeranyl diphosphate, are susceptible to a vast array of cyclizations that produce monoterpenes, sesquiterpenes, and diterpenes, respectively. For example, (+)-α-pinene synthase from *Salvia officinalis*[407] produces (+)-α-pinene, (+)-limonene, and (+)-camphene from geranyl

diphosphate. The same active site produces all these products[408,409] and all three can be explained as arising from the same carbocationic intermediate **5–103**



(5–131)

which in turn can be derived from the carbocationic intermediate produced during dissociation of geranyl diphosphate

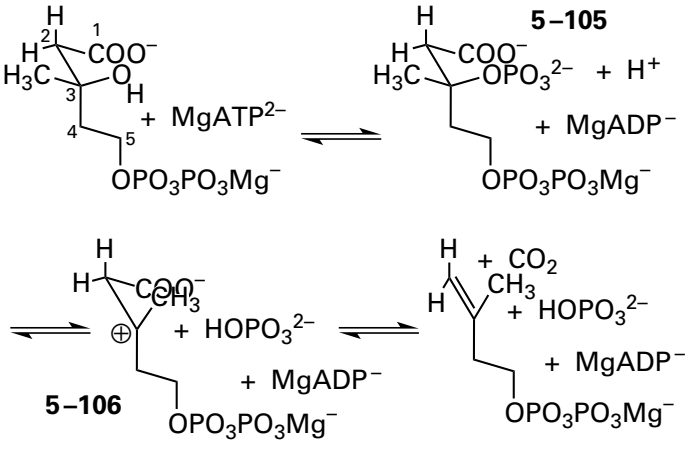


(5–132)

Therefore, the identity of the products is consistent with a particular sequence of carbocationic intermediates in the enzymatic reaction. A **sulfonium cation in an analogue of the intermediate** was chemically synthesized[409] as a mimic of the common carbocationic intermediate (Equation 5–131). Sulfonium cation **5–104** in the presence of diphosphate is a good inhibitor ($K_i = 1\ \mu M$) of (+)-α-pinene synthase, consistent with the involvement of carbocationic intermediate **5–103** in the enzymatic reaction.

Each of the thousands of monoterpenoids, sesquiterpenoids, and diterpenoids that are produced naturally arise from enzymatic cyclizations such as the ones catalyzed by (+)-α-pinene synthase (Equations 5–131 and 5–132) and 5-epiaristolochene synthase (Figure 3–50). The same strategies for identifying the carbocationic intermediates that were used for dimethylallyl*trans*transferase, squalene synthase, lanosterol synthase, and (+)-α-pinene synthase have been used to validate the existence of particular carbocationic intermediates in these enzymatic reactions. A fluorine atom can be placed on a carbon or immediately adjacent to a carbon that should be a carbocation in the proposed intermediate, and the fluoro analogue is shown to be an inhibitor rather than a substrate for the enzyme.[410] Mutants of the enzyme are discovered that produce from the natural reactant unnatural products that arise directly from one or the other of the postulated carbocationic intermediates in the enzymatic mechanism.[411-414] The natural reactant for the enzyme can be mutated synthetically to produce an unnatural reactant that causes the rearrangement to be blocked at one of its steps so that the enzyme produces unnatural products arising from one or the other of the postulated carbocationic intermediates.[415-417] Analogues of the postulated carbocationic intermediates in which an ammonio nitrogen replaces the cationic carbon can be synthesized and shown to inhibit the enzymatic reaction.[407,418]

Similar strategies are used to provide evidence for carbocationic intermediates in the few enzymes other than glycosyltransferases and polyisoprenoid synthases that have them. For example, diphosphomevalonate decarboxylase[419]



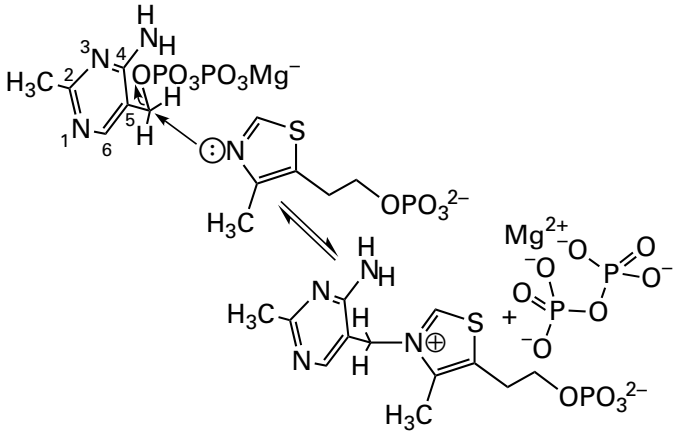
(5–133)

from *S. cerevisiae* catalyzes elimination of the nucleophile, phosphate, and the electrophile, CO_2, from (3*R*)-3-hydroxy-3-(fluoromethyl)-5-diphosphopentanoate, a fluorinated derivative of the normal reactant, that has been phosphorylated at its 3-hydroxy group within the active site by $MgATP^{2-}$ to form the noncovalent intermediate, (3*R*)-3-phospho-3-(fluoromethyl)-5-diphosphopentanoate, at a rate 2500-fold slower than the rate for elimination from the usual noncovalent intermediate, (3*R*)-3-phospho-3-methyl-

5-diphosphopentanoate (**5–105**). This observation is consistent with the existence of tertiary carbocationic intermediate **5–106** in the enzymatic elimination, formed by dissociation from the (3*R*)-3-phospho-3-methyl-5-diphosphopentanoate of phosphate, which is a good leaving group from a tertiary carbon. The resulting carbocationic intermediate at carbon 3 would precede the step in which CO_2 dissociates from carbon 2.[420] The elimination catalyzed by diphosphomevalonate decarboxylase is peculiar because it cannot involve removal of an electrophile such as carbon dioxide or a hydron α to a carbonyl group or acyl group, as almost all biochemical eliminations do. An initial departure of carbon dioxide during the elimination, rather than the phosphate, would produce a primary carbanion with no obvious means of stabilization.

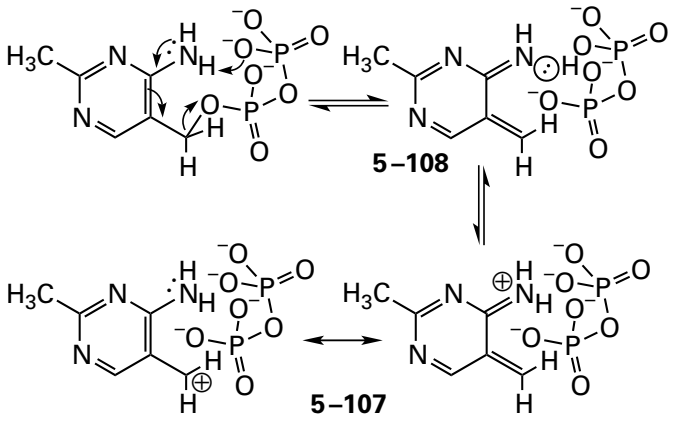
It has already been noted that (*S*)-methylketal phosphate **5–71** is a noncovalent intermediate in the enzymatic reaction catalyzed by 3-phosphoshikimate 1-carboxyvinyltransferase (Equation 5–91) and that oxocarbenium ion **5–73** is probably an intermediate in the elimination that forms the 1-carboxyvinyl group. UDP-*N*-Acetylglucosamine 1-carboxyvinyltransferase also adds phospho*enol*pyruvate to a hydroxy group, the 3-hydroxy group of UDP-*N*-acetyl-α-D-glucosamine. The fact that (*Z*)-3-fluorophospho*enol*pyruvate is a substrate for the enzyme from *E. coli* with a catalytic constant, k_0, 10,000 times slower than that for phospho*enol*pyruvate,[421] is consistent with the existence of an oxocarbenium ion as an intermediate either preceding or following the (*S*)-methylketal phosphate in this enzymatic reaction, or both.

Thiamine phosphate synthase[422]



(5–134)

catalyzes the nucleophilic substitution at the 5-diphosphooxymethyl group of 4-amino-2-methyl-5-(diphosphooxymethyl)pyrimidine of the nitrogen in 4-methyl-5-(2-phosphooxyethyl)thiazole for diphosphate. Thiamine phosphate synthase from *B. subtilis* catalyzes its nucleophilic substitution 16 times faster when the 2-methyl group on 4-amino-2-methyl-5-(diphosphooxymethyl)pyrimidine is replaced by a methoxy group and 1300 times more slowly when it is replaced by a trifluoromethyl group.[423] These differences in rate are almost the same as the differences in rate for hydrolysis of 2-chloro-2-(4-methylphenyl)propane when the 4-methyl group in this alkyl chloride undergoes the same substitutions, and this latter reaction is definitely a dissociative nucleophilic substitution with a carbenium ion as an intermediate. These observations are consistent with an enzymatic mechanism in which 4-amino-2-methyl-5-(diphosphooxymethyl)-pyrimidine dissociates to give diphosphate and the carbenium ion **5–107**



(5–135)

which is stabilized by resonance and to which the nitrogen of the thiazole then adds. In this instance, the reaction is a dissociative nucleophilic substitution.

Crystals of thiamine-phosphate diphosphorylase from *B. subtilis*, in which Serine 130 had been mutated to alanine, were soaked in solutions of the alternative substrate 2-[(2*R*,5*Z*)-2-carboxy-4-methylthiazol-5(2*H*)-ylidene]ethyl phosphate and either the cosubstrate 4-amino-2-methyl-5-(diphosphooxymethyl)pyrimidine or the much slower cosubstrate 4-amino-2-(trifluoromethyl)-5-(diphosphooxymethyl)pyrimidine. In the crystallographic molecular models from these crystals, electron density for separate molecules of diphosphate and the respective intermediate carbenium ion was observed in addition to that for 2-[(2*R*,5*Z*)-2-carboxy-4-methylthiazol-5(2H)-ylidene]ethyl phosphate.[424] In both of these complexes and in complexes with only the intact, unaccompanied substrate 4-amino-2-methyl-

5-(diphosphooxymethyl)pyrimidine, there is a hydrogen bond between a peripheral oxygen of the diphosphate and the 4-imino or 4-amino group of the carbenium ion or the substrate, respectively (Equation 5–135). It is probably the case that the carbenium ion is stabilized in the complexes in which it appears, either during its formation or after its formation, by hydron transfer within this hydrogen bond to produce the neutral noncovalent intermediate **5–108**, which may also be a transient intermediate in the normal reaction.

(*S*)-2-Hydroxypropylphosphonic acid epoxidase catalyzes a 1,2-phosphonomigration when the unnatural substrate (*R*)-2-hydroxypropylphosphonic acid is a reactant. That the migration occurs to an adjacent carbenium ion is consistent with the facts that when the secondary carbon to which the phosphono group migrates is adjacent to a methoxy group or an additional methyl group, groups that stabilize a carbenium ion, the migration occurs, but when the secondary carbon to which the migration would occur is adjacent to a trifluoro methyl group, it does not.[425]

Suggested Reading

An, M., Maitra, U., Neidlein, U., and Bartlett, P. A. (2003) 5-Enolpyruvylshikimate 3-phosphate synthase: Chemical synthesis of the tetrahedral intermediate and assignment of the stereochemical course of the enzymatic reaction, *J. Am. Chem. Soc. 125*, 12759–12767. https://doi.org/10.1021/ja036627+

Problem 5–9: The following reaction is catalyzed by ATP citrate synthase:

$$\text{HSCoA} + \text{citrate} + \text{MgATP}^{2-} \rightleftharpoons \text{MgADP}^{-} + \text{HOPO}_3^{2-} + \text{oxaloacetate} + \text{acetyl-SCoA}$$

On the basis of the following data,[426-428] write a detailed mechanism for the reaction. Give explanations for all the observations. Identify each of your explanations with the letter of its observation.

(A) When Mg[8-^{14}C]ATP^{2-} is incubated with the enzyme in the presence of $MgCl_2$, no radioactivity is associated with the protein that is chromatographically isolated by molecular exclusion.

(B) When Mg[γ-^{32}P]ATP^{2-} is incubated with the enzyme in the presence of $MgCl_2$, radioactivity is associated with the isolated protein. When this radioactive protein is incubated with [1,5-$^{14}C_2$]citrate in the presence of HSCoA but in the absence of $MgCl_2$, [^{14}C]oxaloacetate is formed and all the radioactivity is released from the enzyme.

(C) When the enzyme is incubated with MgATP^{2-} and $HO^{32}PO_3^{2-}$, in the presence of $MgCl_2$, no radioactivity is found in the enzyme or in MgATP^{2-}. When the enzyme is incubated with MgATP^{2-} and Mg[8-^{14}C]ADP^{-} in the presence of $MgCl_2$, no radioactivity is found in the enzyme, but MgATP^{2-} becomes radioactive.

(D) When citryl 1-phosphate is incubated with the enzyme in the presence of HSCoA, oxaloacetate and acetyl-SCoA are formed.

(E) When citryl 1-phosphate and HSCoA are incubated without the enzyme, nothing happens.

Problem 5–10: β-Galactosidase catalyzes the reaction of Equation 5–120. The enzyme acts only on the β-anomer of a galactoside and releases only the β-anomer of the product. It cares little, however, what R_1 and R_2 are.

(A) Write a mechanism for this reaction, as it would occur in the active site, that is consistent with these observations. Position catalytic side chains to explain both the stringency in the stereochemistry of the reaction at carbon 1 and the carelessness in recognizing R. Use

specific amino acid side chains of your choice for catalysis.

(B) The chemical mechanism you have written in part A has the following kinetic mechanism.

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A \xrightarrow{k_2} E{\cdot}C + Y$$

$$E{\cdot}C + B \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E{\cdot}C{\cdot}B \xrightarrow{k_4} E + Z$$

Write out the complete equation for initial rate for the enzymatic reaction for this kinetic mechanism.

(C) Take the limit

$$\lim_{[A]_0,[B]_0 \to \infty} v_0 ([E]_t)^{-1} = k_0$$

and write an expression for the catalytic constant, k_0, that contains only rate constants (k_i) in the kinetic mechanism of part B.

(D) Refer to your molecular mechanism for β-galactosidase, and determine which rate constant in the kinetic mechanism would be most affected by changes in R.

(E) Consider the following table of relative catalytic constants, where $k_{0,R}$ is the catalytic constant for the β-galactoside with the tabulated functional group and $k_{0,2\text{-nitro}}$ is the catalytic constant for 2-nitrophenyl β-galactoside. The various R groups are listed in order of increasing ability to leave.[368,429,430]

R	$k_{0,R}\ (k_{0,2\text{-nitro}})^{-1}$
methyl	0.06
4-bromophenyl	0.02
4-chlorophenyl	0.02
4-methoxyphenyl	0.1
phenyl	0.1
4-nitrophenyl	0.2
3-chlorophenyl	0.5
3-nitrophenyl	0.9
2-nitrophenyl	1.0
2,5-dinitrophenyl	1.1
3,5-dinitrophenyl	1.1
2,4-dinitrophenyl	1.3

(F) Explain, in terms of the expression you derived in part C, why $k_{0,R}\ (k_{0,2\text{-nitro}})^{-1}$ increases as R becomes a better leaving group and then levels off, showing no further increase.

Problem 5–11: Deoxyhypusine synthase catalyzes the reaction

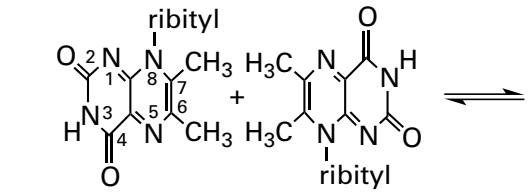
lysyl side chain + spermidine $\rightleftharpoons$
N^6-(4-aminobutyl)lysyl side chain
+ propane-1,3-diamine

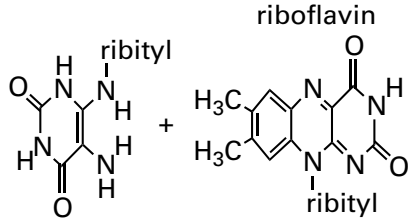
where lysyl side chain is a lysyl side chain in the protein translation initiation factor 4D. The enzyme has a prosthetic NAD^+ in its active site. When the enzyme from *R. norvegicus* was mixed with spermidine in the absence of translation initiation factor 4D, and hence the lysyl side chain, 1-pyrroline and propane-1,3-diamine were isolated from the active site.[431]

(A) What intermediate is formed during the enzymatic reaction?

(B) Write a complete mechanism for the reaction.

Problem 5–12: Riboflavin synthase catalyzes the reaction





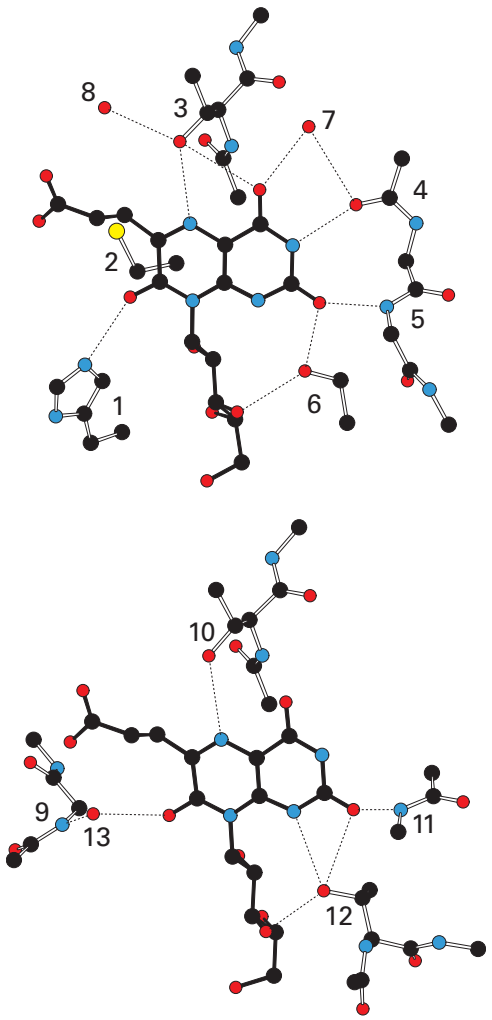
Note that the two reactants are both the same molecule, 6,7-dimethyl-8-(1-D-ribityl)lumazine. The reaction, formally, is the transfer of a 2-butenyl group from two nitrogens to two carbons. That the two molecules of 6,7-dimethyl-8-(1-D-ribityl)lumazine are joined in the noted opposite orientations, one up and the other down, has been demonstrated by

determining the stereochemistry of the product formed from 6-deuteriomethyl-7-methyl-8-(1-D-ribityl)lumazine.[432]

It has been shown that the hydrogens on the 7-methyl group of the lumazine are acidic ($pK_a = 9.8$)[433] and susceptible to exchange with deuterium under basic conditions in the absence of the enzyme.

(A) Write a mechanism for this exchange of protium for deuterium with an enolate as an intermediate.

When one of the two 6,7-dimethyl-9-(1-ribityl)-lumazines associates with riboflavin synthase from *E. coli*, this enolate is formed in its subsite in the active site.[433] The following are two portions of a crystallographic molecular model of the enzyme from *S. pombe* in complex with 6-carboxyethyl-7-oxo-8-(1-D-ribityl)lumazine, an unreactive analogue of 6,7-dimethyl-8-(1-D-ribityl)lumazine.[434]



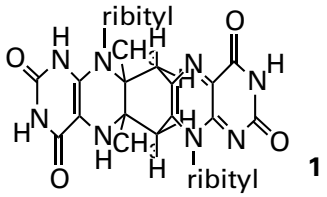
The two drawings are of the two subsites that comprise the active site, one for each of the two 6,7-dimethyl-8-(1-ribityl)lumazines that are substrates for the enzyme and each of which is occupied by a molecule of 6-carboxyethyl-7-oxo-8-(1-D-ribityl)-lumazine.

(B) Make a list numbered 1 to 13 that identifies each donor and acceptor of a hydrogen bond and the side chains of amino acids numbered in the two drawings.

(C) Write a mechanism for the binding of the molecule of 6,7-dimethyl-8-(1-D-ribityl)lumazine that becomes the enolate in the active site. Draw explicitly the functional groups in the crystallographic molecular model of the active site responsible for creating and stabilizing the enolate.

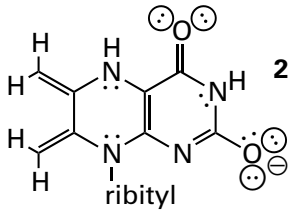
This enolate is the first intermediate in the enzymatic reaction.

Pentacyclic intermediate **1** is produced by a mutant of riboflavin synthase from *E. coli*.



1

When it is mixed with the native, unmutated enzyme, it is converted to riboflavin at a rate that is much greater than the rate at which two molecules of 6,7-dimethyl-8-(1-D-ribityl)lumazine are converted to riboflavin,[435] a fact consistent with it also being an intermediate in the enzymatic reaction. There is a tautomer of the enolate, dienamine **2**, that is nucleophilic at the two requisite carbons.



2

(D) Write a mechanism for formation of dienamine **2** from the enolate in the active site of the enzyme using the functional groups observed in the crystallographic molecular model.

(E) Write a mechanism[436] in which dienamine **2** reacts twice, as two different nucleophiles, with 6,7-dimethyl-8-(1-D-ribityl)lumazine to form pentacyclic intermediate **1**. Which nucleophilic addition has to precede the other?

(F) Write a mechanism in which dienamine **2** participates in a cycloaddition with 6,7-dimethyl-8-(1-D-ribityl)lumazine to form pentacyclic intermediate **1** in a single step.

(G) Explain why one of these two mechanisms seems more likely given the functional groups available in the active site.

(H) Write a mechanism to convert pentacyclic intermediate **1** into the products observed in the enzymatic reaction using the catalytic groups found in the active site, labeling each with its name and number.

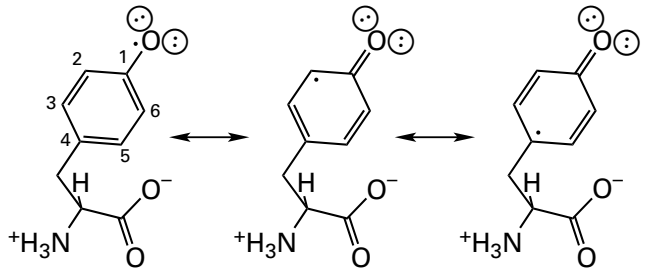
(I) What essential catalytic group for one of these latter steps seems to be missing?

Chemical and Crystallographic Identification of Radical Intermediates

There are instances in which an intermediate or a sequence of intermediates in an enzymatic reaction are radicals. The chemistry of almost all enzymatic reactions is heterolytic because it is based on hydron transfers performed by acid–bases in the active site, which are themselves heterolytic. Far fewer and far less fundamental instances of enyzmatic reactions with radical intermediates have been described. There are a few prosthetic groups, in particular flavins, hemes, and coenzyme B_{12}, and a few enzymes lacking such prosthetic groups that engage in homolytic chemistry.[437] The reason for the relative rarity of homolytic mechanisms is the **difficulty of catalyzing formation of radical intermediates*** and their ability to participate in random hydrogen abstraction.[438]

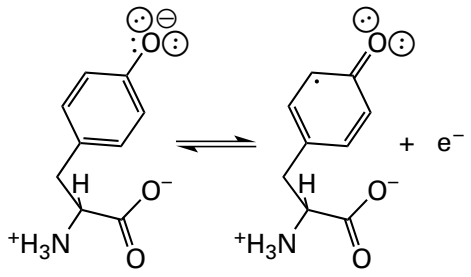
Any **organic radical** can be formally **defined as the product of a hydrogen abstraction.** Consequently, a radical is energetically defined by the **bond dissociation energy** (BDE; kilojoules mole^{-1}),† which is the enthalpy required to break the bond homolytically between a hydrogen and the rest of the particular molecule to form a radical, regardless of whether or not that radical was formed by the abstraction of a hydrogen.[439,440] The more energy that is required to break a bond between the radical and a hydrogen, the more energetic is the radical. A radical with a larger bond dissociation energy will abstract a hydrogen from another molecule in a favorable reaction that produces a radical of lower bond dissociation energy.

An example of a radical involved in several enzymatic reactions is the **tyrosyl radical**. A tyrosyl radical can be formed nonenzymatically upon X-irradiation of a crystal of tyrosine hydrochloride. This radical has the resonance hybrids



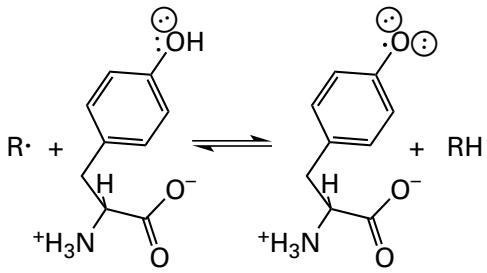
5–109

with spin densities in the solid state of 0.2–0.3 on the oxygen and carbons 1, 3, and 5, respectively,[441] as predicted by the resonance structures. It can be thought of as the product of dissociation of an electron (E^0 = 850 mV) from the π system of the 4-oxidophenyl anion [442]



(5–136)

or the product of hydrogen abstraction (BDE = 380 kJ mol^{-1}) from the oxygen of the 4-hydroxyphenyl group[439]



(5–137)

*As the majority of this discussion has emphasized, it is acid–base chemistry that provides the ability to catalyze heterolytic reactions. Nothing equivalent to such catalysis is available for homolytic reactions, except for the prosthetic groups.

†http://aquila.tversu.ru/LIB/Book/ComprehensiveHClBE.pdf

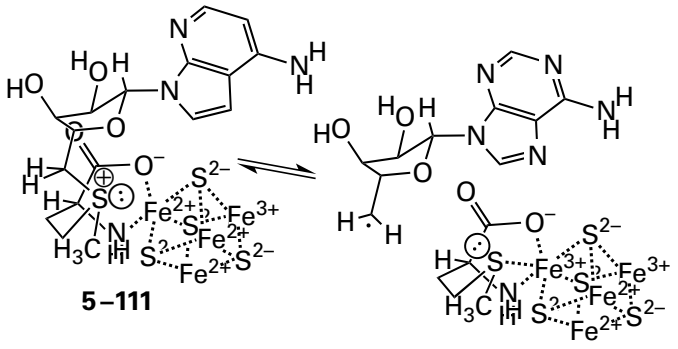
Regardless of the mechanism of its formation, a tyrosyl radical is capable of hydrogen abstraction at its oxygen (reverse of Equation 5–137) from a donor (RH in Equation 5–137) with the same or a smaller bond dissociation energy.

In marked contrast to acid–base chemistry, any hydrogen in a protein or in a substrate is susceptible to **hydrogen abstraction** to form a radical of the protein or substrate itself. The hydrogenated form of any radical is the functional group produced when that radical abstracts a hydrogen from another location. The products of this hydrogen abstraction are a new radical on the atom from which the hydrogen has been abstracted and a new σ covalent bond between the hydrogen and the atom on which the unpaired electron was previously located. If the hydrogenated form of a particular radical formed as an intermediate in an enzymatic reaction has a bond dissociation energy greater than those of hydrogens that necessarily surround it in the active site, the radical will uncontrollably abstract one of these hydrogens—for example, the tertiary hydrogen in a leucine or isoleucine (BDE = 390 kJ mol^{-1})—and produce a radical that would spread over the structure of the protein by successive hydrogen abstractions or electron transfers.

Enzymatic active sites, however, can be constructed so as to surround radicals with hydrogens that are difficult to abstract, such as a hydrogen of water (BDE = 497 kJ mol^{-1}), phenyl hydrogens (BDE = 470 kJ mol^{-1}), or hydrogens in hydroxy groups (BDE = 440 kJ mol^{-1}). The almost unavoidable nature of hydrogen abstraction may explain why most radical intermediates that participate in enzymatic reactions, such as the tyrosine radical (BDE = 380 kJ mol^{-1}), have low values for the bond dissociation energies of their hydrogenated forms, with the notable exceptions of the primary 5′-deoxy-5′-adenosyl radical (BDE = 420 kJ mol^{-1}) and the alkyl radicals thought to be involved in the reactions catalyzed by hemes P-450, which are quite reactive.[443] In these latter two instances, the reactive radicals generated during the enzymatic reaction are either surrounded by molecules of water or are generated immediately adjacent to the hydrogen that is to be abstracted.[438]

The eclectic collection of radicals generated in the mechanisms of enzymes that use a prosthetic adenosylcobalamin; a metallic prosthetic group and molecular oxygen; a prosthetic flavin and molecular oxygen; or a metallic prosthetic group, a prosthetic flavin, and molecular oxygen in concert have already been discussed in detail. There are **three main strategies** that enzymes use to generate radical intermediates without the assistance of any of these previously described prosthetic groups. These three strategies differ in the source of the initial radical that initiates a sequence of radical intermediates in the respective mechanism.

First, there are enzymes that generate a 5′-deoxy-5′-adenosyl radical by catalyzing, with a reduced prosthetic [4Fe–4S] iron–sulfur cluster, the homolytic dissociation* of the appropriate carbon–sulfur bond in *S*-adenosyl-L-methionine[444-448]

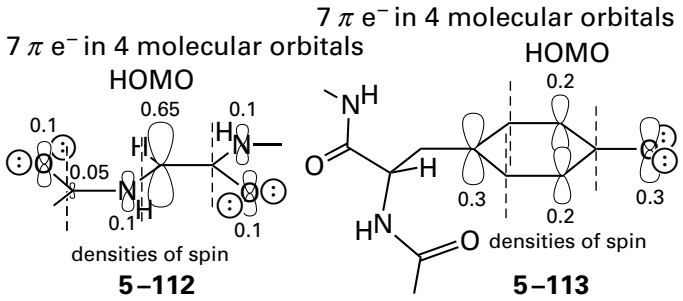


(5–138)

The [4Fe–4S] iron–sulfur cluster and the L-methionine operate as the integrated complex **5–110** in which three lone pairs of electrons from the sulfur, the carboxy oxyanion, and the amino group of the L-methionine are ligands to an iron ion in the cluster. This complex either dissociates homolytically from the 5′-deoxyadenosyl group during association of the sulfur with the iron ion or, in reverse, associates homolytically with the 5′-deoxy-5′-adenosyl radical. Meanwhile, the iron ion adds the other electron to the sulfur or removes the other electron from the sulfur of the sulfide in the L-methioninyl group, respectively. The 5′-deoxy-5′-adenosyl radical produced by this dissociation is identical to the 5′-deoxy-5′-adenosyl radical produced by homolytic dissociation of the carbon–cobalt bond in adenosylcobalamin, but it is surrounded by a different environment.

Second, there are enzymes that contain, at particular locations within their folded polypeptides, a stable glycyl radical (**5–112**)[449,450]

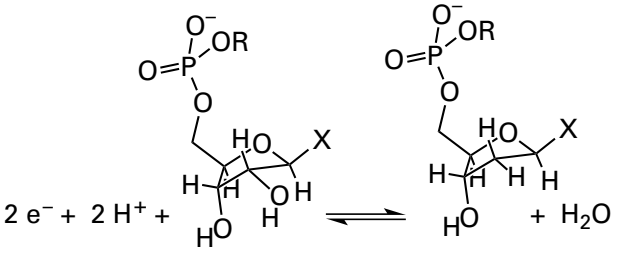
*In the absence of assistance from the [4Fe–4S] iron–sulfur cluster, the bond dissociation energy of the carbon–sulfur bond in *S*-adenosyl-L-methionine is around 300 kJ mol^{-1}.



formally the product of abstraction of a hydrogen from a particular glycine within the sequence of the protein located in the active site. This glycyl radical has the noted distribution of unpaired spin in the highest occupied molecular orbital (HOMO).

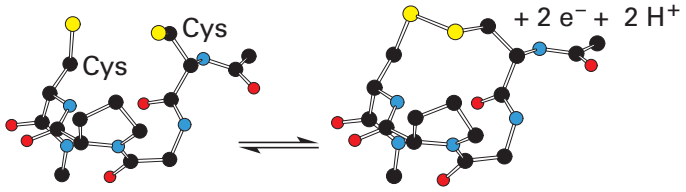
Third, there are enzymes that contain,[451] within their folded polypeptides, a stable tyrosyl radical (**5–109** and **5–113**).

The homologous enzymes ribonucleoside-diphosphate reductase and ribonucleoside-triphosphate reductase, in their various guises, use all three of these strategies as well as adenosylcobalamin to produce the radical initiating the common reaction. Hence, the respective individuals in this family of enzymes are excellent paradigms for all these strategies. Ribonucleoside-diphosphate reductase (R = $-PO_3^{2-}$) and ribonucleoside-triphosphate reductase (R = $-PO_3PO_3^{3-}$) are two enzymes that catalyze the same oxidation–reduction



(5–139)

where X can be uracil, cytosine, adenine, or guanine, and R is either a phosphate or a diphosphate, respectively, none of which participate. In almost all cases, the two electrons are supplied stoichiometrically by two adjacent cysteines in the small electron carrier thioredoxin[452,453]



(5–140)

that end up as a cystine at the end of the reaction. Because these two enzymes, ribonucleoside-diphosphate reductase and ribonucleoside-triphosphate reductase, share a common ancestor[454,455] and a common mechanism, they are each usually given the common unofficial name **ribonucleotide reductase**.

Reduction of carbon 2′ in the ribose would be difficult to perform heterolytically because neither the hydron on carbon 1′ nor the hydron on carbon 3′ is acidic, which would permit a β elimination followed by reduction of the resulting carbon–carbon bond, nor is the hydroxy group on carbon 2′ a reasonable leaving group, so natural selection has discovered a homolytic solution. There are several types of ribonucleotide reductases, all of which use the same homolytic mechanism. These types differ depending on the strategy they use to generate the initial radical intermediate in their respective mechanisms.

In one class of ribonucleotide reductases—some members of which are ribonucleoside-triphosphate reductases and some ribonucleoside-diphosphate reductases and which are found in bacteria and a few eukaryotic microorganisms—each active site uses **adenosylcobalamin** in the usual manner to generate the initial radical intermediate in the sequence of intermediates. The adenosylcobalamin, however, is not a firmly attached prosthetic group and must be present in solution at saturating concentrations for maximum enzymatic activity.[456] That the active sites in this class are able to dissociate the carbon–cobalt bond to form a 5′-deoxy-5′-adenosyl radical follows from the fact that stereochemically labeled (5′-*R*)-[5′-^{2}H]adenosylcobalamin is racemized by an inactive mutant of ribonucleoside-triphosphate reductase from *Lactobacillus leichmannii* in which an adjacent catalytic cysteine in the active site has been converted to serine.[457] The equilibrium constant for dissociation of the carbon–cobalt bond in the active site of the same enzyme has been measured spectroscopically[458] to be 0.2.

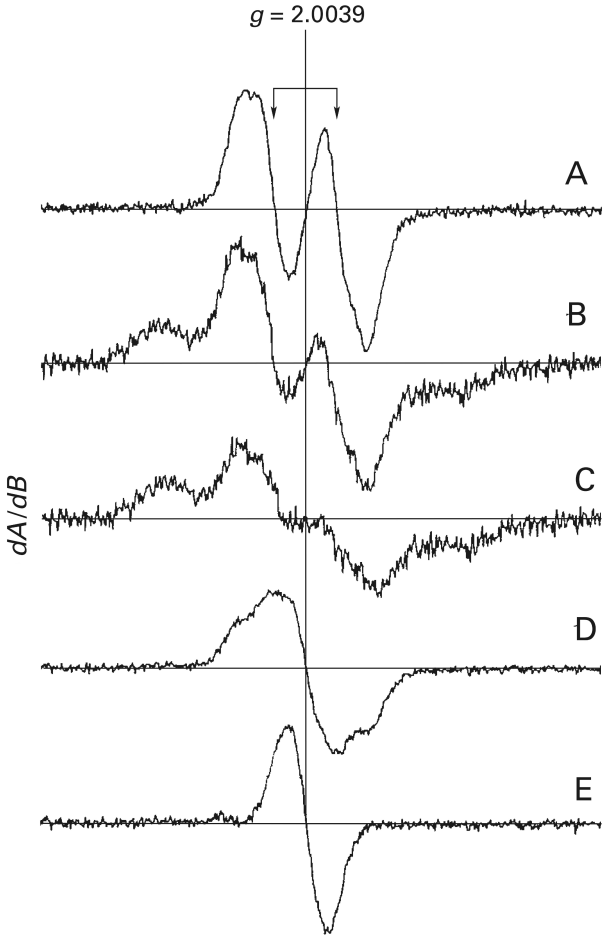


Figure 5–9: Electron paramagnetic resonance spectra of the glycyl radical in anaerobic ribonucleoside-triphosphate reductase encoded by Enterobacteria phage T4.[460] A plasmid encoding the gene from Enterobacteria phage T4 for anaerobic ribonucleoside-triphosphate reductase was replicated anaerobically in *E. coli*. The plasmid permitted significant overexpression so that the final concentration of glycyl radicals in a cytoplasmic extract of the bacteria was 7 μM. Frozen cytoplasmic extracts from the bacteria were used for measurement of electron paramagnetic resonance spectra at 77 K. (**A**) Spectrum of an extract from overexpressing bacterial cells grown on normal medium supplemented with 50 mM unlabeled glycine. (**B**) Spectrum of an extract from overexpressing bacterial cells grown on normal medium supplemented with 50 mM [2-^{13}C]glycine. (**C**) Spectrum B after subtraction of 20% spectrum A to correct for the fact that, in the end, only 80% of the glycine in the enzyme had carbon-13 at its α carbon. (**D**) Spectrum of an extract from overexpressing bacterial cells grown on normal medium supplemented with 50 mM [2,2-$^{2}H_2$]glycine. (**E**) Spectrum D after subtraction of 50% spectrum A to correct for the fact that, in the end, only 50% of the hydrogens on the α carbons of the glycines in the enzyme were deuterium. When Glycine 580 in the enzyme was mutated to alanine, or when the plasmid responsible for overproduction of ribonucleoside-diphosphate reductase was omitted, none of these absorptions were observed in the respective extracts. Vertical lines indicate the center of each absorption at its *g* value.

In the next class—the ribonucleoside-triphosphate reductases found in obligate anaerobic bacteria and facultative anaerobic bacteria under anaerobic conditions—each active site uses an oxygen-sensitive* **glycyl radical** located stably on a particular glycine[459] in the enzyme. The glycyl radical is identified by an absorption in an electron paramagnetic resonance spectrum of the enzyme (Figure 5–9).[460] In the spectrum of a cytoplasmic extract containing the anaerobic ribonucleoside-triphosphate reductase encoded by Enterobacteria phage T4, the absorption of the glycyl radical is a doublet (arrows in Figure 5–9A) because it is split by the nucleus of the single protium on the α carbon of the glycine on which the radical is concentrated (**5–112**). When the bacteria are grown on medium supplemented with [2-^{13}C]glycine, the absorption becomes a complex multiplet (Figure 5–9C) because it is split by the nuclei of both the hydrogen and the carbon-13 on which it is concentrated. When the bacteria are grown on medium supplemented with [2,2-$^{2}H_2$]glycine, the absorption becomes a singlet (Figure 5–9E) because it is not split by either the nucleus of the deuterium on the carbon on which it is concentrated or the nucleus of the carbon-12 on which it is concentrated.† The particular glycine, Glycine 580, that is the radical in the ribonucleoside-triphosphate reductase encoded by Enterobacteria phage T4 has been identified by site-directed mutation.[460] When Glycine 580 is replaced by alanine, electron paramagnetic resonance spectra of the cytoplasmic extracts from bacteria carrying the plasmid with the mutant do not have the absorption due to the radical. The glycyl radical in the enzyme is produced by a 5′-deoxy-5′-adenosyl radical that in turn is formed by the homolytic dissociation of *S*-adenosyl-L-methionine catalyzed by a [4Fe–4S] iron–sulfur cluster (Equation 5–138).[461,462] This 5′-deoxy-5′-adenosyl radical is produced in another protein, anaerobic ribonucleoside-triphosphate reductase-activating protein, that binds tightly to the cognate anaerobic ribonucleoside-triphosphate reductase to effect formation of the glycyl radical.[463]

*The glycyl radical, as is the case with most aliphatic radicals is susceptible to the addition of triplet molecular oxygen.

† Recall that electron paramagnetic resonance spectra are presented as the first derivative of the actual absorption, so the trace in Figure 5–9E is the first derivative of the peak of a singlet and the trace in Figure 5–9A is the first derivative of the peak of a doublet.

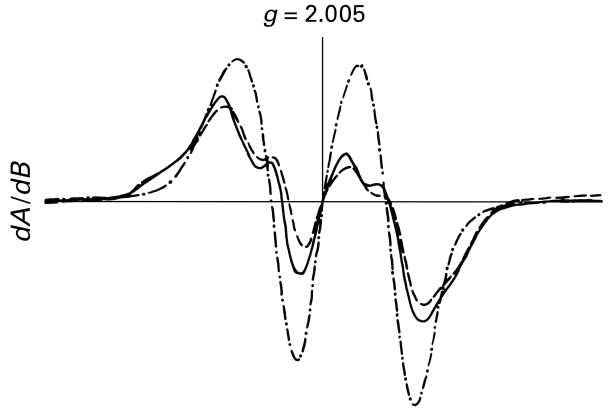

Figure 5–10: Electron paramagnetic resonance spectra of the tyrosyl radical in ribonucleoside-diphosphate reductase.[465] A strain of the bacterium *E. coli* that overproduces its own ribonucleoside-diphosphate reductase was used for these experiments. In this overproducing strain, about 3% of the cytoplasmic protein is the enzyme. Frozen suspensions of intact bacteria were used for measurement of electron paramagnetic resonance spectra at 77 K. Spectra are shown for cells grown on undeuterated L-tyrosine (– – –), for cells grown on [3,5-$^2H_2$]-L-tyrosine (– · – · –), and for cells grown on [2,6-$^2H_2$]-L-tyrosine (——). Vertical lines indicate the center of each absorption at its *g* value. When Tyrosine 122 in the enzyme being overexpressed was mutated to phenylalanine, or when the plasmid responsible for overproduction of ribonucleoside-diphosphate reductase was omitted, none of these absorptions were observed.[464]

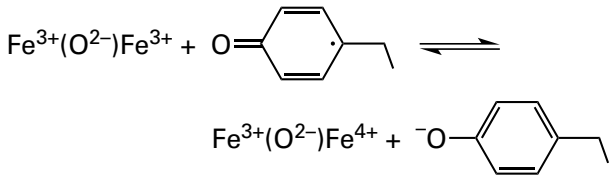
The most widely distributed class of ribonucleotide reductases is that of the ribonucleoside-diphosphate reductases found in eukaryotes and most aerobic bacteria. Each member of this class uses a **stable tyrosyl radical** (**5–109** and **5–113**) to generate the initial radical intermediate in the enzymatic mechanism. These enzymes require two proteins for enzymatic activity. One protein, R1, contains the active site for the reduction; the other, R2, contains the tyrosyl radical.

Protein R2 can thought of as a **radical-carrier protein**, serving a role homologous to biotin carboxyl-carrier protein, acyl-carrier protein, or a small protein serving as an electron-transferring coenzyme, but it seems to fulfill this role only with protein R1, rather than being more promiscuous. The polypeptide that comprises protein R2 from *Homo sapiens* is 351 amino acids long, that from *A. thaliana* (60% identity; 0.8 gap percent) is 341 amino acids long, that from *S. cerevisiae* (43% identity; 0.8 gap percent) is 345 amino acids long, and that from *E. coli* (21% identity; 1.8 gap percent) is 375 amino acids long. Tyrosine 122 of protein R2 from *E. coli* has been identified by site-directed mutation as the stable tyrosyl radical.[464] Its unpaired spin can be detected by electron paramagnetic resonance spectroscopy (Figure 5–10).[464,465] That the unpaired spin is on a tyrosine can be demonstrated by replacing specific hydrogens on the tyrosines in protein R2 with deuteriums and observing changes in the spectra. From electron–nuclear double resonance spectra of this radical in protein R2 from *E. coli*, it has been calculated[466,467] that carbons 3 and 5 of the 4-hydroxyphenyl group each bear a spin density of 0.25; carbon 1, a tertiary carbon, bears a spin density of 0.4; and the oxygen bears a spin density of 0.3 while carbons 2, 4, and 6 bear negligible spin density (**5–113**). When cells of *E. coli* are grown on [2,6-$^2H_2$]-L-tyrosine, there is negligible alteration of the absorption of the radical, but when the cells are grown on [3,5-$^2H_2$]-L-tyrosine, the absorption of the radical becomes a doublet (Figure 5–10). These facts are consistent with a radical producing the absorption being located on a tyrosine and its resonance structures. When Tyrosine 122 in the enzyme is mutated to phenylalanine, the absorption is no longer observed.[464]

Immediately adjacent to this tyrosyl radical in the crystallographic molecular model of protein R2 from *E. coli*[468] is a **diferric cluster with a μ-oxo bridge** and ligation similar to that of the dinuclear cluster in diferric methane monooxygenase (soluble) (Figure 2–57I). The distance between the 4-oxidophenyl oxygen and the nearest iron is 0.35 nm, and the tyrosyl radical is magnetically coupled to the dinuclear iron center.[469] In terms of electron exchange, the equilibrium, heavily in favor of the tyrosyl radical, would be



(5–141)

The high-valent species $Fe^{3+}(O^{2-})Fe^{4+}$ is responsible for formation of the tyrosyl radical by establishing this equilibrium.[470,471] There are versions of ribonucleoside-diphosphate reductases in this class that contain a homologous dimanganic, μ-oxo cluster[472-475] rather than a diferric, μ-oxo cluster, and there are versions in which the tyrosine has been replaced by natural selection with phenylalanine, and the unpaired electron responsible for initiating catalysis remains located in a dinuclear $Fe^{3+}(O^{2-})Mn^{4+}$ cluster.[476-478]

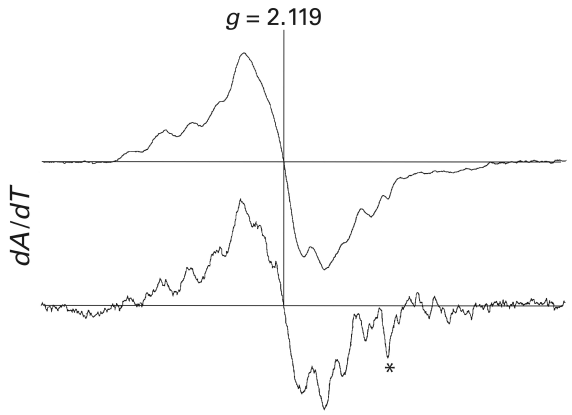


Figure 5–11: Electron paramagnetic resonance spectra of the sulfenyl radical in adenosylcobalamin-dependent ribonucleoside-triphosphate reductase.[479] A solution of 520 μM purified adenosylcobalamin-dependent ribonucleoside-triphosphate reductase from *L. leichmannii*, 50 μM thioredoxin, 3 μM thoredoxin reductase, and 1.7 mM NADPH was mixed with a solution of 400 μM adenosylcobalamin. Each solution also contained 1 μM $dGTP^{4-}$ and 0.1 M sodium dimethylglutarate, pH 7.3. After 175 ms, the mixture was injected into isopentane at −140 °C and then submitted to electron paramagnetic resonance spectroscopy at 100 K. (Upper trace) Unlabeled adenosylcobalamin-dependent ribonucleoside-triphosphate reductase. (Lower trace) Adenosylcobalamin-dependent ribonucleoside-triphosphate in which the cysteines were replaced with [β,β-$^2H_2$]cysteine. The asterisk indicates an absorption arising from a contaminant in the preparation. Reprinted with permission from reference 479. Copyright 1996 American Association for the Advancement of Science. https://doi.org/10.1126/science.271.5248.477

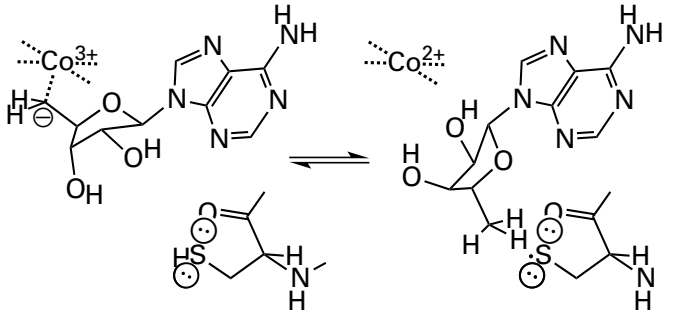
The reaction that initiates the homolytic reduction catalyzed by a ribonucleotide reductase is the production of the **sulfenyl radical** of a particular cysteine in the active site of the enzyme. An intermediate in the reaction catalyzed by the adenosylcobalamin-dependent ribonucleoside-triphosphate reductase from *L. leichmannii*, trapped 175 ms after mixing of the enzyme with adenosylcobalamin and $dGTP^{4-}$, has the electron paramagnetic resonance spectrum (Figure 5–11) of a sulfenyl radical.[479] When the cysteines in the enzyme are replaced with [β,β-$^2H_2$]cysteines, the spectrum of this radical is altered, consistent with it being located on sulfur of a cysteine. This sulfenyl radical is electronically coupled to the cob(II)alamin that results from homolysis of the carbon–cobalt bond.[480] At the same time that the radical is formed, cob(II)alamin and 5′-deoxyadenosine are also formed[481,482]



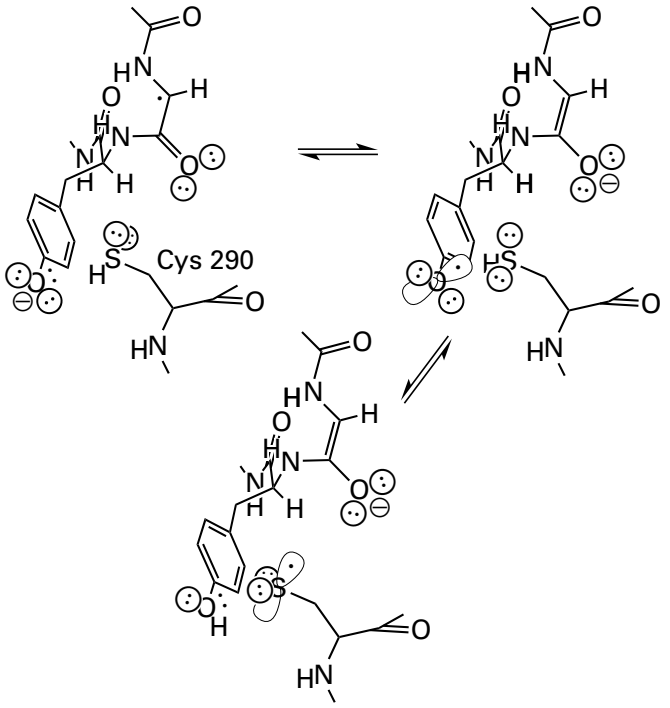
(5–142)

The former is followed by its absorbance at 525 nm; the latter, by chromatographic identification. The sulfanyl group (BDE = 370) of the cysteine that becomes the sulfenyl radical has been identified as Cysteine 408 in the enzyme from *L. leichmannii* by site-directed mutation.[481] Electron paramagnetic absorptions from a transient sulfenyl radical[483] and a stable sulfenyl radical[484] in mutants of protein R1 of ribonucleoside-diphosphate reductase from *E. coli* and *Mus musculus* have also been observed.

The 5′-deoxy-5′-adenosyl radical that is transiently formed during the reaction of Equation 5–142 must **abstract a hydrogen from an acidic position** because tritium is washed out of [5′-^{3}H]adenosylcobalamin, ending up as ^3H_2O, at a rate about as fast as the turnover of the enzyme.[456] This fact is consistent with the conclusion that a 5′-deoxy-5′-adenosyl radical, produced by homolytic dissociation of the carbon–cobalt bond of adenosylcobalamin in the active site of the ribonucleoside-triphosphate reductase of *L. leichmannii*, abstracts a hydrogen directly from the sulfanyl group of Cysteine 408. If this abstraction (Equation 5–142) reverses several times, eventually the tritium will end up on the sulfanyl group and then exchange into the solution.

In the crystallographic molecular model of the complex between ribonucleoside-diphosphate reductase from *T. maritima* and adenosylcobalamin, thymidine triphosphate, and guanosine diphosphate, the ribosyl group of adenosylcobalamin immediately flanks the sulfanyl group of Cysteine 322, which becomes the sulfenyl radical in this structurally homologous enzyme. The 5′-carbon of the adenosyl group in adenosylcobalamin is only 0.65 nm from the sulfur of the sulfanyl group,[482] and there is nothing in the active site to prevent it from reaching the sulfanyl group so that it can **abstract the hydrogen atom directly** once the carbon–cobalt bond dissociates. Nor are there any other nearby hydrogens that the 5′-deoxy-5′-adenosyl radical can abstract on its way to the sulfanyl group, except those on the molecules of water in the vacancy.

There is a crystallographic molecular model of a mutant of the anaerobic ribonucleoside-triphosphate reductase from Enterobacteria phage T4 in which Glycine 580, which harbors the stable radical in this enzyme, has been changed to alanine. The distance between the α carbon of that alanine, on which the glycyl radical resides in the native enzyme, and the sulfanyl group of Cysteine 290, from which a hydrogen is abstracted by the glycyl radical, is 0.55 nm.[485,486] In this instance, unlike that of ribonucleoside-diphosphate reductase from *T. maritima*, in the active site of which the 5′-carbon of the 5′-deoxy-5′-adenosyl radical is free to swing from the cobalt to the sulfanyl group, both the sulfanyl group and the glycine, which is in the polypeptide backbone itself, are rigidly fixed. Consequently, there seems to be no way they can come any closer to each other, and the distance between them is too great for direct hydrogen abstraction. The oxygen of the 4-hydroxy group of Tyrosine 581, however, is only 0.35 nm from the sulfur of the sulfanyl group of Cysteine 290, well within van der Waals contact (0.44 nm). The plane of the 4-hydroxyphenyl group is almost perpendicular to the line between its oxygen and the sulfur, the proper orientation for hydrogen abstraction by a 4-oxyphenyl radical (**5–113**). The stable glycyl radical on Glycine 580, which already has significant spin density (0.05–0.10) on the α-amino group of Tyrosine 581,[449,450] can receive an electron from the 4-oxido group on the anionic conjugate base of Tyrosine 581 by **short-range, through-bond electron transfer**, and the 4-hydroxyphenyl radical that results can then abstract the hydrogen atom directly from the sulfanyl group of Cysteine 290



(5–143)

Both the 4-hydroxyphenyl group of a different tyrosine, Tyrosine 507, and the guanidinio group of Arginine 577 are close enough to form an oxyanion hole for the **1,2-diaminoenolate** that forms on Glycine 580 when the electron is transferred from Tyrosine 581.

Neither direct hydrogen abstraction nor direct, short-range electron transfer between their stable tyrosyl radicals and the sulfanyl groups of the catalytic cysteines in their active sites, however, can occur in the ribonucleoside-diphosphate reductases of aerobic bacteria and eukaryotes. In these enzymes, there is a stable tyrosyl radical that provides the hole for an electron, but the tyrosyl radical and the cysteine in the active site are on separate proteins, R1 and R2. Because both the sulfanyl group in the active site and the tyrosyl radical are buried in their respective proteins, the closest approach that they could ever make to each other is 2.5 nm.[487] In fact, there are measurements by electron paramagnetic resonance spectroscopy which suggest that the distance in the productive complex of ribonucleoside-diphosphate reductase from *E. coli* is actually around 3.5 nm.[488,489] It follows that the tyrosyl radical in protein R2 cannot directly abstract the hydrogen from the sulfanyl group in the active site on protein R1. Consequently, the sulfenyl radical (BDE = 370 kJ mol^{-1}) formed in the active site is the result of **long-range electron transfer** over a significant distance from the sulfanyl group to the tyrosyl radical (BDE = 380 kJ mol^{-1})

to produce the required sulfenyl radical and the 4-oxidophenyl group.

This electron transfer occurs by **hopping between identified relay stations**. There are two tyrosines, Tyrosines 730 and 731, in the catalytic R1 protein from *E. coli*. These two tyrosines, which are homologous to Tyrosines 741 and 742 in the active site of R1 protein from *S. cerevisiae* (Figure 5–12),[490,491] are adjacent to the sulfido group of Cysteine 439, which is homologous to Cysteine 443 in the active site of *S. cerevisiae* and which is the sulfido group that becomes the sulfenyl radical in the active site at which the reduction occurs.[483] Tyrosines 730 and 731 are on the path of the electron transfer. When they are replaced, in turn, by 3-aminotyrosines, and the respective mutant R1 proteins are mixed with R2 protein, an unpaired electron, on its way to the hole in the tyrosyl radical in protein R2, appears on the respective 3-aminotyrosine.[492] In a system in which an artificial one-electron oxidant, rhenium bipyridine, replaces protein R2 in the ribonucleoside-diphosphate reductase from *E. coli*, electron transfer from the sulfanyl group of the cysteine in the active site to the photochemical oxidant cannot occur when either Tyrosine 741 or Tyrosine 742 in protein R1 is mutated to phenylalanine.[493]

When Tyrosine 356 in protein R2 of *E. coli* is replaced by tyrosines that have been variously substituted at their 4-hydroxyphenyl groups, the ribonucleoside-diphosphate reductase activity decreases abruptly when the reduction potential of the substituted 4-hydroxyphenyl group becomes 0.1 V (10 kJ mol^{-1}) more positive than that for the unsubstituted tyrosine. When that 4-hydroxyphenyl group is replaced by a 3,4-dihydroxy group, an unpaired electron builds up on it.[494] When rhenium bipyridine is attached covalently to Cysteine 355 in protein R2, an electron can be removed directly from Tyrosine 356 photochemically. Reduction of CDP^{3-} by a complex of this modified R2 protein and native R1 protein can be driven by light.[495] These observations are evidence that Tyrosine 356 in protein R2 is also one of the relay stations between which the electron hops on the path for electron transfer.[496]

No stable complex between the native R1 α_2 dimer and the native R2 β_2 dimer of any ribonucleotide reductase that requires these two proteins for activity has ever been directly observed or crystallized. Attempts to reveal, by quantitative crosslinking, a complex between proteins R1 and R2 from *E. coli* while that complex is catalyzing the reaction failed to observe any crosslinked product.* This failure suggests that the complex, which must form at some point in the catalytic cycle, is transient—lasting only long enough for the electron to be transferred, catalysis to occur, and the electron to be returned—so that most of the time the two proteins are independent of each other. Measurements of the formation of a complex at short times, immediately after R2 β_2 dimer and reduced R1 α_2 dimer from *E. coli* are mixed together at varying ratios, are consistent with a rate of association between the two proteins of 160 $\mu M\ s^{-1}$ and a rate of dissociation of 75 s^{-1} at these initial times. These results require that the dissociation constant for the complex when protein R1 is reduced should be 0.4 μM. It was also concluded, however, that during steady-state turnover, the rate-limiting step of the enzymatic reaction is reduction of the cystine in the active site (2 s^{-1}), which follows dissociation of the complex between R2 β_2 dimer and R1 α_2 dimer. This reduction, which is the last step in the mechanism, must be completed before the two proteins can again form a complex,[497] so most of the time, the two are not associated with each other, in agreement with the results of quantitative crosslinking.

A stable complex, however, can be formed between native R2 β_2 dimer and an R1 α_2 dimer from *E. coli* in which Tyrosine 730 has been mutated to 3-aminotyrosine.[498] What seems to be the same complex can also be formed from a native R1 α_2 dimer and a mutant of R2 β_2 dimer in which Glutamate 52 has been mutated to glutamine and Tyrosine 122 has been mutated to 2,3,5-trifluorotyrosine.[499] The existence of these two complexes suggests that when the electron being transferred is trapped on one of the relay stations, so that it cannot complete its passage in either direction, the complex between the two proteins cannot dissociate as it does at the end of each complete turnover.

Electron micrographic images (80,386) of the complex between the native R1 α_2 dimer and the mutant of R2 β_2 dimer from *E. coli* embedded in amorphous ice were submitted to image reconstruction to obtain a map of scattering density into which the previously reported crystallographic molecular models of the R1 α_2 dimer and the R2 β_2 dimer could be inserted. Following refinement, a complete molecular model of the complex was produced.[499]

*Smith, S. and Kyte, J., personal communication.

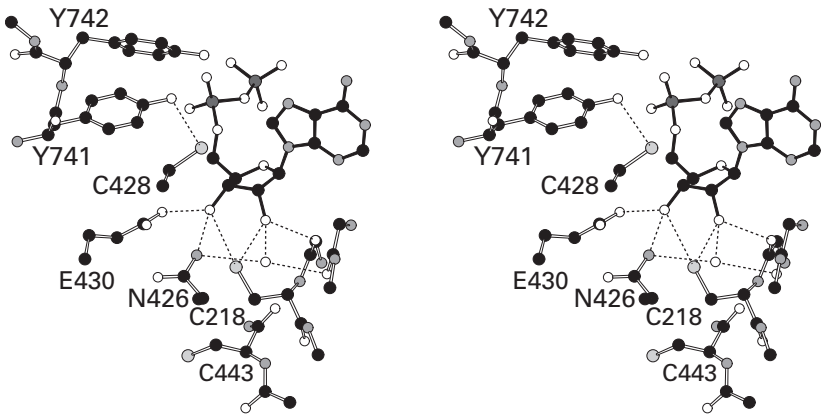


Figure 5–12: Stereodrawing[181] of the crystallographic molecular model[490] of the active site of ribonucleoside-diphosphate reductase from *S. cerevisiae* occupied by the substrate ADP^{3-}. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, large light gray atoms are sulfurs, and large dark gray atoms are atoms of phosphorus. The small white sphere is a water. The protein was overexpressed in *E. coli* and purified by passing the cellular extract over a solid phase to which a heptapeptide with the carboxy-terminal sequence of the R2 protein from *S. cerevisiae* had been covalently attached.[491] The purified catalytic R1 protein was crystallized, and the crystals were soaked in a solution containing 20 mM ADP^{3-}, 20 mM 2′-deoxyguanosine 5′-triphosphate, and 10 mM $MgCl_2$. Reflections to Bragg spacing of 0.26 nm were then collected. In the resulting map of electron density, there was a feature in the active site into which a molecule of ADP^{3-} (black bonds) could be inserted unambiguously. The ribose of ADP^{3-} is held firmly in the active site by hydrogen bonds to Asparagine 246, Glutamate 430, Cysteine 218, a fixed molecule of water, and the amido oxygen of a peptide bond. The sulfanyl group of Cysteine 428 is 0.33 nm from the 3′ carbon of the ribose, and the 3′ hydrogen is almost on a line of centers between sulfur and carbon. In the active site, there are two tyrosines adjacent to each other in the sequence of amino acids, Tyrosines 741 and 742 (upper left-hand corner). The oxygen of Tyrosine 741 is 0.34 nm from the sulfur of Cysteine 428 and almost perfectly aligned to remove the hydrogen from that sulfur.

This complex between the native R1 α_2 dimer and the mutant R2 β_2 dimer is asymmetric. The main reason for the **asymmetry of the complex** is that the twofold rotational axes of symmetry for the R1 α_2 dimer and the R2 β_2 dimer are far from collinear. Collinearity is a requirement of rotational symmetry in a complex between two dimers.[487] Furthermore, association of the face on the surface of an R2 β_2 dimer with the face on the surface of one of the two R1 α subunits to form the specific interface holding the complex together sterically blocks the symmetrically situated face on the other R1 α subunit; therefore, only one of the two symmetricaly identical faces on the R1 α_2 dimer can be occupied by an R2 β_2 dimer at the same time. Consequently, in the complex between an R1 α_2 dimer and an R2 β_2 dimer, only one of the two active sites on the R1 α_2 dimer can be coupled to a path for electron transfer. The asymmetry of this complex and the consequent steric exclusion of a second R2 β_2 dimer, if the molecular model represents the catalytically competent complex between an R1 α_2 dimer and an R2 β_2 dimer, may explain the fact that only half the active sites and half the tyrosyl radicals in a given solution of the enzyme can be involved in catalysis at the same time.[500-502]

In the molecular model from the reconstruction,[499] there is an extensive interface between one R1 α subunit and faces on both R2 β subunits in the R2 β_2 dimer, but the interface between the other α subunit and a β subunit is almost nonexistent (there is a loop in the other R1 α subunit at the tip of which four amino acids make contact with an R2 β subunit). Consequently, only one active site for the reduction on the R1 α_2 dimer is linked to one of the two tyrosyl radicals on the R2 β_2 dimer. Within the molecular model from the reconstruction, this tyrosine and the sulfido group of Cysteine 439 in the active site for the reduction are linked by a chain of relay stations among which the electron can hop during its transfer. **Side chains of Tryptophan β48, Tyrosine β356, Tyrosine α731, and Tyrosine α730 comprise this chain**. The path on these relay stations from the sulfido group in the active site on the associated R1 α subunit and the radical at the nearest Tyrosine β122 is 3.5 nm long, in agreement with the electron paramagnetic resonance spectra.[488] The distance in the molecular model between Tryptophan β48 and Tyrosine β356 is 1.2 nm, and the distance between Tyrosine β356 and Tyrosine α731 is 0.8 nm. The sum of these two distances in the catalytically competent complex has been estimated to be 2.5 nm by pulsed electron–electron double resonance spectroscopy.[489] Tyrosine β356, through which the electron is transferred, is within the extensive interface between its β subunit and the competent α subunit, and the 20 amino acids between it and the carboxy terminus of its polypeptide are also in the interface. A synthetic heptapeptide with the sequence (FTLDADF) of the carboxy-terminal segment of murine protein R2 inhibits enzymatic activity, an observation from which it was concluded that this sequence is involved in association of the two proteins,[491] and this conclusion agrees with the molecular model. All these observations suggest that the complex observed in the electron micrographs is the catalytically competent complex between the R1 α_2 dimer and the R2 β_2 dimer, in which the electron is transferred from the sulfanyl group of Cysteine α439 to the 4-oxidophenyl radical on Tyrosine β122 over a distance of 3.5 nm.

As was discussed earlier in Chapter 2, the **net transfer of the electron by hopping** among these side chains that comprise the relay is accomplished in a sequence of steps. An electron is transferred from the indolyl group of Tryptophan β48 to the hole in the 4-oxyphenyl radical in Tyrosine β122 to produce an indolyl radical in Tryptophan β48; an electron is transferred from the 4-hydroxyphenyl group of Tyrosine β356 to the hole in the indolyl radical in Tryptophan β48 to produce a 4-oxyphenyl radical in Tyrosine β356; an electron is transferred from the 4-hydroxyphenyl group of Tyrosine α731 to the hole in the 4-oxyphenyl radical in Tyrosine β356 to produce a 4-oxyphenyl radical in Tyrosine α731; and an electron is transferred from the 4-hydroxyphenyl group of Tyrosine α730 to the hole in the 4-oxyphenyl radical in Tyrosine α731 to produce a 4-oxyphenyl radical in Tyrosine α730. The 4-oxyphenyl radical in Tyrosine α730 then abstracts a hydrogen from the sulfanyl group of Cysteine α439 or an electron from the sulfido group of Cysteine α439 to produce the sulfenyl radical. As before, it is obvious that although long-range electron transfer seems to imply that the same electron is transferred from one location to the other, this is never the case in any situation, even when hopping does not occur. In fact, in the net transfer of an electron between each relay station in ribonucleoside-diphosphate reductase on a path of covalent bonds or through space, the same electron that leaves one station is not the same electron that arrives at the next.

When an electron is transferred from an indolyl group, that group becomes an indolyl radical cation. It follows that **dehydronation** of the indolyl nitrogen during the transfer, so that the product is a neutral indolyl radical, should assist in the transfer. When an electron is transferred to a neutral, dehydronated indolyl radical, it becomes the anionic conjugate base of an indolyl group ($pK_a = 17$), so **hydronation** of the nitrogen during the transfer will definitely assist in the transfer. In protein R2 from *E. coli*, the nitrogen of the indolyl group of Tryptophan β48 participates in a hydrogen bond (0.30 nm) with the carboxylato group of Aspartate β237, which can remove and then add back a hydron as required, as the indolyl group gives up and takes up an electron.[468]

When an electron is transferred from a neutral 4-hydroxyphenyl group, that group becomes a 4-hydroxyphenyl radical cation, so dehydronation of its oxygen during the transfer should assist in the transfer. When, however, an electron is transferred from an anionic 4-oxidophenyl group, it becomes a neutral 4-oxyphenyl radical, so hydronation of its oxygen during the transfer could be undesirable. When an electron is transferred to a 4-oxyphenyl radical, it becomes a 4-oxidophenyl group ($pK_a = 9.8$), so hydronation of its oxygen during the transfer might assist in the transfer. When the electron arrives at the 4-oxyphenyl radical on Tyrosine β122 in the active site of ribonucleoside-diphosphate reductase from *E. coli*, the resulting 4-oxido group can be hydronated by a hydron on one oxygen of the carboxy group of Aspartic Acid β84,[468,503] which is nearby (0.34 nm) and in the proper orientation to transfer a hydron to a σ lone pair of electrons on the oxido group. The 4-hydroxy group on Tyrosine β356 in the R2 protein is exposed to the solution and could take up a hydron from and give away a hydron to the solution. The planes of the two adjacent tyrosines in the active site in an R1 α subunit, Tyrosines α731 and α730, are roughly parallel to each other in most crystallographic molecular models, and in the image reconstruction of the complex between protein R1 and protein R2, they are stacked upon each other,[499] probably to facilitate electron transfer. In all cases, their respective oxygens are too far apart (0.35 nm) to form a hydrogen bond, and their disposition, especially when they are stacked upon each other, prevents them from attaining the proper orientation for a hydrogen bond,[504] which is usually if not always a requirement of hydron transfer.* The 4-hydroxy group of Tyrosine α731 in the active site, however, does participate in a hydrogen bond with the carboxy group of Glutamate α623.[499]

The 4-oxido group of Tyrosine α730 and the sulfanyl group of Cysteine α439 in protein R1 of ribonucleoside-diphosphate reductase from *E. coli* are in van der Waals contact (0.35 nm) in the resting state of the enzyme. Consequently, they cannot both be the negatively charged conjugate bases, and there must be a hydron on one of them. When the electron is removed from Tyrosine α730 by the hole in the 4-oxyphenyl radical of Tyrosine α731, the product of the one-electron oxidation must be a neutral, hydronated 4-hydroxy group and a neutral cysteinyl radical. The plane of the 4-hydroxyphenyl group of Tyrosine α741 in the enzyme from *S. cerevisiae* (Figure 5–12), homologous to Tyrosine α730 in the enzyme from *E. coli*, is **normal to the line connecting its 4-hydroxy group to the sulfanyl group** of Cysteine α428, homologous to Cysteine α439 in *E. coli*, and the oxygen and sulfur are in van der Waals contact (0.34 nm). This orientation and this intimate contact are as they should be if the 4-oxyphenyl radical (**5–113**) of Tyrosine α741 abstracts the hydrogen from the sulfanyl group of Cysteine α428, or if an electron from the sulfido group of Cysteine α428 is transferred in concert with the transfer of an electron from the 4-hydroxyphenyl group of Tyrosine α741 to the 4-oxyphenyl radical of Tyrosine α742. Both situations produce the sulfenyl radical and the 4-hydroxyphenyl group.

Ribonucleoside-diphosphate reductase from *Chlamydia trachomatis* is a homologue (22% identity; 1.7 gap percent) of ribonucleoside-diphosphate reductase from *E. coli* in which the tyrosine bearing the radical in protein R2 has mutated over time to a phenylalanine and the unpaired electron resides in a dinuclear $Fe^{3+}(O^{2-})Mn^{4+}$ cluster. In this ribonucleoside-diphosphate reductase, a **tryptophan in the vicinity of the dinuclear $Fe^{3+}(O^{2-})Mn^{4+}$ cluster** assumes the role of the missing tyrosine in the chain of relay stations between which the electron hops,[505] even though the electron does not reside in its indolyl group at rest as it does in the 4-hydroxyphenyl group of Tyrosine 122 in protein R2 from *E. coli*. Other than the substitution of this tryptophan, the relay stations in the electron transfer in proteins R1 and R2 in this enzyme are on tyrosines and a tryptophan in homologous positions in the two polypeptides. Significant differences are observed in the absorptions in the electron paramagnetic resonance spectra of mutants of the enzyme from *C. trachomatis* in which each tyrosine is mutated in

*It is sterically difficult if not impossible for a hydron to be transferred between two tyrosines that are immediately adjacent to each other in a polypeptide.

turn when each mutant is in the normal reaction mixture for enzymatic activity. These differences indicate that each mutation in turn obstructs the transfer of the electron, causing it to assume different distributions over the chain of relay stations.[506]

In protein R2 from *Flavobacterium johnsoniae*, the tyrosine homologous to Tyrosine 122 in protein R2 from *E. coli* is present, but it is not a radical. The unpaired electron **remains in the $Mn^{3+}(O^{2-})Mn^{4+}$ cluster adjacent to the tyrosine**, presumably because the equilibrium analogous to Equation 5–141, with manganese ions replacing the two iron ions, favors the dinuclear cluster.[475]

Transfer of an electron from the sulfido or sulfanyl group on the cysteine in the catalytic site on protein R1 to the tyrosyl radical in protein R2 to create the sulfenyl radical initiates reduction of the nucleoside triphosphate. At the end of the catalytic reaction in the active site, the sulfenyl radical is regenerated. It was possible that it could then remain there and participate in subsequent turnovers. By using a mutant of ribonucleoside-diphosphate reductase from *E. coli*, however, in which Tyrosine 122 in protein R2 has been replaced with 2,3,5-trifluorotyrosine to decrease the rate of electron transfer so that its kinetics could be examined, it has been shown that, **at the end of each turnover, the electron is transferred from Tyrosine 122 back to the sulfenyl radical** in the active site of protein R1.[507] These observations are consistent with the conclusion that the complex between proteins R1 and R2 that is required for enzymatic activity exists only from the time the electron is transferred from the catalytic site until the time that it has returned.

Crystallographic molecular models of the active sites of R1 proteins, in the absence of the respective R2 proteins and their tyrosyl radicals and occupied by ribonucleoside diphosphates (Figure 5–12) have been reported,[490,504] as have crystallographic molecular models of an adenosylcobalamin-dependent ribonucleotide reductase in the absence of thioredoxin and occupied by ribonucleotides and, in one case, a ribonucleotide and adenosylcobalamin.[482,508] In each case, the catalytic groups are homologous and similarly aligned.

There is a common mechanism for the ribonucleotide reductases that is consistent with this arrangement of the catalytic groups around the ribonucleotides in these molecular models and with the available chemical evidence. This common mechanism (Figure 5–13)[509] can be described for the ribonucleoside-diphosphate reductase from *S. cerevisiae* operating on ADP^{3-} (Figure 5–12). The sulfenyl radical (BDE = 370 kJ mol^{-1}) at Cysteine 428, homologous to each sulfenyl radical formed in the various ways, abstracts the hydrogen (BDE = 380 kJ mol^{-1}) from carbon 3′ of ADP^{3-} (0.33 nm). The resulting **α-hydroxyalkyl radical** (**5–114**) at carbon 3′ is stabilized by the captodative effect engendered by electron donation from a lone pair of electrons on the adjacent 3′-hydroxy group. This lone pair of electrons is held parallel to the developing radical on carbon 3′ by hydrogen bonds between the hydroxy group and Asparagine 426 and Glutamate 430. Abstraction of the hydrogen from carbon 3′ permits the conjugation of that same lone pair of electrons with the two electrons in the carbon–oxygen bond of the 2′-hydroxy group, a conjugation that was prevented by the hydrogen on carbon 3′. As a result of the creation of this conjugation, the lone pair of electrons on the 3′-hydroxy group can push. The ribosyl group then undergoes a precedented, acid-catalyzed[510,511] elimination of water from carbon 2′. During this elimination, the sulfanyl group of Cysteine 218, as the required acid catalyst, hydronates the leaving oxygen (0.34 nm) while the 3′-hydroxy group, which is becoming a carbonyl oxygen, hydronates the sulfido group of Cysteine 218 (0.33 nm). The elimination produces an **oxallylic radical** with three electrons in two π molecular orbitals (**5–115**) and a sulfanyl group at Cysteine 218. In the highest occupied molecular orbital (drawn in Figure 5–13), the spin density is concentrated almost exclusively on carbon 2′ and the oxygen on carbon 3′. Carbon 2′ of the oxallylic radical (BDE = 400 kJ mol^{-1}) abstracts the hydrogen (BDE = 370 kJ mol^{-1}) from the sulfanyl group of Cysteine 218 to produce ketone **5–116**.* The resulting sulfenyl radical then adds to the sulfanyl group of Cysteine 443 to form the **disulfide radical anion**.[512,513] The α carbons of Cysteines 218 and 443 are 0.51 nm apart, on the shorter end but within the range of 0.45–0.7 nm for that distance in typical disulfides in proteins.[514] The carboxy group of Glutamate 430 then hydronates the carbonyl oxygen of ketone **5–116** while the electron in the disulfide radical anion (electron affinity = 9 kJ mol^{-1})[515] is transferred to the carbonyl group (electron affinity = 95 kJ mol^{-1})[516] at carbon 3′. The resulting α-hydroxyalkyl radical (**5–117**) at carbon 3′ (BDE = 380 kJ mol^{-1}),

*Cysteine 218 illustrates the unique properties of a sulfanyl group in such a reaction. The hydron that its thiolate removes from the 3′-hydroxy group is the hydrogen atom abstracted by carbon 2′ of the oxallylic radical. Thus a hydron on a sulfanyl group becomes a hydrogen atom.

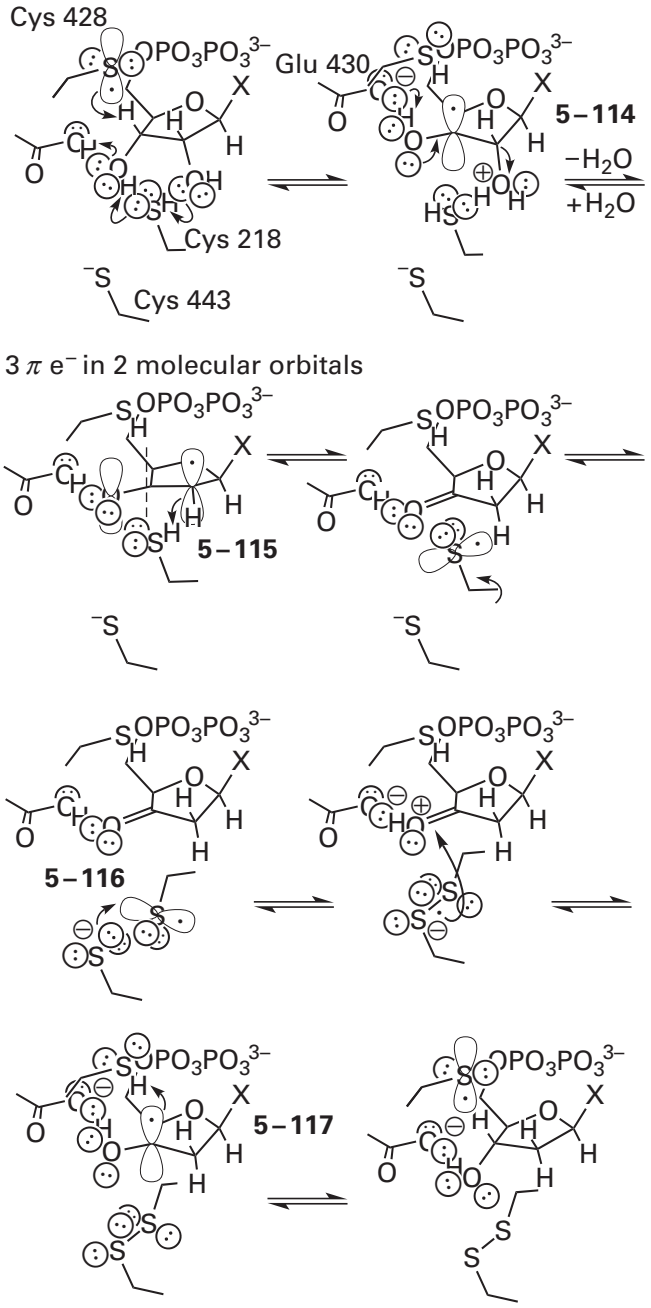

Figure 5–13: A mechanism for ribonucleoside-diphosphate reductase or ribonucleotide-triphosphate reductase involving radical intermediates. The mechanism is drawn as if it were occurring in the active site of ribonucleoside-diphosphate reductase from *S. cerevisiae*. A hydrogen is abstracted from the 3′-carbon of the ribosyl group by the sulfenyl radical of Cysteine 428 to produce the radical **5–114**, and the 2′-hydroxy group of the ribose is hydronated by a composite acid consisting of Cysteine 218, the 3′-hydroxy group of the ribose, and Glutamate 430 to initiate the production of the neutral oxallylic radical **5–115**. The highest occupied molecular orbital (HOMO) of oxallylic radical **5–115** is drawn. It is occupied by the unpaired electron. The complete π molecular orbital system of the oxallylic radical contains three electrons. Formation of this oxallylic radical proceeds by elimination of water and dehydronation of the 3′-hydroxy group so that two electrons can enter the π molecular orbital system of the oxallylic radical. The oxallylic radical abstracts hydrogen from the sulfanyl group of Cysteine 218 to form ketone **5–116**, and the resulting sulfenyl radical of Cysteine 218 forms a cystinyl radical anion with the sulfanylate anion of Cysteine 443. An electron is transferred from the cystinyl radical anion to carbon 3′ of ketone **5–116** to produce the radical at carbon 3′ of the ribose (**5–117**). This radical abstracts the hydrogen from the sulfanyl group of Cysteine 428 to regenerate the original radical at the active site and the 2′-deoxyribosyl group.

which differs from α-hydroxyalkyl radical **5–114** only by the hydrogen that has replaced the hydroxy group at carbon 2′, abstracts the hydrogen (BDE = 370 kJ mol^{-1}) from the sulfanyl group of Cysteine 428, the reverse of the first step in the mechanism, to complete reduction of the substrate. The resulting sulfenyl radical is then converted into a sulfanyl group or a sulfido group by the electron transfer that formed it in the first place. At the end of the reaction, ADP^{3-} has been reduced to deoxyADP^{3-}, and the two cysteines, Cysteines 218 and 443, have been oxidized to a cystine, and everything else is as it was.

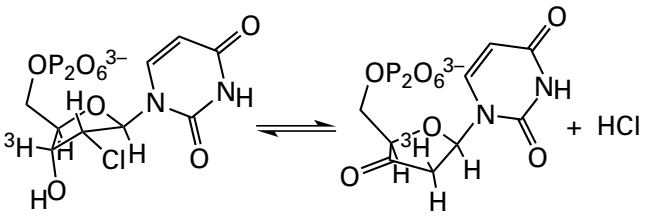
This mechanism and the orientation of the catalytic groups in the active site are consistent with the retention of configuration for replacement of the hydroxy group by a tritium observed at carbon 2′.[517] There are also a number of other observations that support this mechanism.*

When Cysteine 225 in ribonucleotide diphosphate reductase from *E. coli* (homologous to Cysteine 218 in the enzyme from *S. cerevisiae*) is mutated to serine and the mutant is mixed with protein R2 and [3′-^{3}H]UDP^{3-}, the ribosyl of UDP^{3-} slowly decomposes, releasing its uracil, and tritium is released as ^3H_2O at the same rate as the tyrosyl radical in protein R2 is lost.[518] Presumably, the abstraction of the hydrogen from carbon 3′ by the sulfenyl radical of Cysteine 439 (homologous to Cysteine 428 in the enzyme from *S. cerevisiae*) and the electron transfer to Tyrosine 122 in protein R2 from *E. coli* from Cysteine 439 reaches equilibrium because the reaction cannot proceed further in the absence of Cysteine 225. As the oxallylic radical **5–115** slowly decomposes, the 4-oxidophenyl ion of Tyrosine 122 in protein R2 cannot be reoxidized to the tyrosyl radical, and the triton stalled on Cysteine 439 exchanges with water.

*While reading the following observations, you should be referring to your copy of the stereodrawing of Figure 5–12, as well as Figure 5–13.

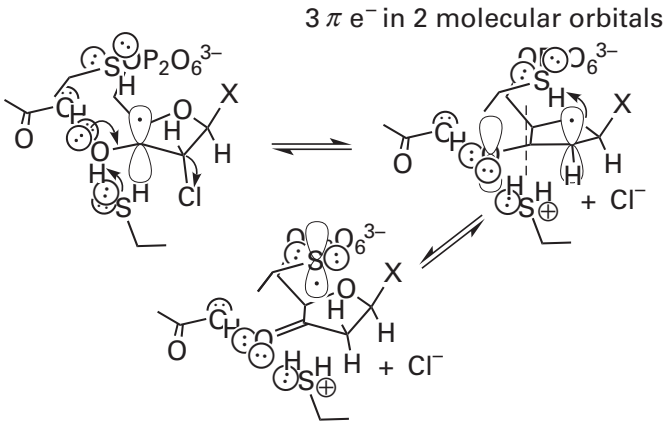
When [3′-^{3}H]UDP^{3-} is used as a reactant in the reaction catalyzed by ribonucleoside-diphosphate reductase from *E. coli*, a **primary kinetic isotope effect** ($^Tk = 3$)[509] is observed, consistent with breaking of the bond between carbon 3′ and its hydrogen. While most of the tritium remains on carbon 3′ in the product [3′-^{3}H]-2′-deoxyuridine diphosphate, about 1% is lost to solvent,[519] a result consistent with a slow loss resulting from isotopic exchange at the sulfanyl group of Cysteine 439 (homologous to Cysteine 428 in the enzyme from *S. cerevisiae*). If the accepted mechanism is correct, the latter observation suggests that either the [^{3}H]sulfanyl group resulting from hydrogen abstraction from carbon 3′ is shielded by the active site from exchange or the lifetime of the [^{3}H]sulfanyl group is so short that very little exchange can occur or both of these possibilities combined.

2′-Chloro-2′-deoxycytidine diphosphate[520] and 2′-chloro-2′-deoxyuridine diphosphate[520,521] are converted by ribonucleoside-diphosphate reductase from *E. coli* to the respective ketones, 2′,3′-dideoxy-3′-oxocytidine diphosphate and 2′,3′-dideoxy-3′-oxouridine diphosphate



(5–144)

These ketones are the respective noncovalent intermediate ketones **5–116** in the proposed mechanism (Figure 5–13). If [3′-^{3}H]-2′-chloro-2′-deoxyuridine diphosphate is used as a reactant, the tritium is transferred[522] intramolecularly to carbon 2′. Both observations are consistent with **radical-assisted dehydrohalogenation***



(5–145)

In this explanation for the observations, the same oxallylic radical **5–115** is formed as during the normal reaction (Figure 5–13), and there is no unequivocal explanation for why it must be quenched by abstracting a hydrogen from Cysteine 439 (homologous to Cysteine 428 from *S. cerevisiae*) to form ketone **5–116** rather than abstracting a hydrogen from Cysteine 225 (homologous to Cysteine 218 from *S. cerevisiae*) as usual and continuing on the normal path. For the dehydrohalogenation of these 2′-chloro-2′-deoxynucleotides to occur, the enzyme must be in its reduced, dithiol form even though the reaction is formally a dehydrohalogenation and not a reduction, so it is not that Cysteine 225 is sequestered in the disulfide with Cysteine 462 (homologous to Cysteine 443 from *S. cerevisiae*) and unreactive. The only difference between the normal reactants and the homologous chlorides is the leaving group. Unlike a hydroxy group, a chloro group does not require hydronation before it leaves, and it is also far more difficult to hydronate the chlorine atom in an alkyl chloride than it is to hydronate the hydroxy group in an alcohol.[523] If the active site is occluded so that hydrons cannot leave or enter over the lifetime of the intermediates, which would be consistent with the lack of tritium exchange when [3′-^{3}H]UDP^{3-} is used as a reactant, then the sulfanyl group ($pK_a = -7$ for RSH_2^+) on Cysteine 225 (homologous to Cysteine 218 from *S. cerevisiae*) would be sharing a hydron with the oxo group ($pK_a = -7$ for R_2COH^+) at carbon 3′ that was the 3′-hydroxy group. The sulfanyl group, however, would be unable to lose simultaneously the hydron it already had at the beginning of the reaction by hydronating the chloride ion, and this double hydronation of sulfur, producing the conjugate acid of the sulfanyl group, would prevent it from donating a hydrogen atom to carbon 2′ (Figure 5–13). In this case, Cysteine 439 (homologous to Cysteine 428 from *S. cerevisiae*) would step

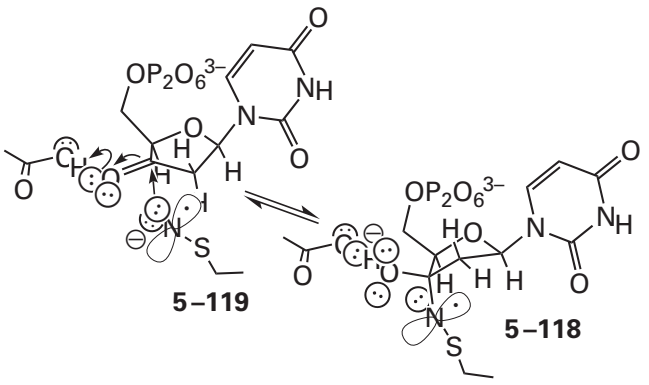
*From here on, when a radical intermediate is drawn in orbital notation, only the highest occupied molecular orbital (HOMO) of that intermediate will be represented, with the appropriate nodes, to indicate the locations of the unpaired spin. Because spin densities in the highest occupied molecular orbital of the respective intermediates are almost always unknown, a single dot, representing an unpaired electron will be placed in one of the lobes of the orbital either over a carbon, which is the atom that probably has the highest spin density (see **5–112** and **5–113**), or over a heteroatom, if spin density over that heteroatom is the focus of the reaction.

in to do so. If this is the case, the dehydrohalogenation of the chlorides catalyzed by the enzyme is consistent with the sulfanyl group of Cysteine 225 (homologous to Cysteine 218 from *S. cerevisiae*) being required to remove the hydron from the 3′-hydroxy group as well as adding a hydron to the 2′-hydroxy group during the elimination that produces the oxallylic radical, which its location in the occupied active site suggests that it must do (Figure 5–12).

The same dehydrohalogenation as that catalyzed by ribonucleoside-diphosphate reductase from *E. coli* (Equation 5–144) is also catalyzed by adenosylcobalamin-dependent ribonucleoside-triphosphate reductase from *L. leichmannii*.[524] This additional, unusual observation demonstrates that the fundamental mechanisms of the reactions catalyzed by ribonucleoside-diphosphate reductases and by ribonucleoside-triphosphate reductases are the same.

A result similar to the dehydrohalogenation is observed when **2′-*C*-methyladenosine diphosphate** is used as a reactant with adenosylcobalamin-dependent ribonucleoside-diphosphate reductase from *Corynebacterium nephridii*. In this case, the methyl group on carbon 2′ seems to hinder the abstraction of a hydrogen from carbon 2′ by the sulfanyl group on the *Si* face of the oxallylic radical (the one homologous to Cysteine 218 in the enzyme from *S. cerevisiae*). As a result, about 35% of the time, carbon 2′ in the oxallylic radical abstracts the hydrogen from the cysteine (the one homologous to Cysteine 428 in the enzyme from *S. cerevisiae*) on the *Re* face rather than the *Si* face. This steric hindrance aborts the reaction and leads to production of the 2′-*C*-methyl version of ketone **5–116**.[525]

When proteins R1 and R2 from *E. coli* are mixed with 2′-azido-2′-deoxyuridine 5′-phosphate, the tyrosyl radical on protein R2 is reduced to the tyrosinate, and **sulfenamido radical 5-118**



(5–146)

is formed at the active site.[526-528] It has been proposed that the nucleophilic sulfenamido radical anion **5–119** of Cysteine 225 (homologous to Cysteine 218 from *S. cerevisiae*) adds to ketone **5-116** formed by the normal mechanism (Figure 5–13) to form the identified product. The sulfenamido radical anion **5–119** would be formed from the azide anion that leaves rather than water from carbon 2′ as the oxallylic radical **5–115** is formed.

When Glutamate 441 in protein R1 of ribonucleoside-diphosphate reductase from *E. coli* (homologous to Glutamate 430 in the enzyme from *S. cerevisiae*) is mutated to glutamine and the mutant is mixed with protein R2 and cytidine 5′-diphosphate, a portion of the tyrosyl radical is lost and a new radical appears with the **electron paramagnetic resonance spectrum of a disulfide radical anion**.[529] Because the carboxy group of Glutamate 441 is unavailable to hydronate the carbonyl oxygen of ketone **5–116** (Figure 5–13), carbon 3′ is not electropositive enough to accept the electron from the disulfide radical anion, and the reaction is arrested at this step.

Finally, the disulfide between Cysteines 225 and 462 in protein R1 from *E. coli* (homologous to Cysteines 218 and 443 in the enzyme from *S. cerevisiae*) has been shown to be **kinetically competent** because it forms at a rate faster than the normal turnover of the enzyme when fully reduced R1 protein, R2 protein, and cytidine diphosphate are mixed in the absence of thioredoxin.[500]

This disulfide in the active site of ribonucleoside-diphosphate reductase from *E. coli*, at the end of the reduction, is reduced by thiol–disulfide exchange (see Equation 5–57) with Cysteines 754 and 759 in protein R1 (homologous to Cysteines 731 and 736 in the enzyme from *S. cerevisiae*). The homologous cysteines, Cysteines 731 and 736, in the adenosylcobalamin-dependent ribonucleoside-triphosphate reductase of *L. leichmannii* are also responsible for reducing the homologous disulfide in its active site.[518,530-532] The resulting, respective cystine of these two distal cysteines is reduced by thiol–disulfide exchange with the two cysteines in reduced thioredoxin.[533]

Model studies of these reductions of ribonucleotides are also consistent with the proposed mechanism (Figure 5–13).[534,535] For example, when a radical is generated at carbon 3′ of 2′-acetyl-6-(*N*-benzoyl)adenosine by replacing its 3′-hydrogen synthetically with a phenylselenol ester and the phenylselenol ester is submitted to photolysis, the homologue of oxallylic radical **5–115** is formed, but

this conversion occurs only when a base, playing the role of Cysteine 218 (Figure 5–12), is present. This oxallylic radical subsequently participates in hydrogen abstraction to form ketone **5–116**.[536] The analogous radical at carbon 3 of 3-methoxytetrahydrofuran can be produced by intramolecular abstraction of hydrogen 3 by a sulfenyl radical.[537]

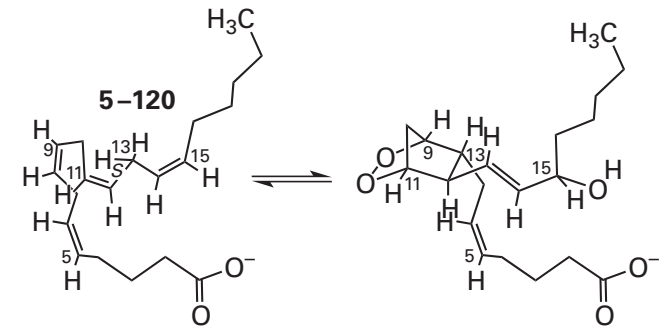
Although several ribonucleoside-triphosphate reductases that initiate their catalytic reactions with a stable glycyl radical (Equation 5–143) can use thioredoxin[453] or other reductants[538] as the ultimate source of reducing equivalents, the anaerobic ribonucleoside-triphosphate reductases (formate), which also use a glycyl radical to initiate their reactions, use **formate**

$$HCOOH \rightleftharpoons 2\,e^- + 2\,H^+ + CO_2 \qquad (5\text{–}147)$$

as the ultimate reductant.[539] Anaerobic ribonucleoside-triphosphate reductases (formate) lack the peripheral cysteines to oxidize the thioredoxin that serves as the reductant in the other ribonucleotide reductases, and they also may lack a sulfanyl group that plays the role of Cysteine 443 in the active site of protein R1 from *S. cerevisiae* (Figure 5–12). In the crystallographic molecular model of the unoccupied active site of anaerobic ribonucleoside-triphosphate reductase (formate) from Enterobacteria phage T4, there is a cysteine near the cysteine that becomes the sulfenyl radical, but its sulfur is 0.94 nm away from the sulfur of the sulfenyl radical,[486] which seems too far away to form a cystine. If this is the case, the formate may enter the reaction at an earlier stage than formation of an unavailable disulfide radical anion between two cysteines.[540] In the absence of formate and the presence of CTP^{4-}, however, an absorbance in an electron paramagnetic resonance spectrum of the closely related (68% identity; 2 gap per cent) anaerobic ribonucleoside-triphosphate reductase (formate) from *E. coli* is observed that has been identified as a thiosulfuranyl radical, which in this instance would be a **disulfide radical between the sulfur of a cysteine and the sulfur of a methionine**. In the enzyme from *E. coli*, a methionine does replace the nearby cysteine in the active site of the enzyme from Enterobacteria phage T4, so observation of the thiosulfuranyl radical suggests that a disulfide radical anion, either between the two cysteines or between the cysteine and the methionine, is also an intermediate in the reaction catalyzed by the anaerobic ribonucleoside-triphosphate reductases (formate). Formation of this radical in the active site of the enzyme from *E. coli* has been shown to be kinetically competent to be an intermediate in the reaction.[541] If it is an intermediate, the formate may not become involved at an earlier stage in the reaction.

The bond dissociation energy for the hydrogen of formic acid is 404 kJ mol^{-1}, which seems too large for its abstraction by a sulfenyl radical (BDE = 370 kJ mol^{-1}) but perhaps not too large for its abstraction by a disulfide radical anion or thiosulfuranyl radical, which would regenerate the two cysteines or a cysteine and a methionine. The **carbon dioxide radical anion** that results from abstraction of the hydrogen from formate is a strong one-electron reductant (electron affinity = -60 kJ mol^{-1}),[542] so it could as easily reduce ketone **5–116** to α-hydroxyalkyl radical **5–117**.[540] If a disulfide radical anion is not an intermediate in the reaction, carbon 2′ of oxallylic radical **5–115** (BDE = 400 kJ mol^{-1}) could abstract the hydrogen from formate, and then the carbon dioxide radical anion could reduce ketone **5–116** to α-hydroxyalkyl radical **5–117**. In this case, the only role for the cysteine in these active sites that is homologous to Cysteine 218 in the active site of the enzyme from *S. cerevisiae* would be as a catalytic acid–base.

In the few other instances in which a tyrosyl or glycyl radical is an intermediate in an enzymatic mechanism, the radical is usually transient rather than permanent, and it usually abstracts a hydrogen from the substrate directly. For example, in the active site of prostaglandin-endoperoxide synthase[543]



(5–148)

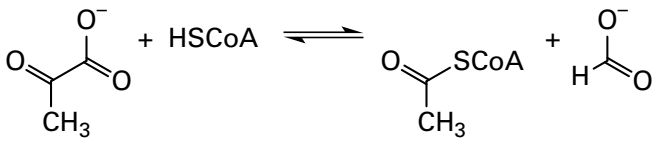
a tyrosine is oxidized to a tyrosyl radical during each turnover of the enzyme. This tyrosyl radical has been identified in ovine prostaglandin-endoperoxide synthase by its characteristic electron paramagnetic resonance spectrum.[544,545] It is a transient intermediate in the enzymatic reaction, and it is followed in the sequence of steps by a **pentadienyl radical**, also

identified by its electron paramagnetic resonance spectrum, that results from abstraction of the *pro-S* hydrogen from carbon 13 (Equation 5–148) of (5*Z*,8*Z*,11*Z*,14*Z*)-icosa-5,8,11,14-tetraenoate (arachidonate, **5–120**).[546] Carbon 13 sits between two carbon–carbon double bonds. In crystallographic molecular models of the complexes of the ovine enzyme[547] or the murine enzyme[543,548] with arachidonate, the 4-hydroxyphenyl group of Tyrosine 385, which becomes the transient radical,[549] is immediately adjacent (0.30 nm) to carbon 13 of arachidonate, well within van der Waals contact (0.44 nm) and in the proper orientation to remove the *pro-S* hydrogen. Consequently, it must be the case that the tyrosyl radical (BDE = 380 kJ mol^{-1}) abstracts a hydrogen directly from carbon 13 (BDE = 320 kJ mol^{-1}) to produce the pentadienyl radical encompassing carbons 11–15 of arachidonate.[437]

The oxidant that produces the tyrosyl radical in prostaglandin-endoperoxide synthase is a ferric heme. This heme is converted first to an oxoiron(IV) porphyrin$^{\bullet+}$ that has an electron paramagnetic resonance spectrum closely resembling that of the oxoiron(IV) porphyrin$^{\bullet+}$ of peroxidase from *Armoracia rusticana*.[550] The porphyrin$^{\bullet+}$ immediately removes an electron from Tyrosine 385 to produce a **hydroxyiron(IV) tyrosyl$^{\bullet+}$** that has an electron paramagnetic resonance spectrum closely resembling that of the hydroxyiron(IV) tryptophanyl$^{\bullet+}$ from cytochrome-*c* peroxidase. One edge of the heme in the murine enzyme is cradled in the segment of polypeptide that Tyrosine 385 and Histidine 386 comprise. One of the pyrroles in this edge of the heme is in van der Waals contact with the imidazolyl group of Histidine 386 (0.37 nm), and one of its vinyl groups is in van der Waals contact with the 4-hydroxyphenyl group of Tyrosine 385 (0.37 nm).[543] These two contacts provide two possible paths for the electron between the tyrosine and the porphyrin$^{\bullet+}$.

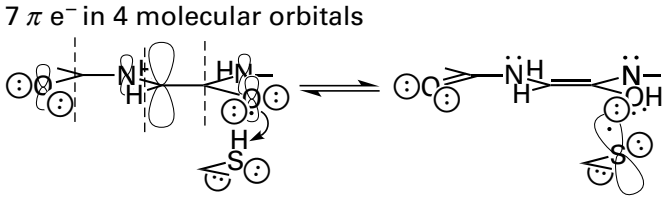
In the mechanism of galactose oxidase, a transient tyrosyl radical abstracts a hydrogen directly from the carbon of a primary alcohol (BDE = 390 kJ mol^{-1}) in a substrate [551,552] to form a radical at that location that is stabilized captodatively. In the decarboxylation catalyzed by hydrogen peroxide-dependent heme synthase from *G. stearothermophilus*, a tyrosyl radical, formed by electron transfer to the oxoiron(IV) porphyrin$^{\bullet+}$ of the reactant Fe-coproporphyrin III, abstracts a hydrogen from carbon 1 on a 2-carboxyethyl group on the porphyrin to produce what should be a stable radical because it is **conjugated to the oxoiron(IV)** in the coproheme.[553] The electron in the radical is immediately withdrawn into oxoiron(IV), leaving a carbenium ion that becomes a carbon–carbon double bond by decarboxylation at the adjacent former carbon 2 of the 2-carboxyethyl group on Fe-coproporphyrin III.

There is a group of enzymes,[554-557] all distantly related to anaerobic ribonucleoside-triphosphate reductase (formate) and consequently to each other,[565-567] in each of which a **stable glycyl radical** is formed by a [4Fe–4S] iron–sulfur cluster and *S*-adenosyl-L-methionine.[558-564] In each of these enzymes, other than anaerobic ribonucleoside-triphosphate reductase of Enterobacteria phage T4, a sulfenyl radical produced directly by the glycyl radical is the first intermediate in the reaction. For example, in the active site of formate *C*-acetyltransferase



(5–149)

from *E. coli*, the sulfanyl group of Cysteine 419 (the structural homologue of Cysteine 290 in anaerobic ribonucleoside-triphosphate reductase of Enterobacteria phage T4)[566] is only 0.31 nm from the amido oxygen of Glycine 734,[568] the glycine on which the stable radical (**5–112**) is located.[556] This amido oxygen is in the proper orientation[566] to abstract directly the hydrogen atom from the sulfanyl group



(5–150)

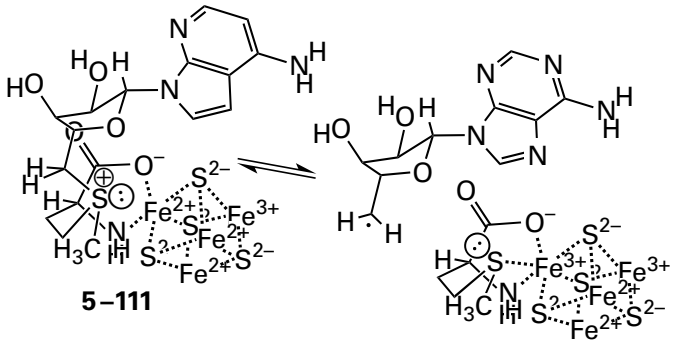
to form the 1,2-diaminoenol and the sulfenyl radical. The radical at Cysteine 419 is then transferred to Cysteine 418, probably by hydrogen abstraction. An absorption from one or the other of these cysteinyl radicals can be observed in an electron paramagnetic resonance spectrum of the enzyme inactivated by 3-sulfanylpyruvate.[569,570] From a crystallographic molecular model of the active site of the enzyme occupied by oxamate,[566] it has been proposed that the radical of Cysteine 418 adds nucleophilically to the carbonyl of pyruvate (0.33 nm away) to create the **radical of a thiohemiacetal** that decomposes to

S-acetylcysteine and a formate radical. The formate radical then abstracts the hydrogen from the sulfanyl group of Cysteine 418. Transfer of the acetyl group on Cysteine 418 to coenzyme A completes the reaction.

In the reaction catalyzed by benzylsuccinate synthase from *Thauera aromatica*, however, the cysteinyl radical itself, formed by abstraction of the hydrogen by the stable glycyl radical from Cysteine 493, abstracts a hydrogen from the methyl group in the reactant toluene to form the delocalized **phenylmethylenyl radical**, which has a benzylic π molecular orbital system. This intermediate radical participates in a radical addition at its methylene group to the carbon–carbon double bond of fumarate, the other reactant. The resulting benzylsuccinyl radical then abstracts the hydrogen from the sulfanyl group of Cysteine 493 to complete the reaction.[555] In a crystallographic molecular model of the active site occupied by toluene and fumarate, the methyl carbon of toluene is 0.39 nm from the sulfanyl group, and the carbon of fumarate to which the phenylmethyl radical adds is 0.34 nm from the methyl carbon of toluene,[571] both distances at or within the respective van der Waals contact.

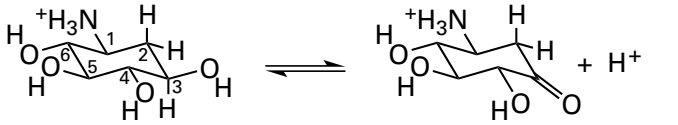
In a crystallographic molecular model of the active site of 4-hydroxyphenylacetate decarboxylase from *Clostridium scatologenes* occupied by the reactant (4-hydroxyphenyl)acetate, the sulfanyl group of Cysteine 503, the cysteine from which a hydrogen is abstracted by the stable glycyl radical, forms a hydrogen bond with the carboxy group of (4-hydroxyphenyl)acetate.[572] A sulfenyl radical at Cysteine 503 (BDE = 370 kJ mol^{-1}), however, should be unable to abstract a hydrogen from a carboxy group (BDE = 470 kJ mol^{-1}). It has been proposed instead[572,573] that the cysteinyl radical removes an electron from the carboxylato group of (4-hydroxyphenyl)acetate, rather than abstracting a hydrogen. This abstraction forms the **acyloxy radical**. Acyloxy radicals are unstable species that **immediately decarboxylate,** regardless of the carbon radical that results. In this instance, however, the decarboxylation leaves behind a stable, delocalized (4-hydroxyphenyl)methyl radical (BDE = 375 kJ mol^{-1}). The (4-hydroxyphenyl)methyl radical then abstracts the hydrogen from the sulfanyl group of Cysteine 503 (BDE = 370 kJ mol^{-1}), the sulfido group of which was hydronated by Glutamate 505, to regenerate the cysteinyl radical and in the process form 4-methylphenol, the other product of the enzymatic reaction.

A significant number[574] of enzymes use 5′-deoxy-5′-adenosyl radicals directly as intermediates. The 5′-deoxy-5′-adenosyl radicals in the active sites of this superfamily of enzymes are produced by homolytic dissociation of complex **5–111***



(5–138)

which is formed from *S*-adenosyl-L-methionine and a [4Fe–4S] iron–sulfur cluster, rather than the homolytic dissociation of the carbon–cobalt bond in a prosthetic adenosylcobalamin. In almost all[575,576] enzymatic reactions in which a 5′-deoxy-5′-adenosyl radical is produced by the homolytic dissociation of complex **5–111**, ***S*-adenosyl-L-methionine is a reactant, and L-methionine and 5′-deoxyadenosine are products**, as in the oxidation catalyzed by 2-deoxy-*scyllo*-inosamine dehydrogenase (AdoMet-dependent)[577]

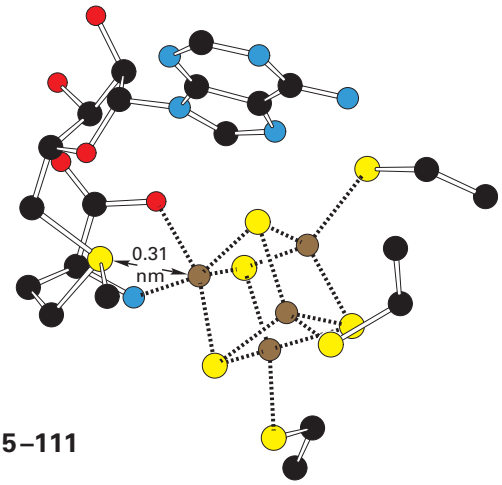


(5–151)

In these enzymatic reactions, the first step is **association of *S*-adenosyl-L-methionine with the prosthetic, catalytic [4Fe–4S] iron–sulfur cluster** in the active site.[578] During this association, both the α-amino group and the α-carboxy group of *S*-adenosyl-L-methionine become ligands to the one iron ion in the [4Fe–4S] iron–sulfur cluster that is not coordinated by a cysteine from the protein and that consequently has open sites for coordination. The conclusion that these two functional groups become ligands to this iron ion was reached by electron–nuclear double resonance spectroscopy[579]

*The enzymes that use a 5′-deoxyadenosyl radical produced by the homolytic dissociation of complex **5–111** are often referred to as *S*-adenosyl-L-methionine-dependent radical enzymes or radical AdoMet enzymes.

and crystallography.[447,561,580-582] In this initial complex, exemplified by the initial complex in the active site of lysine 2,3-aminomutase from *Clostridium subterminale*[447]



5–111

the sulfur of *S*-adenosyl-L-methionine ends up only 0.29–0.35 nm from the same iron ion to which the α-amino and α-carboxy groups are ligands, and spectroscopic measurements identify the sulfur as a ligand to that iron ion following homolytic dissociation of the sulfur–carbon bond (Equation 5–138; **5–110**)[583] During each turnover of one of these enzymes, the resulting L-methionine dissociates from complex **5–110** and leaves the active site as a product, as does 5′-deoxyadenosine, while the catalytic [4Fe–4S] iron–sulfur cluster, which is a prosthetic group covalently bound through the three cysteines, as is the case for all [4Fe–4S] iron–sulfur clusters, remains.

Because it must provide an electron to the sulfur that dissociates from the deoxyadenosyl group to give the sulfide as the product, the **catalytic [4Fe–4S] iron–sulfur cluster must be in the reduced state**, $[(Fe^{2+})_3(Fe^{3+})(^{2-}S)_4(^{-}S-)_3]^{2-}$, for the reductive homolytic dissociation of complex **5–111** to occur.[584] In solution under cyclic voltammetry, *S*-adenosyl-L-methionine displays an irreversible biochemical reduction potential of –1.4 V during successive sweeps of electrode potential between –0.6 and –1.7 V. When the voltage of the electrode is maintained at –1.5 V, 5′-deoxyadenosine (the product of abstraction of a hydrogen from a solute by a 5′-deoxy-5′-adenosyl radical) and 8,5′-cycloadenosine (the product of the intramolecular cyclization of a 5′-deoxy-5′-adenosyl radical) accumulate at a linear rate in the solution.[585] The accumulation of these products occurs only if the electrode is poised at a voltage less than –1.4 V, and the rate of accumulation increases linearly as the voltage of the poise is lowered to –2.8 V. These observations are consistent with a reductive homolytic dissociation of *S*-adenosyl-L-methionine producing 5′-deoxy-5′-adenosyl radical, as normally occurs in the active sites of the enzymes of this family.

Standard biochemical reduction potentials, however, of the catalytic [4Fe–4S] iron–sulfur clusters in the enzymes that use complex **5–111** to produce a 5′-deoxy-5′-adenosyl radical are all in the range[585] from –0.45 to –0.55 V. Formation of complex **5–111**, however, may shift the required reduction potential significantly. Instantaneous abstraction of the immediately adjacent hydrogen[438] on the reactant bound in the active site could also shift a significantly unfavorable equilibrium for dissociation of complex **5–111** to form the 5′-deoxy-5′-adenosyl radical at these greater reduction potentials into the favorable range by mass action.

The intermediate 5′-deoxy-5′-adenosyl radical assumed to exist in these enzymatic reactions has been produced in the active site of [formate-*C*-acetyltransferase]-activating enzyme from *E. coli* at 12 K by photolytically driven electron transfer from the catalytic [4Fe–4S] iron–sulfur cluster to force dissociation of the carbon–sulfur bond. The resulting 5′-deoxy-5′-adenosyl radical has been characterized by electron paramagnetic resonance and electron–nuclear double resonance spectroscopy using isotopic substitution in its ribosyl group. The radical is in a *p* orbital on carbon 5′ and is rotated out of the plane of the ribose ring by 40° to take advantage of the captodative effect provided by an unconjugated lone pair of electrons on the oxygen of the ribosyl ring.

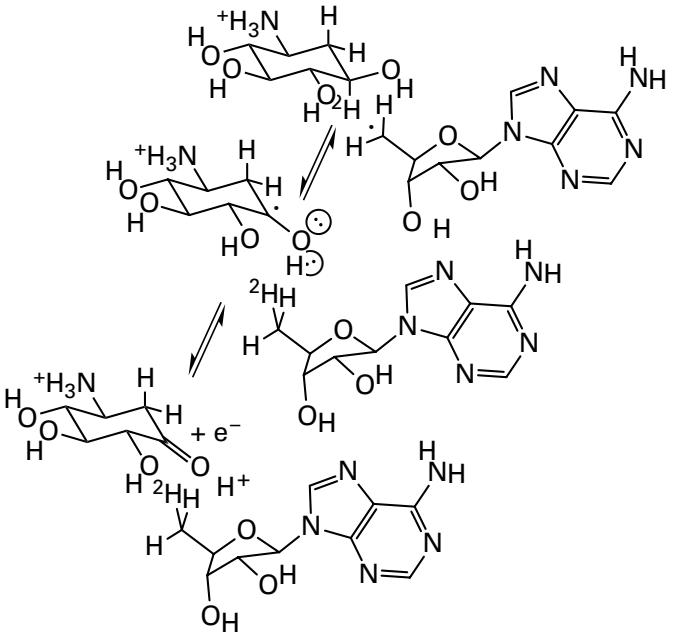
In all other instances in which it is an intermediate, however, the **existence of intermediate 5′-deoxy-5′-adenosyl radical has only been inferred** from the fact that the product of these enzymatic reactions is 5′-deoxyadenosine, the fact that the deuterium on the reactant that does not remain in the product ends up on the methyl group of 5′-deoxyadenosine, the fact that the hydrogen removed from the reactant is usually not acidic, the fact that the bond dissociation energies of carbon–sulfur bonds are fairly small, and the fact that a [4Fe–4S] iron–sulfur cluster usually provides electrons one at a time, which is what is needed to further weaken the carbon–sulfur bond in *S*-adenosyl-L-methionine.

The sulfur of the sulfonium in *S*-adenosyl-L-methionine in complex **5–111** has two secondary aliphatic carbons and a primary aliphatic carbon

attached to it. In the enzymes that use a 5′-deoxy-5′-adenosyl radical as an intermediate, the bond between the adenosyl group and the sulfur dissociates homolytically, but the **other two carbon–sulfur bonds are also susceptible to homolytic dissociation**. In the active site of 2-(3-amino-3-carboxypropyl)histidine synthase from *P. horikoshii*, in which the ligation of the iron ion in the catalytic [4Fe–4S] iron–sulfur cluster[586] in complex **5–111** is almost identical to that in the active site of lysine 2,3-aminomutase from *C. subterminale*, the carbon–sulfur bond to the **(*S*)-3-amino-3-carboxypropyl group** of *S*-adenosyl-L-methionine (8 o'clock position of the sulfur atom in **5–111**), rather than the carbon–sulfur bond to the 5′-deoxyadenosyl group (10 o'clock position of the sulfur atom in **5–111**), dissociates homolytically to produce the (*S*)-3-amino-3-carboxy-1-propyl radical, which then adds to carbon 2 of the imidazolyl group of a histidine in translation elongation factor 2. An absorption in the electron paramagnetic resonance spectrum of the enzyme when it is mixed with *S*-adenosyl-L-methionine has been assigned to this radical on the basis of changes in the spectrum upon isotopic substitutions.[587]

Complex **5–111** can also dissociate homolytically at the sulfur–carbon bond to the **methyl group**, even though a primary methyl radical is significantly less stable. The methyl radical has been observed in the active site of (FeFe) hydrogenase maturation factor HydG, the enzyme responsible for producing, from L-tyrosine, the carbon monoxide and cyanide found in the [FeFe] hydrogenase of *C. acetobutylicum*. It was produced at 12 K by photolytically driven electron transfer from the catalytic [4Fe–4S] iron–sulfur cluster to force dissociation of the carbon–sulfur bond.[588] The methyl radical was identified by its electron paramagnetic resonance spectrum, which was consistent with the conclusion that it was rapidly rotating within the active site, as one might expect. When the decarboxylated analogue of *S*-adenosyl-L-methionine, *S*-adenosyl-*S*-methyl-3-sulfanyl-1-propylamine, is used as a reactant for 2-(3-amino-3-carboxypropyl)histidine synthase from *P. horikoshii* rather than *S*-adenosyl-L-methionine, the carbon–sulfur bond to the *S*-methyl group dissociates homolytically, and that methyl group ends up on a sulfide adjacent to the catalytic iron ion in the [4Fe–4S] iron–sulfur cluster.[586] In the active site of the carbide synthase NifB from *Methanothrix thermoacetophila*, the methyl group that eventually becomes the mononuclear carbide in the center of the [Mo–7Fe–9S–C] cluster in dinitrogenase during its normal reaction is the methyl group of *S*-adenosyl-L-methionine in complex **5–111**. Rather than to a sulfide in the catalytic [4Fe–4S] iron–sulfur cluster, this methyl group is transferred to a sulfide in another [4Fe–4S] iron–sulfur cluster, which is one of the two [4Fe–4S] iron–sulfur clusters that are reactants for the enzyme and that eventually become the [Mo–7Fe–9S–C] cluster.[589]

In most reactions in which a 5′-deoxy-5′-adenosyl radical is produced by homolytic dissociation of complex **5–111**, **the 5′-deoxy-5′-adenosyl radical abstracts a hydrogen** directly from a reactant. For example, in the **dehydrogenation** catalyzed by 2-deoxy-*scyllo*-inosamine dehydrogenase (AdoMet-dependent), the 5′-deoxy-5′-adenosyl radical produced by homolytic dissociation of complex **5–111** abstracts the hydrogen on carbon 3 in the reactant 2-deoxy-*scyllo*-inosamine[577]



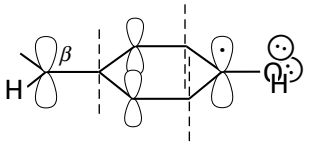
(5–152)

The intermediate radical of 2-deoxy-*scyllo*-inosamine is then **oxidized by the transfer of one electron** to give the ketone, 2,3-dideoxy-3-oxo-*scyllo*-inosamine, which is the product of the reaction. As was observed in this instance,[577] in most cases, the fact that the 5′-deoxy-5′-adenosyl radical has abstracted a hydrogen from one reactant for an enzyme in this superfamily and the identity of the hydrogen abstracted is established by synthetically or biosynthetically deuterating that hydrogen and showing that the deuterium ends up on the 5′-deoxyadenosine that is the product of the reaction.[590-599] Because the deuterium ends up on a methyl group in 5′-deoxyadenosine, it is not susceptible to exchange.

The radical produced by **abstracting a hydrogen adjacent to any hydroxy group**, as occurs in the reaction of ribonucleotide reductase or 2-deoxy-*scyllo*-inosamine dehydrogenase (AdoMet-dependent), is 30 kJ mol^{-1} more stable than the one produced by abstracting a hydrogen from the analogue in which the hydroxy group is replaced by a hydrogen.[440] This stability arises from a **captodative effect**.[600] In both ribonucleotide reductase and 2-deoxy-*scyllo*-inosamine dehydrogenase (AdoMet-dependent), the captodative effect that stabilizes the radical results from electron exchange between the unpaired electron and electrons in a lone pair on a hydroxy group. For this captodative effect to occur, the lone pair must be parallel to the π molecular orbital system of the radical, as it is in the active site of ribonucleotide reductase (Figure 5–12). The radical produced by abstracting a hydrogen adjacent to an amino group is 40 kJ mol^{-1} more stable than the one produced by abstracting a hydrogen from the analogue in which the amino group is replaced by a hydrogen, and the stabilization provided by a sulfanyl group is of the same order of magnitude.

In enzymatic dehydrogenations analogous to that catalyzed by 2-deoxy-*scyllo*-inosamine dehydrogenase (AdoMet-dependent), a 5′-deoxy-5′-adenosyl radical, produced from the adenosyl group by homolytic dissociation of complex **5–111**, abstracts a hydrogen from a carbon bearing a primary hydroxy group,[601] a secondary amino group,[602] or a primary sulfanyl group,[603] each of which can stabilize the resulting radical captodatively. When the reactant is a secondary amine or primary thiol, the product resulting from subsequent removal of the unpaired electron is an imine or thioaldehyde, usually hydrolyzed to a ketone or aldehyde, respectively, to complete the oxidation. In these instances the products are the same as when the hydrogen is abstracted next to a hydroxy group.

Mycofactocin radical SAM maturase from *Mycolicibacterium smegmatis*.[604,605] uses a 5′-deoxy-5′-adenosyl radical produced by homolytic dissociation of complex **5–111** to abstract a hydrogen from the β-carbon of a tyrosine at the carboxyterminus of a short peptide (31aa). In this instance, the unpaired electron in the intermediate radical (**5–121**) is delocalized in a **benzylic π molecular orbital system**

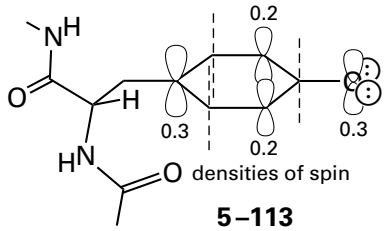


5–122

over its 4-hydroxyphenyl group and stabilized further by a captodative effect of a lone pair of electrons on the 4-hydroxy group.

There is a corollary to the captodative effect in situations in which there is an extended π molecular orbital system, as in the case of mycofactocin radical SAM maturase. When an unpaired electron is delocalized in such a way that there is a **lobe in the highest occupied molecular orbital** of the π molecular orbital system, as identified by resonance structures, on a carbon **next to a heteroatom** with a lone pair of electrons that can exchange with that unpaired electron, the spin density at that carbon will be increased by the interaction, as indicated by placing the unpaired electron at that carbon. This electron exchange increases the stability of the delocalized radical and lowers its potential to abstract a hydrogen from its surroundings, a fact that would be advantagous in a crowded active site. When, however, there is a node in the highest occupied molecular orbital next to a heteroatom, there is no possibility of electron exchange with the unpaired electron.

In the tyrosyl radical

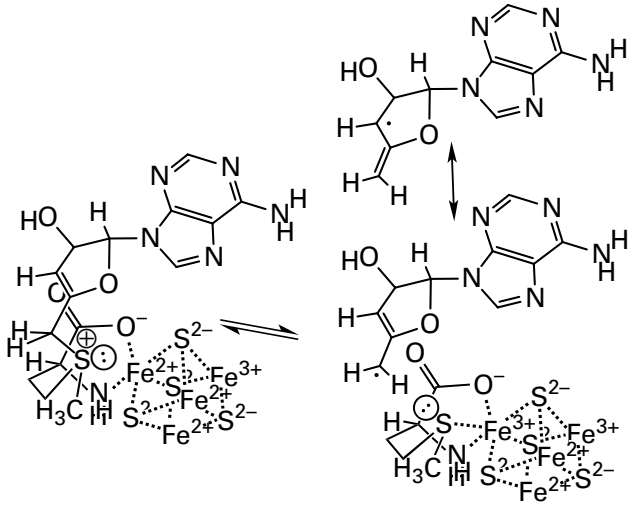


5–113

there is a different type of stabilization. The π molecular orbital system in this radical is also benzylic, and there is a node on the carbon adjacent to the exocyclic oxygen, but there is a lobe on oxygen in the highest occupied molecular orbital system because a hydrogen has been formally abstracted from this oxygen. The increase in spin density in this lobe is not due to the lone pairs of electrons on the oxygen because they are orthogonal to the π molecular orbital system; it is due to the fact that the oxygen, as is the case with a nitrogen, is more electronegative than carbon. The **electronegativity of oxygen increases the spin density** on oxygen.

As has already been discussed, the significant reactivity of the primary radical on carbon 5′ of the 5′-deoxy-5′-adenosyl radical presents a challenge. The active site in an enzyme in the superfamily guards against unfortunate, **unintentional abstractions of hydrogens** in the vicinity that could result from such a reactive primary radical in at least two ways.

First, the 5′-deoxy-5′-adenosyl radical is usually **generated immediately adjacent to the hydrogen that is to be abstracted**. When *S*-3′,4′-anhydroadenosyl-L-methionine is used as a reactant for lysine 2,3-aminomutase from *C. subterminale*, the complex between this analogue of *S*-adenosyl-L-methionine and the catalytic [4Fe–4S] iron–sulfur cluster dissociates in the active site to produce an **allylic analogue** of the 5′-deoxy-5′-adenosyl radical



(5–153)

in which the unpaired electron is delocalized over carbons 3′, 4′, and 5′. This allylic 5′-deoxy-3′,4′-anhydroadenosyl radical is much less reactive (BDE = 370 kJ mol^{-1}) than the primary radical in the 5′-deoxy-5′-adenosyl radical and is unable to abstract a hydrogen efficiently from carbon 3 of L-lysine, the reactant in this enzymatic reaction, when it is formed from *S*-3′,4′-anhydroadenosyl-L-methionine. As a result, the allylic radical accumulates in the active site when the enzyme is in a reaction mixture for the enzymatic reaction, and its absorption in an electron paramagnetic resonance spectrum can be observed and definitively identified.[606]

Electron–nuclear double resonance spectra of L-lysines in which various atoms have been isotopically substituted provide estimates of the distances between a radical on carbon 5′ and both carbons 2 and 3 of L-lysine within the complex between the active site of lysine 2,3-aminomutase from *C. subterminale* and a 5′-deoxy-3′,4′-anhydroadenosyl radical and L-lysine.[438] The measured distance between carbon 5′ of the allylic radical and the hydrogen on carbon 3 of the L-lysines in the respective complexes, the hydrogen that ends up on the product 5′-deoxyadenosine, is 0.2 nm, well within van der Waals contact (0.29 nm). The measured distance between carbon 5′ of the allylic radical and carbon 2 of L-lysine in the complex, the carbon to which the hydrogen is transferred, is 0.3 nm, also within van der Waals contact (0.40 nm). From these measurements, it could be concluded that in the case of the active site of lysine 2,3-aminomutase—and presumably in many, if not most, of the other active sites of enzymes that share this mechanism—the 5′-deoxy-5′-adenosyl radical is generated during turnover of the enzyme at a location so close to the hydrogen it is supposed to abstract that there is no opportunity for it to abstract a hydrogen from any other location in the active site, which it could easily do. This intimacy guarantees the proper outcome for the enzymatic reaction.

Second, if the reactant is not present in the active site of the enzyme when the 5′-deoxy-5′-adenosyl radical is generated, it can add to the catalytic iron ion in the catalytic [4Fe–4S] iron–sulfur cluster to produce a organometallic product with an iron–carbon bond between this iron ion and carbon 5′. This adduct has been observed in electron–nuclear double resonance spectra of intermediates in several of the enzymes in this family.[607] This organometallic complex is analogous to an adenosylcobalamin. It is a way to store the 5′-deoxy-5′-adenosyl radical safely while retaining its reactivity. [4Fe–4S] Iron–sulfur clusters in which one of the iron ions is alkylated with a benzyl group or an *n*-octyl group have been synthesized.[608] The iron–carbon bond in each synthetic complex dissociates readily to give the benzyl radical or the *n*-octyl radical, results that demonstrate the ability of such a complex to preserve the reactivity of the radical. It is also possible that this adenosyliron could be an obligate intermediate in the creation of the 5′-deoxy-5′-adenosyl radical,[607] but this possibility seems unrealistic considering the distance between carbon 5′ and the iron in complex **5–111**.

Most of the intermediate radicals that are formed in the active sites of enzymes that share this mechanism to initiate their reactions are either localized on a carbon adjacent to a heteroatom with a lone pair of electrons that can participate in a captodative effect or are in the highest occupied molecular orbital of a π molecular orbital system that has a lobe or lobes adjacent to one or more heteroatoms with lone pairs of electrons that can participate in a captodative effect. Consequently, it may be the case that these are the intermediate radicals that are produced in the active site simply because they are the **most stable alternatives**. In other words, the 5′-deoxy-5′-adenosyl radical and the subsequent radicals

may be sterically able to abstract more than one hydrogen atom on the reactant in their immediate vicinity, as in the case of lysine 2,3-aminomutase, but the hydrogen each of them abstracts is the one that produces the more stable subsequent radical. If so, this discrimination follows the rule governing the regiochemistry of a nonenzymatic radical chain reaction. It is possible that the particular products of these various enzymatic reactions first appeared adventitiously solely because the intermediates were the most stable before a use was found for those products.

Abstraction of a hydrogen by the 5′-deoxy-5′-adenosyl radical from a substrate usually produces a **radical intermediate of significant lifetime** at the carbon from which it is removed. This longevity was demonstrated by synthesizing an analogue of the substrate for sporulation killing factor maturation protein SkfB from *B. subtilis* in which a cyclopropyl group was added to the carbon from which hydrogen is abstracted. The product of the reaction was not the usual crosslink produced by the enzyme but an ethylmethylene group at that carbon, resulting from the opening of the cyclopropyl ring.[609] This result is consistent with abstraction of a hydrogen from that carbon, producing a radical that has a lifetime long enough (>10 ns) to permit the cyclopropyl ring to open.

Following dissociation of the 5′-deoxy-5′-adenosyl radical from complex **5–111,** the catalytic [4Fe–4S] iron–sulfur cluster in complex **5–110** ends up in the oxidized state, $[(Fe^{2+})_2(Fe^{3+})_2(^{2-}S)_4(^{-}S^{-})_3]^{-}$. Consequently, it is **available to accept an electron** from an intermediate radical in a one-electron oxidation. Most, but not all,[610-612] of the enzymes that share this mechanism, however, also have at least one **auxiliary iron–sulfur cluster** in addition to the catalytic [4Fe–4S] iron–sulfur cluster, so the oxidant in these reactions is often ambiguous. In some instances, an auxiliary cluster may accept the electron from the intermediate radical and transfer it to the oxidized catalytic [4Fe–4S] iron–sulfur cluster of complex **5–110**.

In 2-deoxy-*scyllo*-inosamine dehydrogenase (AdoMet-dependent) (Equation 5–152), there is an auxiliary [4Fe–4S] iron–sulfur cluster in addition to the catalytic [4Fe–4S] iron–sulfur cluster.[613] In a crystallographic molecular model of the enzyme occupied by 2,3-dideoxy-3-oxo-*scyllo*-inosamine, carbon 3, at which the hydrogenation–dehydrogenation occurs (Equation 5–152), is almost equidistant from the two [4Fe–4S] iron–sulfur clusters.[580] The phenyl ring of Phenylalanine 188, however, is almost normal to a line between one of the sulfides in the auxiliary [4Fe–4S] iron–sulfur cluster and carbon 3. A carbon in the phenyl ring is 0.4 nm from carbon 1 of 2,3-dideoxy-3-oxo-*scyllo*-inosamine, and another is 0.5 nm from the sulfide. The phenyl ring could serve as an intermediate relay station for electron transfer from the radical at carbon 1 to the oxidized auxiliary [4Fe–4S] iron–sulfur cluster. The low biochemical reduction potential (–765 mV) of the auxiliary [4Fe–4S] iron–sulfur cluster, however, suggests that it is not a competent oxidant.

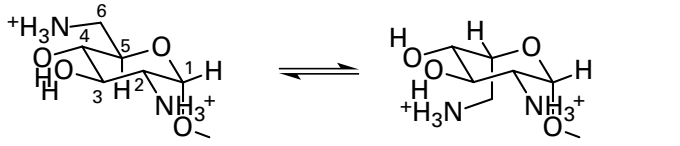
In a crystallographic molecular model of a dehydrogenase from *Streptoalloteichus tenebrarius*, which performs an identical dehydrogenation at carbon 4 of a terminal 2-deoxy-2-amino-D-glucosyl group in an oligosaccharide and which contains only the catalytic [4Fe–4S] iron–sulfur cluster, the 4-hydroxyphenyl group of Tyrosine 216 sits between the catalytic [4Fe–4S] iron–sulfur cluster and carbon 4 of a 2-deoxy-2-amino-D-glucosyl group that occupies the active site and forms a hydrogen bond to the hydroxy group on carbon 3. It has been proposed that this tyrosine transfers the electron from the intermediate radical at carbon 3 of 2-deoxy-*scyllo*-inosamine (see Equation 5–152) to the oxidized catalytic [4Fe–4S] iron–sulfur cluster.[614]

There is also a subfamily of enzymes each of which uses a 5′-deoxy-5′-adenosyl radical generated by the homolytic dissociation of complex **5–111** and each of which contains a **cobalamin**. In the crystallographic molecular model of the complex between *S*-adenosyl-L-methionine and OxsB protein from *Priestia megaterium*,[581] a member of this subfamily, the prosthetic cobalamin in the active site is in contact with the catalytic [4Fe–4S] iron–sulfur cluster, which is the only iron–sulfur cluster in the enzyme, but the cobalt in the cobalamin is too far away (0.75 nm) from carbon 5′ of *S*-adenosyl-L-methionine in complex **5–111** for carbon 5′ to ever become a ligand to the cobalt. In this case, the cobalamin serves the same role as an auxiliary iron–sulfur cluster acting as the acceptor of an electron and then being rereduced.

There are also reactions catalyzed by active sites that share this mechanism in which an **intermediate radical is reduced by accepting an electron** rather than being oxidized by losing an electron. Because the catalytic [4Fe–4S] iron–sulfur cluster is oxidized during the generation of the 5′-deoxy-5′-adenosyl radical, it cannot provide the necessary electron. Consequently, in these cases an auxiliary iron–sulfur cluster in the active site or nearby is usually able to donate the necessary electron and in

turn is rereduced by one of the usual small electron carriers present in the cytoplasm. This auxiliary iron–sulfur cluster can also be involved in reduction of the oxidized catalytic [4Fe–4S] iron–sulfur cluster in complex **5–110**.

In the **epimerization** catalyzed by neomycin C epimerase from *Streptomyces fradiae*



+ *S*-adenosyl-L-methionine + H^+ + 2 e^- ⇌ + 5′-deoxyadenosine + L-methionine

(5–154)

the 5′-deoxy-5′-adenosyl radical abstracts the hydrogen from carbon 5 of the 2,6-diamino-2,6-dideoxy-D-glucosyl group to produce a planar tertiary radical, stabilized by a lone pair on the adjacent oxygen. The tertiary radical, on its opposite face, then abstracts a hydrogen from the sulfanyl group of Cysteine 249 to achieve the epimerization. A signal from the intermediate tertiary radical has been observed in the electron paramagnetic resonance spectrum of the enzyme in which Cysteine 249 has been mutated to alanine when the mutant is mixed with reactant. This result is consistent with this cysteine being the source of the hydrogen abstracted by the initial radical. The resulting sulfenyl radical at Cysteine 249 and the oxidized catalytic [4Fe–4S] iron–sulfur cluster in complex **5–110** are then reduced back to the sulfanyl group and the reduced catalytic [4Fe–4S] iron–sulfur cluster by respective one-electron transfers from an auxiliary [4Fe–4S] iron–sulfur cluster within the active site.[597] These transfers provide in turn the two electrons needed for the overall reaction. The auxiliary [4Fe–4S] iron–sulfur cluster is reduced in two one-electron steps by small electron carriers in the cytoplasm. The two electrons are required because the S-adenosyl-L-methionine becomes 5′-deoxyadenosine and L-methionine. An epimerase in an uncharacterized bacterial symbiont in the sponge *Theonella swinhoei* uses the same mechanism to epimerize L-valine to D-valine in a peptide that is a precursor to polytheonamide A.[615]

The rather remarkable diversity (Figure 5–14) of the reactions catalyzed within the family of enzymes that initiate their respective reactions by homolytic dissociation of complex 5–111 illustrates the variety of homolytic transformations that active sites are able to perform and the control over regiochemistry they are able to exert. This regiospecificity, in particular, is a further demonstration of the steric control possible in an active site, reminiscent of the stereochemical control in the terpene cyclases.

Mycofactocin radical SAM maturase (Figure 5–14A) abstracts a hydrogen from a tyrosine at the carboxy terminus of mycofactocin precursor peptide during the synthesis of mycofactocin.[604,605] The resulting intermediate 4-hydroxybenzylic radical (**5–122**) is then oxidized by the transfer of an electron to one of the three [4Fe–4S] iron–sulfur clusters in the enzyme to produce the intermediate 1-carboxymethylene-2,5-cyclohexadien-4-one, which is a ketone at carbon 4 of the former 4-hydroxyphenyl group. This intermediate, which is a vinylogous β-oxo acid, then decarboxylates.

In biotin synthase

sulfur–(sulfur carrier) + 2 reduced [2Fe–2S] ferredoxin + dethiobiotin + 2 *S*-adenosyl-L-methionine ⇌ biotin + 2 L-methionine + 2 5′-deoxyadenosine + 2 oxidized [2Fe–2S] ferredoxin + (sulfur carrier)

(5–155)

which is a **sulfurtransferase**, two *S*-adenosyl-L-methionines are reactants, and they are converted in succession to two 5′-deoxyadenosines and two L-methionines that leave the active site as products during each turnover.[590] In the active site of biotin synthase, there is a single catalytic [4Fe–4S] iron–sulfur cluster that generates these two 5′-deoxy-5′-adenosyl radicals in succession by consecutive homolytic dissociations of complex **5–111**. The two reduced [2Fe–2S] ferredoxins that are reactants for the enzyme each provide an electron that is needed to rereduce complex **5–110** after each of the two rounds of hydrogen abstraction. An auxiliary [2Fe–2S] iron–sulfur cluster, which does not act as a donor or acceptor of an electron from an intermediate radical, is the source of the necessary sulfide ion.

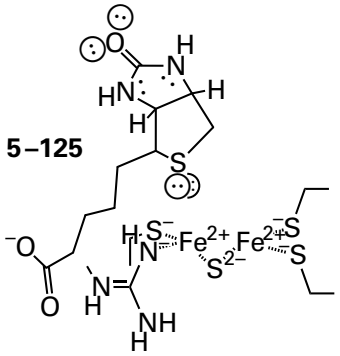
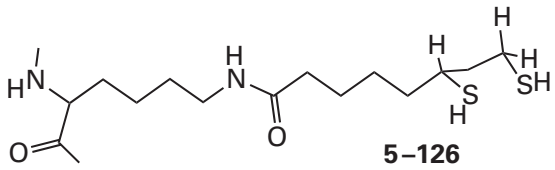
The first 5′-deoxy-5′-adenosyl radical generated in the active site of biotin synthase by homolytic dissociation of complex **5–111**[616] abstracts a hydrogen from carbon 9 of dethiobiotin (Figure 5–14B),[590,617] and the resulting dethiobiotin radical **5–123** then **inserts into a sulfide** in the auxiliary [2Fe–2S] iron–sulfur cluster[616,618,619] that is immediately adjacent to it.[612] The conjugate base of the 9-sulfanyldethiobiotin (**5–124**) that is formed as an intermediate in this first half of the overall reaction remains as a ligand through its sulfur to one or both of the iron ions in the auxiliary [2Fe–2S] iron–sulfur cluster, and an absorption in an electron paramagnetic resonance spectrum has been assigned to this complex on the basis of changes that occur on isotopic substitutions.[620] 9-Sulfanyldethiobiotin has been isolated from a reaction mixture containing biotin synthase from *E. coli* and identified chemically.[621] In the second half of the overall reaction, a second 5′-deoxy-5′-adenosyl radical, produced in the same way at the same catalytic [4Fe–4S] iron–sulfur cluster, abstracts a hydrogen from carbon 6 of the intermediate 9-sulfanyldethiobiotin, and the resulting radical inserts into the same sulfur, in a sequence of steps similar to the first, to produce biotin



That each hydrogen is abstracted by the respective 5′-deoxy-5′-adenosyl radical follows from the fact that deuterium on carbon 9 and tritium on carbon 6 of dethiobiotin end up in 5′-deoxyadenosine produced in the reaction catalyzed by biotin synthase from *E. coli*.[590] The auxiliary [2Fe–2S] iron–sulfur cluster is reassembled after each turnover by an assembly system that uses a sulfur atom on a sulfur-carrier protein, which becomes a sulfide in the reassembled auxiliary cluster.

Lipoyl synthase also catalyzes two successive radical additions to sulfides. The first 5′-deoxy-5′-adenosyl radical generated in the active site of lipoyl synthase by homolytic dissociation of complex **5–111** abstracts a hydrogen from carbon 6 of an octanoyl group in an amide with the 6-amino group of a lysine in a protein that is a substrate for the enzyme. The resulting secondary alkyl radical at carbon 6 then inserts into a sulfide in an auxiliary [4Fe–4S] iron–sulfur cluster that is immediately adjacent to it. The sulfide becomes a sulfido group on carbon 6 of the octanoyl group. In a crystallographic molecular model between a peptide containing this 6-sulfidooctanoyl group and lipoyl synthase from *E. coli*,[622] the **sulfido group remains a ligand to three iron ions** in the auxiliary [4Fe–4S] iron–sulfur cluster.[623] In a second round, a second 5′-deoxy-5′-adenosyl radical generated in the active site by homolytic dissociation of a subsequent complex **5–111** at the same catalytic [4Fe–4S] iron–sulfur cluster abstracts a hydrogen from carbon 8 of the 6-sulfanyloctanoyl group. The resulting primary radical inserts into a sulfide across the face of the auxiliary [4Fe–4S] iron–sulfur cluster in which the first sulfide was located to form a sulfido group on carbon 8. The N^6-(dihydrolipoyl)lysine

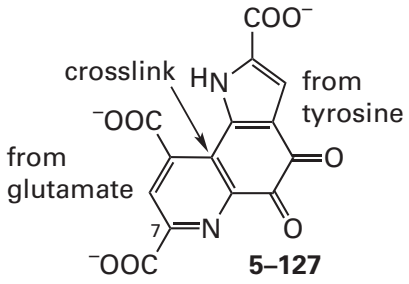


in the peptide or protein that is a substrate for the enzyme then dissociates from the auxiliary [4Fe–4S] iron–sulfur cluster as the nominal product of the reaction, leaving two vacancies where the two sulfides once were. The auxiliary [4Fe–4S] iron–sulfur cluster has to be regenerated before the next turnover can occur.

In addition to the dehydrogenases, the epimerases, and sulfurtransferases that have already been discussed, there are enzymes that use 5′-deoxy-5′-adenosyl radicals generated by homolytic dissociation of complexes **5–111** to initiate numerous posttranslational crosslinkings within peptides; alkylations and methylations of purines; alkylations and methylations by radical additions; and oxidative decarboxylations. There are also lyases that use L-tyrosine and L-tryptophan as substrates. These disparate outcomes result from an initial abstraction of a hydrogen by a 5′-deoxy-5′-adenosyl radical. Nevertheless, it seems again as if the various outcomes may well have been adventitious because the products of many of these enzymatic reactions are of only isolated utility, unlike the product of lipoyl synthase, which is present in all organisms,

and the product of biotin synthase, which is present in bacteria and plants.

There are a number of **posttranslational crosslinks** that enzymes from prokaryotes perform on short peptides to produce natural products by using a 5′-deoxy-5′-adenosyl radical generated by homolytic dissociation of complex **5–111**.[604,624-631] For example, PqqA peptide cyclase from *Methylorubrum extorquens* catalyzes formation of a crosslink between Glutamate 16 and Tyrosine 20 (Figure 5–14C) in PqqA, a peptide 29 amino acids long, as the first step in the biosynthesis of pyrroloquinoline quinone (**5–127**)[632]



5–127

In the mechanism of this enzyme, an intermediate radical is formed by **radical aromatic addition** of the initial intermediate radical at the γcarbon of Glutamate 16 to carbon 3 of the 4-hydroxyphenyl group of Tyrosine 20. The unpaired electron in the resulting intermediate radical in the radical aromatic addition is delocalized over five carbons of the former 4-hydroxyphenyl group in the highest occupied molecular orbital of a pentadienyl πmolecular orbital system that has a lobe adjacent to the original 4-hydroxy group. This delocalized intermediate radical is oxidized by one electron, which is removed either by the oxidized catalytic [4Fe–4S] iron–sulfur cluster or one of the two auxiliary iron–sulfur clusters, a [4Fe–4S] iron–sulfur cluster and a [2Fe–2S] iron–sulfur cluster,[632] also in the enzyme. Following removal of a hydron from the resulting cyclopentadienyl carbenium ion or removal of a hydron during the transfer of the electron, the crosslinked product is formed.

A homologous (20% identity; 1.4 gap percent)[632] enzyme from streptococci, KxxxW cyclic peptide radical SAM maturase, forms a similar crosslink between Lysine 15 and Tryptophan 19 in a peptide 29 amino acids long by an analogous mechanism as the first step in the biosynthesis of streptide, a cyclic peptide secreted by the bacteria. Addition of the initial intermediate radical, located on the β-carbon of Lysine 15, to carbon 7 of Tryptophan 19 also produces an intermediate radical with an unpaired electron delocalized in the highest occupied molecular orbital of a pentadienyl πmolecular orbital system that has a lobe adjacent to the nitrogen of the indolyl group. The fact that enzymatic activity is lost when one of the two auxiliary [4Fe-4S] iron–sulfur clusters in this enzyme,[633] the one homologous to the lone auxiliary [4Fe–4S] iron–sulfur cluster in PqqA peptide cyclase, is removed by site-directed mutation suggests that this auxiliary [4Fe–4S] iron–sulfur cluster is the one-electron oxidant of this delocalized radical[627] rather than the catalytic [4Fe–4S] iron–sulfur cluster.

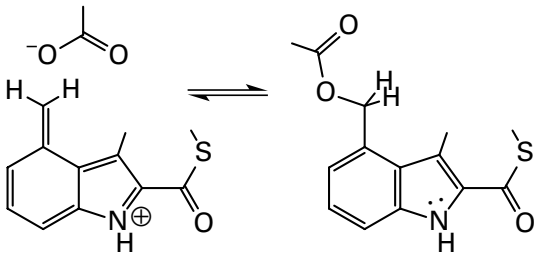
GTP 3′,8-Cyclase from *S. aureus* catalyzes the intramolecular **radical addition** of carbon 3′ in the ribosyl group of GTP^{4-} to carbon 8 of GTP^{4-} (Figure 5–14D). The 5′-deoxy-5′-adenosyl radical generated in the active site abstracts the hydrogen from carbon 3′ and the resulting initial radical, adjacent to the 3′-hydroxy group, adds to carbon 8 to produce an intermediate radical with an unpaired electron delocalized in the highest occupied molecular orbital of an allyl πmolecular orbital system that has a lobe adjacent to nitrogen 3 of the former guanine. Oxidation of this intermediate radical by one-electron transfer and the loss of a hydron produces tetracyclic product **5–128**. There is an auxiliary [4Fe–4S] iron–sulfur cluster in the active site, and it has been shown by electron paramagnetic resonance spectroscopy[634] and crystallography[635] that the *N*-acylguanidino group of the guanine associates with this cluster in a coordination with nitrogen 1 and its 2-amino group as ligands to an iron ion. Because the electron to be transferred in the one-electron oxidation is in the guanine, this auxiliary [4Fe–4S] iron–sulfur cluster may be the acceptor in this oxidation. The tetracyclic product **5–128** of these steps in the enzymatic reaction is actually an intermediate in the overall reaction, which produces pyranopterin monophosphate, a precusor to molybdopterin, so this enzyme is found in all organisms. Tetracyclic intermediate **5–128** has been isolated and identified by mass spectrometry from reaction mixtures of enzyme and substrates.[636]

So far, in the various reactions in which 5′-deoxy-5′-adenosyl radicals produced by homolytic dissociation of complex **5–111**, 5′-deoxy-adenosine and L-methionine are products of the overall reaction. In the condensation catalyzed by viperin, an enzyme in animals that has antiviral activity, 5′-deoxy-adenosine is incorporated into one of the products. The 5′-deoxy-5′-adenosyl radical produced in the active site, instead of abstracting a hydrogen to give a radical of one of the reactants which then adds to

an unsaturated carbon, adds directly to the peripheral carbon in the carbon–carbon bond of isopentenyl diphosphate to give a tertiary radical at the distal carbon. The tertiary radical is then reduced by an electron and a hydron to give the unsaturated alkane. The product of the condensation is 5′-deoxy-5′-(4-diphospho-2-methylbutyl)adenosine.[637]

A number of enzymes that share this common mechanism catalyze **methylations**. The methyl group is usually derived from a second molecule of *S*-adenosyl-L-methionine, either directly or indirectly. For example, thiazole methyltransferase (Figure 5–14E) **uses the second *S*-adenosyl-L-methionine directly** as the source of the methyl group. The 5′-deoxy-5′-adenosyl radical initially abstracts a hydrogen from the methyl group of the second *S*-adenosyl-L-methionine, and the resulting *S*-methylene radical **5–129**, captodatively stabilized by a lone pair of electrons on the sulfonium sulfur, participates in a radical aromatic addition at carbon 5 of a thiazolyl group. This radical aromatic addition produces an intermediate radical with an unpaired electron delocalized over the highest occupied molecular orbital of an allyl π molecular orbital system that has a lobe adjacent to the sulfur of the thiazolyl group and a node on the nitrogen of the thiazolyl group. Elimination of an acidic hydron and L-methionine, which is an excellent leaving group, from the sulfonium ion, leads to an even more stable intermediate, radical **5–130**, in which the unpaired electron is in the highest occupied molecular orbital of a pentadienyl π molecular orbital system. Radical **5–130** is reduced by one electron, concerted with the transfer of a hydron to the distal carbon of its exocyclic carbon–carbon bond. The product of this reduction and hydronation is the methylated thiazolyl group. It has been shown, by using deuterated reactants and the enzyme from *Thermobispora bispora*, that the hydrogen abstracted from the methyl group of the second *S*-adenosyl-L-methionine ends up on 5′-deoxyadenosine and the hydrogen on carbon 5 of the thiazolyl group ends up on the final methyl group (Figure 5–14E).[592]

An enzyme in *Streptomyces actuosus* transfers a methylene radical from the same initial *S*-methylene radical **5–129** of *S*-adenosyl-L-methionine[595] to carbon 4 of an indolyl group by radical aromatic addition to produce an intermediate radical with an exocyclic double bond, analogous to intermediate radical **5–130**. Transfer of the methylene occurs through an intermediate formed by addition of *S*-methylene radical **5–129** to carbon 4 of the indolyl group to form a chemically identified adduct in which the methylene group bridges the indolyl and *S*-adenosylhomocysteinyl groups.[638] The adduct then undergoes heterolytic elimination of the hydrogen that was on carbon 4 as a hydron and *S*-adenosyl-L-homocysteine, again an excellent leaving group from the sulfonium that is the adduct, to produce the 4-methyleneindolyl radical. This intermediate radical is oxidized by the transfer of one electron, and the resulting **electrophilic exocyclic carbon on the 4-methylene group,** on the antiaromatic 4-methyleneindole, then reacts with a nucleophilic carboxylato group to give the aromatic adduct



(5–156)

23S rRNA (Adenine^{2503}-C^2)-methyltransferase (Figure 5–14F) from *E. coli* uses the other *S*-adenosyl-L-methionine **indirectly as the source of the methyl group** in the methylation that it catalyzes. Cysteine 355 in the active site is methylated[611] by an *S*-adenosyl-L-methionine in complex **5–111** with the catalytic [4Fe–4S] iron–sulfur cluster. This initial methylation of the cysteine is an example of complex **5–111** dissociating at the methyl group rather than at the 5′-deoxyadenosyl group. The resulting *S*-adenosyl-L-homocysteine dissociates from complex with the catalytic [4Fe–4S] iron–sulfur cluster and is replaced by a second *S*-adenosyl-L-methionine. The resulting second complex **5–111**,[639] dissociates homolytically at the 5′-deoxy-5′-adenosyl group to give the 5′-deoxy-5′-adenosyl radical necessary to abstract a hydrogen from the methyl group on Cysteine 355. The enzyme contains only this one iron–sulfur cluster,[640] so it is required to do double duty.

The intermediate *S*-methylene radical on Cysteine 355 then participates in a radical addition to carbon 2 of Adenine 2503 in 23S rRNA to form intermediate radical **5–131** with an unpaired electron delocalized in the highest occupied molecular orbital of a 3-vinylpentadienyl π molecular orbital system that has lobes over nitrogens 1 and 3 of adenine that stabilize the radical by their electronegativity. Intermediate radical **5–131** within the active site of the native enzyme has been observed by electron

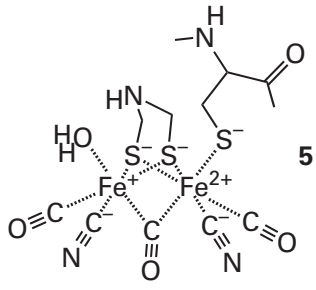
paramagnetic resonance spectroscopy.[641] This radical has also been observed crystallographically[640] and by electron paramagnetic resonance spectroscopy[642] in the active site of a mutant of the enzyme in which Cysteine 118, the base that removes the hydron from carbon 2 during its oxidation, has been mutated to alanine. These latter observations suggest that removal **of the hydron must be concerted with the one-electron oxidation**. Intermediate radical **5–131** is then oxidized by the transfer of one electron—concerted with removal of a hydron—to the oxidized catalytic [4Fe–4S] iron–sulfur cluster in complex **5–110**, which is the only iron–sulfur cluster in the enzyme,[611] to produce covalent intermediate **5–132**. A peptide containing covalent intermediate **5–132** was isolated from a tryptic digest of the same mutant, and its structure was defined by collision-induced dissociation in a mass spectrometer.[643]

The sulfido group of Cysteine 105 then participates[641] in a nucleophilic substitution at the sulfur of Cysteine 355 that produces a cystine and a non-covalent intermediate in which the adenine has gained an exocyclic methylene group. The carbon of this methylene group is in an enamine and can be easily hydronated. Results from reactions with deuterated substrates are consistent with the conclusion that the exocyclic methylene group is deuteronated by the same deuteron that was removed from carbon 2 of intermediate radical **5–131**. The product of the reaction[591] is 2-methyladenine[2503].

In the active site of an enzyme in *Cystobacter* that methylates the methyl group in a 3-methoxy group on a 4-aminobenzoyl thioester, the methyl group is transferred from the other *S*-adenosyl-L-methionine to a cob(I)alamin rather than the sulfido group of a cysteine.[644] Cob(I)alamin is the nucleophile in the usual concerted nucleophilic substitution that forms methylcob(III)alamin rather than adenosylcob(III)alamin. Methylcob(III)alamin then provides the equivalent of a methyl radical that colligates with a methylene radical on the methoxy group formed by abstraction of a hydrogen from the methyl group by the 5′-deoxy-5′-adenosyl radical to produce a carboxyethyl group. The resulting cob(II)alamin is eventually reduced by one electron to regenerate cob(I)alamin.

The 5′-deoxy-5′-adenosyl radical generated by homolytic dissociation of complex **5–111** in the active site of tRNA 4-demethylwyosine synthase (AdoMet-dependent) from *M. jannaschii* (Figure 5–14G) abstracts a hydrogen atom from the methyl group of 1-methylguanine[594] at position 37 in transfer RNA^{Phe}. This intermediate radical adjacent to nitrogen 1 of guanine then adds to carbon 2 of an imine of pyruvate, which spectroscopic studies indicate is a bidentate ligand to a open iron ion on an auxiliary [4Fe–4S] iron–sulfur cluster,[645,646] to give the intermediate radical on the iminium nitrogen. One-electron oxidation of this intermediate radical, coupled to its decarboxylation, produces the imine of 1-(acetylmethyl)guanine, a precusor to 4-demethylwyosine. Consistent with this mechanism, it has been shown that all the hydrogens on the methyl group of pyruvate remain on the methyl group in the product.[594] The extreme exclusivity of 23S rRNA (adenine^{2503}-C^2)-methyltransferase and tRNA 4-demethylwyosine synthase (AdoMet-dependent) are examples of the boutique character of many of the reactions catalyzed by enzymes in this family.

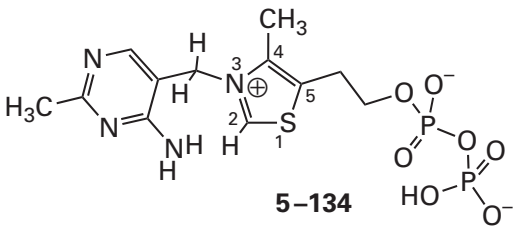
Several **lyases of L-tryptophan and L-tyrosine** use a 5′-deoxy-5′-adenosyl radical generated by homolytic dissociation of complex **5–111** to rearrange or decompose these amino acids and in the process provide unusual products for particular purposes. For example, 3-methyl-2-indolic acid synthase (Figure 5–14H) **decomposes the entire aminocarboxymethyl group** of L-tryptophan while transferring the carboxy group to carbon 2 of the indolyl group to produce 3-methyl-2-indolic acid, which is incorporated into the antibiotic nosiheptide. (FeFe) hydrogenase maturation factor HydG (Figure 5–14I) decomposes the entire aminocarboxymethyl group of L-tyrosine, turning it into carbon monoxide[647] and hydrogen cyanide,[648] which are then incorporated into the prosthetic iron cluster (previously **2–137**)



5–133

of ferredoxin hydrogenase.[649] These decompositions are reminiscent of the decomposition of the aminocarboxymethyl group of the serine that replaces Cysteine 225 (homologous to Cysteine 218 in the enzyme from *S. cerevisiae*; Figure 5–13) in a mutant of ribonucleoside-diphosphate reductase from *E. coli* when it is mixed with a nucleoside diphosphate.[650] In this instance, it is assumed that a radical is formed on the serine that then decomposes.

2-Iminoacetate synthase (Figure 5–14J), however, simply dissociates the aminocarboxymethyl group of L-tyrosine and converts it into 2-iminoacetate,[651] the useful product of the reaction, which becomes carbon 2 and nitrogen 3 of thiamine diphosphate



5–134

The 5′-deoxy-5′-adenosyl radical generated in the active site of 3-methyl-2-indolic acid synthase from *S. actuosus* initiates the reaction (Figure 5–14H) by abstracting a hydrogen from the α-amino group of L-tryptophan. This conclusion follows from several facts. First, a hydrogen abstracted and ending up in the 5′-deoxyadenosine that is the product of the enzymatic oxidation is on a heteroatom in L-tryptophan that exchanges with deuterons when ^2H_2O is used as the solvent.[652] Second, when analogues of L-tryptophan in which the only exchangeable hydrogens are on the α-amino nitrogen are used in the enzymatic oxidation, deuterons from solvent are again incorporated into 5′-deoxyadenosine.[653-655] Third, a hydrogen on the amino group of L-tryptophan is only 0.33 nm from carbon 5′ of 5′-deoxyadenosine in a crystallographic molecular model of the active site occupied by this reactant and this product of the enzymatic oxidation.[610]

In the next step, a **carboxy radical** dissociates from the α carbon and adds to carbon 2 of the indolyl group.[656] This conclusion follows in part from the fact that the carbon of the α-carboxy group of L-tryptophan in the crystallographic molecular model is only 0.34 nm from carbon 2 of the indolyl group. The result of this radical aromatic addition is radical **5–135**, an intermediate radical with an unpaired electron delocalized in the highest occupied molecular orbital of a heptatrienyl π molecular orbital system that has a lobe adjacent to the nitrogen of the former indolyl group. An absorption in the electron paramagnetic resonance spectrum taken while the enzyme was catalyzing its reaction has been identified as radical **5–135** on the basis of both its pattern of splitting and changes in its shape when various atoms in the L-tryptophan used as a reactant were replaced with deuterium, nitrogen 15, and carbon 13, respectively.[657] In radical **5–135**, the aminocarboxymethyl group of L-tryptophan has become an imine, a conclusion consistent with the fact that when L-tryptophan thiocarboxylate is used as a reactant, the product of the enzymatic reaction is (1*H*-indol-3-yl)-3-propanal. This aldehyde is the product expected if the thiocarboxy radical that dissociates from the initial intermediate radical, which results from the abstraction of a hydrogen from the α-amino group of the L-tryptophan thiocarboxylate, is too weak or decomposes too rapidly to participate in intramolecular radical aromatic addition to carbon 2. In this case, the reaction goes no further than the production of 3-(2-iminoethyl)-indole (**5–136**), which dissociates from the active site and hydrolyzes to (1*H*-indol-3-yl)-3-propanal.[655]

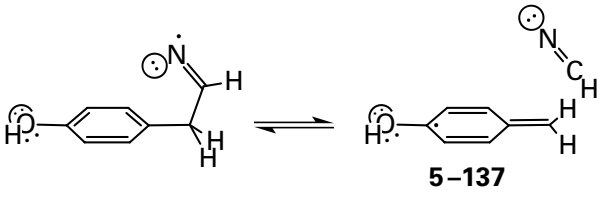
In the normal reaction, radical **5–135** is then oxidized by one electron. Since the enzyme contains only the catalytic iron–sulfur cluster complex **5–110**,[610] it must be the one-electron oxidant in this step. The penultimate step is dissociation of an electrophile, dihydrogen cyanide, from the vinylogous iminium ion. In the crystallographic molecular model of the active site occupied by L-tryptophan, the carbon–carbon bond between the α and β carbons, which will be the bond broken in this penultimate step, is parallel to the π molecular orbital system of the indolyl group in the active site,[610] as it should be. The final step is a tautomerization initiated by removal of a hydron from an acidic carbon α to a carboxy group.

Both (FeFe) hydrogenase maturation factor HydG (Figure 5–14I) from *C. acetobutylicum* (21% identity; 3 gap percent) and 2-iminoacetate synthase (Figure 5–14J) from *E. coli* (22% identity; 3.4 gap percent) are homologues of 3-methyl-2-indolic acid synthase from *S. actuosus*, and both are even closer homologues (27% identity; 1.9 gap percent) of each other. One product of the reaction catalyzed by (FeFe) hydrogenase maturation factor HydG is hydrogen cyanide, which is also a product of 3-methyl-2-indolic acid synthase.[658] The 5′-deoxy-5′-adenosyl radical generated by homolytic dissociation of complex **5–111** in the active site of this latter enzyme initiates its reaction by abstracting a hydrogen atom from the amino group of L-tyrosine.[659] These facts imply that the mechanisms of these three enzymes should be similar and that each amino acid that is a reactant is positioned in the respective active site in the same orientation.

Because the product in each case[651] is 4-methylphenol—unlike the reaction catalyzed by 3-methyl-2-indolic acid synthase, which is electron neutral (Figure 5–14H)—the reactions catalyzed by (FeFe) hydrogenase maturation factor HydG and 2-iminoacetate synthase each require two electrons from

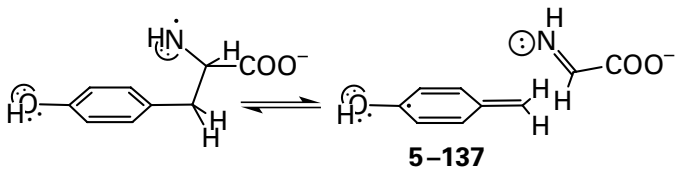
small electron carriers. An absorption in the electron paramagnetic resonance spectrum taken while (FeFe) hydrogenase maturation factor HydG was catalyzing its reaction[660] has been identified as the **radical of 4-methylphenol** (**5–137**; Figure 5–14I) on the basis of both its pattern of splitting and changes in its shape when 3-hydroxy-L-phenylalanine replaces L-tyrosine. This radical of 4-methylphenol is an intermediate radical with an unpaired electron delocalized in the highest occupied molecular orbital of a benzyl π molecular orbital system that has a lobe adjacent to the oxygen of the hydroxy group (**5–122**). Consequently, one of the two electrons required by the reaction catalyzed by this enzyme reduces the radical of 4-methylphenol and the other rereduces the catalytic [4Fe–4S] iron–sulfur cluster. (FeFe) Hydrogenase maturation factor HydG from *C. acetobutylicum* has an auxiliary [4Fe–4S] iron–sulfur cluster that may be able to shuttle these two electrons to these intermediates.[661] 2-Iminoacetate synthase from *E. coli*, however, does not have the same auxiliary [4Fe–4S] iron–sulfur cluster. Nevertheless, two reduced flavodoxins are able to provide the required two electrons, one at a time, to this latter enzyme,[662] presumably through the catalytic [4Fe–4S] iron–sulfur cluster.

There seems to be no reasonable heterolytic way to break the bond between the α and β carbons of the L-tyrosine that is a substrate in these two tyrosine lyases as there was in the reaction catalyzed by the tryptophan lyase, 3-methyl-2-indolic acid synthase. There are, however, homolytic possibilities. For (FeFe) hydrogenase maturation factor HydG, the homolytic dissociation



(5–157)

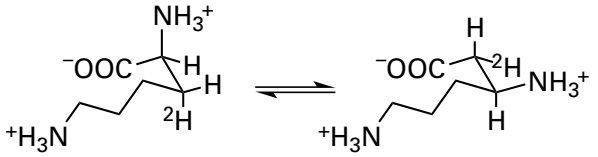
would break the carbon–carbon bond and give both the observed radical of 4-methylphenol and hydrogen cyanide, one product of the reaction. The initial radical in this enzymatic reaction is formed by abstraction of a hydrogen from a heteroatom, presumably—by analogy with the reaction catalyzed by 3-methyl-2-indolic acid synthase—a hydrogen on the α-amino group of the L-tyrosine that is a reactant, because a deuterium is abstracted by the 5′-deoxy-5′-adenosyl radical when the reaction is run in ^2H_2O.[659] Following formation of this initial radical, nothing is known about the later steps, but an intermediate radical formed in the reaction could easily abstract a hydrogen from the nitrogen (BDE = 360 kJ mol^{-1}) of 4-(2-iminoethyl)phenol, the homologue of 3-(2-iminoethyl)indole (**5–136**), to give its radical. For 2-iminoacetate synthase, the homolytic dissociation



(5–158)

would break the carbon–carbon bond and give both the radical of 4-methylphenol and 2-iminoacetate, one product of the reaction.

Lysine 2,3-aminomutase uses a 5′-deoxy-5′-adenosyl radical produced by homolytic dissociation of complex **5–111** to initiate a **migration**[663]



(5–159)

homologous to those performed by mutases

(5–160)

that use a 5′-deoxy-5′-adenosyl radical produced by homolytic dissociation of a prosthetic adenosylcobalamin. In the reaction catalyzed by lysine 2,3-aminomutase, X is the external pyridoximine of the L-lysine, the reactant, and the external pyridoximine of the (3*S*)-3,6-diaminohexanoate, the product, just as in the reaction catalyzed by the active site of β-lysine 5,6-aminomutase (Table 2–3), in which there is a prosthetic adenosylcobalamin.

The difference between lysine 2,3-aminomutase and the other enzymes that use a 5′-deoxy-5′-adenosyl radical produced by homolytic dissociation of complex **5–111** and that have been discussed so far is that ***S*-adenosyl-L-methionine is not a reactant** in the overall reaction, nor are L-methionine and 5′-deoxyadenosine products. Undissociated complex **5–111** is a prosthetic group covalently

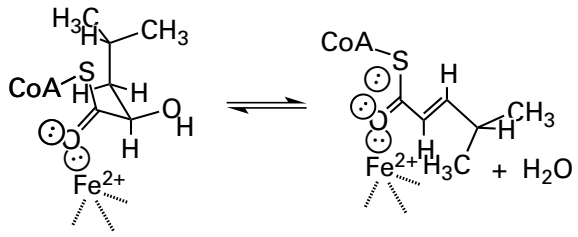
bound to the active site through three cysteines, and it is re-formed by reassociation of the 5′-deoxy-5′-adenosyl radical that is regenerated during every turnover by the reverse of Equation 5–138 with the methionyl [4Fe–4S] iron–sulfur cluster, just as adenosylcobalamin is re-formed after each turnover by reassociation of the 5′-deoxy-5′-adenosyl radical that is regenerated during every turnover with cob(II)alamin. Nevertheless, *S*-adenosyl-L-methionine must be present in the solution for efficient enzymatic turnover to occur,[664] presumably because it is not bound to the active site tightly enough and slowly dissociates from complex **5–111**.

The 5′-deoxy-5′-adenosyl radical produced in the active site of lysine 2,3-aminomutase abstracts a hydrogen from carbon 2 of the reactant (3*S*)-3,6-diaminohexanoate to produce the radical at that location. The external pyridoximine of the amino group at carbon 3 of the radical[665] migrates to the site of the radical at carbon 2, leaving behind a radical at carbon 3, which then abstracts a hydrogen from 5′-deoxyadenosine to regenerate the 5′-deoxy-5′-adenosyl radical, which reassociates with complex **5–110** to re-form complex **5–111**. The absorption of the former intermediate, the radical of (3*S*)-3,6-diaminohexanoate at carbon 2, has been observed in an electron paramagnetic resonance spectrum of a reaction mixture,[666] and isotopic substitutions identify it as the source of the absorption.[667] This radical was shown to be kinetically competent to be an intermediate in the enzymatic reaction.[668] The absorption of the latter radical, the one at carbon 3, has been observed in an electron paramagnetic resonance spectrum of a reaction mixture of the enzyme and either the alternative reactant 4-thialysine, the sulfur of which stabilizes the radical at carbon 3,[669] or the alternative reactant *trans*-4,5-dehydro-L-lysine,[670] which gives an allylic radical at carbons 3, 4, and 5. There is a nonenzymatic radical reaction, initiated by forming a radical on a carbon immediately adjacent to a carbon the amino group of which is in a benzylimine, that mimics the migration of the external pyridoximine of the amino group of either L-lysine or (3*S*)-3,6-diaminohexanoate between the two adjacent carbons.[671]

Propanediol dehydratase from *Klebsiella oxytoca*, unlike a propanediol dehydratase that requires adenosylcobalamin as a prosthetic group (Table 2–3), uses a 5′-deoxy-5′-adenosyl radical produced by homolytic dissociation of complex **5–111**. As in the case of lysine 2,3-aminomutase, *S*-adenosyl-L-methionine is not a reactant in the overall reaction, nor are L-methionine and 5′-deoxyadenosine products. Unlike the reaction catalyzed by lysine 2,3-aminomutase, however, the reaction catalyzed by propanediol dehydratase from *K. oxytoca* does not involve a migration because when the hydroxy group on carbon 2 is labeled with oxygen-18, none of the oxygen-18 ends up in the product.[672]

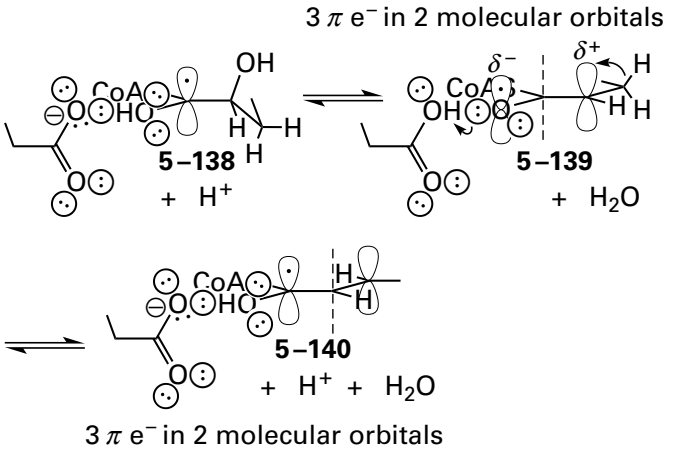
Spore photoproduct lyase, as does lysine 2,3-aminomutase, uses a 5′-deoxy-5′-adenosyl radical produced by homolytic dissociation of complex **5–111**; but when the enzyme is turning over at limiting rate, the 5′-deoxy-5′-adenosyl radical is regenerated at the end of each turnover[673] rather than complex **5–111**. Complex **5–110**, however, is present in the active site, presumably to capture the 5′-deoxy-5′-adenosyl radical when turnover is not proceeding at a rapid enough pace. As with lysine 2,3-aminomutase, even though *S*-adenosyl-L-methionine is not a reactant in the overall reaction, it must be present in the solution.

There are several enzymes that use a [4Fe–4S] iron–sulfur cluster alone to produce a radical or a carbanion on a substrate. For example, there is a [4Fe–4S] iron–sulfur cluster in the active site of (*R*)-2-hydroxyisocaproyl-CoA dehydratase



(5–161)

from *C. difficile*.[674] In this elimination, the hydrogen involved is not on a carbon α to either a carbonyl or an acyl group, so it cannot be removed as a hydron before the hydroxy group leaves; and the hydroxy group cannot leave first because it is α to the electropositive carbon of a thioacyl group. Natural selection has solved these problems by performing the reaction homolytically. The only iron ion in the [4Fe–4S] iron–sulfur cluster that lacks a cysteine as a ligand associates with the acyl oxygen of the substrate.[674] The reduced [4Fe–4S] iron–sulfur cluster then donates an electron to the acyl group while the acyl oxygen is hydronated by Glutamic Acid 55 to produce a radical on carbon 1 (**5–138**)



(5–162)

The electron that is donated to produce radical **5–138** has to be one of quite low biochemical reduction potential (<–600 mV), and there is another protein, (*R*)-2-hydroxyisocaproyl-CoA dehydratase activator, that provides this **electron of low potential** to the catalytic [4Fe–4S] iron–sulfur cluster. Remarkably, it is structurally unrelated but functionally related to dinitrogenase reductase.[675] As with dinitrogenase reductase, (*R*)-2-hydroxyisocaproyl-CoA dehydratase activator is a homodimer with only one [4Fe–4S] iron–sulfur cluster, and it lowers dramatically the reduction potential of this [4Fe–4S] iron–sulfur cluster[676] by hydrolyzing $MgATP^{2-}$.

Radical **5–138** conjugates the lone pair of electrons on the oxygen of the former acyl group with the carbon–oxygen bond of the hydroxy group on carbon 2, just as such a conjugation is established in the active site of ribonucleotide reductase (Figure 5–13). While Glutamate 55 dehydronates the former acyl oxygen of radical **5–138**, the hydroxy group, following its hydronation, leaves as a molecule of water to form the oxallylic radical **5–139** (see second step in Figure 5–13). While the acyl oxygen is again hydronated, oxallylic radical **5–139** dissociates a hydron to become the allylic radical **5–140**, the electron paramagnetic resonance spectrum of which has been observed in the active site of the enzyme.[677] While the acyl oxygen is again dehydronated, the unpaired electron in the highest occupied molecular orbital of the allylic radical is then transferred back to the oxidized [4Fe–4S] iron–sulfur cluster, still attached to the acyl oxygen, to produce the product.

There are several enzymes that can use a [4Fe–4S] iron–sulfur cluster to produce **carbanionic intermediates that are neither enolates or enamines** in reactants that have neither a carbonyl, nor an imine, nor a derivative of a carboxylic acid. As do the catalytic [4Fe–4S] iron–sulfur clusters discussed so far, the [4Fe–4S] iron–sulfur clusters in the active sites of these enzymes have an iron ion that is not coordinated by a sulfido group from a cysteine and is open to coordination by substrates.

In the active site of 4-hydroxy-3-methylbut-2-en-1-yl diphosphate reductase from *E. coli*, the open site on the reduced [4Fe–4S] iron–sulfur cluster forms a π adduct with a carbon–carbon double bond in the reactant (*E*)-4-hydroxy-3-methylbut-2-en-1-yl diphosphate adjacent to carbon 4 that has the hydroxy group. After the [4Fe–4S] iron–sulfur cluster is further reduced by one electron, the hydroxy group is hydronated by Glutamic Acid 126 in the active site and dissociates heterolytically from carbon 4 as a molecule of water while two electrons flow from the overreduced [4Fe–4S] iron–sulfur cluster onto the 4-hydroxy-3-methylbut-2-en-1-yl diphosphate to produce an **intermediate allylic carbanion**, coordinated to the iron ion in the now-oxidized [4Fe–4S] iron–sulfur cluster. The allylic carbanion is hydronated at one end or the other to produce either isopentenyl diphosphate or dimethylallyl diphosphate, the two products of the reaction.[678,679] An absorption in electron paramagnetic resonance spectra has been assigned to an unpaired electron within the [4Fe–4S] iron–sulfur cluster in the π adduct of the overreduced [4Fe–4S] iron–sulfur cluster in the active site of a mutant in which Glutamate 126 was converted to alanine or glutamine to prevent hydronation of the hydroxy group.[680,681] Another absorption in electron paramagnetic resonance spectra has been assigned to the unpaired electron in the [4Fe–4S] iron–sulfur in the complex between the allyl carbanion and the oxidized [4Fe–4S] iron–sulfur in the active site of the unmutated enzyme.[681] Finally, there is a crystallographic molecular model of the π adduct between 4-fluoro-3-methylbut-2-en-1-yl diphosphate and the [4Fe–4S] iron–sulfur cluster in the active site of the enzyme.[679]

In the active site of (*E*)-4-hydroxy-3-methylbut-2-enyl-diphosphate synthase (flavodoxin), which produces the reactant for 4-hydroxy-3-methylbut-2-en-1-yl diphosphate reductase, the conjugate base of the 3-hydroxy group on the reactant 2-*C*-methyl-D-erythritol 2,4-cyclodiphosphate becomes a ligand to the open site on the reduced [4Fe–4S] iron–sulfur cluster. The diphosphate dissociates from carbon 2 of 2-*C*-methyl-D-erythritol 2,4-cyclodiphosphate to form a tertiary carbenium ion stabilized by intramolecular electron transfer from the reduced [4Fe–4S] iron–sulfur cluster. An electron is then

transferred from a flavodoxin in the solution while **two electrons are transferred to the carbenium ion to produce the tertiary carbanion** stabilized by intramolecular electron transfer and perhaps direct coordination to the iron ion in the now-oxidized [4Fe–4S] iron–sulfur cluster group. This intermediate has an unpaired electron, which resides mainly on the oxidized [4Fe–4S] iron–sulfur cluster, and has an absorption in an electron paramagnetic resonance spectrum.[682,683] Following reduction of the oxidized [4Fe–4S] iron–sulfur cluster by one electron, the oxygen of the former 3-hydroxy group dissociates from the carbanionic intermediate while the two electrons in the carbanion push in to produce the carbon–carbon double bond in the product, (*E*)-4-hydroxy-3-methylbut-2-enyl-diphosphate. The 2-*C*-methyl-D-erythritol 2,4-cyclodiphosphate coordinated to the iron ion,[684] the carbenium ion stabilized by the reduced [4Fe–4S] iron–sulfur cluster, the carbanion stabilized by the oxidized [4Fe–4S] iron–sulfur cluster, and the hydroxide that leaves coordinated to the iron ion adjacent to the product (*E*)-4-hydroxy-3-methylbut-2-enyl-diphosphate have all been observed in crystallographic molecular models of the active site of (*E*)-4-hydroxy-3-methylbut-2-enyl-diphosphate synthase (flavodoxin) from *T. thermophilus*.[683]

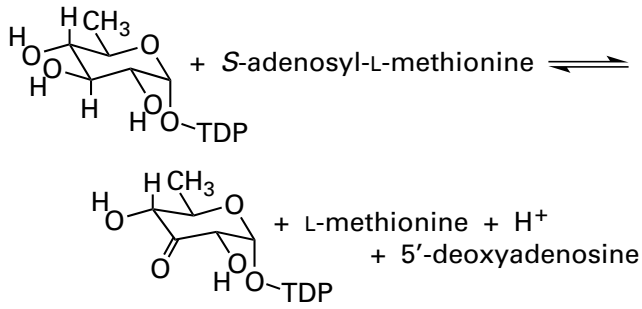
Problem 5–13: Write a complete mechanism for the reaction catalyzed by prostaglandin-endoperoxide synthase (Equation 5–148). The mechanism should include reductions and oxidations of both the heme and the complex between the heme and molecular oxygen, formation of the tyrosyl radical, abstraction of a hydrogen by the tyrosyl radical, and formation of the two rings with an allylic carbocation as an intermediate. Abbreviate the heme as a parallelogram as usual (see Chapter 2).

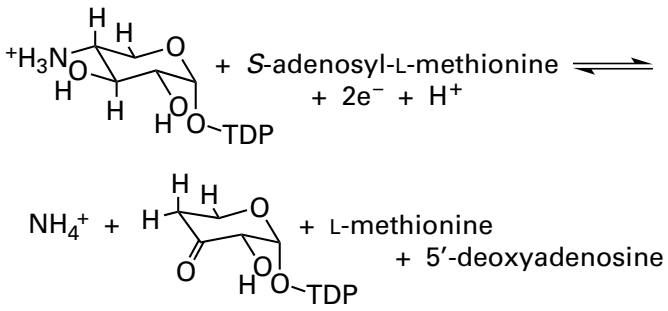
Problem 5–14: An enzyme from *Streptomyces venezuelae* catalyzes the reaction[602]



where TDP^{3-} is a thymidine diphospho group. The enzyme contains a [4Fe–4S] iron–sulfur cluster as a prosthetic group.

(A) Write a complete mechanism for the reaction. Note the oxidation state of the [4Fe–4S] iron–sulfur cluster at each step.

(B) Write a complete mechanism for the following reaction



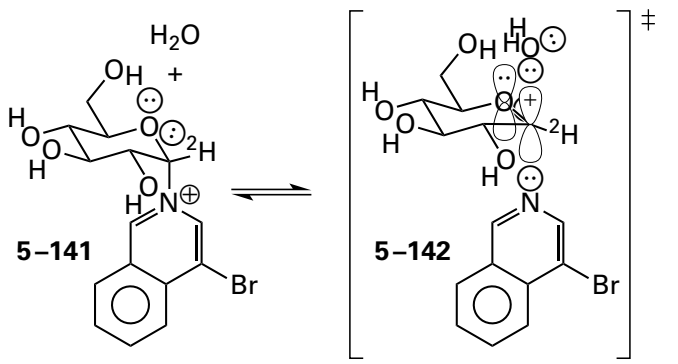
catalyzed by the same enzyme.

(C) If the second reaction were carried out in ^2H_2O, what should be the products? Why is this question ambiguous?

Problem 5–15: Based on the description given in the text, draw a detailed mechanism for the reaction catalyzed by 4-hydroxy-3-methylbut-2-en-1-yl diphosphate reductase[681] and a detailed mechanism for the reaction catalyzed by (*E*)-4-hydroxy-3-methylbut-2-enyl-diphosphate synthase (flavodoxin).[683]

Secondary Kinetic Isotope Effects

The kinetic isotope effects discussed in Chapter 4 were for isotopic substitutions in which an atom in a bond that is broken during an enzymatic reaction is replaced with a heavier isotope of the same element. The resulting decrease in the rate of the enzymatic reaction is used to give either an indication of the extent to which that bond is broken in the transition state for the step in which it is broken or, in a less sophisticated sense, simply to provide evidence that the bond in question is broken in a rate-affecting step in the enzymatic mechanism. These are **primary kinetic isotope effects**. Kinetic isotope effects also can be observed when the isotopic substitution occurs at another atom that is attached covalently to an atom participating in the breaking of a bond, other than the two atoms between which the bond is broken. For example, when the hydrogen on the anomeric carbon in α-D-glucopyranosyl 4′-bromoisoquinolinium (**5–141**)



(5–163)

is replaced with a deuterium, the rate constant for the uncatalyzed hydrolysis of the glucopyranoside at 80 °C decreases, and the deuterium kinetic isotope effect, ${}^{D}k_{hyd}$,* is 1.19 ± 0.01.[685] Such changes in rate constant are secondary kinetic isotope effects, and they provide information about **how the neighboring bond is being broken** in the transition state.

A secondary kinetic isotope effect is a kinetic isotope effect in which the isotopic substitution occurs at another atom that is attached covalently to an atom participating in the breaking of a bond, other than the two atoms between which the bond is broken. A secondary kinetic isotope is a **reporter of a change in the zero-point energies** of vibrational modes in which the atom to be substituted participates between ground state and transition state as the ground state of the molecule is turned into the transition state during the reaction involving dissociation of the neighboring bond. A change in zero-point energy, $E_{0,j}$, of vibrational mode j in which the atom that will be substituted participates will change the frequency of the absorption of infrared light by that vibrational mode j, ν_j, as the transition state is approached, even though that change in absorption cannot be measured as the reaction coordinate is traversed. As before (Equations 4–211, 4–212, and 4–214)

$$E_{0,j} = \frac{h}{4\pi}\sqrt{\frac{f_j}{\mu_j}} \tag{5–164}$$

and

$$h\nu_j = \frac{h}{2\pi}\sqrt{\frac{f_j}{\mu_j}} \tag{5–165}$$

where h is Planck's constant, f_j is the force constant for vibrational mode j, and μ_j is the reduced mass

$$\frac{1}{\mu_j} = \sum_{k=1}^{o}\frac{1}{m_k} \tag{5–166}$$

of the o atoms participating in vibrational mode j.

If the force constant, f_j, for vibrational mode j is determined only by the function for the potential energy of vibrational mode j and unaffected by the change in isotope and if, during a reaction in which a molecule participates, the frequency of the quantum of light absorbed by vibrational mode j in the molecule containing the unsubstituted, lighter atom changes when the ground state is transformed into the transition state, then it follows that the change in frequency

$$\Delta\nu^{\ddagger}_{j,l} = \frac{1}{2\pi\sqrt{\mu_{j,l}}}\left(\sqrt{f^{\ddagger}_{j}} - \sqrt{f_{j,gs}}\right) \tag{5–167}$$

where ${}^{\ddagger}f_j$ is the force constant for vibrational mode j in the transition state and $f_{j,gs}$ is the force constant for vibrational mode j in the ground state. In either the ground state or the transition state, the difference between the zero-point energy for vibrational mode j for the heavy isotope and the zero-point energy for vibrational mode j for the light isotope (previously Equation 4–213)

*As before (Equation 4–176), ${}^{D}k_i = k_{iH}\,k_{iD}^{-1}$.

$$\Delta E_{0,\mathrm{ie},j} = \frac{h\sqrt{f_j}}{4\pi}\left(\sqrt{\frac{1}{\mu_{j,\mathrm{h}}}} - \sqrt{\frac{1}{\mu_{j,\mathrm{l}}}}\right) < 0 \qquad (5\text{–}168)$$

It follows from all these considerations that the difference in the differences in zero-point energy between ground state and transition state when the lighter isotope is replaced by the heavier

$$\Delta\Delta E^{\ddagger}_{0,\mathrm{ie},j} = \sqrt{\frac{1}{\mu_{j,\mathrm{h}}}}\left(\frac{h\sqrt{f^{\ddagger}_j}}{4\pi} - \frac{h\sqrt{f_{j,\mathrm{gs}}}}{4\pi}\right) - \sqrt{\frac{1}{\mu_{j,\mathrm{l}}}}\left(\frac{h\sqrt{f^{\ddagger}_j}}{4\pi} - \frac{h\sqrt{f_{j,\mathrm{gs}}}}{4\pi}\right) = \frac{h}{2}\left(\sqrt{\frac{\mu_{j,\mathrm{l}}}{\mu_{j,\mathrm{h}}}} - 1\right)\Delta\nu^{\ddagger}_{j,\mathrm{l}} \qquad (5\text{–}169)$$

Because $\mu_{j,\mathrm{h}}$ is greater than $\mu_{j,\mathrm{l}}$, it follows that the change in the difference in zero-point energy between ground state and transition state, $\Delta\Delta^{\ddagger}E_{0,\mathrm{ie},j}$, for a particular vibrational mode j in which the atom to be substituted participates will have a sign opposite to the difference in zero-point energies between transition state and ground state for vibrational mode j in the unsubstituted molecule containing the lighter isotope (Equation 5–169).

Consider the sums of the zero-point energies for those vibrational modes in which the atom to be substituted participates. If the sum in the transition state for the unsubstituted molecule is *less* than the sum in the ground state, so that the difference in the two sums between the two states is a negative number, then $\Delta\Delta^{\ddagger}E_{0,\mathrm{ie},j}$ will be a positive number; it will take more energy for the molecule substituted with the heavier isotope to reach the transition state than it does for the unsubstituted molecule; and a kinetic isotope effect greater than 1, a **normal kinetic isotope effect**, will be observed. Contrariwise, if the sum in the transition state for the unsubstituted molecule is *greater* than the sum in the ground state, so that the difference in the two sums between the two states is a positive number, then $\Delta\Delta^{\ddagger}E_{0,\mathrm{ie},j}$ will be a negative number; it will take less energy for the molecule substituted with the heavier isotope to reach the transition state than for the unsubstituted molecule; and a kinetic isotope effect less than 1, an **inverse kinetic isotope effect**, will be observed. For example, the secondary deuterium kinetic isotope effect on the rate of hydrolysis of α-D-glucopyranosyl 4′-bromoisoquinolinium ion is a normal kinetic isotope effect of 1.19. This fact means that the sum of the zero-point energies for the vibrational modes in which the hydrogen that is to be substituted participates decreases as the transition state is approached, and $\Delta\Delta^{\ddagger}E_{0,\mathrm{ie},j}$ has a positive value. If this is so, then $\Delta^{\ddagger}\nu_{j,\mathrm{l}}$ must have a negative value since $\mu_{j,\mathrm{h}}$ is greater than $\mu_{j,\mathrm{l}}$. Consequently, at least one of the infrared vibrational absorptions must decrease significantly in frequency in the transition state relative to the ground state (Equation 5–169).

An α-secondary kinetic isotope effect is a secondary kinetic isotope effect in which the isotopic substitution occurs at an atom bonded directly to one atom in a bond being broken during the reaction. The secondary kinetic isotope effect on hydrolysis of α-D-glucopyranosyl 4′-bromoisoquinolinium is an example of an α-secondary kinetic isotope effect. In the case of an α-secondary kinetic isotope effect from a carbon–hydrogen bond, the difference in zero-point energies, $\Delta E_{0,\mathrm{ie},j}$, on arrival at the transition state (Equation 5–168) is usually believed to result from a change in the hybridization of the carbon atom to which the hydrogen is attached.[686] In the case of hydrolysis of α-D-glucopyranosyl 4′-bromoisoquinolinium ion, the uninvolved carbon–hydrogen bond has become a **reporter of the change in hybridization**.

The absorptions of infrared light by stretching vibrations of carbon–hydrogen bonds on sp^3 carbons in hydrocarbons (2850–3000 cm^{-1}) are not significantly different from the absorptions of those on sp^2 carbons (2950–3100 cm^{-1}),[687] and the absorptions of infrared light by in-plane bending vibrations for carbon–hydrogen bonds on sp^2 carbons (1250–1450 cm^{-1}) are not significantly different from the absorptions of those on sp^3 carbons (1350–1500 cm^{-1}). The absorptions of infrared light by the **out-of-plane bending vibrations**, however, for carbon–hydrogen bonds on sp^2 carbons in hydrocarbons occur at considerably lower frequencies (650–1000 cm^{-1}), and these out-of-plane vibrational modes are unique to sp^2 carbons. This lower frequency of absorption results from the lack of steric hindrance and a decrease in electron repulsion above and below the plane of an sp^2 carbon relative to an sp^3 carbon.

The frequency at which an out-of-plane bending mode for a carbon–hydrogen bond on an sp^2 carbon absorbs infrared light is less than the frequency at which the bending modes on an sp^3 carbon absorb infrared light. Consequently, when an sp^3 carbon is becoming an sp^2 carbon in a transition state, the

zero-point energy is decreasing as the transition state is approached. In addition, the zero-point energy for that particular bending vibration is smaller in the transition state than in the ground state. As a result, the difference in energy between the transition state and the ground state is more positive for the deuterated molecule than the protiated molecule (Equations 5–168 and 5–169), and the rate of the reaction should decrease when a hydrogen is replaced by a deuterium. **When a carbon to which a hydrogen is bound changes from sp^3 hybridization in the ground state in the direction of sp^2 hybridization in the transition state, the α-secondary kinetic deuterium isotope effect will be normal**. A normal α-secondary kinetic deuterium isotope effect is usually taken to mean that the sp^3 carbon on which the hydrogen is located has become more like an sp^2 carbon in the transition state.

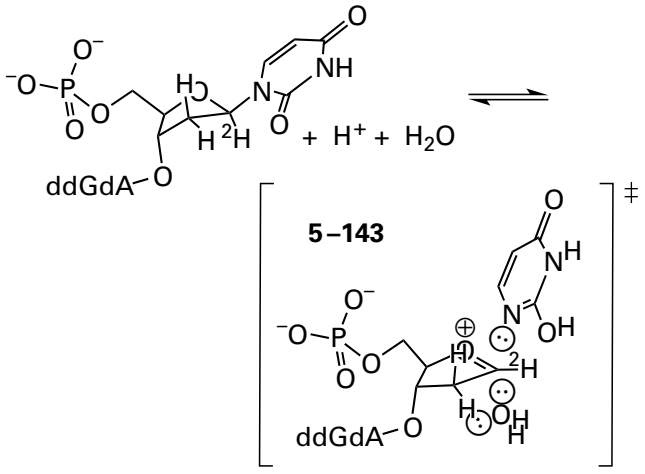
In theory, if it is assumed that the change in absorption frequency for the bending vibrational mode that becomes the out-of-plane vibration when an sp^3 carbon is converted to an sp^2 carbon is 500–600 cm^{-1}, then the change in the difference in zero-point energy producing the α-secondary deuterium kinetic isotope effect should be between 800 and 960 J mol^{-1} (Equation 5–169). When this difference is inserted into the Arrhenius equation (previously Equation 4–216)

$$\frac{k_{CH}}{k_{CD}} = e^{-\Delta\Delta G^{\circ\ddagger}/RT} = 7 \qquad (5\text{–}170)$$

The result is an α-secondary deuterium kinetic isotope effect of 1.4–1.5. The usual α-secondary deuterium kinetic isotope effect on the rate constant for reaction i, ${}^{\alpha D}k_i$, when reaction i is thought to involve, or proven to involve, a change from an sp^3 carbon in the direction of an sp^2 carbon in its transition state[686] is normal, but the observed values are usually between 1.0 and 1.2. An sp^3 carbon seldom if ever becomes a fully hybridized sp^2 carbon in the transition state, and even if it were to become fully rehybridized, a transition state is quite different from a simple ground state in which a carbon has sp^2 hybridization. Changes in the zero-point energies of other vibrational modes—in particular the small increases in the frequencies of stretching vibration and in-plane bending vibrations of the carbon–hydrogen bond—also contribute to the magnitude of the maximum value to be expected for an α-secondary deuterium kinetic isotope effect as an sp^3 carbon is becoming an sp^2 carbon. When an sp^2 carbon in the ground state is becoming an sp^3 carbon in the transition state of a reaction, the α-secondary deuterium kinetic isotope effect is inverse, with observed values between 0.83 and 1.0.

Because the reaction has a normal α-secondary deuterium kinetic isotope of 1.19 ± 0.01, it was proposed that the transition state for the uncatalyzed hydrolysis of α-D-glucopyranosyl 4′-bromoisoquinolinium (Equation 5–163) resembles an oxocarbenium ion, in which the carbon has vibrational energy levels resembling those on an sp^2 carbon, and that the 4′-bromoisoquinoline has almost completely left the carbon, while the molecule of water has not yet significantly added (**5–142**). If the leaving group is still associated with the oxocarbenium ion, the reaction would be a concerted nucleophilic substitution with a single **expanded transition state** proceeding with inversion of configuration at the anomeric carbon. If the leaving group has completely departed from the oxocarbenium ion, the oxocarbenium ion would be an intermediate in a dissociative nucleophilic substitution, and the reaction would proceed with racemization at the anomeric carbon.[688]

The distinction between concerted and dissociative nucleophilic substitution in the mechanism of such a reaction in solution is significant. In the active site of an enzyme, however, it is usually insignificant. For example, uracil-DNA glycosylase from *E. coli*[689] catalyzes the nucleophilic substitution of the uridinyl group in the trinucleotide 5′-phosphodeoxyuridyl-deoxyadenosyl-3′,5′-dideoxyguanosine (UAG) by a molecule of water after the uracil has been hydronated on oxygen 2

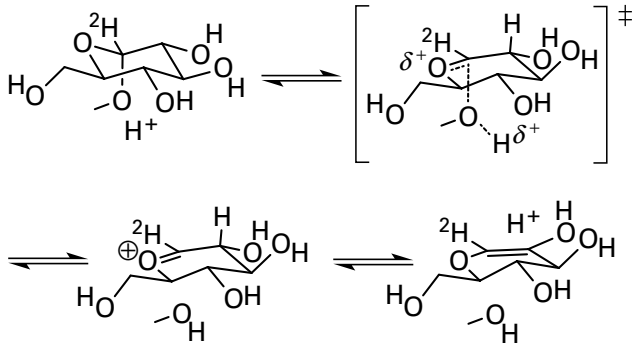


(5–171)

The reaction proceeds with inversion of configuration at the glycosidic carbon. The α-secondary deuterium kinetic isotope effect, however, on the specificity

constant, ${}^{\alpha D}k_{UAG}$, for the enzymatic reaction when the protium on the glycosidic carbon is replaced with deuterium is 1.20 ± 0.02.[690] This result is consistent with a transition state that contains almost an oxocarbenium ion from which the leaving group has almost completely departed and to which the molecule of water may or may not already be adding. Consequently, this kinetic isotope effect is consistent with a concerted nucleophilic substitution with a single, expanded transition state (**5–143**) in which the carbon is planar, with vibrational energy levels resembling those of an sp^2 carbon, or a dissociative nucleophilic substitution with an oxocarbenium ion as an intermediate. On the active site of the enzyme, however, where the molecule of water is held in position adjacent to the glycosidic carbon directly opposite the leaving group,[690] the difference between these two possibilities is inconsequential. For most glycosidases and glycosyltransferases that have been examined, the α-secondary kinetic isotope effects are normal and fall between 1.07 and 1.20.[690,691] This fact suggestis that most if not all glycosidases and glycosyltransferases have mechanisms that pass through **transition states resembling oxocarbenium ions** or that actual oxocarbenium ions are intermediates in the nucleophilic substitutions.

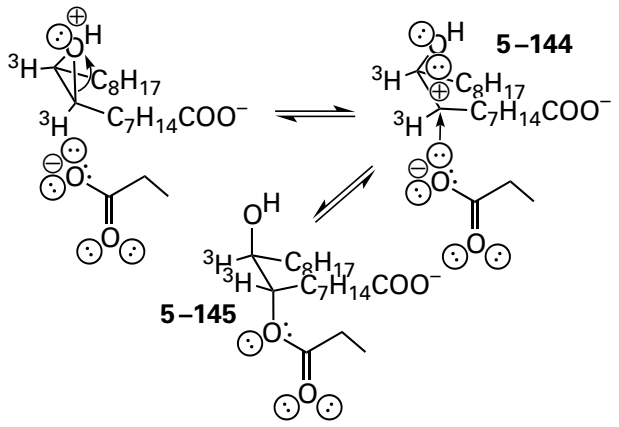
The catalytic constant for the elimination catalyzed by exo-(1→4)-α-D-glucan lyase



(5–172)

from *Gracilariopsis lemaneiformis* has a large normal α-secondary deuterium kinetic isotope effect of 1.19 ± 0.02 and a Brønsted coefficient for the leaving group of 0.32. From these values, it was concluded that the transition state for the first step in the reaction resembles an oxocarbenium ion and involves considerable hydron donation to the leaving group.[692]

In the case of soluble epoxide hydrolase from *Glycine max*



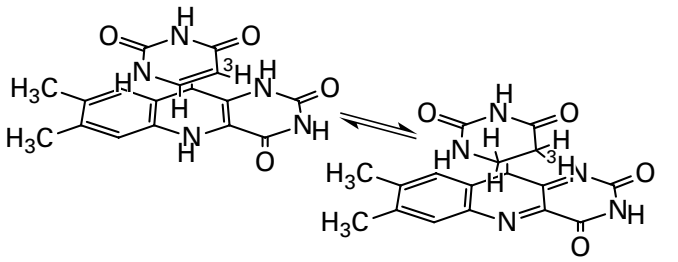
(5–173)

which has a covalent acyl intermediate at Aspartate 126 in the active site,[693,694] the specificity constant for 9,10-epoxystearic acid (eps) for the enzymatic reaction has an ***α*-secondary tritium kinetic isotope effect**, ${}^{\alpha T}k_{eps}$, of 1.30 ± 0.06 when the enzyme is hydrolyzing (*R*,*S*)-[9,10-$^3H_2$]-9,10-epoxystearic acid.[694] This result suggests two possibilities. First, a secondary **carbocationic intermediate** (**5–144**) may precede the covalent acyl intermediate (**5–145**). Second, there may be a single transition state for the nucleophilic substitution, in which the bond to the leaving hydroxy group is mostly broken and the bond to the carboxy group of Aspartate 126 has only begun to form, and the carbon is planar, with vibrational energy levels resembling those of an sp^2 carbon. In this situation, in which a carbenium ion and the nucleophile would be held in place, the difference between these two possibilities is again inconsequential.

The primary deuterium and tritium kinetic isotope effect for the catalytic and specificity constants for thymidylate synthase (Equation 5–50) from *E. coli* for [6-^{2}H]-5,10-methylenetetrahydrofolate and [6-^{3}H]- 5,10-methylenetetrahydrofolate, respectively, where the isotopic substitution is at the hydride on carbon 6 of the tetrahydrofolate that is transferred to the methylene at carbon 5 of the thiolyl adduct of deoxyuridine 5′-monophosphate in the last step of the proposed mechanism (Figure 5–5), demonstrate that hydride transfer is the rate-limiting step in the reaction and that hydride transfer is kinetically irreversible when 5,10-methylenetetrahydrofolate and deoxyuridine 5′-monophosphate are reactants.[223,224] There is, however, an α-secondary tritium kinetic isotope effect of 1.104 ± 0.004 on the specificity constant, ${}^{\alpha T}k_{dUMP}$, for deoxyuridine 5′-monophosphate (dUMP) when the hydrogen on carbon 6 of deoxyuridine 5′-monophosphate is replaced with tritium.[222] This hydrogen is on the

carbon from which the sulfanyl sulfur of the cysteine that forms the covalent adduct leaves in the last step of the mechanism. If this sulfur were to leave in a separate step, which would have to be after the transfer of the hydride from carbon 6 of tetrahydrofolate, there could not be an α-secondary kinetic isotope effect because the transfer of the hydride between carbon 6 of tetrahydrofolate and the methylene at carbon 5 of the thiolyl adduct of deoxyuridine 5′-monophosphate is the rate-limiting step in the reaction, and by definition, no step following the rate-limiting step can affect the kinetics of the reaction. Consequently, hydride transfer and the leaving of the sulfanyl group of cysteine from carbon 6 of the thiolyl adduct must be concerted (as shown in Figure 5–5).[222] The fact that the α-secondary kinetic isotope effect is greater than 1 is consistent with a change in hybridization at the carbon that becomes carbon 6 of thymidine 5′-monophosphate from sp^3 to sp^2, as expected.

An **inverse α-secondary deuterium or tritium kinetic isotope effect** is consistent with the **conversion of an sp^2 carbon into an sp^3 carbon** in the transition state for the reaction. For example, dihydropyrimidine dehydrogenase (NADP$^+$) is a flavoenzyme that reduces the carbon–carbon double bond in uracil through transfer of the hydride on nitrogen 5 of flavin to carbon 6 of the uracil[695]



(5–174)

When the hydrogen at carbon 5 on uracil is replaced with tritium, the α-secondary tritium kinetic isotope effect on the specificity constant for uracil of porcine dihydropyrimidine dehydrogenase (NADP$^+$)[696] is inverse, with a value of 0.90 ± 0.03. This result indicates that carbon 5 is converted from the sp^2 carbon in the ground state in the direction of an sp^3 carbon in the transition state and is consistent with hydronation of carbon 5 occurring in the rate-limiting step in the reaction, which may or may not be concerted with transfer of the hydride. If transfer of the hydride precedes hydronation of the carbon, the enolate of the *N*-carbamoylcarbamoyl group in uracil, in which carbon 5 remains hybridized sp^2, would be an intermediate in the reduction.

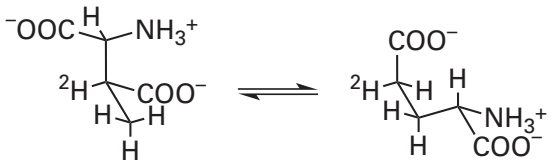
An inverse α-secondary deuterium kinetic isotope effect is also observed for a fully **concerted nucleophilic substitution** that has a transition state in which the bond to the leaving group is mostly intact while the bond to the nucleophile has been mostly established so that there is a pentavalent transition state. In the confines of the pentavalent carbon, what were ground-state energies for vibrational modes become more positive because steric effects and electron repulsion increase in the transition state relative to the ground state. For example, in the concerted nucleophilic substitution at a primary methyl carbon catalyzed by cyclopropane-fatty-acyl-phospholipid synthase from *E. coli*

phospholipid olefinic fatty acid +
S-adenosyl-L-methionine $\rightleftharpoons$
S-adenosyl-L-homocysteine + H^+ +
phospholipid cyclopropane fatty acid
(5–175)

in which a carbon–carbon double bond, as a nucleophile, attacks the electrophilic methyl group on *S*-adenosyl-L-methionine. The fact that the α-secondary deuterium kinetic isotope effect on the catalytic constant, ${}^{\alpha D}k_0$, for [*methyl*-$^2H_3$]-*S*-adenosyl-L-methionine is 0.87 ± 0.08 is consistent with a concerted nucleophilic substitution,[697] as one might expect for a nucleophilic substitution at a methyl group. Even though the nucleophile is a poor one and the leaving group is a good one, a dissociative nucleophilic substitution would require a methyl carbenium ion.

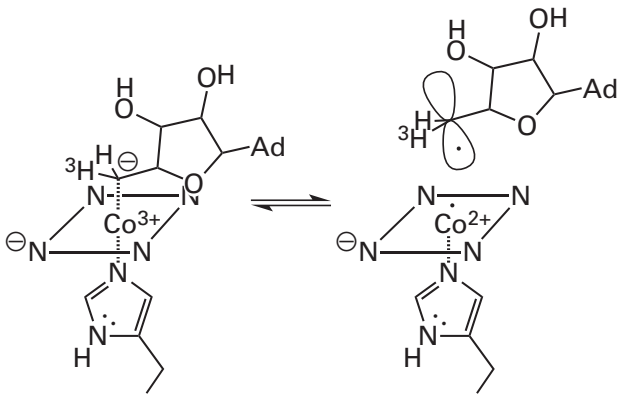
Because the α-secondary deuterium or tritium kinetic isotope effect on a concerted nucleophilic substitution is always inverse, the significant normal α-secondary deuterium and tritium kinetic isotope effects observed for the glycosidases and epoxide hydrolase, and any other enzymatic reaction, must result from either a dissociative nucleophilic substitution or a nucleophilic substitution with a transition state that is so expanded that the usual constraints on the out-of-plane vibrational energies in the transition state for a concerted nucleophilic substitution do not occur. Consequently, the normal α-secondary deuterium and tritium kinetic isotope effects observed in these situations are definitive.

Another example of an inverse α-secondary tritium kinetic isotope effect is encountered in the reaction catalyzed by methylaspartate mutase (previously Equation 2–360)



(5–176)

from *Clostridium* sp. When [5′-^{3}H]-5′-adenosylcobalamin, in which the tritium is upon the carbon that dissociates from cobalt (previously Equation 2–362)

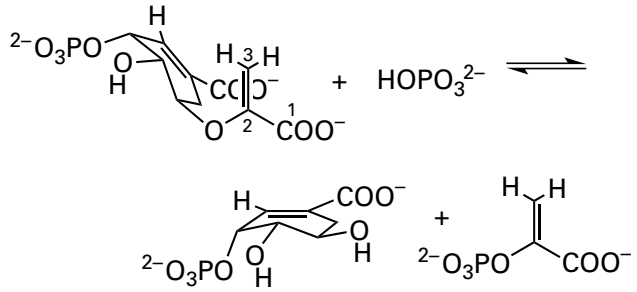


(5–177)

was incorporated into the enzyme as a prosthetic group, an α-secondary tritium kinetic isotope effect on the catalytic constant, $^{\alpha T}k_0$, of 0.76 ± 0.02 was observed.[698] This inverse effect, however, cannot be the result of a transition state in which there is concerted formation of a radical on the *threo*-3-methyl-L-aspartate proceeding through a pentavalent transition state in which the cobalt is leaving and the hydrogen being abstracted from *threo*-3-methyl-L-aspartate is entering carbon 5′. Such a transition state cannot occur because in the crystallographic molecular model of a complex between methylaspartate mutase from *Clostridium cochlearium* and cobalamin, 5′-deoxyadenosine, and L-glutamate, the cobalt from which the 5′-deoxy-5′-adenosyl radical leaves is 0.7 nm from the γcarbon of the glutamate from which a hydrogen is abstracted.[699] It follows that, as might be expected, the rate-limiting step in the reaction is abstraction of hydrogen from *threo*-3-methyl-L-aspartate (Equation 5–176), a step in which an sp^2 radical at carbon 5′ becomes an sp^3 carbon.

α-Secondary kinetic isotope effects are also observed when an atom of carbon, nitrogen, or oxygen adjacent to one atom in the bond that is being broken is replaced with another of its isotopes. For example, the normal **α-secondary carbon-13 kinetic isotope effect** on the specificity constant, $^{\alpha 13}k_{mgp}$, for hydrolysis of methyl [2-^{13}C]-α-D-glucopyranoside (mgp) by α-glucosidase from *S. cerevisiae* of 1.01 ± 0.004. This value is consistent with a transition state resembling an oxocarbenium ion.[700]

An **α-secondary oxygen-18 kinetic isotope effect indicates a change in bond order to oxygen** in the transition state. If a double bond between oxygen and the adjacent atom is partially or entirely broken in the transition state, the α-secondary oxygen-18 kinetic isotope effect will be normal; if a double bond between oxygen and the adjacent atom is partially or entirely formed, the effect will be inverse. For example, the first step in the nucleophilic substitution of an alcohol, 3-phosphoshikimate, by phosphate catalyzed by 3-phosphoshikimate 1-carboxyvinyltransferase (Equations 5–91 and 5–92)

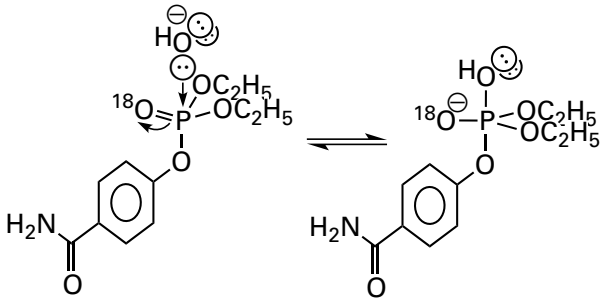


(5–178)

from *E. coli* is thought to be hydronation of carbon 3 of the carboxyvinyl group to form an oxocarbenium ion at carbon 2. Because this hydronation is a rather difficult one, this first step should be rate-limiting for the nucleophilic substitution. The enzyme also catalyzes the hydrolysis of 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate, in a nucleophilic substitution in which a molecule of water is the nucleophile instead of phosphate, a nucleophilic substitution with a much more favorable equilibrium constant than that for the phosphorolysis. The inverse α-secondary oxygen-18 kinetic isotope effect for the oxygen on carbon 2 of the carboxyvinyl group is 0.986 ± 0.008. This value is consistent with a transition state that resembles an oxocarbenium ion, with a carbon–oxygen double bond at carbon 2 resulting from hydronation of carbon 3, where there was a carbon–oxygen single bond in the ground state. The inverse secondary oxygen-18 kinetic isotope effect for the two oxygens of the carboxy group at carbon 1 is 0.979 ± 0.006. This value is also consistent with such a carbocationic transition state, in which the positive charge on carbon 2 draws electron density from the oxygens onto carbon 1, increasing the bond order of those oxygens. There is also an inverse α-secondary deuterium kinetic isotope effect of 0.990 ± 0.001 for the two hydrogens on carbon 3.

This value is consistent with a conversion of this carbon from sp^2 to sp^3 in the transition state[701] as a result of its hydronation.

An α-secondary oxygen-18 kinetic isotope effect can be observed when one or both of the nonbridging oxygen-16 atoms on phosphorus in the reactant for a **nucleophilic substitution at phosphorus** are replaced by oxygen-18. It is usually assumed that such an α-secondary oxygen-18 kinetic isotope effect arises when the bonds between these oxygens and phosphorus change from double to single bonds or vice versa.[702] The theoretically calculated, normal α-secondary oxygen-18 kinetic isotope effect when a P=O double bond becomes a P–O single bond should be 1.04. The α-secondary oxygen-18 kinetic isotope effect for the uncatalyzed alkaline hydrolysis of *O,O*-diethyl-*O*-(4-carbamoylphenyl)phosphate is 1.025 ± 0.002.[703] This normal α-secondary oxygen-18 kinetic isotope effect is evidence for the conclusion that, in this nucleophilic substitution at phosphorus, the transition state is associative and resembles a phosphorane



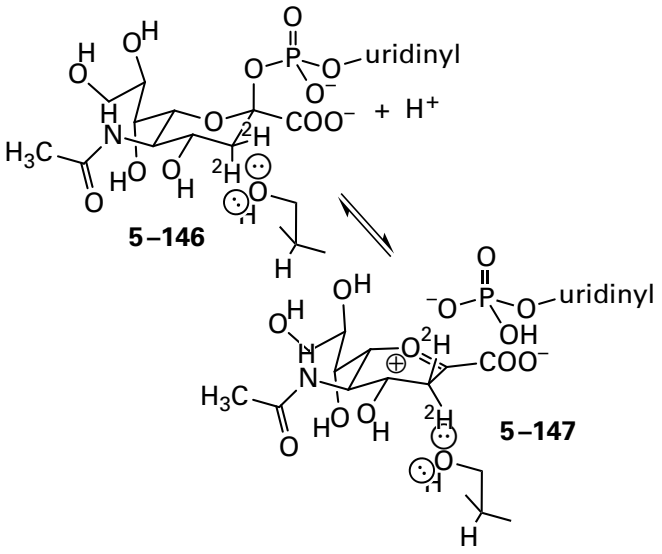
(5–179)

This phosphorane, in which the bonds are fully formed, is probably an intermediate in the reaction because the nucleophile is a strong one and the leaving group ($pK_a \cong 8.6$) is a poor one. If the transition state resembles this intermediate phosphorane, the phosphorus–oxygen double bond in the phospho group has been almost completely converted to a phosphorus–oxygen single bond, and a normal kinetic isotope of this magnitude is to be expected. In contrast, the normal α-secondary oxygen-18 kinetic isotope effect on the specificity constant, ${}^{\alpha 18}k_{\mathrm{nbp}}$, for the transfer of a 3-nitrobenzyl phosphate from 3-nitrobenzyl triphosphate (nbp) to kanamycin by gentamicin 2″-nucleotidyltransferase from *S. aureus* is 1.0033 ± 0.0004. This much smaller value has been interpreted to indicate that the bond order of phosphorus decreases partially in a slightly associative transition state resembling an expanded phosphorane.[704]

A dissociative nucleophilic substitution at phosphorus with a transition state that resembles monomeric metaphosphate should have an inverse α-secondary oxygen-18 kinetic isotope effect because monomeric metaphosphate has two phosphorus–oxygen double bonds while a phospho group has only one. The α-secondary oxygen-18 kinetic isotope effect for the specificity constant for $MgATP^{2-}$ in the nucleophilic substitution catalyzed by hexokinase from *S. cerevisiae* is 0.996 ± 0.002. This value has been presented as evidence for a partially dissociative transition state in the enzymatic reaction.[705]

Conclusions from α-secondary oxygen-18 kinetic isotope effects for nucleophilic substitutions at phosphorus involving phosphomonoesters, however, are complicated by questions of whether the monoanion or the dianion is the reactant and whether or not a nonbridging oxygen is being hydronated or dehydronated in the transition state.[702] As a result, they are often uninformative.

A β-secondary kinetic isotope effect is a secondary kinetic isotope effect in which the isotopic substitution occurs at an atom bonded to an atom that, in turn, is bonded to an atom in the bond being broken during a reaction. For example, when the two hydrogens on carbon 3 of UMP-*N*-acetylneuraminate (Uran, **5–146**)



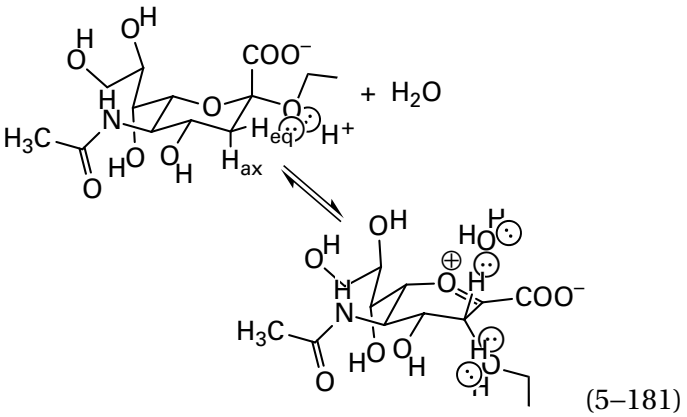
(5–180)

are replaced with deuteriums, the specificity constant k_{Uran} for transfer of the sialyl group to the 6-hydroxy group of *N*-acetyllactosamine catalyzed by β-galactoside α-2,6-sialyltransferase from *R. norvegicus* decreases. This normal, double **β-secondary deuterium kinetic isotope** effect, ${}^{\beta D}k_{\mathrm{Can}}$, is 1.22 ± 0.01,[706]

close to the value (1.28 ± 0.01) for the uncatalyzed hydrolysis of [3,3-$^2H_2$]-CMP-*N*-acetylneuraminidate, in which the alcohol to which the sialyl group is transferred is water. A normal β-secondary deuterium isotope effect of this magnitude suggests that, in the transition state, the carbon–hydrogen bond that is to be isotopically substituted has become hyperconjugated to an adjacent carbenium ion, such as the oxocarbenium ion **5–147**, that is developing in the transition state. This **hyperconjugation in the transition state** weakens the carbon–hydrogen bond that is to be isotopically substituted. This weakening of the bond decreases the zero-point energy of the carbon–hydrogen stretching vibration in the transition state, which produces a normal β-secondary deuterium kinetic isotope effect (Equation 5-169). Again, the kinetic isotope effect is reporting this decrease in the zero-point energy of the stretching vibration as ground state becomes transition state.

The product following the transition state in the active site of this inverting glycosyltransferase could be oxocarbenium ion **5–147** as a carbocationic intermediate (Equation 5–180), or the bond to the 6-hydroxy group of the *N*-acetyllactosamine could be starting to form as the bond to the phospho leaving group is almost completely broken. Again, however, the difference between these alternatives, in the case of the enzymatic reaction, is slight.

That the establishment of hyperconjugation can be the explanation for a normal β-secondary deuterium kinetic isotope effect is consistent with the kinetic isotope effects observed[707] with exo-α-sialidase from *Vibrio cholerae*, which hydrolyzes a peripheral α-sialyl group from an oligosaccharide



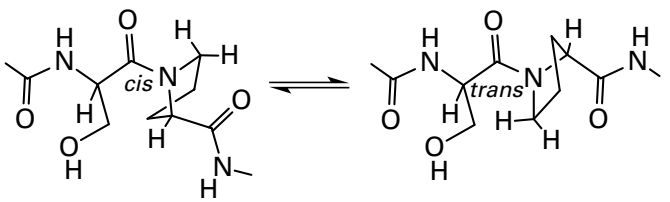
(5–181)

The β-secondary deuterium kinetic isotope effect for the axial hydrogen on carbon 3, the σ bond of which is parallel to the developing oxocarbenium ion and properly positioned for hyperconjugation, is 1.043 ± 0.002. The β-secondary deuterium kinetic isotope effect for the equatorial hydrogen on carbon 3, however, which is not parallel in the ground state but is approaching an orientation equivalent to that of the axial hydrogen in the transition state but not quite there, is only 1.034 ± 0.002.

The β-secondary deuterium kinetic isotope effect, $^{\beta D}k_{hyd}$, for the uncatalyzed hydrolysis of α-D-glucopyranosyl 4′-bromoisoquinolinium (**5–141**), produced by replacement of the protium on carbon 2 of the glucosyl group by a deuterium, is 1.09 ± 0.01.[685] This value is also consistent with a dissociative transition state that resembles an oxocarbenium ion (Equation 5–163). The β-secondary deuterium kinetic isotope effect for the same replacement on the catalytic constant, $^{\beta D}k_0$, for hydrolysis of α-D-glucopyranosyl isoquinolinium by α-glucosidase from *S. cerevisiae* is 1.11 ± 0.01. This value suggests that the transition state for the enzymatic reaction closely resembles that for the uncatalyzed reaction.

Inverse β-secondary kinetic isotope effects are also observed. For example, there is an inverse β-secondary deuterium kinetic isotope effect on the catalytic constant, $^{\beta D}k_0$, of 0.81 ± 0.02 for hydrolysis by β-lactamase from *S. aureus* at pH 6.0 of a 3-carboxyphenyl ester in which the two protiums on the α carbon of the carboxylic acid in the ester are replaced with deuteriums. This value suggests that, at least in this instance, the rate-limiting step in the mechanism is nucleophilic addition of the hydroxy group of Serine 70 in the active site[708] to the acyl carbon of the 3-carboxyphenyl ester or addition of water to the acyl carbon of the seryl ester. In either instance, the sp^2 carbon that is hyperconjugated in the ground state to these two α-hydrogens is converted in the transition state to a carbon resembling the sp^3 carbon of the tetrahedral intermediate that cannot hyperconjugate.[709]

Peptidylprolyl isomerase catalyzes isomerization of a *cis*-prolyl peptide bond to a *trans*-prolyl peptide bond



(5–182)

Because an amide is planar,[710] the hybridization of the nitrogen in a peptide bond in which proline

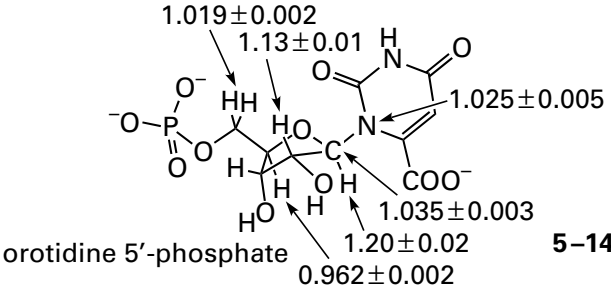
participates is sp^2. The lowest unoccupied σ^* antibonding orbital of the carbon–hydrogen bond on the α carbon adjacent to that nitrogen, which is parallel to the π molecular orbital system of the amide, can engage in hyperconjugation with the lobe on nitrogen in the highest occupied π molecular orbital of the amide. The inverse β-secondary deuterium kinetic isotope on the catalytic constant of human peptidylprolyl isomerase is 0.86 ± 0.08 when all seven hydrogens in the proline in a peptide substrate are changed to deuteriums. This value is consistent with a decrease in this hyperconjugation in the transition state.[711] It was concluded that, in the transition state, the nitrogen rehybridizes from sp^2 toward sp^3 in such a way that the now developing σ lone pair of electrons on the nitrogen can no longer participate in this hyperconjugation.

The more interesting kinetic isotope effect, however, is the normal α-secondary deuterium kinetic isotope of 1.6 ± 0.2 observed on the catalytic constant when the three hydrogens in the serine on the amino-terminal side of the proline (Equation 5–182) are changed to deuterium. In an amide, the π molecular orbital system has a node over the acyl carbon in its lowest unoccupied molecular orbital so that carbon cannot participate in hyperconjugation with the carbon–hydrogen bond of the α carbon of the serine. If in the transition state, however, the nitrogen in the amide can no longer conjugate with the carbon–oxygen double bond, then the amide becomes a carbonyl group that has a lobe of its lowest unoccupied molecular orbital over a partially positive carbon and that can participate in hyperconjugation with the carbon–hydrogen bond on the α carbon if the serine. The loss of the π molecular orbital system of the amide in the transition state that is reported by both of these secondary kinetic isotope effects could result from its hydronation ($pK_a = -6$). A more likely explanation, however, is a steric effect that twists the two carbons of the proline to which the nitrogen in the amide is attached, turning the nitrogen and forcing it to lose its conjugation with the carbon–oxygen double bond even though it is not hydronated. If it is, however, twisted out of conjugation by a steric effect, then the nitrogen becomes equivalent to an amino nitrogen, which is far more basic, so twisting and hydronation could function in concert.

The intrinsic primary and secondary kinetic isotope effects arising from several single isotopic substitutions in the same reactant can be **combined to obtain a fuller definition of the transition state** for a particular step in an enzymatic reaction. Orotate phosphoribosyltransferase (previously Equation 3–227)

$$\begin{gathered}\text{orotidine 5′-phosphate} + H^+ + \\ MgOPO_3PO_3^{2-} \rightleftharpoons \text{orotate} + \\ \text{magnesium 5-phospho-}\alpha\text{-D-ribose 1-diphosphate}\end{gathered} \qquad (5\text{–}183)$$

transfers a 5-phospho-D-ribosyl group between orotate and magnesium diphosphate. The rate-limiting step of the reaction becomes this nucleophilic substitution at carbon 1 of the ribosyl group if a slow substrate such as phosphonoacetic acid (an analogue of diphosphate) or orotidine (which is dephosphorylated orotidine 5′-phosphate) is used in kinetic studies. In this way, intrinsic isotopic effects can be measured directly. When various isotopic substitutes of orotidine 5′-phosphate were used as reactants in transfer of the 5-phospho-D-ribosyl group from orotate to phosphonoacetic acid catalyzed by human orotate phosphoribosyltransferase, the intrinsic kinetic isotope effects for the step in the enzymatic mechanism in which the carbon–nitrogen bond is broken were[712]



5–148

where the observed kinetic isotope effects are the numbers connected with the atom that was substituted with a heavier isotope. Each kinetic isotope effect is for a single isotopic substitution of tritium for protium, carbon-14 for carbon-12, or nitrogen-15 for nitrogen-14. Values for kinetic isotope effects that are identical or almost identical within experimental error to these values had been observed earlier for orotate phosphoribosyltransferase from *S. enterica*[713] and subsequently for human orotate phosphoribosyltransferase with orotidine and magnesium diphosphate as substrates.[714]

Nitrogen-15 and carbon-14 primary kinetic isotope effects for the reaction catalyzed by orotate phosphoribosyltransferase are consistent with significant dissociation of the carbon–nitrogen bond in the transition state. The sizable normal α-secondary tritium kinetic isotope effect for the hydrogen at

carbon 1′ is consistent with a rehybridization of carbon 1 from sp^3 to sp^2. The normal β-secondary tritium kinetic isotope effect for the hydrogen at carbon 2′ is consistent with the establishment of hyperconjugation with a developing oxocarbenium ion. The inverse γ-secondary tritium kinetic isotope effect for the hydrogen at carbon 4′ is consistent with a decrease of hyperconjugation between the σ^* antibonding orbital of the 4′ carbon–hydrogen bond and a lone pair of electrons on the 4′-oxygen in the furanosyl ring, as an incipient carbenium ion at carbon 1′ draws electron density away from the 4′-oxygen into an oxocarbenium ion. This inverse γ-secondary kinetic isotope effect at the hydrogen on a carbon adjacent to the oxygen in a furanosyl or pyranosyl ring has been observed for another ribosyltransferase[715] and has also been observed for the uncatalyzed hydrolysis of both methyl α-glucopyranoside and methyl β-glucopyranoside in strong acid.[716] The normal δ-secondary tritium kinetic isotope effect at carbon 5′ is consistent with a change in the conformation of this exocyclic carbon as a transition state resembling an oxocarbenium ion is achieved.

All kinetic isotope effects for human orotate phosphoribosyltransferase (**5–148**) are those expected from **calculations for a transition state** in which the bond between the nitrogen and the anomeric carbon (0.15 nm in the ground state) is almost completely broken (0.28 nm); the bond to the phospho oxygen (0.14 nm in the ground state) is beginning to form (0.22 nm); and the 5′-phosphoribosyl group is similar if not identical to an oxocarbenium ion.[712,714] In the case of orotate phosphoribosyltransferase from *S. enterica* (25% identity; 2.2 gap percent), rather than the human enzyme, the kinetic isotope effects observed for the reaction of orotidine 5′-phosphate and diphosphate were consistent with a calculated transition state in which the distance between the leaving nitrogen and the anomeric carbon is only 0.19 nm while that between the phospho oxygen and the anomeric carbon is 0.38 nm, even though the respective kinetic isotope effects were either identical or almost identical within experimental error to those for the human enzyme (**5–148**).[713] For human nicotinamide phosphoribosyltransferase, however, in which nicotinamide replaces orotate and nicotinamide D-ribonucleotide replaces orotidine 5′-phosphate, these two calculated distances are 0.23 and 0.26 nm, which are much closer to those for human orotate phosphoribosyltransferase even though four of the six kinetic isotope effects, although in the same direction, are different in magnitude.[717] In the case of purine nucleosidase

$$\text{a purine nucleoside} + H_2O \rightleftharpoons \text{a purine base} + \text{D-ribose} \qquad (5\text{–}184)$$

from *Crithidia fasciculata*, the observed kinetic isotope effects were consistent with a calculated transition state in which the distance between the leaving nitrogen and the anomeric carbon is 0.20 nm while that between the entering oxygen of the water is 0.30 nm, even though, again, the respective kinetic isotope effects were similar in direction and magnitude to those (**5–148**) for human orotate phosphoribosyltransferase.[715] All these results suggest that calculations of dimensions in a transition state are quite sensitive to the exact values for the individual kinetic isotope effects. Nevertheless, in these instances, in which the nucleophilic substitutions all occur at carbon 1 of a ribosyl group, the kinetic isotope effects are consistent with the respective transition states resembling an oxocarbenium ion with nucleophile approaching but only weakly bonded and a leaving group well dissociated and only weakly bonded.

Alcohol dehydrogenase removes the *pro-R* hydrogen from benzyl alcohol (bna) during its oxidation to benzaldehyde. When the *pro-S* hydrogen is replaced with tritium, the α-secondary tritium kinetic isotope effect for the specificity constant of alcohol dehydrogenase from *S. cerevisiae*, which is the ratio between the specificity constants, k_{bna}, for oxidation of benzyl alcohol and [1(*S*)-^{3}H]benzyl alcohol,[718-720] is 1.30 ± 0.02. This tritium kinetic isotope effect is normal, as would be expected for a transition state in which a carbon is changing from sp^3 to sp^2 hybridization. When the enzyme removes a deuterium rather than a hydrogen, however, from [1(*S*)-^{3}H,1(*R*)-^{2}H]benzyl alcohol, the α-secondary tritium kinetic isotope effect[718] decreases to 1.18 ± 0.03. The numerical values for these two α-secondary tritium kinetic isotope effects have been cited as evidence for a particular theoretical explanation of hydrogen tunneling in this particular reaction. In this instance, the rate-limiting step in the enzymatic reaction is transfer of the hydride, so these two kinetic isotope effects are thought to be intrinsic. Formally, however, the latter measurement is that for a double kinetic isotope effect, in which a

kinetic isotope effect decreases when a second heavy isotope is incorporated into a substrate. Double kinetic isotope effects are usually evidence for the existence of two rate-affecting steps in the kinetic mechanism of an enzymatic reaction.

Problem 5–16: When the hydrogen on carbon 3 of 1-deoxy-D-xylulose 5-phosphate is replaced by deuterium, the deuterium kinetic isotope effect on the catalytic constant, ${}^{D}k_0$, for 1-deoxy-D-xylulose-5-phosphate reductoisomerase (Equation 5–114) from *E. coli* is 1.04 ± 0.02. When the hydrogen on carbon 4 is replaced by deuterium, it is 1.11 ± 0.02.[721]

(A) Write a mechanism for the reaction catalyzed by 1-deoxy-D-xylulose-5-phosphate reductioisomerase consistent with these kinetic isotope effects.

L-Ribulose-5-phosphate 4-epimerase from *E. coli*, which does not contain a nicotinamide-adenine dinucleotide as a prosthetic group, catalyzes the reaction

L-ribulose 5-phosphate $\rightleftharpoons$ D-xylulose 5-phosphate

When carbon 3 of L-ribulose-5-phosphate (r5p) is replaced with carbon-13, the kinetic isotope effect on the specificity constant, ${}^{13}k_{r5p}$, is 1.025 ± 0.001, and when carbon 4 is replaced by carbon-13, it is 1.021 ± 0.001. When the protium on carbon 3 is replaced by deuterium, the kinetic isotope effect, ${}^{D}k_{r5p}$, is 1.03 ± 0.01, and when the protium on carbon 4 is replaced by deuterium, it is 1.14 ± 0.01 at pH 5.5.[722]

(B) Write a mechanism for L-ribulose-5-phosphate 4-epimerase consistent with these kinetic isotope effects.

Problem 5–17: When [β,β-${}^{2}H_2$]-L-tryptophan is used as a reactant for tryptophanase (Equation 2–14), there is a kinetic isotope effect of 1.17 ± 0.03.[723] With what intermediate in the enzymatic reaction is this consistent?

Double Kinetic Isotope Effects

If one remembers that association of a hydron is formation of a bond and dissociation of a hydron is breaking of a bond, it follows that in almost every enzymatically catalyzed reaction more than one bond is formed or broken. If each of these bonds is formed or broken in a different kinetic step, then intermediates are necessarily produced during the reaction. If two or more bonds are formed or broken in the same step through a single transition state, then these formations or breakings are concerted, and fewer or perhaps no intermediates are involved in the mechanism. Therefore, the order in which or simultaneity with which specific bonds are made or broken can **define the chemical structures and the number of intermediates in a particular enzymatic reaction**.

To review, if a particular bond in reactant A is broken during a particular step *i* in the kinetic mechanism of an enzymatic reaction and an atom participating in that bond is changed to a heavier isotope, step *i* will experience an **intrinsic primary kinetic isotope effect**, and the microscopic rate constants for that step, both forward and reverse, will decrease. The **influence of the intrinsic primary kinetic isotope effect for step *i* on a steady-state rate constant** for the overall enzymatic reaction is determined by the extent to which that step is a rate-affecting step in the overall kinetic mechanism. For example, for a primary deuterium kinetic isotope effect resulting from the substitution of a hydrogen in reactant A with a deuterium on the specificity constant for reactant A (previously Equation 4–199)

$$ {}^{D}k_A \equiv \frac{k_{AH}}{k_{AD}} = \frac{{}^{D}k_i + c_f + c_r({}^{D}K_{eqi})}{1 + c_f + c_r} \qquad (5–185) $$

where ${}^{D}k_i$ is the intrinsic primary deuterium isotope effect on step *i*, c_f is the commitment forward, c_r is the commitment in reverse, and ${}^{D}K_{eqi}$ is the equilibrium isotope effect for step *i*. This equation determines whether or not the step in which the intrinsic primary kinetic isotope effect is exerted has an effect on the specificity constant significant enough to be measured.

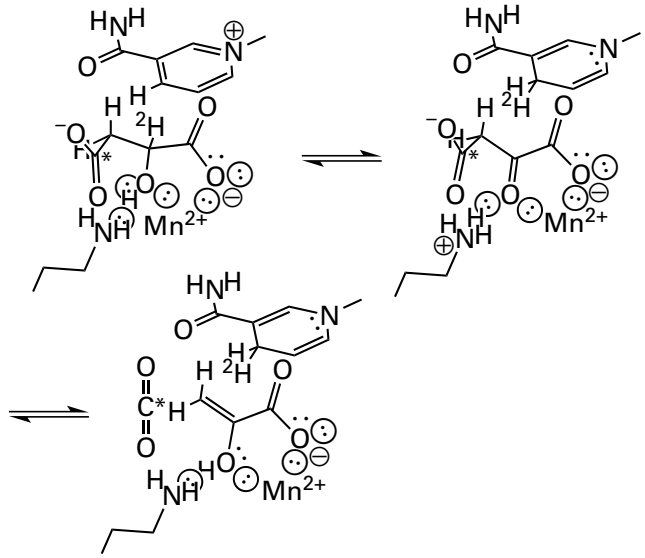
Malate dehydrogenase (oxaloacetate-decarboxylating) ($NADP^+$)[724] catalyzes an oxidative decarboxylation (previously Equation 4–208)

$$NADP^+ + (S)\text{-malate} \rightleftharpoons CO_2 + \text{pyruvate} + NADPH \qquad (5\text{–}186)$$

In the direction written, the bond between carbon 2 of malate and its hydrogen is necessarily broken when it is removed as a hydride, and the bond between carbons 4 and 3 of malate is necessarily broken as carbon dioxide dissociates. Both a primary deuterium kinetic isotope effect and a primary carbon-13 kinetic isotope effect are observed on the steady-state kinetics[725] of the overall reaction catalyzed by the enzyme from *G. gallus*, resulting from substitutions of the hydrogen on carbon 2 and carbon 4 itself, respectively.

A double kinetic isotope effect is the change in a primary kinetic isotope effect associated with the overall enzymatic reaction brought about by substituting a heavier isotope at another position in the molecule at which another bond is formed or broken. For example, in the case of malate dehydrogenase (oxaloacetate-decarboxylating) ($NADP^+$), a double kinetic isotope effect would be either a change in the overall primary carbon-13 kinetic isotope effect at carbon 4 of malate on a steady-state rate constant brought about by substituting a deuterium at carbon 2 or a change in the overall primary deuterium kinetic isotope effect at carbon 2 of malate on a steady-state rate constant brought about by substituting a carbon-13 at carbon 4. Because, however, heavy atom kinetic isotope effects are so small, it is technically difficult or impossible to detect the small change in a deuterium kinetic isotope effect produced by the substitution of a heavy atom with a heavier isotope, such as carbon-13 for carbon-12. Only the **effect of substituting a deuterium** for a hydrogen on a deuterium, tritium, carbon-13, nitrogen-15, or oxygen-18 primary kinetic isotope effect, or even a secondary tritium kinetic isotope effect,[696,718] usually can be measured with sufficient precision.

A double kinetic isotope effect can be used to determine whether, in a particular enzymatic reaction, **breakings of two different bonds occur in two separate steps or take place in one step** and are concerted.[725] For example, based on the fact that 2-oxo carboxylic acids readily decarboxylate under catalysis by a metallic cation and the fact that there is a Mn^{2+} cation at the appropriate location in the active site,[726] a possible mechanism for the oxidative decarboxylation catalyzed by malate dehydrogenase (oxaloacetate-decarboxylating) ($NADP^+$) involves two steps



(5–187)

with oxaloacetate as an intermediate. If each of the two bonds is broken in a separate step, the substitution of hydrogen with deuterium at carbon 2 will decrease the rate only of the step involving hydride transfer, causing it to become more rate-affecting at the expense of the other steps in the reaction. Consequently, the primary carbon-13 kinetic isotope effect on the overall reaction would have to decrease in magnitude because the step in which this bond is broken has **become less rate-affecting**. It is also possible, however, that the two bond breakings, carbon–hydrogen and carbon–carbon, are concerted and occur in the same step. If the reaction were concerted and both bonds were broken in the same step, the substitution of hydrogen with deuterium at carbon 2 would decrease the rate of this single step, **causing it to become more rate-affecting** in the overall reaction, and the primary carbon-13 kinetic isotope effect on the overall reaction would have to increase in magnitude. Such an argument can apply to any two bond breakings or bond formations in any enzymatic reaction.

This intuition can be verified mathematically.[725,727] The primary carbon-13 kinetic isotope effect on the specificity constant for [4-^{13}C]-(*S*)-malate (mal), when it is a reactant in the oxidative decarboxylation catalyzed by malate dehydrogenase (oxaloacetate-decarboxylating)(NADP$^+$) (Equation 5–185)

$$^{13}k_{\text{mal}} \equiv \frac{k_{\text{mal},12}}{k_{\text{mal},13}} = \frac{^{13}k_i + c_\text{f} + c_\text{r}(^{13}K_{\text{eq}i})}{1 + c_\text{f} + c_\text{r}} \tag{5–188}$$

where the rate constants $k_{\text{mal},12}$ and $k_{\text{mal},13}$ are the specificity constants for malate for the reaction run with unsubstituted [4-^{12}C]-(*S*)-malate and with [4-^{13}C]-(*S*)-malate, respectively; $^{13}k_i$ is the intrinsic primary carbon-13 kinetic isotope effect on the forward rate constant for step *i*, the step in which the bond to carbon 4 is broken; c_f and c_r are the commitments forward and in reverse, respectively; and $^{13}K_{\text{eq}i}$ is the carbon-13 equilibrium isotope effect on step *i*. Suppose that the kinetic mechanism for the reaction is (previously Equation 4–192)

$$\begin{aligned} \text{E}_1 \underset{k_{-1}}{\overset{k_1[\text{A}]_0}{\rightleftharpoons}} \text{E}_2 \underset{k_{-2}}{\overset{k_2[\text{B}]_0}{\rightleftharpoons}} \text{E}_3 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \text{E}_4 \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \\ \text{E}_5 \underset{k_{-5}[\text{X}]_0}{\overset{k_5}{\rightleftharpoons}} \text{E}_6 \underset{k_{-6}[\text{Y}]_0}{\overset{k_6}{\rightleftharpoons}} \text{E}_7 \underset{k_{-7}[\text{Z}]_0}{\overset{k_7}{\rightleftharpoons}} \text{E}_1 \end{aligned} \tag{5–189}$$

where reactants A and B are NADP$^+$ and (*S*)-malate, respectively; products X and Y are either carbon dioxide and pyruvate or pyruvate and carbon dioxide, respectively; and product Z is NADPH.[728] If the step in which the hydride is transferred between carbon 2 and NADP$^+$ (step 3) precedes the step in which the bond between carbons 3 and 4 is broken (step 4), the more chemically reasonable order, then when $[\text{B}]_0 > 0$, the commitment forward (see Equation 4–197)

$$c_\text{f} \equiv \frac{k_{4,12}}{k_{\text{r}i}} = \frac{k_{4,12}(k_2k_3[\text{B}]_0 + k_3k_{-1} + k_{-1}k_{-2})}{k_{-1}k_{-2}k_{-3}} \tag{5–190}$$

where $k_{4,12}$ is the forward rate constant for step 4 when the carbon is carbon-12. The **commitment forward will increase** because k_{-3} decreases when deuterium replaces protium. If the step in which the hydrogen is transferred between carbon 2 and NADP$^+$ (step 4) follows the step in which the carbon–carbon bond is broken during the decarboxylation (step 3), then the commitment in reverse (see Equation 4–198)

$$c_\text{r} \equiv \frac{k_{4,12}}{k_{\text{f}i}} = \frac{k_{4,12}(k_{-3}k_{-4} + k_{-3}k_5 + k_4k_5)}{k_3k_4k_5} \tag{5–191}$$

The **commitment in reverse will increase** because k_4 decreases when deuterium replaces protium. Neither $^{13}k_i$ nor $^{13}K_{\text{eq}i}$ will be affected significantly in either case when a hydrogen on carbon is changed to a deuterium because the β-secondary kinetic isotope effect should be insignificant. Therefore, because $^{13}k_i > 1$, the observed kinetic isotope effect on the specificity constant, $^{13}k_{\text{mal}}$, will be less when deuterium is on carbon 2 than when protium is on carbon 2, regardless of whether the step in which the hydrogen is removed precedes or follows the step in which the carbon–carbon bond breaks.

If the step in which the hydrogen is transferred between carbon 2 and NADP$^+$ is the same step in which the carbon–carbon bond is broken, then c_f (Equation 5–190) decreases because k_i, the rate constant for step *i* in which the carbon–carbon bond is broken, decreases when the hydrogen is replaced by deuterium. Therefore, because $^{13}k_i > 1$, the observed kinetic isotope effect increases when transfer of the hydrogen between carbon 2 and NADP$^+$ occurs in the same transition state in which the carbon–carbon bond is breaking.

Whether the actual change in a carbon-13 kinetic isotope effect is large enough to be observed will depend on the respective magnitudes of the commitments themselves as well as the changes that occur in them. For example, if both c_f and c_r are small so that the carbon-13 kinetic isotope effect on the specificity constant is the intrinsic kinetic isotope effect, there will be a negligible effect of substituting the deuterium for the protium; and if either commitment is large, there will also be a negligible effect. In the former case, however, there will be only a small primary deuterium kinetic isotope effect on the specificity constant, and in the latter case, there will not be a significant primary carbon-13 kinetic isotope effect on the specificity constant. If both deuterium and carbon-13 kinetic isotope effects are observed, then there is a good chance that they will interact with each other.

What this explanation emphasizes is that the double kinetic isotope effect arising from substituting the second atom with a heavier isotope is not exerted on the intrinsic kinetic isotope effect itself

for breaking the bond in which the first atom participates. Rather, the effect of substituting the second atom with a heavier isotope results from the effect that the intrinsic kinetic isotope effect for the second atom has on the primary kinetic isotopic effect for the substitution of the first atom on the specificity constants or the catalytic constant, or both of them, for the overall reaction. In other words, it is an **effect on the steady-state rate constants**. A double kinetic isotope effect is observed because specificity constants and catalytic constants are usually composite macroscopic rate constants, often quite complicated ones, determined by several or many microscopic rate constants, and an intrinsic kinetic isotope effect is exerted on only two microscopic rate constants.

The foregoing mathematical development is not unique to carbon-13–deuterium double kinetic isotope effects and can be applied to the double kinetic isotope effect between deuterium and any other isotopic substitution.

For malate dehydrogenase (oxaloacetate-decarboxylating) ($NADP^+$) from *G. gallus* at pH 8.0 and 25 °C, the carbon-13 kinetic isotope effect, $^{13}k_{mal}$, on the specificity constant for malate (mal) is 1.0302 ± 0.0005.[725] If the hydrogen at carbon 2 is changed to a deuterium, this carbon-13 kinetic isotope effect decreases to 1.0250 ± 0.0007. Therefore, the bond between carbon 2 and hydrogen is broken in a different step in the kinetic mechanism than that in which the bond between carbons 4 and 3 is broken. There must be **two steps and an intermediate**. When 3-acetylpyridine adenine dinucleotide phosphate, however, is used as a reactant in place of nicotinamide adenine dinucleotide phosphate, the catalytic constant increases twofold and the specificity constant for 3-acetylpyridine adenine dinucleotide phosphate increases threefold. The fact that the primary carbon-13 kinetic isotope effect on the specificity constant for substituting carbon 4 now increases from 1.0056 ± 0.0005 to 1.0087 ± 0.0007 when a deuterium replaces a hydrogen at carbon 2 indicates that the reaction has become concerted, with removal of the hydride coinciding with breaking of the carbon–carbon bond, and that oxaloacetate can no longer be an intermediate.[729]

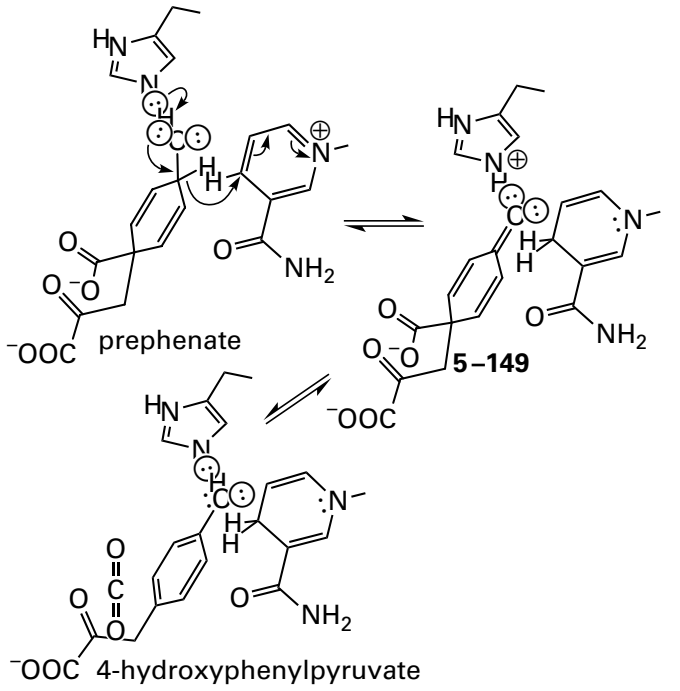
Only when the microscopic rate constants for each of the two steps altered by the respective isotopic substitutions are by themselves rate-affecting will a double kinetic isotope effect be observed. Unless the single concerted step or each of the two steps involving breaking and formation of the two bonds is rate-affecting, a **shift in the relative importance of the rate-affecting steps** cannot occur. Consequently, each isotopic substitution alone must produce a primary kinetic isotope effect on a steady-state rate constant, and to be reassured of the interpretations of the results of these experiments, both single kinetic isotope effects must be observed. In the case of malate dehydrogenase (oxaloacetate-decarboxylating) ($NADP^+$), the primary deuterium kinetic isotope effect, $^{D}k_{mal}$, on the specificity constant for malate is 1.47, and as already mentioned, the primary carbon-13 kinetic isotope effect, $^{13}k_{mal}$, is 1.302.[725] In this case, the primary deuterium kinetic isotope effect is not that much different from 1, which suggests, as required by all the foregoing development, that while it is rate-affecting, transfer of the hydride from (*S*)-malate to $NADP^+$ is not rate-limiting.

If breakings or formings of the two bonds, respectively, are not concerted and if the equilibrium isotope effects for the two steps in a mechanism in which their intrinsic kinetic isotope effects are exerted are sufficiently different from each other, then it is also **possible to determine which step precedes the other.** In this situation, because c_r is multiplied by the equilibrium isotope effect in Equation 5–188 and c_f is not, different relations will exist among the various observed kinetic isotope effects, depending on which step comes first.[725] For example, malate dehydrogenase (oxaloacetate-decarboxylating) ($NADP^+$) has a deuterium equilibrium isotope effect[730] of 1.18. In other words, the equilibrium constant for the reaction when hydride is transferred between oxaloacetate and $NADP^+$ is 1.18 times greater, in favor of oxaloacetate and NADPH, than the equilibrium constant when deuteride is transferred between oxaloacetate and $NADP^+$ (Equation 5–187). Taken together, this value for the deuterium equilibrium isotope effect and values for the carbon-13 equilibrium isotope effect, deuterium kinetic isotope effect, carbon-13 kinetic isotope effect, and carbon-13 kinetic isotope effect after substitution of deuterium at carbon 2 are consistent only with a kinetic mechanism in which hydride transfer precedes decarboxylation.[725] Therefore, oxaloacetate must be an intermediate in the enzymatic reaction, the conclusion which always made the most chemical sense.

Phosphogluconate dehydrogenase ($NADP^+$-dependent, decarboxylating) catalyzes formally the same reaction (compare Equations 5–76 and 5–187) as does malate dehydrogenase (oxaloacetate-decarboxylating) ($NADP^+$). The carbon-13 kinetic isotope effect for carbon-13 substitution at carbon 1 of 6-phospho-D-gluconate on the specificity con-

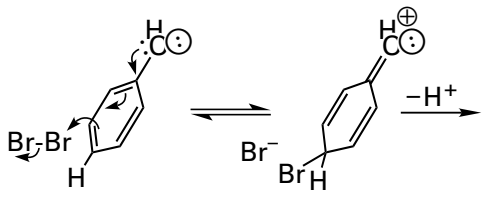
stant, k_{6pg}, for 6-phospho-D-gluconate (6pg) for the enzyme from *S. cerevisiae* is 1.0096 ± 0.0006. When the hydrogen on carbon 3 of 6-phospho-D-gluconate is replaced with deuterium, the carbon-13 kinetic isotope effect on the specificity constant decreases to 1.0081 ± 0.0002. Therefore, hydride transfer from carbon 3 and decarboxylation of carbon 1 are not concerted.[731] Similar results were obtained with the ovine enzyme and the enzyme from *C. jadinii*.[732] In the enzyme from *S. cerevisiae*, the magnitudes of the various kinetic isotope effects are together consistent with a kinetic mechanism in which hydride transfer precedes decarboxylation and in which 3-oxo-6-phospho-D-gluconate is the β-oxo acid that is the intermediate in the enzymatic reaction (Equation 5–76).

Prephenate dehydrogenase also catalyzes a reaction in which a hydride transfer and a decarboxylation occur. The reaction can be written with a reasonable divinylketone (**5–149**), a vinylogous β-oxo acid, as an intermediate



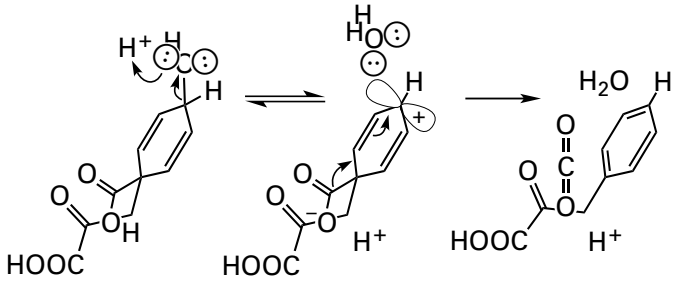
(5–192)

The divinyl ketone resembles the intermediate in the electrophilic aromatic substitution of a phenol at its carbon 4



(5–193)

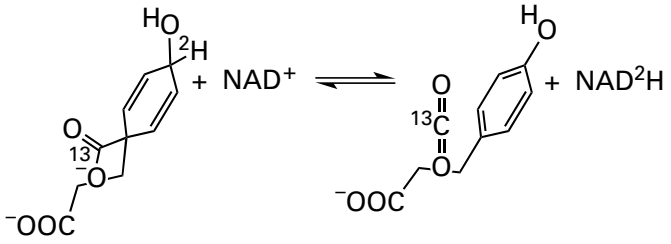
and explains the role of the imidazolyl group of a histidine that forms a hydrogen bond to the hydroxy group of the substrate 4-hydroxyphenylpyruvate in the active site.[733] It has also been shown[734] that the related nonenzymatic, acid-catalyzed 1,4-elimination of water and carbon dioxide from prephenate passes through a carbocationic intermediate



(5–194)

even though that intermediate is even less stable than divinyl ketone **5–149**.

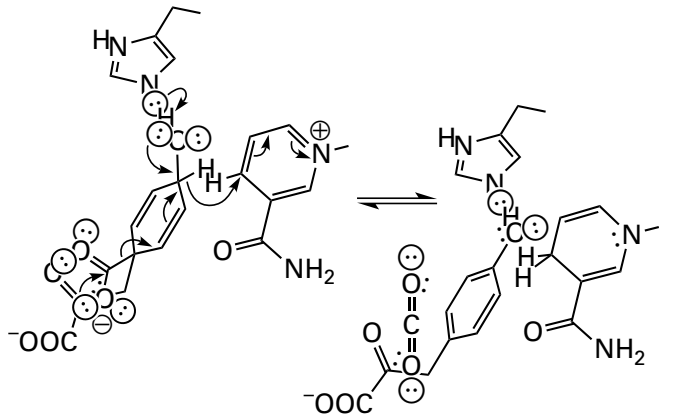
Nevertheless, when the hydrogen on carbon 4 of the alternative reactant for prephenate dehydrogenase, 3-(*cis*-1-carboxy-4-hydroxy-2,5-cyclohexadien-1-yl)propanoic acid (chp)



(5–195)

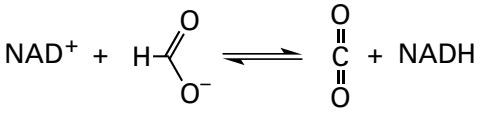
is replaced with a deuterium, the carbon-13 kinetic isotope effect on the specificity constant, k_{chp}, for [^{13}C]carboxy substitution at carbon 1 increases from 1.0033 ± 0.0008 to 1.0103 ± 0.0013.[734] This unmistakable, statistically significant increase is consistent only with a concerted mechanism for prephenate dehydrogenase in which hydride transfer and decarboxylation occur in the same transition state. This mechanism is different from the one expected (Equation 5–192), and intermediate **5–149** must not be formed. Therefore, the σ bond between carbon 1 and the carboxylato group that is forming

carbon dioxide must provide antarafacial push to the hydride leaving the 3-(*cis*-1-carboxy-4-hydroxy-2,5-cyclohexadien-1-yl)propanoic acid from carbon 4, in addition to the push provided by the 4-hydroxy group, in a **concerted reaction with no intermediate**



(5–196)

The double kinetic isotope effects discussed so far have been for situations in which a primary kinetic isotope effect increases or decreases when another atom is changed to a heavier isotope. It is also possible that **no change occurs in the kinetic isotope effect** upon isotopic substitution at the other position even though individual kinetic isotope effects are observed for isotopic substitution at each position independently. Formate dehydrogenase (previously Equation 4–171)



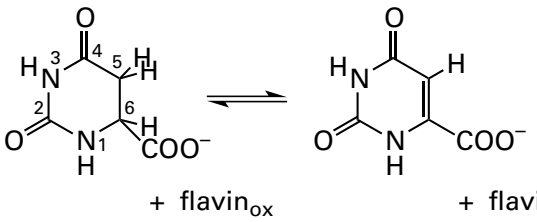
(5–197)

from *S. cerevisiae* displays both a primary carbon-13 kinetic isotope effect (1.0413 ± 0.0006) for [^{13}C]formate and a primary deuterium kinetic isotope effect (2.85 ± 0.04) for [^{2}H]formate on the specificity constant, k_{fm}, for formate (fm) when the pyridine aldehyde derivative of NAD$^+$, 3-formylpyridine adenine dinucleotide, is used as the other reactant.[735] When the two deuterated formates, [^{12}C,^{2}H]formate and [^{13}C,^{2}H]formate, are used as reactants, the carbon-13 kinetic isotope effect is identical (1.414 ± 0.0001) to that for the hydronated formates. In this instance, the bond involving the deuterium is the same bond as that involving carbon-13—namely, the carbon–hydrogen bond of formate—so these results can say nothing about intermediates in the reaction. They do, however, speak to the issue of the rate-limiting step in the enzymatic reaction. If any steps other than hydride transfer contributed to the rate constant k_{fm}—in other words, if the commitments c_f and c_r in the equivalent of Equation 5–188 were other than nearly zero—then the carbon-13 kinetic isotope effect would have to increase when deuterium replaces hydrogen. Only if hydride transfer is the rate-limiting step in the enzymatic reaction and if all steps preceding it are so much faster that they do not contribute to the value for k_{fm} will the slowing of this step by substituting deuterium for hydrogen have no effect on the observed carbon-13 kinetic isotope effect. Because no effect was seen, it could be concluded[736] that both the deuterium and carbon-13 kinetic isotope effects were the intrinsic isotope effects for the step in which the carbon–hydrogen bond was broken heterolytically. From these intrinsic kinetic isotope effects, arguments could be made concerning the structure of the transition state for the step in which hydride transfer occurs at the active site.[735]

Even though they rely only on kinetic isotope effects on steady-state rate constants, double kinetic isotope effects, again because they provide additional independent equations, can be used in concert with other results to **estimate intrinsic kinetic isotope effects**. For example, intrinsic kinetic isotope effects for malate dehydrogenase (oxaloacetate-decarboxylating) (NADP$^+$) could be calculated from carbon-13–deuterium double kinetic isotope effects and tritium, deuterium, and carbon-13 primary kinetic isotope effects on the steady-state rate constants.[725] For carbon–hydrogen bond cleavage during hydride transfer, the intrinsic primary deuterium kinetic isotope effect, ^{D}k, was estimated to be 5.6 ± 0.5. For carbon–carbon bond cleavage during decarboxylation, the intrinsic primary carbon-13 kinetic isotope effect, ^{13}k, was estimated to be 1.05 ± 0.01. These values were confirmed by later intermediate partitioning experiments.[737] They define, in the absence of tunneling, a transition state for hydride transfer in which the bond to malate is almost entirely broken and a transition state in which the bond to the carbon that becomes carbon dioxide is also almost entirely broken.

So far, only double kinetic isotope effects for the substitution of hydrogen with deuterium on a primary carbon-13 kinetic isotope effect have been described. If two bonds broken or formed during an enzymatic reaction involve hydrogen, but the hydrogens are on different atoms, a **deuterium–deuterium double kinetic isotope effect** for substitution of the other protium with deuterium on a primary deuterium kinetic isotope effect may be observed.[738] For example, in the reaction catalyzed

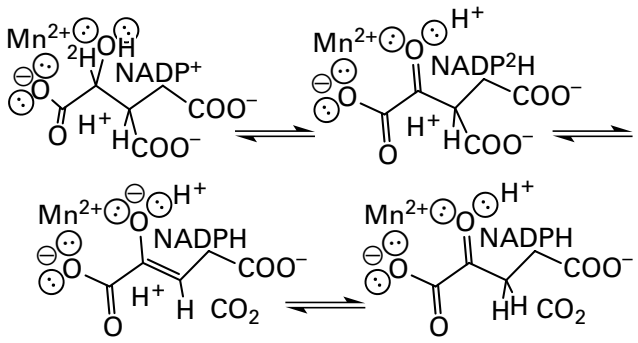
by the flavoenzyme dihydroorotate dehydrogenase (fumarate), the prosthetic flavin mononucleotide is oxidized by fumarate, and the oxidized flavin mononucleotide then oxidizes dihydroorotate by removing two hydrogens (previously Equation 4–177)



(5–198)

The latter reaction, in isolation, can be followed spectrophotometrically by monitoring the decrease in A_{475} of the flavin after oxidized enzyme is rapidly mixed with a saturating concentration of dihydroorotate in the absence of fumarate. The primary deuterium kinetic isotope effect on the catalytic constant for this reduction of the oxidized enzyme from *L. lactis* for substitution of the two hydrogens at carbon 5 with deuterium is 1.83 ± 0.04. When this same substitution is made when there is deuterium rather than hydrogen at carbon 6, the primary deuterium kinetic isotope effect is 1.95 ± 0.12. The primary deuterium kinetic isotope effect on this same rate constant for substitution of the hydrogen on carbon 6 with deuterium is 2.21 ± 0.04. If this same substitution is made when there are two deuteriums in place of protiums on carbon 5, the primary kinetic isotope effect is 2.35 ± 0.16.[739] The facts that, within the margin of error, neither primary kinetic isotope effect was affected by the other substitution, but that in both cases the primary kinetic isotope effects increase, are consistent with three conclusions: both hydrogens are removed in the same transition state; the commitments forward and reverse from this step are negligible within the error of the measurements; and concerted removal of the hydrogens is the rate-limiting step in the reaction.

It is also possible to measure the double kinetic isotope effect of a solvent deuterium kinetic isotope effect on a primary deuterium kinetic isotope effect and vice versa. For example, isocitrate dehydrogenase (NADP$^+$)



(5–199)

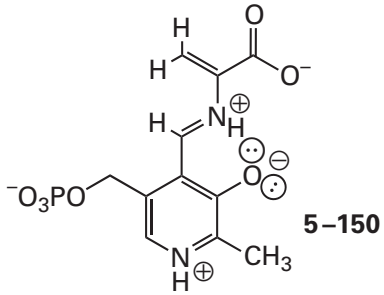
from *M. tuberculosis* catalyzes a reaction analogous to that catalyzed by malate dehydrogenase (oxaloacetate-decarboxylating) (NADP$^+$) (Equations 5–186 and 5–187), in which a reduction by nicotinamide and a decarboxylation occur. When isocitrate and [2-^{2}H]isocitrate are used as reactants in H_2O, the primary deuterium kinetic isotope effect on the catalytic constant is 1.3 ± 0.1, and the primary deuterium kinetic isotope effect on the specificity constant for isocitrate is 1.5 ± 0.2. In ^2H_2O, these primary kinetic isotope effects decrease to 1.2 ± 0.1 and 1.0 ± 0.3, respectively. When unsubstituted isocitrate is used as a reactant, the solvent deuterium kinetic isotope effect on the catalytic constant is 3.0 ± 0.2, and the solvent deuterium kinetic isotope effect on the specificity constant for isocitrate is 1.5 ± 0.3. When [2-^{2}H]isocitrate is used as a reactant, these solvent deuterium kinetic isotope effects decrease to 1.7 ± 0.2 and 1.0 ± 0.2, respectively.

The fact that both primary deuterium kinetic isotope effects decrease when H_2O is changed to ^2H_2O and the fact that both solvent deuterium kinetic isotope effects decrease when isocitrate is changed to [2-^{2}H]isocitrate[740] are consistent with transfer of the hydride from carbon 2 of isocitrate to NADP$^+$ occurring in a step separate from hydron transfer from or to a catalytic acid–base. The manganese complex of isocitrate is the reactant, and as a result, removal of the hydron from the hydroxy group should be so rapid as to not be rate-affecting and probably concerted with transfer of the hydride. Consequently, the only reasonable transfer of a hydron that could produce the solvent deuterium kinetic isotope effects is transfer from a catalytic acid in the active site, which has been identified crystallographically[741] as Tyrosine 142, to carbon 3 of the enolate (Equation 5–199). Hydronation of carbon is always a slow reaction.

The deuterium kinetic isotope effect for hydride transfer from [4(*R*)-^{2}H]NADH to pyruvate by human L-lactate dehydrogenase, however, increases from

2.64 ± 0.02 to 2.74 ± 0.04 when the solvent is changed from H_2O to ^2H_2O. The solvent deuterium kinetic isotope effect increases from 2.51 ± 0.02 to 2.61 ± 0.04 when NADH is changed to [4(*R*)-^{2}H]NADH. These increases in the two kinetic isotope effects are consistent with concerted transfer of the hydride and a hydron in the same step in the kinetic mechanism of the enzyme.[742]

The pyridoximine of 2-aminoacrylate (see Equation 2–13)

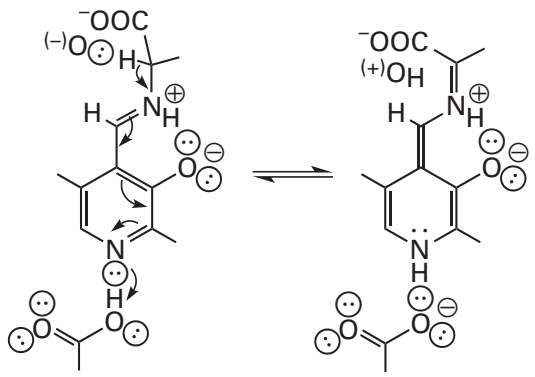


5–150

absorbs strongly at 340 nm. It is possible to follow formation of the pyridoximine of 2-aminoacrylate on the active site of tryptophanase (see Equation 2–14)

$$\text{L-tryptophan} + H_2O \rightleftharpoons \text{indole} + \text{pyruvate} + NH_4^+ \qquad (5\text{–}200)$$

from *E. coli* by following the increase in A_{345} after rapid mixing of the enzyme and a saturating concentration of L-tryptophan. The solvent deuterium kinetic isotope effect on the rate constant for formation of this intermediate is 1.8 ± 0.1. The primary kinetic isotope kinetic effect on the same rate constant when [α-^{3}H]-L-tryptophan is used as a reactant increases from 3.0 ± 0.3 to 4.3 ± 0.2 when the water used as the solvent for the reaction is replaced with deuterium oxide.[723] This result suggests that, in the same transition state in which the hydron is removed from the α carbon of the external pyridoximine of L-tryptophan, another exchangeable hydron on a catalytic acid in the active site is being transferred to this same intermediate in the enzymatic reaction. The most likely candidate for this acid is the carboxy group of Aspartic Acid 227, which forms a hydrogen bond to the pyrimidino nitrogen of pyridoxal phosphate in the active site.[743] This carboxy group would be hydronating the pyrimidino nitrogen as the α-hydron is being removed from the external pyridoximine to give the quinonoid intermediate derived from L-tryptophan (see Equation 2–4)



(5–201)

Unfortunately, the rates of most of the steps in an enzymatic reaction, even steps involving conformational changes of the protein, are decreased when water is replaced by deuterium oxide, so no unambiguous conclusions, even the conclusion that a dissociable hydron on a catalytic base is not transferred in the step exhibiting the primary kinetic isotope effect, can be reached from the observation that a primary kinetic isotope effect decreases when water is replaced by deuterium oxide.[744,745]

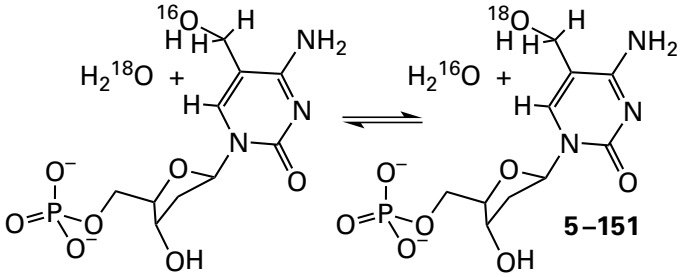
Isotopic Exchange

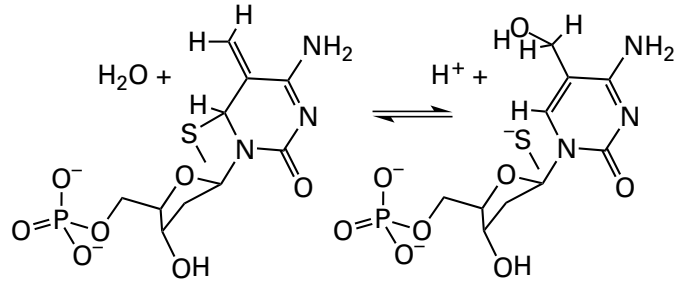
Isotopic exchange is the exchange of one isotope of an atom in a reactant for a different isotope of that atom catalyzed by the active site of an enzyme. The exchanged isotope then appears in the solution in the reactant or a product of the enzymatic reaction. A simple example of isotopic exchange is that observed when glycerone phosphate, in the absence of D-glyceraldehyde 3-phosphate, is mixed with fructose-bisphosphate aldolase (Figure 4–36) from *O. cuniculus* in tritiated water (^3H_2O).[747] When the specific radioactivity of the water was 9800 cpm (μmol of hydrogen)$^{-1}$, the specific radioactivity of glycerone phosphate in the solution monotonically increased from 0 to 9800 cpm (μmol of glycerone phosphate)$^{-1}$, after which only a slow nonenzymatic increase in its specific radioactivity was seen. Because no glyceraldehyde 3-phosphate was added, no fructose 1,6-bisphosphate was produced. The enzyme, however, was able to transform one reactant in the absence of the other by exchanging a tritium for a protium. This situation is an example of **hydrogen isotopic exchange**, which is the exchange of one isotope of hydrogen—protium, deuterium, or tritium—for a different isotope of hydrogen, catalyzed by the active site of an enzyme. Usually, the protium, deuterium, or tritium in the reactant or an intermediate produced from the reactant is at an acidic position and is removed as a **hydron**—a proton, deuteron, or triton—by a catalytic base in the active site from the reactant or intermediate, replaced on the resulting catalytic conjugate acid by a hydron of the other isotope in a series of acid–base reactions, and then returned as the other isotope—a triton, deuteron, or proton—to the reactant or intermediate.

A simple example of oxygen isotopic exchange is encountered in the reaction catalyzed by deoxycytidylate 5-hydroxymethyltransferase (Equation 5–56) from Enterobacteria phage T4



(5–202)

In the penultimate step of the reaction, a hydroxide anion, or a molecule of water from which a hydron is being removed in concert by a catalytic base, adds as a nucleophile to the methylene of the intermediate homologous to intermediate **5–38** for the reaction catalyzed by thymidylate synthase (Figure 5–5)



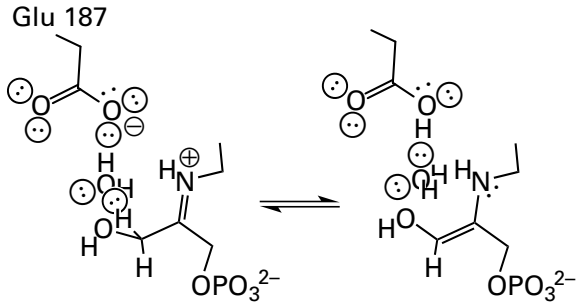
(5–203)

rather than a hydride from 5,6,7,8-tetrahydrofolate. In the absence of 5,6,7,8-tetrahydrofolate, deoxycytidylate 5-hydroxymethyltransferase catalyzes the isotopic exchange of oxygen-16 in the hydroxy group of the substrate 5-hydroxymethylcytidine 5′-monophosphate (**5–151**) for oxygen-18 in $H_2{}^{18}O$ (Equation 5–202), which was followed in mass spectra by the transformation of [5-^{16}O]-5-hydroxymethylcytidine 5′-monophosphate into [5-^{18}O]-5-hydroxymethylcytidine 5′-monophosphate.[748]

Oxygen isotopic exchange is the exchange of one isotope of oxygen—oxygen-16, oxygen-17, or oxygen-18—for a different isotope of oxygen catalyzed by the active site of an enzyme. Usually, oxygen isotopic exchange **involves molecules of water**. The oxygen-16, oxygen-17, or oxygen-18 in the reactant or an intermediate produced from the reactant leaves as a hydroxide that is being hydronated as it leaves by a catalytic acid in the active site. The resulting molecule of water is replaced by a molecule of water containing an oxygen of the other isotope, and then that exchanged molecule of water returns as a nucleophile to the reactant or intermediate in the reverse of the original elimination.

With both hydrogen isotopic exchange and oxygen isotopic exchange, there is significant ambiguity about the origin of the hydron or the molecule of water with the different isotope that ultimately registers the respective isotopic exchange. Originally, it was thought that active sites would be accessible enough to the solution that any hydron removed from the substrate by a catalytic base or any molecule of water that was a leaving group in the active site would exchange almost immediately with a hydron or a molecule of water in solution.[749] How this might occur at the molecular level seemed to draw little attention. As more and more crystallographic molecular models of enzymatic active sites became available, it became apparent that the catalytic acid–bases and molecules of water in the active site were often, if not usually, occluded from contact with the solvent, especially in active sites that closed around their substrates. There were also situations where a substrate or the intermediates themselves sat between the catalytic acid–base or the molecule of water and the solvent, preventing exchange with the solvent.

For a hydrogen isotopic exchange at an acidic position in a reactant, there is a catalytic acid–base in the active site that removes a proton, deuteron, or triton from—or adds a proton, deuteron, or triton to—the reactant or an intermediate produced from that reactant. For example, a catalytic acid–base removes a hydron from the lysyl imine of glycerone phosphate in the active site of fructose-bisphosphate aldolase, and the glycerone phosphate, into which a tritium from ^3H_2O is exchanged,[747] is the reactant that ultimately registers this isotopic exchange. The **catalytic acid–bases** performing these hydrogen isotopic exchanges have almost always been identified in crystallographic molecular models, so the actual molecular events leading to the particular hydrogen isotopic exchange being followed can be surmised. For example, there is a crystallographic molecular model[179] of the active site of fructose-bisphosphate aldolase from *O. cuniculus* occupied by the imine between Lysine 229 and the carbonyl of glycerone phosphate from which a hydron is removed or to which a hydron is added. In this model, the catalytic base that removes the *pro-S* hydrogen from carbon 3 of glycerone phosphate to produce the enamine during the normal enzymatic reaction has been identified as either a molecule of water relaying the basicity of the carboxylato group of Glutamate 187



(5–204)

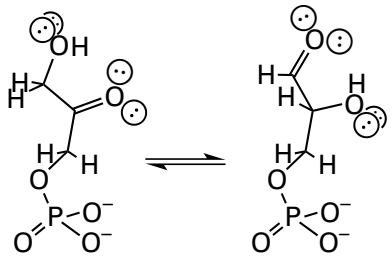
or the compound base formed by the carboxylato group of Glutamate 187 and the 4-hydroxyphenyl group of Tyrosine 363. The hydroxy group on the 4-hydroxyphenyl group displaces the molecule of water as Tyrosine 363 swings into the active site, in a conformational change reminiscent of the swoop of Tyrosine 248 into the active site of bovine carboxypeptidase A.

The molecule of water that may relay the basicity of Glutamate 187 is part of an extensive cluster of hydrogen bonds in which both oxygens in the carboxylato group of Glutamate 187, another molecule of water, both oxygens in the carboxy group of Glutamate 189, the 6-amino group of Lysine 146, the 3-hydroxy group of glycerone phosphate, both oxygens of the carboxy group of Aspartate 33, yet another molecule of water, an oxygen on the phospho group of glycerone phosphate, and a guanidinio nitrogen of Arginine 303 are participants. Within this cluster there are 11 hydrogen bonds and, therefore, at least 11 tritons when the enzyme is dissolved in ^3H_2O. These tritons comprise a **reservoir of tritons available for isotopic exchange**. Once the hydron is removed from carbon 3 of glycerone phosphate, if the molecule of water removes it, there is a high probability that the hydron will be rapidly replaced by a triton in the reservoir. When Tyrosine 363 swings into the active site, its hydroxy group is surrounded by two molecules of water with four tritons and its hydroxy group brings in a triton. If its hydroxy group removes the hydron by relaying the basicity of Glutamate 187, there will be at least five tritons available to rapidly exchange with the hydron. In fact, if Tyrosine 363 actually does swing in and out of the active site, isotopic exchange of the hydron with a triton in the solution would be inescapable. Consequently, whether the molecule of water or the 4-hydroxyphenyl group relays the basicity of Glutamate 187, the hydron that was removed will usually exchange with a triton in the active site, which in the back reaction will be

added to glycerone phosphate to accomplish the hydrogen isotopic exchange.

These considerations illustrate the fact that, in many if not most cases of hydrogen isotopic exchange at an acidic position, there are **more than enough hydrons, deuterons, or tritons**, depending on the design of the experiment, within the active site itself. There is no need for the proton, deuteron, or triton exchanging to enter and leave the active site from the solution, although such an isotopic exchange with hydrons in the solvent may indeed be involved. This consideration simply is a corollary to the fact that active sites occupied by substrates are usually rich in hydrogen bonds, in each of which there must be a hydron.

When an **active site is occluded from the solution** by a conformational change that occurs after all reactants have associated and when the occlusion persists for the entire duration of the chemical steps in its mechanism, hydrogen isotopic exchange can still occur while the reactants are occluded. For example, when either glycerone phosphate or D-glyceraldehyde 3-phosphate associates with the active site of triose-phosphate isomerase (previously Equation 3–384)



(5–205)

a lid closes over the active site, occluding it from the solution (Figure 3–58). Even so, the enzyme from *G. gallus* in ^3H_2O catalyzes the isotopic exchange of the hydron at carbon 3 of glycerone phosphate for a triton at early times during the approach to equilibrium before the back reaction becomes established.[750] When triose-phosphate isomerase from *O. cuniculus* or *S. cerevisiae* is equilibrated in ^3H_2O in the absence of glycerone phosphate and then diluted rapidly into a large volume of ^1H_2O containing a saturating concentration of glycerone phosphate, the observed amount of tritium incorporated into glycerone phosphate by hydrogen isotopic exchange can be explained only if the equivalent of one triton (in the case of the enzyme from *O. cuniculus*) or 2–3 tritons (in the case of the enzyme from *S. cerevisiae*) trapped in the respective occluded active site are able to exchange with the hydron removed by the catalytic base.[751] These tritons, in the active site before the dilution, must be trapped in the active site during association of glycerone phosphate and the subsequent closing of the lid because the solution is mainly ^1H_2O. If isotopic exchange of the hydron on glutamate were occurring only with the hydrons in this solution of ^1H_2O, then no hydrogen isotopic exchange would be observed. The difference between the enzymes from the different species in the number of tritons trapped in the active site that are able to exchange with the hydron is not due to a difference in the catalytic groups in the respective active sites because they are all the same (52% identity; 0.4 gap percent); it is due to a difference in how many tritons exchange for hydrons before the respective active site closes around glycerone phosphate. It follows that, in the situation in which the solvent is continuously ^3H_2O, more tritons capable of exchanging with a hydron on carbon 3 of glycerone phosphate are occluded within the active site upon closing of the lid than when the solvent has been rapidly changed from ^3H_2O to ^1H_2O before the occlusion begins.

Crystallographic observations (Figure 3–37) and active-site labeling[752] have shown that the catalytic base that removes the hydron from carbon 3 of glycerone phosphate in the active site of triose-phosphate isomerase is the carboxylato group of a glutamate. The tritons trapped in an occluded active site and available internally for isotopic exchange with the hydron removed from carbon 3 of glycerone phosphate by the carboxylato group are probably located on the fixed molecule of water that forms a hydrogen bond to the other oxygen of the carboxy group (0.27 nm), on the π nitrogen of the imidazolyl group in van der Waals contact (0.38 nm) with that molecule of water, and on the oxygen on carbon 2 of glycerone phosphate. This last oxygen is in van der Waals contact (0.35 nm) with the oxygen on the carboxy group that removed the hydron and which becomes a tritoxy group during the reaction by being tritonated on the 6-amino group of the lysine that is in a hydrogen bond (0.27 nm) with it (Figure 3–37).[753,754]

In an oxygen isotopic exchange, a molecule of water is the leaving group from the reactant in one direction and the nucleophile in the other direction. This molecule of water can also be identified in a crystallographic molecular model. For example, the molecule of water that leaves and returns in the elimination–addition catalyzed by deoxycytidylate 5-hydroxymethyltransferase from Enterobacteria phage T4 (Equation 5–203) has been identified in the crystallographic model of a complex between 5,6,7,8-tetrahydrofolate and 2′-deoxycytidine

5′-monophosphate, in which the methylene that is normally transferred in the enzymatic reaction is missing.[755] This molecule of water is found on the periphery of a **hydrogen-bonded cluster of six molecules of water** fixed in the active site. The five molecules of $H_2{}^{18}O$ that are not the leaving group are available to rapidly change places with it and then be incorporated into 5-hydroxymethylcytidine 5′-monophosphate. There are always fewer fixed molecules of water occupying an active site in which substrates are undergoing their transformation than there are hydrons in hydrogen bonds; nevertheless, because water is the solvent in which a protein has evolved, there are usually some. There may, however, be situations in which the active site is so dehydrated that there are no molecules of water within it that can exchange with the molecule of water that is a leaving group. It is even less likely that an active site would be so bereft of hydrons that there would be no hydrons within it that were derived from the solvent and that are available to exchange with a hydron removed from a substrate.

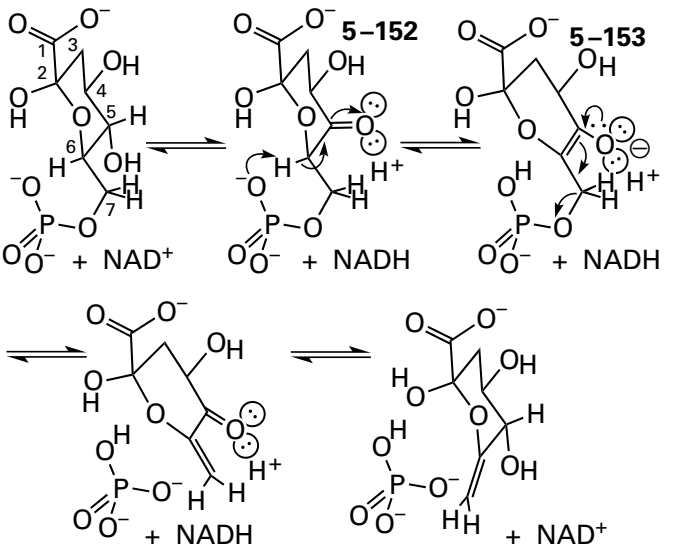
There are several ways in which isotopic exchanges are observed. They differ in how the solution in which they are observed is prepared, which reactants are used, and how the isotopic exchange is monitored.

Isotopic exchange in the absence of one or more reactants is exemplified by the hydrogen isotopic exchange observed for glycerone phosphate catalyzed by fructose-bisphosphate aldolase and the oxygen isotopic exchange observed for 5-hydroxymethylcytidine 5′-monophosphate catalyzed by deoxycytidylate 5-hydroxymethyltransferase (Equation 5–202). If an intermediate in the enzymatic reaction can be formed in the absence of the missing reactant or reactants and if the intermediate has lost one or more of the atoms present in the added reactant, then isotopic exchange of those atoms in that reactant may be observed.

All observed properties for hydrogen isotopic exchange in glycerone phosphate catalyzed by fructose-bisphosphate aldolase are **consistent with the existence of an intermediate in the enzymatic reaction** and consistent with the mechanism (Figure 4–36) in which an intermediate enamine is formed stereospecifically at the active site and the reaction can proceed no further because the electrophile to which the enamine would normally add, glyceraldehyde 3-phosphate, has been omitted. Even though there are four acidic hydrogens on the iminium adduct, two on carbon 3 and two on carbon 1 (Equation 5–204), the final specific radioactivity of glycerone phosphate at equilibrium was not 39,000 cpm μmol^{-1} when the specific activity of the water was 9800 cpm (μmol of hydrogen)$^{-1}$ because only one of the four acidic hydrons, the *pro-S* hydrogen on carbon 3, is removed and replaced with a triton by the molecule of water or the 4-hydroxyphenyl group in the active site. When the enzymatic reaction comes to equilibrium, the specific radioactivity of that one hydrogen, and hence that of glycerone phosphate itself, must be equivalent to the specific radioactivity of a hydrogen in the water. The slow increase in specific radioactivity of glycerone phosphate results from nonenzymatic isotopic exchange of the other three acidic hydrons.

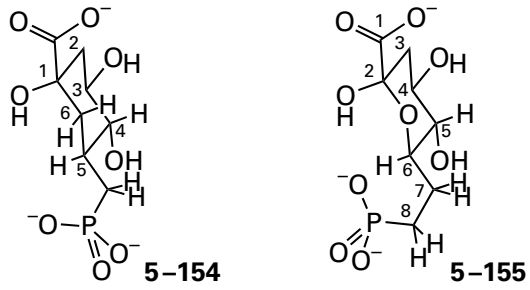
The fact that, in the absence of 5,6,7,8-tetrahydrofolate, deoxycytidylate 5-hydroxymethyltransferase catalyzes oxygen isotopic exchange at the hydroxy group of the reactant 5-hydroxymethylcytidine 5′-monophosphate (Equation 5–202)[748] is evidence for the reversible addition of hydroxide anion or a molecule of water to the methylene group in the intermediate in the enzymatic mechanism (Equation 5–203), as well as the existence of the intermediate itself. The oxygen isotopic exchange arises from association of [5-^{16}O]-5-hydroxymethylcytidine 5′-monophosphate with the active site, dehydration to produce the intermediate, isotopic exchange of the molecule of $H_2{}^{16}O$ that was the leaving group for a molecule of $H_2{}^{18}O$, conversion of the intermediate to [5-^{18}O]-5-hydroxymethylcytidine 5′-monophosphate, and dissociation of [5-^{18}O]-5-hydroxymethylcytidine 5′-monophosphate into the solution. In this oxygen isotopic exchange, the reactant added is 5-hydroxymethylcytidine 5′-monophosphate, and the reactant omitted is 5,6,7,8-tetrahydrofolate. When 5-deazatetrahydrofolate, an inactive analogue of 5,6,7,8-tetrahydrofolate, is added to the reaction, oxygen isotopic exchange increases 26-fold, a fact that can be explained if 5-deazatetrahydrofolate produces an induced fit of the active site that aligns the catalytic groups more effectively.

Isotopic exchange into an analogue of a reactant that is incapable of participating in the complete enzymatic reaction resembles the strategy for isotopic exchange in the absence of one or more reactants because the use of the analogue prevents the reaction from proceeding beyond a particular step in the kinetic mechanism, as does the omission of one reactant. For example, 3-dehydroquinate synthase catalyzes a reaction in which a ketone is formed so that an elimination can occur[756]



(5–206)

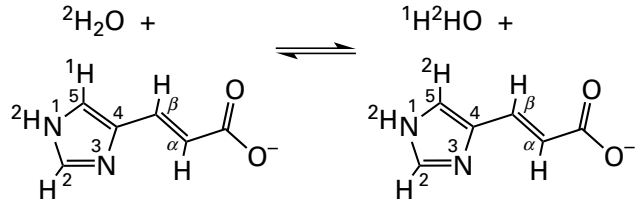
The enzyme requires only catalytic amounts of NAD^+ ($K_{mNAD} = 1\ \mu M$)[757] since NAD^+ is not a stoichiometric participant in the overall reaction and is regenerated in the last step of the mechanism. Chemical evidence for the requirement for intermediate ketone **5–152** is that the carbacyclic phosphonate **5–154**



which is an analogue of the substrate 3-deoxy-D-*arabino*-hept-2-ulosonate 7-phosphate, is oxidized to the corresponding ketone by the enzyme from *E. coli* at its carbon 4, which is in the analogous position to carbon 5 of the normal substrate. Isotopic evidence for removal of the hydron from carbon 6 of ketone **5–152** prior to the elimination is that that the enzyme in ^2H_2O catalyzes hydrogen isotopic exchange at carbon 6 of phosphonate **5–155**, which is also an analogue of 3-deoxy-D-*arabino*-hept-2-ulosonate 7-phosphate.[758] Analogue **5–155** is the phosphonate rather than the phosphate, so the forward reaction is blocked at the step in which elimination of phosphate would normally occur because the phospho oxygen has been replaced with a carbon, and there is no competition in the forward direction with the reversal of the reaction following removal of the hydron. Consequently, hydrogen isotopic exchange supports the conclusion that elimination of phosphate must take place in a step following removal of the hydron from carbon 6.

In the crystallographic molecular model of the active site of dehydroquinate synthase from *Aspergillus nidulans* (Equation 5–206) occupied by carbacyclic phosphonate **5–154**, the hydron on its carbon 5 is immediately adjacent (0.32 nm) to an oxygen on the phosphono group.[759] The other two oxygens of the phosphono group have the 6-ammonio groups of Lysine 152 and Lysine 356, respectively, as ligands. Most likely the hydrogen isotopic exchange in analogue **5–155** occurs by exchange of the hydron on the phosphono group in the analogue of intermediate enolate **5–153**, which has just been removed from intermediate **5–152**, for one of the six deuterons on these two lysines.

Isotopic exchange at initial rate is the isotopic exchange observed at an atom in one reactant when all the reactants and none of the products are present and the reaction is proceeding only in one direction. For example, urocanate hydratase (Figures 4–49 and 4–50) has a tightly bound, prosthetic NAD^+ at its active site, and the ultimate product of the reaction has been formally oxidized to an oxo group at carbon 5 of its imidazolyl group



(5–207)

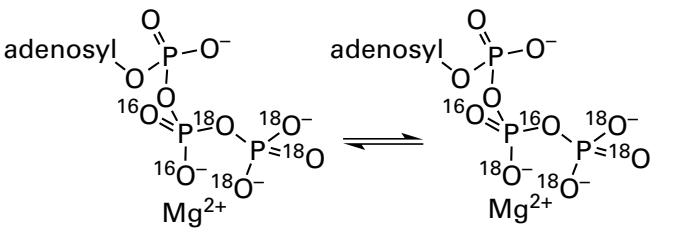
while being formally reduced at other carbons in the reactant. These facts raised the possibility that the hydrogen at carbon 5 was removed by this prosthetic NAD^+ as a hydride during the reaction. [5-^{1}H]Urocanate was mixed with the enzyme from *P. putida* in ^2H_2O. At various times, the reaction was stopped, and the concentrations of [5-^{1}H]urocanate and [5-^{2}H]urocanate were determined (Figure 5–15).[760] Although urocanate was continuously disappearing, [5-^{2}H]urocanate was being produced by hydrogen isotopic exchange of the hydron for a deuteron at a rate significantly in excess of the rate of the overall reaction, and it accumulated before it was in turn converted to product.

Because the hydrogens at carbon 4 of the nicotinamide in NADH are not acidic, the existence of this rapid hydrogen isotopic exchange is consistent with the proposed mechanism for the reaction (first two steps in Figure 4–49) in which the hydrogen at carbon 5 of urocanate becomes acidic during the reaction and is removed as a hydron by the carboxylato group of Aspartate 443 (Figure 4–50). The oxygen in this carboxylato group that removes the hydron is also in a hydrogen bond within a chain of molecules of water leading out of the active site, and the deuteron leaves the active site and enters this chain, to be replaced by a hydron already in the chain.[761] In this instance, the hydron removed is formally exchanging with a deuteron in the solution, but the isotopic exchange at Aspartic Acid 443 probably involves a deuteron already in the active site on a fixed molecule of water.

Positional isotopic exchange is the intramolecular exchange of one atom in a substrate with another atom, of the same element but a different isotope, in such a way that the product of the isotopic exchange is chemically identical to the reactant except that the two isotopes within the molecule have been interchanged. The interchange of the isotopically different atoms within the same molecule registers the fact that a reaction has occurred even though no otherwise apparent chemical change has taken place. For example, when $MgATP^{2-}$ containing **oxygen-18 in the bridging position** between the β and γ phosphorus atoms, as well as the other three positions on the γ phosphorus, was mixed with L-glutamate and ovine glutamine synthetase (previously Equation 3–405)

$$\text{L-glutamate} + NH_3 + MgATP^{2-} \rightleftharpoons MgADP^{-} + HOPO_3^{2-} + \text{L-glutamine} \qquad (5\text{–}208)$$

or glutamine synthetase from *E. coli*, in the absence of ammonia, the ^{18}O was found[762] to exchange to a nonbridging position on the β-phosphate of the $MgATP^{2-}$



(5–209)

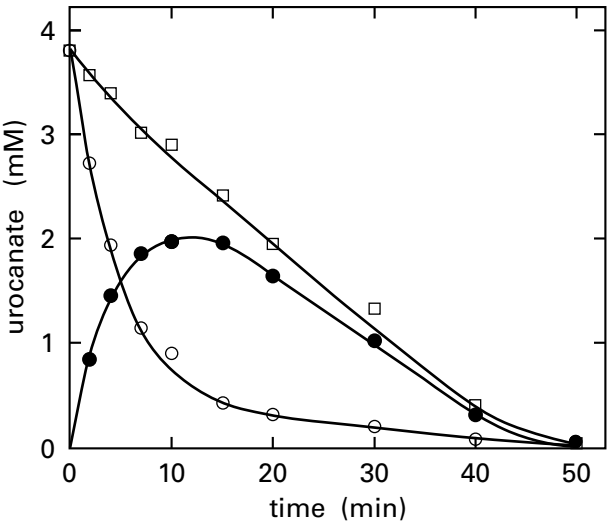


Figure 5–15: Isotopic exchange of hydrogen at carbon 5 of urocanate during the reaction catalyzed by urocanate hydratase from *P. putida*.[760] The reaction mixture (3 mL) contained 4 mM urocanate in ^2H_2O (99.9% deuterium) at p^{2}H 7.5 and 25 °C. The reaction was initiated with 0.4 mg of urocanate hydratase. The total concentration of urocanate (millimolar) was followed by its absorbance at 317 nm (□). Samples were removed at various intervals, quickly frozen, and lyophilized. The fraction of the remaining urocanate that had incorporated one deuterium at carbon 5 was assessed by gas chromatography followed by mass spectrometry. That the deuterium substitution was at carbon 5 was confirmed by nuclear magnetic resonance spectroscopy. From the fraction of urocanate that was deuterated and the total concentration of urocanate, the millimolar concentrations of [5-^{2}H]urocanate (●) and [5-^{1}H]urocanate (○) could be calculated. These concentrations are plotted as a function of the respective intervals (minutes).

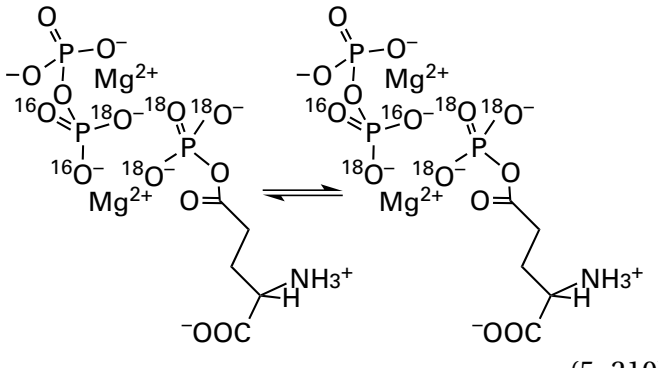
even though no other isotopic exchanges could be observed.

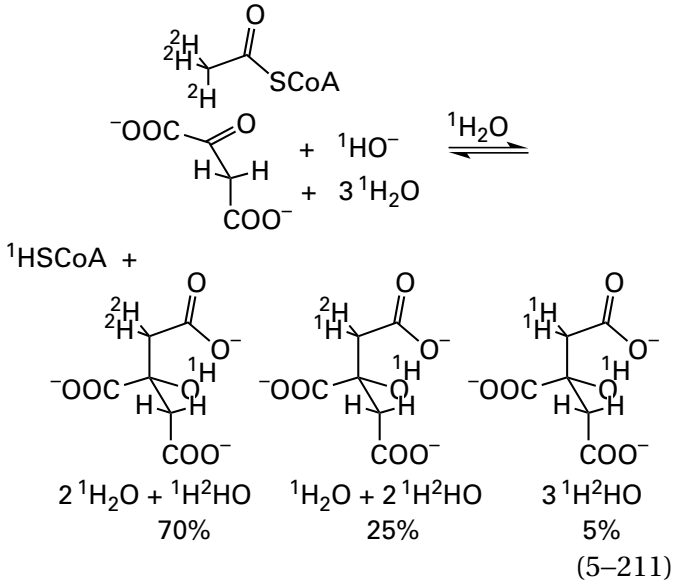
Three steps provide the explanation for this positional oxygen isotopic exchange. First, in the active site,[763] the γ-phosphate is transferred to the oxygen of L-glutamate to form L-γ-glutamyl phosphate. Second, the β-phosphate of $MgADP^-$, tightly held in the active site at other positions in its structure, rotates about the oxygen–phosphorus bond to interchange the oxygen-18 and an oxygen-16



(5–210)

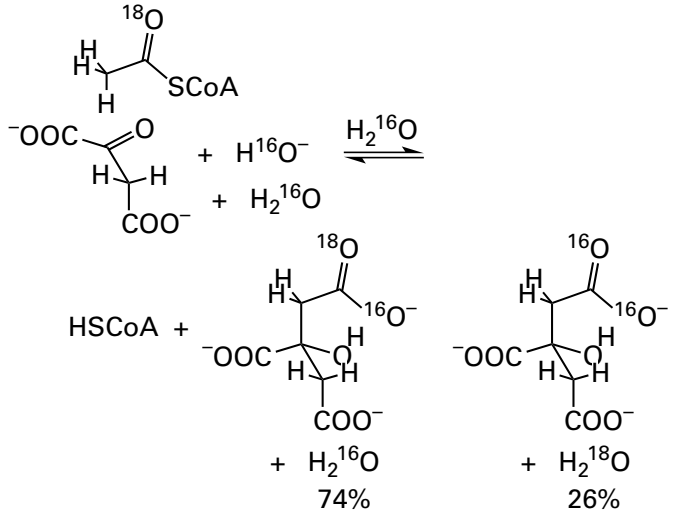
Third, the phospho group is transferred back from the L-glutamate to this oxygen-16 of the rotationally isomerized MgADP$^-$. This positional oxygen isotopic exchange can occur because the reaction cannot proceed beyond the complex of the active site with MgADP$^-$ and L-γ-glutamyl phosphate because no ammonia was added to the solution. When ammonia was added to permit the reaction to proceed forward, the rate of the positional oxygen isotopic exchange was diminished. In the absence of ammonia, the initial rate for the positional oxygen isotopic exchange was equal to the initial rate for the complete enzymatic reaction in the presence of ammonia, and this equality demonstrated the kinetic competence of the positional exchange. All these results are consistent with the existence of L-γ-glutamyl phosphate as an intermediate in the enzymatic reaction.

Intermediate isotopic exchange is hydrogen isotopic exchange or oxygen isotopic exchange observed at a position in one product as the reaction is proceeding in one direction, but the exchanged isotope is not an atom that would have been incorporated into the product from a stoichiometric hydron or a stoichiometric molecule of water during the normal course of the reaction.[764,765] Intermediate isotopic exchange can detect the **reversibility of intermediate steps** that occur after association of the reactant with the active site. During intermediate isotopic exchange, one reactant enters the active site. Isotopic exchange occurs while that reactant is reversibly converted to an intermediate, while an intermediate in the reaction is reversibly converted into another intermediate, or while the last intermediate is converted reversibly into product; and the product leaves the active site bearing the exchanged isotope. For example, intermediate hydrogen isotopic exchange could be observed in the reaction catalyzed by porcine citrate (*Si*)-synthase (see Equation 4–224)



(5–211)

When [$^2H_3$]acetyl-SCoA was used as a reactant in ^1H_2O, 0.35 atom of protium was incorporated at carbon 2 of the [2-^{2}H]citrate produced.[766] This **superstoichiometric incorporation** of protium was the result of hydrogen isotopic exchange at that carbon in an intermediate in the reaction. Furthermore, when [^{18}O]acetyl-SCoA was used as a reactant in $H_2{}^{16}O$, 0.26 atom of oxygen-16 beyond the one oxygen-16 stoichiometrically incorporated was found in the carboxylato group of citrate derived from the thioester of the citryl-SCoA that is the intermediate in this reaction



(5–212)

In the active site of citrate (*Si*)-synthase, the enolate of acetyl-SCoA is formed, and it adds in an aldol condensation to the carbonyl of oxaloacetate. The resulting citryl-SCoA is then hydrolyzed in the next step in the reaction. The intermediate hydrogen

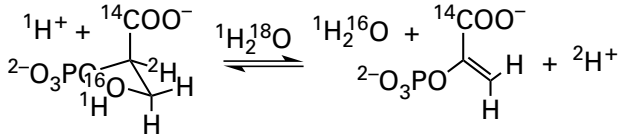
isotopic exchange (Equation 5–211) during the reaction catalyzed by porcine citrate (*Si*)-synthase occurs because the step in which the enolate of acetyl-SCoA is formed, before formation of the carbon–carbon bond in its nucleophilic addition to the carbonyl, is reversible. This step reverses after the deuteron on the carboxy group of Aspartic Acid 375 in the active site,[767] which removed the deuteron from [$^2H_3$]acetyl-SCoA, is exchanged for a proton, probably a proton on a nearby (0.27 nm)[768-770] molecule of water fixed in the active site. The enolate is protonated, once and sometimes twice, before citryl-SCoA is formed from that molecule of [$^2H_3$]acetyl-SCoA and then is turned into citrate and released as a product. The isotopic exchange of two or even three deuterons does not have to occur in consecutive steps while a molecule of acetyl-SCoA is bound in an active site. The singly labeled acetyl-SCoA can dissociate and then reassociate with a different active site between each exchange.

The intermediate oxygen isotopic exchange (Equation 5–212) occurs because the step during which [1-^{18}O]citryl-SCoA is hydrolyzed by $H_2{}^{16}O$ to [1-^{18}O,1-^{16}O]citrate, the major product, reverses after the carboxylato group of [1-^{18}O,1-^{16}O]citrate flips over in the active site. This reversal of the hydrolysis forms [1-^{16}O]citryl-SCoA, which is then hydrolyzed by another molecule of $H_2{}^{16}O$, but it must occur before citrate and HSCoA can be released as products. The molecule of $H_2{}^{16}O$ that is responsible for the both the first and the second hydrolysis of citryl-SCoA forms a hydrogen bond (0.32 nm) with a second molecule of $H_2{}^{16}O$ within the active site.[770] This second molecule of water, after exchanging with the molecule of $H_2{}^{18}O$ that dissociates during the reversal of the hydrolysis that forms [1-^{16}O]citryl-SCoA, could easily be responsible for all 26% of intermediate oxygen isotopic exchange that is observed. The fact that intermediate oxygen isotopic exchange is observed requires that hydrolysis of a thioester, which is exergonic in solution (–18 kJ mol^{-1}, Table 1–3) is nevertheless reversible in the active site.

For intermediate isotopic exchange to be observed, the atom in either the reactant or product on which the atom is being exchanged must be bound to **more than one of the type of atom** that is being substituted. In most cases, at least one of those equivalent atoms being substituted is a stoichiometric participant in the reaction. For example, the carbon atom on which the deuteriums were exchanged for protiums in the case of citrate (*Si*)-synthase has three equivalent hydrons on the methyl group in the reactant, and one of them is a silent stoichiometric product of the reaction. The carboxy carbon of the product, citrate, has two equivalent oxygens, one of which comes from the water that is a designated stoichiometric reactant and is therefore also silent. The distinction between isotopic exchange at initial rate and intermediate isotopic exchange is that the isotopic exchange that occurs into the intermediate is **registered in the product rather than in the reactant**. The intermediate isotopic exchanges of hydrogen and oxygen that occur with citrate (*Si*)-synthase, however, could also have been registered in the reactant acetyl-SCoA at initial rate if acetyl-SCoA is produced in the back reaction from the respective isotopically exchanged intermediate and dissociates from the enzyme at a great enough rate.

Isotopic exchange at equilibrium is the isotopic exchange within one reactant that is observed when all reactants and products of the enzymatic reaction are present in the solution at concentrations that satisfy the equation for the equilibrium constant. If the absolute molar concentrations of reactants and products present in solution are such that their ratio is equal to the equilibrium constant, the reaction does not cease; rather, the rate at which reactants are converted to products will simply be equal to the rate at which products are converted to reactants. This balance of rapid conversions is an important feature of the state of equilibrium that is often not stressed sufficiently, so the mistaken impression is often left that a reaction at equilibrium is quiescent. Actually, it is often at equilibrium that the most is happening. When appropriate isotopes are used, the rates of these otherwise hidden reactions contributing to this active interconversion of reactants and products can be determined.

For the reaction catalyzed by phosphopyruvate hydratase



(5–213)

the equilibrium constant between pH 6 and 8 is

$$\frac{[\text{phospho}\textit{enol}\text{pyruvate}]_{eq}}{[\text{2-phospho-D-glycerate}]_{eq}} = K_{eq} = 6.3 \qquad (5\text{–}214)$$

Equilibrium concentrations of phospho*enol*pyruvate (0.11 M) and 2-phospho-D-[2-^{2}H]glycerate (0.018 M), as well as a trace amount of 2-phospho-D-[1-^{14}C]glycerate, dissolved in $H_2{}^{18}O$ (isotopic labels in Equation 5–213), were mixed with phosphopyruvate hydratase from *O. cuniculus*. The trace amount of 2-phospho-D-[1-^{14}C]glycerate provided a radioactive label for 2-phospho-D-glycerate without diluting the 2-phospho-D-[2-^{2}H]glycerate. A trace amount of 2-phospho-D-[2-^{3}H]glycerate was also added to the first solution so that the exchange of protium for tritium in D-glycerate could be followed simultaneously. In this mixture, several isotopic exchanges could be monitored as a function of time.[749]

Because the concentrations of phospho*enol*pyruvate and 2-phospho-D-glycerate remained constant, appearance of phospho[1-^{14}C]*enol*pyruvate in the solution is the result of a **carbon isotopic exchange** at equilibrium

$$\begin{aligned}&\text{phospho[1-}^{12}\text{C]}\textit{enol}\text{pyruvate} + \\ &\quad \text{2-phospho-D-[1-}^{14}\text{C]glycerate} \rightleftharpoons \\ &\qquad \text{2-phospho-D-[1-}^{12}\text{C]glycerate} + \\ &\qquad\quad \text{phospho[1-}^{14}\text{C]}\textit{enol}\text{pyruvate}\end{aligned} \qquad (5\text{–}215)$$

This carbon isotopic exchange at equilibrium is accomplished in six steps: association of phospho[1-^{12}C]*enol*pyruvate with the active site; its conversion to 2-phospho-D-[1-^{12}C]glycerate; dissociation of this product; association of 2-phospho-D-[1-^{14}C]glycerate with the active site; its conversion to phospho-[1-^{14}C]*enol*pyruvate; and dissociation of this product. The same exchange can be accomplished by association of 2-phospho-D-[1-^{14}C]glycerate with the active site; its conversion to phospho[1-^{14}C]*enol*-pyruvate; dissociation of this product; association of phospho[1-^{12}C]*enol*pyruvate with the active site; its conversion to 2-phospho-D-[1-^{12}C]glycerate; and dissociation of this product.

In contrast to hydrogen isotopic exchange involving hydrons or oxygen isotopic exchange involving molecules of water, in the case of the carbon isotopic exchange observed with phosphopyruvate hydratase, there is **no ambiguity about the source of the exchanged isotope**—it must be a molecule of 2-phospho-D-[1-^{14}C]glycerate or a molecule of phospho[1-^{12}C]*enol*pyruvate from the solution. This certainty results from the fact that the carbon is an integral part of the substrates and remains in the intermediates as other transformations—removal of a hydron and dissociation of the leaving hydroxy group—occur at other locations. The carbon in this instance has to associate with the active site as a part of the reactant, remain in the body of the molecule as it is transformed into product, and then dissociate from the active site in the product. In other words, this isotopic exchange monitors the complete reaction. This sequence of events is a consequence of the fact that carbon-14 is neither in a hydron nor in a molecule of water, both of which are ubiquitous.

The appearance of oxygen-18 in 2-phospho-D-[3-^{18}O]glycerate is a direct measure of the **oxygen isotopic exchange**

$$\begin{aligned}&\text{2-phospho-D-[3-}^{16}\text{O]glycerate} + H_2{}^{18}O \rightleftharpoons \\ &\qquad H_2{}^{16}O + \text{2-phospho-D-[3-}^{18}\text{O]glycerate}\end{aligned} \qquad (5\text{–}216)$$

This oxygen isotopic exchange at equilibrium is accomplished in five steps: association of 2-phospho-D-[3-^{16}O]glycerate with the active site; breaking of the carbon–oxygen bond in 2-phospho-D-[3-^{16}O]glycerate on the active site to produce a molecule of $H_2{}^{16}O$ and an intermediate bound in the active site; isotopic exchange of that molecule of $H_2{}^{16}O$ for a molecule of $H_2{}^{18}O$; insertion of that molecule of $H_2{}^{18}O$ back into the intermediate still bound in the active site; and dissociation of 2-phospho-D-[3-^{18}O]glycerate from the active site.

There is a molecule of water, which must be $H_2{}^{18}O$ in the case where oxygen isotopic exchange is observed, in van der Waals contact (0.36 nm) with the 3-hydroxy group of 2-phospho-D-glycerate in the complex between this substrate and the active site and in a hydrogen bond (0.26 nm) with the other oxygen of the carboxy group of Glutamic Acid 211 that hydronates the leaving group (Figure 4–43).[155] This $H_2{}^{18}O$ could change places with the $H_2{}^{16}O$ that is the leaving group in the elimination catalyzed by the enzyme and could be responsible for some of the oxygen isotopic exchange that is observed, but there is probably some isotopic exchange of $H_2{}^{16}O$ with $H_2{}^{18}O$ in the solvent as well.

The appearance of $^{3}H_2{}^{18}O$ is a direct measure of the **hydrogen isotopic exchange**

$$\begin{aligned}&\text{2-phospho-D-[2-}^{3}\text{H]glycerate} + {}^{1}H_2{}^{18}O \rightleftharpoons \\ &\qquad {}^{3}H_2{}^{18}O + \text{2-phospho-D-[2-}^{1}\text{H]glycerate}\end{aligned} \qquad (5\text{–}217)$$

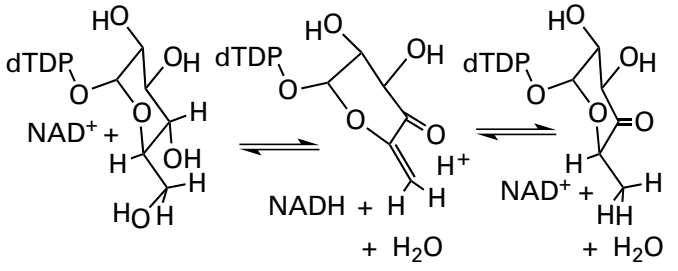
This hydrogen isotopic exchange at equilibrium is accomplished in five steps: association of 2-phospho-D-[2-^{3}H]glycerate with the active site; removal of the triton from carbon 2 of 2-phospho-D-[2-^{3}H]glycerate by the amino group of Lysine 345 (Figure 4–43); rotation of the ammonio group; addition of one of its two protons, or one of the two protons on the molecule of water on the Mg^{2+} to which the ammonio group is hydrogen-bonded, to carbon 2; and dissociation of 2-phospho-D-[2-^{1}H]glycerate.

The appearance of $^2H_2{}^{18}O$ is a direct measure of the hydrogen isotopic exchange

2-phospho-D-[2-^{2}H]glycerate + $^1H_2{}^{18}O$ $\rightleftharpoons$
$^2H_2{}^{18}O$ + 2-phospho-D-[2-^{1}H]glycerate

(5–218)

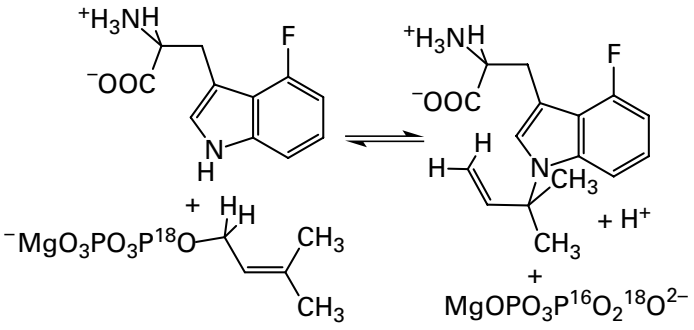
Site-directed mutation of the enzyme can reveal or accentuate an isotopic exchange. The enzyme dTDP-glucose 4,6-dehydratase catalyzes a reaction



(5–219)

similar to the one catalyzed by 3-dehydroquinate synthase (Equation 5–206), with the exception that NADH reduces the methylene group in the intermediate α,β-unsaturated ketone by adding a hydride to carbon 6 rather than adding a hydride to the carbonyl at carbon 4 to complete the reaction. The carboxy group of Aspartic Acid 135 in the active site of the enzyme from *E. coli* is responsible for hydronating the leaving hydroxy group at carbon 6.[771] In a mutant of the enzyme, in which Aspartate 135 is replaced by alanine, the catalytic constant is decreased by a factor of 220. Unlike the wild-type enzyme, the mutant catalyzes hydrogen isotopic exchange of a deuteron at carbon 5 of dTDP-D-glucose for a hydron.[772] The mutation has decreased elimination of the hydroxy group significantly so that removal of the hydron is able to reverse.

Just as in the case of site-directed mutation, using an **alternative reactant**, equivalent to mutating the normal reactant, can reveal an isotopic exchange catalyzed by an enzyme. For example, when 4-fluoro-L-tryptophan ($k_0\,K_{m,FTrp}{}^{-1}$ = 5 $mM^{-1}\,s^{-1}$) is used as a reactant in the reaction catalyzed by N^1-(1,1-dimethylallyl)tryptophan synthase



(5–220)

from *Salinispora arenicola*, a positional oxygen isotopic exchange at initial rate for the bridging oxygen-18 between the diphospho group and carbon 1 of the dimethylallyl diphosphate into a nonbridging position is observed even though this exchange is not observed when the natural reactant, L-tryptophan ($k_0\,K_{m,Trp}{}^{-1}$ = 26 $mM^{-1}\,s^{-1}$), is used.[773] This observation is evidence for the existence of a dimethylallyl carbenium ion as an intermediate in the enzymatic reaction (see Figure 1–26). Fluorination increases the pK_a of the indolyl nitrogen and slows its dehydronation sufficiently that dissociation of the diphosphate from the dimethylallyl diphosphate to form dimethylallyl carbenium ion is able to reverse.

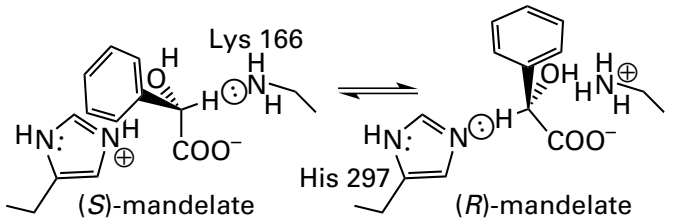
Crystallographic molecular models provide explanations for situations in which hydrogen isotopic exchange is not observed when it is expected. Whenever an example of hydrogen isotopic exchange was discussed in the foregoing definitions of the various types of isotopic exchange, the reservoir of hydrons in the respective crystallographic molecular model of the enzyme being discussed that is connected directly to the catalytic acid–base performing hydrogen isotopic exchange was described. The hydrons in these reservoirs are able to provide the hydrons that exchange with the one that the catalytic acid–base has removed from the reactant or intermediate, whether or not the active site is completely sequestered from the solution. Since such reservoirs should be common, it is actually situations in which hydrogen isotopic exchange is not observed that are unexpected, not situations in which it is. For example, fumarate hydratase (Equation 5–119) catalyzes a hydration homologous to that catalyzed by phosphopyruvate hydratase (Equation 5–213). There is ample, convincing evidence that dehydra-

tion of (*S*)-malate in the active site of this enzyme proceeds with initial removal of the hydron from carbon 3 to produce a *gem*-enediolate (Equation 5–118).[365] Hydrogen isotopic exchange, however, of tritium at carbon 3 of (2*S*,3*R*)-[3-^{3}H]malate with a hydron, catalyzed by porcine fumarate hydratase in ^1H_2O, is slower than isotopic exchange of carbon-14 in [1-^{14}C]fumarate into (*S*)-malate at equilibrium, even though isotopic exchange of the hydroxy group in unlabeled (*S*)-malate with oxygen-18 in $H_2{}^{18}O$ at equilibrium is more rapid than isotopic exchange of the carbon-14 in [1-^{14}C]fumarate into (*S*)-malate.[774]

These observations require that the triton removed from carbon 3 of (2*S*,3*R*)-[3-^{3}H]malate cannot exchange with any of the hydrons in the active site and also must dissociate from and reassociate with the active site more slowly than the product fumarate. That this counterintuitive conclusion is correct follows from the fact that porcine fumarate hydratase is able to transfer tritium from (2*S*,3*R*)-[1,4-$^{14}C_2$,3-^{3}H]malate to unlabeled [1,4-$^{12}C_2$]fumarate.[775] This capability requires that the product [1,4-$^{14}C_2$]fumarate must be able to dissociate from the enzyme and be replaced by unlabeled fumarate before the triton that was removed from (2*S*,3*R*)-[1,4-$^{14}C_2$,3-^{3}H]malate can dissociate from the active site. That this conclusion is correct also follows from the fact that the enzyme is able to transfer deuterium from (2*S*,3*R*)-[3-^{2}H]malate to 1,2-dicarboxyethyne, an analogue of fumarate, to produce [3-^{2}H]-2-hydroxyfumarate.[776] Nevertheless, the fact that the rate of dissociation of the tritium removed from (2*S*,3*R*)-[3-^{3}H]malate from the active site is accelerated by certain general bases added to the solution demonstrates that it is located on a catalytic acid–base.[775]

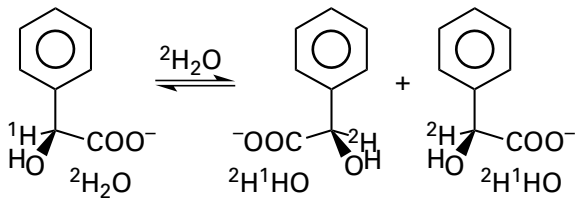
In the active site of porcine fumarate hydratase, tritium is removed from (2*S*,3*R*)-[3-^{3}H]malate by the oxido group of Serine C318 (Figure 4–27). This **oxido group is in an oxyanion hole** formed by two hydronated amido groups from the polypeptide backbone. The role of this oxyanion hole is to lower the pK_a of the hydroxy group so that its conjugate base, an oxido group, is present upon association of substrate and can remove the triton. Presumably, the protons on the amido groups do not participate in hydrogen isotopic exchange with the now-hydroxy group of Serine C318 because, to do so, one of them (pK_a = 17) would have to protonate the hydroxy group (pK_a = –3), which would be difficult, if not impossible, in the time available. Why the hydroxy group on the serine does not exchange with hydrons in the solution while fumarate dissociates and reassociates nevertheless remains puzzling.

Mandelate racemase (previously Equation 4–126)



(5–221)

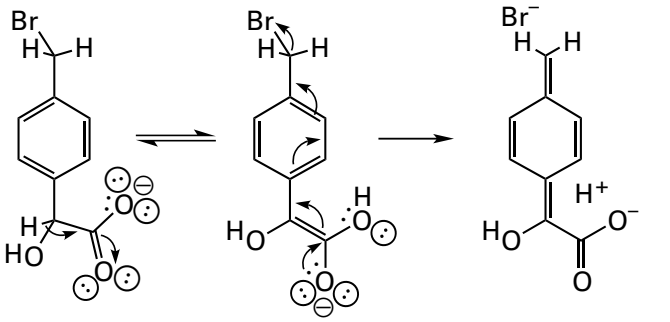
provides the clearest example of the effect that the identity of the catalytic acid–base and hydrogen bonds in which it participates has on an observed hydrogen isotopic exchange. In this instance, because the enzyme has only one reactant and one product, one reactant cannot be omitted to observe hydrogen isotopic exchange. Consequently, it was followed at initial rate before significant concentrations of product accumulated. When mandelate racemase from *P. putida* is catalyzing the epimerization of (*S*)-mandelate in ^2H_2O*



(5–222)

deuterium appears on the α carbon of the reactant, (*S*)-mandelate, as well as in the product, (*R*)-mandelate.[777] This observation has been presented as evidence that the enzyme proceeds through an intermediate *gem*-enediolate formed by direct removal of a hydron from the α carbon by a catalytic base in the active site. The observation that the enzyme catalyzes elimination of HBr from racemic 4-(bromomethyl)mandelate[778]

*Equal quantities of both (*S*)-mandelate and (*R*)-mandelate are produced, regardless of which enantiomer is the reactant, because the equilibrium constant for the epimerization must be 1.



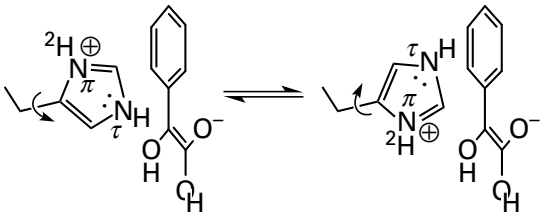
(5–223)

is also consistent with the participation of the *gem*-enediolate in the normal reaction.

While mandelate racemase catalyzes the hydrogen isotopic exchange (4%) of protium at the α carbon of (*S*)-mandelate for deuterium in ^2H_2O (Equation 5–222) during early stages (<5%) of the approach to equilibrium, no measurable hydrogen isotopic exchange (≤0.4%) is observed at the α carbon of (*R*)-mandelate when it is the reactant over the same extent of the approach to equilibrium.[779] One explanation for this difference between the two enantiomers is that there are two bases involved in the mechanism, one that removes the hydron from (*S*)-mandelate and another that removes the hydron from (*R*)-mandelate. If there were only one base, after it had removed a hydron from either enantiomer of mandelate, there would be the same *gem*-enediolate and the same conjugate acid. That acid should then participate in hydrogen isotopic exchange at the same initial rate in both cases, not just in the case of (*S*)-mandelate.

The bases in the active site of mandelate racemase from *P. putida* that remove the hydrons from (*S*)-mandelate and (*R*)-mandelate have been unambiguously assigned crystallographically as Lysine 166 and Histidine 297, respectively (Equation 5–221).[780,781] The 6-amino group of Lysine 166 has only two deuteriums on it whenever the active site associates with (*S*)-mandelate because it is the catalytic base. In addition, however, Lysine 166 is a participant in a cluster of hydrogen bonds in which the two oxygens of the carboxy group of Glutamate 221, a molecule of water, the hydroxy group of Serine 139, the 6-amino group of Lysine 164, and the 4-hydroxy group of Tyrosine 137 are participants. There are six hydrogen bonds in this cluster and, consequently, at least six deuterons. In any reversal of formation of the intermediate *gem*-dienolate from (*S*)-mandelate at the active site, deuterium would almost always be incorporated into the resulting (*S*)-mandelate, as is observed.

The τ nitrogen of the imidazolyl group of Histidine 297 removes the hydron from (*R*)-mandelate, and the π nitrogen–hydrogen of its imidazolyl group forms a hydrogen bond (0.28 nm) with an oxygen of the carboxy group of Aspartate 270. This hydrogen bond is responsible for holding the imidazolyl group in the proper orientation. In this distal hydrogen bond, there must be a deuteron, but the imidazolyl group of Histidine 297 would have to flip over to bring that deuteron into the vicinity of carbon 2 of the enolate. If it were to flip over, however, the nitrogen–deuterium bond of the π nitrogen would be in a completely different orientation and location, relative to the carbanionic carbon of the enolate, than the nitrogen–hydrogen bond of the τ nitrogen

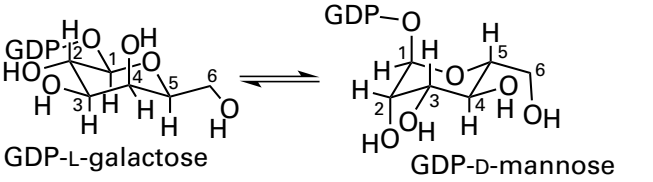


(5–224)

and it would be difficult, if not impossible, for the deuteron on the π nitrogen to deuteronate that carbon. Consequently, hydrogen isotopic exchange into (*R*)-mandelate should be significantly slower than that into (*S*)-mandelate, as is observed. This instance is an educational example of the fact that **the two nitrogens in the imidazolyl group of a histidine are not symmetrically arrayed**, as well as an illustration of the fact that hydrogens exchanged in most hydrogen isotopic exchanges are already within the active site.

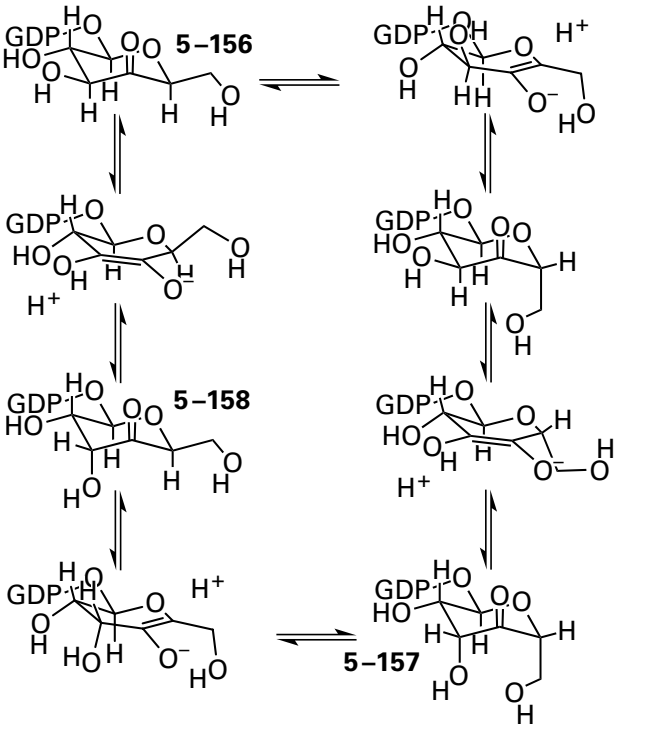
Hydrogen isotopic exchange is usually taken as evidence that a hydrogen is removed from the substrate as a hydron. For example, GDP-mannose 3,5-epimerase, which contains a prosthetic NAD^+ in its active site,[782] is able to interconvert GDP-L-galactose and GDP-D-mannose, a reaction requiring a double epimerization*

*Upon double epimerization, the more stable configuration of the ring changes due to the shift of the two substituents from equatorial to axial in the initial configuration.



(5–225)

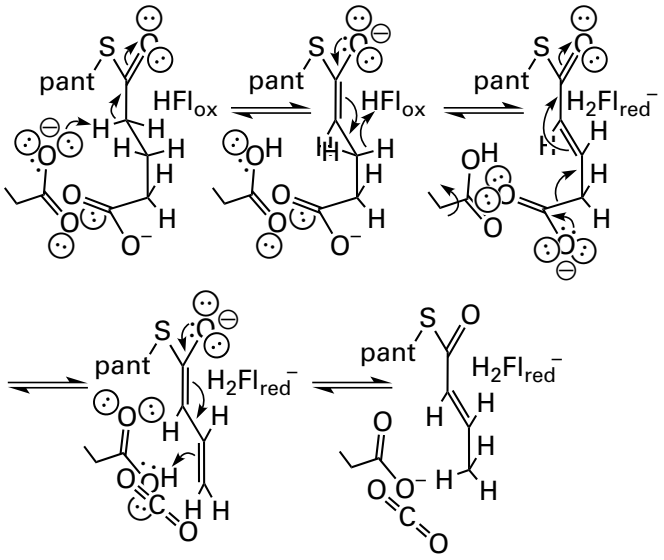
one at carbon 3 and one at carbon 5. Neither position in either substrate is acidic. When the reaction, however, is carried out with the enzyme from *Auxenochlorella pyrenoidosa* in ^3H_2O, tritium is incorporated into both GDP-L-galactose and GDP-D-mannose at both carbons 3 and 5.[783] The existence of these hydrogen isotopic exchanges suggests a mechanism in which GDP-4-oxo-4-dehydro-L-galactose (**5–156**) is formed from GDP-L-galactose and GDP-4-oxo-4-dehydro-D-mannose (**5–157**) is formed from GDP-D-mannose. The two adjacent epimerizations occur through the two respective enolates at carbon 3 and the two respective enolates at carbon 5



(5–226)

formed by removals of hydrons from the respective carbons α to the respective oxo group. Because the percentage of tritium incorporated into the two substrates at carbon 3 was the same as that incorporated into carbon 5, the hydrogen isotopic exchange provides no indication of a preferential order for the double epimerizations, forward and reverse. On the path to the left, the hydron on carbon 3 of **5–156** is removed first and the hydron on carbon 5 of **5–157** is removed first. On the path to the right, the hydron on carbon 5 of **5–156** is removed first and the hydron on carbon 3 of **5–157** is removed first. One product at equilibrium, however, when the reaction is catalyzed by GDP-mannose 3,5-epimerase from *A. thaliana* (72% identity; 0.5 gap percent), is GDP-L-gulose, the monosaccharide that is the product of reduction of GDP-4-oxo-4-dehydro-L-gulose (**5–158**).[784] This observation suggests that, at least in the case of this species, the left path in Equation 5–226 predominates.

The existence of hydrogen isotopic exchange, however, does not necessarily demonstrate that a hydrogen was initially removed as a hydron. During the reaction catalyzed by the flavoenzyme glutaryl-CoA dehydrogenase (ETF) (Equation 5–64) from *P. fluorescens* with glutarylpantetheine as the reactant in ^2H_2O, hydrogen isotopic exchange of protium for deuterium at carbon 3 of glutarylpantetheine is observed.[785] The first step in this reaction is removal of a hydron from carbon 2 of the reactant to produce the enolate with its oxyanion sitting in an oxyanion hole.[249] The enolate is then oxidized to the olefin by flavin



(5–227)

During this second step, the hydrogen on carbon 3 is probably transferred to nitrogen 5 of the oxidized flavin (HFl_{ox}) as a hydride. On nitrogen 5 of the flavin, the hydride becomes acidic and susceptible to isotopic exchange, probably with the deuterons on the deuteroxy group of Threonine 172 that forms a hydrogen bond with nitrogen 5 (0.28 nm) or the molecule of ^2H_2O that is in a hydrogen bond

(0.24 nm) with that deuteroxy group.[249] This example illustrates a feature peculiar to flavin, which is the ability to convert a hydride into a hydron.

Isotopic exchange in the absence of one or more reactants, isotopic exchange into an analogue of a reactant, isotopic exchange at initial rate, positional isotopic exchange, and intermediate isotopic exchange usually provide information about the existence of intermediates in the enzymatic reaction. The isotopic exchanges observed with fructose-bisphosphate aldolase, deoxycytidylate 5-hydroxymethyltransferase, 3-dehydroquinate synthase, urocanate hydratase, glutamine synthetase, and citrate (*Si*)-synthase are examples of this ability.

In the absence of the appropriate transfer RNA but the presence of the appropriate amino acid, amino acid—tRNA ligases catalyze **phosphorus isotopic exchange**[786]

$$Mg[^{32}P]OPO_3PO_3^{2-} + Mg[^{31}P]ATP^{2-} \rightleftharpoons Mg[^{32}P]ATP^{2-} + Mg[^{31}P]OPO_3PO_3^{2-} \quad (5\text{–}228)$$

It was the existence of this phosphorus isotopic exchange in the absence of a reactant in leucine—tRNA ligase from *E. coli* that led to the identification of the **amino acid adenylates**[787] that are the central intermediates in these fundamental enzymatic nucleophilic substitutions.

Pyruvate carboxylase catalyzes the carboxylation of pyruvate (previously Equation 1–144)

$$\text{pyruvate} + HOCO_2^- + MgATP^{2-} \rightleftharpoons HOPO_3^{2-} + MgADP^- + H^+ + \text{oxaloacetate} \quad (5\text{–}229)$$

Consistent with the existence of ***N*-carboxybiotin** as the central intermediate in this carboxylation (Figure 1–29), both the enzyme from *G. gallus*[788] and the enzyme from *R. norvegicus*[789] catalyze the carbon isotopic exchange

$$Mg[^{12}C]ATP^{2-} + Mg[^{14}C]ADP^- \rightleftharpoons Mg[^{12}C]ADP^- + Mg[^{14}C]ATP^{2-} \quad (5\text{–}230)$$

that requires addition of bicarbonate[788,789] but proceeds in the absence of pyruvate. Unfortunately, this carbon isotopic exchange in the absence of pyruvate is eliminated by removal of biotin from the active site,[790] so it could not be determined if the exchange results from reversal of the first step in the phosphorylation of bicarbonate by $MgATP^{2-}$

$$E{\cdot}MgATP^{2-}{\cdot}HCO_3^-{\cdot}\text{biotin} \rightleftharpoons E{\cdot}MgADP^-{\cdot}HOPO_3CO_2^{2-}{\cdot}\text{biotin} \rightleftharpoons E{\cdot}MgADP^-{\cdot}HOPO_3^{2-}{\cdot}\textit{N}\text{-carboxybiotin} + H^+ \quad (5\text{–}231)$$

a result that would provide evidence for carboxyphosphate as an intermediate. In the absence of HCO_3^-, $MgATP^{2-}$, $MgADP^-$, and $HOPO_3^{2-}$, the enzyme catalyzes the carbon isotopic exchange

$$[3\text{-}^{14}C]\text{pyruvate} + [3\text{-}^{12}C]\text{oxaloacetate} \rightleftharpoons [3\text{-}^{14}C]\text{oxaloacetate} + [3\text{-}^{12}C]\text{pyruvate} \quad (5\text{–}232)$$

that results from reversible formation of the intermediate, *N*-carboxybiotin

$$E{\cdot}\text{oxaloacetate}{\cdot}\text{biotin} \rightleftharpoons E{\cdot}\text{pyruvate}{\cdot}\textit{N}\text{-carboxybiotin} \quad (5\text{–}233)$$

The design of these experiments was based on similar isotopic exchanges that had been observed with porcine propionyl-CoA carboxylase[791] and methylcrotonyl-CoA carboxylase from *Mycobacterium* and *Achromobacter*.[792]

Pyruvate, phosphate dikinase from *P. freudenreichii* catalyzes the phosphorylation of phosphate by the γ-phospho group of $MgATP^{2-}$ and then the phosphorylation of pyruvate by the β-phospho group of $MgATP^{2-}$ (previously Equation 3–500)

$$MgATP^{2-} + HOPO_3^{2-} + \text{pyruvate} \rightleftharpoons 2\,H^+ + AMP^{2-} + MgOPO_3PO_3^{2-} + \text{phospho}\textit{enol}\text{pyruvate} \quad (5\text{–}234)$$

The enzyme catalyzes the carbon isotopic exchange[793]

$$Mg[^{12}C]ATP^{2-} + [^{14}C]AMP^{2-} \rightleftharpoons [^{12}C]AMP^{2-} + Mg[^{14}C]ATP^{2-} \quad (5\text{–}235)$$

in the absence of all four of the other substrates. It catalyzes the phosphorus isotopic exchange

$$[^{32}P]HOPO_3^{2-} + Mg[^{31}P]OPO_3PO_3^{2-} \rightleftharpoons Mg[^{32}P]OPO_3PO_3^{2-} + [^{31}P]HOPO_3^{2-} \quad (5\text{–}236)$$

in the presence of $MgATP^{2-}$ but the absence of the three other substrates. It catalyzes the carbon isotopic exchange

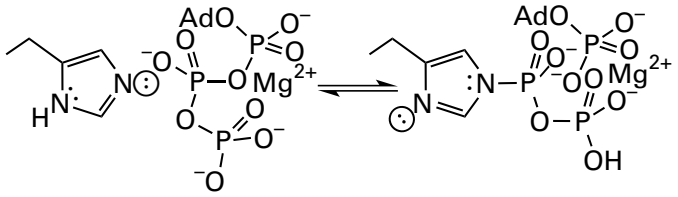
$$[^{14}C]\text{pyruvate} + \text{phospho}[^{12}C]\textit{enol}\text{pyruvate} \rightleftharpoons \text{phospho}[^{14}C]\textit{enol}\text{pyruvate} + [^{12}C]\text{pyruvate} \quad (5\text{–}237)$$

in the absence of all four of the other substrates.

A kinetic mechanism[794,795] that is consistent with all these isotopic exchanges in the absence of one or more substrates has been proposed that involves a diphosphorylated intermediate[796]

$$EH + MgATP^{2-} \rightleftharpoons E\text{-}PO_3PO_3^{3-}\cdot Mg^{2+} + H^+ + AMP^{2-} \quad (5\text{–}238)$$

as the first chemical step in the direction written (Equation 5-234). This first step by itself explains the carbon isotopic exchange of Equation 5–235. The covalent intermediate $E\text{-}PO_3PO_3Mg^-$ is a **diphosphoimidazolyl group**[154,797] on Histidine 453 (previously Equation 3–503)



(5–239)

The diphosphorylated covalent intermediate first phosphorylates phosphate (see Equation 3–502)

$$E\text{-}PO_3PO_3^{3-}\cdot Mg^{2+} + HOPO_3^{2-} \rightleftharpoons E\text{-}PO_3^{2-} + MgOPO_3PO_3^{2-} + H^+ \quad (5\text{–}240)$$

to produce magnesium diphosphate. This second step explains the phosphorus isotopic exchange of Equation 5–236 and its requirement for $MgATP^{2-}$, which is necessary to produce the diphosphoimidazolyl group. The resulting phosphoimidazolyl intermediate, $E\text{-}PO_3^{2-}$, then phosphorylates the enolate of pyruvate (see Equation 3–501)

$$E\text{-}PO_3^{2-} + \text{pyruvate} \rightleftharpoons EH + \text{phospho}\textit{enol}\text{pyruvate} \quad (5\text{–}241)$$

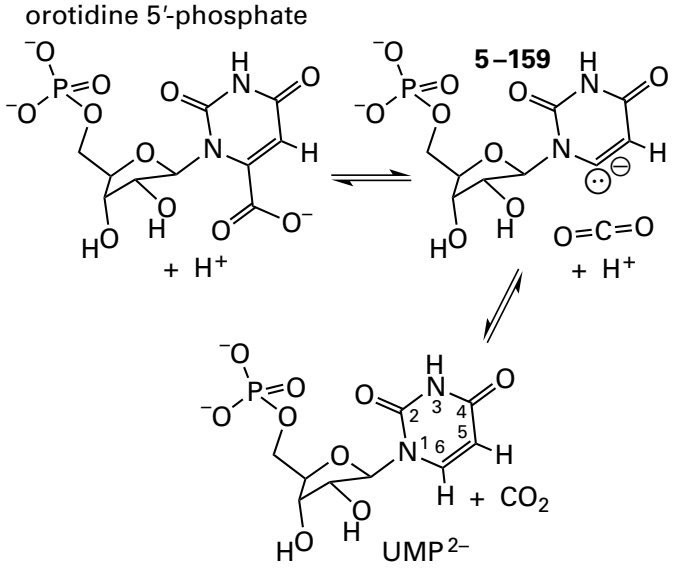
This third step by itself explains the carbon isotopic exchange of Equation 5–237, and the fact that it occurs in the absence of any other substrates.

Pyruvate, phosphate dikinase from *Clostridium symbiosum* (Equation 5–234) also catalyzes the positional oxygen isotopic exchange of oxygen-18 from the $\alpha\beta$-bridging position in $Mg[\alpha\beta\text{-}^{18}O,\beta,\beta\text{-}^{18}O_2]ATP^{2-}$ to a nonbridging position on the α-phospho group. This positional oxygen isotopic exchange[794] produces $Mg[\alpha\text{-}^{18}O,\ \beta,\beta\text{-}^{18}O_2]ATP^{2-}$. Its existence is also consistent with the involvement of a covalent diphospho intermediate. The fact that this positional oxygen isotopic exchange is almost completely dependent on the presence of $HOPO_3^{2-}$ suggests that the active site in this species must close around both $MgATP^{2-}$ and $HOPO_3^{2-}$ before the covalent diphospho intermediate can form (Equation 5–238). The same positional isotopic exchange within $MgATP^{2-}$ is observed during the reaction catalyzed by glutamine kinase

$$MgATP^{2-} + \text{L-glutamine} + H_2O \rightleftharpoons N^5\text{-phospho-L-glutamine} + Mg^{2+} + HOPO_3^{2-} + AMP^{2-} + 2\,H^+ \quad (5\text{–}242)$$

from *Campylobacter jejuni*, which also has a diphosphoimidazolyl group as a covalent intermediate.[798] The diphosphoimidazolyl intermediate phosphorylates a molecule of water to produce phosphate, and the resulting phosphoimidazolyl group phosphorylates the nitrogen of the carbamoyl group of L-glutamine rather than the oxygen of *enol*pyruvate.

Orotidine-5′-phosphate decarboxylase catalyzes the exchange of carbon dioxide, a Lewis acid, for a hydron, a Brønsted acid[799]



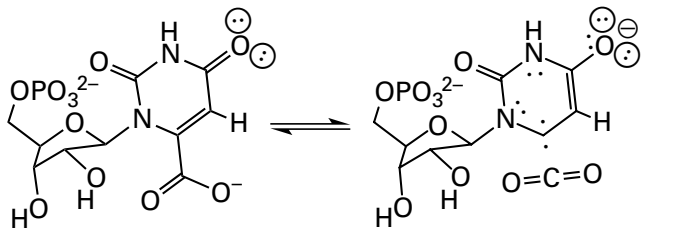
(5–243)

The strongest evidence for the existence of **carbanionic intermediate 5–159** is that, in ^2H_2O and in the absence of CO_2, the enzyme from *S. cerevisiae* catalyzes hydrogen isotopic exchange[800] of a deuteron for the hydron on carbon 6 of UMP^{2-}. The catalytic base in the active site of the enzyme from *Methanothermobacter thermoautotrophicus* that is responsible for removing the hydron from carbon 6 of UMP during this hydrogen isotopic exchange is Lysine 72.[801,802] The 6-amino group of Lysine 72 is in a hydrogen-bonded cluster in which the two oxygens of the carboxy group of Aspartate 70, the two oxygens of the carboxy group of Aspartate 75, the amino group of Lysine 42, and the two hydroxy groups on the ribosyl group of orotidine 5′-phosphate are participants. There are five hydrogen bonds in this cluster and, consequently at least five deuterons. The 6-amino group of Lysine 72 removes the hydron on carbon 6 of [6-^{1}H]UMP^{2-}, the hydron on the ammonio group can exchange for a deuteron in the cluster, and the deuteron on the ammonio group deuteronates carbanionic intermediate **5–159** to form [6-^{2}H]UMP^{2-}.

Additional evidence for the existence of carbanionic intermediate **5–159** comes from experiments with orotidine-5′-phosphate decarboxylase from *S. cerevisiae*. When the complete enzymatic reaction is run in a 1:1 mixture of H_2O to D_2O, the rate at which a deuteron is incorporated at carbon 6 of the product UMP^{2-} is equal to the rate for incorporation of protium, as would be expected if a base considerably more basic than hydroxide were an intermediate in the reaction.[803] A strongly basic carbanion, such as carbanionic intermediate **5–159**, would not discriminate between removing a hydron from the catalytic ammonio group of the lysine and removing a deuteron. When the hydrogen on carbon 5 of UMP^{2-} is replaced with a fluorine to give 5-fluoro-UMP^{2-}, the initial rate constant for hydrogen isotopic exchange[800,804] increases from 1.2×10^{-5} s^{-1} (0.04 h^{-1}) to 0.04 s^{-1}. This increase is consistent with the conclusion that the normal mechanism includes carbanionic intermediate **5–159**, which would be stabilized by the electron withdrawal of the adjacent fluorine. Finally, when the hydrogen on carbon 5 of the orotyl group in 1-(*β*-D-erythrofuranosyl)orotic acid (EO), a poor alternative reactant (k_{EO} = 0.026 M^{-1} s^{-1}), is replaced with a fluorine to give 1-(*β*-D-erythrofuranosyl)-5-fluoroorotic acid (FEO), the specificity constant (k_{FEO} = 10 M^{-1} s^{-1}) for the decarboxylation increases significantly.[805] This result is also consistent with the electron withdrawal of fluorine stabilizing a carbanionic intermediate in the orotyl group. There is, however, still the difficulty that the hydrogen isotopic exchange is far slower than the catalytic constant (20 s^{-1} at 25 °C) for the decarboxylation.[806] The equilibrium constant for the decarboxylation might provide an explanation of this disparity by providing estimates of the intrinsic rate constant for removal of the hydrogen from UMP^{2-} during the carboxylation catalyzed by the enzyme.

The intermediate carbanion **5–159**, if it exists, is one of the few carbanionic intermediates in an enzymatic reaction that is **not an enolate**, a fact that has contributed to the reluctance to accept its existence. The pK_a of UMP at carbon 6 while it is in the active site of the enzyme has been estimated from the rate of hydrogen isotopic exchange at carbon 6 to be less than or equal to 22.[800] The pK_a of the hydrogen on carbon 6 of UMP in solution is 34,[807] which is consistent with lack of conjugation of the lone pair of electrons in carbanion **5–159** with anything that can withdraw its electron density in the unsubstituted orotyl group. Its inability to conjugate with anything results from the fact that the lone pair of electrons is orthogonal to the π molecular orbital system of the orotyl group. Consequently, the enzyme would be able to stabilize the carbanion by a factor of 10^{12} or 68 kJ mol^{-1}, if the estimate is accurate.

Although intermediate carbanion **5–159** is a strong base and consequently difficult to form, it has been pointed out that it may be the case that decarboxylation produces the carbene



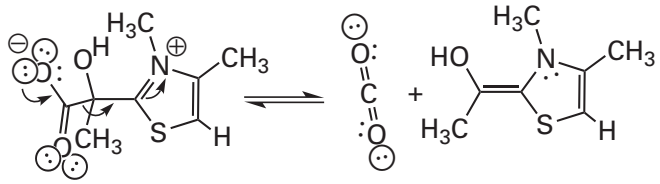
(5–244)

rather than the carbanion. The carbene should be more stable than the carbanion,[808] but its formation would require an intersystem crossing, which may not be kinetically competent. Intersystem crossing would be required both during formation of the carbene and in the transformation of the carbene into the carbanion, either before or during the hydronation. If this **intermediate carbene** can be formed in the active site, it should be an oxyanion. The nitrogen–hydrogen bond of the amido group of Serine 154 in the polypeptide backbone of orotidine-5′-phosphate decarboxylase from *S. cerevisiae* forms a hydrogen bond (0.29 nm) with the oxygen of the carbonyl group in the crystallographic molecular model of the active site occupied by 6-hydroxyuridine 5′-phosphate.[799] When the homologous amido group in orotidine-5′-phosphate decarboxylase from *Methanothermobacter thermautotrophicus* (24% identity; 4.4 gap percent) is chemically mutated to an ester oxygen,[809] the value for $k_0\,K_{m,OMP}{}^{-1}$ decreases by a factor of 75.

Hydronation of the acyl oxygen at carbon 2 in orotidine 5′-phosphate should increase[810,811] its rate of decarboxylation by a factor of 10^8. In a crystallographic molecular model of the active site of the enzyme from *M. thermautotrophicus* occupied by 6-aza-UMP, an analogue[812] of carbanionic intermediate **5–159**, the amido nitrogen in the carbamoyl group of Glutamine 185 forms a hydrogen bond (0.27 nm) with the acyl oxygen on carbon 2 of 6-aza-UMP.[802] This hydrogen bond could explain in part, but only in small part, the stabilization of intermediate carbanionic intermediate **5–159** by the active site.

Another contributor to the stabilization of carbanionic intermediate **5–159,** relative to the substrate orotidine 5′-phosphate, is the carboxylato group of Aspartate 70 in orotidine-5′-phosphate decarboxylase from *M. thermautotrophicus*, which is immediately adjacent to the carboxylato group of orotidine 5′-phosphate when it is bound to the active site. The carboxylato group of the aspartate should destabilize orotidine 5′-monophosphate by electrostatic repulsion relative to carbanionic intermediate **5–159,** in which the anion is farther away.[801,813] When the homologous aspartate, Aspartate 91, in the enzyme from *S. cerevisiae* is mutated to alanine,[814] the catalytic constant decreases by a factor of greater than 10^5, When the homologous aspartate, Aspartate 70, in the enzyme from *M. thermautotrophicus* is mutated to glycine, the rate constant $k_0\,(K_{mOMP})^{-1}$ for decarboxylation of orotidine 5′-phosphate (OMP)[802] decreases by a factor of 10^4 while the rate constant for isotopic exchange of the hydrogen on carbon 6 of 5-fluoro-UMP catalyzed by unmutated Lysine 72, which does not involve the carboxy group, is unchanged.

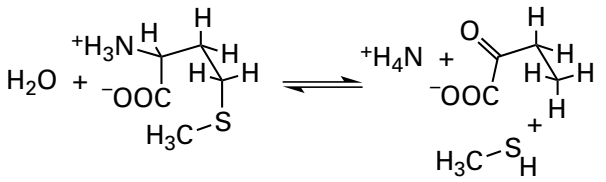
Finally, in the crystallographic molecular model[815] of a complex between orotidine-5′-phosphate decarboxylase from *E. coli* and 6-hydroxy-UMP$^-$ and the crystallographic molecular model[802] of a complex between orotidine-5′-phosphate decarboxylase from *M. thermautotrophicus* and 5,6-dihydro-UMP, the respective uracilyl groups are surrounded by hydrophobic amino acids, which form a hydrophobic pocket similar to that found in the active sites of other decarboxylases.[816] When these side chains are mutated in turn, decreases in the rate constant $k_0\,(K_{mOMP})^{-1}$ of 10–400 are observed.[817] These decreases recall the observation that decarboxylation of 2-(1′-carboxy-1′-hydroxyethyl)-3,4-dimethylthiazolium (previously Equation 2–54)



(5–245)

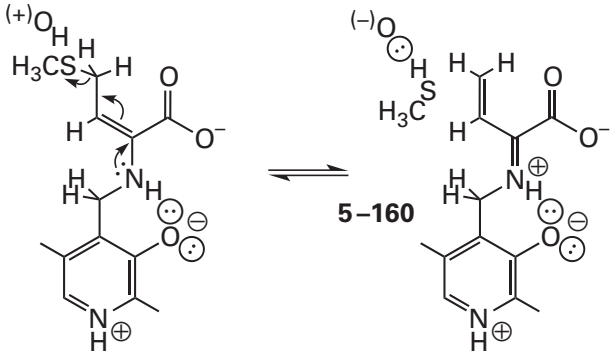
occurs about 10^5 times more rapidly in ethanol than in water.[818] The role of these hydrophobic amino acids in catalysis is supported by the fact that the rate of decarboxylation of 1-methylorotate, a model compound for orotidine 5′-monophosphate, increases 6000-fold when the decarboxylation occurs in tetrahydrofuran or dioxane rather than in water.[819]

Methionine γ-lyase uses pyridoxal 5′-phosphate as a prosthetic group to catalyze the elimination



(5–246)

The reaction is based on the ability of the pyridoxal phosphate to project a π molecular orbital system over the carbon skeleton of L-methionine until it is adjacent to the methylsulfanyl group and to provide push to the leaving group, methanethiol (see Equation 4–259)[820]



(5–247)

The ultimate intermediate in elimination of the methanethiol is ***N*-(5′-phosphopyridoxyl)-1-carboxyprop-2-enimine (5–160).**

The **individual steps in the expansion of this π molecular orbital system** and the sequence of intermediates could be followed by hydrogen isotopic exchange at initial rate. L-Methionine (100 mM) was mixed with methionine γ-lyase (2.4 μM) from *P. putida* in ^2H_2O, and the α-hydrogen and β-hydrogens on the L-methionine in the solution were monitored by nuclear magnetic resonance spectroscopy. The initial rate at which the α-hydrogen of L-methionine was replaced by deuterium was more rapid than the initial rate at which one of the two β-hydrogens was replaced by deuterium, and formation of the products, 2-oxobutanoate and methanethiol, was much slower than both hydrogen isotopic exchanges (Figure 5–16).[821] This hierarchy provides evidence for sequential formation of the three intermediates—the quinonoid, *N*-(5′-phosphopyridoxyl)imine, and *N*-(5′-phosphopyridoxyl)enamine

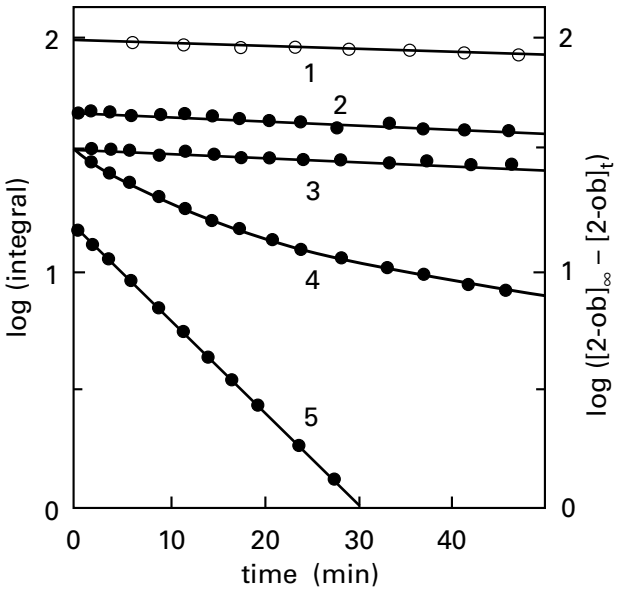


Figure 5–16: Isotopic exchange of hydrogens on the α and β carbons of L-methionine, as well as loss of methanethiol during the overall reaction, for the enzymatic reaction catalyzed by methionine γ-lyase from *P. putida*.[821] A solution (0.5 mL) was prepared at p^{2}H 8.6 and 28 °C that contained 100 mM L-methionine in ^2H_2O (99.8% isotopic enrichment). The reaction was initiated by adding 0.8 nmol of active sites of methionine γ-lyase, and the solution was placed in a nuclear magnetic resonance spectrometer. At various intervals, spectra were recorded. Amplitudes of the absorptions in spectra from the α-hydrogen (curve 5), the β-hydrogens (curve 4), the γ-hydrogens (curve 3), and the *S*-methyl hydrogens (curve 2) were determined by integration of the respective peaks on each spectrum. The common logarithms of these integrals are plotted (●) as a function of the intervals (minutes) that had elapsed from initiation of the reaction to the time at which each peak was recorded. The two β-hydrogens exchange at different rates, and this heterogeneity accounts for the nonlinear behavior of their absorption. At various intervals, samples were withdrawn and quenched, and the appearance of 2-oxobutanoate was followed by reacting the ketone with 3-methyl-2-benzothiozolone. The disappearance of L-methionine as a result of the enzymatic reaction was assumed to be equal to the difference between the concentration (millimolar) of 2-oxobutanoate (2-ob) at infinite time ($[2\text{-ob}]_\infty$) and its concentration at any particular time ($[2\text{-ob}]_t$). The common logarithms of these differences (○) are plotted as a function of time (minutes). Because the equilibrium for the enzymatic reaction favors the products (methanethiol, NH_4^+, and 2-oxobutanoate), the yield of 2-oxobutanoate at the completion of the reaction was close to 100 mM. The fact that absorptions from the γ-hydrogens and the *S*-methyl hydrogens decrease at the same rate as the concentration of reactant indicates that no isotopic exchange takes place at these positions.

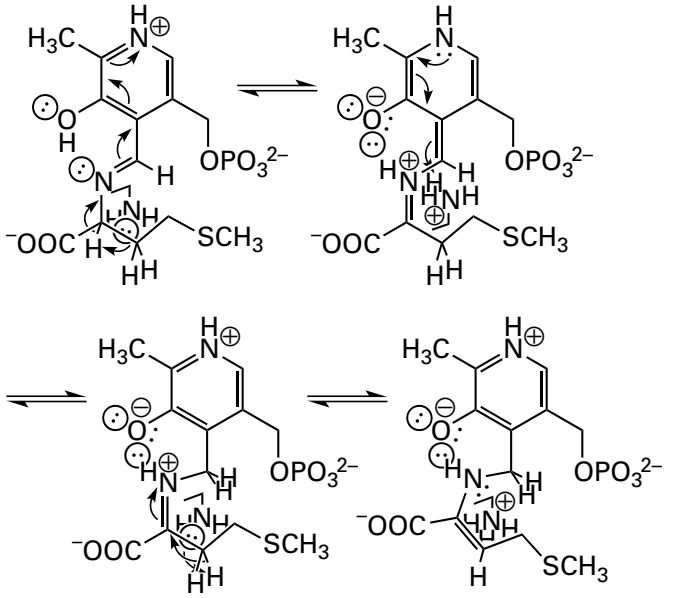


(5–248)

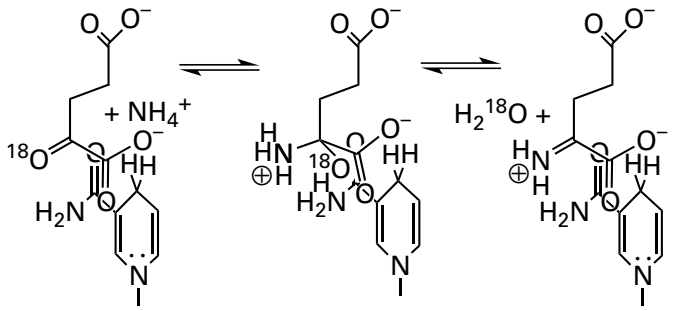
in the enzymatic reaction before elimination of methanethiol (Equation 5–247). The catalytic base that removes the hydrons from the α carbon, hydronating carbon 4′ of the 5′-phosphopyridoxyl group, and the β carbon and that is responsible for the hydrogen isotopic exchanges is the 6-amino group of Lysine 211, which also forms the internal pyridoximine.[820,822] Between removal of each hydron and the addition of each deuteron to the intermediates, the amino group of Lysine 211 is in a cluster of hydrogen bonds in which the 4-hydroxy group of Tyrosine 59, an oxygen from the phosphate of the pyridoxal 5′-phosphate, and the hydroxy group of Serine 340 are participants. This cluster has three hydrogen bonds and, consequently, contains at least three deuterons, and it is probably the immediate source of the deuterons incorporated by hydrogen isotopic exchange at initial rate into the L-methionine.

Bovine glutamate dehydrogenase [NAD(P)$^+$] catalyzes a reaction with three reactants and three products (previously Equation 3–319)[247,823]

$$\text{NAD(P)H} + \text{2-oxoglutarate} + \text{NH}_4^+ + \text{H}^+ \rightleftharpoons \text{H}_2\text{O} + \text{L-glutamate} + \text{NAD(P)}^+$$

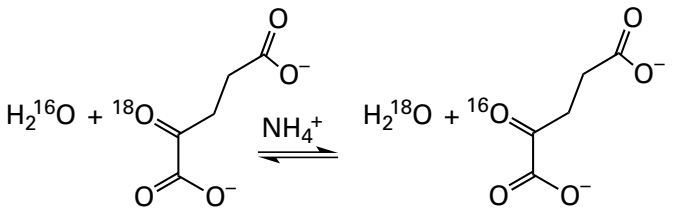
(5–249)

The intermediate after the first two chemical steps should be the iminium of 2-oxoglutarate



(5–250)

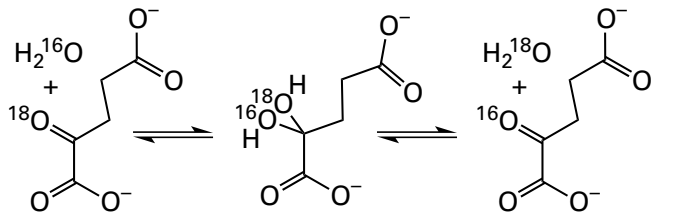
along with a molecule of water that should be able to participate in oxygen isotopic exchange. The molecule of water of the other isotope with which it exchanges should be able to hydrolyze the imine back to ammonia and 2-oxoglutarate. Enzymatically catalyzed oxygen isotopic exchange, however



(5–251)

could not be observed in the absence of NADPH, which should be unnecessary for oxygen isotopic exchange.[824]

The following strategy was designed to reveal oxygen isotopic exchange at initial rate during a period in which the forward reaction dominates. The enzyme (250 μM in active sites) was mixed with [2-^{18}O]-2-oxoglutarate (0.3 mM, 58% isotopic enrichment), NADPH (1.1 mM), and amounts of ammonium less than the concentration of active sites (<200 μM), so that when the reaction had reached equilibrium, most of the 2-oxoglutarate would still remain in solution. Under these conditions, a rapid decrease is observed in [2-^{18}O]-2-oxoglutarate over a period of less than 10 s (Figure 5–17) as a result of oxygen isotopic exchange occuring in the first two chemical steps on the active site (Equation 5–250) and their subsequent reversal.[824] This rapid depletion of [2-^{18}O]-2-oxoglutarate was followed by the normal uncatalyzed oxygen isotopic exchange that takes place in solution and that results from nonenzymatic hydration of the ketone



(5–252)

The slow decrease in the isotopic enrichment of [2-^{18}O]-2-oxoglutarate over the next 150 s is a consequence of this uncatalyzed oxygen isotopic exchange ($t_{1/2}$ = 5 min), the rate of which is defined by the course of oxygen isotopic exchange in the absence of enzyme (●). For each course in the presence of enzyme, the rapid decrease in [2-^{18}O]-2-oxoglutarate occurs during the rapid, unresolved approach to equilibrium. In each course, this rapid decrease is revealed by extrapolation (dashed lines) of the uncatalyzed course to zero time. The oxygen isotopic exchange revealed in these measurements is consistent with nucleophilic substitution at the carbonyl groups of 2-oxoglutarate producing the **iminium of 2-oxoglutarate as an intermediate** (Equation 5–250) prior to the reduction.

The enzymatically catalyzed oxygen isotopic exchange occurs only during the rapid approach to equilibrium of the enzymatic reaction. After equilibrium has been established, almost all the ammonium has been converted to glutamate, and the rates of the enzymatic reaction in both directions are much less than the rate of the forward reaction when ammonium was still present. Because the rate of oxygen isotopic exchange decreases dramatically as the ammonia is depleted, it could be concluded that the oxygen isotopic exchange observed in less than 10 s is isotopic exchange during the approach to equilibrium and is not due to reversal of the complete reaction. If it were due to reversal, the oxygen isotopic exchange would have proceeded at the same rapid rate after equilibrium had been reached, but only the uncatalyzed oxygen isotopic exchange (Equation 5–252) is observed at longer times. It was concluded that, to observe the isotopic exchange, NADPH had to be present to close the active site around the reactants, but its reduction of the imine was not required for the isotopic exchange to proceed. Because the uncatalyzed oxygen isotopic exchange by itself was appreciable ($t_{1/2}$ = 5 min), large concentrations of the enzyme (250 μM) were used to complete the approach to equilibrium immediately (<1 s) so that the rapid enzymatically

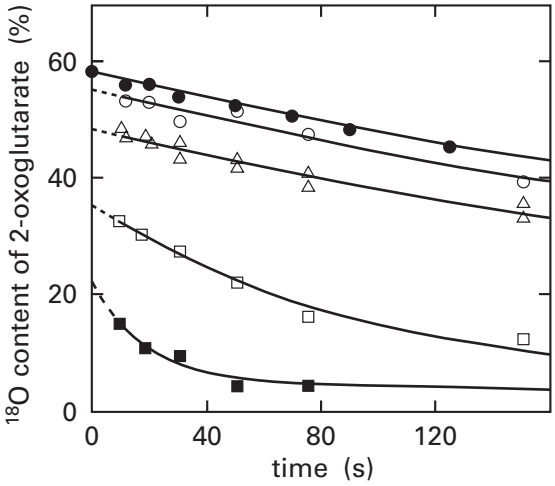


Figure 5–17: Rate of oxygen isotopic exchange from the carbonyl group of 2-oxoglutarate catalyzed by bovine glutamate dehydrogenase (NADP$^+$).[824] Solutions at pH 7.6 and 25 °C contained 250 μM glutamate dehydrogenase (NADP$^+$) and 1.1 mM NADPH and 6 μM (○), 55 μM (△), 118 μM (□), or 180 μM (■) ammonium ion. As ammonium ion was always present at concentrations less than that of the enzyme, each molecule of enzyme on average could complete less than one turnover before equilibrium was reached. The reaction was initiated by adding [2-^{18}O]-2-oxoglutarate (58% isotopic enrichment) to a final concentration of 310 μM. Samples of the reaction mixture were withdrawn at intervals and quenched with an equal volume of 50% H_2O_2, which converted [2-^{18}O]-2-oxoglutarate to [^{18}O]succinate by oxidative decarboxylation, and the oxygen-18 contents of the succinate were determined by mass spectrometry. These values were used to calculate the percentages of isotopic enrichment in the carbonyl oxygen of [2-^{18}O]-2-oxoglutarate (percent ^{18}O content) as a function of each interval (seconds). For each set of data, the solid line extending from 10 to 160 s represents a single first-order curve fit to the loss of ^{18}O due to uncatalyzed isotopic exchange. These solid lines are extrapolated to zero time by dashed lines to indicate the level of oxygen-18 that would be in 2-oxoglutarate if the enzymatically catalyzed reaction had reached equilibrium instantaneously following addition of reactant. The difference between these extrapolated values and the initial value of 58% isotopic enrichment is the amount of oxygen-18 isotopic exchange that occurred before the ammonia had been depleted by the enzymatic reaction. The uncatalyzed oxygen isotopic exchange from [2-^{18}O]-2-oxoglutarate in the absence of enzyme, ammonia, and NADPH is also plotted (●).

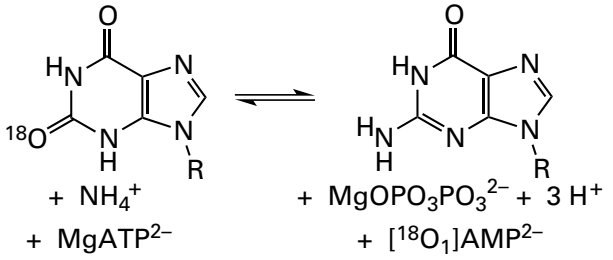
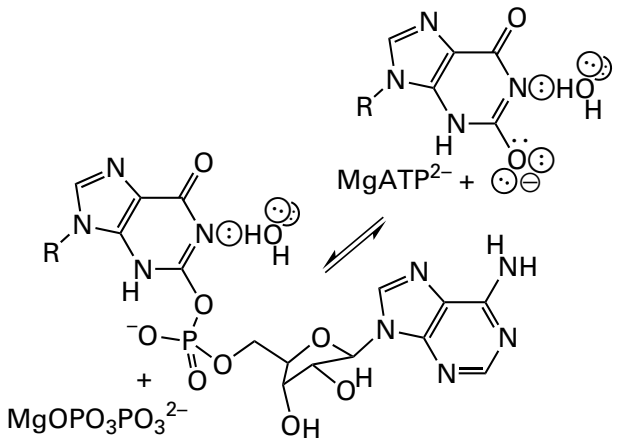
catalyzed isotopic exchange could be clearly distinguished from the slower uncatalyzed isotopic exchange.

The enzyme GMP synthase (glutamine-hydrolysing) catalyzes the conversion of xanthosine monophosphate to guanosine monophosphate



(5–253)

where R is D-ribos-1-yl 5′-monophosphate. The enzyme uses L-glutamine and a glutaminase at a distant active site as the source of the ammonia, hence the notation in parenthesis within the name of the enzyme. Formally, the reaction is a simple nucleophilic substitution at a carbonate carbon in which the nitrogen of ammonia as a nucleophile replaces the oxygen on the ureido carbon 2 of xanthosine 5′-monophosphate with water as the leaving group. That substitution, however, has quite a small equilibrium constant, so the enzyme couples it to hydrolysis of $MgATP^{2-}$. When [2-^{18}O]xanthosine 5′-monophosphate was used as a reactant for GMP synthase (glutamine-hydrolysing) from *Columba livia*, oxygen-18 was found in the phosphate of the AMP^{-} formed during the reaction.[825] This incorporation of isotope led to the suggestion that xanthosine adenylate[826] is formed as an intermediate



(5–254)

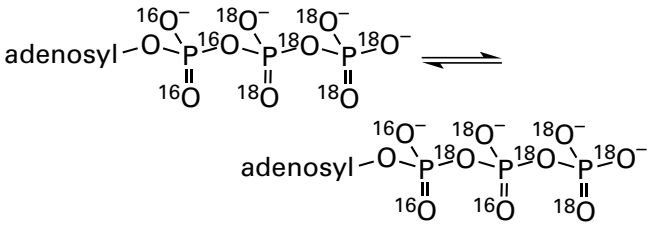
by the nucleophilic substitution at phosphorus of the conjugate base of xanthosine ($pK_a = 13.0$) for magnesium diphosphate. This nucleophilic substitution would create an activated O-adenylated ureido group and, in the process, couple directly and chemically the hydrolysis of $MgATP^{2-}$ to the nucleophilic substitution. This direct chemical coupling ensures that every time the nucleophilic substitution occurs, a molecule of $MgATP^{2-}$ is hydrolyzed. This enforcement necessarily adds the free energy of hydrolysis of $MgATP^{2-}$ to the change of free energy for the overall reaction.

The direct MgATP–diphosphate phosphorus isotopic exchange

$$Mg[\gamma\text{-}^{31}P]ATP^{2-} + Mg[^{32}P]OPO_3PO_3^{2-} \rightleftharpoons Mg[^{31}P]OPO_3PO_3^{2-} + Mg[\gamma\text{-}^{32}P]ATP^{2-}$$

(5–255)

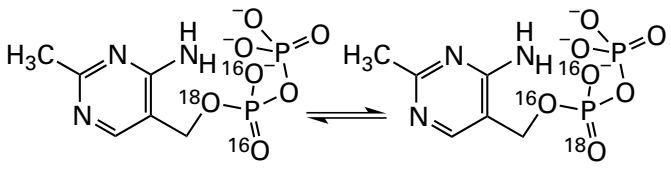
that might have accompanied this mechanism could not be detected in the absence of ammonia. It was possible, however, to detect a positional oxygen isotopic exchange of a nonbridging oxygen into a bridging position



(5–256)

that required the presence of xanthosine but not ammonia.[827] This positional oxygen isotopic exchange is consistent with the existence of **xanthosine adenylate** as an intermediate. The explanation for why positional oxygen isotopic exchange (Equation 5–256) is observed but not phosphorus isotopic exchange (Equation 5–255) is that the active site seems to remain closed to protect the xanthosine adenylate, prohibiting the diphosphate from leaving, a requirement for phosphorus isotopic exchange, until the guanosine monophosphate is formed after the ammonia has been delivered.

Positional oxygen isotopic exchange of a bridging oxygen into a nonbridging position was observed for the diphosphate in 4-amino-2-methyl-5-(diphosphooxymethyl)pyrimidine



(5–257)

when thiamine phosphate synthase (Equation 5–134) from *B. subtilis* was mixed with 4-amino-2-methyl-5-(diphospho[^{18}O]oxymethyl)pyrimidine in the absence of the other substrate in the enzymatic

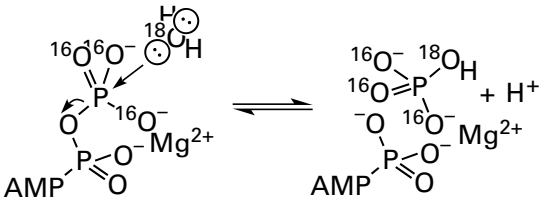
reaction, 4-methyl-5-(2-phosphooxyethyl)thiazole.[828] The reaction catalyzed by the enzyme is the nucleophilic substitution of diphosphate by the nitrogen of the thiazolyl group in 4-methyl-5-(2-phosphooxyethyl)thiazole at a primary carbon. This positional oxygen isotopic exchange in the absence of the thiazolyl group requires that the diphosphate dissociate reversibly from the carbon, which is consistent with it being the leaving group in a **dissociative nucleophilic substitution** (Equation 5–135) with 2-methyl-4-imino-5-methylenepyrimidine (**5–108**) or its conjugate acid (**5–107**), a formal carbenium ion, as an intermediate.

Positional isotopic exchange at initial rate within the reactant UDP-α-D-galactopyranose of a bridging oxygen-18 between the diphospho group of UDP and carbon 1 of galactopyranose into a nonbridging position during the ring contraction catalyzed by UDP-galactopyranose mutase

$$\text{UDP-}\alpha\text{-D-galactopyranose} \rightleftharpoons \text{UDP-}\alpha\text{-D-galactofuranose} \qquad (5\text{–}258)$$

from *E. coli* was also consistent with a dissociative nucleophilic substitution of the diphospho group for nitrogen 5 of the prosthetic flavin in the active site with an oxocarbenium ion as an intermediate. In the case of thiamine phosphate synthase, positional oxygen isotopic exchange was observed in the absence of 4-methyl-5-(2-phosphonooxyethyl)-thiazole. In contrast, when nitrogen 5 of the prosthetic flavin, which is the nucleophile in the reaction, was replaced by a carbon by using 5-deazaflavin as the prosthetic group, the positional oxygen isotopic exchange no longer occurred.[829] This result **ruled out an intermediate oxocarbenium ion** and a dissociative nucleophilic substitution, and it is consistent with a concerted nucleophilic substitution in which a covalent bond to nitrogen 5 must be forming as the covalent bond to the phospho oxygen is breaking.

Myosin ATPase hydrolyzes $MgATP^{2-}$ to $MgADP^{-}$ and $HOPO_3^{2-}$ to obtain the free energy necessary for contraction of muscle. On the active site of myosin ATPase, hydrolysis occurs without any intermediates by a direct in-line attack of water



(5–259)

with inversion of configuration at phosphorus.[830] When myosin ATPase from *O. cuniculus*, in the absence of actin, hydrolyzes $MgATP^{2-}$ to $MgADP^{-}$ and $HOPO_3^{2-}$ in $[^{18}O]H_2O$, instead of containing only one atom of oxygen-18, as expected (Equation 5–259), $HOPO_3^{2-}$ contains almost four atoms of oxygen-18.[765,831] The reasons for this intermediate oxygen isotopic exchange at initial rate are that, on the active site, the equilibrium constant for hydrolysis of $MgATP^{2-}$ has been shifted dramatically in the direction of 1 and that the **release of products from the active site** of myosin ATPase is very slow in the absence of actin.[832] For both reasons, hydrolysis of $MgATP^{2-}$ (Equation 5–259) reverses many times, as the phosphate tumbles in the active site, before the products depart. In this instance, because there are no fixed molecules of water in its vicinity[833] aside from two molecules of water on the nearby Mg^{2+}, the molecule of H_2O that is a reactant probably has enough time to enter and leave the active site during these reversals while the $MgATP^{2-}$ remains tightly bound. The $H_2{}^{16}O$ leaving the active site carries away, one at a time and at random,[834] oxygens-16 on phosphorus; and the $H_2{}^{18}O$ entering the active site replaces them with oxygens-18. The existence of this rapid reversal of a reaction that is significantly exergonic in solution is one demonstration that the standard free energy of a particular reaction catalyzed by an enzyme can be dramatically altered by the environment of the active site.

As actin is added to the solution, the rate of the overall hydrolysis increases and the magnitude of the intermediate oxygen isotopic exchange decreases[831] by a relation predicted for random isotopic exchange of all three oxygens on the γ-phosphate of $MgATP^{2-}$ until high concentrations of actin are reached. At this point, only one atom of oxygen-18, from the stoichiometric $H_2{}^{18}O$, is incorporated into the phosphate during the hydrolysis, and no intermediate oxygen isotopic exchange is observed (Figure 5–18).[835,836] This result is one illustration of the fact that the main effect of actin on the rate at which myosin ATPase hydrolyzes $MgATP^{2-}$ in the solution to $MgADP^{-}$ and $HOPO_3^{2-}$ in the solution, as opposed to on its active site, is to accelerate the rate at

which the two products dissociate from the active site, not an acceleration of the hydrolysis of $MgATP^{2-}$ itself on the active site. At high enough concentrations of actin, products are released from the active site so rapidly that no reversal of hydrolysis of $MgATP^{2-}$ can occur before their dissociation.

Such measurements of intermediate oxygen isotopic exchange can also **rule out the existence of two paths** as an explanation for the decrease in incorporation of oxygen-18 into phosphate upon acceleration of a reaction in which $MgATP^{2-}$ is hydrolyzed. Bovine H^+-transporting two-sector ATPase also catalyzes hydrolysis of $MgATP^{2-}$ as well as its synthesis from $MgADP^-$ and $HOPO_3^{2-}$, the reverse reaction. As the rate for hydrolysis of $MgATP^{2-}$ decreases when the concentration of $MgATP^{2-}$ is lowered, the number of oxygens-18 incorporated into the product $HOPO_3^{2-}$ increases, just as when the concentration of actin is decreased with myosin ATPase. One explanation for such an observation is that at high concentrations of $MgATP^{2-}$ the reaction proceeds on a path in which reversal of hydrolysis cannot occur, while at low concentrations of $MgATP^{2-}$ the reaction proceeds on a different path on which complete reversal and consequently complete isotopic exchange occurs at the hydrolytic step. By determining the relative concentrations of the isomeric forms of $HOPO_3^{2-}$ with one, two, three, and four oxygens-18 at several different concentrations of $MgATP^{2-}$, the possibility that two paths were operating could be ruled out.[837]

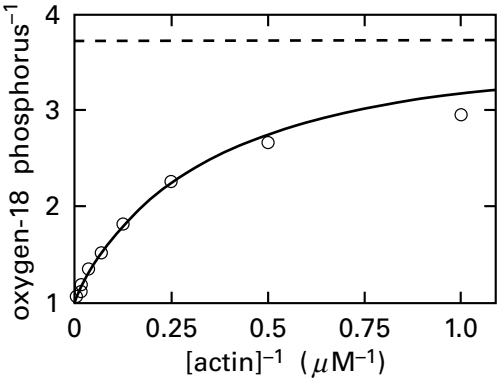


Figure 5–18: Effect of the concentration of actin on intermediate isotopic exchange of oxygen-18 for oxygen-16 into the phosphate produced from $Mg[^{16}O]ATP^{2-}$ in $[^{18}O]H_2O$ by subfragment 1 of myosin.[835] Myosin was digested with chymotrypsin, and the large globular fragment (subfragment 1), missing the coiled coil of the intact protein[836] but still containing the active site at which $MgATP^{2-}$ is hydrolyzed, was purified by anion-exchange chromatography. Solutions (3 mL) containing 1 mM $MgCl_2$, 0.5 mM $MgATP^{2-}$, 1.75 mM phospho*enol*pyruvate, and 200 μg of pyruvate kinase (to regenerate the $Mg[^{16}O]ATP^{2-}$ as it was hydrolyzed) were prepared at pH 7 and 23 °C. Various amounts of actin were added, and hydrolysis of $MgATP^{2-}$ was initiated in each case by adding enough subfragment 1 to produce 80% hydrolysis of $MgATP^{2-}$ and phospho*enol*pyruvate over 2 h. Reaction mixtures were quenched at 2 h with perchloric acid, and the remaining nucleotide and protein were removed by adding activated charcoal and submitting the samples to centrifugation. The phosphate was isolated, and oxygens in the phosphate were converted to gaseous carbon dioxide by reaction with guanidinium chloride. The isotopic composition of $[^{18}O]CO_2$ was determined by mass spectrometry. From these measurements, the ratios of oxygen-18 to phosphorus (oxygen-18 phosphorus^{-1}) in the phosphate could be calculated. These ratios are plotted as a function of the inverse of the concentrations of actin (micromolar^{-1}). The horizontal dashed line is placed at the value for oxygen-18 phosphorus^{-1} for the phosphate produced by subfragment 1 in the absence of actin.

The observed rate of a particular isotopic exchange is determined by a sequence of rates. If a reactant is registering the isotopic exchange, as in the case of fructose-bisphosphate aldolase, then the sequence of rates is the rate of association of the reactant in which the isotope is to be exchanged; the rate at which the bound reactant is transformed into the species responsible for the actual exchange of the isotope; the rate at which this species with the original isotope is exchanged for the same species but with the other isotope; the rate at which the species with the other isotope is modified to re-form the isotopically substituted reactant on the active site; and the rate at which that now isotopically exchanged reactant dissociates from the active site. If a product is registering the isotopic exchange, as in the case of citrate (*Si*)-synthase, then the sequence of rates is the rate of association of the reactant in which the isotope is to be exchanged; the rate at which the bound reactant is transformed into the species responsible for the actual exchange of the isotope; the rate at which this species with the original isotope is exchanged for the same species but with the other isotope; the rate at which the species with the other isotope is converted into the product associated with the active site; and the rate at which that product with the other isotope dissociates from the active site. These considerations emphasize that, because the isotopic exchange is registered in isotopically exchanged reactant or isotopically exchanged product, both accumulating in the solution, associations and dissociations of substrates with the active site are essential steps in the isotopic exchange.

Isotopic exchange can be described by a **universal kinetic mechanism**[838,839]

$$\begin{array}{ccccc} E_1 + A & \underset{k_{-1i}}{\overset{k_{1i}}{\rightleftharpoons}} & E_i(I)(X) & \underset{k_{-i1}}{\overset{k_{i1}}{\rightleftharpoons}} & E_1 + Z \\ & & k_{ex} \Big\downarrow \Big\uparrow k_{-ex} & & \\ E_1 + A' & \underset{k'_{-1i}}{\overset{k'_{1i}}{\rightleftharpoons}} & E_i(I)(X') & \underset{k'_{-i1}}{\overset{k'_{i1}}{\rightleftharpoons}} & E_1 + Z' \end{array} \qquad (5\text{–}260)$$

If **isotopic exchange into a reactant** is being observed, reactant A carries the original isotope and reactant A′ carries the exchanged isotope. The species that accomplishes the switch of the isotopes is indicated as X with the original isotope or X′ with the other isotope. Species X′ may already be in the active site—for example, a hydron or a molecule of water—and simply switch places with species X, in which case the rate constants k_{ex} and k_{-ex} are simple first-order rate constants. Species X may have to dissociate from the active site and species X′ may have to associate with the active site, in which case the rate constants k_{ex} and k_{-ex} are composite rate constants involving concentrations of species X and X′ in solution. Species X can be a nonstoichiometric molecule from the solution entering and leaving the active site—for example, a molecule of water carrying hydrons or an oxygen of the other isotope in and out of the active site—even though a hydron or a molecule of water does not appear in the stoichiometric reaction for the enzymatic reaction. Species E_i can be a complex between the enzyme and an intermediate in the reaction from which species X has just dissociated and with which species X′ associates to accomplish the isotopic exchange. Species X, however, could itself be a substrate for the enzyme, substrate X, and its dissociation from the active site and subsequent association of species X′, a molecule of substrate X bearing the other isotope, accomplishes the isotopic exchange. In this case, the rate constants k_{ex} and k_{-ex} are again composite rate constants involving concentrations of species X and X′ in solution.

If **isotopic exchange into a product** is being observed, product Z is the product of the reaction that carries the original isotope. This product may or may not be present in the solution, and it may or may not be required to associate with the active site for isotopic exchange to be observed. Product Z′ is the product of the reaction that carries the other isotope. When species X itself is a stoichiometric product of the reaction, it carries the original isotope and species X′ is the same stoichiometric product of the reaction that carries the other isotope. In this case, there is no product Z or Z′, and product X or X′ simply dissociates from the active site. Most if not all types of isotopic exchange can be described by Equation 5–260.

Oxygen isotopic exchange in the absence of 5,6,7,8-tetrahydrofolate catalyzed by deoxycytidylate 5-hydroxymethyltransferase (Equation 5–202) is an isotopic exchange in the absence of one or more reactants. In this example, reactant A is 5-hydroxymethylcytidine 5′-monophosphate; species X is a molecule of $H_2{}^{16}O$; and species X′ is a molecule of $H_2{}^{18}O$. A molecule of water is formally a product of the reaction in the direction written, but the molecule of $H_2{}^{18}O$ that switches with the molecule of $H_2{}^{16}O$ is probably already in the active site. After 5-hydroxymethylcytidine 5′-monophosphate has associated with the active site, a molecule of $H_2{}^{16}O$ leaves the 5-hydroxymethylcytidine 5′-monophosphate to produce species E_i, which is a complex between the active site and the methylene intermediate. The molecule of $H_2{}^{16}O$ is then replaced by the molecule of $H_2{}^{18}O$, and isotopically substituted 5-hydroxymethylcytidine 5′-monophosphate dissociates from the active site. Because the other reactant, 5,6,7,8-tetrahydrofolate, has been omitted, no stoichiometric products of the reaction, 5,10-methylenetetrahydrofolate and deoxycytidylate, can be produced; the reaction cannot proceed beyond the methylene intermediate; and the reaction is confined to the left half and central vertical step of Equation 5–260.

The hydrogen isotopic exchange catalyzed by 3-dehydroquinate synthase (Equation 5–206) is an example of an isotopic exchange into an analogue of a reactant. In this instance, reactant A is phosphonate **5–155**; species X is a hydron removed from carbon 6 of the ketone formed from phosphonate **5–155**; species E_i is a complex between the active site and the enolate resulting from removal of the hydron from the ketone; and species X′ is a deuteron probably already in the active site. Again, because phosphonate **5–155** cannot be turned into the product of the reaction, 3-dehydroquinate, the reaction is confined to the left half and central vertical step of Equation 5–260.

The hydrogen isotopic exchange catalyzed by urocanate hydratase (Equation 5–207) is an example of an isotopic exchange at initial rate. Reactant A is urocanate; species X is the hydron that has been removed from carbon 5 of the intermediate formed from urocanate; species E_i is a complex between the active site and the second intermediate result-

ing from removal of the hydron from the first; and species X′ is a deuteron, probably on a molecule of water already in the active site. In this instance, the product of the reaction, 3-(5-oxo-4,5-dihydro-3*H*-imidazol-4-yl)propanoate, species Z, is accumulating as the isotopic exchange into urocanate is proceeding. Although carbon 5 of the product 3-(5-oxo-4,5-dihydro-3*H*-imidazol-4-yl)propanoate no longer has a hydrogen, there must be exchange of a deuteron into the intermediate that is then removed in later steps. Product Z′ is the product that arises from the deuterated intermediate and product Z is the product that arises from the hydronated intermediate, but products Z′ and Z are indistinguishable because neither bears a deuterium. The kinetic mechanism is the complete form of Equation 5–260.

The oxygen isotopic exchange catalyzed by glutamine synthetase (Equation 5–209) is an example of positional isotopic exchange. Reactant A is $MgATP^{2-}$; species X is oxygen-18 on the β-phospho group of $MgADP^-$ with that oxygen-18 having just left and still directed at the phosphorus of L-glutamyl phosphate; species E_i is the complex between the active site and $MgADP^-$ and L-glutamyl phosphate; and species X′ is the rotated [^{18}O]-β-phospho group with one of its two oxygens-16 now directed at the phosphorus of L-glutamyl phosphate and about to add as a nucleophile. Because ammonia is not present, no products of the reaction—$MgADP^-$, phosphate, and L-glutamine—can be produced, and the reaction is confined to the left half and central vertical step of Equation 5–260.

The oxygen isotopic exchange catalyzed by citrate (*Si*)-synthase (Equation 5–212) is an example of intermediate isotopic exchange. Reactant A is [^{18}O]acetyl-SCoA; reactant A′ is [^{16}O]acetyl-SCoA; product Z is [1-^{18}O]citrate; product Z′ is [$^{16}O_7$]citrate; species X is a molecule of $H_2{}^{18}O$ formed during reversal of the hydrolysis of [1-^{18}O]citryl-SCoA; species X′ is a molecule of $H_2{}^{16}O$ that switches with the molecule of $H_2{}^{18}O$ and then hydrolyzes the [1-^{16}O]citryl-SCoA formed by reversal of the hydrolysis of [1-^{18}O]citryl-SCoA; and species E_i is the complex between the active site and that molecule of [1-^{16}O]citryl-SCoA. In this instance, both products Z and Z′ are produced, so the kinetic mechanism is Equation 5–260 in its entirety. There is, however, another reactant, oxaloacetate, and another product, coenzyme A, in the enzymatic reaction. Consequently, regeneration of the form of the enzyme E_1, with which acetyl-SCoA associates, from the form of the enzyme from which citrate dissociates may involve dissociation of coenzyme A and association of oxaloacetate.

The carbon isotopic exchange catalyzed by phosphopyruvate hydratase (Equation 5–215) is an example of isotopic exchange at equilibrium. Reactant A is phospho[1-^{12}C]*enol*pyruvate; species X is 2-phospho-D-[1-^{12}C]glycerate; species X′ is 2-phospho-D-[1-^{14}C]glycerate; and reactant A′ is phospho-[1-^{14}C]*enol*pyruvate. In reverse, reactant A is 2-phospho-D-[1-^{14}C]glycerate; species X is phospho[1-^{14}C]-*enol*pyruvate; species X′ is phospho[1-^{12}C]*enol*pyruvate; and reactant A′ is 2-phospho-D-[1-^{12}C]glycerate. Species E_i is simply the empty active site from which the respective substrates have dissociated. Because species X is product Z and species X′ is product Z′, there is neither product Z nor product Z′, and the reaction is confined to the left half and central vertical step of Equation 5–260. Species X must dissociate from the active site and be replaced by species X′ associating with the active site from solution.

In the forward direction, E_1 is the form of the enzyme that associates with reactant A, the reactant in which the isotopic exchange occurs or the reactant that is transformed into the intermediate in which the isotopic exchange occurs. In the reverse direction after the switching of the isotopes has occurred, E_1 is also the form of the enzyme from which the isotopically exchanged reactant A′ has just dissociated. The form of the enzyme E_i(X) is the one in which species X has just been formed. The form of the enzyme E_i(X′) is the one with which species X′ either has just associated after species X has dissociated or in which species X′ has just switched places with species X′ if species X′ is already in the active site. The rate constant k_{1i} in Equation 5–260 is the forward composite rate constant for all steps between the two forms of the enzyme, E_1 and E_i(X). The rate constant k_{-1i} is the backward composite rate constant for all steps between the two forms of the enzyme, E_i(X) and E_1, from which reactant A dissociates. The rate constants k'_{1i} and k'_{-1i} are similar to the rate constants just described, but they occur between the form of the enzyme E_1 and the complex E_i(X′). The primes indicate that these two rate constants may be different from the rate constants k_{1i} and k_{-1i}, respectively, because of the isotopic substitution.

The rate constant k_{i1} in Equation 5–260 is the forward composite rate constant for all steps between the two forms of the enzyme, E_i(X) and E_1, with which reactant A associates in the next round of catalysis. This composite rate constant includes the steps between E_i(X) and the form of the enzyme from

which product Z dissociates and the steps between the form of the enzyme from which product Z dissociates and E_1. The steps in the latter sequence of steps may include dissociation of another product to clear the active site, a conformational change in the unoccupied enzyme to prepare it for association of reactant A, or association of another reactant that must precede association of reactant A, or two or all three of these transformations. The term k_{-i1} is the backward composite rate constant for all steps in the mechanism between the two forms of the enzyme, E_1 and E_i(X). This composite rate constant includes the steps between E_1 and the form of the enzyme with which product Z associates and the steps between the form of the enzyme with which product Z associates and E_i(X). The steps in the former sequence may include dissociation of another reactant that clears the active site, a conformational change in the enzyme to prepare it for association of product Z, or association of another product that must precede association of product Z, or two or all three of these transformations. Again, the rate constants k'_{i1} and k'_{-i1} are similar to the rate constants just described, but they occur between the complex of the enzyme with species X′ and the form of the enzyme with which reactant A associates.

The rate constant k_{ex} is the rate constant for replacement of species X by species X′. It is usually a composite rate constant as well. Even in cases where species X′ is already in the active site and simply switches places with species X so that k_{ex} is a first-order rate constant, there are probably several steps in this switching of places, each with its own intrinsic forward and reverse rate constants. In situations in which species X must dissociate into the solution from the active site and species X′ must then associate with the active site, the rate constant k_{ex} is a composite rate constant that includes the intrinsic rate constants for dissociations and associations of both species X and X′. The rate constant k_{-ex} is the composite rate constant for the reverse reaction.

The **initial rate for any particular isotopic exchange** ($v_{0,ie}$) can be defined by the equation

$$v_{0,ie} = \frac{d[Q']}{dt} \qquad (5\text{–}261)$$

where $d[Q']/dt$ is the initial rate at which the other isotope, replacing the initial isotope, appears in the molecule Q into which it is being exchanged and which is registering the isotopic exchange. Molecule Q can be either a reactant, reactant A, or a product, species X or product Z. For example, the initial rate for isotopic exchange could be the initial rate at which [5-^{2}H]urocanate, reactant A′, is produced in the hydrogen isotopic exchange at initial rate catalyzed by urocanate hydratase (Figure 5–15) before the rate at which this [5-^{2}H]urocanate is converted into 3-(5-oxo-4,5-dihydro-3*H*-imidazol-4-yl)propanoate, product Z, is sufficient to decrease the rate at which [5-^{2}H]urocanate is formed. The initial rate for isotopic exchange could also be the initial rate at which carbon-14 appears in phospho*enol*pyruvate in the isotopic exchange catalyzed by phosphopyruvate hydratase before enough of this phospho-[1-^{14}C]*enol*pyruvate, reactant A′, has accumulated that it is converted back to 2-phospho-D-[1-^{14}C]glycerate, species X, at a rate sufficient to begin to decrease the rate at which 2-phospho-D-[1-^{14}C]glycerate is converted to phospho-[1-^{14}C]*enol*pyruvate. The initial rate for isotopic exchange could also be the initial rate at which [$^{16}O_7$]citrate, product Z′, appears before [$^{16}O_7$]citrate produced by the reassociation of [1-^{18}O]citrate, product Z, with the active site of citrate (*Si*)-synthase and the reversal of its hydrolysis begins to increase the rate of production of [$^{16}O_7$]citrate.

By defining the rate of isotopic exchange as an initial rate, the intention is to determine the **rate of isotopic exchange in the absence of isotopic exchange resulting from any back reaction**. The conversion of reactant to final product through the steps that accomplish the complete, stoichiometric reaction catalyzed by the enzyme and the subsequent conversion of that product back to reactant almost always produces isotopic exchange, which is uninformative and complicates measurement of the informative isotopic exchange. In situations in which the complete, stoichiometric reaction is not permitted to occur, at isotopic equilibrium for whatever transformation is occurring, the rate of isotopic exchange, by definition, becomes zero. It follows that the initial rate constant for a particular isotopic exchange provides the most uncomplicated information.

The difficulty with measuring the initial rates for isotopic exchange, which is seldom encountered with measurements of the initial rates for enzymatic reactions because there is no product in the solution to begin with, is that accurately measuring the amount of isotope incorporated into a molecule already present at significant concentration in the solution requires that a significant percentage of that molecule be converted to the form containing the exchanged isotope. If the system, however, is **at chemical**

equilibrium, even though it is not at isotopic equilibrium, the incorporation of the other isotope into the substrate registering the isotopic exchange can be treated as a simple **approach to isotopic equilibrium**. The integrated equation for the initial rate of isotopic exchange at chemical equilibrium from the observed concentrations of the products of isotopic exchange measured over the entire course of the reaction is[838,840]

$$v_{0,ie} = \frac{[A]_t[X]_t}{[A]_t + [X]_t}\left[\frac{\ln(1-f)}{t}\right] \qquad (5\text{–}262)$$

where $[A]_t$ and $[X]_t$ are the total molar concentrations of reactant A and species X, and f is the fraction of isotopic exchange achieved at time t relative to the level of isotopic exchange achieved at isotopic equilibrium. It should be emphasized that Equation 5–262 is used to determine the numerical value for the initial rate from a set of experimental observations in the absence of any assignment of kinetic mechanism.

The four isotopic exchanges at equilibrium catalyzed by phosphopyruvate hydratase—the appearance of phospho[1-^{14}C]*enol*pyruvate (Equation 5–215), the appearance of oxygen-18 in 2-phospho-D-[3-^{18}O]glycerate (Equation 5–216), the appearance of ^3H_2O (Equation 5–217), and the appearance of ^2H_2O (Equation 5–218)—behaved as approaches to equilibrium (Figure 5–19)[749] that could be fit by Equation 5–262 to obtain the initial rate for each isotopic exchange (Table 5–2).[749] In both of the two latter isotopic exchanges, reactant A is 2-phospho-D-glycerate and species X is a hydron. Because the concentration of hydrons was 110 M in the solution

$$\frac{[A]_t[X]_t}{[A]_t + [X]_t} = [A]_t \qquad (5\text{–}263)$$

In the case of the oxygen isotopic exchange at equilibrium, the concentration of $H_2{}^{18}O$ was 0.7 M, so Equation 5–263 is approximately correct.

It is obvious that for observations of isotopic exchange at equilibrium, such as the isotopic exchanges observed with phosphopyruvate hydratase, the **system is at chemical equilibrium** because that is the design of the experiment. It is also the case, however, that in measurements of isotopic exchange in the absence of one or more reactants, isotopic exchange into an analogue of a substrate, positional

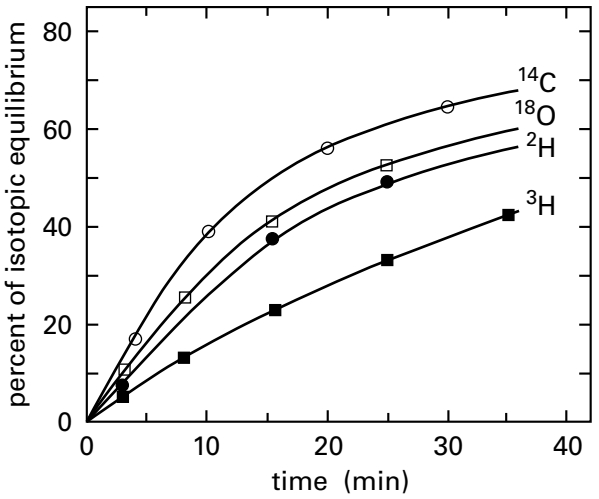

Figure 5–19: Time courses for isotopic exchange at equilibrium of carbon-14, oxygen-18, deuterium, and tritium into and out of 2-phospho-D-glycerate catalyzed by phosphopyruvate hydratase from *O. cuniculus*.[749] The reaction mixture contained 18 mM 2-phospho-D-[2-^{2}H]glycerate (97% ^{2}H), 25 mM $MgCl_2$, traces of 2-phospho-D-[1-^{14}C]glycerate and 2-phospho-D-[2-^{3}H]glycerate, and 110 mM phospho*enol*pyruvate, pH 6.5, in a total volume of 1.5 mL of 1.33 atom % $H_2{}^{18}O$. The reaction was initiated by adding 50 μg of phosphopyruvate hydratase. At various intervals, samples (50 μL) were removed and quenched at 115 °C for 40 s. Values for the isotopic distributions at equilibrium were measured at 18 h. The ^{2}H and ^{3}H exchanged into the H_2O in each sample were determined by distilling the water. The ^{18}O exchanged into 2-phospho-D-glycerate was determined from the residue following distillation of the water. Carbon-14 exchanged into phospho*enol*pyruvate was determined by separating the two substrates chromatographically. For each isotope, the values at each interval (minutes) are plotted as a percentage of their values at equilibrium (18 h). The data were fit to the general equation for isotopic exchange at equilibrium,[840] rate = $\{[A][X]/([A] + [X])\}\{[\ln(1-f)]/t\}$, where "rate" is the rate of the isotopic exchange, [A] and [X] are total molar concentrations of each of the two species exchanging the isotope, and f is the fraction of isotopic exchange achieved at time t. From these fits, the rates (millimolar minute^{-1}) can be calculated for each isotopic exchange (Table 5–2). When one of the species that is exchanging is H_2O, the factor to the left of the expression becomes unity.

isotopic exchange in the absence of a reactant, and intermediate isotopic exchange in the absence of a reactant, the various steps in the truncated reaction come to equilibrium on the active site almost immediately because in each instance, by design, the enzymatic reaction is not progressing to products and the time required to reach equilibrium is less than the time required to complete one round of catalysis. Consequently, in these situations, the system is at chemical equilibrium during the entire course of its approach to isotopic equilibrium, and Equation 5–262 can be fit to the incorporation of the other isotope as a function of time to determine the initial rate of the isotopic exchange.

Table 5–2: Rates of Equilibrium Isotopic Exchange for Phosphopyruvate Hydratase[749]

isotopic equilibrium[a]	observed initial rate[b] (mM min^{-1})	relative rate
[^{14}C]PGA ⇌ [^{14}C]PEP	0.68	1.0
[^{18}O]H_2O ⇌ [^{18}O]PGA	0.71	1.1
[^{3}H]PGA ⇌ [^{3}H]H_2O	0.34	0.5
[^{2}H]PGA ⇌ [^{2}H]H_2O	0.62	0.8
[^{1}H]PGA ⇌ [^{1}H]H_2O		6.2[c]

[a]2-Phospho-D-glycerate is abbreviated as PGA, and phospho-*enol*pyruvate is abbreviated as PEP. [b]Reaction conditions and measurements are given in the legend for Figure 5–19. [c]Estimated from exchange rates for ^{2}H and ^{3}H.

The isotopic exchanges at equilibrium catalyzed by phosphopyruvate hydratase illustrate the use of numerical values of the initial rates for isotopic exchange, rather than the simple fact that the isotopic exchanges occur, to draw a mechanistic conclusion. The initial rates for the observed tritium and deuterium isotopic exchanges at equilibrium catalyzed by phosphopyruvate hydratase were each slower than the initial rate for protium isotopic exchange would have been because of the respective primary **kinetic isotope effects**, but from the initial rates of tritium and deuterium isotopic exchanges, the initial rate for protium isotopic exchange

$$\text{2-phospho-D-[2-}^{1}\text{H]glycerate} + {}^{1}H_2O \rightleftharpoons {}^{1}H_2O + \text{2-phospho-D-[2-}^{1}\text{H]glycerate} \quad (5\text{–}264)$$

could be calculated (previously Equations 4–205 and 4–199)

$${}^{T}k_i \equiv \frac{k_{i\mathrm{H}}}{k_{i\mathrm{T}}} = \left(\frac{k_{i\mathrm{H}}}{k_{i\mathrm{D}}}\right)^{1.44} = {}^{D}k_i{}^{1.44} \quad (5\text{–}265)$$

$${}^{D}k_{\mathrm{B}} \equiv \frac{k_{\mathrm{BH}}}{k_{\mathrm{BD}}} = \frac{{}^{D}k_i + c_{\mathrm{f}} + c_{\mathrm{r}}({}^{D}K_{\mathrm{eq}i})}{1 + c_{\mathrm{f}} + c_{\mathrm{r}}} \quad (5\text{–}266)$$

The initial rate for **hydrogen isotopic exchange of a proton for a proton** at carbon 2 of 2-phospho-D-glycerate was faster than the initial rate for oxygen isotopic exchange at carbon 3 of 2-phospho-D-glycerate (Table 5–2), which was the same as the initial rate for carbon isotopic exchange accomplished by the forward and then the backward operation of the entire reaction. The hydrogen isotopic exchange of a proton for a proton (Equation 5–218) at carbon 2 of 2-phospho-D-glycerate does not require that a proton enter the active site because there are two protons already present on the ammonio group of Lysine 345 and two protons on the molecule of water on the Mg^{2+} that is in a hydrogen bond with the ammonio group. The oxygen isotopic exchange (Equation 5–216) may also involve a molecule of $H_2{}^{18}O$ already in the active site, but there seems to be only one other molecule of water nearby (Figure 4–43), so this isotopic exchange should be slower than a hydrogen isotopic exchange that has four protons on which to draw. The carbon isotopic exchange must incorporate all steps in the hydrogen and oxygen isotopic exchanges as well as dissociation of phospho[^{14}C]*enol*pyruvate, so it is strange that it should have the same initial rate as the oxygen isotopic exchange. The fact that the initial rate for oxygen isotopic exchange is the same as that for carbon isotopic exchange, however, would be consistent with steps in these two isotopic exchanges following a common rate-limiting step that obscures any difference in their respective isotopic exchanges. This rate-limiting step should be removal of the hydron from carbon, which is the most difficult chemical step in the reaction.

Both hydrogen and oxygen isotopic exchanges at equilibrium in the reaction catalyzed by phosphopyruvate hydratase start with association of 2-phosphoglycerate. Consequently, the fact that the initial rate for hydrogen isotopic exchange on carbon 2 of 2-phospho-D-glycerate at equilibrium was greater than the initial rate for oxygen isotopic exchange on carbon 3 at equilibrium was originally presented as evidence that the hydron is removed by a catalytic base in the active site from 2-phospho-D-glycerate before the hydroxy group dissociates as a molecule of water and that there is a *gem*-enediolate as an intermediate in the reaction.[749] This conclusion, drawn from the relative initial rates for the isotopic exchanges, although chemically reasonable, was based on the assumption that the isotopic exchanges at each step in the enzymatic reaction would be so rapid that they would be complete before the next step commenced.

This assumption seems to be too wishful. The rate of exchange (governed by the rate constant k_{ex} in Equation 5–260) of one isotope of a hydron for another isotope of a hydron should be greater than the initial rate for one isotope of oxygen for another isotope of oxygen if there are four hydrons to draw upon but only one molecule of water. Consequently, it seems reasonable that if the water were to leave before the hydron in the enzymatic reaction, oxygen isotopic exchange of $H_2{}^{16}O$ for $H_2{}^{18}O$ could still be slower than hydrogen isotopic exchange of a proton for the proton that is removed from the substrate or an intermediate in the reaction and exchanged for another hydron. Furthermore, the exchange of a fixed molecule of water, almost always pinned down by four hydrogen bonds, should be slower intrinsically than the exchange of a hydron. In this instance, however, hydrogen isotopic exchange is considerably more rapid than oxygen isotopic exchange, a fact in favor of removal of the hydron preceding dissociation of the hydroxy group.

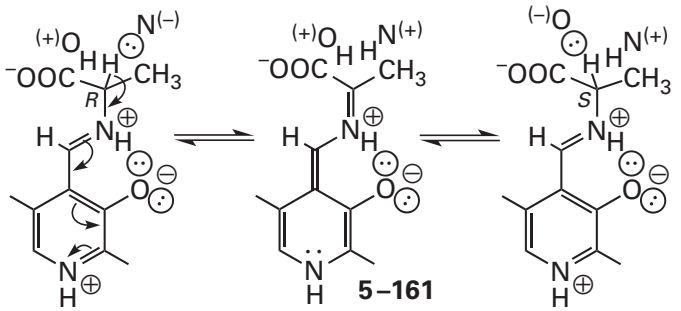
Nevertheless, this particular ambiguity is an example of the fact that, unlike simple observation of the existence of isotopic exchange in the absence of one or more reactants or into an analogue of a reactant, both of which are not based on any reference to initial rates, the relative initial rates for isotopic exchange do not provide unambiguous information for the identification of intermediates in an enzymatic reaction. The ambiguity arises from the details of the exchange of species X′ for species X. If species X′ is a hydron or molecule of water within the active site, its exchange for species X may be slower than the rates of the steps that convert intermediates into subsequent intermediates or into the product within the active site. If species X is a product in the stoichiometric reaction other than a hydron or molecule of water, so that it must dissociate from the active site and a molecule of species X′ must associate with the active site before isotopic exchange can occur, and if species X remains in the active site and only dissociates from the active site after product Z, then an isotopic exchange in which species X is a participant will be less rapid than an isotopic exchange in which product Z participates, even though species X is formed in a chemical step in the active site before the chemical step forming product Z occurs.

So far the kinetics of situations in which the system is at chemical equilibrium while measurements of the initial rate for the isotopic exchange are made have been examined. In contrast, for measurements of isotopic exchange at initial rate, positional isotopic exchange at initial rate, and intermediate isotopic exchange at initial rate, the system is not at chemical equilibrium, and the chemical **concentrations of substrates and intermediates are constantly changing**. This constant change makes determination of the initial rate for isotopic exchange more difficult. In such situations, the percentage of isotopic exchange at a particular time relative to the percentage at complete equilibration of isotope can be plotted as a function of the percentage of conversion of reactant into product relative to the concentration of product at complete chemical equilibration. The data on such a plot can then be fit to equations derived from the universal kinetic mechanism.[839,841] These equations are complex and their form depends on the particular situation, so there is no common equation for all situations. Fitting the data to the appropriate equation for the particular set of measurements, however, can provide the initial rate for isotopic exchange. When the system is in neither isotopic equilibrium nor chemical equilibrium, the fit to the data also provides **information about the partition of an intermediate back into reactant and forward into product.**

Hydrogen isotopic exchange at initial rate for tritons from ^3H_2O onto carbon 2 of D-[2-^{1}H]alanine is observed during the conversion of D-[2-^{1}H]alanine to L-[2-^{3}H]alanine catalyzed by alanine racemase (previously Equation 4–345)

$$\text{D-alanine} \rightleftharpoons \text{L-alanine} \qquad (5\text{–}267)$$

of *G. stearothermophilus*. The intermediate in the reaction is quinonoid **5–161** (see Equation 2–4)



(5–268)

The catalytic acid, $^{(+)}$OH, that normally hydronates quinonoid intermediate **5–161** to give the product L-alanine is the 4-hydroxyphenyl group of Tyrosine 265, which should be completely tritonated throughout the reaction, so the product of the reaction is exclusively L-[2-^{3}H]alanine. The catalytic base, $\odot N^{(-)}$, that normally removes the hydron from D-alanine

to give quinonoid intermediate **5–161** is the 6-amino group of Lysine 39,[842] which is also ditritonated. Consequently, the reactant at early intervals, before the back reaction is significant, is a mixture of the original D-[2-^{1}H]alanine and the exchanged D-[2-^{3}H]alanine. The 6-amino group of Lysine 39 that is responsible for the hydrogen isotopic exchange participates in a cluster of hydrogen bonds involving an oxygen from the carboxy group of an aspartate, a molecule of water, an oxygen in the carboxy group and the imino nitrogen in quinonoid intermediate **5–161**, and a nitrogen in the guanidinio group of an arginine. This cluster contains five hydrogen bonds and therefore at least five tritons, more than enough to exchange with the proton removed from D-[2-^{1}H]alanine by the 6-amino group of Lysine 39 without having to go outside the active site. The 4-hydroxyphenyl group of Tyrosine 265 that removes the hydron from the α carbon of the external pyridoximine of L-alanine is the donor to a cluster of three molecules of water,[842] which provide ample hydrons for hydrogen isotopic exchange into L-alanine that was observed when L-[2-^{1}H]alanine rather than D-[2-^{1}H]alanine was chosen as the reactant.

The percentages of hydrogen isotopic exchange relative to complete isotopic equilibration were plotted as a function of the percentage of conversion of reactant into product relative to the concentration of product at complete chemical equilibration to determine the initial rates for the hydrogen isotopic exchanges. The initial rate for hydrogen isotopic exchange of tritium into the initial D-[2-^{1}H]alanine derived from fitting the data is 0.5 times the initial rate for its conversion to L-[2-^{3}H]alanine. For the reaction in reverse (Equations 5–267 and 5–268), the extrapolated initial rate for hydrogen isotopic exchange of tritium into the initial L-[2-^{1}H]alanine is 0.33 times the initial rate for its conversion to D-[2-^{3}H]alanine.[841] These results, along with steady-state rate constants and kinetic isotope effects, could be used to calculate that under normal circumstances, when no tritium is present in the solvent, the initial rate at which quinonoid intermediate **5–161** is converted to D-alanine free in solution is twice the initial rate at which quinonoid intermediate **5–161** is converted to L-alanine free in solution.*

As was the case with alanine racemase, the initial rate for an isotopic exchange, when combined with other kinetic observations, can provide **rate constants for the steps in the kinetic mechanism** of an enzymatic reaction. For example, the initial rate for positional oxygen isotopic exchange of the bridging oxygen in $MgATP^{2-}$ (Equation 5–209) in the absence and presence of the other two reactants, coenzyme A and citrate; the rate at which the covalent phosphorylated intermediate of the enzyme is formed as a function of the concentration of $MgATP^{2-}$; the catalytic constant; and the two specificity constants from steady-state kinetics could be used to provide experimentally observed parameters within the necessary simultaneous equations. From these equations, the rate constants, both forward and reverse, and hence the equilibrium constants for each step in the kinetic mechanism proposed for the reaction catalyzed by human ATP citrate synthase

$$MgATP^{2-} + \text{citrate} + HSCoA \rightleftharpoons MgADP^{-} + HOPO_3^{2-} + \text{acetyl-SCoA} + \text{oxaloacetate} \quad (5\text{–}269)$$

could be calculated.[843] Such calculations, however, are valid only if the kinetic mechanism proposed for the reaction is correct. Usually, however, if the proposed mechanism is not correct but only incomplete, then the calculated rate constants are composite rate constants that combine steps that occur but do not appear in the proposed kinetic mechanism.

If measurements are confined to the relative initial rates for individual isotopic exchanges into stoichiometric substrates in the enzymatic reaction that are neither hydrogen nor oxygen isotopic exchanges, then isotopic exchange at equilibrium can provide information about the sequence in which reactants associate and products dissociate rather than information about the order of the chemical transformations that occur within the active site and the existence of particular intermediates. Such determinations provide information about a kinetic mechanism rather than a chemical mechanism. Isotopic exchanges in which neither a molecule of water nor a hydron carries the isotope exchanged always require that a stoichiometric reactant participating in the isotopic exchange must associate with the active site and be chemically converted to a stoichiometric product, and this product must dissociate into the solution before the same product with a different isotope, participating in the isotopic exchange in the other direction,

*These rates do not violate the requirement that the equilibrium constant for the reaction must be 1. The rates of formation of the quinonoid intermediate from the two enantiomers differ by the correct amount to satisfy the Haldane relation.

takes the place of the just-dissociated product in the active site. Following its association, this isotopically different product must be chemically transformed into the original reactant, albeit with a different isotopic signature, and that reactant must dissociate from the active site for the isotopic exchange to be accomplished.

Glutamine synthetase (previously Equation 4–453)

$$\text{L-glutamate} + NH_4^+ + MgATP^{2-} \rightleftharpoons MgADP^- + H_2OPO_3^- + \text{L-glutamine} \quad (5\text{–}270)$$

catalyzes a reaction with three reactants and three products. On the basis of other evidence,[763,844,845] including positional isotopic exchange (Equation 5–209),[762] it has been concluded that the central intermediate in the reaction is L-γ-glutamyl phosphate (Equation 5–210). Formation of L-γ-glutamyl phosphate should require only L-glutamate and $MgATP^{2-}$. In the simplest situation, $MgATP^{2-}$, should reversibly phosphorylate an oxygen in the γ-carboxy group of L-glutamate in the absence of ammonium ion; yet, in the presence of L-glutamate but in the absence of ammonium ion, no carbon isotopic exchange (<0.01% that seen in the presence of ammonium ion) between $MgATP^{2-}$ and $MgADP^-$

$$Mg[^{12}C]ATP^{2-} + Mg[^{14}C]ADP^- \rightleftharpoons Mg[^{12}C]ADP^- + Mg[^{14}C]ATP^{2-} \quad (5\text{–}271)$$

was observed with the enzyme from *E. coli*.[846] This isotopic exchange would result from formation of a ternary complex of L-γ-glutamyl phosphate ($GluOPO_3^{2-}$), $Mg[^{12}C]ADP^-$, and enzyme from $Mg[^{12}C]ATP^{2-}$ and L-glutamate (Glu^-)

$$E + Glu^- + Mg[^{12}C]ATP^{2-} \rightleftharpoons E{\cdot}GluOPO_3^{2-}{\cdot}Mg[^{12}C]ADP^- \quad (5\text{–}272)$$

dissociation of the $Mg[^{12}C]ADP^-$ formed

$$E{\cdot}GluOPO_3^{2-}{\cdot}Mg[^{12}C]ADP^- \rightleftharpoons E{\cdot}GluOPO_3^{2-} + Mg[^{12}C]ADP^- \quad (5\text{–}273)$$

association of $Mg[^{14}C]ADP^-$ with the complex of enzyme and glutamyl phosphate, formation of $Mg[^{14}C]ATP^{2-}$ and L-glutamate in the active site, and dissociation of $Mg[^{14}C]ATP^{2-}$ from the active site

$$E{\cdot}GluOPO_3^{2-} + Mg[^{14}C]ADP^- \rightleftharpoons E + Glu^- + Mg[^{14}C]ATP^{2-} \quad (5\text{–}274)$$

The explanation for why no carbon isotopic exchange (Equation 5–271) occurs in the absence of ammonium while positional oxygen isotopic exchange (Equation 5–209) is observed is that, in the absence of ammonium ion, $Mg[^{12}C]ADP^-$ cannot dissociate from the active site, which is a requirement for the carbon isotopic exchange to occur (Equation 5–273). The reason $Mg[^{12}C]ADP^-$ cannot dissociate is that the active site closes around $MgATP^{2-}$, L-glutamate, $MgADP^-$, and L-γ-glutamyl phosphate, preventing $MgADP^-$ from dissociating and exposing L-γ-glutamyl phosphate to hydrolysis.[763,845] When equilibrium concentrations of all six substrates are present, however, MgATP–MgADP carbon isotopic exchange at equilibrium (Equation 5–271) is observed. Because this isotopic exchange does not occur in the absence of ammonium ion, it must result from reversal of the complete reaction at equilibrium.

The initial rates for several of the isotopic exchanges at equilibrium observed with glutamine synthetase from *E. coli* are contrary to expectation. They present an even clearer example of the danger of attempting to correlate relative initial rates for isotopic exchange with the sequence in which covalent bonds are formed or broken within the active site. The initial rate for the carbon isotopic exchange between L-glutamate and L-glutamine

$$\text{L-}[^{14}C]\text{glutamate} + \text{L-}[^{12}C]\text{glutamine} \rightleftharpoons \text{L-}[^{14}C]\text{glutamine} + \text{L-}[^{12}C]\text{glutamate} \quad (5\text{–}275)$$

at equilibrium is 3.6-fold greater than the initial rate for the carbon isotopic exchange between $MgATP^{2-}$ and $MgADP^-$ at equilibrium (Equation 5–271).[846] The carbon isotopic exchange between L-glutamate and L-glutamine must represent the sum of all chemical steps in the reaction in which bonds are formed and broken because, once L-glutamate has been converted to L-glutamine, all chemical steps have been accomplished. Because L-γ-glutamyl phosphate is the intermediate in the enzymatic reaction, $MgADP^-$ must be formed in a step in the overall

enzymatic reaction that precedes the step in which L-glutamine is formed, yet the magnitudes of the initial rates for the isotopic exchanges were in the opposite relation. Even the initial rate for the **nitrogen isotopic exchange**

$$\text{L-}[^{14}\text{N}]\text{glutamine} + [^{15}\text{N}]\text{NH}_4^+ \rightleftharpoons [^{14}\text{N}]\text{NH}_4^+ + \text{L-}[^{15}\text{N}]\text{glutamine} \quad (5\text{–}276)$$

at equilibrium, which requires that phosphate ion, a poor nucleophile, engage in a nucleophilic substitution for ammonia, a poor leaving group, at the γ-carboxy group of the L-glutamyl group was 2.1-fold greater than the initial rate for the MgATP–MgADP isotopic exchange at equilibrium, which only requires that $MgATP^{2-}$ be able to phosphorylate a carboxylato group and then $MgADP^-$ be rephosphorylated by the resulting acyl phosphate in an almost isoergonic nucleophilic substitution at phosphorus. Clearly the relative initial rates for the various isotopic exchanges provide no information about the intermediate in the enzymatic reaction.

The ultimate product $MgADP^-$ must be formed within the active site of glutamine synthetase before L-glutamine is formed in the direction written (Equation 5–270). Nonetheless, at equilibrium, the initial rates for glutamate–glutamine carbon isotopic exchange (Equation 5–275) and ammonium–glutamine nitrogen isotopic exchange (Equation 5–276) are more rapid than the initial rate for MgATP–MgADP carbon isotopic exchange (Equation 5–271). This fact means that either $MgATP^{2-}$ is slower to dissociate from the enzyme than L-glutamate and ammonia in the reverse direction or $MgADP^-$ is slower to dissociate than L-glutamine in the forward direction or both of these requirements apply or $MgATP^{2-}$ is required to associate with the active site before L-glutamate and ammonium can associate or L-glutamine must dissociate from the active site before $MgADP^-$ can dissociate or both of these requirements apply. In other words, associations and dissociations have a preferential order or they have a required order.

Consequently, these relative initial rates, although they fail to provide reliable information about the intermediate in the enzymatic reaction, provide supporting evidence for the conclusion, drawn from steady-state kinetic measurements in the forward direction of the enzymatic reaction (Equation 5–270), that association of reactants is ordered, and $MgATP^{2-}$ is the first reactant to add, L-glutamate the second, and ammonia the third.[845,847] It follows that $MgADP^-$ should be the last product to dissociate and L-glutamine the penultimate product to dissociate. If all these orders of association and dissociation are those followed by the enzymatic reaction, the MgATP–MgADP isotopic exchange at equilibrium would have to be the isotopic exchange accomplished by the entire enzymatic reaction in one direction and then the entire enzymatic reaction in the other while the glutamate–glutamine and nitrogen isotopic exchanges would be accomplished by shorter sequences of interior steps of associations and dissociations of L-glutamate, L-glutamine, and ammonia. Consequently, at the very least, isotopic exchanges at equilibrium provide **evidence consistent with a preferential order for association of reactants and a preferential order for dissociation of products in the enzymatic reaction.**

As already discussed, however, there is a distinction between a situation in which reactants associate with, and products dissociate from, an active site in a preferential order because the rate of association of one reactant is simply greater than that of the other at all concentrations of reactants examined or the rate of dissociation of one product is greater than the rate of dissociation of another, and a situation in which reactants are required to add to, or products are required to dissociate from, the active site in an obligatory order. For example, a second reactant may not be able to associate with the active site until the first reactant does because the first reactant forms a portion of the site with which the second associates or induces a conformational change in the active site required to create the site with which the second reactant associates. In either case, the site for the second reactant does not exist until the first reactant associates. Another example would be a situation in which a second product cannot dissociate from the active site until the first product dissociates because the first product is bound in the active site between the second product and the solution and sterically prevents the second from dissociating or dissociation of the first induces a conformational change required to occur before the second product can dissociate.

Isotopic exchange at equilibrium can be used to draw a distinction between a preferential order, resulting from a simple difference in the rates of association with and dissociation from the active site, and an obligatory order in which one substrate must associate before its cosubstrate can and that same substrate must dissociate only after its cosubstrate has dissociated.[838,848] The following distinctions

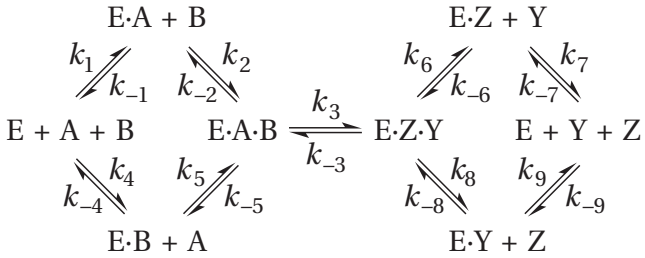
are one of the few ways to **assess the difference between obligation and preference**.

Suppose that substrates A and Z must associate with the active site before the active site is capable of associating with their respective cosubstrates, B and Y, and that substrates B and Y must dissociate from the active site before their respective cosubstrates, A and Z, can gain access to the solution and dissociate

$$\mathrm{E + A + B} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}A + B} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{E{\cdot}A{\cdot}B} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \mathrm{E{\cdot}Z{\cdot}Y} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \mathrm{E{\cdot}Z + Y} \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} \mathrm{E + Y + Z} \qquad (5\text{–}277)$$

Suppose also that one isotopic exchange at equilibrium can be measured between substrates B and Y, the proximal pair, and another isotopic exchange at equilibrium can be measured between substrates A and Z, the distal pair. When the absolute equilibrium concentrations of all substrates are raised in concert, the distal isotopic exchange between A and Z will increase, reach a maximum, and decrease to zero because the concentrations of E·A and E·Z, from which the respective substrates must dissociate for the distal isotopic exchange to occur, will begin to decrease and approach zero as the concentrations of B and Y are increased and the complexes E·A·B and E·Z·Y come to account for almost all the enzyme in the solution. The proximal isotopic exchange at equilibrium between B and Y, however, will increase and approach a maximum asymptotically because substrate B will always be able to dissociate from the complex E·A·B and substrate Y will always be able to dissociate from the complex E·Z·Y. The rates of these two dissociations are not influenced by the concentrations of substrates. In addition, reformation of complex E·A·B following dissociation of substrate B and re-formation of complex E·Z·Y following dissociation of substrate Y will be almost immediate because there are high concentrations of substrates B and Y to capture the complexes E·A and E·Z immediately after the respective dissociations and before substrates A and Z, respectively, are able to dissociate.

If there is no obligate order and substrates can associate at random



(5–278)

All isotopic exchanges will increase and approach a maximum asymptotically, even though the rates of association and dissociation for one substrate are such that it almost always associates with the active site before its cosubstrate can and, because it binds more tightly, dissociates less readily than its cosubstrate. In this instance, there will be a preferential order in which substrates associate with and dissociate from the enzyme. Complexes E·A and E·B are not distinguished from each other by the order in which substrates A and B are required to associate with and dissociate from complex E·A·B. In addition, complexes E·Z and E·Y are also not distinguished from each other by the order in which substrates Z and Y are required to associate with and dissociate from complex E·Z·Y.

Because glutamate–glutamine carbon isotopic exchange (Equation 5–275) is catalyzed by glutamine synthetase (Equation 5–270) more rapidly than MgATP–MgADP carbon isotopic exchange (Equation 5–271), it was possible that there might be an obligatory order in which substrates must associate with and dissociate from the active site. Other kinetic observations[847] and crystallographic observations[845] were also consistent with an obligate order of addition for substrates $MgATP^{2-}$ and L-glutamate, the former preceding the latter, and an obligate order for association of substrates $MgADP^{-}$ and L-glutamine, the former preceding the latter. Both isotopic exchanges at equilibrium, however, increased and approached their respective maxima asymptotically when the concentrations of substrates were increased in concert for both glutamine synthetase from *E. coli*[846] and ovine glutamine synthetase.[849] It follows that either substrate, $MgATP^{2-}$ or L-glutamate, or either substrate, $MgADP^{-}$ or L-glutamine, may associate with and dissociate from the active site first. The microscopic rate constants for associations and dissociations of the nucleotides, however, are such that they usually associate first with the empty active site and usually dissociate last from a fully occupied active site, but they are not required to do so.

Similar results were observed with isotopic exchanges at equilibrium catalyzed by bovine ketohexokinase[850]

$$MgATP^{2-} + \text{D-fructose} \rightleftharpoons \text{D-fructose 1-phosphate} + MgADP^{-} + H^{+} \quad (5\text{–}279)$$

Although the initial rate for MgATP–MgADP carbon isotopic exchange

$$Mg[^{14}C]ATP^{2-} + Mg[^{12}C]ADP^{-} \rightleftharpoons Mg[^{14}C]ADP^{-} + Mg[^{12}C]ATP^{2-} \quad (5\text{–}280)$$

at equilibrium is 4 times greater at saturation than the initial rate for fructose–fructose phosphate carbon isotopic exchange

$$\text{D-}[^{12}C]\text{fructose 1-phosphate} + \text{D-}[^{14}C]\text{fructose} \rightleftharpoons \text{D-}[^{12}C]\text{fructose} + \text{D-}[^{14}C]\text{fructose 1-phosphate} \quad (5\text{–}281)$$

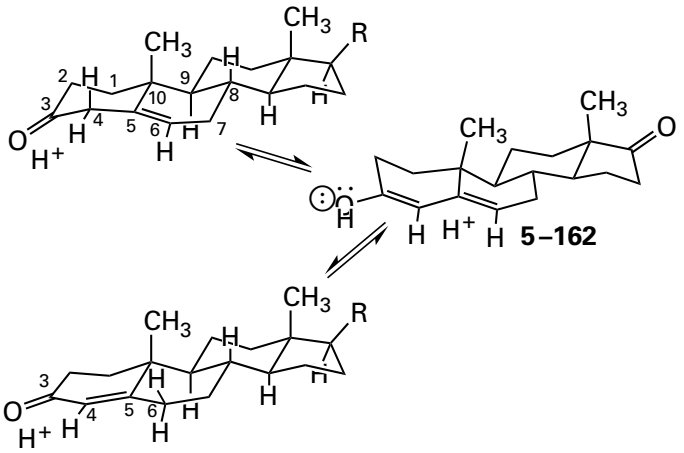
at equilibrium, the initial rates for both carbon isotopic exchanges at equilibrium approach their respective maxima asymptotically as concentrations of reactants and products are increased. Therefore, any of the four reactants can associate first and any of the four products can dissociate first, but the microscopic rate constants for associations or dissociations of the nucleotides are such that they usually associate after instead of before, and dissociate before instead of after, the monosaccharides.

In the case of diphosphate—fructose-6-phosphate 1-phosphotransferase from *P. freudenreichii*

$$\text{D-fructose 6-phosphate} + MgOPO_3PO_3^{2-} \rightleftharpoons Mg^{2+} + HOPO_3^{2-} + \text{D-fructose 1,6-bisphosphate} \quad (5\text{–}282)$$

the initial rates for three isotopic exchanges at equilibrium—carbon isotopic exchange for D-[U-^{14}C]fructose 1,6-bisphosphate with D-[U-^{12}C]fructose 1-phosphate, phosphorus isotopic exchange for [^{32}P]phosphate with magnesium [^{31}P]diphosphate, and phosphorus isotopic exchange for magnesium [^{32}P]diphosphate with D-fructose [1,6-$^{31}P_2$]bisphosphate—increased in concert when each concentration of the four possible substrate pairs—diphosphate and phosphate, magnesium diphosphate and D-fructose 1,6-bisphosphate, D-fructose 6-phosphate and phosphate, and D-fructose 6-phosphate and D-fructose 1,6-bisphosphate—were increased.* The initial rates for each of the three isotopic exchanges reached the **same limiting rate at saturation** with all substrates.[851] These results are **evidence consistent with a kinetic mechanism in which substrates associate with and dissociate from the active site at random**.

Intramolecular isotopic transfer is sometimes observed in enzymatic reactions. For example, in the reaction catalyzed by steroid Δ-isomerase



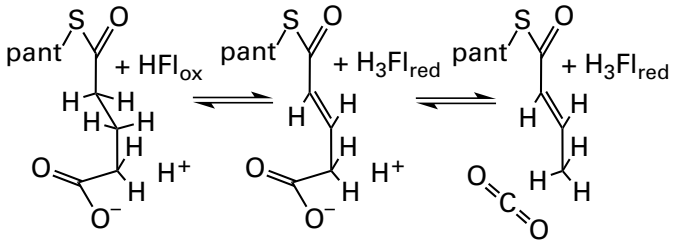
(5–283)

from *C. testosteroni* in ^2H_2O with the reactant androst-5-ene-3,17-dione, only a small amount of deuterium (6–9%) is incorporated into the product androst-4-ene-3,17-dione.[852] Because the enzyme was initially dissolved in ^2H_2O and all the hydrons on any possible catalytic acid were immediately exchanged for deuterons before the reaction was initiated, the only source of protons in this instance is androst-5-ene-3,17-dione itself. Because only the hydron on carbon 4 is removed from androst-5-ene-3,17-dione, this observation requires that the hydron be intramolecularly transferred between carbons 4 and 6 during the enzymatic reaction. When the reaction is catalyzed by the enzyme in ^1H_2O with the reactant [4,4-$^2H_2$]androst-5-ene-3,17-dione, a deuterium on carbon 4 is transferred intramolecularly to carbon 6 of the steroid that is a reactant with little isotopic exchange.[853] Aspartate 38 in the active site of the enzyme performs this intramolecular transfer of a deuteron or hydron, respectively.[854] The carboxy

*Recall that in the equilibrium constant for the reaction, these four pairs appear as quotients, so increasing them in concert does not affect the equilibrium.

group of an aspartate can carry only one hydron at a time, and all that is needed to perform the intramolecular transfer from one carbon to the other is for the carboxy group of Aspartate 38 to rotate around the β carbon–γ carbon bond since removal of the hydron from carbon 4 of androst-5-ene-3,17-dione and its addition to carbon 6 occurs on the same face of the steroid.[853] The carboxy group must, however, also be isolated from hydrons on other acid–bases in the active site that could participate in exchange of its hydron before it has a chance to hydronate carbon 6 of the steroid, which must be relatively slow because it is a hydronation of carbon.

In the reaction catalyzed by glutaryl-CoA dehydrogenase (ETF) from *P. fluorescens*

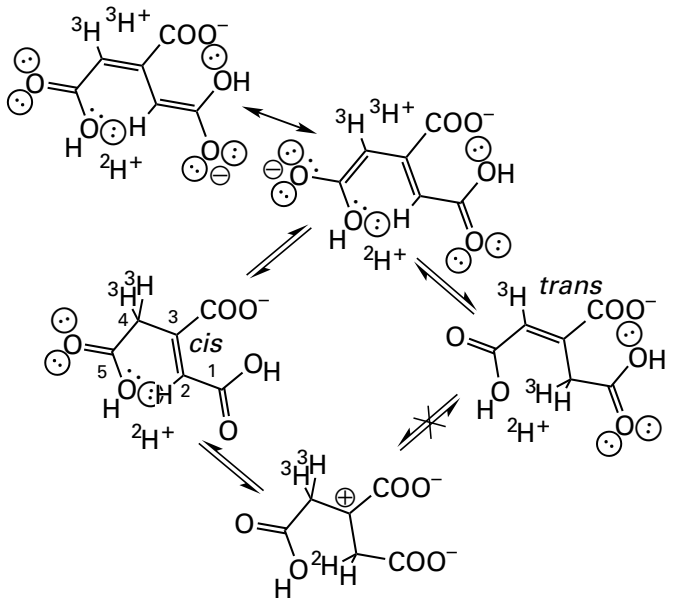


(5–284)

where pant is a pantetheinyl group, there is no incorporation (≤0.5%) of tritium into (*E*)-but-2-enoyl-pantetheine when glutarylpantetheine is oxidized and decarboxylated by the enzyme in ^3H_2O and no hydrogen isotopic exchange of protium with tritium at carbon 2 of the unreacted glutarylpantetheine.[785] The former result requires that the hydron removed from carbon 2 of glutarylpantetheine by a catalytic base be transferred without hydrogen isotopic exchange to carbon 4 because the formal protide ion removed by the prosthetic flavin from carbon 3 does undergo hydrogen isotopic exchange with tritons and therefore cannot be the source of the protium at carbon 4 in the product. The hydron is transferred between carbons 2 and 4 by the catalytic carboxy group of a glutamate that is located in the active site immediately adjacent to carbons 2 and 4 of glutarylpantetheine (Equation 5–227).[249] Again, all that is required for intramolecular isotopic transfer is for the carboxy group of the glutamate to be isolated from other hydrons and to rotate around its γ carbon–δ carbon bond.

The fact that there is no incorporation of tritium from ^3H_2O is consistent with a requirement that no hydrogen isotopic exchange of a proton on the carboxy group of glutamate occur with a triton. Human glutaryl-CoA dehydrogenase (decarboxylating), however, which is closely related (57% identity; 0.5 gap percent), does catalyze hydrogen isotopic exchange of protium for deuterium at both carbon 4 of (*E*)-but-2-enoyl-SCoA ($k_{ex} = 10\ s^{-1}$) and carbon 2 of glutaryl-SCoA in ^2H_2O.[855] In this enzyme with these substrates, the hydron on the carboxy group of the homologous glutamate must be able to exchange ($k_{ex} \geq 10\ s^{-1}$) with deuterons, either on other acid–bases in the active site or in the solvent. The side chains of the amino acids surrounding the carboxy group of the glutamate responsible for dehydronation and hydronation of carbons 2 and 4 in the human enzyme are all hydrophobic,[249] two leucines and a valine, but the same side chains are present at the homologous positions in the enzyme from *P. fluorescens*, so there is no obvious molecular explanation for the difference in isotopic exchange between these two species of the enzyme.

The addition–elimination catalyzed by aconitate Δ-isomerase could have proceeded either of two ways[856]



(5–285)

where the reactant is *cis*-aconitate and the product is *trans*-aconitate. The lower path would be through a carbenium ion as an intermediate and the upper through an enolate. The carbocation is not so appealing because the hydron would have to add to a carbon next to the electropositive carbon of a carboxy group and the resulting carbenium ion would also be forced to reside next to a carboxy group. The enolate is the more appealing possibility because it spreads the negative charge over seven atoms in its highest occupied π molecular orbital with lobes over the two electropositive oxygens at its two ends.

Because, in the complete reaction, a hydron is added to carbon 2 and a hydron is removed from carbon 4, the issue again is the timing. It was observed[856] that during the enzymatic isomerization of *cis*-[4*S*-$^3H_2$]aconitate in ^2H_2O, the *pro*-*S* tritium was removed from carbon 4 of the reactant and a fraction of that tritium (44%) was transferred to carbon 2. The tritium or deuterium added to carbon 2 occupied the *S* position in the product. All these observations are consistent with removal of a hydron from carbon 4 of the reactant by a base, its transfer across that same face of the intermediate by the base, and its subsequent addition to carbon 2 from that same face. Consequently, the intermediate should be the more appealing enolate (Equation 5–285).

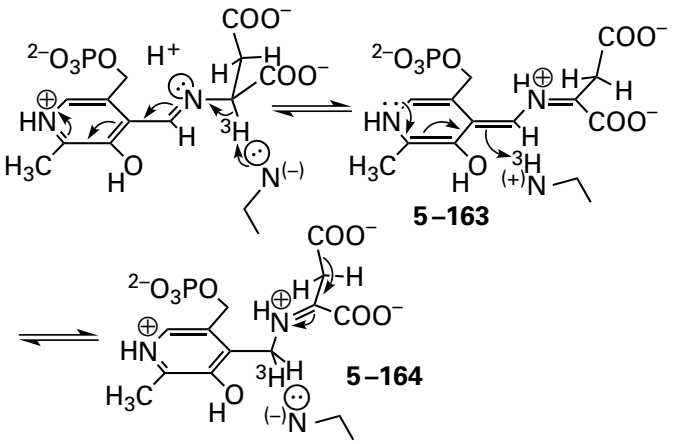
Aspartate 4-decarboxylase uses a prosthetic pyridoxal 5′-phosphate to catalyze the reaction

$$\text{L-aspartate} + H^+ \rightleftharpoons CO_2 + \text{L-alanine} \qquad (5\text{–}286)$$

the replacement of carbon dioxide by a hydron. Occasionally (0.05% of the time) the enzyme from *Alcaligenes faecalis* fails to complete the normal reaction and the following side reaction occurs

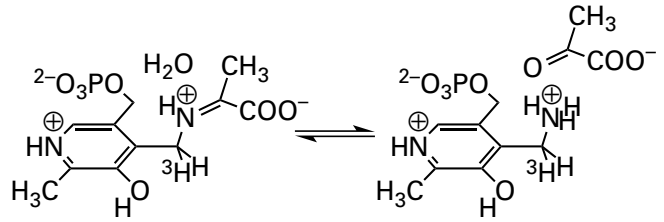
$$\text{L-aspartate} + H^+ + \text{pyridoxal 5′-phosphate} \rightleftharpoons CO_2 + \text{pyruvate} + \text{pyridoxamine 5′-phosphate} \qquad (5\text{–}287)$$

In the abortive reaction, the prosthetic group has become a substrate. When L-[2-^{3}H]aspartate is used as a reactant, a significant amount of tritium (equivalent to 17% intramolecular transfer)[857] is found at carbon 4′ of the pyridoxamine phosphate formed as a result of abortive Equation 5–287. The existence of this intramolecular isotopic transfer suggests that the same base that removes the α-hydron from the external succinyl pyridoximine hydronates the 4′-carbon of pyridoxal phosphate to form *N*-pyridoxylimine **5–164**, which would be necessary to promote the decarboxylation (see Equation 2–5)[858]



(5–288)

Following decarboxylation and hydronation, the resulting *N*-pyridoxylimine hydrolyzes occasionally before the hydron can be transferred back to the carbon of the imino group



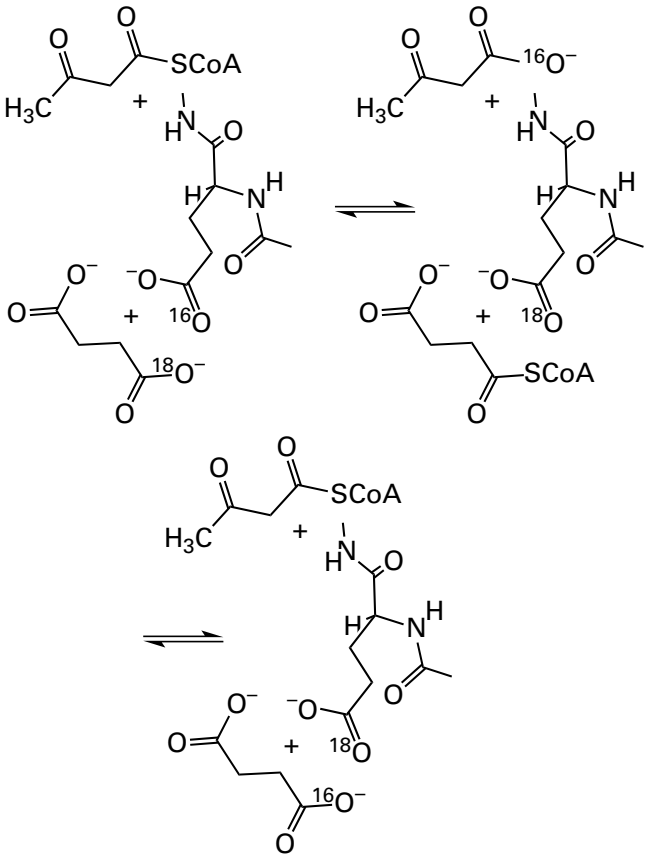
(5–289)

This hydrolysis could occur either on the active site or after the decarboxylated *N*-pyridoxylimine has dissociated intact from the active site. The existence of the intramolecular isotopic transfer, as well as the existence of the abortive reaction itself, provides evidence that *N*-pyridoxylimine **5–164** is an obligatory intermediate in the enzymatic reaction. This conclusion is reasonable because quinonoid **5–163** should be too electron-rich to promote decarboxylation, a reaction that requires π electron withdrawal. In other words, the carbanion that would be formed if quinonoid **5–163** decarboxylated directly would have 10 π molecular orbitals—5 bonding and 5 antibonding—and 12 π electrons, a circumstance that would require two π electrons to occupy an antibonding molecular orbital or two degenerate molecular orbitals.

Methylphosphonate synthase is an oxygenase that converts 2-hydroxyethylphosphonate to methylphosphonate by oxidizing the hydroxymethyl group in 2-hydroxyethylphosphonate to carbon dioxide. The two hydrogens on carbon 1 of 2-hydroxyethylphosphonate remain in the final methyl group in methylphosphonate, but the active site transfers the *pro*-*R* hydrogen on the hydroxymethyl group in

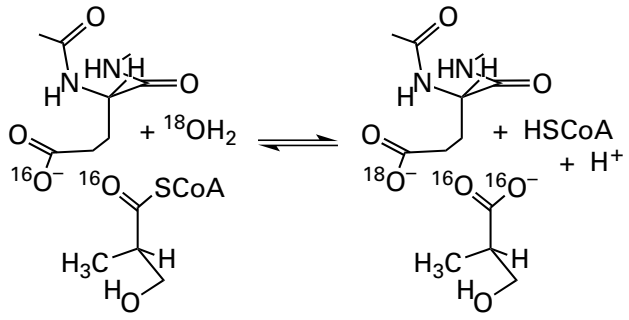
2-hydroxyethylphosphonate to carbon 1 during the oxidation so that it ends up on the methyl group of methylphosphonate.[859] In this instance, however, a catalytic base does not perform the transfer because there is none in the vicinity.[860] It has been proposed that, in the process of oxidizing carbon 2, a formate on a prosthetic iron ion is produced and its **hydrogen is directly transferred** either as a hydrogen atom to a phosphonomethyl radical or, less likely, as a hydride to a primary phosphonomethylene carbenium ion.

Isotopic transfer between a substrate of the enzymatic reaction and the enzyme itself has also been observed. The mechanism of 3-oxoacid CoA-transferase involves formation of an anhydride between a glutamate at the active site[90] and the carboxylic acids that are substrates for the enzyme (Equation 5–14). When [^{18}O]succinate and acetoacetyl-SCoA were used as reactants for the porcine enzyme, the isotopic transfer



(5–290)

into the protein itself could be detected.[861] This isotopic transfer into the protein is consistent with the existence of the anhydride as an intermediate in the enzymatic reaction. The incorporation of one atom of oxygen-18 into 3-hydroxyisobutyryl-CoA hydrolase from *P. aeruginosa* during the hydrolysis catalyzed by the enzyme



(5–291)

was also presented as evidence for an intermediate anhydride.[862]

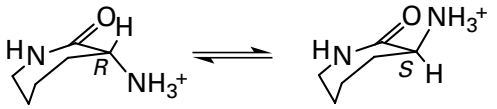
Problem 5–19: 2-Aminohexano-6-lactam racemase is an enzyme that uses pyridoxal phosphate as a prosthetic group to catalyze the racemization of the lactam of lysine.



When (*R*)-[2-^{1}H]-2-aminohexano-6-lactam was mixed with the enzyme from *Achromobacter obae* in ^2H_2O, (*R*)-[2-^{2}H]-2-aminohexano-6-lactam was formed at an initial rate that was 80% the initial rate at which (*S*)-2-aminohexano-6-lactam was formed.[863]

(A) Write a mechanism for the enzymatic reaction, incorporating the pyridoxal phosphate and catalytic acids and bases, that explains this hydrogen isotopic exchange at initial rate.

(*R*)-[2-^{1}H]-2-Aminohexano-6-lactam was converted with 2-aminohexano-6-lactam racemase to (*S*)-2-aminohexano-6-lactam in ^2H_2O in the presence of excess L-lysine-lactamase so that the product of the first reaction was immediately hydrolyzed. A significant fraction (17%) of the resulting L-lysine had protium at carbon 2.

(B) What does this observation suggest about the catalytic acid and catalytic base catalyzing the racemization?

(C) There are two reasons to suspect that one particular amino acid is used as a catalytic acid–base in this reaction.[864] What is the amino acid and what are the two reasons? Use this amino acid as the catalytic base in your answer to part A.

Problem 5–20: The reaction catalyzed by ribulose-bisphosphate carboxylase (Equations 3–424 and 5–90) was initiated by mixing enzyme from *R. rubrum* with D-ribulose 1,5-bisphosphate and CO_2 in ^3H_2O. As the reaction progressed at initial rate, tritium appeared at carbon 3 of the ribulose 1,5-bisphosphate remaining in the solution.[865]

extent of reaction (%)	specific radioactivity of remaining ribulose bisphosphate (cpm μmol$^{-1} \times 10^{-5}$)
21	0.9
38	1.9
56	3.3
70	5.2
82	7.4
86	8.4
98	17

(A) Write a mechanism demonstrating why this hydrogen isotopic exchange at initial rate is evidence for an enediol intermediate in the enzymatic reaction.

(B) The specific radioactivity of the water was 7.0×10^5 cpm (μmol of hydrogen)$^{-1}$. Why does the specific radioactivity of the remaining ribulose bisphosphate exceed this value when the reaction has reached equilibrium (98% completion)?

Problem 5–21: Na^+/K^+-Exchanging ATPase catalyzes the following reaction

$$2\,K_o^+ + H_2O + MgATP^{2-} + 3\,Na_i^+ \rightleftharpoons H^+ + HOPO_3^{2-} + 2\,K_i^+ + MgADP^- + 3\,Na_o^+$$

in which the subscripts i and o refer to the inside and the outside of a cell, respectively. This reaction will be referred to as overall turnover. Overall turnover is always measured in, and requires, the presence of all substrates: $MgATP^{2-}$, Na^+, and K^+. In the cell, the cations are moved against their concentration gradients at the expense of hydrolysis of $MgATP^{2-}$. When the cell is fragmented, the enzyme continues to move the cations across itself but accomplishes nothing even though it still hydrolyzes $MgATP^{2-}$. Thus, it is named an adenosinetriphosphatase (ATPase).

The enzyme catalyzes several isotopic exchanges in the absence of certain reactants. In the presence of K^+ and Mg^{2+} but the absence of Na^+ and $MgATP^{2-}$, porcine Na^+/K^+-exchanging ATPase catalyzes the following oxygen isotopic exchange.[866]

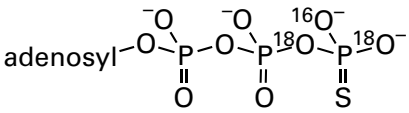
$$[^{16}O]HOPO_3^{2-} + [^{18}O]H_2O \rightleftharpoons [^{16}O]H_2O + [^{18}O]HOPO_3^{2-}$$

This oxygen isotopic exchange occurs at an initial rate greater than that of the overall turnover seen when Na^+ and $MgATP^{2-}$ are added. In the presence of Na^+ but the absence of K^+, the enzyme very slowly catalyzes the following carbon isotopic exchange.[867]

$$Mg[^{12}C]ATP^{2-} + Mg[^{14}C]ADP^- \rightleftharpoons Mg[^{12}C]ADP^- + Mg[^{14}C]ATP^{2-}$$

When the enzyme is treated with *N*-ethylmaleimide, the initial rate for this ATP–ADP carbon isotopic exchange increases greater than 100-fold and becomes 3 times faster than the overall turnover was before the treatment. The overall turnover is eliminated by treatment with *N*-ethylmaleimide. *N*-Ethylmaleimide, however, has no effect on the $HOPO_3^{2-} \rightleftharpoons H_2O$ oxygen isotopic exchange observed in the absence of Na^+ and $MgATP^{2-}$. When both Na^+ and K^+ are omitted, none of the isotopic exchanges occur.

(A) Write a kinetic mechanism for the overall reaction, involving a covalent intermediate, that explains both the $HOPO_3^{2-} \rightleftharpoons H_2O$ oxygen isotopic exchange and the ATP–ADP carbon isotopic exchange.
(B) Write the steps in the overall mechanism that produce the Na^+-dependent ATP–ADP carbon isotopic exchange.
(C) Write the steps in the overall mechanism that produce the K^+-dependent $HOPO_3^{2-} \rightleftharpoons H_2O$ oxygen isotopic exchange.
(D) Considering the initial rates for the isotopic exchanges when the enzyme is not treated with *N*-ethylmaleimide, decide whether the intermediate is a high-energy or a low-energy intermediate in this situation.
(E) Show that the effects of *N*-ethylmaleimide can be explained by adding to your mechanism a step that involves a conformational change between two forms of the covalent intermediate, a high-energy form and a low-energy form, and that is blocked by reaction with *N*-ethylmaleimide.
(F) Considering your mechanism and assuming that all biochemical phosphostransfers are in-line, draw the two products, with proper stereochemistry, that result when the following substrate is hydrolyzed by the enzyme in $[^{17}O]H_2O$.



Oxygen-17 ends up in one product.

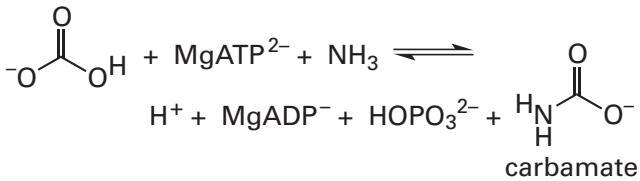
Problem 5–22: When the reaction catalyzed by 2-hydroxy-6-oxonona-2,4-dienedioate hydrolase

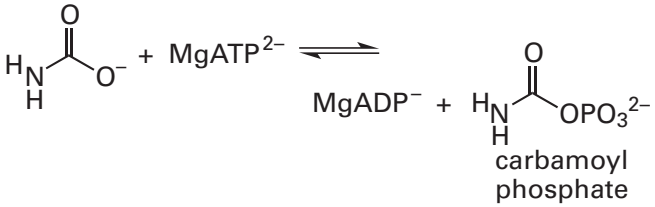
(2*Z*,4*E*)-2-hydroxy-6-oxonona-2,4-diene-1,9-dioate + $H_2O \rightleftharpoons$ succinate + H^+ + (2*Z*)-2-hydroxypenta-2,4-dienoate

from *E. coli* is performed in $H_2{}^{18}O$ with the reactant [6-^{16}O]-(2*Z*,4*E*)-2-hydroxy-6-oxonona-2,4-diene-1,9-dioate, [^{18}O]succinate (95%) and doubly labeled [1,1-$^{18}O_2$]succinate (5%) are produced as products and oxygen isotopic exchange of oxygen-16 for oxygen-18 at the carbonyl group on carbon 6 of 2-hydroxy-6-oxonona-2,4-diene-1,9-dioate is observed as well.[868]

(A) Write a mechanism for the enzymatic reaction consistent with both the intermediate oxygen isotopic exchange and the oxygen isotopic exchange into the reactant at initial rate.
(B) Write out separately the sequence of individual steps in the mechanism of part A that explains the respective oxygen isotopic exchanges.

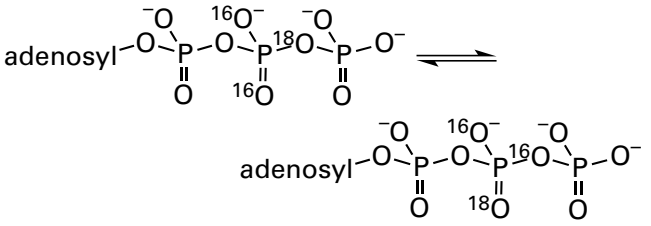
Problem 5–23: Carbamoyl-phosphate synthase (ammonia) catalyzes the reaction comprising just Equations 3–532 and 3–533





using stoichiometric ammonia rather than ammonia derived from hydrolysis of L-glutamine. In the presence of HCO_3^- but the absence of NH_4^+, the

enzyme from *R. norvegicus* catalyzes the positional oxygen isotopic exchange[869]



When the enzyme is mixed with $MgATP^{2-}$ and $[^{18}O]HOCO_2^-$ in the absence of NH_4^+, it catalyzes a slow ATPase activity in which 1 mol of oxygen-18 appears in $HOPO_3^{2-}$ for every $MgATP^{2-}$ hydrolyzed. There is a related enzyme (39% identity; 0.7 gap percent) in *E. coli*, carbamoyl-phosphate synthase (glutamine-hydrolysing), that catalyzes the same sequence of reactions and that produces the necessary NH_4^+ by hydrolyzing L-glutamine in a distant glutaminase domain. It also catalyzes a slow bicarbonate-dependent ATPase reaction and the same positional oxygen isotopic exchange.[870] When carbamoyl-phosphate synthase (glutamine-hydrolysing) is mixed with $MgATP^{2-}$ and $HOCO_3^-$ in $H_2{}^{18}O$ in the absence of L-glutamine and NH_4^+, it catalyzes the oxygen isotopic exchange

$$H^{16}OC^{16}O_2^- + {}^{18}OH_2 \rightleftharpoons {}^{16}OH_2 + H^{18}OC^{16}O_2^-$$

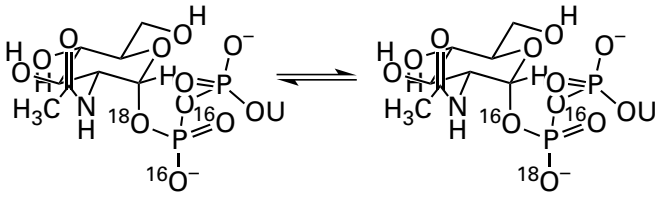
at an initial rate equal to the initial rate for the bicarbonate-dependent ATPase reaction.[871]

(A) Write a mechanism for the overall enzymatic reaction that is catalyzed by both enzymes from NH_4^+, $MgATP^{2-}$, and $HOCO_2^-$ and that contains an intermediate that can explain these observations.
(B) Why is the positional oxygen isotopic exchange in the enzyme from *R. norvegicus* inhibited by NH_4^+?
(C) Why is oxygen isotopic exchange of oxygen-18 into $HC^{16}O_3^-$ catalyzed by the enzyme from *E. coli* eliminated in the presence of saturating L-glutamine?
(D) If necessary, add side reactions involving nonstoichiometric species from your main linear mechanism for formation of carbamoyl phosphate from $HOCO_2^-$, $MgATP^{2-}$, and NH_4^+ that explain the positional oxygen isotopic exchange, ATPase reaction, incorporation of oxygen-18 into $HOPO_3^{2-}$, and oxygen isotopic exchange of oxygen-18 into $HOCO_2^-$.

Problem 5–24: UDP-*N*-Acetylglucosamine 2-epimerase (non-hydrolysing)

UDP-*N*-acetyl-α-D-glucosamine $\rightleftharpoons$ UDP-*N*-acetyl-α-D-mannosamine

catalyzes the following positional oxygen isotopic exchange[872]



where U is uridinyl.

(A) Write a mechanism that explains both the epimerization and the positional oxygen isotopic exchange catalyzed by the enzyme.
(B) Write just the sequence of steps from the overall mechanism that explains the positional oxygen isotopic exchange.
(C) In a crystallographic molecular model of the active site occupied by UDP-*N*-acetyl-α-D-glucosamine,[873] one of the two nonbridging oxygens on the phospho group attached directly to carbon 1 of *N*-acetyl-α-D-glucosamine forms a hydrogen bond to the τ-nitrogen of the imidazolyl group of a histidine. What is the role of this histidine in catalysis?
(D) What should be the most important acid–base catalyst in the active site?

Problem 5–25: 3-Phosphoshikimate 1-carboxyvinyltransferase (Equation 5–178; Problem 4–26) is present in plants and bacteria and has been purified from *Klebsiella pneumoniae*. From here on, you should abbreviate 3-phosphoshikimate as ROH because the only participant in the reaction is its hydroxy group. When 3-phosphoshikimate and phospho*enol*pyruvate labeled with ^{18}O in the oxygen between phosphorus and carbon 2 are converted by the enzyme, the products are $[^{18}O]HOPO_3^{2-}$ and unlabeled 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate. When [3,3-$^2H_2$]phospho*enol*pyruvate was used as a substrate in the enzymatic reaction and the reaction was allowed to proceed in $[^1H]H_2O$ only a short way (7–18%) toward equilibrium, the isotopic composition of the product 5-*O*-(1-carboxyvinyl)-3-phospho-

shikimate and of the remaining phospho*enol*pyruvate were as follows.[874]

pH	extent of reaction (%)		initial PEP (%)	5-*enol*pyruvylshikimate 3-phosphate (%)	final PEP (%)
6.25	14	d_0	<1	9	<1
		d_1	8	47	7
		d_2	92	44	93
6.25	13	d_0	<1	6	<1
		d_1	5	47	6
		d_2	95	46	93
9.35	18	d_0	<1	6	<1
		d_1	8	42	10
		d_2	92	52	89
10.4	7	d_0	<1	6	<1
		d_1	5	40	7
		d_2	95	54	93

In this table, d_0, d_1, and d_2 signify the percent of molecules of 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate or percent of molecules of phospho*enol*pyruvate, either as initially present or after the reaction was quenched, that were produced during the reaction and that contain no deuterium, one deuterium, or two deuteriums, respectively, as determined by mass spectrometry. By nuclear magnetic resonance spectroscopy, it was shown that the ^{1}H introduced into the product was uniformly distributed between the *E* and *Z* positions.

(A) Write a mechanism to explain the appearance of ^{1}H in the product. Your mechanism should contain a step in which a hydrogen or deuterium is removed from carbon.

(B) For the sake of argument, assume every step in your mechanism is irreversible, and from the percentages of deuterium in the products when the reaction is run at pH 10.4, calculate the deuterium isotope effect for the step in the reaction during which hydrogen or deuterium is removed from carbon. Do not forget that intermediates with two deuteriums and one hydrogen are twice as likely to lose a deuterium as a hydrogen and that intermediates with two hydrogens and one deuterium are twice as likely to lose a hydrogen as a deuterium even when no isotope effect is operating.

3-Phosphoshikimate 1-carboxyvinyltransferase was mixed with phospho*enol*pyruvate in $[^3H]H_2O$ in the absence of 3-phosphoshikimate and incubated under the noted conditions. Phospho*enol*pyruvate was isolated, and its radioactivity was determined.[875]

additions[a]	reaction time (h)	total cpm of ^{3}H in PEP ($\times 10^{-3}$)
1 mM PEP	3	<1
5 mM PEP	3	<1.5
1 mM PEP, 20 mM dd3PS	3	76.4
5 mM PEP, 20 mM dd3PS	3	185
1 mM PEP, 20 mM dd3PS	1	28.7
1 mM PEP, 20 mM dd3PS, 5 mM glyphosate	3	54.5

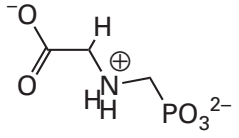
[a]Phospho*enol*pyruvate is abbreviated as PEP, and 4,5-dideoxy-3-phosphoshikimate is abbreviated as dd3PS. The reaction at 37 °C contained, in addition to the noted ingredients, 10 mM NaF and 100 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol chloride, pH 7.6, in a total volume of 0.25 mL of $[^3H]H_2O$ (3×10^{11} cpm mL^{-1}) and 0.29 unit [0.29 μmol of 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate min^{-1}]of enzyme.

(C) Write a mechanism to explain tritium incorporation into phospho*enol*pyruvate in the presence of 4,5-dideoxy-3-phosphoshikimate.

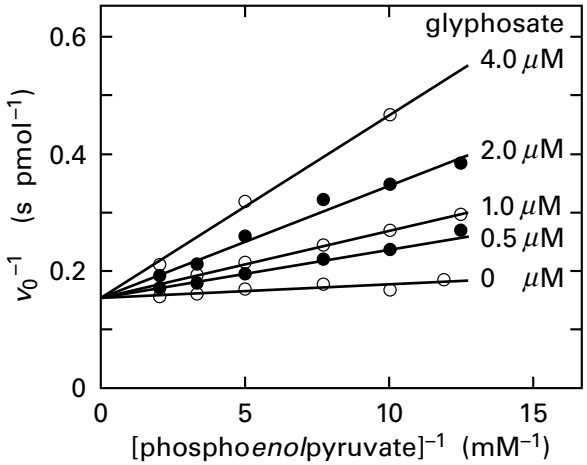
(D) The 4,5-dideoxy-3-phosphoshikimate is acting by an induced-fit mechanism. Explain what this means in this situation.

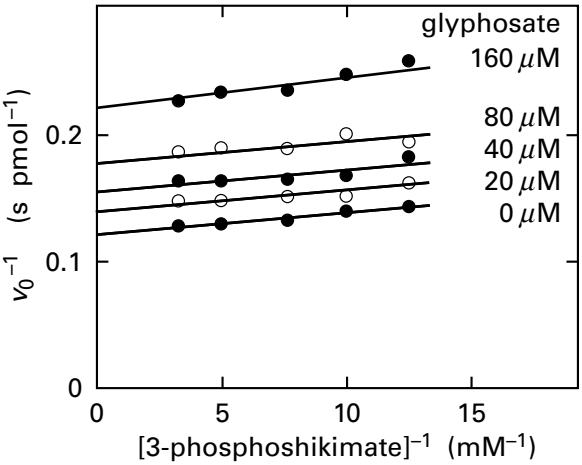
(E) What damaging side reaction is the induced-fit mechanism of this enzyme designed to prevent?

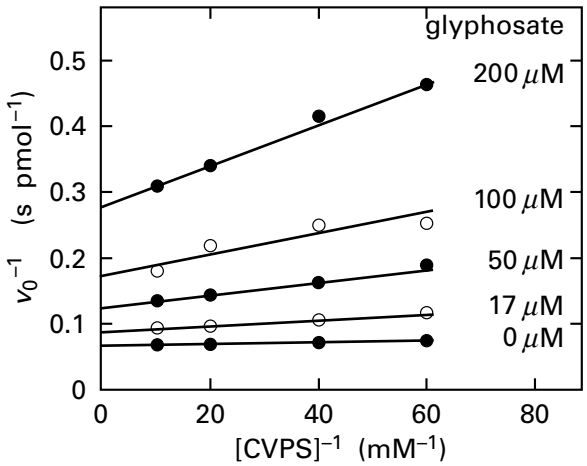
Glyphosate, *N*-phosphonomethylglycine (previously **3–51**)

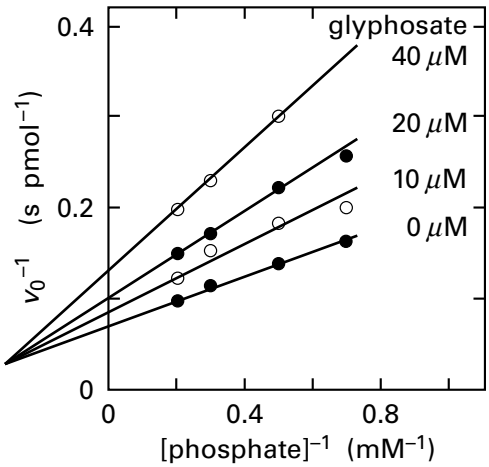


inhibits 3-phosphoshikimate 1-carboxyvinyltransferase. When the kinetics of its inhibition were examined, the following results were obtained.[876]





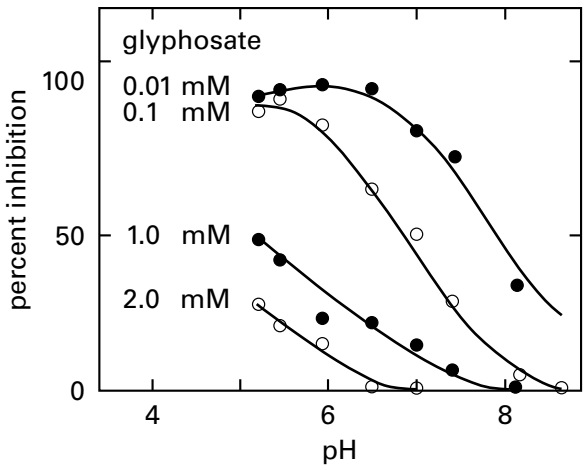




Kinetic analysis of inhibition of 3-phosphoshikimate 1-carboxyvinyltransferase by glyphosate.[876] Enzymatic assays were run in 20 mM sodium 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate, pH 7 and 30 °C. One reactant was varied while the other remained at a constant concentration. The reactants varied and the identities and concentrations of the unvaried reactants are (A) phospho*enol*pyruvate ([3-phosphoshikimate] = 5 mM); (B) 3-phosphoshikimate ([phospho*enol*pyruvate] = 5 mM); (C) 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate ([phosphate] = 20 mM); (D) phosphate ([5-*O*-(1-carboxyvinyl)-3-phosphoshikimate] = 0.2 mM). 5-*O*-(1-Carboxyvinyl)-3-phosphoshikimate is abbreviated as CVPS. In each panel, the reciprocals of the observed initial rates (picomoles second^{-1}) are plotted as a function of the reciprocals of the concentrations of the varied reactant (millimolar). To the right of each line is listed the concentration of glyphosate in the set of assays defining that line.

(F) Against which substrate is glyphosate a competitive inhibitor?

The inhibition caused by glyphosate was also examined as a function of pH.[876]



Dependence of inhibition of 3-phosphoshikimate 1-carboxyvinyltransferase by glyphosate on pH.[876] Initial rates for the reaction in the direction from phospho*enol*pyruvate (5 mM) and 3-phosphoshikimate (5 mM) to phosphate and 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate were measured in 100 mM tris(hydroxymethyl)methylammonium maleate at different values of pH in the absence and presence of glyphosate at the four indicated concentrations. The results are presented as the percent of activity at the same pH in the absence of glyphosate as a function of pH.

(G) Complete this table for the experiments described in the second figure. Parameter I_{50} is defined as the concentration of inhibitor necessary to inhibit an enzyme by 50% under a set of fixed conditions.

pH	I_{50} (mM)
	2
	1
	0.1
	0.01

(H) To explain this behavior, assume the following kinetic mechanism.

$$\mathrm{I{\cdot}E + H^+ + A \overset{K_I}{\rightleftharpoons} I + E + H^+ + A \overset{K_a}{\rightleftharpoons}}$$

$$\mathrm{I + EH + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} I + EH{\cdot}A \xrightarrow{k_2} I + E + Z}$$

Assume that A is the reactant with which the glyphosate, I, competes, and assume that the other reactant is saturating and does not enter the mechanism, and determine the rate equation for the initial rate of the enzymatic reaction, v_0, from this mechanism.

(I) When [I] = 0, $v_0 = v_{\text{uninhibited}}$, and when [I] = I_{50}, $v_0 = 0.5 v_{\text{uninhibited}}$. Using the equation you derived in part H, solve for I_{50} as a function of $[H^+]$ and [A].

(J) Show that the behavior of I_{50} with pH seen in part G can be explained by the equation you derived in part I.

(K) What intermediate in your mechanism for part C is glyphosate supposed to resemble?

(L) Why would glyphosate bind to a form of the enzyme with one less hydron than the form to which phospho*enol*pyruvate binds? Answer this question by drawing two structures of the active site, one occupied by the intermediate and one by glyphosate, and include a catalytic acid–base from the enzyme in your drawing.

(M) What other kinetic mechanism would also explain the observations?

(N) What would you need to know to decide between the two possible mechanisms?

Problem 5–26: Phospho*enol*pyruvate carboxylase from *E. coli* catalyzes the following reaction.

$$\text{phospho}\textit{enol}\text{pyruvate} + HOCO_2^- \rightleftharpoons HOPO_3^{2-} + \text{oxaloacetate}$$

When the reaction is carried out with $[^{18}O_3]HOCO_2^-$, one atom of oxygen-18 is incorporated into the $HOPO_3^{2-}$ formed. When the reaction is carried out with $[^{18}O_3]HOCO_2^-$ and chiral $[^{16}O,^{17}O]$thiophospho*enol*pyruvate, inversion of configuration at phosphorus is observed. 3-Methylphospho*enol*pyruvate does not substitute for phospho*enol*pyruvate in the normal reaction but is slowly hydrolyzed to 3-methylpyruvate and $HOPO_3^{2-}$ in a reaction catalyzed by the enzyme and requiring the presence of $HOCO_2^-$. When this bicarbonate-dependent hydrolysis is performed in the presence of $[^{18}O_3]HOCO_2^-$, oxygen-18 is incorporated into the $HOPO_3^{2-}$ produced during the hydrolysis. The molar proportions of this labeled phosphate having one, two, or three atoms of oxygen-18 were 70%, 25%, and 5%.[877] Write a mechanism for the bicarbonate-dependent hydrolysis of 3-methylphospho*enol*pyruvate that explains the observed intermediate oxygen isotopic exchange and incorporates the inversion of configuration at phosphorus observed in the normal reaction.

Problem 5–27: Write a mechanism for 3-oxoacid CoA-transferase that can explain the oxygen isotopic exchange observed between succinate and the enzyme (Equation 5–290) by proceeding through an anhydride as an intermediate.

Stopped Flow and Quenched Flow

If sufficiently high molar concentrations of the active site of an enzyme are used in an experiment, then measurable quantities of the intermediates in the enzymatic reaction can be generated. The catalytic constants, however, of most enzymes between 20 and 37 °C lie in the range between 1 and 10^6 s^{-1}. This range of rate constants means that once reactants are assembled on the active site of an enzyme, each individual step between the successive intermediates in the enzymatic reaction usually has rate constants in excess of 1 s^{-1}, and **each step in the chemical mechanism of the enzymatic reaction takes less than a second to occur**.

The device used to observe formation, interconversion, or decay of these intermediates must be able to initiate a particular step in an enzymatic reaction rapidly and immediately (<10 ms) monitor its progress. For most kinetic studies, reactions are usually **initiated by mixing two solutions**. If the two solutions to be mixed are introduced through separate ports of a specially designed mixing chamber at rapid, continuous, and uniform flows, then the fluid emerging immediately adjacent to the mixing chamber will have been mixed for only a short time.[878] If the flow through the mixing chamber is stopped abruptly, then the reaction occurring in the fluid immediately adjacent to the mixing chamber will have progressed during the short time it was passing through the mixing chamber but will continue to proceed in the fluid now at rest.[879] If an observation chamber is located as close to the mixing chamber as possible and the flow is stopped as abruptly as possible,[880,881] the fluid within the observation chamber will have been mixed only a short time before, and the progress of the reaction can then be followed within the still fluid. The interval between the time at which the fluid in the observation chamber was mixed and the time at which the flow has ceased completely is referred to as the **dead time** because no observation can be made of changes occurring during this interval. An important focus in advancing the design of such an apparatus has been to decrease its dead time so that measurements can be made at shorter times after the mixing occurs.

A device that accomplishes this strategy is an **apparatus for stopped flow** (Figure 5–20).[881,882] The two solutions are delivered to the mixer by two syringes that are driven by a plunger. The window to the observation chamber is immediately adjacent to the mixer. During the flowing phase, the continuously emerging fluid fills and expands a stop syringe until its distending plunger strikes a solid barrier. This collision stops the flow abruptly within the completely sealed system. The progress of the reaction in the observation chamber is usually followed spectroscopically by passing light through the chamber. Apparatuses for stopped flow of this type can have dead times of less than 1 ms.[883]

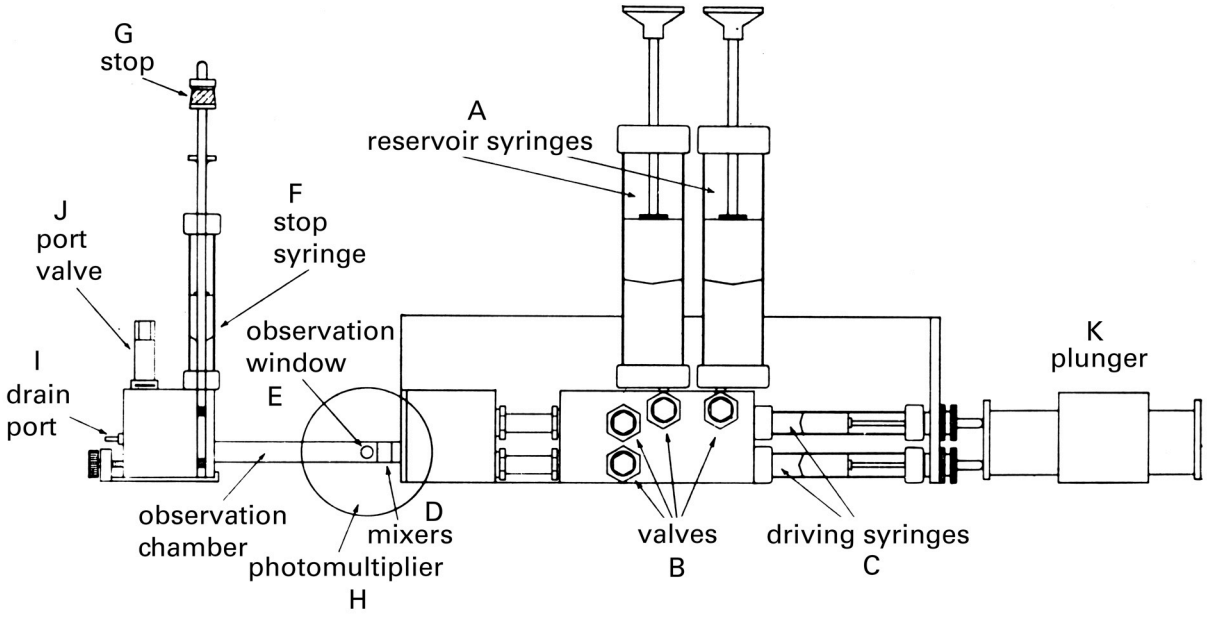


Figure 5–20: Apparatus for stopped flow.[882] The two reservoir syringes (A) store large quantities of the two solutions to be mixed. Small amounts of these two solutions are introduced through valves (B) into the two respective driving syringes (C). After the driving syringes are filled, the valves are turned so that the two drive syringes become connected directly to the two ports of the mixing chamber (D), which efficiently mixes the two fluids passing through it at high velocity. Just to the downstream side of the mixing chamber is a window (E) through which observations can be made. The observation chamber that contains this window is connected directly to a syringe (F) that fills as the fluid flows through the chamber until the end of its shaft hits a solid barrier or stop (G). After the stop has been struck by the shaft, all flow through the apparatus ceases. A photomultiplier (H) monitors the change in absorbance in the still fluid inside the observation window. Light of the desired wavelength passing through the observation window is produced by a monochromator. The stop syringe is drained through a port (I) by turning a valve (J). The hydraulic plunger (K), because it travels so rapidly in order to promote flow of high velocity, develops significant hydrostatic pressure in the fluids, so all valves and tubes must be designed to withstand this high pressure. Figure 5–21: Monitoring the transfer of a hydride from NADH to pyruvate at the active site of L-lactate dehydrogenase by stopped flow.[884] A solution of porcine L-lactate dehydrogenase (28 μM in active sites) and NADH (20 μM) in one syringe of the apparatus for stopped flow was mixed with an equal volume of a solution of pyruvate (2.0 mM) in the other syringe. Both solutions were at pH 9.0 and 22 °C. The dead time of the apparatus was 1.3 ms. (**A**) Kinetic course of the reaction. The flow of fluid through the apparatus ceased at the point indicated by the arrow (labeled "flow stops"), and the absorbance of the solution in the observation chamber was monitored at 340 nm, the wavelength at which NADH absorbs. The upper trace on the oscilloscope displays the voltage from the photomultiplier tube as a function of time (milliseconds) immediately following cessation of flow. The lower, flat trace is a second sweep after all change in voltage had ceased (labeled "end of reaction"). (**B**) Observed first-order rate constants from stopped flow and steady-state kinetics. Values for the first-order rate constants from stopped flow were obtained by fitting an exponential function to the observed decrease in absorbance (Panel A) as a function of time at each concentration of pyruvate (pyr). First-order rate constants for hydride transfer (second^{-1}) measured by stopped flow are plotted (○) as a function of the concentrations of pyruvate (millimolar). The initial rates of the enzymatic reaction, v_0, were also measured at several different initial concentrations of pyruvate at saturating concentrations of NADH, also at pH 9.0 and 22 °C. Each initial rate (micromolar second^{-1}) was divided by the respective molar concentration of active sites (micromolar) in the solution to obtain an initial rate constant (v_0 $[E]_t^{-1}$) for the active site in catalyzing the overall reaction at that initial concentration of pyruvate. These initial rate constants (second^{-1}) are also plotted (●) as a function of the initial concentrations of pyruvate (millimolar). The curve is a fit of Equation 5–328 to the data with $k_2 = 243 \pm 9$ s^{-1} and $K_{pyr} = 7 \pm 0.5$ mM. Adapted with permission from ref 884. Copyright 1971 Biochemical Society. https://doi.org/10.1042/bj1210235

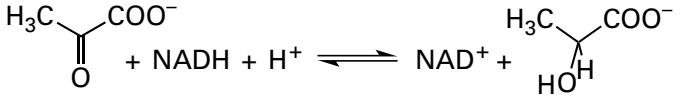
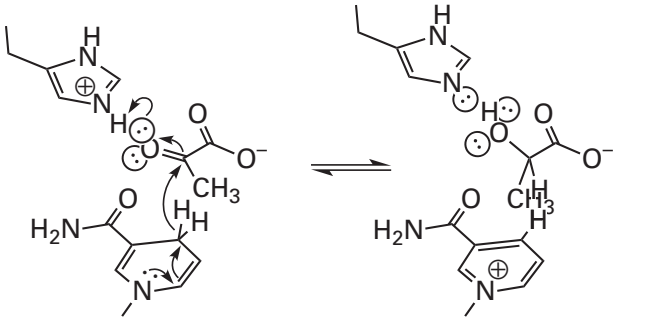
From an examination of this apparatus for stopped flow, it is clear that **the contents of the two syringes define the reaction observed.** For example, one of the two syringes in an apparatus for stopped flow was filled with a solution 20 μM in NADH and 30 μM in active sites of porcine L-lactate dehydrogenase (previously Equation 3–27)



(5–292)

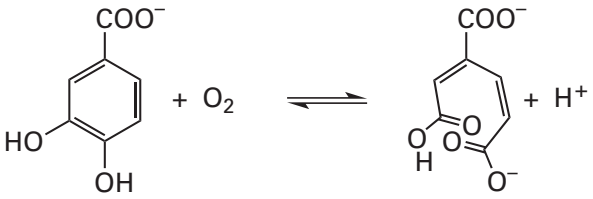
At these concentrations, almost all (85%) of the NADH present was already bound to active sites of the enzyme before mixing occurred, and the solution in this syringe contained almost entirely the complex, E·NADH, and free enzyme. The other syringe was filled with 2.0 mM pyruvate. After cessation of flow, the fluid in the observation chamber was monitored by its absorbance at 340 nm, a wavelength at which NADH absorbs light strongly but NAD^+ does not. Therefore, the decrease in absorbance at 340 nm (Figure 5–21A)[884] directly monitors the transfer of a hydride from NADH to pyruvate



(5–293)

as it occurs on the active site.[885] Because the dead time of the apparatus was 1.3 ms, this reaction could be monitored from 1.3 ms after mixing to its completion. One advantage of the ability to monitor the transfer of a hydride from NADH or NADPH to a reactant by stopped flow is that by using [4′(*R*)-^{2}H]NADH or [4′(*R*)-^{2}H]NADPH, the intrinsic kinetic isotope effect for the transfer can often be obtained directly.[886]

Changes that have occurred within the dead time of the apparatus can be documented even though their kinetic courses cannot be recorded. For example, protocatechuate 3,4-dioxygenase (previously Equation 2–274)



(5–294)

contains tightly bound prosthetic iron (Figure 2–57B), and in the absence of oxygen, its active site forms a complex with protocatechuate that absorbs visible light in a broad range from 400 to 600 nm. Changes in the composition of this complex could be followed by monitoring absorbance in this range. When a solution of the complex between the enzyme from *P. putida* and protocatechuate in one syringe of a stopped-flow spectrophotometer was mixed with a solution of oxygen in the other, a three-step process was observed (Figure 5–22).[887] The steps of this process could be dissected by performing measurements at two different wavelengths (403 and 460 nm). The initial absorbance at either wavelength at the dead time following mixing (1.3 ms) was substantially different from the absorbance of the complex of enzyme and protocatechuate that would have been observed in the absence of oxygen (arrows).

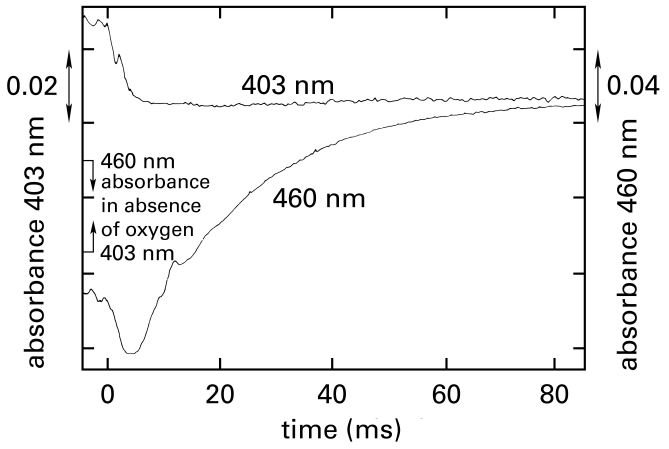


Figure 5–22: Three successive relaxations that occur when the complex between protocatechuate and protocatechuate 3,4-dioxygenase from *P. putida* is mixed with oxygen.[887] A solution containing 0.24 mM protocatechuate and 0.24 mM active sites of protocatechuate 3,4-dioxygenase was mixed with an equal volume of a solution containing 12 mM O_2. The solutions were at pH 8.3 and 10 °C . The absorbance of the mixture was followed at either 403 nm (top trace) or 460 nm (bottom trace). The absorbance (0.02 absorbance unit division^{-1} at 403 nm and 0.04 unit division^{-1} at 460 nm) was monitored as a function of time (milliseconds) in the still fluid just beyond the mixing chamber after flow stopped (at 0 ms). The absorbances at 460 and 403 nm that would have been observed had an oxygen-free solution been mixed are indicated on the respective axes of the ordinate. That these levels differ from those observed at cessation of flow shows that a relaxation faster than the dead time of the apparatus (1.3 ms) had occurred immediately upon mixing. The second relaxation is observed at both 403 and 460 nm and is complete after 5 ms. The third relaxation is observed only at 460 nm and is complete at 100 ms.

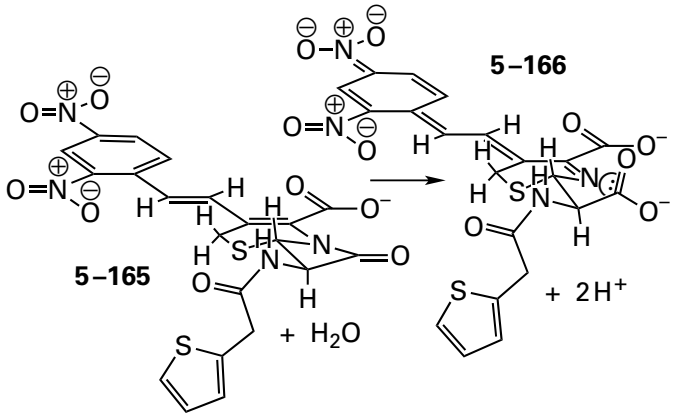
Because the absorbance at 403 nm increased within the dead time and was observed to be decreasing following the dead time, an initial intermediate, the absorbance of which at 403 nm is greater than that of the complex between enzyme and protocatechuate in the absence of oxygen as well as being greater than that of the second intermediate that is being formed following the dead time, must have formed during the dead time. The conversion of the first intermediate into this second intermediate is registered by the observed decrease in absorbance at 403 nm. An increase in absorbance at 460 nm then occurs while the absorbance at 403 nm remains constant. This increase in absorbance at 460 nm is due to formation of a third intermediate in the reaction. The absorbance at 403 nm remains constant because it is at an isosbestic point in the transition from the second to the third intermediate.

In an apparatus for stopped flow, the fluid emerging from the mixing chamber usually enters an optical

cuvette and must be **monitored by either absorbance**, as for NADH in the active site of porcine L-lactate dehydrogenase or prosthetic iron in protocatechuate 3,4-dioxygenase, **or fluorescence**, which is often a more sensitive, albeit more complicated, property and which can permit lower concentrations of enzyme to be used.

Complete spectra of absorbance can be followed at successive short intervals. For example, when β-lactamase encoded by the bacterial plasmid NDM-1, which has two prosthetic Zn^{2+} in its active site, was mixed with the chromogenic reactant nitrocefin (**5–165**) and spectra of absorbance were recorded every 2 ms (Figure 5–23A),[888] it could be observed that the absorbance of nitrocefin (λ_{max} = 390 nm) was rapidly lost as a new peak of absorbance (λ_{max} = 665 nm) appeared in a transition that displayed an isosbestic point at 425 nm (dashed vertical line). The majority of this first transition was complete in the dead time (2 ms) of the instrument. The intermediate responsible for the peak of absorbance at 665 nm was then more slowly (15 s^{-1}) converted into hydrolyzed nitrocefin (λ_{max} = 485 nm) in a transition with isosbestic points at 382 and 550 nm (dashed vertical lines). The existence of the initial isosbestic point and the subsequent pair of isosbestic points establish that there are only three species interconverting: nitrocefin, the intermediate that absorbs at 665 nm, and hydrolyzed nitrocefin. The intermediate has been assigned as the trianion of hydrolyzed nitrocefin (**5–166**)



(5–295)

In this trianion, the negative elementary charge, other than the two negative elementary charges on the carboxylato groups, is delocalized from the nitrogen that has just left the tetrahedral intermediate formed by addition of a hydroxide on one catalytic Zn^{2+} in the active site to the acyl carbon of the lactam in nitrocefin (the four-membered ring in **5–165**).

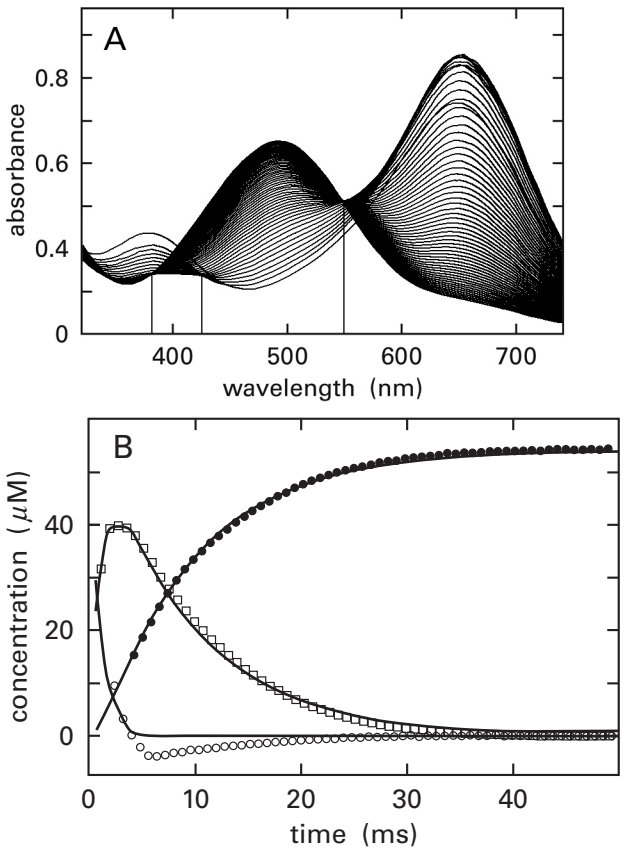


Figure 5–23: Monitoring hydrolysis of nitrocefin (**5–165**) at the active site of the metallo-β-lactamase encoded by the bacterial plasmid NDM-1 by stopped flow.[888] A solution of β-lactamase (100 μM) in one syringe of the apparatus for stopped flow (dead time of 2 ms) was mixed with an equal volume of a solution of nitrocefin (100 μM) in the other syringe. Both solutions also contained 0.2 M NaCl and 30 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol chloride, at pH 7.6 and 22 °C. (**A**) Kinetic course of the reaction. After the flow of fluid through the apparatus ceased, the absorbance of the solution in the observation chamber was monitored at wavelengths between 320 and 740 nm every 2 ms. The resulting spectra are superposed in the drawing. After 50 ms, no further changes were observed. Isosbestic points are indicated with vertical lines. (**B**) Concentrations of the three species observed in a kinetic course of the reaction as a function of time. The peaks of absorbance at 390, 485, and 665 nm were identified as nitrocefin (**5–165**), hydrolyzed nitrocefin, and the trianion of hydrolyzed nitrocephin (**5–166**), respectively (see Equation 5–295). With extinction coefficients for each of these three species, the absorbances at the various intervals were converted to molar concentrations. These molar concentrations of nitrocefin (○), hydrolyzed nitrocefin (●), and the trianion of hydrolyzed nitrocephin (□) are plotted as a function of the intervals between mixing and observation (milliseconds). The curves are fits of the data by numerical integration to a kinetic mechanism in which the complex between enzyme and nitrocephin is formed reversibly, and hydrolysis of nitrocephin to the anion in the active site is also reversible, but hydronation of the anion on the active site and its release from the active site are both kinetically irreversible. Adapted with permission from reference 888. Copyright 2012 American Chemical Society. https://doi.org/10.1021/bi300056y

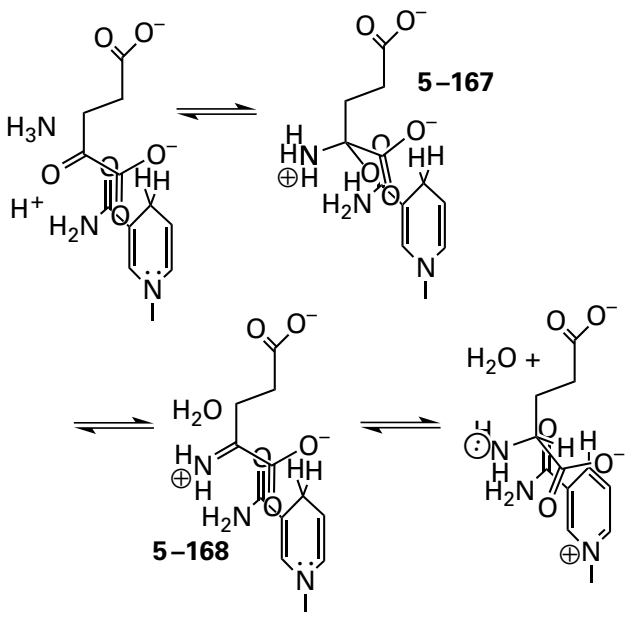
This accumulating negative charge is delocalized from the nitrogen as it is leaving the tetrahedral intermediate through the extensive π molecular orbital system of ten carbons, two nitrogens, and four oxygens that is conjugated with it, and it ends up concentrated on the four oxygens of the two nitro groups (Equation 5–295). This extensive delocalization allows the nitrogen to leave the tetrahedral intermediate without the hydronation that is required during hydrolysis of a normal lactam by the enzyme. A molecule of water on the other catalytic Zn^{2+} normally hydronates the nitrogen as it is leaving from the tetrahedral intermediate formed from a normal lactam.[889] During hydrolysis of nitrocefin, however, this molecule of water hydronates the anionic nitrogen in intermediate **5–166** after it has left the tetrahedral intermediate, rather than while it leaves. This hydronation gives the secondary amine that is the product of hydrolysis and that is the third spectral component in Figure 5–23A, and the second transition is a simple hydronation.

The progress of the reaction within the cuvette of an apparatus for stopped flow can be monitored in a number of different ways. The experiment is often designed to follow the chemical transformation of the molecule that is absorbing or fluorescing, as was the case with β-lactamase. It is also possible, however, to obtain information even when that molecule remains intact. For example, the absorbance of NADH, bound to an active site as a coenzyme, can **respond to nearby changes in the active site** prior to the transfer of its hydride. In the active site of bovine glutamate dehydrogenase [$NAD(P)^+$], the absorbance of NADPH bound in the active site shifts to longer wavelengths as 2-oxoglutarate becomes hemiaminal **5–167** and then to shorter wavelengths when the hemiaminal becomes 2-iminoglutarate (**5–168**)



(5–296)

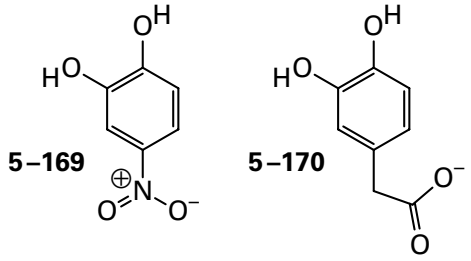
These two steps occur before the hydride is transferred (last step in Equation 5–296).[890] The fluorescence of NADPH in an active site can also be used to monitor events occurring in its vicinity before the transfer of the hydride.[891] For example, the fluorescence of prosthetic NADPH in glucose-fructose oxidoreductase from *Zymomonas mobilis* is quenched as the reactant gluconolactone associates with the active site before its absorbance decreases as the hydride is transferred to gluconolactone.[892]

The **absorbance or fluorescence of a normal reactant** for a particular enzyme other than NADH can also be followed. For example, the absorbance between 340 and 400 nm of the normal reactant, 2-amino-3-(3-oxoprop-1-en-1-yl)but-2-enedioate, in the active site of aminocarboxymuconate-semialdehyde decarboxylase from *P. fluorescens*[893] and the fluorescence of the normal reactant, *N*-(5-phospho-β-D-ribosyl)anthranilate, in the active site of phosphoribosylanthranilate isomerase from *E. coli*[894] have been used to monitor the respective enzymatic reactions by stopped flow. The **absorbance of a normal product**, such as the absorbance of AMP^{2-} as it is produced in the active site of adenine phosphoribosoyltransferase from *Leishmania donovani*,[895] or the fluorescence of a normal product can also be used.

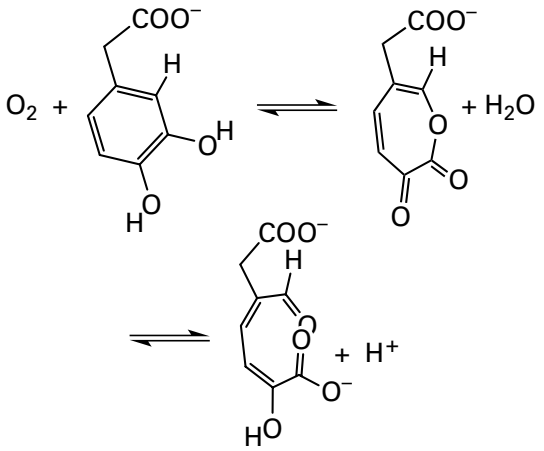
In most instances, a distinction cannot be made between a reactant that is bound in the active site and a reactant that is still in solution before it associates with the active site or between a product that is bound in the active site and a product that has dissociated from the active site and is now free in

solution. If, however, an assay can couple rapidly enough, through one or two other enzymatic reactions, the release of product into the solution to the production of the chromophore or the fluorophore being monitored spectroscopically, then only **product that is free in solution** is observed. For example, $MgGDP^-$ that dissociates from the active site of the GTPase associated with sulfate adenyltransferase from *E. coli* can be monitored over milliseconds by coupling its appearance in solution to a decrease in the concentration of NADH by using pyruvate kinase and phospho*enol*pyruvate to rephosphorylate $MgGDP^-$ to $MgGTP^{2-}$ and reduce the resulting pyruvate to lactate while NADH is oxidized to NAD^+ by L-lactate dehydrogenase.[896] At high enough concentrations of these other two enzymes and their substrates, the rates for conversion of $MgGDP^-$ and disappearance of NADH are rapid enough to be essentially instantaneous relative to the rate at which $MgGDP^-$ dissociates from the active site of the GTPase into the solution. The decrease in the concentration of NADH was monitored by its fluorescence.

A **chromophoric or fluorophoric analogue of the natural reactant**, such as nitrocefin (Figure 5–23; Equation 5–295), can also be used to monitor rapid enzymatic reactions occurring in the cuvette. For example, 2-hydroxy-4-nitrophenol (**5–169**) is an enzymatically active analogue of the natural reactant 3,4-dihydroxyphenylacetate (**5–170**)



for 3,4-dihydroxyphenylacetate 2,3-dioxygenase (see Equation 2–278)



(5–297)

from *Brevibacterium fuscum*. The changes in absorbance of 2-hydroxy-4-nitrophenol can be followed as it associates with the active site and is then converted successively into two intermediates in the enzymatic reaction.[897]

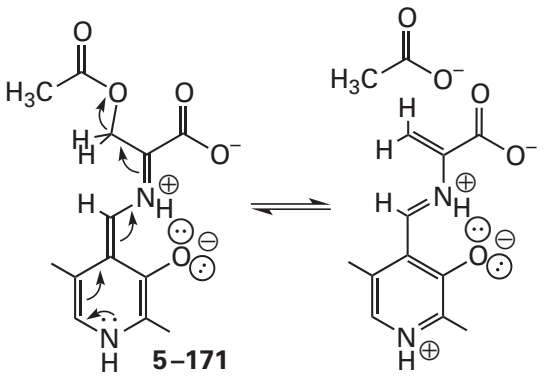
In another example, the chromophoric reactant (*E*,2*S*)-2-amino-5-phenylpent-4-enoic acid, which is the styryl analogue of the normal reactant L-phenylalanine, is also a reactant for phenylalanine aminomutase (L-β-phenylalanine forming) from *Taxus canadensis*. The first step in the chemical mechanism of the aminomutase when L-phenylalanine is the reactant is an elimination of the *pro-S* hydron on its β carbon as well as the α-amino group to form 3-phenylpropenoic acid as an intermediate in the enzymatic reaction. When (*E*,2*S*)-2-amino-5-phenylpent-4-enoic acid is the reactant, the analogous intermediate in the enzymatic reaction is (2*E*,4*E*)-5-phenylpenta-2,4-dienoic acid, the appearance of which can be monitored by the strong absorbance at 310 nm of the π molecular orbital system that includes the entire molecule.[898]

In a third example, the fluorescence of magnesium 2′(3′)-*O*-(*N*-methylanthraniloyl)adenosine 5′-triphosphate, which is $MgATP^{2-}$ with an attached fluorescent *N*-methylanthraniloyl group, could be monitored as it associated with the active site of human kinesin ATPase and was then hydrolyzed.[899]

If an enzyme contains a **prosthetic group that absorbs or that absorbs and then fluoresces**, it can be used to monitor changes in the active site as the enzyme steps through its reaction. **Pyridoxal 5′-phosphate** is particularly useful in this regard because the absorption spectra of many of the intermediates in the reactions that it catalyzes are well characterized (Figure 2–1). For example, cysteine synthase

O-acetyl-L-serine + H_2S $\rightleftharpoons$ H^+ + acetate + L-cysteine (5–298)

from *S. enterica* was mixed with only one reactant, *O*-acetyl-L-serine, and spectra of absorbance were collected over 1.7 s (Figure 5–24).[900] It was observed that absorbance of the internal pyridoximine (λ_{max} = 412 nm) rapidly shifts to higher wavelength in a transition with an isosbestic point at 340 nm (thin vertical line) as the external pyridoximine forms (Figure 2–1; λ_{max} = 416 nm). The external pyridoximine is then converted (see Equation 2–13) into the pyridoximine of 2-aminoacrylate (λ_{max} = 330 and 469 nm)



(5–299)

in a transition with isosbestic points at 363 and 430 nm (thin vertical lines). In this case, quinonoid intermediate **5–171** was not observed, probably because the elimination (Equation 5–299) is almost immediate after removal of the hydron from the α carbon.

The same intermediate pyridoximine of 2-aminoacrylate is the central intermediate in cysteine lyase from *Fusobacterium nucleatum*. This active site can form the intermediate by β-elimination of acetate from the quinonoid of *O*-acetyl-L-serine (**5–171** in Equation 5–299) but also by β-elimination of hydrogen sulfide from the quinonoid of L-cysteine or β-elimination of L-cysteine from the quinonoid of L-lanthionine. Changes in the absorbance between 300 and 500 nm could be followed by stopped flow from 0.75 ms to monitor conversion of the respective internal pyridoximines to *gem*-diamines, to external pyridoximines (Figure 2–1), and then to the pyridoximine of 2-aminoacrylate, but again, in each case, the quinonoid intermediate between the external pyridoximine and the pyridoximine of 2-aminoacrylate was not observed.[901]

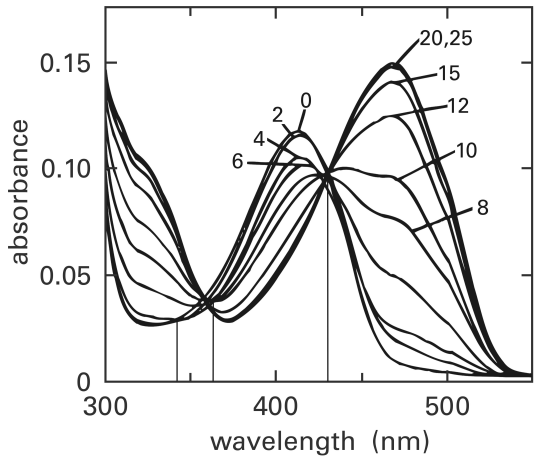


Figure 5–24: Monitoring the intermediates formed on the prosthetic pyridoxal 5′-phosphate in the active site of cysteine synthase from *S. enterica* by stopped flow.[900] A solution of cysteine synthase (20 μM) in one syringe of the apparatus for stopped flow was mixed with an equal volume of a solution of *O*-acetyl-L-serine (2 mM) in the other syringe. Both solutions also contained 0.1 M KCl and 100 mM sodium 2-(*N*-morpholino)-ethanesulfonate, pH 6.5. After the flow of fluid through the apparatus ceased, the absorbance of the solution in the observation chamber was monitored at wavelengths between 300 and 550 nm at the noted intervals (numbers designating each trace in milliseconds). The resulting spectra are superposed in the drawing. After 25 ms, no further changes were observed. Isosbestic points are indicated with thin vertical lines. Adapted with permission from reference 900. Copyright 1996 American Chemical Society. https://doi.org/10.1021/bi952938o

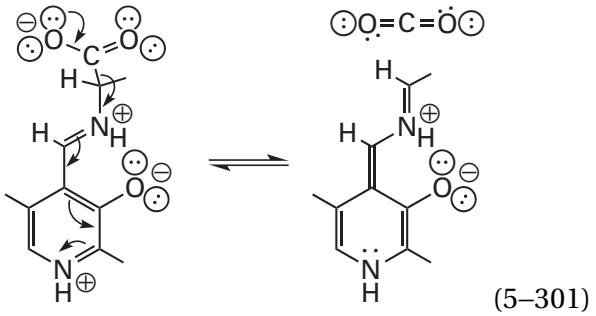
In the case of ornithine decarboxylase

L-ornithine + H^+ $\rightleftharpoons$ 1,4-diaminobutane + CO_2 (5–300)

from *Trypanosoma brucei brucei*, which also has pyridoxal phosphate as a prosthetic group, full spectra taken at intervals of 1.3 ms, following the mixing of the enzyme with L-ornithine, could be resolved into four distinct components. The spectrum for the first species detected was assigned to the external pyridoximine of the reactant L-ornithine, which formed within the dead time of the apparatus. The spectrum of the second intermediate was assigned to the quinonoid (previously Equation 2–5)



(5–301)

that follows the decarboxylation of L-ornithine, and the spectrum of the fourth species was assigned to the external pyridoximine of the product 1,4-diaminobutane. Consequently, three consecutive chemical intermediates in the enzymatic reaction—the external pyridoximine of the reactant L-ornithine, the quinonoid that follows the decarboxylation of L-ornithine, and the external pyridoximine of the product 1,4-diaminobutane—could be followed (Figure 5–25).[902]

Histidine 123 is the catalytic base that removes a hydron from Cysteine 364, the nucleophile in the active site of cysteine desulfurase from *E. coli* that participates in nucleophilic substitution at the sulfanyl group in *N*-(5′-phosphopyridoxyl)-1-carboxy-2-sulfanylethylimine produced by hydronation of carbon 4′ of the 5′-phosphopyridoxyl group in the quinonoid of L-cysteine (see Equation 5–288). This nucleophilic substitution transfers that sulfanyl group from the 1-carboxy-2-sulfanylethylimine to Cysteine 364 during the desulfurization of L-cysteine. When Histidine 123 is mutated to alanine, the rate at which *N*-(5′-phosphopyridoxyl)-1-carboxy-2-sulfanylethylimine is formed can be followed by stopped flow[903] by its absorbance at 350 nm. In the native enzyme this intermediate is converted to the *N*-(5′-phosphopyridoxyl)-1-carboxyenamine, under catalysis by Histidine 123, too rapidly to be observed.

Flavins, however, are the prosthetic groups most often used to monitor steps in an enzymatic reaction by stopped flow. For example, the steps in the addition of molecular oxygen to flavin (Equation 2–217) to create an oxidant able to perform several oxygenations

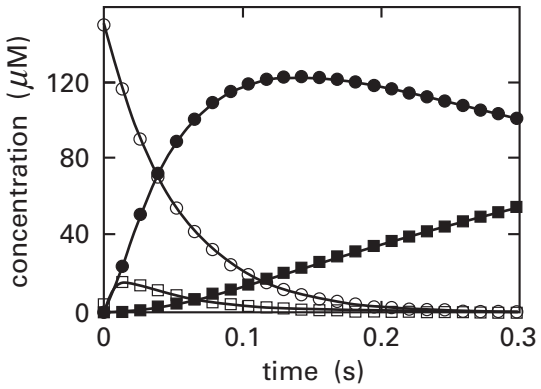


Figure 5–25: Kinetic courses for the concentrations of four intermediates in the reaction catalyzed by ornithine decarboxylase.[902] Full spectra between 310 and 500 nm were gathered at intervals of 3 ms after a solution of ornithine decarboxylase from *T. brucei brucei* (0.32 mM) was mixed with an equal volume of a solution of L-ornithine (20 mM) in 10 mM sodium phosphate, pH 7.3. All solutions were at 4 °C. The resulting spectra could be resolved by numerical analysis into spectra for four different intermediates, the contributions of which to the complete spectrum changed with time. Three intermediates were assigned, by their spectra (see Figure 2–1), to be the external pyridoximine of the reactant L-ornithine (○; λ_{max} = 337 and 424 nm), the quinonoid that follows the decarboxylation of L-ornithine (□; λ_{max} = 349 and 447 nm), and the external pyridoximine of the product, putrescine (■; λ_{max} = 335 and 420 nm). The other intermediate (●; λ_{max} = 338 and 422 nm) could not be assigned definitively. From the complete spectrum at each point, the magnitudes of the constituent spectra for the four intermediates at each point, and the fact that the molar concentrations of the four intermediates at each point had to sum to give the molar concentration of active sites in the solution, the concentrations of each of the intermediates at each of intervals could be calculated. The concentrations of each intermediate (micromolar) are plotted as a function of the intevals between mixing and observation (seconds). The curves are a fit of the kinetic mechanism of Equation 5–359 to the data by numerical analysis with rate constants of $k_1 = 21.1 \pm 0.4\ s^{-1}$, $k_2 = 145 \pm 5\ s^{-1}$, and $k_3 = 1.03 \pm 0.01\ s^{-1}$.

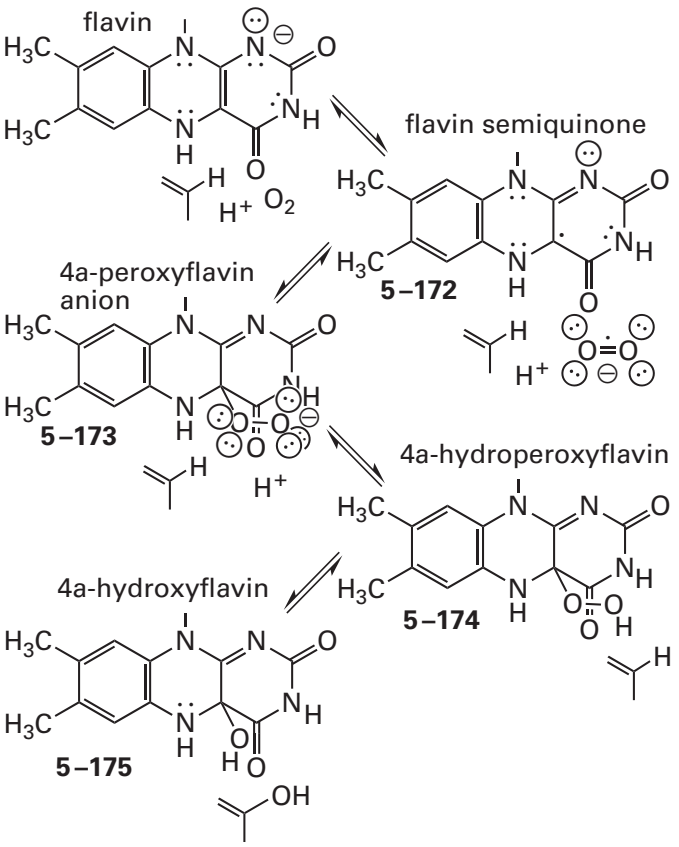
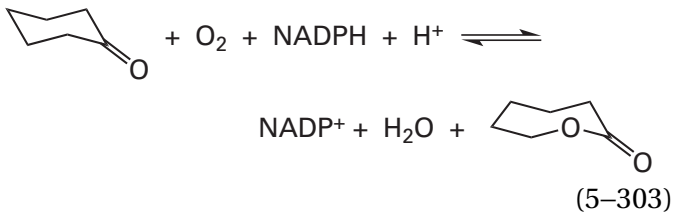


(5–302)

can be followed. Upon mixing human (*S*)-2-hydroxy-acid oxidase containing reduced prosthetic flavin with high concentrations of O_2 dissolved in the second solution, the rapid (2 ms), transient appearance of absorbance that could be assigned to flavin semiquinone (**5–172**) could be observed during the formation of 4a-peroxyflavin anion (**5–173**) from O_2 and the prosthetic flavin.[904] The semiquinone is formed by the transfer of an electron from the reduced flavin to the O_2. Formation of 4a-peroxyflavin anion (**5–173**) in the active site of cyclohexanone mono-oxygenase (previously Equation 2–213)



(5–303)

from *Acinetobacter* could be monitored by changes in the spectrum of the reduced prosthetic flavin as oxygen was adding to it. After formation of the 4a-peroxyflavin anion, the subsequent oxidation of cyclohexanone to produce hexano-6-lactone and oxidized flavin (Figure 2–47) could also be monitored.[905] In the case of 3-hydroxybenzoate 6-mono-oxygenase

$$\text{3-hydroxybenzoate} + \text{NADPH} + \text{H}^+ + \text{O}_2 \rightleftharpoons \text{3,6-dihydroxybenzoate} + \text{NADP}^+ + \text{H}_2\text{O} \quad (5\text{–}304)$$

association of oxygen, formation of 4a-peroxyflavin anion (**5–173**), hydronation of the 4a-peroxyflavin anion to form 4a-hydroperoxyflavin (**5–174**), and hydroxylation of the 3-hydroxybenzoate at carbon 6 by the 4a-hydroperoxyflavin (see Figure 2–48) could all be followed by monitoring changes in absorbance at wavelengths characteristic for these intermediates.[906] The subsequent hydrolysis of the 4a-hydroxyflavin (**5–175**) produced during the hydroxylation of the 3-hydroxybenzoate was too rapid, which precluded its observation, but the case of the flavoenzyme 4-hydroxybenzoate 3-monooxygenase [NAD(P)H] from *P. aeruginosa*, formation of the 4a-hydroxyflavin produced on its active site during the hydroxylation of 4-hydroxybenzoate by 4a-hydroperoxyflavin (**5–174**) could be followed by its strong fluorescence.[907]

Changes in the absorbance spectra of prosthetic **hemes**,[908] **iron–sulfur clusters**,[909,910] and prosthetic **nonheme iron clusters** (Figure 2–57)[911] are further examples of prosthetic groups the spectroscopy of which can be used to follow steps in an enzymatic reaction by stopped flow.

It is often the case, however, that neither substrates for the enzyme nor enzymatically active analogues of those substrates absorb or fluoresce, and the enzyme has no prosthetic groups that do either. In such cases, there may be a **tryptophan in the protein**, in the vicinity of the active site or affected by conformational changes, the absorbance or fluorescence of which changes as the enzyme steps through its reaction. For example, association of each of the two reactants, $MgATP^{2-}$ and L-threonine, with the active site of threonine—tRNA ligase from *E. coli,* as well as conversion of the complex of both reactants to the threonyladenylate that is an intermediate in the reaction, could be monitored by following changes in fluorescence of one or more of the 11 tryptophans in the enzyme.[912]

Crystallographic molecular models suggest that when NADH and pyruvate bind to L-lactate dehydrogenase (Equation 5–292) from *G. stearothermophilus*, a lid composed of a loop of polypeptide closes over the active site. When the three tryptophans in the enzyme were replaced with tyrosines and a **trypto-**

phan was inserted by site-directed mutation into this loop, the closure of the lid could be followed by the quenching of fluorescence of this tryptophan when it is transferred from the solution to the surface of the protein. The fact that the rate constant ($125\ s^{-1}$) for the closing of the lid upon NADH and oxamate, an analogue of pyruvate, is equal to the rate constant ($140\ s^{-1}$) for production of a molecule of L-lactate when the complex between NADH and the enzyme is mixed with pyruvate (see Figure 5–21A) suggests that closing of this lid is the rate-limiting step in reduction of pyruvate by the enzyme.[913]

It is also possible to **modify a protein with a fluorescent functional group** other than an indolyl group of a tryptophan to produce an even more fluorescent protein. If the modification occurs near enough to the active site, the **fluorescent reporter** incorporated into the enzyme can register, by changes in its fluorescence, changes occuring in the active site as reactants associate and are converted into intermediates. For example, a fluorescent 3,6-diamino-9-(2,4-dicarboxyphenyl)-4,5-disulfoxanthylium was covalently attached to a loop of polypeptide that closes down over the active site of dihydrofolate reductase (previously Equation 4–148)

$$\text{NADPH} + \text{7,8-dihydrofolate} + \text{H}^+ \rightleftharpoons \text{5,6,7,8-tetrahydrofolate} + \text{NADP}^+ \qquad (5\text{–}305)$$

from *E. coli* after the reactants 7,8-dihydrofolate and NADPH associate with the enzyme, and its fluorescence could be used to monitor rates of association of each reactant, closing of the lid, and hydride transfer in the active site.[914]

The rates of **hydron uptake into or hydron release** from the active site of an enzyme can also be observed by stopped flow by adding an **pH indicator** to the solution. For example, release of a hydron from the active site of equine alcohol dehydrogenase at pH 5.9 during the oxidation of 1-propanol by NAD^+ could be monitored by following the absorbance of chlorophenol red in the solution.[915]

The progress of a reaction can also be followed by the technique of quenched flow. If the outlet from a mixing chamber fed by two coupled syringes that are compressed at a constant rate by a plunger is attached to a length of tubing that is connected to a second mixing chamber or that simply ends in a quench solution, the time that the fluid spends between the first mixing chamber and the second mixing chamber or the quench solution is determined only by the flow rate through the first mixing chamber and the length and cross-sectional area of the tubing. Suppose the reaction is initiated in the first mixing chamber, by analogy with the apparatus for stopped flow, and abruptly halted at the second mixing chamber or in the solution into which it flows at the end of the tubing, for example, by quenching with strong acid. The final solution produced by the device will provide a measure of the progress of the reaction over the time spent within the tubing between the two mixing chambers or between the first mixing chamber and the quench solution. The advantage of this technique of quenched flow is that products of the reaction are collected and can be assayed chemically rather than only spectroscopically. Its disadvantage is that only one time point in the progress of the reaction is provided by each measurement. To obtain the whole course of the reaction, a sequence of tubings that vary in length or a coupled pair of syringes driven by a plunger the speed of which can be varied[916] is used to provide a sequence of reaction times.

One syringe of an apparatus for quenched flow was filled with a solution of 3-phosphoshikimate 1-carboxyvinyltransferase ($20\ \mu M$ in active sites) from *E. coli* (Equation 5–178) and $200\ \mu M$ 3-phosphoshikimate, and the other syringe was filled with $7\ \mu M$ phospho[^{14}C]*enol*pyruvate. After these solutions were mixed in a mixing chamber at a constant rate of flow, the mixture passed through a tube of a particular length and was then quenched with 0.6 M HCl. This sequence of events was repeated 18 times with tubing of varying lengths (Figure 5–26). Each quenched sample, each of which spent a different interval of time between mixing and quenching, or in the case of reproduction, the same amount of time, was then submitted to chromatography to separate the reactant phospho[^{14}C]*enol*pyruvate (○) and the product 5-*O*-(1-[^{14}C]carboxyvinyl)-3-phosphoshikimate (□).[308] Because the concentration of active sites ($20\ \mu M$) was greater than the concentration of phospho[^{14}C]*enol*pyruvate ($7\ \mu M$), only one turnover or no turnovers occurred at each active site. Because all the reactant was converted into product over a period of 100 ms, the decrease in the concentration of phospho*enol*pyruvate and the increase in the concentration of 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate could both be accurately followed at intervals of 5 ms.

Often, especially when the concentrations of reactants are required to be much greater than the concentration of enzyme so that the decrease in

the concentration of reactants is insignificant, only the **accumulation of a product of the enzymatic reaction** is followed by quenched flow. For example, formation of orotidine 5′-phosphate from orotate and 5-phospho-α-D-ribose and, in the opposite direction, formation of orotate from orotidine 5′-phosphate and diphosphate catalyzed by orotate phosphoribosyltransferase (Equation 5–183) from *S. enterica* could be followed by quenched flow. The respective products from each quenched solution were separated from the much larger amounts of reactants by thin-layer chromatography.[917]

Usually, as in the preceding examples, the reactants or products or both of them in the quenched solutions are separated and identified chromatographically, but other **types of analysis** can be used. Differences in the partition of reactants and products between water and an organic solvent[918,919] or differences in their adsorption to a solid phase[920] can be used as rapid assays for a large number of samples. When the various products and reactants are identified chromatographically or separated by solvent extraction or adsorption, radioactive reactants are often used to increase the sensitivity of the assay and decrease the needed concentration of enzyme, which determines the concentration of intermediates accumulated or product produced during a single turnover and which determines the amount of enzyme irretrievably lost in each quenched sample. Other methods that have been used to quantify products from quenched flow are mass spectrometry,[921] electron paramagnetic resonance spectroscopy,[922,923] and Mössbauer spectroscopy.[924] It is also possible to assay the concentration of a particular reactant or product in a quenched sample by using a sensitive coupled enzymatic assay.[925] In all these instances, because the samples must always be quenched, a step that must inactivate and usually denature the enzyme, reactants and products that were free in solution at the time the sample was quenched cannot be distinguished from reactants and products that were bound in the active site.

If the identity of an intermediate is known, it is also possible to follow the **appearance of an intermediate** in an enzymatic reaction by quenched flow as the reaction progresses by identifying it chromatographically[926] or by mass spectrometry.[921] For example, solutions of acyl-homoserine-lactone-synthase[927]

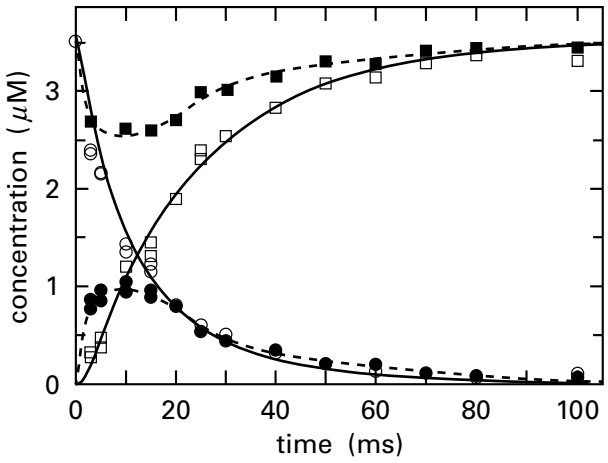


Figure 5–26: Kinetic courses for the concentrations of the reactant phospho*enol*pyruvate, the product 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate, and an intermediate in the reaction catalyzed by 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli*.[308] A solution of 3-phosphoshikimate 1-carboxyvinyltransferase (20 μM in active sites) and 200 μM 3-phosphoshikimate was mixed with an equal volume of a solution of 7 μM phospho[^{14}C]*enol*pyruvate (32 mCi mmol^{-1}). Both solutions contained 50 mM KCl and 50 mM potassium 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate, pH 7.0 and 20 °C. The two solutions were mixed in a mixing chamber, the mixture flowed through a tube of a particular length, and the mixture was then quenched with 0.6 M HCl. This procedure was repeated with the same two solutions, varying the time each mixture spent between the mixing chamber and the quench solution by choosing different lengths of tubing. Each quenched solution was then extracted with chloroform and neutralized with KOH. Phospho[^{14}C]*enol*pyruvate (○, solid line), 5-*O*-(1-[^{14}C]carboxyvinyl)-3-phosphoshikimate (□, solid line), and [^{14}C]pyruvate (●, dashed line) were separated by high-pressure liquid chromatography and quantified by their counts per minute. The concentrations of each compound in the unquenched mixture (micromolar) are plotted as a function of the intervals between mixing and quenching (milliseconds). The sums of the concentrations of phospho[^{14}C]*enol*pyruvate and 5-*O*-(1-[^{14}C]carboxyvinyl)-3-phosphoshikimate are also plotted (■, dashed line). The concentrations of [^{14}C]pyruvate observed were equal to the missing differences between sums of the concentrations of the other two substrates and the initial concentration of phospho*enol*pyruvate, and the [^{14}C]pyruvate observed was assumed to represent an intermediate in the unquenched mixture that decomposed to pyruvate during the quench. The curves for the concentrations of phospho[^{14}C]*enol*pyruvate and 5-*O*-(1-[^{14}C]carboxyvinyl)-3-phosphoshikimate are fits of the kinetic mechanism of Equation 5–360 to the data by numerical integration.

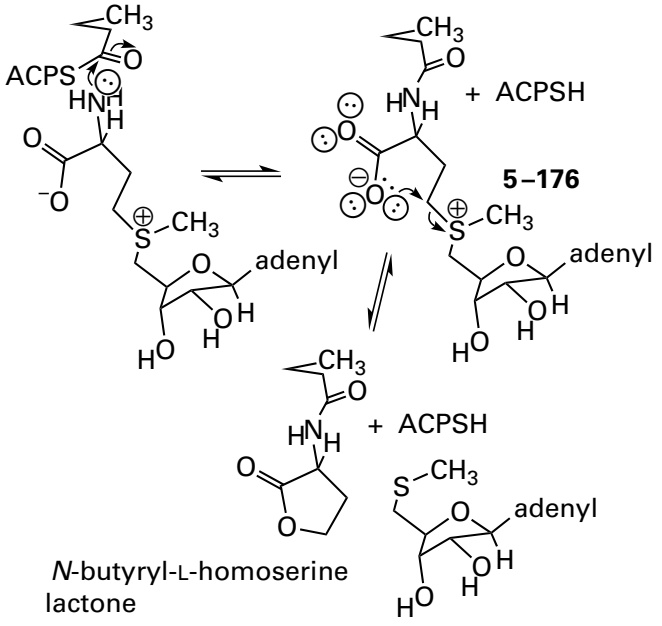

(5–306)

from *P. aeruginosa* and *S*-adenosyl-[*carboxy*-^{14}C]-L-methionine were mixed with solutions of butyryl-SACP, where ACP is acyl-carrier protein, and the reactions were quenched after various intervals. The decrease in *S*-adenosyl-[*carboxy*-^{14}C]-L-methionine and the increase in the intermediate *N*-butyryl-2-adenosyl-[*carboxy*-^{14}C]-L-methionione (**5–176)** could be followed chromatographically. The decrease in the intermediate could then be followed as *N*-butyryl-[*carboxy*-^{14}C]-L-homoserine lactone, the ultimate product of the enzymatic reaction, was formed at the active site by intramolecular nucleophilic substitution.[926]

It is also possible to follow formation of the **covalent intermediate of an enzyme** by quenched flow. For example, one syringe in an apparatus for quenched flow was filled with a solution of active, ^{31}P-phosphorylated phosphoglucomutase (α-D-glucose-1,6-bisphosphate-dependent) (Equation 5–36) from *O. cuniculus*, and the other was filled with D-glucose 1-[^{32}P]phosphate. After these solutions were mixed in a rapid mixing chamber at a constant flow rate, the mixture passed through a tube of a particular length and was then mixed with trichloroacetic acid to precipitate the protein. Using a series of tubes of different lengths, the amount of [^{32}P]phosphate attached covalently to the protein resulting from its phosphorylation of the 6-hydroxy group of D-glucose 1-[^{32}P]phosphate and the subsequent phosphorylation of the enzyme by the 1-[^{32}P]phospho group (Equation 5–36). This exchange of phospho groups on the enzyme could be followed as a function of the time spent between the mixing chamber and the quench solution (Figure 5–27).[928]

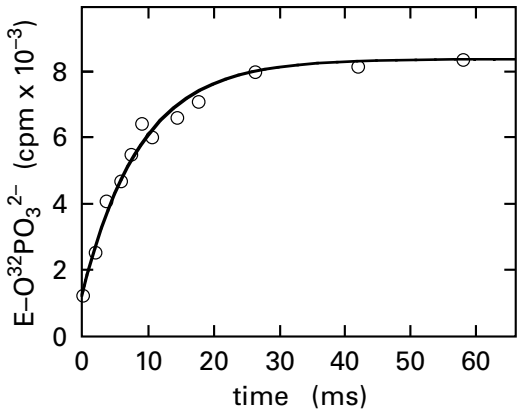

Figure 5–27: Increase in [^{32}P]phosphoenzyme after active, fully phosphorylated phosphoglucomutase from *O. cuniculus* was mixed with D-glucose 1-[^{32}P]phosphate.[928] A solution containing ^{32}P-phosphorylated phosphoglucomutase [8.1×10^3 cpm (nmol of active sites)$^{-1}$] at a concentration of 0.15 μM was mixed with an equal volume of a solution of 2 μM D-glucose 1-[^{32}P]phosphate (75×10^3 cpm nmol^{-1}). Both solutions contained 1 mM $MgCl_2$ and were buffered at pH 7.5 and room temperature. The two solutions were mixed in a mixing chamber, the mixture flowed through a tube of a particular length, and the mixture was then introduced through the end of the tube into a rapidly swirling quench solution of 5% trichloroacetic acid. The protein that precipitated was collected by filtration, and the radioactivity (counts per minute) attached to the protein was determined by liquid scintillation counting. This procedure was repeated with the same two solutions, varying the interval each mixture spent between the mixing chamber and the quench solution by choosing different lengths of tubing. The individual measurements of the amount of phosphorus-32 attached to protein (E–O^{32}PO$_3^{2-}$ in counts per minute $\times 10^{-3}$) are plotted as a function of intervals the mixtures spent in the tubing between the mixing chamber and the quench solution (milliseconds). Because the enzyme had some phosphorus-32 attached at the beginning of the reaction, the amount at time zero does not equal 0. The curve is a fit of the data to Equation 5–321 with a rate constant, k_{obs}, of 112 s^{-1}.

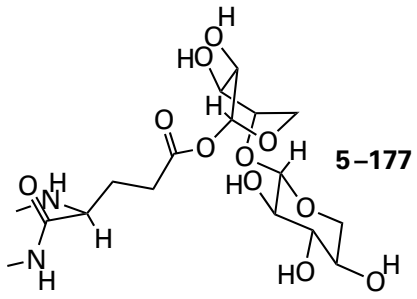
Pyruvate, phosphate dikinase from *C. symbiosum* (Equation 5–234) was rapidly mixed with Co[β-^{32}P]ATP^{2-} to follow the sum of the concentrations of [^{32}P]diphosphoenzyme (Equation 5–238) and [^{32}P]phosphoenzyme (Equation 5–240) or with Co[γ-^{32}P]ATP^{2-} to follow only the concentration of [^{32}P]diphosphoenzyme. These mixtures were then quenched with 0.6 M HCl after various intervals (Figure 5–28).[929] When the protein from these two time courses was precipitated with CCl_4, it could be shown, by difference, that formation of [^{32}P]diphosphoenzyme (●) preceded formation of [^{32}P]phosphoenzyme (■), a result consistent with the proposed

mechanism of the enzyme.[929] It could also be shown that formation of [^{32}P]diphosphate (□) followed formation of [^{32}P]diphosphoenzyme (●) and that formation of [^{32}P]phospho*enol*pyruvate (△) followed formation of [^{32}P]phosphoenzyme (■). This entire sequence is that expected from the proposed mechanism (Equations 5–238 to 5–241).

It is also possible to **inject the effluent** emerging from the mixing chamber, after it passes for a certain amount of time through a segment of tubing, directly **into a mass spectrometer** and thereby monitor the mass of the enzyme. For example, endo-1,4-β-xylanase from *N. circulans* was mixed with the unnatural reactant 2,5-dinitrophenyl-β-xylobioside and, after passing for a defined interval through a length of tubing, the mixture was injected as an electrospray into a mass spectrometer. The appearance of a peak of molecular mass 20,649 Da could be followed as a function of time.[930] This peak represents a xylobiosyl group (molecular mass = 265 Da) esterified to a glutamyl group



that is a covalent intermediate[931,932] in the reaction catalyzed by the enzyme (molecular mass = 20,384 Da). Again, only atoms covalently attached to the protein, not those noncovalently attached such as molecules of water, remain associated with the polypeptide in the vacuum of the instrument.

More chemically explicit information about the identity of a covalent intermediate of an enzyme can be obtained as its formation is being followed. For example, the two cysteines that form a cystine during the mechanism of ribonucleoside-diphosphate reductase from *E. coli* (Figure 5–13) are found in the sequences –RQFSSCVLIECGD– and –ENGEIALCTLSAFNLG–. When the enzyme is digested with glutamyl endopeptidase and chymotrypsin, these two cysteines end up in the peptides SSCVLIE and IALCTLSAF. Ribonucleoside-diphosphate reductase was mixed with the reactant CDP^{3-}, and the effluent from the mixing chamber was quenched with acetic acid after various intervals. The protein was then

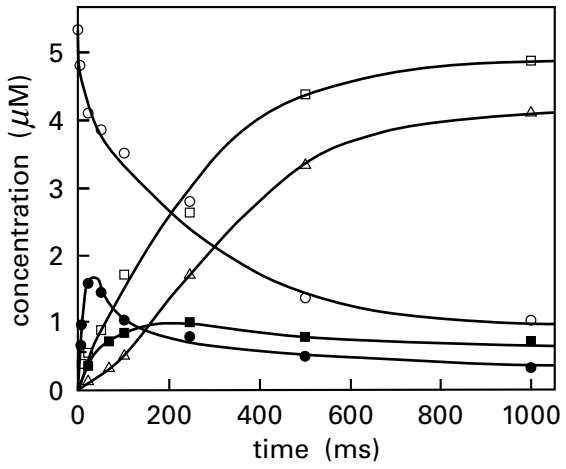


Figure 5–28: Kinetic courses for the concentrations of the reactant MgATP^{2-}, the diphosphorylated enzymatic intermediate, the product diphosphate, the phosphorylated intermediate, and the product phospho*enol*pyruvate in the reaction catalyzed by pyruvate, phosphate dikinase from *C. symbiosum*.[929] A solution containing pyruvate, phosphate dikinase (40 μM in active sites) was mixed with an equal volume of a solution of 12 μM AT[γ-^{32}P]P^{2-} or 12 μM AT[β-^{32}P]P^{2-} and 2 mM pyruvate. Both solutions contained 2.5 mM $CoCl_2$, 10 mM NH_4Cl, 2 mM $HOPO_3^{2-}$, and 50 mM potassium 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate, pH 7.0 and 25 °C. The two solutions were mixed in a mixing chamber, the mixture flowed through a tube of a particular length, and the mixture was then quenched with 0.6 M HCl. The protein in the quenched solution was precipitated with CCl_4, and the radioactivity in the precipitate was measured. This procedure was repeated with the same two solutions, varying the time each mixture spent between the mixing chamber and the quench solution by choosing different lengths of tubing. Radioactivity in the precipitates from AT[γ-^{32}P]P^{2-} was assumed to represent only the diphosphorylated intermediate while that from AT[β-^{32}P]P^{2-} was assumed to represent both the diphosphorylated and phosphorylated intermediates. The supernate that remained after collecting the precipitated protein was submitted to high-pressure liquid chromatography to separate unreacted MgAT[^{32}P]P^{2-}, magnesium [^{32}P]diphosphate, and [^{32}P]phospho*enol*pyruvate, which were quantified by their radioactivity. The concentrations (micromolar) of MgAT[^{32}P]P^{2-} (○), ^{32}P-diphosphorylated intermediate (●), magnesium [^{32}P]diphosphate (□), ^{32}P-phosphorylated intermediate (■), and [^{32}P]phospho*enol*pyruvate (△) in the reaction mixtures are plotted as a function of the intervals between mixing and quenching (milliseconds).

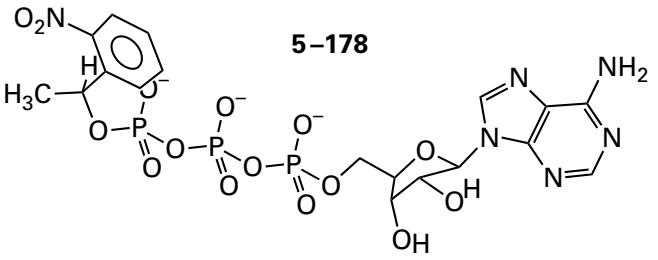
digested with glutamyl endopeptidase and chymotrypsin, the digest was passed over an immunoadsorbent specific for the carboxy-terminal sequence –VLIE, and the peptides eluted from the immunoadsorbent were submitted to chromatography. By this procedure, transformation of the peptide SSCVLIE into the peptide in which SSCVLIE is connected by a cystine with the peptide IALCTLSAF could be followed.[500]

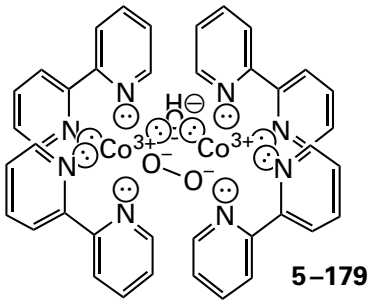
Enzymatic reactions can also be initiated rapidly by using a caged reactant without the need for the methods of either stopped flow or quenched flow. A caged reactant is a photolabile derivative of the reactant for an enzyme that is catalytically inactive but that decomposes upon photolysis to produce the catalytically active reactant. The photolysis that releases the actual reactant takes place in an optical cuvette, and the subsequent reaction, following release from the cage, can be followed spectroscopically. For example, caged ATP^{3-}



5–178

when photolyzed at 347 nm, decomposes to produce ATP^{4-} at a rate of 2.2×10^6 $[H^+]$ M^{-1} ms^{-1}, which at pH 6 is 2.2 ms^{-1}. The released ATP^{4-} then combines with Mg^{2+} in the solution to give $MgATP^{2-}$. Depending on the structure of the active site, a caged reactant can either associate to form a catalytically inactive complex or fail to associate with the active site at all until photolysis is performed.[933]

A solution of cytochrome-*c* oxidase and the binuclear complex



5–179

which upon photolysis at 355 nm decomposes in less than 40 ns to produce O_2 from the peroxide coordinated to the two Co^{3+},[934] was submitted to photolysis. Reduction of the O_2 released from the cage by the two reduced hemes and the two Cu^+ in the active site of cytochrome-*c* oxidase could be followed spectroscopically in the range between 450 and 750 nm.[935] The enzymatic reaction passed through three distinct intermediates over an interval of 1 μs–10 ms. At least two of these intermediates would have formed and decayed within the dead time for stopped flow and would have been inaccessible by that method.

There is a similar strategy to observe intermediates that form in microseconds and that has long been employed in the study of hemoproteins. The tight complex between the iron of a hemoprotein and carbon monoxide is dissociated by light.[936] Such a complex is mixed in an apparatus for stopped flow with a solution of another ligand for the iron in the hemoprotein at a concentration high enough to outcompete carbon monoxide for reassociation with the iron. Upon cessation of the flow, the solution is exposed to an intense flash that causes the carbon monoxide to dissociate immediately, and association of the other ligand with the vacant iron and subsequent events can be monitored. For example, a complex between carbon monoxide and ferrous ubiquinol oxidase (H^+-transporting)

$$2\ \text{ubiquinol} + O_2 + n\,H^+_{\text{cyt}} \rightleftharpoons 2\ \text{ubiquinone} + 2\,H_2O + n\,H^+_{\text{extra}} \qquad (5\text{–}307)$$

from *E. coli*, where cyt refers to the cytoplasmic face of the enzyme and extra to the extracellular face, was mixed rapidly, in the absence of ubiquinol to prevent rereduction of the hemes, with a saturated solution of O_2. The mixture was immediately exposed to a short (7 ns) flash of light (532 nm) from a neodymium:yttrium–aluminum–garnet laser. Carbon monoxide dissociated, and from the first microsecond, association of oxygen and the sequence of five subsequent intermediates formed during reduction of the O_2 to two molecules of water could be observed by following the absorbance spectrum of the heme between 350 and 500 nm.[937]

There are two regimes under which an observation can be made by stopped flow or quenched flow. First, if the enzyme is mixed with concentrations of reactants that are all significantly greater than the concentrations of enzyme, then the enzyme will turn over many times until the equilibrium it catalyzes is reached. Rapid changes, however, occur as the steady state is being established during the pre-steady state. After this initial period, the appearance of products or the disappearance of reactants then proceeds at the normal, steady-state rate, and the concentrations of intermediates remain constant at their steady-state levels. Second, if the kinetic experiment is purposely designed so that the enzyme

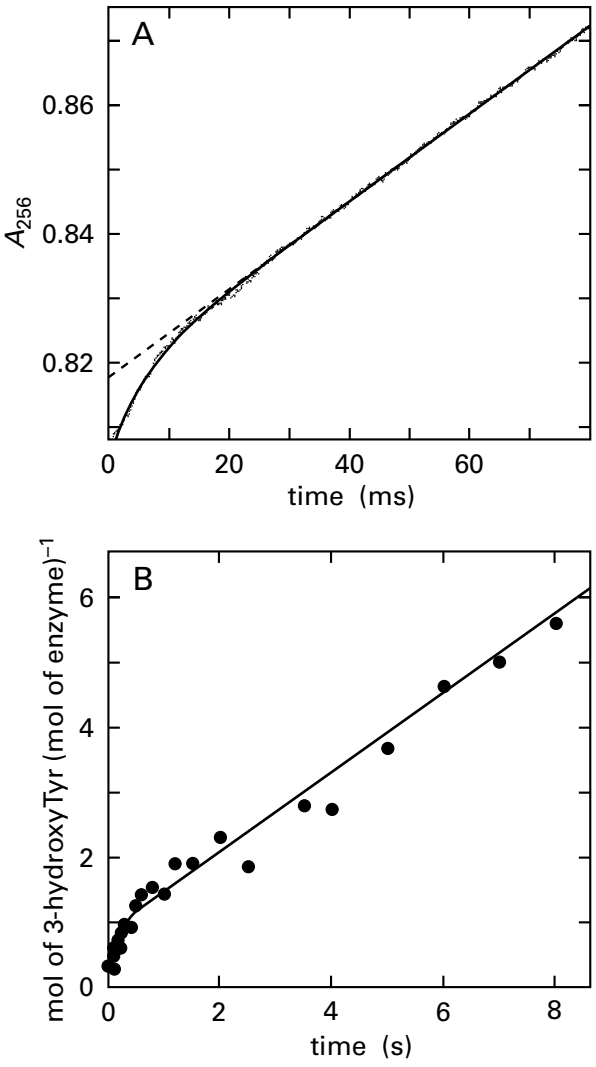


Figure 5–29: Bursts monitored by stopped flow and quenched flow. (**A**) Burst in formation of AMP^{2-} observed by stopped flow after the complex between adenine phosphoribosyltransferase and magnesium 5-phospho-α-D-ribose 1-diphosphate was mixed with a solution of adenine.[895] A solution containing 250 μM magnesium 5-phospho-α-D-ribose 1-diphosphate and 11 μM active sites of adenine phosphoribosyltransferase from *L. donovani* was mixed with an equal volume of a solution of 70 μM adenine in an apparatus for stopped flow. The solutions contained 10 mM MgCl and 100 mM tris(hydroxymethyl)methylammonium chloride at pH 7.5 and 27 °C. The absorbance of the solution was monitored at 256 nm, the wavelength at which there is the largest difference in absorbance between AMP^{2-} and adenine, and the absorbance (A_{256}) is plotted as a function of time (milliseconds). The curve is a fit of Equation 5–309 to the data (irregular dotted line), and the dashed line is an extrapolation of the later, linear portion of the curve (k_0t). (**B**) Burst in formation of 3-hydroxy-L-tyrosine observed by quenched flow after solutions of tyrosine 3-monooxygenase saturated with 6-methyltetrahydropterin were mixed with solutions of L-tyrosine and O_2.[938] A solution of tyrosine 3-monooxygenase (40 μM in active sites) from *R. norvegicus* and 2 mM 6-methyltetrahydropterin was mixed with an equal volume of a solution containing 500 μM L-tyrosine and 1.9 mM O_2. Both solutions contained 10% glycerol, 0.1 M KCl, and 200 mM potassium 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate, pH 7.5 and 5 °C. The two solutions were mixed in a mixing chamber, the mixture flowed through a tube of a particular length, and the mixture was then quenched with 5 M HCl. The quenched solution was submitted to high-pressure liquid chromatography to isolate 3-hydroxy-L-tyrosine, which was quantified by its fluorescence. This procedure was repeated with the same two solutions, varying the time each mixture spent between the mixing chamber and the quench solution by choosing different lengths of tubing. The moles of 3-hydroxy-L-tyrosine (mole of active sites of tyrosine 3-monooxygenase)$^{-1}$ in the reaction mixtures are plotted as a function of the intervals (seconds) between mixing and quenching. Adapted with permission from reference 895. Copyright 2002 American Chemical Society. https://doi.org/10.1021/bi0158730

is prevented from completing more than one turnover, then the enzymatic reaction will proceed until a single turnover or a portion of a single turnover has been completed and will proceed no further. The rapid changes observed are uncomplicated by the establishment of a steady state when molecules of enzyme individually and stochastically complete their first turnover. These molecules of enzyme proceed with the second or even third turnover while other molecules are still finishing their first or have finished their first earlier.

In a measurement of the **pre-steady state**, when the appearance of a certain product or intermediate in an enzymatic reaction is being monitored by stopped flow or quenched flow, if that product or intermediate is formed in a step followed by significantly slower steps, then a burst of that product or intermediate will be observed before the steady state is established.

A **burst of product** is the rapid appearance of an amount of product that is equal in molar concentration to the molar concentration of active sites in the solution and that can be distinguished kinetically from the much slower accumulation of product that follows the burst and proceeds at the normal steady-state rate. For example, when a solution of adenine phosphoribosyltransferase (Problem 3–15)

$$\text{magnesium 5-phospho-}\alpha\text{-D-ribose 1-diphosphate} + \text{adenine} \rightleftharpoons AMP^{2-} + MgOPO_3PO_3^{2-} + H^+ \quad (5\text{–}308)$$

from *L. donovani*, the active site of which had been saturated with magnesium 5-phospho-α-D-ribose 1-diphosphate, was mixed with a solution of adenine, an increase in the molar concentration of AMP^{2-} proceeded rapidly in a burst (Figure 5–29A).[895] The data could be fit to the equation

$$A_{256} = \Delta A e^{-k_{obs}t} + k_0 t \qquad (5\text{–}309)$$

The size of the burst (ΔA), determined by extrapolation to zero time, was directly proportional to the molar concentration of active sites in a series of measurements at different concentrations of enzyme. Following the burst, AMP^{2-} was produced at a linear rate equal to the steady-state initial rate (v_0) separately measured under these conditions. The explanation for this behavior is that there is a step in the enzymatic reaction following formation of AMP^{2-} on the active site that is slower than all steps preceding formation of AMP^{2-}. For that reason, the initial formation of AMP^{2-} at each active site is more rapid than the steady-state rate for subsequent formation of AMP^{2-}, which is limited by the slower steps following the production of AMP^{2-}.

A solution of tyrosine 3-monooxygenase

$$\text{tetrahydrobiopterin} + \text{L-tyrosine} + O_2 \rightleftharpoons \text{3-hydroxy-L-tyrosine} + \text{4a-hydroxytetrahydrobiopterin} \qquad (5\text{–}310)$$

from *R. norvegicus*, the active site of which had been saturated with 6-methyltetrahydropterin, was mixed with a solution of L-tyrosine and O_2, and then the reaction was quenched after various intervals with 5 M HCl. An increase in the concentration of the product 3-hydroxy-L-tyrosine in the quenched solutions proceeded rapidly in a burst (Figure 5–29B),[938] the size of which was equivalent to the molar concentration of active sites, and then 3-hydroxy-L-tyrosine was produced at the steady-state rate for the concentrations present.

In observations made by stopped flow or quenched flow, it is also possible to observe a **lag** in the accumulation of product. If the actual formation of the product being monitored is preceded by one or several slow steps, the increase in its concentration will proceed slowly at first and then accelerate until the steady-state rate is established. For example, when sulfate adenylyltransferase from *E. coli*, saturated with AMP^{2-} and magnesium diphosphate, is mixed with $MgGTP^{2-}$, the GTPase that is an inherent activity of the enzyme, even though it is unrelated to catalysis, is initiated. The $MgGDP^-$ released from the active site of this GTPase into the solution was monitored in an apparatus for stopped flow by a coupled enzymatic assay that registered $MgGDP^-$ in the solution by a decrease in the absorbance of NADH. Since its dissociation from the active site is the last step in the enzymatic reaction, it is not surprising that a lag in its appearance in the solution was observed (Figure 5–30, lower trace).[896] When the production of $MgGDP^-$ was followed by quenched flow, however, where $MgGDP^-$ in solution and $MgGDP^-$ within the

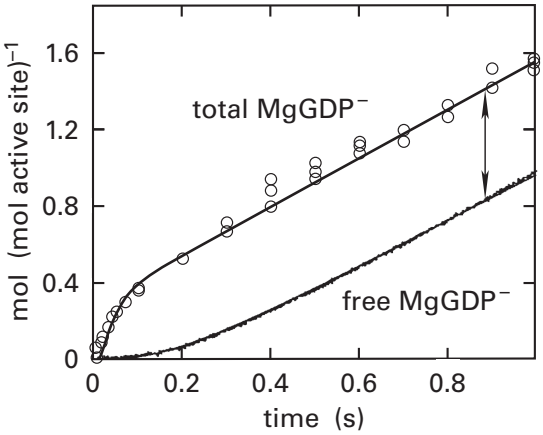

Figure 5–30: Lag in formation of $MgGDP^-$ free in solution, observed by stopped flow, and burst in formation of $MgGDP^-$ within the site for hydrolysis of $MgGTP^{2-}$ on sulfate adenylyltransferase, observed by quenched flow.[896] A solution of sulfate adenylyltransferase from *E. coli* (40 μM in active sites) was mixed with an equal volume of a solution of 1.0 mM $MgGTP^{2-}$ at 25 °C. Both solutions also contained 1.0 mM AMP, 0.1 mM diphosphate, 2.2 mM $MgCl_2$, and 50 mM potassium 2-[4-(2-hydroxyethyl)-piperazin-1-yl]ethanesulfonate, pH 8.0. For the stopped-flow observations, the second solution also contained a coupled assay for $MgGDP^-$ free in solution consisting of 200 μM pyruvate kinase, 2.0 mM phospho*enol*pyruvate, 72 mM lactate dehydrogenase, and 0.28 mM NADH. For the quenched-flow observations, the second solution contained 80 mCi mL^{-1} of [γ-^{32}P]$MgGTP^{2-}$. In the stopped-flow experiments, the $MgGDP^-$ free in solution was converted to $MgGTP^{2-}$ by pyruvate kinase; the pyruvate produced was converted to lactate by lactate dehydrogenase; and the NADH, monitored by its fluorescence, decreased in concentration as it was converted to NAD^+. The increase in $MgGDP^-$ free in solution (data points in lower trace) was calculated from the decrease in fluorescence. In the quenched-flow experiments, the two solutions were mixed in a mixing chamber, the mixture flowed through a tube of a particular length, and the mixture was then quenched with 0.1 M sodium hydroxide and 0.1 M sodium ethylenediaminetetraacetate. This procedure was repeated with the same two solutions, varying the time each mixture spent between the mixing chamber and the quench solution by choosing different lengths of tubing. Each quenched solution was submitted to thin-layer chromatography to isolate GDP^{3-}, which was quantified by its radioactivity. The moles of $MgGDP^-$ free in solution (mole of active sites of GTPase)$^{-1}$ (data points in lower trace) and the moles of total $MgGDP^-$ (mole of active sites of GTPase)$^{-1}$ (○) in the reaction mixtures are plotted as a function of the intervals between mixing and observation or between mixing and quenching (seconds). The curves through the data are fits of a kinetic mechanism proposed by the authors. Adapted with permission from reference 896. Copyright 2001 American Chemical Society. https://doi.org/10.1021/bi015735a

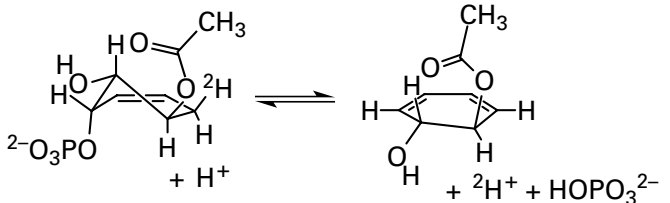
active site cannot be distinguished because the quench denatured the enzyme and released $MgGDP^-$ bound in the active site, it was observed that $MgGDP^-$ appeared rapidly in a burst rather than a lag (Figure 5–30; ○). These results together demonstrate that the rate-limiting step of the reaction is not hydrolysis of $MgGTP^{2-}$ on the active site but dissociation of $MgGDP^-$ from the active site into the solution. In this sense, the reaction resembles that of myosin ATPase in the absence of actin. After the burst and after the lag, once the steady state had been established, both the appearance of $MgGDP^-$ in the solution and the appearance of $MgGDP^-$ within the active site proceeded at the same rate because that is a fundamental property of a steady state. By definition, once an active site has achieved steady state, all the rates for formation of intermediates and products are identical. The size of the burst (extrapolation of the rate at steady state) was equivalent to 0.32 active site. After the steady state was established, however, the lag between the two lines, which registers the amount of $MgGDP^-$ bound in the active site in the steady state, is equivalent to 0.57 active site (vertical double arrow). This increase in the amount of $MgGDP^-$ associated with the active site occurs as the steady state is established.

A paradigm of an experiment in which an **active site is confined to a single turnover** is the one in which a solution of chorismate synthase (previously Equation 4–175)



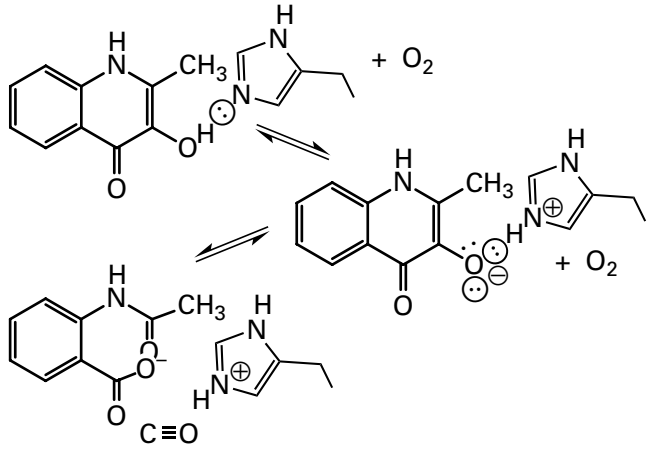
(5–311)

from *E. coli* was mixed with a solution of its single reactant 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate so that the final concentrations were 105 μM in active sites and 70 μM in reactant. The dissociation constant for enzyme and reactant is less than 0.2 μM, so as soon as the reactant had associated with the enzyme (> 50 ms^{-1}), every molecule of the reactant (>99.4%) was associated with an active site of the enzyme and was then converted to product in a single turnover.[939]

In the experiment in which pyruvate is reduced by the complex between L-lactate dehydrogenase and NADH (Figure 5–21), almost all (85%) of the molecules of NADH (20 μM) in the initial solution with the enzyme (28 μM) are associated with active sites (K_d = 2 μM) and are oxidized to NAD^+ in a single turnover. In the experiment (Figure 5–26) in which 3-phosphoshikimate 1-carboxyvinyl transferase (20 μM), the active sites of which were fully saturated (96%) with 3-phosphoshikimate (200 μM; K_d = 7 μM), was mixed with a solution of phospho[^{14}C]*enol*pyruvate, so that the final concentration of the complex of enzyme and 3-phosphoshikimate was 9.3 μM and that of phospho[^{14}C]*enol*pyruvate was 3.5 μM, the active sites initially were only partially occupied by phospho*enol*pyruvate. In this instance, however, the almost 3-fold excess of enzyme over phospho*enol*-pyruvate ensured that the reaction was confined to a single turnover. An extreme example of enzyme in excess is a kinetic experiment with orotidine-5′-phosphate decarboxylase (Equation 5–243) from *S. cerevisiae*, in which enzyme (7 μM) was mixed at 14-fold molar excess over orotidine 5′-phosphate (0.5 μM) so that almost all (86%) of the molecules of orotidine 5′-phosphate would occupy an active site initially. As these molecules of orotidine 5′-phosphate were decarboxylated, their decarboxylation would draw the rest into other active sites by mass action. In this way, a minority of the active sites ended up catalyzing only a single turnover while the majority catalyzed no turnover at all.

Enzymatic reactions that convert more than one reactant to products, which represent the majority of enzymes, can be **confined to only a portion of their reaction by leaving out one reactant**. For example, when cysteine synthase (Equation 5–298) is mixed only with *O*-acetyl-L-serine, the enzymatic reaction ceases after the pyridoximine of 2-aminoacrylate (Equation 5–299) is formed (Figure 5–24) because no hydrogen sulfide is present. The steps preceding production of the pyridoximine of 2-aminoacrylate could be spectroscopically defined. The pyridoximine of 2-aminoacrylate was pre-formed in the active site of the enzyme under the same conditions and then mixed with hydrogen sulfide, and its conversion to L-cysteine (k_{obs} > 1 ms^{-1}) could be followed separately.[900]

When 3-hydroxy-2-methylquinolin-4-one 2,4-dioxygenase



(5–312)

from *Paenarthrobacter nitroguajacolicus* is mixed with the reactant 3-hydroxy-2-methyl-1*H*-quinolin-4-one in the absence of oxygen, the active site is unable to complete the reaction (second step in Equation 5–312). Upon mixing the reactant and the enzyme anaerobically at pH 6.5 in an apparatus for stopped flow, there is a rapid (430 s^{-1}) change in the absorbance spectrum of the solution as an intermediate in the enzymatic reaction is formed. The absorbance spectrum of the intermediate is that of the anionic conjugate base of 3-hydroxy-2-methyl-1*H*-quinolin-4-one, which is not present at pH 6.5 ($pK_a = 10.4$). It was concluded that the first step in the reaction is removal of a hydron from the 3-hydroxy group of 3-hydroxy-2-methyl-1*H*-quinolin-4-one by a catalytic base in the active site.[940] In the crystallographic molecular model of the active site of a mutant of the enzyme occupied by 3-hydroxy-2-methyl-1*H*-quinolin-4-one, the side chain adjacent to the 3-hydroxy group is the imidazolyl group of Histidine 251. When Histidine 251 is mutated to alanine, the rate constant $k_0\,K_m^{-1}$ at pH 6.5 decreases by a factor of 5×10^5, and there was no longer a change in absorbance indicative of dehydronation of 3-hydroxy-2-methyl-1*H*-quinolin-4-one even at long times after it was mixed anaerobically with the enzyme. The rate constant for dehydronation of 3-hydroxy-2-methyl-1*H*-quinolin-4-one in the unmutated active site increases through an apparent pK_a of 7.2 to a maximum rate of 1.3 ms^{-1}. This pK_a has been assigned to the imidazolyl group of Histidine 251 when it is in a hydrogen bond with the 3-hydroxy group of 3-hydroxy-2-methyl-1*H*-quinolin-4-one in the Michaelis complex. At low pH, the imidazolyl group is hydronated and unable to participate in the hydrogen bond. **Direct observation of the transfer of the hydron** simplifies the assignment of this pK_a.

A variation on this strategy of leaving out one reactant is applied when the enzyme of interest catalyzes an oxidation–reduction and **oscillates between a reduced and an oxidized form**. Usually, a prosthetic group on the enzyme is either oxidized or reduced. For example, fructosyl amine oxidase (glucosone-forming)

N-(1-deoxy-D-fructos-1-yl)glycine + O_2 + H_2O
$\rightleftharpoons$ D-*arabino*-hexos-2-ulose + glycine + H_2O_2

(5–313)

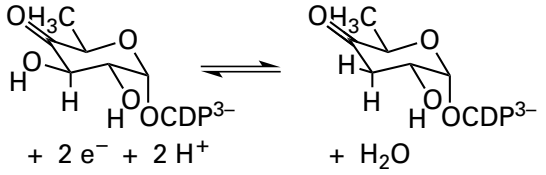
from *Aspergillus fumigatus* is a flavoenzyme. When enzyme in which the flavin is oxidized is mixed with only *N*-(1-deoxy-D-fructos-1-yl)glycine, the flavin is reduced, and the reaction ceases in the middle of the first turnover because no O_2 is present to reoxidize the flavin. When enzyme in which the flavin is reduced is mixed with O_2, the flavin is oxidized, and the reaction ceases in the middle of the first turnover because no *N*-(1-deoxy-D-fructos-1-yl)glycine is present.[941] Consequently, both reduction and oxidation of the flavin, each of which are half of a single turnover, can be monitored separately.

When the active site of 4-hydroxybenzoate 3-monooxygenase [NAD(P)H] (see Equation 5–304) was occupied by 4-hydroxybenzoate at saturation and its prosthetic flavin was then reduced with dithionite, a solution of the complex of 4-hydroxybenzoate and reduced enzyme was produced. This complex was then mixed with a solution containing O_2. Following addition of O_2 to the flavin (Equation 5–302) to produce 4a-hydroperoxyflavin (**5–174**), hydroxylation of 4-hydroxybenzoate by 4a-hydroperoxyflavin (Figure 2–48) proceeds, but the reaction ceases in the middle of the first turnover because there is no NADPH to reduce the oxidized flavin. By monitoring changes in absorbance of the flavin at 385 and 470 nm as well as the fluorescence of 4a-hydroxyflavin (**5–175**), three individual steps—formation of 4a-hydroperoxyflavin from oxygen and a hydron, hydroxylation of 4-hydroxybenzoate by 4a-hydroperoxyflavin, and dissociation of the resulting 4a-hydroxyflavin (**5–175**) to produce oxidized flavin and a molecule of water—could each be followed.[907]

A major reason for examining an enzymatic reaction by stopped flow or quenched flow is to discover intermediates. As the last example and several earlier ones demonstrate, stopped flow and quenched flow can be used to observe the enzyme **stepping through its intermediates**. So far, examples

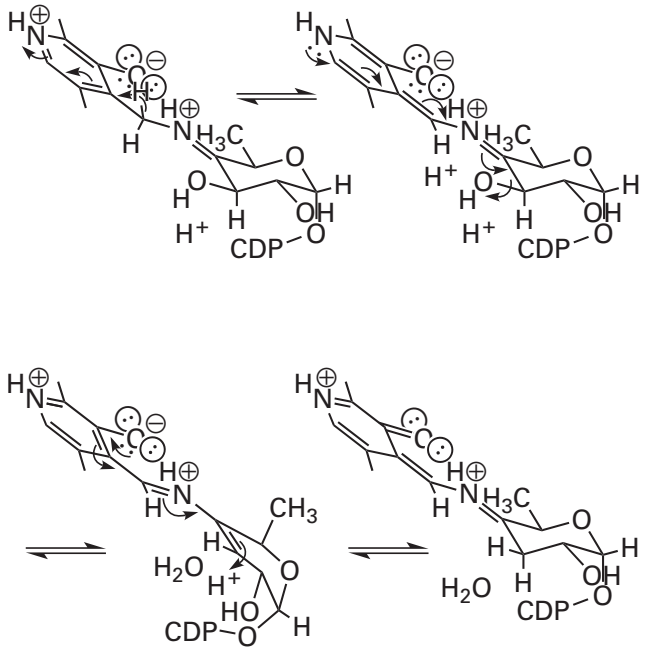
have been presented in which the accumulation of an intermediate and its conversion to the next intermediate or to product are followed directly. In the case of hydrolysis of nitrocefin by β-lactamase (Figure 5–23), the accumulation and subsequent conversion of the single intermediate in the reaction was monitored by its absorbance (λ_{max} = 655 nm). In this case of acyl-homoserine-lactone synthase (Equation 5–306), the accumulation and subsequent conversion of the single kinetic intermediate (**5–176**) in the enzymatic reaction was followed chromatographically. The single covalent xylobiosyl covalent intermediate (**5–177**) in the reaction catalyzed by endo-1,4-β-xylanase was observed by mass spectrometry. In the cases of cysteine synthase (Figure 5–24) and ornithine decarboxylase (Figure 5–25), the two intermediates and the three intermediates, respectively, were distinguished by the unique spectra of their adducts with pyridoxal phosphate. The prosthetic flavins in the three consecutive intermediates in reduction of the oxidized prosthetic flavin in the active site of dihydrolipoyl dehydrogenase from *M. tuberculosis* have unique absorption spectra and could be monitored spectrally as they successively increased and then decreased in concentration,[942] just as consecutive spectra of the prosthetic flavin and its fluorescence could be used to monitor the consecutive intermediates in oxidation of reduced 4-hydroxybenzoate 3-monooxygenase and in oxidation of reduced 3-hydroxybenzoate 6-monooxygenase.

A deoxygenation is catalyzed by CDP-4-dehydro-6-deoxyglucose reductase (previously Equation 2–41)



(5–314)

The overall reaction is a reduction requiring two electrons. These two electrons are provided in two consecutive electron transfers from a single prosthetic [4Fe–4S] iron–sulfur cluster within the active site. The prosthetic [4Fe–4S] iron–sulfur cluster in the active site is reduced in turn by a unique electron-carrier protein, which is a flavoprotein containing its own single prosthetic [4Fe–4S] iron–sulfur cluster, and, upon transferring two electrons, with flavin semiquinone as an intermediate, its oxidized prosthetic flavin is reduced by NADH. CDP-4-Dehydro-6-deoxyglucose reductase from *Y. pseudotuberculosis*, in which the prosthetic [4Fe–4S] iron–sulfur cluster is oxidized and in the absence of the electron-carrier protein, was mixed with CDP-4-dehydro-6-deoxyglucose. Four consecutive intermediates (previously Equation 2–42)

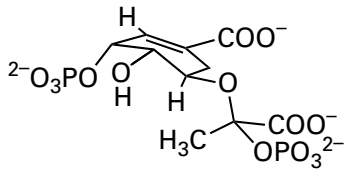


(5–315)

each of which accumulates and is then turned into the next, could be identified in an apparatus for stopped flow by following the absorbance of the prosthetic pyridoxamine 5′-phosphate at eight different wavelengths. The reaction ceases when the fourth intermediate has formed because no reductant is available. CDP-4-Dehydro-6-deoxyglucose reductase on which the fourth intermediate had accumulated was then mixed with NADH and reduced flavoprotein in an apparatus for quenched flow in which the solution emerging after passage through tubes of different lengths was rapidly frozen. A fifth intermediate, which was a radical that could be identified by electron paramagnetic resonance spectroscopy of the frozen samples, was formed from the fourth intermediate by transfer of one electron from the now-reduced prosthetic [4Fe–4S] iron–sulfur cluster in the active site. A sixth, fully reduced intermediate, the *N*-(5′-phosphopyridoxyl)-imine of the final product CDP-4-dehydro-3,6-dideoxy-D-glucose, was then produced by a second electron transfer. These results from quenched flow revealed the intermediate radical in the final reduction, which is widely delocalized over the π molecular orbital system of the *N*-(5′-phosphopyridoxyl)imine.[943]

There are also several ways in which formation and conversion of intermediates can be **observed indirectly**.

When the concentrations of both reactants and products of the stoichiometric reaction catalyzed by an enzyme are followed, a **failure of the sum of the molar concentrations of reactants and products to remain constant** with time and to equal the initial concentration of reactant is evidence that an intermediate which accounts for the missing moles is accumulating. For example, the sum of the molar concentrations (Figure 5–26) of phospho[^{14}C]*enol*-pyruvate (○), a stoichiometric reactant in the reaction catalyzed by 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli* (Equation 5–178), and 5-*O*-(1-[^{14}C]carboxyvinyl)-3-phosphoshikimate (□), a stoichiometric product, could be calculated for each interval of quenched flow.[308] This sum of the concentrations (■) decreases and then increases as the single turnover of the enzyme proceeds. In this instance, the missing moles could be accounted for by an increase and then a decrease in the concentration of [^{14}C]pyruvate (●), which also appeared on the chromatograms of the quenched samples. The accepted intermediate in this enzymatic reaction (previously **3–81**)



5–180

because it is the phosphorylated hemiketal of pyruvate, should be hydrolyzed in the strong acid used to quench the reaction to give pyruvate, so the increase and then the decrease in the amounts of [^{14}C]pyruvate in the quenched solutions represent the accumulation of this intermediate on the active site and then its conversion to product, respectively.

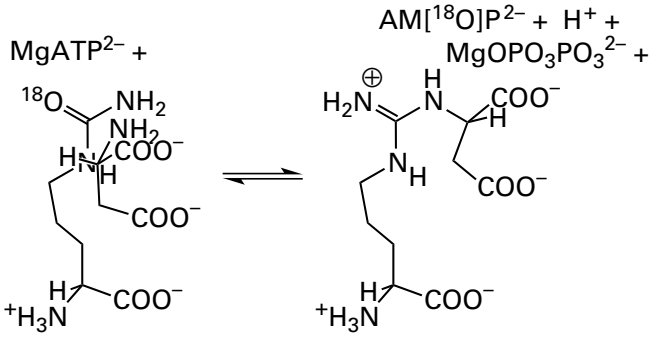
In the case of the single turnover of chorismate synthase from *E. coli*, the sum of the molar concentrations of the reactant, 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate, and the product, chorismate, in measurements quenched flow decreases as the reaction begins and then increases again as it ends, just as was observed for 3-phosphoshikimate 1-carboxyvinyltransferase (Figure 5–26). The missing moles increase to a maximum at 20 ms and then decrease. This increase and decrease in the missing moles coincides with the increase and decrease in the amount of an intermediate detected spectrally by following the changes in the complete absorption spectrum of the prosthetic flavin in the active site of the enzyme.[939] In this instance, because no extinction coefficient for the intermediate observed spectroscopically was available, its molar concentration could not be estimated from the spectra alone. Nevertheless, because of the coincidence over the course of the reaction, it was concluded that this spectrally identified species accounted entirely for the missing moles, and hence its molar concentration and consequently its extinction coefficient could be estimated.

Another indication of the accumulation of an intermediate in an active site is a **lag between the appearance of one product of the reaction and the appearance of another product**. For example, haloalkane dehalogenase (750 μM) from *Rhodococcus rhodochrous*, which catalyzes the reaction

$$\text{1,3-dibromopropane} + H_2O \rightleftharpoons \text{3-bromopropan-1-ol} + Br^- + H^+ \qquad (5\text{–}316)$$

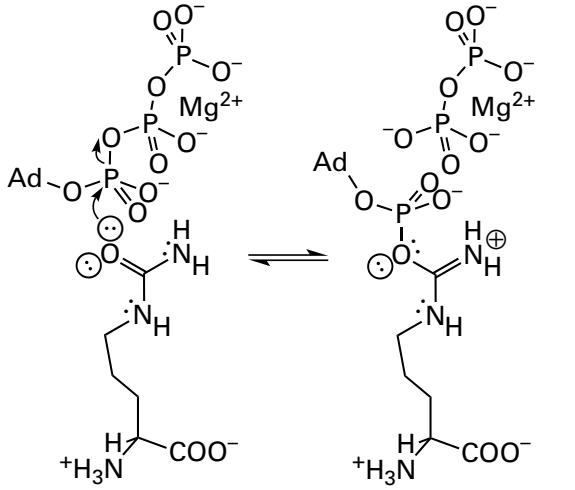
was mixed with 1,3-dibromopropane (400 μM; K_d = 200 μM), and the concentrations of reactants and products were followed by quenching the reaction at different times and submitting the quenched samples to chromatography (Figure 5–31).[944] The increase in the concentration of Br^- (□) over the first 20 ms (0.3 ms^{-1}) was stoichiometric with the decrease in the concentration of 1,3-dibromopropane (○), but the appearance of the other product, 3-bromopropan-1-ol (●), was much slower (0.015 ms^{-1}) and lagged significantly behind the production of Br^-. It was concluded that this behavior was a consequence of rapid accumulation of the β-aspartyl ester of 3-bromopropan-1-ol as a covalent intermediate (see Equations 5–10 and 5–11), which was stable in the 0.6 M HCl used to quench the reaction, and its subsequent slow hydrolysis (Equation 5–12).

In the case of argininosuccinate synthase, the lag between the appearance of two products is not the result of formation of a covalent intermediate but formation of a noncovalent intermediate. Argininosuccinate synthase catalyzes the nucleophilic substitution



(5–317)

at a carbonate carbon. During the reaction catalyzed by the bovine enzyme, oxygen-18 in [*ureido*-^{18}O]-L-citrulline is transferred to the phosphate of the product AMP^{2-}.[945] This observation suggests that L-citrulline adenylate is formed as a noncovalent intermediate in the enzymatic reaction in the active site[946]



(5–318)

This adenylation would activate the L-citrulline for nucleophilic substitution and explain in molecular terms how the free energy of hydrolysis of $MgATP^{2-}$ is firmly and chemically coupled to the nucleophilic substitution. No isotopic exchanges in the absence of L-aspartate, however, which would be expected from Equation 5–318, have been observed.[947]

Solutions of bovine argininosuccinate synthase were mixed in an apparatus for quenched flow with solutions containing L-citrulline, $MgATP^{2-}$, and L-aspartate, the stoichiometric reactants in the equation. After each individual reaction had proceeded for a specific interval, the mixtures were quenched with 0.25 M H_2SO_4. The molar concentrations of AMP^{2-} (○) and 2-(N^{ω}-L-arginino)succinate (●), the

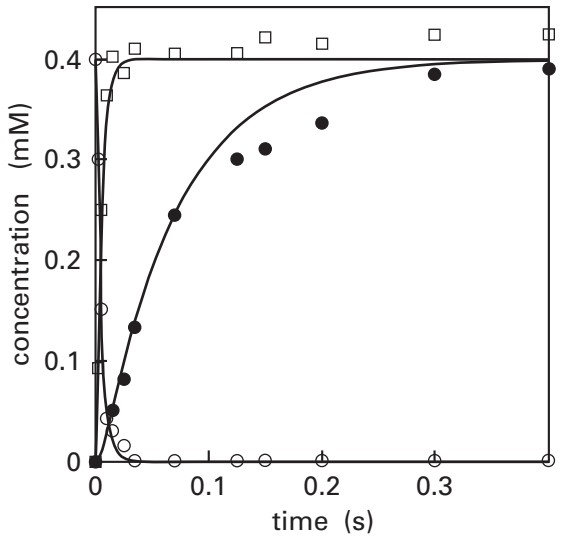


Figure 5–31: Kinetic courses for the concentrations of the reactant 1,3-dibromopropane and the products Br^- and 3-bromopropan-1-ol in the reaction catalyzed by haloalkane dehalogenase from *R. rhodochrous*.[944] A solution of haloalkane dehalogenase (1.5 mM in active sites) was mixed with an equal volume of a solution of 0.8 mM 1,3-dibromopropane. Both solutions contained 1 mM dithiothreitol and 50 mM $NaHCO_3$, pH 9.4 and 30 °C. The two solutions were mixed in a mixing chamber, the mixture flowed through a tube of a particular length, and the mixture was then quenched with 0.8 M H_2SO_4. This procedure was repeated with the same two solutions, varying the time each mixture spent between the mixing chamber and the quench solution by choosing different lengths of tubing. Each quenched solution was then extracted with diethyl ether and neutralized with $NaHCO_3$. 1,3-Dibromopropane (○) and 3-bromopropan-1-ol (●) in the diethyl ether were separated and quantified by gas chromatography, and Br^- (□) in the aqueous phase was isolated by ion-exchange chromatography and quantified. The concentrations of each compound in the unquenched mixture (millimolar) are plotted as a function of the intervals between mixing and quenching (seconds). The curves are the fit to the data by numerical integration of the kinetic mechanism of Equation 5–368.

stoichiometric products, in the acid solutions emerging from the second mixing chamber increased as the time spent between the two mixing chambers was increased (Figure 5–32).[948] The concentration of 2-(N^{ω}-L-arginino)succinate increased at a rate equal to the steady-state rate of the enzymatic reaction from the first instant, but a burst in the concentration of AMP^{2-} occurred before the rate of its production became equal to that of 2-(N^{ω}-L-arginino)succinate. An explanation for these observations is that the burst of AMP^{2-} in the acid solution resulted from a burst of L-citrulline adenylate in the active site that decomposed rapidly to AMP^{2-} and L-citrulline after

being released from the active site by denaturation of the protein. If this is so, then L-citrulline adenylate is formed rapidly (k_{obs} = 9.7 s^{-1}), early in the enzymatic reaction, and 2-(N^{ω}-L-arginino)succinate is formed subsequently in a slow step (k_{obs} = 0.6 s^{-1}) that is rate-limiting for turnover of the enzyme.

Another purpose of stopped flow and quenched flow is to determine numerical values for the rate constants governing the steps in the enzymatic reaction in which intermediates participate. Because these measurements, both for pre-steady-state observations and for observations of single turnovers, are made before a steady state is established, the kinetics are not steady-state kinetics, such as those applied to initial rates for enzymatic reactions, but those for normal chemical reactions. Consequently, standard derivations of integrated rate equations for first-order, pseudo-first-order, second-order, and consecutive first-order reactions and numerical integration of the differential equations for more complex circumstances are the relevant treatments. Again, as with all kinetic measurements, **the observations must be distinguished from the explanation** in the form of a kinetic mechanism provided by the investigators for those observations and the observed rate constants.

Most of the kinetic courses in observations made by stopped flow or quenched flow are, by design, for first-order reactions or consecutive first-order reactions. The kinetic course of such a reaction or series of reactions is referred to as a first-order relaxation or a sequence of first-order relaxations. The reciprocal of the first-order rate constant observed for a given first-order relaxation is referred to as a **relaxation time**, τ. It is the time during which the overall change in concentration falls to e^{-1} of its initial value. If a first-order relaxation or a series of first-order relaxations is not observed, the system is often altered by varying the initial conditions until one is.

The general equation for **a single first-order relaxation*** is

$$\frac{\xi - \xi_{\infty}}{\xi_0 - \xi_{\infty}} = e^{-k_{obs}t} \qquad (5\text{–}319)$$

where ξ is either the molar concentration of a reactant, intermediate, or product in the reaction or any physical property—such as absorbance, fluorescence, or counts per minute—that is directly proportional to the concentration of a reactant, intermediate, or product; ξ_0 is the value for that quantity at time zero; ξ is the value for that quantity at any time during the kinetic course; and ξ_{∞} is the value for that quantity when the reaction reaches equilibrium and changes in physical properties cease.

Because the extinction coefficients or any other constants proportional to concentration are the same for all ξ, these constants of proportionality, as well as the units of concentration, cancel in the quotient. The rate constant obtained by the fit of

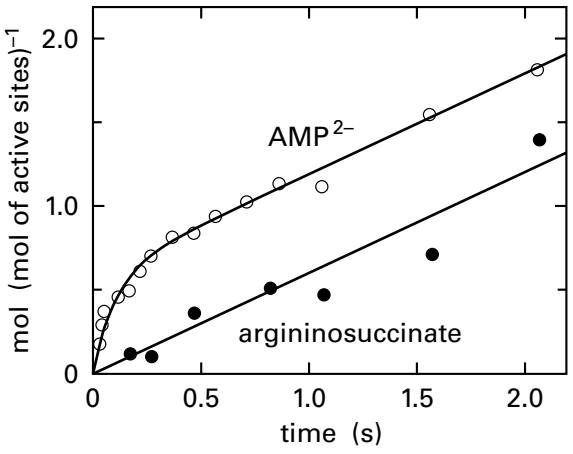

Figure 5–32: Burst in formation of AMP^{2-} observed by quenched flow during the reaction of argininosuccinate synthase.[948] A solution of bovine argininosuccinate synthase (34 μM in active sites) was mixed with an equal volume of a solution containing 5.0 mM L-citrulline, 2.0 mM $MgATP^{2-}$, and 5.0 mM L-aspartate. Both solutions contained 9 mM $MgCl_2$ and 100 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol chloride, pH 8.0 and 22 °C. The two solutions were mixed in a mixing chamber, the mixture flowed through a tube of a particular length, and the mixture was then quenched with 0.25 M H_2SO_4. This procedure was repeated with the same two solutions, varying the time each mixture spent between the mixing chamber and the quench solution by choosing different lengths of tubing. A portion of each quenched solution was submitted to high-pressure liquid chromatography to isolate AMP^{2-}, which was quantified by its absorbance. Another portion of each quenched solution was brought to pH 7 and mixed with a solution of bovine argininosuccinate lyase to hydrolyze 2-(N^{ω}-L-arginino)succinate (argininosuccinate) to fumarate and L-arginine. Each sample was then submitted to high-pressure liquid chromatography to isolate fumarate, which was quantified by its absorbance. The moles of AMP^{2-} (mole of active sites of argininosuccinate synthase)$^{-1}$ and the moles of 2-(N^{ω}-L-arginino)succinate (mole of active sites of argininosuccinate synthase)$^{-1}$ in the reaction mixtures are plotted as a function of the intervals between mixing and quenching (seconds).

*The relaxation time is formally defined as the time, τ, during which the overall change in concentration falls to e^{-1} of its initial value. Consequently, at the relaxation time, the quotient in Equation 5–319 is equal to e^{-1} and $k_{obs}\tau$ must equal 1.

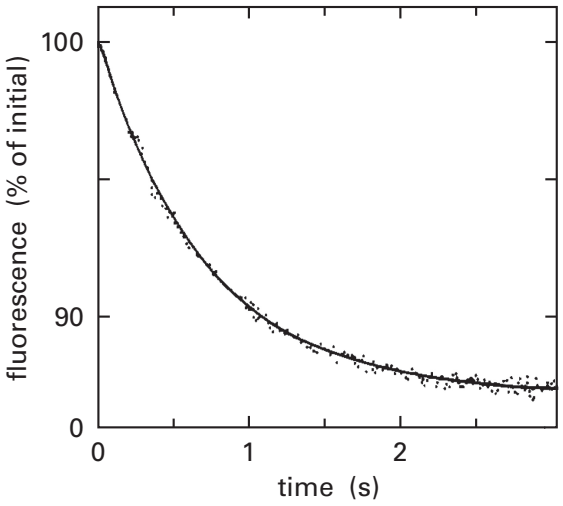

Figure 5–33: Monitoring the dissociation of 5,6,7,8-tetrahydrofolate from the active site of dihydrofolate reductase by stopped flow.[950] A solution containing dihydrofolate reductase from *E. coli* (1.0 μM in active sites) and 4.4 μM 5,6,7,8-tetrahydrofolate was mixed with an equal volume of a solution of 106 μM methotrexate in an apparatus for stopped flow. Both solutions also contained 50 mM sodium 2-(*N*-morpholino)-ethanesulfonate, 25 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol chloride, and 25 mM ethanolammonium chloride, pH 6.0 and 25 °C. The solution in the observation chamber was monitored by fluorescence at 340 nm with excitation at 290 nm. The intrinsic fluorescence of the enzyme was monitored in this way. The decrease in intrinsic fluorescence of the enzyme as a percentage of the initial reading (data points) is presented as a function of time (seconds). The solid curve is the fit of Equation 5–319 to the data with a rate constant of $1.4 \pm 0.2\ s^{-1}$. Adapted with permission from reference 950. Copyright 1987 American Chemical Society. https://doi.org/10.1021/bi00387a052

Equation 5–319 to the data is an **observed rate constant**. For example, the kinetic course for the absorbance at 340 nm (A_{340}), recording the loss of NADH in the active site of L-lactate dehydrogenase (Figure 5–21), could be fit with the equation

$$\frac{A_{340} - A_{340,\infty}}{A_{340,0} - A_{340,\infty}} = e^{-k_{obs}t} \qquad (5–320)$$

The observed rate constant (k_{obs}) governing the first-order decrease in absorbance[884] is 22 s^{-1}. The increase in counts per minute of phosphorus-32 bound to phosphoglucomutase (E–$O^{32}PO_3^{2-}$ in Figure 5–27) could be fit (solid line) with the equation

$$\frac{E{-}^{32}P - E{-}^{32}P_\infty}{E{-}^{32}P_0 - E{-}^{32}P_\infty} = e^{-k_{obs}t} \qquad (5–321)$$

where E–^{32}P is E–$O^{32}PO_3^{2-}$. The observed rate constant governing the first-order increase in counts per minute is 110 s^{-1}.

An observed first-order rate constant provides no insight into the events that are occurring in the active site. As usual, an explanation for the observed rate constant requires that the investigator propose a kinetic mechanism. The simplest case of a first-order relaxation is a situation in which **a reaction, by design, is confined to one step**. For example, dihydrofolate reductase (1.0 μM) from *E. coli* (Equation 5–305) that was saturated with 5,6,7,8-tetrahydrofolate (4.4 μM; $K_d = 0.1\ \mu$M) was mixed with a solution of methotrexate (106 μM), which rapidly associates, with high affinity ($K_d = 9$ nM),[949] with an empty active site of the enzyme in place of 5,6,7,8-tetrahydrofolate. As 5,6,7,8-tetrahydrofolate dissociates from an active site, that active site is immediately and stoichiometrically occupied with methotrexate. As methotrexate associates with vacated active sites, its fluorescence is quenched. The decrease in fluorescence of methotrexate measures the rate at which 5,6,7,8-tetrahydrofolate vacates the active site (Figure 5–33).[950] The first-order decrease in fluorescence can be fit with Equation 5–319 (solid line).

To explain this observed behavior, it was assumed by the investigators that the dissociation of 5,6,7,8-tetrahydrofolate being monitored is a **simple uncomplicated dissociation** that proceeds in a single step, for which the kinetic mechanism is

$$E{\cdot}A \xrightarrow{k_{-1}} E + A \qquad (5–322)$$

where, in this instance, E is an active site of dihydrofolate reductase that does not have 5,6,7,8-tetrahydrofolate associated with it and A is 5,6,7,8-tetrahydrofolate. Because methotrexate immediately occupies any empty active sites, at the outset of the observation all active sites that will be monitored as time passes are occupied with 5,6,7,8-tetrahydrofolate so that at any time t

$$[E] + [E{\cdot}A] = [E{\cdot}A]_0 \qquad (5–323)$$

where [E] is the concentration of active sites from which 5,6,7,8-tetrahydrofolate has dissociated since the reaction was initiated and that have been filled immediately with methotrexate, [E·A] is the concentration of active sites still occupied by 5,6,7,8-tetrahydrofolate, and $[E{\cdot}A]_0$ is the concentration of occupied active sites at the beginning of the

reaction. From **the kinetic mechanism proposed** in Equation 5–322, it follows that

$$\frac{d[\mathrm{E}]}{dt} = k_{-1}[\mathrm{E{\cdot}A}] \tag{5–324}$$

The rate equation upon integration is

$$[\mathrm{E}] = [\mathrm{E{\cdot}A}]_0\left(1 - \mathrm{e}^{-k_{-1}t}\right) \tag{5–325}$$

which, because $[\mathrm{E}]_\infty = [\mathrm{E{\cdot}A}]_0$ and $[\mathrm{E}]_0 = 0$, upon rearrangement becomes

$$\frac{[\mathrm{E}] - [\mathrm{E}]_\infty}{[\mathrm{E}]_0 - [\mathrm{E}]_\infty} = \frac{F - F_\infty}{F_0 - F_\infty} = \mathrm{e}^{-k_{-1}t} \tag{5–326}$$

where F is fluorescence, the quenching of which is directly proportional to [E]. From an examination of this integrated rate equation, it can be seen that $k_{obs} = k_{-1}$. A rate constant k_{-1} of 1.4 s^{-1} was obtained from a fit of Equation 5–326 to the data.

In the case of L-lactate dehydrogenase (Figure 5–21), the observed first-order rate constants (k_{obs}) measured at various concentrations of pyruvate displayed saturation (Figure 5–21B), an observation that can be explained with the kinetic mechanism

$$\mathrm{E{\cdot}NADH} + \text{pyruvate} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}NADH{\cdot}pyruvate} \xrightarrow{k_2} \mathrm{E} + \mathrm{NAD^+} + \text{lactate} \tag{5–327}$$

but only if k_1 and k_{-1} are so large that the complex E·NADH·pyruvate is in equilibrium at all times with E·NADH and free pyruvate (pyr). If this is the case, then the observed first-order rate constant, k_{obs}, will be

$$k_{obs} = \frac{k_2[\mathrm{pyr}]}{K_{pyr} + [\mathrm{pyr}]} \tag{5–328}$$

where the dissociation constant for pyruvate $K_{pyr} = k^{-1}\,(k_{-1})^{-1}$. Therefore, at saturation with pyruvate, the observed first-order rate constant for the reaction should be k_2, the rate constant for transfer of the hydride from NADH to pyruvate after both NADH and pyruvate are bound to the active site. This process was measured directly by stopped flow. At pH 9.0 and 22 °C, k_2 had a value of 243 ± 9 s^{-1} and K_{pyr} had a value of 7 ± 0.5 mM. The rate constants for transfer of the hydride measured directly in these experiments made with stopped flow (○) at several concentrations of pyruvate equaled the rate constant for the steady-state initial rates (●) for the overall reaction at the same concentration of pyruvate (Figure 5–21B). All these observations suggest that, for the reaction catalyzed by porcine lactate dehydrogenase under these conditions, the rate-limiting step in the reaction is transfer of the hydride.

As with most kinetic explanations, however, there are alternatives. For example, the observations are also consistent with the mechanism

$$\mathrm{E{\cdot}NADH} + \text{pyruvate} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}NADH{\cdot}pyruvate} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{E{\cdot}NAD^+{\cdot}}\text{lactate} \xrightarrow{k_3} \mathrm{E} + \mathrm{NAD^+} + \text{lactate} \tag{5–329}$$

where $k_{-1} >> k_2$, $k_{-2} >> k_3$, and $k_{-2} > k_2$ and dissociation of the lactate is the rate-limiting step.

The first-order relaxations observed with dihydrofolate reductase and lactate dehydrogenase were explained with kinetic mechanisms (Equations 5–322 and 5–327, respectively) in which the governing steps were irreversible first-order steps. All chemical reactions, however, are approaches to equilibrium. If the equilibrium constant for a first-order reaction is heavily in favor of the reactant, no reaction will be observed even though a small, perhaps immeasurable, concentration of the product must be formed to reach equilibrium. If the equilibrium constant is heavily in favor of product, the reaction will proceed to apparent completion, even though a small, perhaps immeasurable, equilibrium concentration of reactant remains. If the equilibrium constant for a first-order reaction is neither too large nor too small, a measurable quantity of reactant will remain when the reaction ceases and a measurable quantity of product will be formed. In this case, the **approach to equilibrium is a first-order relaxation**.

Suppose that, by designing the experiment properly, the kinetic mechanism for the reaction being followed is

$$\mathrm{E_2} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{E_3} \tag{5–330}$$

where E_2 and E_3 are two forms of the enzyme, for example, E·NADH·pyruvate and E·NAD^+·lactate at saturation with pyruvate or E–^{31}P·Glc-1-^{32}P and E–^{32}P·Glc-6-^{31}P at saturation with D-glucose 1-[^{32}P]phosphate. Suppose that, again by design, the sum

$$[E_2] + [E_3] = [E]_t \tag{5–331}$$

at all time points, where $[E]_t$ is the total concentration of enzyme. As a result, the sum must remain constant over the duration of the reaction. Suppose also, for the sake of argument, that the physical property being monitored is absorbance, A, but any other property, such as counts per minute incorporated into protein, that is proportional to the molar concentration of either form of the enzyme would be equivalent. The absorbance due to the two forms of the enzyme at any time is then

$$A = \varepsilon_2[E_2] + \varepsilon_3[E_3] \tag{5–332}$$

where ε_2 and ε_3 are the respective extinction coefficients. From Equations 5–330 and 5–331

$$-\frac{d[E_2]}{dt} = k_2[E_2] - k_{-2}[E_3] \tag{5–333}$$

$$-\frac{d[E_2]}{(k_2 + k_{-2})[E_2] - k_{-2}[E]_t} = dt \tag{5–334}$$

which upon integration gives

$$-\ln\left\{\frac{(k_2 + k_{-2})[E_2] - k_{-2}[E]_t}{(k_2 + k_{-2})[E_2]_0 - k_{-2}[E]_t}\right\} = (k_2 + k_{-2})t \tag{5–335}$$

where $[E_2]_0$ is the concentration of form E_2 at the beginning of the reaction and $[E_2]$ is its concentration at any instant. If $[E_2]_{eq}$ and $[E_3]_{eq}$ are the concentrations of the two forms at the end of the reaction

$$k_2[E_2]_{eq} = k_{-2}[E_3]_{eq} \tag{5–336}$$

$$k_{-2}[E]_t = (k_2 + k_{-2})[E_2]_{eq} \tag{5–337}$$

$$-\ln\left\{\frac{[E_2] - [E_2]_{eq}}{[E_2]_0 - [E_2]_{eq}}\right\} = (k_2 + k_{-2})t \tag{5–338}$$

$$\frac{(\varepsilon_2 - \varepsilon_3)[E_2] - (\varepsilon_2 - \varepsilon_3)[E_2]_{eq}}{(\varepsilon_2 - \varepsilon_3)[E_2]_0 - (\varepsilon_2 - \varepsilon_3)[E_2]_{eq}} = e^{-(k_2 + k_{-2})t} \tag{5–339}$$

$$\frac{\varepsilon_2[E_2] + \varepsilon_3[E_3] - \varepsilon_3[E]_t - \varepsilon_2[E_2]_{eq} - \varepsilon_3[E_3]_{eq} + \varepsilon_3[E]_t}{\varepsilon_2[E_2]_0 + \varepsilon_3[E_3]_0 - \varepsilon_3[E]_t - \varepsilon_2[E_2]_{eq} - \varepsilon_3[E_3]_{eq} + \varepsilon_3[E]_t} = e^{-(k_2 + k_{-2})t} \tag{5–340}$$

$$\frac{A - A_{eq}}{A_0 - A_{eq}} = e^{-(k_2 + k_{-2})t} \tag{5–341}$$

Equation 5–341 states that if the reaction observed is described by the kinetic mechanism of Equation 5–330, then the behavior of any physical property the magnitude of which is proportional to the concentrations of both product and reactant will display first-order behavior. First-order behavior will be seen regardless of whether measurements were initiated when all the enzyme was E_2 or in midreaction ($[E_3]_0 > 0$); regardless of whether the reaction goes to completion ($k_{-2} = 0$) or reaches an equilibrium; regardless of whether both product and reactant display the physical property ($\varepsilon_2 > 0$ and $\varepsilon_3 > 0$) or only one displays the physical property; and regardless of whether the rate constants k_{-2} and k_2 are unimolecular rate constants or pseudo-first-order rate constants ($k_2 = k_2'[A]$ or $k_{-2} = k_{-2}'[Z]$). The only requirement for observing the reaction is that the two extinction coefficients (constants of proportionality) for the two forms of the enzyme must be different enough that a significant change occurs in the magnitude of the physical property during the measurement. Because of this generality, such first-order relaxations are commonly observed in kinetic measurements. It can also be seen that a reaction consisting of a single irreversible first-order step is simply a special case of an approach to equilibrium.

Because it does not matter whether or not one of the concentrations of the participants in an approach to equilibrium is initially zero, it follows that when a system at equilibrium is perturbed in some way that changes the value for the equilibrium constant, the

system will then approach the new, perturbed equilibrium. Each microscopic step in the overall equilibrium will approach its own new equilibrium, with a rate constant governed by Equation 5–341. This fact is the basis for temperature jump. **Temperature jump** is a relaxation technique in which the temperature of a chemical system is suddenly raised, and the system then relaxes to a new state of equilibrium. Analysis of the relaxation process provides rate constants for the step or steps through which the system proceeds to reach the new equilibrium. The advantage of temperature jump is that the dead time during which the temperature is raised can be much shorter than the dead times for stopped flow and quenched flow, so measurements can be made at much shorter times. The disadvantage is that, when the system is at equilibrium before the temperature is raised, there should be measurable concentrations of reactants, products, and intermediates to follow as the new equilibrium is achieved. Consequently, temperature jump has seldom been applied to enzymatic reactions, but there are situations in which it has. For example, temperature jump monitoring the absorbance of proflavin has been applied to a solution of this competitive inhibitor in equilibrium with its complex with the active site of bovine chymotrypsin. Upon a jump of temperature, the system relaxes to the new equilibrium in a process that involves the rate constants for association and dissociation of the inhibitor and rate constants for a transition assigned to a conformational change in the enzyme.[951] Temperature jump has also been applied to the complex of lactate dehydrogenase from *G. stearothermophilus* and the coenzyme NADH at saturation. In this instance, both fluorescence of NADH and fluorescence of four tryptophans placed in turn by site-directed mutation at different locations in the protein were monitored in order to measure rate constants for rapid conformational changes of the protein within the complex as equilibrium is reestablished.[952]

Because it does not matter whether the rate constants governing the relaxation for the approach to an equilibrium are unimolecular or pseudo-first-order rate constants, the first-order rate constant observed for association of reactant A with an active site E

$$\mathrm{E} + \mathrm{A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}A} \qquad (5\text{–}342)$$

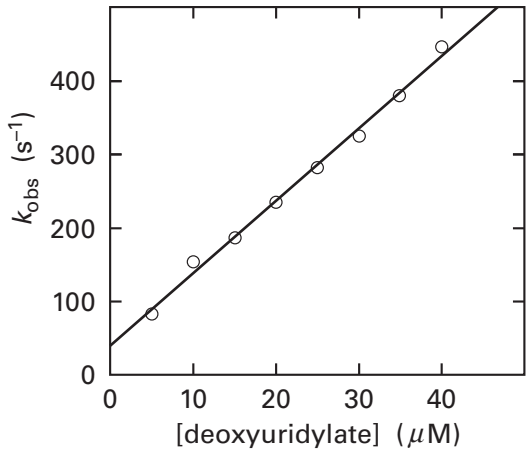

Figure 5–34: Effect of the concentration of deoxyuridylate on the observed rate constant for its association with the active site of thymidylate synthase.[224] A solution of thymidylate synthase from *E. coli* (2.1 μM in active sites) in one syringe of an apparatus for stopped flow was mixed with an equal volume of a solution of deoxyuridylate in the other syringe, and the mixture was immediately introduced into a cuvette. Both solutions contained 50 mM 2-sulfanylethanol, 1 mM ethylenediaminetetraacetate, and 100 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol chloride, pH 7.4 and 20 °C. This procedure was repeated several times with different concentrations of deoxyuridylate. The kinetic courses for association of deoxyuridylate with the active site of the enzyme were followed by monitoring the fluorescence of one or more of the seven tryptophans in a subunit of the enzyme, which decreases as the deoxyuridylate binds. The decreases in fluorescence with time could all be fit with Equation 5–319 to obtain observed first-order rate constants, k_{obs}. The rate constants (second^{-1}) are plotted as a function of the final concentrations (micromolar) of deoxyuridylate in the reaction mixture. The line is a fit of Equation 5–343 to the data.

when the concentration of reactant is in great excess over the concentration of active sites, is

$$k_{obs} = k_1[\mathrm{A}] + k_{-1} \qquad (5\text{–}343)$$

Consequently, if the **observed rate constant for association of reactant A is plotted as a function of the concentration of reactant A,** a straight line with a slope of k_1(molar^{-1} second^{-1}) and an intercept of k_{-1} (second^{-1}) will be observed if this is the applicable mechanism. For example, when the individually observed rate constants for the purely first-order relaxations produced by association of deoxyuridine monophosphate with the active site of thymidylate synthase (Equation 5–50) from *E. coli*, in the absence of 5,10-methylenetetrahydrofolate, are plotted as a function of the concentration of deoxyuridine monophosphate (Figure 5–34), they define a line with a slope of 10 μM^{-1} s^{-1} and an intercept of 40 s^{-1}. Because (previously Equation 3–338)

$$K_{dL} = \frac{k_{-1}}{k_1} \tag{5–344}$$

together these rate constants give a dissociation constant of 4 μM, which is the same as the dissociation constant measured directly.[224]

Association of a reactant can also be an essentially irreversible reaction. When the observed rate constant for association of oxygen with the complex between protocatechuate 3,4-dioxygenase and protocatechuate (see Figure 5–22) was plotted against the molar concentration of O_2 in the solution, it was a linear relation, but the intercept at the axis of the ordinate, which would be the rate of dissociation of O_2 from the complex, was <5 s^{-1} and indistinguishable from zero.[887]

A behavior of **first-order relaxations at different concentrations of a reactant** is also observed that is a hybrid of the behavior of first-order relaxations observed at different concentrations of pyruvate with L-lactate dehydrogenase (Figure 5–21B) and the behavior of first-order relaxations observed at different concentrations of deoxyuridine monophosphate with thymidylate synthase (Figure 5–34). For example, when fluorescence from tryptophans in glutamine synthetase (Equation 5–270) from *E. coli* was followed after the enzyme was mixed with the substrate MnADP$^-$ in the absence of phosphate and L-glutamine, the change in fluorescence was a first-order relaxation at all concentrations of MnADP$^-$. A plot of the observed first-order rate constants as a function of the concentration of MnADP$^-$ (Figure 5–35)[953] could be fit (solid line) with the equation

$$k_{obs} = \frac{k_a[\text{MnADP}^-]}{k_b + [\text{MnADP}^-]} + k_c \tag{5–345}$$

This observed behavior can be explained with the kinetic mechanism

$$\text{E} + \text{MnADP}^- \underset{K_{dADP}}{\rightleftharpoons} \text{E}\cdot\text{MnADP}^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{E}^*\cdot\text{MnADP}^- \tag{5–346}$$

where E* is a different conformation of the enzyme. The observed first-order rate constant for the analytically integrated rate equation for this kinetic mechanism

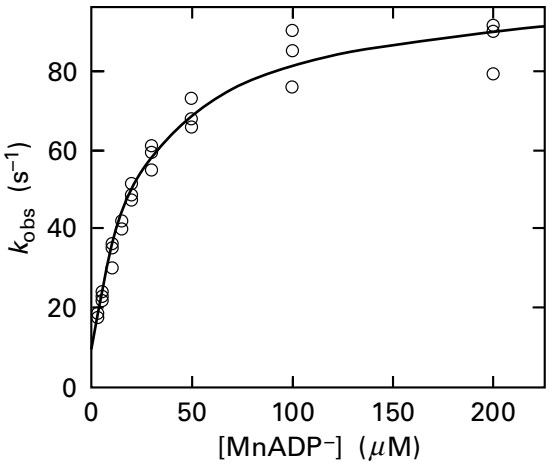

Figure 5–35: Effect of the concentration of MnADP$^-$ on the observed rate constant for its association with the active site of glutamine synthetase.[953] A solution containing glutamine synthetase from *E. coli* (2 μM in active sites) in one syringe of an apparatus for stopped flow was mixed with an equal volume of a solution of MnADP$^-$ in the other syringe, and the mixture was immediately introduced into a cuvette. Both solutions contained 0.1 M KCl, 1 mM $MnCl_2$, and 50 mM potassium 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate, pH 7.0 and 15 °C. This procedure was repeated several times with different concentrations of MnADP$^-$. The kinetic courses for association of MnADP$^-$ with the active site of the enzyme were followed by monitoring the fluorescence of one or both of the two tryptophans in a subunit of the enzyme, which increases as the MnADP$^-$ binds. The increases in fluorescence with time could all be fit with Equation 5–319 to obtain observed first-order rate constants, k_{obs}. The rate constants ($second^{-1}$) are plotted as a function of the final concentrations (micromolar) of MnADP$^-$ in the reaction mixtures. The curve is a fit of Equation 5–347 to the data.

$$k_{obs} = \frac{k_2[\text{MnADP}^-]}{K_{dADP} + [\text{MnADP}^-]} + k_{-2} \tag{5–347}$$

In this case, at low [MnADP$^-$] the initial line for k_{obs} is defined by

$$k_{obs} = \frac{k_2}{K_{dADP}}[\text{MnADP}^-] + k_{-2} \tag{5–348}$$

and at high [MnADP$^-$] the observed rate constant is equal to $k_2 + k_{-2}$. The two rate constants (k_2 = 90 s^{-1} and k_{-2} = 9 s^{-1}) and the dissociation constant (K_{dADP} = 25 μM) can be calculated from parameters of the fit of Equation 5–347 to the data. In this situation, there is a change in rate-limiting step from the rate of association of MnADP$^-$ to the rate of approach to equilibrium between E·MnADP$^-$ and E*·MnADP$^-$. The fact that the directly measured, apparent disso-

ciation constant ($K_{d,app}$) for $MnADP^-$ ($4.6 \pm 1.5\ \mu M$) is within statistical error of the dissociation constant ($2.7 \pm 0.6\ \mu M$) calculated from these values ($K_{d,app} = k_{-2}\ K_{dADP}\ k_2^{-1}$) is evidence in favor of the mechanism proposed as the explanation of the observed behavior.

As the examples of L-lactate dehydrogenase (Figure 5–21B) and glutamine synthetase (Figure 5–35) illustrate, the dependence or lack of dependence of an observed rate constant on the concentration of a reactant is often used to incorporate association of the reactant into the kinetic mechanism and obtain values for the dissociation constant of the reactant or the rate constants for its dissociation and association.[897,899,954,955]

When there are **two consecutive first-order relaxations** connecting three distinct species, the equation fit to observations has the general form

$$\frac{\xi - \xi_\infty}{\xi_0 - \xi_\infty} = a + b e^{-k_{obs1} t} + c e^{-k_{obs2} t} \qquad (5\text{–}349)$$

where, as before, ξ is either the molar concentration of one reactant, intermediate, or product in the reaction or any physical property—such as absorbance, fluorescence, or counts per minute—that is directly proportional to the concentration of a reactant, intermediate, or product in the reaction. In this instance, the magnitudes of the parameters in the equation, *a*, *b*, and *c*, depend on the species being observed. For example, the three species the concentrations of which are being followed in the kinetic course of hydrolysis of nitrocefin by β-lactamase (Figure 5–23) were assigned to be the Michaelis complex with nitrocefin, [E·nit], formed during the dead time for the apparatus; the complex between the active site and the intermediate anion, [E·an] (Equation 5–295); and the neutral hydrolyzed nitrocefin, [hyd], that is the product of the enzymatic reaction. These three kinetic courses (Figure 5–23B) can be fit with the equations

$$[E{\cdot}nit] = [E{\cdot}nit]_0\, e^{-k_{obs1} t} \qquad (5\text{–}350)$$

which is Equation 5–349 with $a = 0$, $b = 0$, and $c = [E{\cdot}nit]_0$

$$[E{\cdot}an] = [E{\cdot}nit]_0 \left(b_2 e^{-k_{obs1} t} + c_2 e^{-k_{obs2} t}\right) \qquad (5\text{–}351)$$

which is Equation 5–349 with $a = 0$, and

$$[hyd] = [E{\cdot}nit]_0 \left(1 + b_3 e^{-k_{obs1} t} + c_3 e^{-k_{obs2} t}\right) \qquad (5\text{–}352)$$

which is Equation 5–349 with all three of its terms. In these equations, $[E{\cdot}nit]_0$ is the initial concentration of the Michaelis complex between enzyme and nitrocefin. Fitting the equations to the data gives the following parameters: $k_{obs1} = 150 \pm 30\ s^{-1}$, $k_{obs2} = 13 \pm 1\ s^{-1}$, $b_2 = -1.09$, $c_2 = 1.09$, $b_3 = 0.095$, and $c_3 = -1.09$.

The simplest and most obvious explanation for such behavior is that the reaction passes through three species, A, B, and C, that are connected by **two consecutive irreversible steps** governed by rate constants k_1 and k_2

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \qquad (5\text{–}353)$$

for which the integrated rate equations are[956]

$$[A] = [A]_0\, e^{-k_1 t} \qquad (5\text{–}354)$$

$$[B] = [A]_0 \left(\frac{k_1}{k_2 - k_1}\right)\left(e^{-k_1 t} - e^{-k_2 t}\right) \qquad (5\text{–}355)$$

$$[C] = [A]_0 \left(1 + \frac{k_2}{k_1 - k_2} e^{-k_1 t} - \frac{k_1}{k_1 - k_2} e^{-k_2 t}\right) \qquad (5\text{–}356)$$

It was concluded that hydrolysis of nitrocefin by β-lactamase in the apparatus for stopped flow proceded with this kinetic mechanism[888] with rate constants of $k_1 = 150\ s^{-1}$ and $k_2 = 13\ s^{-1}$. The kinetic courses of the absorbances at 403 and 460 nm for the reaction of the complex between protocatechuate 3,4-dioxygenase and protocatechuate with O_2 (Figure 5–22) in an apparatus for stopped flow following the abrupt changes in absorbance during the dead time could be fit[887] by the integrated rate equations for a simple two-step mechanism with $k_2 = 450\ s^{-1}$ and $k_3 = 36\ s^{-1}$. The respective kinetic courses for the concentrations of *S*-adenosyl-L-methionine, intermediate **5–176**, and *N*-butyryl-L-homoserine lactone for the reaction catalyzed by acylhomoserine-lactone synthase (Equation 5–306) could also be fit satisfactorily with Equations 5–354 through 5–356, respectively, when enzyme saturated with *S*-adenosyl-[*carboxy*-^{14}C]-L-methionine (91%) was mixed in an

apparatus for quenched flow in 2.5-fold molar excess with butyryl-SACP.[926]

As is the case with a single first-order relaxation, it is also possible to fit such data with more complicated kinetic mechanisms. For example, the inclusion of rapid, kinetically silent steps or rapid intermediate equilibria do not affect the form of the derived equations.

The kinetic mechanism with **two consecutive reversible steps**

$$\mathrm{A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{B} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{C} \qquad (5\text{–}357)$$

also produces observed behavior that can be fit by Equations 5–354 through 5–356 even though the reverse rate constants, k_{-1} and k_{-2}, do not appear in these equations. If it cannot be demonstrated that addition of two reverse rate constants improves the fit significantly in comparison with the irreversible mechanism of Equation 5–353,[957] there is no justification for adding them.[926] If they do exist, however, and are of significant magnitude, then the rate constants obtained by fitting the data to the irreversible kinetic mechanism of Equation 5–353 will not be accurate.

The general form of the equation for **multiple first-order relaxations** is

$$\frac{\xi - \xi_\infty}{\xi_0 - \xi_\infty} = a_0 + \sum_{i=1}^{n} a_i e^{-k_{\mathrm{obs}i}t} \qquad (5\text{–}358)$$

and again the explicit form of this equation in a given circumstance depends on which species, reactant, Michaelis complex, intermediate, or product, is being monitored, which, in turn, determines the physical property that is being monitored. In many instances, the different species connected consecutively by the relaxations can be independently followed. For example, four spectrally distinct intermediates in the reaction catalyzed by ornithine decarboxylase (Figure 5–25),[902] the first of which is formed in the dead time of the apparatus, can be distinguished one from the other by their unique absorbance spectra. The increases and decreases in the concentrations of intermediate A (○), intermediate B (□), intermediate C (●), and intermediate D (■), over the course of the observations can each be fit with Equation 5–358. The observed behavior can be satisfactorily explained with the proposal that the kinetic mechanism is the simplest one possible

$$\mathrm{A} \xrightarrow{k_1} \mathrm{B} \xrightarrow{k_2} \mathrm{C} \xrightarrow{k_3} \mathrm{D} \qquad (5\text{–}359)$$

with rate constants $k_1 = 21\ \mathrm{s}^{-1}$, $k_2 = 145\ \mathrm{s}^{-1}$, and $k_3 = 1.03\ \mathrm{s}^{-1}$. The fact that $k_1 < k_2$ explains why so little of the second intermediate accumulates during the reaction.

Often, however, only one species can be distinguished, for example, the product of the reaction. In such instances, Equation 5–358 is fit to the data, using the smallest number of relaxations necessary to fit the data satisfactorily. Since the inclusion of more terms always improves the fit of any equation to any set of data, the question of how many terms to include is, to a certain extent, a subjective decision, but usually it is obvious how many are required.[909,958]

Once it has been decided how many first-order relaxations are required to fit the data satisfactorily and observed pre-exponential parameters and observed rate constants have been estimated from the fits of the data to Equation 5–358, it is then incumbent upon the investigators to provide a kinetic mechanism with its accompanying rate constants to explain the observations. Because of the significant difficulties in directly deriving an analytical solution, integrated rate equations for a proposed kinetic mechanism involving a sequence of three or more irreversible steps or a sequence of two or more reversible steps can be derived by **linear algebra**.[959]

The observed pre-exponential parameters and first-order rate constants governing a sequence of first-order relaxations are functions of the microscopic rate constants in the actual kinetic mechanism of the enzyme being studied. As always, there is no way to determine the actual kinetic mechanism of a particular enzyme at the level of its microscopic rate constants. As was the case in the simpler examples of kinetic mechanisms—for dihydrofolate reductase (Equation 5–322), L-lactate dehydrogenase (Equation 5–327), glutamine synthetase (Equation 5–346), β-lactamase (Equation 5–353), and ornithine decarboxylase (Equation 5–359)—the investigator, usually relying on an intuitive understanding of the chemical mechanism of the events occurring in the active site as well as knowledge of the relaxations that have been observed, proposes a kinetic mechanism and then demonstrates that the **proposed kinetic mechanism** is consistent with all available observations. The examples presented so far of this process have been simple enough that algebraic derivations of integrated rate equations can be readily derived from a proposed kinetic mechanism

and its rate constants and fit to the experimental data.

In complicated situations, however, that involve two or more reversible rate-affecting steps and branching within the kinetic mechanism, rather than performing the derivation of a set of analytical, integrated rate equations by linear algebra, **the differential equations describing the steps in the proposed kinetic mechanism are usually submitted to numerical integration.**[960] For example, 3-phosphoshikimate 1-carboxyvinyltransferase (E) from *E. coli* saturated with 3-phosphoshikimate (3PS) was mixed with phospho*enol*pyruvate (PEP) (Figure 5–26)[308] so that the final concentrations of enzyme and phospho*enol*pyruvate were only 10 μM and 3.5 μM, respectively. At these concentrations, even if association of phospho*enol*pyruvate were rapid, only 30% of the phospho*enol*pyruvate (K_d = 20 μM) in the solution would occupy an active site at the beginning of the reaction. It was proposed that the kinetic mechanism for the reaction being observed was

$$\begin{aligned} \text{E}\cdot\text{3PS} + \text{PEP} &\underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{E}\cdot\text{3PS}\cdot\text{PEP} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \\ \text{E}\cdot\text{I} &\underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \text{E}\cdot\text{CVPS} \xrightarrow{k_5} \text{E} + \text{CVPS} \end{aligned} \qquad (5\text{–}360)$$

where I (●) is intermediate **5–180** and CVPS (□) is the product 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate (Equation 5–178). The differential equations that describe this kinetic mechanism were submitted to numerical integration. The curves drawn in Figure 5–26 are fits produced by this numerical integration for rate constants k_2 = 15 μM^{-1} s^{-1}, k_{-2} = 280 s^{-1}, k_3 = 1200 s^{-1}, k_{-3} = 100 s^{-1}, k_4 = 320 s^{-1}, k_{-4} = 240 s^{-1}, and k_5 = 100 s^{-1}.

When D-amino-acid oxidase from *Trigonopsis variabilis* with its prosthetic flavin in the oxidized state ($E\cdot Fl_{ox}$) was mixed anaerobically in an apparatus for stopped flow with the reactant D-phenylglycine (DPG)

$$\begin{aligned} \text{E}\cdot\text{HFl}_{ox} + \text{D-phenylglycine} + \text{H}_2\text{O} &\rightleftharpoons \\ \text{E}\cdot\text{H}_3\text{Fl}_{red} + \text{phenylglyoxylate} + \text{NH}_4^+ & \end{aligned} \qquad (5\text{–}361)$$

so that there was no O_2 to reoxidize the reduced flavin, each active site could complete only one turnover regardless of the concentration of D-phenylglycine. Reduction of the prosthetic flavin during a single turnover could be followed as the absorbance at 454 nm decreased. The decreases in absorbance for a series of concentrations of D-phenylglycine could be fit satisfactorily with the equation

$$\frac{A_{454} - A_{454,\infty}}{A_{454,0} - A_{454,\infty}} = a_0 - a_1 e^{-k_{obs1}t} - a_2 e^{-k_{obs2}t} \qquad (5\text{–}362)$$

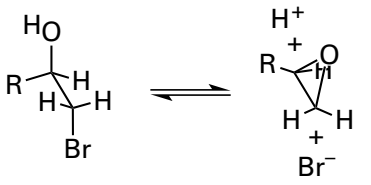
The kinetic mechanism

$$\begin{aligned} \text{E}\cdot\text{Fl}_{ox} + \text{DPG} &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{E}\cdot\text{Fl}_{ox}\cdot\text{DPG} \\ &\underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{E}\cdot\text{Fl}_{red}\cdot\text{PGO} \xrightarrow{k_3} \text{E}\cdot\text{Fl}_{red} + \text{PGO} \end{aligned} \qquad (5\text{–}363)$$

where PGO is phenylglyoxylate, the product of oxidation of D-phenylglycine, can explain the observed behavior of the two observed first-order rate constants, k_{obs1} and k_{obs2}, as a function of the concentration of reactant.[961] This kinetic mechanism was fit by numerical integration of its differential equations to the changes in absorbance for the series of single turnovers at different concentrations of D-phenylglycine with k_1 = 60 mM^{-1} s^{-1}, k_{-1} = 40 s^{-1}, k_2 = 30 s^{-1}, k_{-2} = 4 s^{-1}, and k_3 = 6 s^{-1}.

These observations of the behavior of D-amino-acid oxidase by stopped flow probably give values of the microscopic rate constants for the transfer of a hydride between D-phenylglycine and the prosthetic flavin. Consequently by the use of [2-^{2}H]-D-phenylglycine as a reactant, it was possible to obtain values for the intrinsic kinetic deuterium isotope effects (6.3 and 4.7, respectively) on the rate constants k_2 and k_{-2}, as well as a value for the intrinsic deuterium isotope effect on the equilibrium constant (1.35) for the transfer. Because the deuterated reactant decreases the rate constant k_2 by a factor of 6.3, association of [2-^{2}H]-D-phenylglycine reaches equilibrium before the hydride is transferred, and this association becomes a pre-equilibrium in the kinetic mechanism with the deuterated reactant.

When halohydrin dehalogenase



(5–364)

from *Rhizobium radiobacter* is mixed with the reactant (1*R*)-2-bromo-1-(4-nitrophenyl)ethanol (Equation 5–364 with R = 4-nitrophenyl)) under conditions permitting the enzyme to complete only one turnover, the production of Br^- in the active site of the enzyme during that single turnover can be followed as fluorescence of one or more of the four tryptophans in the protein increases. The fluorescence of those tryptophans then returns to the value for the unoccupied active site as the Br^- dissociates (trace a in Figure 5–36A).[962] This change in fluorescence (F) for the production and dissociation of Br^- at this one concentration of reactant can be fit satisfactorily with the equation

$$\frac{F_t - F_\infty}{F_0 - F_\infty} = ae^{-k_{obs2}t} - ae^{-k_{obs1}t} \quad (5–365)$$

which is consistent for an intermediate in a kinetic mechanism with two consecutive first-order reactions (Equation 5–355). The enzyme can also be mixed with concentrations of (1*R*)-2-bromo-1-(4-nitrophenyl)ethanol over a broad range. At these higher concentrations of reactant, multiple turnovers of the enzyme have to occur. Each burst of fluorescence that is observed preceding the multiple turnovers can be fit with a first-order relaxation to provide a first-order rate constant k_{obs}.

The kinetic mechanism

$$E + BNE \underset{K_{dBNE}}{\rightleftharpoons} E{\cdot}BNE \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} E{\cdot}epox{\cdot}Br^- \xrightarrow{k_3} E + epox + Br^- \quad (5–366)$$

where BNE is the reactant (1*R*)-2-bromo-1-(4-nitrophenyl)ethanol and epox is the product (*S*)-(4-nitrophenyl)oxirane, can explain the observed behavior of these observed first-order rate constants, k_{obsi}, as a function of the concentration of reactant (Figure 5–36B). In this instance, as was the case with the deuterated reactant for D-amino-acid oxidase, association of the reactant is a pre-equilibrium. This kinetic mechanism (Equation 5–366) can be fit

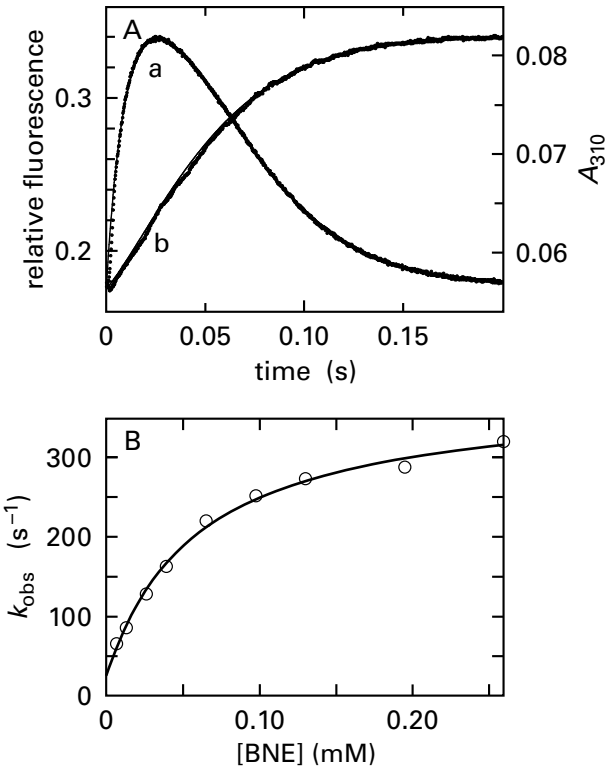


Figure 5–36: Stopped-flow measurements of the kinetics of the reaction catalyzed by halohydrin dehalogenase from *R. radiobacter*.[962] (**A**) Observation of a single turnover of the enzyme. Halohydrin dehalogenase (26.5 μM in active sites) in one syringe was rapidly mixed with (1-*R*)-2-bromo-1-(4-nitrophenyl)-ethanol (23.5 μM) in the other syringe. Fluorescence (curve a; $\lambda_{excitation}$ = 290 nm, $\lambda_{emission}$ = >320 nm), arising from an enhancement of the fluorescence of tryptophans by Br^- bound in the active site, and absorbance at 310 nm (curve b, A_{310}), arising from the change in absorbance as (*S*)-(4-nitrophenyl)oxirane dissociates, were monitored as a function of time (seconds). The solid curves are fits by numerical integration of the differential equations for the mechanism in Equation 5–366. (**B**) Rate constants for bursts of fluorescence. Halohydrin dehalogenase (0.8 μM in active sites) in one syringe was mixed with increasing concentrations of (1*R*)-2-bromo-1-(4-nitrophenyl)ethanol in the other syringe. The observed rate constants for the bursts ($second^{-1}$) are plotted as a function of the final concentrations of (1*R*)-2-bromo-1-(4-nitrophenyl)ethanol (millimolar). The solid curve is a fit of Equation 5–367 to the data. Adapted with permission from reference 962. Copyright 2003 American Chemical Society. https://doi.org/10.1021/bi0273361

by numerical integration of its differential equations to the change in fluorescence during the single turnover with $K_{dBNE} = 100 \pm 9$ μM, $k_2 = 380 \pm 20$ s^{-1}, $k_{-2} = 3$ s^{-1}, and $k_3 = 21 \pm 1$ s^{-1} (solid curve a in Figure 5–36A). The change in absorbance at 310 nm rather than fluorescence that occurs during the single turnover (trace b in Figure 5–36A) could also be fit with the equilibrium constant and the rate constants (solid curve b in Figure 5–36A) derived from measurements of fluorescence. To obtain a satisfactory fit with the same rate and equilibrium constants, however,

it had to be assumed that the absorbance of the 4-nitrophenyl group increases significantly only when (*S*)-(4-nitrophenyl)oxirane dissociates from the active site. From the kinetic mechanism (Equation 5–366), an integrated equation for the behavior of k_{obs} for the bursts

$$k_{obs} = k_{-2} + k_3 + \frac{k_2\,[BNE]}{[BNE] + K_{dBNE}} \quad (5–367)$$

can be derived analytically, and the same values for the dissociation constant and the three rate constants that fit the data for the single turnover provide a satisfactory fit, within experimental error, of the behavior of k_{obs} for the bursts as a function of the concentration of (1*R*)-2-bromo-1-(4-nitrophenyl)-ethanol (solid curve in Figure 5–36B).

The kinetic mechanism

$$E + DBP \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}DBP \xrightarrow{k_2} E{-}I + Br^- \xrightarrow{k_3} E{\cdot}BrPOH \quad (5–368)$$

was proposed to explain the data for hydrolysis of 1,3-dibromopropane (DBP) by haloalkane dehalogenase (E) (Figure 5–31),[944] which passes through the covalent acyl intermediate E–I before the product 3-bromopropan-1-ol (BrPOH) is produced. Numerical integration was used to obtain rate constants $k_1 = 1\ \mu M\ s^{-1}$, $k_{-1} = 200\ s^{-1}$, $k_2 = 300\ s^{-1}$, and $k_3 = 15\ s^{-1}$ that could fit (solid curves) simultaneously the kinetic mechanism to the data for the decrease in concentration of 1,3-dibromopropane (○) and the production of Br^- (□), as well as the production of 3-bromopropan-1-ol (●).

The animal fatty-acid synthase system is known to catalyze five consecutive reactions (see Equations 3–492 to 3–496, Problem 4–20)

$$\text{acetyl-SCoA} + \text{HSACD} \rightleftharpoons \text{HSCoA} + \text{acetyl-SACD} \quad (5–369)$$

$$\text{acetyl-SACD} + \text{HSE} \rightleftharpoons \text{HSACD} + \text{acetyl-SE} \quad (5–370)$$

$$\text{malonyl-SCoA} + \text{HSACD} \rightleftharpoons \text{HSCoA} + \text{malonyl-SACD} \quad (5–371)$$

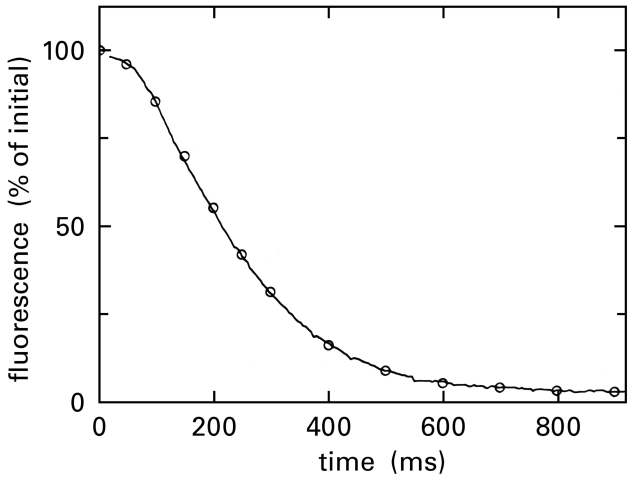

Figure 5–37: Lag in oxidation of NADPH when the complex between NADPH and the fatty-acid synthase system is mixed with acetyl-SCoA and malonyl-SCoA.[963] A solution containing the fatty-acid synthase system from *G. gallus* (4.3 μM in active sites) and 1.5 μM NADPH was mixed with a solution of 110 μM acetyl-SCoA and 200 μM malonyl-SCoA in an apparatus for stopped flow (dead time 2 ms). The two solutions were buffered at pH 7.0 with 0.1 M potassium phosphate at 25 °C. Fluorescence of the solution in the observation chamber at wavelengths greater than 420 nm ($\lambda_{excitation} = 367$ nm), which was due to NADPH, was monitored as a function of time (milliseconds). The solid trace is the direct observation of fluorescence as a percentage of the initial reading, and the open circles are values calculated by Equation 5–376 with $k_1 = 4.3\ s^{-1}$, $k_2 = 9.5\ s^{-1}$, and $[NADPH]_0 = 100\%$. It was necessary to add a background of 18% to all calculated values to obtain a satisfactory fit. Adapted with permission from reference 963. Copyright 1983 American Chemical Society. https://doi.org/10.1021/bi00295a037

$$\text{acetyl-SE} + \text{malonyl-SACD} + H^+ \rightleftharpoons \text{HSE} + CO_2 + \text{acetoacetyl-SACD} \quad (5–372)$$

$$\text{NADPH} + \text{acetoacetyl-SACD} + H^+ \rightleftharpoons (R)\text{-3-hydroxybutanoyl-SACD} + NADP^+ \quad (5–373)$$

where HSACD is a sulfanyl group on the phosphopantotheinyl group attached as a phosphodiester to a serine in the acyl-carrier domain and HSE is a sulfanyl group of a cysteine in the active site of β-ketoacyl-[acyl-carrier-protein] synthase I. When a solution of the fatty-acid synthase system from *G. gallus* and NADPH in one syringe was mixed with a solution of acetyl-SCoA and malonyl-SCoA in the other syringe so that the final concentrations of enzyme (2.1 μM) and NADPH (0.8 μM) were less than their dissociation constant (6.0 μM), a lag was observed in oxidation of NADPH (Figure 5–37).[963]

In part to avoid numerical integration, the situation was considerably simplified. The first four reactions were considered to be only one composite reaction

$$\text{acetyl-SCoA} + \text{malonyl-SCoA} + \text{H}^+ + \text{HSACD} \rightleftharpoons 2\,\text{HSCoA} + \text{CO}_2 + \text{acetoacetyl-SACD} \quad (5\text{–}374)$$

Furthermore, the 15% of NADPH that was already associated with the active site for 3-oxoacyl-[acyl-carrier-protein]reductase (Equation 5–373) before mixing was ignored, and it was assumed that, within the dead time of the apparatus, the various active sites were saturated with acetyl-SCoA and malonyl-SCoA. The significantly simplified kinetic mechanism that was proposed to explain the observations was

$$\text{E·acSCoA·malSCoA} + \text{HSACD} \xrightarrow{k_1} 2\,\text{HSCoA} + \text{CO}_2 + \text{E·acacSACD} + \text{NADPH} \xrightarrow{k_2} \text{E·hbSACD·NADP}^+ \quad (5\text{–}375)$$

where E·acSCoA·malSCoA is the complex between the enzyme and acetyl-SCoA and malonyl-SCoA, E·acacSACD is the acetoacetyl thioester of the acyl-carrier domain, and E·hbSACD is the (3*R*)-3-hydroxybutyryl thioester of the acyl-carrier domain. The analytically integrated rate equation for this simplified kinetic mechanism for the concentration of NADPH is

$$[\text{NADPH}] = [\text{NADPH}]_0 \exp\left\{-k_2\left(t + \frac{e^{-k_1 t} - 1}{k_1}\right)\right\} \quad (5\text{–}376)$$

which fits the data satisfactorily (open circles in Figure 5–37). This exercise again illustrates the fact that kinetic measurements often cannot reveal steps in the mechanism of an enzymatic reaction that are known to exist if Occam's razor that the simplest kinetic mechanism consistent with the observations is accepted.

Monitoring association of reactants with an active site by stopped flow or quenched flow or both methods can provide an answer to the vexing question of whether reactants associate with the active site in an obligate order or a preferential order. For example, coenzyme-B sulfoethylthiotransferase (previously Equation 4–273)

$$\text{CoBSH} + \text{methyl-SCoM} \rightleftharpoons \text{methane} + \text{CoBS–SCoM} \quad (5\text{–}377)$$

from *Methanothermobacter marburgensis* catalyzes a reaction with two reactants, coenzyme B (CoBSH) and methylcoenzyme M (methyl-SCoM). Association of each reactant alone with the active site could be followed in an apparatus for stopped flow by changes in fluorescence of the prosthetic nickel tetrapyrrole, coenzyme F_{430}, in the active site, and rate constants for these respective associations and dissociations could be obtained. The complexes between each reactant and the active site at saturation could then be mixed in turn with the other reactant in the apparatus for stopped flow, and association of the other reactant to the complex of the coreactant could be monitored again by changes in the absorbance of coenzyme F_{430}. Finally, the disappearance of [^{14}C]methyl-SCoM and the coincident appearance of [^{14}C]methane could be monitored by quenched flow. From the observed rate constants for the relaxations observed in these separate experiments, numerical values for all rate constants for association and dissociation of each reactant, both in the absence and in the presence of the other, and the rate constant for the production of methane in the active site occupied by both reactants could be calculated. It was found that either reactant can associate first with the active site, but if coenzyme B associates before methyl-SCoM, a nonproductive complex is formed that cannot produce methane. For methane production, methyl-SCoM must associate before coenzyme B.[964] Consequently, in this instance, which probably represents the minority, there is an obligate order to addition of reactants for the enzyme to catalyze its reaction.

Similar measurements were performed for the reaction catalyzed by phenylalanine 4-monooxygenase

$$\text{5,6,7,8-tetrahydrobiopterin} + \text{L-phenylalanine} + \text{O}_2 \rightleftharpoons \text{L-tyrosine} + \text{4a-hydroxy-5,6,7,8-tetrahydrobiopterin} \quad (5\text{–}378)$$

from *Chromobacterium violaceum*. Association of the reactant 5,6,7,8-tetrahydrobiopterin alone with the active site could be followed in an apparatus for

stopped flow by monitoring changes in the absorbance of the prosthetic mononuclear nonheme iron ion in the active site. Unfortunately, no absorbance changes were observed when the enzyme was mixed with L-phenylalanine, so the rates of its association and dissociation from the active site could not be monitored directly. When the enzyme, however, was premixed with various concentrations of L-phenylalanine and then mixed with 5,6,7,8-tetrahydrobiopterin and when the enzyme was premixed with various concentrations of 5,6,7,8-tetrahydrobiopterin and then mixed with L-phenylalanine, distinct relaxations in absorbance of the prosthetic mononuclear nonheme iron ion were observed that were unique to each order of addition. These relaxations could only be explained if both L-phenylalanine and 5,6,7,8-tetrahydrobiopterin are able to associate with the active site in the absence of the other before the other reactant then associates. Finally, when the complex between the enzyme and L-phenylalanine and 5,6,7,8-tetrahydrobiopterin was first formed and then mixed with O_2, the relaxations in absorbance that were observed were consistent with the conclusions that the ternary complex formed when L-phenylalanine associates first is the same as the ternary complex when 5,6,7,8-tetrahydrobiopterin associates first and that a single ternary complex is catalytically competent.

When a kinetic mechanism incorporating all these conclusions was fit to all changes in absorbance with time, although the kinetic mechanism must be one with random association of reactants, three additional determinations were made. First, the bimolecular rate constant for association of 5,6,7,8-tetrahydrobiopterin with the empty active site is 170 times greater than that for L-phenylalanine. Second, the bimolecular rate constant for association of L-phenylalanine with the active site occupied by 5,6,7,8-tetrahydrobiopterin is 80 times greater than that for its association with the empty active site. Third, the bimolecular rate constant for association of 5,6,7,8-tetrahydrobiopterin with the active site occupied by L-phenylalanine is 0.5 times that for its association with the empty active site.[965] Consequently, association of these two reactants is preferential, with initial association of 5,6,7,8-tetrahydrobiopterin highly favored over initial association of L-phenylalanine because of the values for these rate constants and equilibrium constants, but the order of association is not obligate.

Yet another purpose for stopped flow and quenched flow is to demonstrate the kinetic competence of an intermediate. The kinetic competence of any intermediate in an enzymatic reaction is its capacity to be formed and unformed, or unformed and formed, at rates equal to or greater than the overall rate of the normally occurring enzymatic reaction. All actual intermediates in the actual mechanism for an enzyme must be kinetically competent, even though this has not been demonstrated that they are. It is, however, important to know that they are. If a particular molecule, either a noncovalently bound molecule or a covalent adduct of the enzyme, is not kinetically competent, then that molecule cannot be an intermediate on the main path of the enzymatic mechanism. For example, both the peptide SSCVLIE and the peptide in which SSCVLIE is covalently attached to the peptide IALCTLSAF by a disulfide between the respective cysteines can be isolated from a digest of ribonucleoside-diphosphate reductase from *E. coli* by immunoadsorption. When ribonucleoside-diphosphate reductase was mixed in an apparatus for quenched flow with its reactant CDP in the absence of its reactant thioredoxin, it could be shown that this disulfide, which had been proposed to be an intermediate in the enzymatic reaction (Figure 5–13), was formed with an observed rate constant of 8 s^{-1}.[500] The catalytic constant for turnover of the enzyme at steady state under the same conditions is 4 s^{-1}. Because the rate constant for formation of the disulfide is larger than the rate constant for a complete turnover, the disulfide that is formed in the active site is kinetically competent.

In the enzymatic reaction catalyzed by phosphoglucomutase (Equation 5–3), only enzyme already covalently phosphorylated at its active site is enzymatically active. If phosphoglucomutase from *O. cuniculus* that has [^{32}P]phosphate covalently attached at its active site is mixed in an apparatus for quenched flow with D-glucose 1-[^{31}P]phosphate, the [^{32}P]phosphate is replaced by [^{31}P]phosphate with a rate constant[928] of 98 s^{-1}. If enzyme phosphorylated with [^{31}P]phosphate is mixed with D-glucose 1-[^{32}P]phosphate, the enzyme becomes phosphorylated with [^{32}P]phosphate with a rate constant of 110 s^{-1} (solid curve in Figure 5–27). Under the same conditions, the catalytic constant for the enzyme with D-glucose 1-phosphate as reactant is 103 s^{-1}. Because these three numbers are identical within experimental error, the intermediate phosphoenzyme is kinetically competent. When Mg^{2+}, an obligatory cofactor that was present in both solutions that were mixed together, is replaced with Zn^{2+}, the rate constant for loss of the [^{32}P]phosphoenzyme inter-

mediate upon addition of D-glucose 1-[^{31}P]phosphate decreases to 25 s^{-1}, but the catalytic constant for the enzyme decreases to 10 s^{-1}. Again, the phosphoenzyme intermediate is kinetically competent. In the mechanism proposed for this enzymatic reaction (Equation 5–36),[966,967] the phosphate on the enzyme is replaced by a phosphate from one substrate during each turnover. The active form of the enzyme that binds the reactant is phosphorylated, and the enzyme from which the product dissociates is also phosphorylated.

A remarkable result of studying enzymatic reactions by stopped flow and quenched flow has been the discovery that steps other than those in which the actual chemical transformations occur are often kinetically rate-affecting or rate-limiting. When experiments are performed at saturating concentrations of reactants, associations of reactants cannot be rate-limiting, but dissociations of products often are. Myosin ATPase from *O. cuniculus* (Equation 5–259) is an extreme case of this situation, in which hydrolysis of the reactant is 1000 times more rapid than dissociation of products in the absence of actin. The rate-limiting step in the reaction catalyzed by hexokinase from *S. cerevisiae* is the release of $MgADP^-$ as a product from the active site.[968]

In many instances, however, relaxations have been observed that cannot be assigned either to the chemical transformation of substrates bound at the active site or to dissociation of products from the active site. Such unexplained relaxations have been **observed when substrates or intermediates are being monitored.** Relaxations in the reductive dephosphorylation catalyzed by glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) from *Homarus gammarus* (Equation 5–26), which were observed while monitoring the change in absorbance of NADH, were assigned to a conformational change in the enzyme.[969] A comparison of the steady-state rate constants with rate constants for relaxations observed in the transfer of a hydride from NADH to 2-amino-4-hydroxy-6,7-dimethyldihydropteridine during its reduction by bovine 6,7-dihydropteridine reductase led to the conclusion that a step preceding hydrogen transfer was a conformational change in the enzyme.[970] Relaxations in the hydrolysis of 2,4-dinitrophenyl phosphate catalyzed by alkaline phosphatase (Equation 5–33) from *E. coli*, which were observed while monitoring the absorbance of 2,4-dinitrophenol formed during the hydrolysis, were assigned to a conformational change in the enzyme.[971]

Other similar intramolecular relaxations occur following association of competitive inhibitors. Relaxations in the absorbance of proflavin, which is a competitive inhibitor of bovine chymotrypsin (Figure 3–6), as it associates with the active site were assigned to a conformational change in the enzyme.[951] Relaxations in the absorbance of 2-hydroxy-5-nitrobenzylphosphonate, which is a competitive inhibitor of alkaline phosphatase from *E. coli*, as it associates with the active site were assigned to a conformational change in the enzyme.[972] Relaxations for which there are no other conceivable explanations are usually assigned by exclusion, and often in the absence of any other information, to conformational changes in the protein. It should be pointed out that argument by exclusion is invalid in chemistry.

Assignments of relaxations to conformational changes in the enzyme are far more defensible when the chromophore or fluorophore monitoring the progress of the reaction is located in the protein at a position well removed from the active site so that association of reactants and their chemical conversion cannot be responsible for those relaxations. Five relaxations[883] observed in the fluorescence of 2-aza-1,N^6-etheno-AMP, covalently attached through its phospho group to the 4-hydroxyphenyl group of Tyrosine 398, upon mixing glutamine synthetase from *E. coli* (Equation 5–270) with its several reactants—L-glutamate, $MgATP^{2-}$, and NH_4^+—can be assigned more confidently as conformational changes in the protein that occur in five steps during the progress of the two nucleophilic substitutions because the 4-hydroxyphenyl group of Tyrosine 398 is at least 2 nm from the active site.[973] Five relaxations[974] observed in the absorbance and fluorescence of tryptophans in the protein upon mixing GMP synthase (glutamine-hydrolysing) from *E. coli* with its several reactants—L-glutamine, $MgATP^{2-}$, and xanthosine 5′-phosphate—either by themselves or in various combinations can be assigned more confidently as conformational changes in the protein that occur in five steps during the progress of the two nucleophilic substitutions catalyzed by the enzyme because each of the eight tryptophans is 2–3 nm from the active site.[975] Three relaxations[976] observed in the fluorescence of Tryptophan 8 in the protein, as well as fluorophores attached covalently to a cysteine inserted in place of Aspartate 61, upon mixing indole-3-glycerol-phosphate synthase from *Saccharolobus solfataricus* with its single reactant, 1-(2-carboxyphenylamino)-1-deoxy-D-ribulose 5-phosphate, can be assigned more confidently as conformational

changes in the protein that occur in three steps during the progress of the electrophilic aromatic substitution catalyzed by the enzyme because Tryptophan 8 is 1 nm from the active site, with a loop of polypeptide in between, and the carboxy group of Aspartate 61 is 1.7 nm from the active site.[977] The initial conformational change monitored by the fluorophores attached to position 61 probably resulted from the closing of the loop in which it is located over the active site once it has been occupied by the reactant.

Even though conformational changes are being monitored by these reporter groups, the effects of changing the concentrations of reactants on these various relaxations indicate that many of them are accompanying associations and dissociations of reactants and chemical steps in the mechanism of the enzyme. These observations suggest that many, if not most, associations and dissociations of substrates with an active site and chemical transformations that subsequently occur within an active site may require coincident conformational changes in the protein to proceed. If so, it is possible that these conformational changes are necessary for catalysis to occur and that controlling them could be a way to control association of reactants and the overall rate of the enzymatic reaction.

Problem 5–28: In the reaction catalyzed by L-lactate dehydrogenase (Equation 5–327), the substrate NADH absorbs light with $\lambda_{max} = 339$ nm, while the substrate NAD^+ has negligible absorbance (<1% of that for NADH) at this wavelength.

(A) Write the simplest kinetic mechanism that could describe this enzymatic reaction. Do not derive an equation for v_0. Include in your kinetic mechanism only steps involving binding of substrates and the interconversion of substrates and products once they are bound.

This enzymatic reaction has been studied by stopped-flow spectrophotometry. A solution containing a higher concentration of active sites (28 μM) than NADH (20 μM) was added to one syringe of an apparatus for stopped flow, and a solution of pyruvate at a saturating concentration (2 mM) was added to the other. The decrease in A_{340} was followed (Figure 5–21A). At the original concentrations of enzyme (28 μM) and NADH (20 μM) in the experiment described in Figure 5–21, almost all (>85%) of the NADH was bound to active sites of the enzyme.

(B) Write the step or steps in your kinetic mechanism from part A that are being directly monitored in Figure 5–21.

This stopped-flow experiment was repeated at several different concentrations of pyruvate (pyr), and an observed first-order rate constant (k_{obs}) was calculated for each of them. Measurements of initial rate were also made at saturating NADH, and initial rate constants ($v_0\,[E]_t^{-1}$) at various pyruvate concentrations were calculated from these measurements. Both the first-order rate constants (k_{obs}) from measurements by stopped flow and the rate constants from measurements of initial rate for the enzymatic reaction were plotted on the same graph against the initial concentration of pyruvate ($[pyruvate]_0$) (Figure 5–21B). The rate constants from the steady-state experiments are equal, within experimental error, to the observed rate constants from stopped flow as a function of the concentration of pyruvate. The value for the catalytic constant determined from Figure 5–21B is 260 s^{-1}.

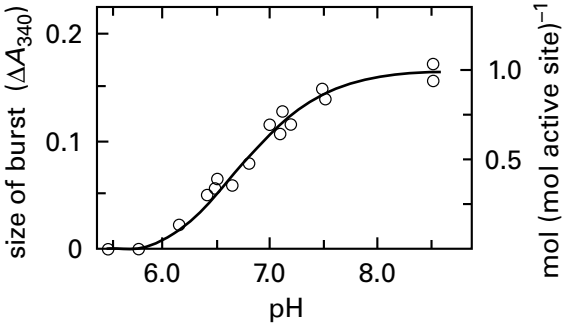
(C) The bimolecular rate constant for association of pyruvate with the enzyme under the conditions of Figure 5–21 is greater than 10^3 mM^{-1} s^{-1}. Calculate the lower limit of the pseudo-first-order rate constant for association

of pyruvate with the enzyme at the smallest concentration (1 mM) used in these experiments.

(D) According to the results in Figure 5–21 and the calculation of part C, which step in the mechanism that you wrote in part A is rate-limiting for L-lactate dehydrogenase in the direction of pyruvate reduction?

(E) When the experiment shown in Figure 5–21 was repeated with NAD^{2}H, both the catalytic constant and the observed rate constant from stopped flow at a saturating concentration of pyruvate were found to be 200 s^{-1}. Why does this result suggest that the actual kinetic mechanism is more complicated than what you wrote in part A?

Enzyme and a saturating concentration of NAD^+ were added to one syringe of an apparatus for stopped flow, and a saturating concentration of lactate was added to the other. The solutions were rapidly mixed in an apparatus for stopped flow that had a dead time of 1.3 ms. A burst in A_{340}, the rate of which was so fast that it was complete within the dead time ($k_{obs} > 1\ ms^{-1}$), occurred upon mixing. The size of this burst of NADH production could be calculated from the extinction coefficient of enzyme-bound NADH. At pH 9, the nanomoles of NADH formed in the burst were equal to the nanomoles of active sites present.[884]



Effect of pH on the magnitude of the initial burst of NADH production. A solution of 40 mM NAD^+ and 55 μM lactate dehydrogenase was mixed with an equal volume of 0.50 M lithium DL-lactate. The buffer was 67 mM potassium phosphate and the temperature was 22 °C. Each pH was recorded after completion of the reaction.

(F) Write the step or steps in the kinetic mechanism in part A that are being monitored in this last experiment.

The catalytic constant k_0 of porcine L-lactate dehydrogenase for oxidation of lactate by NAD^+ was determined to be 150 s^{-1} at pH 9 when measurements of initial rate were performed under the conditions of those for measurements from stopped flow, but the rate of the burst described in the figure is greater than the dead time of the instrument ($k > 1\ ms^{-1}$). It was calculated that pyruvate release from the enzyme is greater than 10,000 s^{-1} under the conditions of these experiments. The rate constant of the reaction E·NADH → E + NADH was measured at pH 8 and found to be 460 s^{-1}.

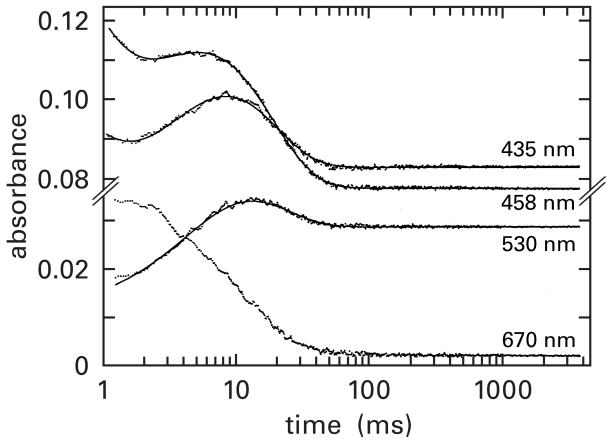
(G) The results just described and those presented in part E are inconsistent with the mechanism of part A but can be explained if a required conformational change of the enzyme is added as a step of the kinetic mechanism. Write a kinetic mechanism that incorporates the conformational change in the proper place and makes the mechanism consistent with the results.

Problem 5–29: Dihydrolipoyl dehydrogenase is a flavoenzyme that reduces or oxidizes N^6-(lipoyl)-lysines (**2–31**) by using NADH to reduce the oxidized prosthetic flavin and NAD^+ to oxidize the reduced prosthetic flavin (Equations 2–71 and 2–112)

$$N^6\text{-(dihydrolipoyl)lysine} + NAD^+ \rightleftharpoons N^6\text{-(lipoyl)lysine} + NADH + H^+$$

The enzyme is responsible for reducing or oxidizing lipoyl groups on a separate enzyme, dihydrolipoyllysine-residue acetyltransferase, using the same mechanism that the related enzyme (23% identity; 1.4 gap percent) glutathione-disulfide reductase (Equation 2–134, Figure 2–11) uses to reduce or oxidize glutathiones.

When a 20 μM solution of dihydrolipoyl dehydrogenase from *M. tuberculosis*, the prosthetic flavin and catalytic cysteines of which were fully oxidized, was mixed with a solution of 2 mM NADH and the mixture was monitored at 435, 458, 530, and 670 nm, the following kinetic courses were observed.[942]



Kinetic courses of absorbance in stopped flow. In addition to oxidized dihydrolipoyl dehydrogenase and NADH, each solution contained 0.1 M sodium phosphate, pH 7.5 and 4 °C. The time elapsed following mixing (milliseconds) is shown on a logarithmic scale. The dots are the experimental data, and the solid lines are fits of a proposed kinetic mechanism to the data.

The dissociation constant for NADH from the enzyme is 180 μM.

(A) What chromophore is being monitored?
(B) Why does the reaction cease after 100 ms even though a large excess of reactant over enzyme was added?
(C) Write complete chemical equations for the three consecutive reductions that are occurring during reduction of the fully oxidized dihydrolipoyl dehydrogenase.
(D) How many relaxations are observed in the four kinetic traces? The same relaxation observed in two or more traces is considered to be only one relaxation.
(E) Over what range of times (milliseconds) does each relaxation occur?
(F) A charge-transfer band can be observed in partially reduced dihydrolipoyl dehydrogenase that arises from electron transfer between oxidized flavin and the closest of the two catalytic cysteines in the active site of the enzyme. Over which range of times is this charge-transfer band lost? In which of the relaxations you identified in part D is the charge-transfer band lost?

The first phase of the kinetic course shows a kinetic isotope effect of 4.2 when [4,4-$^2H_2$]NADH is used as reactant.

(G) Propose assignments for each relaxation to a specific step in your mechanism for the reduction of dihydrolipoyl dehydrogenase being observed.

Problem 5–30: Succinate—CoA ligase (ADP-forming) from *E. coli* catalyzes the following reaction.

$$\text{succinate} + \text{MgATP}^{2-} + \text{CoASH} \rightleftharpoons \text{MgADP}^{-} + \text{HOPO}_3^{2-} + \text{succinyl-SCoA}$$

The purified enzyme contains a stable N^{τ}-phosphohistidinyl group in its active site.[132] The following three steps have been proposed for the overall reaction

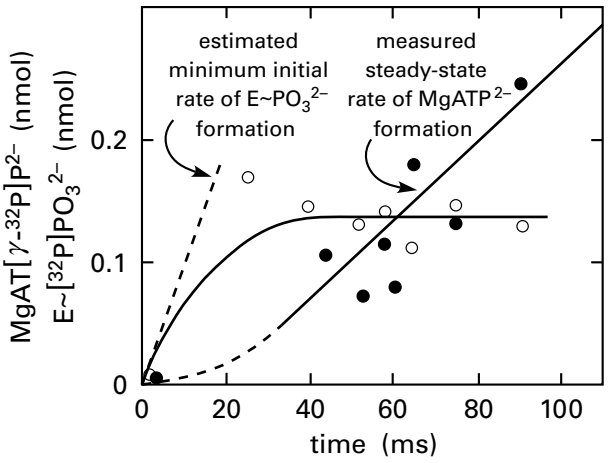
$$\text{E}\sim\text{PO}_3^{2-} + \text{succinate} \rightleftharpoons \text{E}\cdot\text{succinyl phosphate}$$

$$\text{E}\cdot\text{succinyl phosphate} + \text{CoASH} \rightleftharpoons \text{E} + \text{succinyl-SCoA} + \text{HOPO}_3^{2-}$$

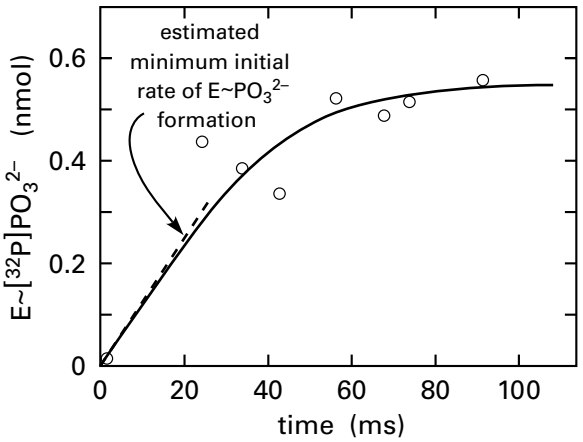
$$\text{E} + \text{MgATP}^{2-} \rightleftharpoons \text{E}\sim\text{PO}_3^{2-} + \text{MgADP}^{-}$$

where succinyl phosphate is 1-phosphobutanedioic acid.

Two experiments were performed on the dephosphorylated form (E) of succinate—CoA ligase (ADP-forming) by quenched flow. In both experiments, the two syringes of the apparatus were connected to a mixing chamber, the outlet of which was attached to a tube that terminated in a solution of 8% phenol, which inactivated the enzyme instantaneously. The time between mixing of the two solutions and entry into the quench solution was varied between 20 and 100 ms by changing the flow rates of the fluids that entered the mixing chamber. The results are displayed in the following two figures.



Rates of E~$[^{32}P]PO_3^{2-}$ and MgAT[γ-$^{32}P]P^{2-}$ formation from $HO[^{32}P]PO_3^{2-}$.[978] Measurements were made at 24 °C. One syringe contained 0.05 mM $HO[^{32}P]PO_3^{2-}$ (1.2×10^7 cpm μmol^{-1}), 0.1 mM ADP^{3-}, and 0.2 mM succinyl-SCoA at pH 6.6. The other syringe contained 17 μM dephosphoenzyme in 0.1 M KCl, 8 mM $MgCl_2$, and 0.1 mM EDTA at pH 7.4. The observed MgAT[γ-$^{32}P]P^{2-}$ (nanomoles; ●) and the observed E~$[^{32}P]PO_3^{2-}$(nanomoles; ○) are plotted as a function of time (milliseconds). The slope of the solid line that was chosen to fit the points for the observed nanomoles of MgAT[γ-$^{32}P]P^{2-}$ as a function of time is that of the initial steady-state rate for formation of $MgATP^{2-}$ that was measured separately in reactions of 2–15 s duration under the same conditions. The horizontal placement of that solid line was determined by the points for the observed nanomoles of MgAT[γ-$^{32}P]P^{2-}$.



Rate of E~$[^{32}P]PO_3^{2-}$ formation from MgAT[γ-$^{32}P]P^{2-}$.[978] One syringe contained 8 μM dephosphoenzyme in 0.1 M KCl, 8 mM $MgCl_2$, and 0.1 mM EDTA at pH 7.4. The other syringe contained 0.02 mM HSCoA, 0.08 mM AT[γ-$^{32}P]P^{4-}$(900 cpm nmol^{-1}), and 0.05 M sodium succinate at pH 7.4. The observed values for E~$[^{32}P]PO_3^{2-}$ (nanomoles) are plotted as a function of time (milliseconds).

(A) Write the step-by-step mechanism for the enzymatic reaction that produces the E~$[^{32}P]PO_3^{2-}$ and MgAT[γ-$^{32}P]P^{2-}$ observed in the first figure. Draw the structures of all substrates explicitly, abbreviating coenzyme A as $CoAS^-$, $MgATP^{2-}$ as $MgADPOPO_3^{2-}$, and $MgADP^-$ as $MgADPO^-$. Use the explicit structure of the imidazolyl group and the β carbon of the histidine.

(B) Write the step-by-step mechanism for the enzymatic reaction that produces the E~$[^{32}P]PO_3^{2-}$ observed in the second figure as well as the $HO[^{32}P]PO_3^{2-}$ at completion of the overall reaction.

The two mechanisms you write in parts A and B must be identical to each other, except for the isotopes and the direction of each, because of the principle of microscopic reversibility.

In the reaction displayed in the first figure, the rate of E~$[^{32}P]PO_3^{2-}$ formation was ≥10 nmol s^{-1} because equilibrium had been reached at the earliest times that could be measured. The steady-state rate for production of MgAT[γ-$^{32}P]P^{2-}$ under the same conditions was measured in a separate experiment and found to be 3 nmol s^{-1}. The solid line in the first figure has this slope but has been shifted to coincide with the actual measurements of MgAT[γ-$^{32}P]P^{2-}$ in the apparatus for quenched flow.

For the experiment displayed in the second figure, the rate of E~$[^{32}P]PO_3^{2-}$ formation was ≥13 nmol s^{-1} and the steady-state rate of $HOPO_3^{2-}$ formation, determined with the same preparations under the same conditions in a separate experiment, was 10 nmol s^{-1}.

(C) What important fact concerning formation of E~$[^{32}P]PO_3^{2-}$ do these two experiments establish? Why was quenched flow needed to establish this fact?

Succinate—CoA ligase (ADP-forming) from *E. coli* was mixed with several substrates, the phosphate bearing the noted isotopic labels, as described in the following paragraph and table, which are quoted with slight adaptation from the original report.[979]

> The incubation of the purified enzyme with O^{18}-labeled phosphate in the presence of succinate, ATP, and CoA led to a rapid exchange of oxygen between succinate and phosphate (table). The phosphate was additionally labeled with phosphorus^{32} [sic] to indicate the extent of over-all reversal of the reaction. The use of relatively large amounts of enzyme in this

experiment to achieve 50% equilibration between inorganic phosphate and ATP revealed a slow phosphate–ATP exchange in the absence of succinate (line 5, table). This probably is due to the presence of an unknown contaminating enzyme since succinate—CoA ligase (ADP-forming) isolated from other sources has an absolute succinate requirement for the phosphate–ATP exchange. Within experimental error, the O^{18} exchange reaction between inorganic phosphate and succinate is completely dependent upon ATP, CoA, and enzyme. A comparison of the rate of O^{18} exchange into succinate and the P^{32} exchange into ATP indicates that oxygen exchange can occur independently of the over-all reaction. Assuming that the one succinate oxygen would be replaced during complete reversal of the reaction, the theoretical per cent O^{18} exchange into succinate would be ¼ the value for the ^{32}P exchange into ATP (100% exchange representing replacement of all four succinate oxygen atoms). In contrast to this prediction, the O^{18} exchange into succinate is some 5-fold greater than the theoretical value (table). This finding implies the reversible formation and cleavage of an intermediate compound, independent of the over-all reversal of the reaction.

additions[a]	$[^{32}P]HOPO_3^{2-}$–$MgATP^{2-}$ exchange		$[^{18}O]HOPO_3^{2-}$–succinate exchange		
	cpm μmol^{-1} in $MgATP^{2-}$	% exchange	mass ratio of CO_2 (46/44)	oxygen-18 (% excess)	% exchange[b]
complete system	20,650	56	0.00762 0.00744	0.338	66.9
complete system – enzyme	<100	<1	0.00422 0.00421	<0.001	<0.1
complete system – CoASH	2000	5	0.00439 0.00441	0.024	4.7
complete system – $MgATP^{2-}$	<100	<1	0.00441 0.00447	0.024	4.7
complete system – succinate	5900	16	0.00433 0.00425[c]	0.010	2.0

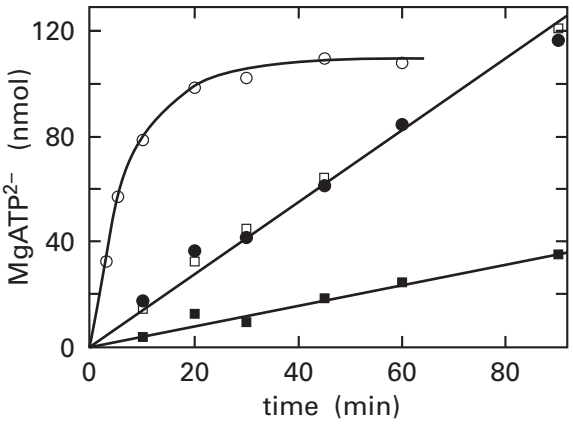
[a]The complete system contained 10 mM $MgCl_2$, 10 mM L-cysteine, 5 mM $MgATP^{2-}$, 50 mM succinate, 1 mM CoASH, 1.6 mg mL^{-1} enzyme, and either 5 mM $K_2[^{32}P]HOPO_3$ (73,400 cpm μmol^{-1}) or 5 mM $K_2[^{18}O]HOPO_3$ (5.05% excess ^{18}O). The reaction was run at 30 °C for 1 h. [b]Calculated on the basis of 100% exchange being equal to replacement of four oxygens-18 on succinate by oxygens-18 from phosphate and corrected for the 10-fold excess of succinate over phosphate. [c]Succinate added after acidification and extraction.

(D) Write a step-by-step mechanism to explain the transfer of oxygen-18 from $[^{18}O]HOPO_3^{2-}$ to succinate.

(E) Expand your mechanism to show why this exchange is 5 times faster than the overall reaction.

(F) What is the "intermediate compound" required for this exchange of oxygen for phosphate into succinate?

A solution containing succinate—CoA ligase (ADP-forming) from *E. coli* and $MgADP^-$ was mixed with other substrates, as described in the following figure, and the synthesis of $MgATP^{2-}$ was followed.[980]



Synthesis of $MgATP^{2-}$ from succinyl phosphate and from succinyl-SCoA plus phosphate.[980] To a solution of 5 mM $MgADP^{-}$, 5 mM $MgSO_4$, 0.08 mM dithiothreitol, 1 mM ethylenediaminetetraacetate, and 50 mM 2-ammonio-2-(hydroxymethyl)-propane-1,3-diol, pH 7.8 and 17 °C, were added the following: (○) 0.20 mM succinyl-SCoA and 0.20 mM potassium phosphate; (●) 1.0 mM succinyl phosphate and 0.025 mM HSCoA; (□) 1.0 mM succinyl phosphate and 0.025 mM desulfoCoA; (■) 1.0 mM succinyl phosphate.

(G) Write a step-by-step mechanism to explain the synthesis of $MgATP^{2-}$ from succinyl phosphate (■). Expand your mechanism to explain synthesis of $MgATP^{2-}$ from succinyl-SCoA and $HOPO_3^{2-}$ (○). How could a reaction with fewer steps (■) be slower than one with more steps (○)?

(H) Desulfocoenzyme A is coenzyme A lacking the sulfanyl group. How can it activate formation of $MgATP^{2-}$ from succinyl phosphate? Why does coenzyme A have the same effect?

(I) What other isotopic exchanges, such as the $[^{18}O]HOPO_3^{2-} \rightleftharpoons$ succinate reaction described above, should succinate—CoA ligase (ADP-forming) catalyze if the three-step mechanism presented in the first paragraph of this problem is correct?

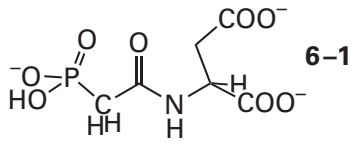
Chapter 6
Global Conformational Change

Because many instances have been documented crystallographically, there is no doubt that most molecules of protein can exist in more than one conformation. In retrospect, this observation is not surprising. If all the information necessary to produce one native structure of lowest free energy is encoded in the sequence of amino acids for the polypeptide or polypeptides comprising the protein, it must also be the case that the **information necessary to produce two or more different native structures** can be encoded in the same sequence of amino acids. If a polypeptide can fold and the folded polypeptides can assemble to produce one particular conformation, there is no reason that the same polypeptide cannot fold and assemble to produce a different conformation or several different conformations as well. The surprising fact is that these different conformations are usually in rapid equilibrium with each other without the necessity of passing through the unfolded random coil during their interconversion. The frequency with which these rapid equilibria between conformations are encountered among the proteins probably reflects the fact that they have been naturally selected during evolution for their significant functional utility.

Although there is a continuous spectrum for the extent of differences between two conformations of the same protein, there are several **classes of conformational changes** that can be distinguished. The conformational changes of least extent—such as local rearrangements of the side chains of amino acids in an active site upon association of reactants (Figures 3–56 and 3–57), closing of a lid over the active site upon assembly of all the reactants (Figure 3–58), and closing of the two domains of a subunit around the reactants to occlude them from the solution and in the process produce the active site (Figure 3–55)—have already been discussed. These are all local conformational changes. A **local conformational change** is a conformational change that occurs within the tertiary structure of a single folded polypeptide, that is confined to that folded polypeptide, and that has an insignificant effect on neighboring subunits when, as is almost always the case, that folded polypeptide is one of several folded polypeptides within a larger oligomer.

Most molecules of protein are **oligomers of subunits** that are folded polypeptides, each of which has the same sequence of amino acids. A conformational change can alter the spatial relations among the subunits in such an oligomer. A **quaternary conformational change** is a conformational change in an oligomer that includes two or more of its subunits (but usually all of them), that usually occurs with retention of the symmetry of the oligomer, and that usually involves a change in the orientation of its constituent folded polypeptides with respect to each other. For example, the conformational change between deoxyhemoglobin, in which all the hemes are unoccupied, and oxyhemoglobin, in which all four hemes have molecular oxygen bound, involves the rotation of one $\alpha\beta$ dimer with respect to the other $\alpha\beta$ dimer by 15° and an increase in the distance between the two dimers of 0.1 nm along a screw axis (Figure 6–1).[1-3]

The conformational change between unliganded aspartate carbamoyltransferase and aspartate carbamoyltransferase in which the bisubstrate analogue *N*-(phosphonacetyl)-L-aspartate (previously **3–6**)



6–1

is bound in all six active sites of the $(\alpha\beta)_6$ oligomer involves a rotation of one catalytic α_3 trimer with respect to the other by 10° and a widening of the distance between the two by 1.2 nm (Figure 6–2)[4-7] and also a reorientation along a screw axis that coincides with the threefold rotational axes of symmetry in each of the two conformations. During this change, the three regulatory β_2 dimers rotate about their respective twofold rotational axes of symmetry by 15°. The interfaces between the regulatory β_2 dimers and the catalytic α_3 trimers act as pivots during this conformational change.

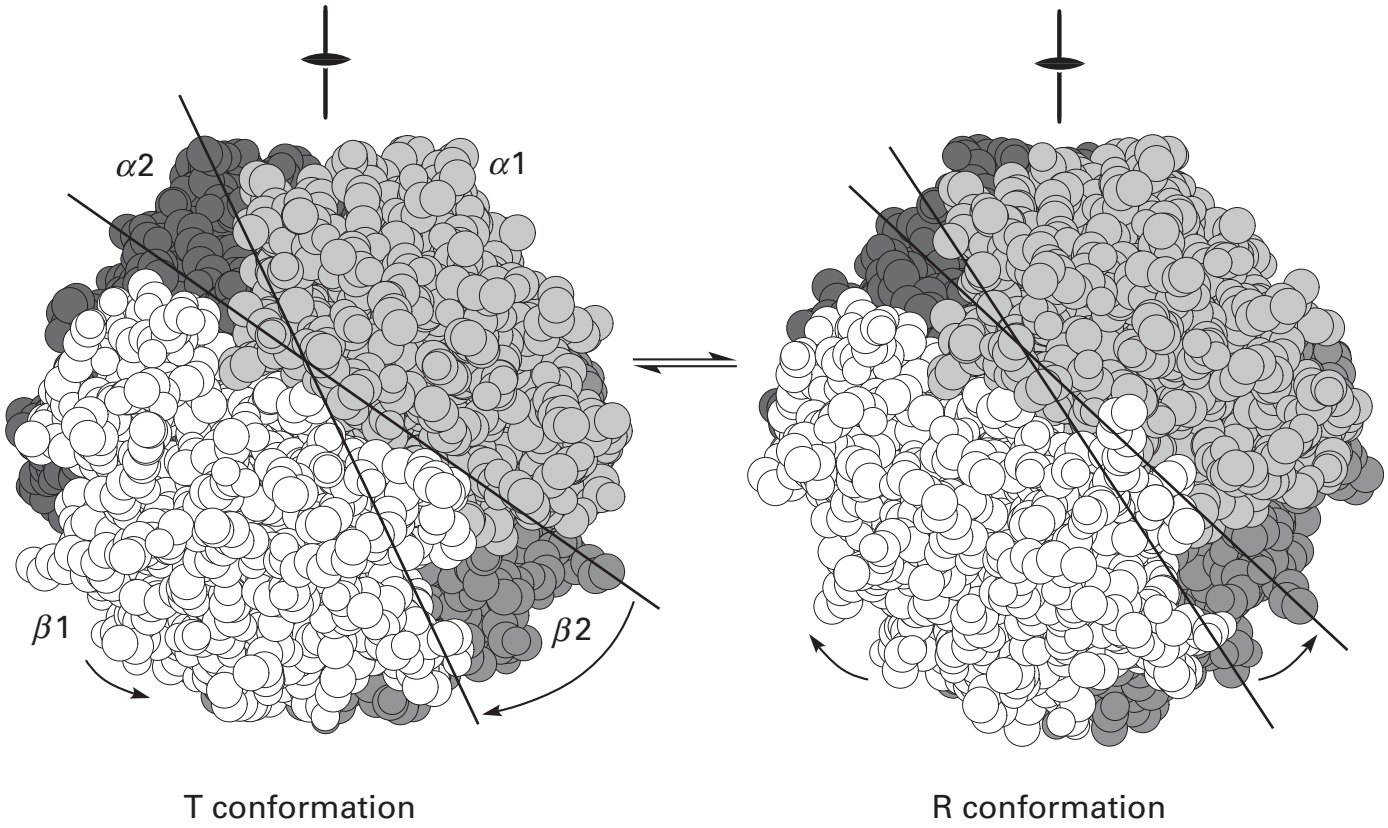


Figure 6–1: Drawings[485] of crystallographic molecular models of human hemoglobin in its two quaternary conformations, the R conformation (oxy) and the T conformation (deoxy).[1] Crystals of hemoglobin in the R conformation, the hemes of which were occupied by carbon monoxide, were grown in 2.5 M sodium/potassium phosphate at pH 6.7. Crystals of the space group $P4_12_12$ were obtained with an $\alpha\beta$ dimer in each asymmetric unit. Reflections were collected from these crystals to Bragg spacing of 0.22 nm.[3] Crystals of hemoglobin in the T conformation, the hemes of which were unoccupied, were grown in solutions of 1 mM ferrous citrate, ammonium sulfate (2–2.5 M), and ammonium phosphate (2–2.5 M) at pH 6.5. Crystals of the space group $P12_11$ were obtained with the entire $(\alpha\beta)_2$ heterotetramer in the asymmetric unit. Reflections were collected from these crystals to Bragg spacing of 0.174 nm.[2] The space-filling drawings are of the two refined, complete crystallographic molecular models, that for the R conformation (left) and that for the T conformation (right). The two $\alpha\beta$ dimers of the $(\alpha\beta)_2$ heterotetramer, $\alpha1\beta1$ to the front and $\alpha2\beta2$ to the back, are drawn in light gray and white and in dark gray and gray, respectively. The two $\alpha\beta$ dimers are arrayed around the exact, crystallographic twofold rotational axis of symmetry of the R conformation or the noncrystallographic twofold rotational axis of symmetry of the T conformation, each running vertically in the plane of the page. There is a twofold rotational axis of pseudosymmetry relating $\alpha1$ and $\beta1$ and $\alpha2$ and $\beta2$, normal to the plane of the page in the middle of the $\alpha1\beta1$ dimer in front, and there is a horizontal twofold rotational axis of pseudosymmetry relating $\alpha1$ and $\beta2$ and $\alpha2$ and $\beta1$ in the plane of the page. The two lines in each drawing are drawn through two side chains on the opposite sides of the $\alpha1\beta1$ dimer and through two side chains on the opposite sides of the $\alpha2\beta2$ dimer, respectively. In each drawing, the lines are drawn through the same side chains to illustrate the 15° rotation between the two dimers that occurs upon the change in conformation.

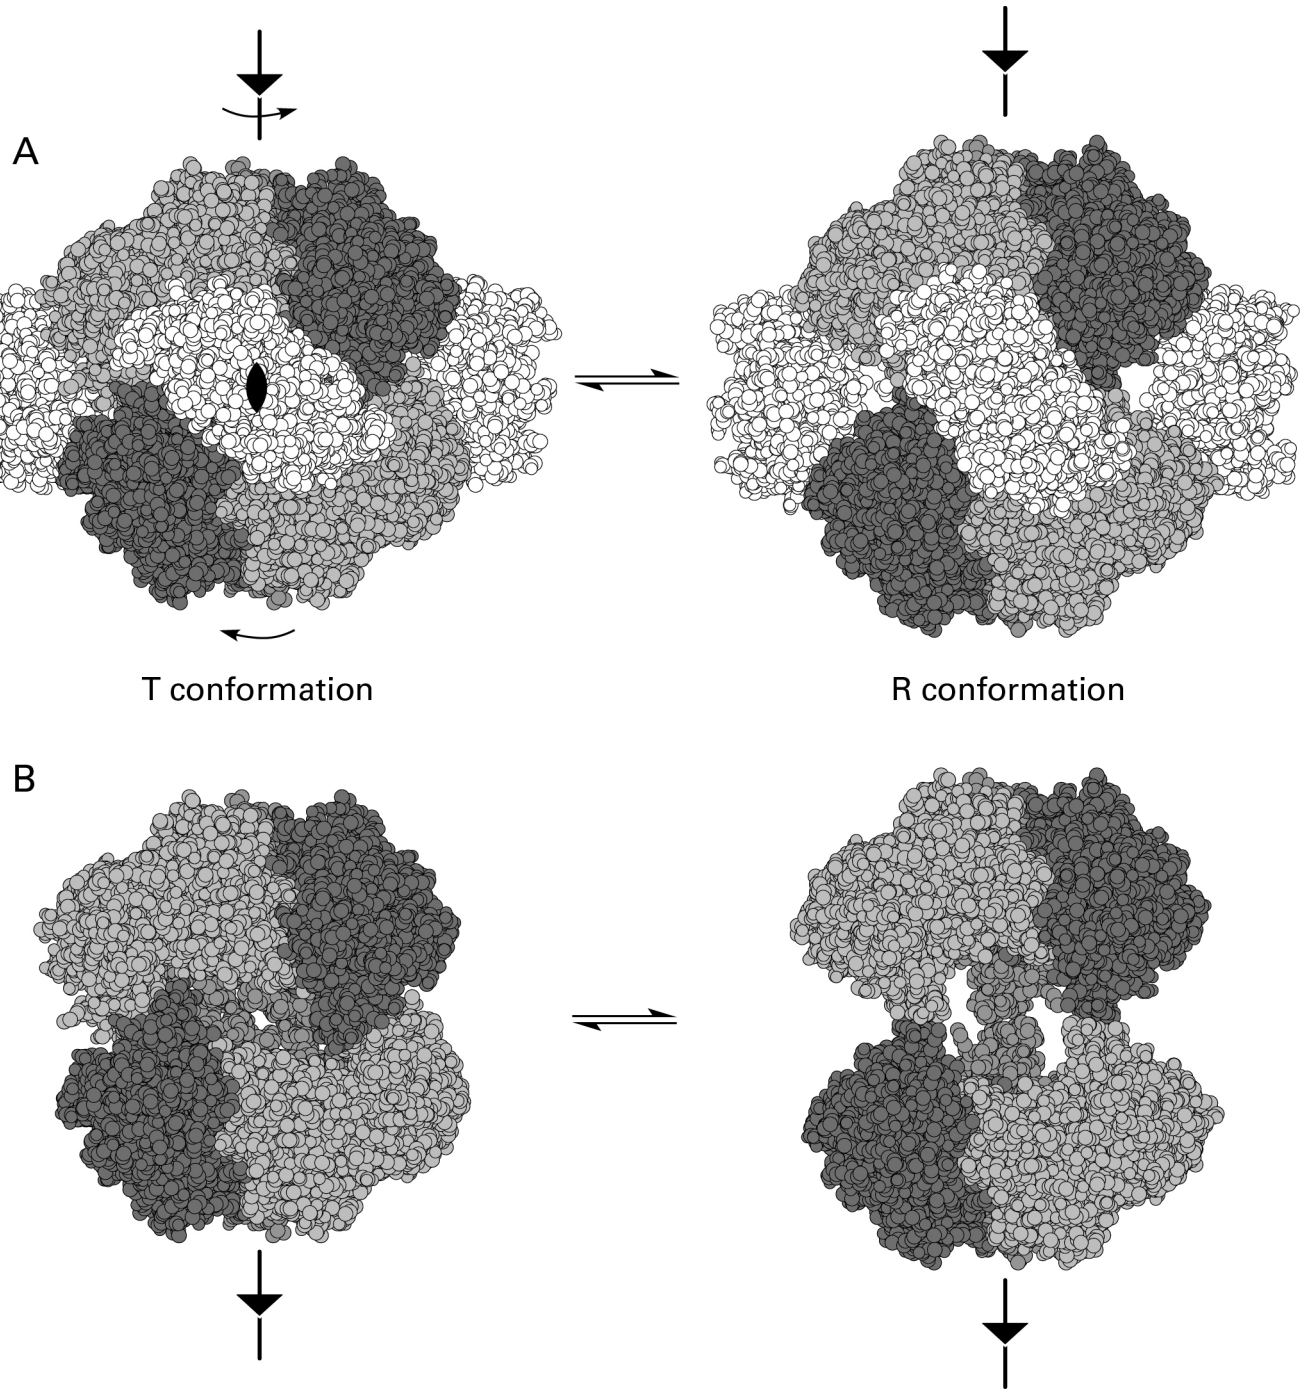

Figure 6–2: Drawings[485] of crystallographic molecular models of aspartate carbamoyltransferase from *E. coli* in its two quaternary conformations.[5] Crystals of the enzyme in the R conformation, the active sites of which were occupied by *N*-(phosphonacetyl)-L-aspartate (**6–1**), were produced by dialyzing the enzyme at high concentration into 50 mM *N*-ethylmorpholinium maleate at pH 6.9 and 21 °C in the presence of 1 mM *N*-(phosphonacetyl)-L-aspartate. Crystals of the space group *P*321 were obtained. Reflections were collected from these crystals to Bragg spacing of 0.25 nm.[6] Crystals of the enzyme in the T conformation, the regulatory sites of which were occupied by CTP^{4-}, were formed by dialysis against 1 mM 2-sulfanylethanol, 0.2 mM ethylenediaminetetraacetic acid, 10 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol chloride, and 100 mM sodium maleate at pH 6.35. Crystals of space group *P*321 were obtained. These were soaked in the aforementioned buffer with 2.5 mM CTP^{4-}. Reflections one at the top in each drawing and one at the bottom, are drawn in three shades of gray, and the three folded α polypeptides in each catalytic α_3 trimer are arrayed around an exact crystallographic threefold rotational axis of symmetry running vertically in the plane of the page. The three regulatory β_2 dimers, drawn in white, connect the two catalytic α_3 trimers, and a twofold rotational axis of symmetry runs through the center of each of the three regulatory β_2 dimers. One of those twofold rotational axes of symmetry is normal to the plane of the page in the middle of the regulatory β_2 dimer in front. Both views are down this twofold rotational axis of symmetry. (**B**) Rearrangement of catalytic α_3 trimers during the conformational change. The drawings of the R conformation (left) and the T conformation (right) are the same drawings as in Panel A except that the three regulatory β_2 dimers have been removed so that the central cavity in the molecule of the enzyme

from the soaked crystals were collected to Bragg spacing of 0.26 nm.[7] (**A**) Equilibrium between the R and T conformations. The space-filling drawings are of the two refined, complete crystallographic molecular models, that for the R conformation (left) and that for the T conformation (right). The two catalytic α_3 trimers, can be seen. As the conformation changes, the two catalytic α_3 trimers rotate in opposite directions. As they slide past each other, they fit together more snugly and the central cavity becomes narrower.

The rotation of the pivoting regulatory β_2 dimers spreads apart and rotates the two catalytic α_3 trimers with respect to each other. In such quaternary conformational changes, the subunits can, to a first approximation, be treated as **rigid bodies that reorient with respect to each other** by mechanical movements of defined geometry.

Within the tertiary conformation of each constituent folded polypeptide of an oligomeric protein, **local conformational changes always accompany a quaternary conformational change** that involves the entire molecule of protein. For example, local conformational changes on the distal side of the heme in hemoglobin (Figure 2–53) occur during the quaternary conformational change promoted by the binding of molecular oxygen. Such local conformational changes within the subunits must occur during a quaternary conformational change. Every inter*face* in a homooligomeric protein, by definition, is formed from two *faces*. These two words must be clearly distinguished because they refer to different things. If the tertiary conformations of the folded polypeptides constituting the subunits were to remain the same, the structures of the faces within the interfaces that create the oligomer would also have to remain the same. Because the structures of these two faces are all that determine the structure of the interface, the quaternary conformational change could not occur. If the faces that form the interface do not change, the interface cannot change. Local conformational changes, however, do not always affect or effect quaternary conformational changes. A local conformational change confined to a region of the subunit well isolated from the interfaces, for example, the closing of a loop of polypeptide over an active site upon association of reactants, **can occur independently of a quaternary conformational change**.

Aspartate carbamoyltransferase (previously Equation 3–220)

$$\text{carbamoyl phosphate} + \text{L-aspartate} \rightleftharpoons \text{H}^+ + \textit{N}\text{-carbamoyl-L-aspartate} + \text{HOPO}_3^{2-} \quad (6\text{–}1)$$

catalyzes the first committed reaction in the metabolic pathway leading to the pyrimidine nucleotides: orotidine 5′-phosphate, uridine 5′-triphosphate, cytidine 5′-triphosphate, thymidine 5′-triphosphate, and deoxycytidine 5′-triphosphate. The **first committed reaction** in any metabolic pathway is the earliest step in the pathway in which a metabolite is produced that can be used only in that pathway. For example, *N*-carbamoyl-L-aspartate, a product of the reaction catalyzed by aspartate carbamoyltransferase (Equation 6–1), is used only to synthesize pyrimidine nucleotides.

The simplest form of metabolic regulation is **end-product inhibition**, a situation where one or several end products of a metabolic pathway inhibit the first committed reaction in that pathway. When the cytoplasmic concentrations of pyrimidine nucleotides are too high, the flux through the pathway for their biosynthesis is diminished by decreasing the rate of the reaction catalyzed by aspartate carbamoyltransferase. This decrease occurs because several of the pyrimidine nucleotides, in particular $MgCTP^{2-}$ and $MgUTP^{2-}$ acting together, are inhibitors of the catalysis performed by the enzyme (Figure 6–3).[8,9] If, however, the concentrations of purine nucleotides, in particular $MgATP^{2-}$ and $MgGTP^{2-}$, are in significant excess over those of pyrimidine nucleotides, the biosynthesis of pyrimidine nucleotides is increased by accelerating the rate of the reaction catalyzed by aspartate carbamoyltransferase. This increase occurs because $MgATP^{2-}$ and $MgGTP^{2-}$ are activators of the catalysis performed by the enzyme. Metabolic regulation can also be exerted at the branch points of major metabolic pathways; for example, citrate activates acetyl-CoA carboxylase to divert acetyl-SCoA from the citric acid cycle to the biosynthesis of fatty acids, from the immediate production of energy to the storage of energy.

It is known, from studies in which the catalytic α_3 trimers were separated from the regulatory β_2 dimers,[10] that the active sites for aspartate carbamoyltransferase from *Escherichia coli* are on its catalytic α subunits[10] and the binding sites for nucleotides are on its regulatory β subunits.[9,11,12] In the intact native enzyme, the six active sites are symmetrically

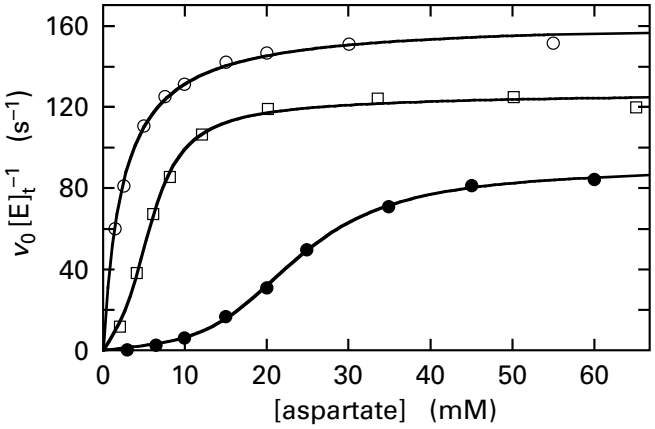

Figure 6–3: Behavior of the initial rates of the reaction catalyzed by aspartate carbamoyltransferase from *E. coli* as a function of the initial concentrations of its reactant L-aspartate.[9] The initial rates of the enzymatic reaction were determined colorimetrically at various concentrations of L-aspartate in 2.0 mM carbamoyl phosphate, 2.0 mM MgCl, 20 mM 2-[bis(2-hydroxyethyl)amino]-2-(hydroxymethyl)propane-1,3-diol, 20 mM 2-amino-2-hydroxymethylpropane-1,3-diol, and 20 mM 3-(cyclohexylamino)-1-propanesulfonic acid at pH 7 and 28 °C with either no other additions (□), 2 mM $MgCTP^{2-}$ and 2 mM $MgUTP^{2-}$ (●), or 2 mM $MgATP^{2-}$ and 2 mM $MgGTP^{2-}$ (○). From the concentration of purified enzyme and its molar mass, the measured activity was converted to moles of *N*-carbamoyl-L-aspartate (mole active sites)$^{-1}$ second^{-1} (s^{-1}). Each initial rate (v_0 in second^{-1}) is plotted as a function of the respective initial concentration of L-aspartate. The curves drawn for the lower two sets of data are fits of Equation 6–36 to the points, and the curve drawn to the upper set of data is a fit of Equation 3–40 to the points.

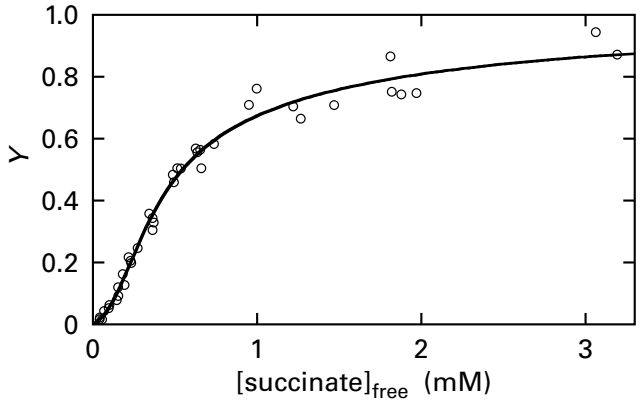

Figure 6–4: Measurement of the binding of [U-^{14}C]succinate to aspartate carbamoyltransferase from *E. coli* by equilibrium dialysis.[11] For measurements by equilibrium dialysis, a series of apparatuses, each separating two chambers by a dialysis membrane, was used. In one chamber of each apparatus, aspartate carbamoyltransferase (5–20 mg mL^{-1}) in buffer containing 4 mM carbamoyl phosphate (CAP) was present; in the other chamber, only buffer and 4 mM carbamoyl phosphate were present. A different initial concentration of [U-^{14}C]succinate (succ) was added to the side of each chamber without enzyme, and the chambers were allowed to reach equilibrium across the membrane. The final concentration of [U-^{14}C]succinate, as determined by scintillation counting, in the chamber lacking enzyme in each apparatus is the free concentration of the succinate at equilibrium in both chambers of that apparatus; the final concentration of [U-^{14}C]succinate in the chamber containing the protein is the sum of free and bound concentrations of ligand. The value for the concentration of bound [U-^{14}C]succinate at saturation was obtained with the version of Equation 6–35 in which the concentration of total sites is a known parameter rather than an unknown variable. With this value for the concentration of bound [U-^{14}C]succinate at saturation, a value for the fraction of sites occupied, Y, was calculated for each point. Each value for Y is plotted as a function of the respective free concentration of succinate at equilibrium. When the data were fit to Equation 6–35 without inserting a value for the concentration of sites, the value for $K'_{d,succ}$ from the fit was a large but negative number. Because negative dissociation constants are meaningless, it was assumed that $K'_{d,succ}$ must be too large to be defined by the observations. Values for $K'_{d,succ}$ larger than 1 M all produced the same fit to the data that was obtained when the value for $K'_{d,succ}$ was not constrained. The curve in the figure[76] is for $K'_{d,succ} = 1$ M, $L_{CAP} = 6.8 \pm 2.4$, and $K_{d,succ} = 0.48 \pm 0.04$ mM.

displayed on the two catalytic α_3 trimers,[5] and the six binding sites for nucleotides are symmetrically displayed on the three regulatory β_2 dimers (Figure 6–2). In the crystallographic molecular model for the intact enzyme,[13] each site on a folded regulatory polypeptide at which nucleotides, either $MgCTP^{2-}$ and $MgUTP^{2-}$ or $MgATP^{2-}$ and $MgGTP^{2-}$, are bound[6,9,14] is 6.0 nm distant from and makes no direct contacts with the closest active site.[5] As a result, the **active sites are distinct and separate from the regulatory sites**, and the inhibition or activation of catalysis is an allosteric effect.[15]

An allosteric effect is an indirect interaction between distinct, spatially separated sites on a protein during which the conformation of the protein is altered by association of a ligand at one or more of the sites, causing a change at one or more of the other sites. The ligands the association of which causes the alteration of the conformation can be inhibitors, activators, antagonists, agonists, or substrates for an active site, and the sites that change as a result of the change in conformation can be active sites or sites for agonists, activators, inhibitors, or antagonists.

A **heterotropic allosteric effect** is the allosteric effect that occurs when the interacting sites bind different ligands. An example of a heterotropic allosteric effect would be an interaction between a regulatory site on aspartate carbamoyltransferase that associates with $MgCTP^{2-}$ and $MgUTP^{2-}$ or $MgATP^{2-}$ and $MgGTP^{2-}$ on the one hand and an active site on aspartate carbamoyltransferase that associates with L-aspartate and carbamoyl phosphate on the other. Two examples of heterotropic

allosteric effects are the inhibition of aspartate carbamoyltransferase from *E. coli* by $MgCTP^{2-}$ and $MgUTP^{2-}$ and the activation of the same enzyme by $MgATP^{2-}$ and $MgGTP^{2-}$ (Figure 6–3).

A **homotropic allosteric effect** is the allosteric effect that occurs when two or more interacting sites are composed of the same respective amino acids within two or more constituent subunits, each formed from a folded polypeptide of the same sequence, and consequently associating with the same ligand or set of ligands. An example of a homotropic allosteric effect would be the interactions among the active sites on aspartate carbamoyltransferase, one on each catalytic α subunit, that, by definition, associate with L-aspartate and carbamoyl phosphate.

There are two consequences of homotropic allosteric effects among the active sites of aspartate carbamoyltransferase from *E. coli*. First, at saturating concentrations of succinate, association of carbamoyl phosphate at one or two of the six active sites in aspartate carbamoyltransferase increases the affinity of the remaining active sites for carbamoyl phosphate.[16] Second, at saturating concentrations of carbamoyl phosphate, association of succinate, an analogue of L-aspartate, at one or two of the six active sites increases the affinity of the remaining active sites for succinate (Figure 6–4).[11] The effect of the concentrations of L-aspartate on the initial rate of the reaction catalyzed by aspartate carbamoyltransferase (Figure 6–3) mimics the dependence of the binding of succinate on its concentration (Figure 6–4). This behavior suggests that when one or two of the active sites become occupied with L-aspartate, the affinity of the remaining active sites for L-aspartate increases.

Homotropic allosteric behavior is also of **regulatory significance**. Because association of the first few molecules of a reactant with active sites on an oligomer that displays homotropic allosteric behavior increases the affinity of the yet-to-be-occupied sites on the same oligomer, the range of concentration for that reactant between an occupancy of 10% and an occupancy of 90% is much narrower than it would have been if a homotropic allosteric effect did not exist. Consequently, increases and decreases in enzymatic activity are more pronounced when changes in the concentration of that reactant occur in the cytoplasm, and such changes in the concentration of reactant exert greater control over the enzymatic activity. In the specific case of aspartate carbamoyltransferase, the activity of the enzyme is shut down more effectively when L-aspartate, which is used widely in other metabolic reactions, is present at a low concentration in the cytoplasm.

Both heterotropic and homotropic allosteric effects are consequences of the ability of the protein to exist in two or more conformations that are in rapid equilibrium with each other. In addition to their role in heterotropic and homotropic allosteric control of enzymatic activity, conformational changes are also used by proteins to convert the potential energy in a covalent bond, usually the potential energy in the γ-phosphoanhydride of $MgATP^{2-}$, into kinetic energy or the electrochemical potential of a gradient of ions across a membrane and vice versa. For example, the movements of muscle, the movements of individual cells, the synthesis of $MgATP^{2-}$ from an electrochemical gradient of hydrons during oxidative phosphorylation, and the maintenance of the concentration gradients of ions and metabolites across the plasma membranes of cells are all a consequence of conformational changes in the enzymes responsible for these processes.

Cooperativity

In the usual, ideal case, when measurements are made of the occupancy for a ligand with a set of independent sites, regardless of whether they are each on a monomer of the protein or they are independent, identical sites on an oligomer, the data follow a rectangular hyperbola. The slope of the curve describing the occupancy decreases continuously from its initial value as it approaches its rectangularly hyperbolic asymptote at saturation (Figure 3–17). Association of succinate, however, with the active sites on aspartate carbamoyltransferase from *E. coli* that are saturated with carbamoyl phosphate (Figure 6–4) displays a **positive deviation from ideal behavior**. Such positive deviation is often referred to as **sigmoid behavior**. Instead of decreasing from its initial value at the lowest concentrations of succinate, the slope of the curve describing occupancy of the sites actually increases as the concentration of succinate is increased before it then decreases. The resulting curve is S-shaped (sigmoid). **Cooperativity** is an allosteric interaction between two or more identical sites, usually but not always active sites, on an oligomeric protein in which the association of a ligand or substrate at one or more of the sites induces conformational changes in the remaining

unoccupied sites, leading to an increase in the affinity of those sites for their ligand or substrate—or an increase in the limiting rate of the remaining active sites—and typically producing sigmoid behavior. Cooperativity is observed in the binding of ligands to many proteins (Figures 6–4 and 6–5). Association of the first ligands with the protein increases its affinity for the last ligands to associate. The ligands cooperate with each other to fill the sites. Because hemoglobin is a protein that displays this type of behavior and because it has been studied longer than any of the others, it serves as a useful example. When the fraction of the hemes in human hemoglobin that are occupied by molecular oxygen is measured as a function of the concentration of molecular oxygen, positive deviation from ideal behavior is observed (Figure 6–5).[17]

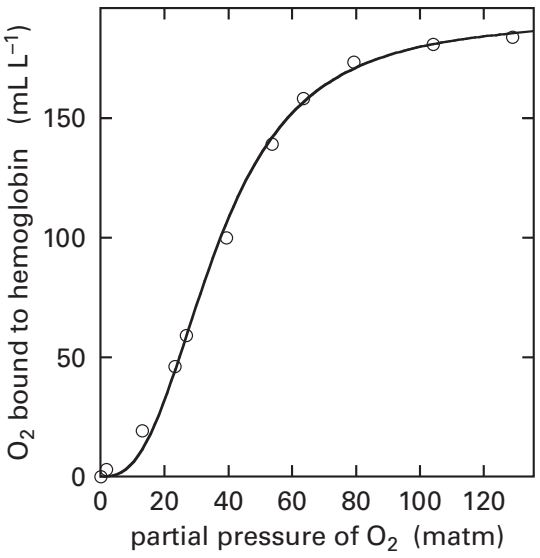

Figure 6–5: Dissociation curve for molecular oxygen from human hemoglobin.[17] Samples of whole blood from C. G. Douglas were equilibrated with various mixtures of N_2 gas and O_2 gas and 53 matm of CO_2 at 38 °C. After equilibrium was reached, the molecular oxygen bound to hemoglobin was driven off the hemes by adding potassium ferricyanide. The volume of O_2 gas liberated into the vapor phase above the blood (milliliters) was then measured manometrically. This volume represents the amount of O_2 bound to hemoglobin in the blood before ferricyanide was added. The volume of O_2 bound [milliliters of O_2 released by ferricyanide (liter of blood)$^{-1}$] is plotted as a function of the respective partial pressure of O_2 over the blood (oxygen tension in milliatmospheres). The curve is a fit of Equation 6–6 to the data with $[ST]_t = 192 \pm 4$ mL of O_2 L^{-1}, $n = 2.7 \pm 0.2$, and $K_d = (16{,}000 \pm 700 \text{ matm})^{2.7}$.

Two equations, the Hill equation and the Adair equation, which involve no explanation for cooperativity, are used to fit sigmoid behavior. They are simply mathematical equations that happen to describe the observations.

Consider a protein, P, with n sites, ST, for ligand L. Suppose that each molecule of protein, for some unknown reason, were required to bind simultaneously all n molecules of ligand L to those n sites and that, as a result, each molecule of that protein were always either fully occupied or completely unoccupied

$$\mathrm{P} + n\mathrm{L} \underset{K_{dL}}{\rightleftharpoons} \mathrm{P}\cdot n\mathrm{L} \tag{6–2}$$

The dissociation constant for this reaction would be

$$K_{dL} = \frac{[\mathrm{P}][\mathrm{L}]^n}{[\mathrm{P}\cdot n\mathrm{L}]} \tag{6–3}$$

and if Y is defined as the fraction of sites occupied (previously Equation 3–293)

$$Y \equiv \frac{[\mathrm{ST}\cdot\mathrm{L}]_{eq}}{[\mathrm{ST}]_t} \tag{6–4}$$

then

$$\frac{[\mathrm{ST}\cdot\mathrm{L}]}{[\mathrm{ST}]_t} \equiv Y = \frac{n[\mathrm{P}\cdot n\mathrm{L}]}{n[\mathrm{P}]_t} = \frac{[\mathrm{L}]^n}{K_{dL} + [\mathrm{L}]^n} \tag{6–5}$$

Equation 6–5 displays sigmoid behavior. It can be rearranged to give the equation

$$[\mathrm{ST}\cdot\mathrm{L}] = \frac{[\mathrm{ST}]_t [\mathrm{L}]^n}{K_{dL} + [\mathrm{L}]^n} \tag{6–6}$$

which is analogous to (previously Equation 3–298)

$$\Delta A = \frac{\Delta A_t [\mathrm{L}]_{eq}}{K_{dL} + [\mathrm{L}]_{eq}} \tag{6–7}$$

Equation 6–6 can be fit directly to the data for the binding of molecular oxygen to hemoglobin (Figure 6–5). Nevertheless, the otherwise rearranged version

$$\frac{Y}{1 - Y} = \frac{[\mathrm{L}]^n}{K_{dL}} \tag{6–8}$$

$$\log\left(\frac{Y}{1-Y}\right) = n\log[\mathrm{L}] + \mathrm{p}K_{\mathrm{dL}} \qquad (6\text{–}9)$$

has historically been used to fit the data and obtain a value for n. Once $[\mathrm{ST}]_t$ is estimated from a fit of Equation 6–6 to the data directly, values for log $[Y(1-Y)^{-1}]$ are plotted as a function of log [L]. The common logarithmic form of the equation (Equation 6–9) is the **Hill equation**.[18] Parameter n, the **Hill coefficient**, is the slope of a plot of log $[Y(1-Y)^{-1}]$ against log [L].

Although the preceding derivation is based on a particular mechanism, the mechanism in which **each molecule of protein is required to bind all its ligands simultaneously** (Equation 6–2), the uselessness of this stipulation as an explanation for the sigmoid behavior of the binding of a ligand to a protein as a function of free concentration of the ligand is apparent. Only a very peculiar protein, unlike any that currently exists, would bind all its ligands simultaneously. Nevertheless, experimental data are often fit with the Hill equation even though it usually fails to fit the data if they are gathered over a large enough range. Observed values for the occupancy of a site by a ligand L or the initial rate of an enzymatic reaction that shows sigmoid behavior as a function of the concentration of a reactant A are plotted in the format log $[Y(1-Y)^{-1}]$ against log [L], or log $[v_0\,(V-v_0)^{-1}]$ against log [A]; and, over a limited range, the plot is usually linear as demanded by the equation.

Even though the Hill coefficient obtained from such a plot provides no insight into the reason for the sigmoid behavior, it serves as a semiquantitative **measure of the degree of cooperativity**. If the number of sites for the ligand on a molecule of the protein is known, the closer the value of the Hill coefficient is to that number, the greater is the cooperativity among the sites. If the Hill coefficient were to equal the number of sites, the cooperativity would be complete; the remaining ligands would associate immediately upon association of the first.

There are several reasons that plotting experimental data by the Hill equation (Equation 6–9) is unsatisfactory. While there are a few instances in which it comes close, such as the α_4 tetramer of 6-phosphofructokinase from *E. coli* ($n = 3.8$),[19] the value of the Hill coefficient rarely equals the known number of sites that are cooperating with each other. In addition, the value of the Hill coefficient is almost never an integer. For example, for human hemoglobin (Figure 6–5) the Hill coefficient is 2.7, which

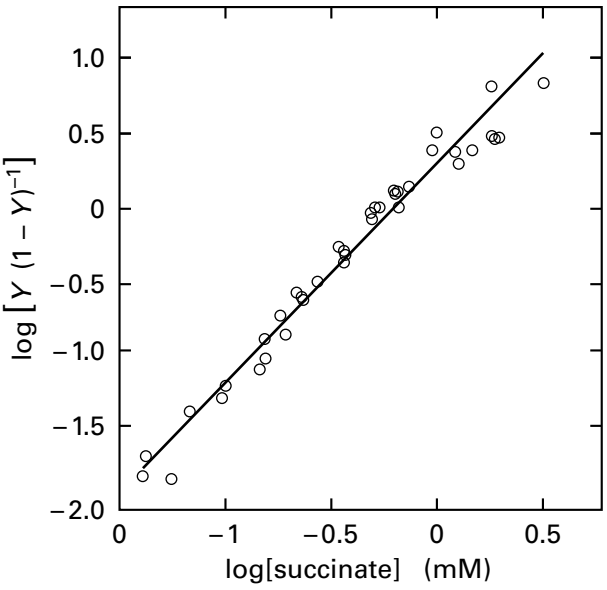

Figure 6–6: Hill plot of the binding of [U-^{14}C]succinate to aspartate carbamoyltransferase from *E. coli*. Values for the total concentration of sites and the fractional saturation Y as a function of the free concentration of ligand are those plotted in Figure 6–4. The quotient $Y(1-Y)^{-1}$ was calculated for each concentration of succinate, and each common logarithm of $Y(1-Y)^{-1}$ is plotted as a function of the respective common logarithm of the concentration of succinate (millimolar). A line was fit to the data. The slope of the line, the Hill coefficient, is 1.45 ± 0.04.

is neither equal to the number of sites for binding molecular oxygen on the protein nor an integer. In theory, the Hill coefficient can never exceed the number of cooperating sites because Equation 6–2 describes, by definition, a completely cooperative situation. In practice, however, there are instances in which the Hill coefficient exceeds the number of protomers in the protein.[20] Finally, the value of the Hill coefficient varies depending on the position on the curve at which the slope is determined. According to the Hill equation (Equation 6–9), a plot of log $[Y(1-Y)^{-1}]$ against log [L] should be a straight line at all values of [L]. Most observations are made around the mid-region (Figure 6–5) of the curve for binding ($0.10 < Y < 0.90$), and within this range the data in a Hill plot, within the errors of the experiment, usually define a line, as is the case for binding of succinate to aspartate carbamoyltransferase (Figure 6–6). When, however, measurements are taken over a broad enough range, log $[Y(1-Y)^{-1}]$ is not a linear function of log [L] (Figure 6–7).[21]

The complete set of observations, however, for association of molecular oxygen with human hemoglobin (Figure 6–7), and almost always, if not always,

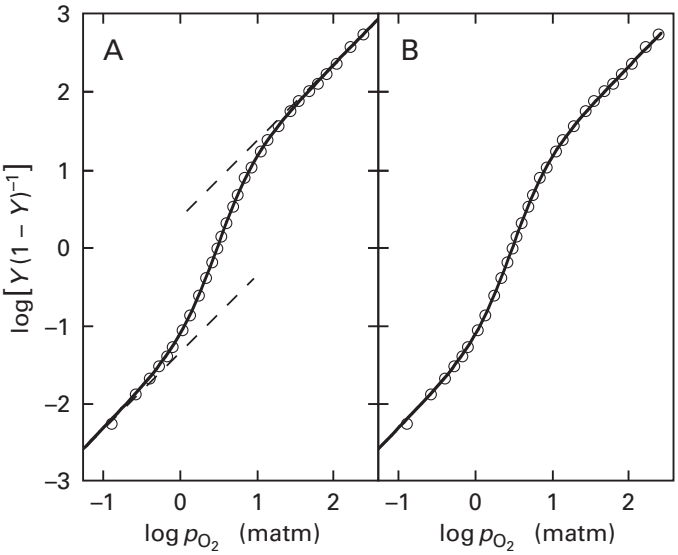

Figure 6–7: Dissociation of molecular oxygen from human hemoglobin,[21] measured over a range of greater than 3 orders of magnitude in the concentration of O_2. Hemoglobin A was prepared from human blood and was stripped of all organic phosphates. Solutions of this hemoglobin at a concentration of 0.6 mM in heme were prepared in 0.1 M NaCl at pH 9.1 and 25 °C. The fractional saturation of hemoglobin, *Y*, was determined as a function of the partial pressure of molecular oxygen (pO_2) in the gas phase above the solution. For each measurement, the concentration of molecular oxygen in the solution of hemoglobin was measured directly with an oxygen electrode that had been calibrated with standard gas mixtures at the same time that transmittance of the solution was measured at a wavelength of 620 nm. Absorbance of the solution purged with N_2 was assumed to be the absorbance of hemoglobin unoccupied with molecular oxygen, and absorbance extrapolated to infinite concentration of molecular oxygen was assumed to be that of hemoglobin fully saturated with molecular oxygen. The fractional saturation, *Y*, was assumed to be directly proportional to the observed absorbance relative to these limits (Equation 3–297). After a measurement was taken at one concentration, the mixture of molecular nitrogen and molecular oxygen was changed. All consecutive readings were taken on the same solution at a particular temperature. The reversibility of the process was demonstrated by returning frequently to concentrations of earlier measurements. From individual measurements of *Y*, the function $\log [Y(1-Y)^{-1}]$ was calculated, and each calculated value is plotted as a function of the respective common logarithm of the partial pressure (milliatmospheres) of molecular oxygen. (**A**) Fit of the data with the Adair equation (Equation 6–11). The dashed lines are the two limits of Equations 6–18 and 6–19. Values for K_{d1} and K_{d4} obtained from these limits were used as starting values for these parameters in a complete fit of the equation to the data. The final values for the dissociation constants from the full fit were $K_{d1} = 5.6 \pm 0.7$ matm, $K_{d2} = 5.8 \pm 2.4$ matm, $K_{d3} = 1.6 \pm 0.7$ matm, and $K_{d4} = 1.9 \pm 0.2$ matm. The solid curve is the fit to the data. (**B**) Fit of the same data with Equation 6–35. Values for parameters of the fit are $L_0 = 1700 \pm 300$, $K'_{dO_2} = 22 \pm 1$ matm, and $K_{dO_2} = 0.49 \pm 0.02$ matm. Again, the solid curve is the fit to the data.

associations of other ligands with other proteins and enzymes that display sigmoid behavior, can be fit with an equation that does not require the unrealistic assumption that the molecule of protein binds all its ligands simultaneously.[22] For example, hemoglobin contains four hemes and binds four molecular oxygens at saturation. If this process, as one might reasonably assume, occurs in four simple steps

$$\begin{aligned} \mathrm{Hb} + 4\,\mathrm{O_2} &\underset{K_{d1}}{\rightleftharpoons} \mathrm{Hb{\cdot}O_2} + 3\,\mathrm{O_2} \\ &\underset{K_{d2}}{\rightleftharpoons} \mathrm{Hb{\cdot}(O_2)_2} + 2\,\mathrm{O_2} \underset{K_{d3}}{\rightleftharpoons} \\ &\mathrm{Hb{\cdot}(O_2)_3} + \mathrm{O_2} \underset{K_{d4}}{\rightleftharpoons} \mathrm{Hb{\cdot}(O_2)_4} \end{aligned} \tag{6–10}$$

where the K_{di} are all macroscopic dissociation constants for molecular oxygen, then

$$Y = \frac{K_{d2}K_{d3}K_{d4}[\mathrm{O_2}] + 2K_{d3}K_{d4}[\mathrm{O_2}]^2 + 3K_{d4}[\mathrm{O_2}]^3 + 4[\mathrm{O_2}]^4}{4(K_{d1}K_{d2}K_{d3}K_{d4} + K_{d2}K_{d3}K_{d4}[\mathrm{O_2}] + K_{d3}K_{d4}[\mathrm{O_2}]^2 + K_{d4}[\mathrm{O_2}]^3 + [\mathrm{O_2}]^4)} \tag{6–11}$$

This relation is an Adair equation.

The **Adair equation** is not exclusive to association of molecular oxygen with hemoglobin. Nor is it only applicable to a molecule of protein with four sites; the number of sites on the molecule of protein can be any integer. As already mentioned, it can be applied to association of any ligand or substrate to any protein, whether or not the association displays sigmoid behavior. In fact, in situations in which there are several different, independent sites on a protein for the same ligand, each of which is composed of a different set of amino acids and each of which associates with a ligand with its own distinct dissociation constant, the Adair equation can be used to obtain values for those several dissociation constants. In such a situation, association of the ligand with the

protein must show **negative deviation from ideal behavior** as the ligand associates successively with sites of lower and lower affinity.

The **general form for the Adair equation** is

$$Y = \frac{\left\{\sum_{i=1}^{n-1} i\left(\prod_{i+1}^{n} K_{\mathrm{d}i}\right)[\mathrm{L}]^i\right\} + n[\mathrm{L}]^n}{\left\{\sum_{i=0}^{n-1} n\left(\prod_{i+1}^{n} K_{\mathrm{d}i}\right)[\mathrm{L}]^i\right\} + n[\mathrm{L}]^n} \qquad (6\text{–}12)$$

where n is the number of sites for ligand L on the protein and $K_{\mathrm{d}i}$ are formally dissociation constants with units of molarity. The Adair equation is also not confined to association of a ligand with a molecule of protein. Association of a ligand with any molecule or ion, for example, association of imidazole with Zn^{2+} and Cu^{2+}, can be described with an Adair equation.[23] From these considerations, it should be clear that the intent of the equation is to be **as independent of any explanation as possible** and to provide a **broadly applicable equation to fit any set of observations**.

Because each coefficient in the Adair equation is simply the previous coefficient multiplied by a number that can have any positive value, each coefficient is actually independent of the others. Consequently, the general form of the Adair equation can be restated as

$$Y = \frac{\left\{\sum_{i=1}^{n-1} i a_i[\mathrm{L}]^i\right\} + n[\mathrm{L}]^n}{\left\{\sum_{i=0}^{n-1} n a_i[\mathrm{L}]^i\right\} + n[\mathrm{L}]^n} \qquad (6\text{–}13)$$

where the n coefficients, a_0 to a_{n-1}, with units of M^{n-i}, can have any value greater than 0. In this formulation, the Adair equation is independent of any proposed mechanism and independent of any explanation for the behavior that is observed. It is simply an equation that has been found to describe accurately observations of association of a ligand with a protein whether cooperative or not.

In the case of hemoglobin, an Adair equation is being applied to a situation where a great deal is known about the protein. It should be noted, however, that in deriving the equation for hemoblobin, no assumptions were made as to the properties of the sites to which molecular oxygen is binding. The only assumption made was that there are four sites on each molecule of protein, a fact which can be ascertained by quantifying the moles of molecular oxygen that associate with each mole of hemoglobin at saturation. In situations in which almost nothing is known about a protein binding a particular ligand other than a fairly accurate approximation of its molar mass,* the first property that is ascertained is the ratio between the moles of bound ligand at saturation and the moles of protein. It is then assumed that each molecule of protein in the solution† can associate with that number of ligands, and the value for n in the Adair equation is chosen to be that molar ratio.

For the general Adair equation (Equation 6–12)[23]

$$\lim_{[\mathrm{L}] \to 0} \log\left(\frac{Y}{1-Y}\right) = \log\left(\frac{1}{nK_{\mathrm{d}1}}\right) \qquad (6\text{–}14)$$

and

$$\lim_{[\mathrm{L}] \to \infty} \log\left(\frac{Y}{1-Y}\right) = \log\left(\frac{n}{K_{\mathrm{d}n}}\right) \qquad (6\text{–}15)$$

and for the algebraic form (Equation 6–13)

$$\lim_{[\mathrm{L}] \to 0} \log\left(\frac{Y}{1-Y}\right) = \log\left(\frac{a_1[\mathrm{L}]}{na_0}\right) \qquad (6\text{–}16)$$

and

$$\lim_{[\mathrm{L}] \to \infty} \log\left(\frac{Y}{1-Y}\right) = \log\left(\frac{n[\mathrm{L}]}{a_{n-1}}\right) \qquad (6\text{–}17)$$

It follows from these limits that the **asymptotes** at either end of plots of $\log [Y(1-Y)^{-1}]$ against $\log [\mathrm{L}]$, which should have slopes of 1 as required by Equations 6–14 and 6–15, fix values for K_1 and K_n. These constraints then allow values for the other parameters to be determined more precisely. For example, for

*Today, the molar mass of a subunit of an enzyme is usually known before it is purified because its sequence of amino acids is usually known before it is purified.

†Some problems with this assumption are that it is quite difficult to determine precisely the concentration of protein in a solution, to estimate the purity of the protein being studied, and to know what percentage of the molecules of that particular protein, although present, are defunct.

*From here on a unidirectional arrow, rather than two opposing arrows, will be used to designate an equilibrium as

dissociation of molecular oxygen from hemoglobin at 30 °C (Figure 6–7), the limits for Equation 6–11 are

$$\lim_{[O_2] \to 0} \log\left(\frac{Y}{1-Y}\right) = \log\left(\frac{[O_2]}{4K_{d1}}\right) \quad (6–18)$$

and

$$\lim_{[O_2] \to \infty} \log\left(\frac{Y}{1-Y}\right) = \log\left(\frac{4[O_2]}{K_{d4}}\right) \quad (6–19)$$

Values for K_{d1} and K_{d4} were determined from the asymptotes (dashed lines in Figure 6–7A), and values for K_{d2} and K_{d3} could then be obtained[23] by fitting the data to Equation 6–11, with the result that $K_{d1} = 5.6 \pm 0.7$ matm, $K_{d2} = 5.8 \pm 2.4$ matm, $K_{d3} = 1.6 \pm 0.7$ matm, and $K_{d4} = 1.9 \pm 0.2$ matm. Because the data are of such high accuracy, extend over almost 4 orders of magnitude in the concentration of molecular oxygen (Figure 6–7), and include both asymptotes, the errors of estimate are small even though the data are fit with four parameters. Much of this precision is due to the fact that the asymptotes, at each end of the curve, were used to determine K_{d1} alone and K_{d4} alone, a fact that explains the greater precision of these two parameters relative to the other two.

If data are available for only the midrange, as is usually the case, then the **errors of estimate** are usually much greater. For example, when the Adair equation is fit to the data for binding of succinate to the active sites on aspartate carbamoyltransferase from *E. coli* that are saturated with carbamoyl phosphate (Figure 6–4), which is an unusually extensive set of observations, a satisfactory coincidence between the resulting curve and the points is obtained ($R = 0.99$), but standard deviations on the six parameters governing the fit are all larger than the numbers for the parameters themselves, and the values for dissociation constants are strange. In this case, the data span only two orders of magnitude, asymptotes of slope 1 with which to fix values for K_1 and K_6 independently are not reached (Figure 6–6), and there are six parameters in the Adair equation rather than four. Nevertheless, the behavior can be fit with the equation.

One of the more important points, however, that can be established by examining an Adair equation is that the sigmoid behavior observed for association of ligands with certain homooligomeric proteins is **not simply a consequence of the fact that a homooligomer has more than one site** for a particular ligand. Unoccupied homooligomers are, with few exceptions, rotationally symmetric. If the asymmetric unit of a symmetric homooligomer has one site with which a ligand associates, then each of the other asymmetric units will have an identical site for that ligand. If they are identical and independent of each other, each site should have the same microscopic dissociation constant, K_{dL}, for the ligand. The macroscopic dissociation constant, however, for the ith step, K_{di}, in the association is the product of a **statistical correction** and that microscopic dissociation constant

$$K_{di} = \frac{i}{n-i+1} K_{dL} \quad (6–20)$$

Before the ith ligand associates with the protein, there are $n-i+1$ identical unoccupied sites at which association can occur, a fact that decreases its macroscopic dissociation constant, while the product of its association has i identical sites occupied by ligand from which dissociation can occur, a fact that increases its macroscopic dissociation constant. For example, in the case of a homotetramer in which every site binds the ligand with the same microscopic dissociation constant, K_{dL}, and every site is independent and unlinked to any other site, when the statistical correction is applied

$$K_{dL} = 4K_{d1} = {}^3/_2 K_{d2} = {}^2/_3 K_{d3} = {}^1/_4 K_{d4} \quad (6–21)$$

The macroscopic dissociation constant for the first step always has one-fourth the value of the microscopic dissociation constant for the sites because the reactant has four sites at which association can occur while the product has only one site from which dissociation can occur. The macroscopic dissociation constant for the second step always has two-thirds the value for the microscopic dissociation constant because the reactant has three sites for association but the product has only two sites for dissociation, and so forth.

When **statistically corrected values of the macroscopic dissociation constants** (Equation 6–20) are entered into the general Adair equation (Equation 6–12)

$$Y = \frac{[L]}{K_{dL} + [L]} \quad (6–22)$$

In this instance, all sites are binding the ligand independently, and no sigmoid behavior is observed, only the usual rectangularly hyperbolic behavior of

binding to unlinked sites. Notice that the number of sites in the oligomer is not involved in Equation 6–22. Only if the macroscopic dissociation constants in the Adair equation (Equation 6–12) differ from the statistically corrected values (Equation 6–20)—in other words, the sites are not independent—does the Adair equation, when plotted, produce deviations from ideal behavior, either positive or negative.

When the statistical corrections are applied to values for the individual macroscopic dissociation constants obtained from the fit of the Adair equation to dissociation of molecular oxygen from hemoglobin (Figure 6–7A), values for the four intrinsic dissociation constants are $K_{d0,1}$ = 22 matm, $K_{d0,2}$ = 8.8 matm, $K_{d0,3}$ = 1.1 matm, and $K_{d0,4}$ = 0.48 matm. On the basis of this analysis, the microscopic dissociation constants, as expected, decrease with occupancy, and the largest increase in intrinsic affinity occurs between association of the second and third oxygens.

Although both the Hill equation within the mid-range (Figures 6–5 and 6–6) and the Adair equation (Figure 6–7) can usually produce curves that fit observed cooperative behavior quite precisely, neither provides an explanation for that observed behavior. An explanation of cooperativity, however, has been provided by Monod, Wyman, and Changeux.[15] This explanation is based on the established ability of many proteins to exist in two conformations, on thermodynamic linkage relations that establish the ability of association of a ligand with such a protein to shift the equilibrium between the two conformations, and, most especially, on the almost universal observation that the quaternary conformations of homooligomeric proteins are rotationally symmetric.

Proteins that display cooperative behavior can be shown by crystallography to exist in at least two different quaternary conformations. It has already been noted that hemoglobin (Figure 6–1) and aspartate carbamoyltransferase (Figure 6–2) do exist in two quaternary conformations. In the simplest situation, one could assume that there are only two quaternary conformations of a protein. For irrelevant historical reasons,[15] these two quaternary conformations are called the T and R conformations. By definition, the **T conformation** is the one that predominates when a ligand or substrate, the behavior of which is being examined and which displays cooperativity in its association with the protein, is absent and often only when an allosteric inhibitor or cosubstrate is present. The **R conformation** is the one that predominates when a ligand or substrate, the behavior of which is being examined and which displays cooperativity in its association with the protein, is present at saturating concentrations and often only when an allosteric activator or cosubstrate is present. In the case of aspartate carbamoyltransferase, the T conformation predominates in the absence of substrates and heterotropic allosteric effectors, and the R conformation predominates in the presence of saturating concentrations of substrates and the absence of heterotropic allosteric effectors. To simplify the following explanation, it can be assumed for the moment that, as is the case with aspartate carbamoyltransferase, the T conformation predominates in the absence of all ligands, even though this assumption will later be shown neither to describe the usual case nor to be a necessary one for the explanation of cooperative behavior to be valid.

The cooperativity displayed by aspartate carbamoyltransferase is **observed only when the R and T conformations can be interconverted**. Alanine 241 in aspartate carbamoyltransferase is in a loop of polypeptide distant from the active site of the enzyme and also distant from the interfaces between catalytic α subunits and regulatory β subunits. It is, however, located in the space between the two catalytic α_3 trimers. Each Alanine 241 from a catalytic α subunit in one catalytic α_3 trimer is immediately adjacent to an Alanine 241 from a catalytic α subunit in the other catalytic α_3 trimer in the R conformation (opposed loops between catalytic α_3 trimers in Figure 6–2B) but not in the T conformation. When the Alanines 241 were replaced with cysteines and cystines were formed between pairs of these cysteines when the enzyme was in the R conformation, the resulting disulfides locked the enzyme in the R conformation (Figure 6–8), and this crosslink prevents the conversion between the T and R conformations. The enzyme locked in the R conformation shows a smaller Michaelis constant for L-aspartate than the concentration of L-aspartate at which the initial rate of the enzymatic reaction is half its limiting rate in the unmodified enzyme, and the initial rate of the enzymatic reaction as a function of the concentration of L-aspartate, unlike the reaction catalyzed by the unmutated enzyme, displays no cooperativity. When the cystines are reduced to cysteines, cooperativity reappears and the concentration of L-aspartate at which the initial rate is half the limiting rate returns to the value for the unmutated enzyme.[24]

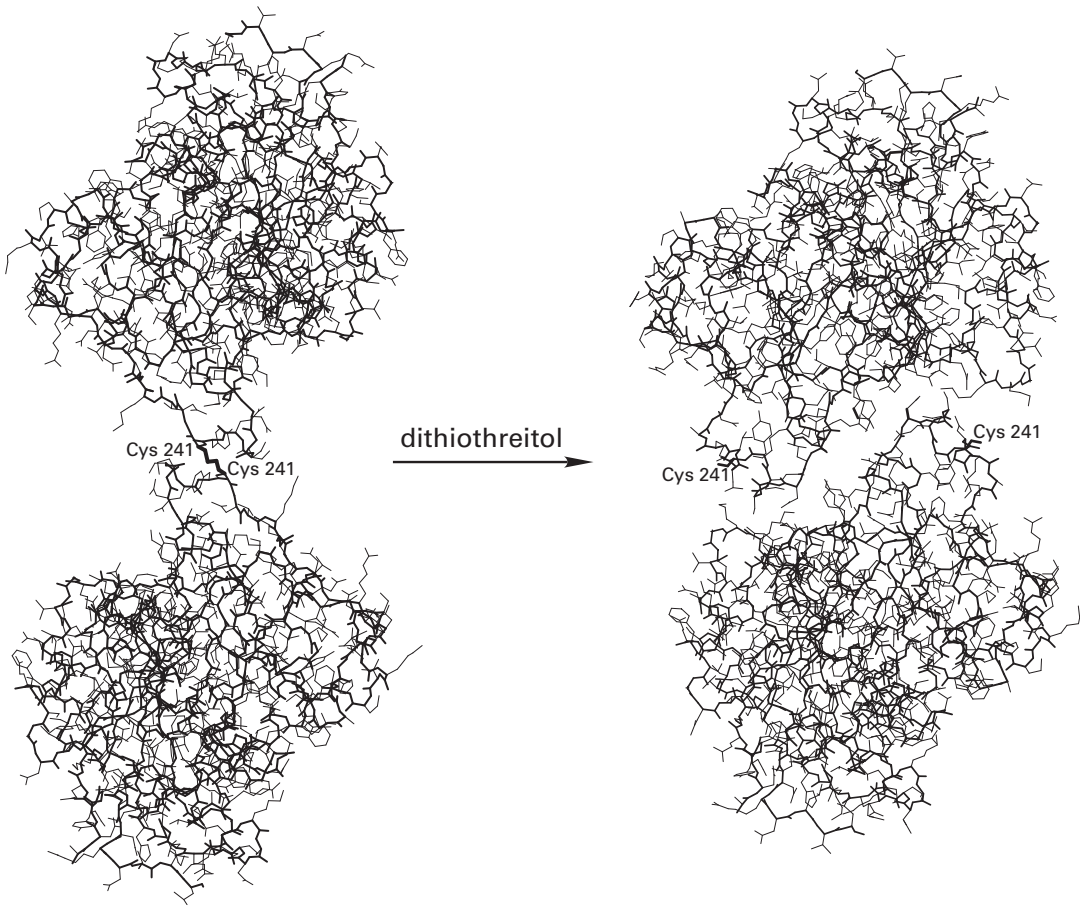

Figure 6–8: Drawings[485] of the locking of aspartate carbamoyltransferase in the R conformation. The codon in the chromosome of *Escherichia coli* for Alanine 241 in the α catalytic subunit of aspartate carbamoyltransferase was changed to a codon for cysteine, and the codon for the only cysteine in the α catalytic subunit was changed to one coding for alanine. The mutant aspartate carbamoyltransferase was overproduced in the resulting cells of *E. coli* and purified to homogeneity. It was discovered that in the purified enzyme, in the absence of reducing agents, there was a cystine connecting each α catalytic subunit in one α_3 trimer to a catalytic α subunit in the opposite α_3 trimer. Only in the R conformation is the single cysteine in a mutated catalytic α subunit, Cysteine 241, close enough to one of the other Cysteines 241 in the intact holoenzyme to form a cystine. The cysteines that are close together in the R conformation are each in a flexible loop of polypeptide. One of these flexible loops in an α catalytic subunit in an α_3 trimer is immediately adjacent to the flexible loop in an α catalytic subunit in the other α_3 trimer (Figure 6–2B). The loops are related to each other by a twofold rotational axis of symmetry, which should pass through the disulfide in the cysteine. It was assumed that the cystines in the purified enzyme formed while it was in the R conformation. It was also assumed that the cystine was between the respective cysteines in the flexible loops in these adjacent catalytic subunits. The crystallographic molecular model of the R conformation used for the drawing in Figure 6–2 was used here to represent two α catalytic subunits in an R conformation covalently connected to each other by a cystine. The crystallographic molecular models of two adjacent α catalytic subunits in the R conformation are presented to the left as skeletal drawings. The polypeptide backbone is drawn with a thicker line than the lines for the side chains of the amino acids. The loops of polypeptide containing Alanine 241 in this crystallographic molecular model of the R conformation were arbitrarily stretched out by rotating bonds in the polypeptide until the β carbons of the Alanines 241 were close enough together, and a cystine (even thicker lines) was then drawn in place of the two alanines. The drawing to the left is therefore not a drawing of an actual crystallographic molecular model. The drawing to the right, however, is of two α catalytic subunits from the crystallographic molecular model of the T conformation used in Figure 6–2 that are related by the same twofold rotational axis of symmetry. The cystine locks the enzyme in the R conformation, but when the cystine is reduced by dithiothreitol, in the absence of any ligands, the enzyme reverts to the T conformation because the two catalytic α_3 trimers can now rotate relative to each other. As the catalytic α_3 trimers rotate, they slide past each other, and this sliding displaces the cysteines.

The explanation of how **association of a ligand is able to shift the equilibrium between two quaternary conformations** of a protein relies upon casting the situation as a linkage relation. If the two conformations, R and T, are accessible to each other, the difference in free energy between them in the absence of ligands defines an equilibrium constant*

$$\mathrm{R} \xrightarrow{L_0} \mathrm{T} \tag{6–23}$$

$$L_0 = \frac{[\mathrm{T}]_{eq}}{[\mathrm{R}]_{eq}} \tag{6–24}$$

For historical reasons again, the equilibrium is written with the T conformation as product and the R conformation as reactant, and the equilibrium constant between the two conformations in the absence of any ligands is designated as L_0, the equilibrium constant between the R and T conformations.[15] This equilibrium constant is an allosteric constant.

An **allosteric constant** is the constant for the equilibrium between two conformations of an enzyme or protein that displays allosteric behavior. A **fundamental allosteric constant**, L_0, is the allosteric constant for an enzyme in the absence of any of its ligands. A **conditional allosteric constant** is the allosteric constant for an enzyme in the presence of saturating concentrations of one or more of its ligands. The following argument is for the general case of association of any ligand capable of shifting any conformational equilibrium of a protein. The special case in which association of a substrate causes an active site to close around that substrate has already been discussed (Equations 3–437 to 3–440). For the moment, it will be assumed that the protein is a monomer and that the sole subunit of the monomer has only one site with which the ligand can associate, even though association of a ligand to a single site on a monomer does not display cooperativity.

If the two conformations of the protein, the T and R conformations, exist as definable states in equilibrium with each other so that each is accessible from the other and both are populated in either the presence or absence of a particular ligand L for the protein, then the following **linkage relation** can be written

$$\begin{array}{ccc} \mathrm{R} + \mathrm{L} & \xleftarrow[K_{dL}]{\Delta G^\circ_L} & \mathrm{R{\cdot}L} \\ L_0 \downarrow \Delta G^\circ_E & & L_L \downarrow \Delta G^\circ_{E\cdot L} \\ \mathrm{T} + \mathrm{L} & \xleftarrow[K'_{dL}]{\Delta G^{\circ\prime}_L} & \mathrm{T{\cdot}L} \end{array} \tag{6–25}$$

where K_{dL} is the dissociation constant for ligand L from the R conformation, K'_{dL} is the dissociation constant for ligand L from the T conformation, and L_L is the equilibrium constant between the two conformations when both are occupied by ligand L. Both conformations have a site for the binding of ligand L, but it is unlikely, given the changes in structure that occur in the protein when one conformation becomes the other, that the dissociation constants for that ligand from that site will be the same in the two conformations. If the ligand L binds more tightly to the R conformation than it does to the T conformation ($K_{dL} < K'_{dL}$), it necessarily follows that **association of the ligand with the protein will shift the equilibrium between T and R** in favor of the R conformation ($L_A < L_0$) because, by linkage

$$\Delta G^\circ_L + \Delta G^\circ_E = \Delta G^\circ_{E\cdot L} + \Delta G^{\circ\prime}_L \tag{6–26}$$

and

$$K_{dL} L_0 = L_L K'_{dL} \tag{6–27}$$

Equation 6–26 is a corollary of the definition of a state function, and Equation 6–27 can be validated by inserting the definitions of the four equilibrium constants. If the **T conformation predominates in the absence of the ligand** ($L_0 < 1$) and the difference in dissociation constants for the ligand between the T and R conformations is large enough $[L_0 K_{dA} (K'_{dA})^{-1} > 1]$, then association of the ligand will shift the equilibrium constant so much that the **R conformation predominates in its presence**, just as association of *N*-(phosphoacetyl)-L-aspartate does to aspartate carbamoyltransferase (Figure 6–2). The difference in standard free energy of dissociation of the ligand from the two conformations provides the standard free energy necessary to shift the equilibrium between the two conformations.

As is the case with quaternary structures observed in crystallographic molecular models of almost all homooligomers in their fully liganded or fully unoccupied states, it is assumed that, when they are in solution, the T and R conformations of

*From here on a unidirectional arrow, rather than two opposing arrows, will be used to designate an equilibrium so that products and reactants are clearly defined.

a homooligomer displaying cooperativity in association of a ligand are rotationally symmetric. Although reasons can be given as to why this rotational symmetry should be so,[15,25] the fact remains that, crystallographically at least, it is so.

The initial rate for the reaction catalyzed by 6-phosphofructokinase (previously Equation 3–300)

$$\text{D-fructose 6-phosphate} + \text{MgATP}^{2-} \rightleftharpoons \text{H}^+ + \text{MgADP}^- + \text{D-fructose 1,6-bisphosphate} \quad (6\text{–}28)$$

from *Geobacillus stearothermophilus* is a sigmoid function of the concentration of the reactant fructose 6-phosphate when the allosteric sites on the enzyme are occupied by the heterotropic allosteric inhibitor phospho*enol*pyruvate,[19,26] as well as when they are not.[27] When the allosteric sites of the enzyme are fully occupied by phosphoglycolate, an analogue of phospho*enol*pyruvate, it crystallizes in the T conformation in the space group $P2_12_12_1$. The α_4 tetramer is necessarily the asymmetric unit in this space group that lacks crystallographic rotational axes of symmetry. Nevertheless, the four subunits in the asymmetric unit of the crystallographic molecular model are arrayed in molecular 222 (D_2) symmetry, and superpositions of α carbons, following rotations around the three molecular axes of symmetry, have root mean square deviations of 0.03 nm,[28] well within the positional errors of the coordinates of the crystallographic molecular model. When the enzyme is in the R conformation, fully occupied by the substrate fructose 6-phosphate in the absence of any heterotropic allosteric inhibitor, it crystallizes in the space group $I222$ with a single subunit of the homotetramer in the asymmetric unit, and all molecular axes of symmetry coincide with crystallographic axes of symmetry and are therefore precise.[29] Even though the R and T conformations crystallized under these different conditions differ significantly in both tertiary structure and the quaternary disposition of the subunits around the molecular axes of symmetry,[28] each tetramer is itself fully symmetric.

When the heterotropic allosteric inhibitor L-phenylalanine occupies its sites on the homotetramer, the initial rate for the reaction catalyzed by pyruvate kinase (previously Equation 3–222)

$$\text{phospho}\textit{enol}\text{pyruvate} + \text{H}^+ + \text{MgADP}^- \rightleftharpoons \text{MgATP}^{2-} + \text{pyruvate} \quad (6\text{–}29)$$

from *Oryctolagus cuniculus* is a sigmoid function of the concentration of the reactant phospho*enol*-pyruvate.[30] The unoccupied T conformation of the mammalian enzyme fails to crystallize, but when the T conformation of the human enzyme is stabilized by the heterotropic allosteric inhibitor L-phenylalanine, it crystallizes in the space group $P2_1$. The R conformation of the enzyme with its active sites occupied by $MgATP^{2-}$ and oxalate, an analogue of the *cis*-enediolate intermediate in the enzymatic reaction (Figure 4–52), also crystallizes in the space group $P2_1$. Although, in each case, the homotetramer is necessarily the asymmetric unit of the space group, the homotetramers in the respective crystallographic molecular models of the T and R conformations both have 222 symmetry (D_2).[31] The homologous homotetramer (47% identity; 0.6 gap percent) of pyruvate kinase from *Leishmania mexicana* does crystallize in its unoccupied conformation, which closely resembles the T conformation of the human enzyme and also has 222 symmetry,[32,33] from which it can be concluded that the unoccupied human enzyme is also a rotationally symmetric homotetramer.

The R conformation of the α_4 homotetramer of porcine fructose-bisphosphatase, with its active sites occupied by the substrates D-fructose 6-phosphate and phosphate, crystallizes in both the space groups $P2_12_12$ and $P3_221$ with the α_2 dimer as the asymmetric unit in each case and one of the three molecular rotational axes of symmetry of the tetramer coinciding with a crystallographic rotational axis of symmetry and consequently precise. Rotational superpositions of the α carbons of the α_2 dimer in the asymmetric unit around its molecular rotational axis of symmetry, however, have root mean square deviations of only 0.02 nm[34] and 0.03 nm.[35] Consequently, the R conformation is rotationally symmetric around all its molecular rotational axes of symmetry within the errors of the coordinates of the two crystallographic molecular models. The T conformation of the enzyme, with its heterotropic allosteric sites occupied by AMP^{2-} and its active sites occupied by fructose 6-phosphate and phosphate, crystallizes in the $P2_12_12$ space group.[36] Although its tertiary structure and arrangement of its subunits around the molecular axes of symmetry are significantly different from those of the R conformation,[37] it is also rotationally symmetric around all three of its molecular rotational axes of symmetry (root mean square deviation within the dimer again equals 0.02 nm).[38] Two other quaternary conformations of this enzyme have been identified, and they also are

rotationally symmetric within the error of the coordinates of their respective crystallographic molecular models.[39,40]

L-Lactate dehydrogenase from *Bifidobacterium longum* is activated by D-fructose 1,6-bisphosphate. The enzyme was crystallized from a solution containing the coenzymatic substrate NADH; oxamate, an analogue of the substrate pyruvate; and D-fructose 1,6-bisphosphate, an activator of the enzyme. Under these conditions, the major conformation present in solution should be the conformation of high enzymatic activity. The space group of the crystal was *F*222. When the map of electron density was examined, it was found that the unit cell contained two subunits of the enzyme and that they were in different conformations. Examination of the arrangement of the unit cells in relation to the three orthogonal arrays of twofold rotational axes of symmetry, however, demonstrated that the crystal was actually an array of two different types of tetramers in equal numbers. All the tetramers were occupied by NADH and D-fructose 1,6-bisphosphate, but one type was unoccupied by oxamate and in the other all four of its active sites were occupied by oxamate.

Within each of the two different quaternary conformations, all four subunits had the same conformation because in each type of tetramer, the three orthogonal, molecular twofold rotational axes of symmetry coincided with crystallographic twofold rotational axes of symmetry. From this fact, it could be concluded that the molecular twofold rotational axes of symmetry were exact; that every subunit in both quaternary conformations of the tetramer had the same local conformations; and that within each conformation of the homotetramer, the subunits were symmetrically arranged.[41] The quaternary conformation of the one type of tetramer in the crystallographic molecular model was identical to that of the tetramer in an earlier crystallographic molecular model of the enzyme crystallized from a solution lacking D-fructose 1,6-bisphosphate.[42] In this conformation, in both the earlier model and the more recent one, an α helix is sterically blocking the site at which oxamate, the analogue of the substrate pyruvate, binds, so it is assumed to be the conformation with low or no activity. In the other type of tetramer, an oxamate is bound in each of the four active sites as well as an NADH, and it is assumed that this tetramer is the active conformation. The fact that molecules of enzyme in the two different fully symmetric quaternary conformations cocrystallized permitted the two quaternary conformations in the crystal to be compared under identical conditions.

The preceding examples are crystallographic observations of the retention of complete rotational symmetry by the conformations of oligomeric proteins that display homotropic cooperativity even though the two conformations differ significantly in both tertiary and quaternary structure. In each instance, however, the conformations crystallized were either unoccupied or fully occupied with their respective ligands. **No crystallographic molecular models of proteins displaying homotropic cooperativity in which the oligomer can be shown to be only partially liganded** rather than fully liganded are available, so intermediate states of ligation have not been directly observed. Even in the case of L-lactate dehydrogenase from *B. longum*, in which both conformations of the enzyme were fully occupied by NADH at the active sites and D-fructose 1,6-bisphosphate at sites for this heterotropic allosteric effector, the active sites, both those occupied by oxamate and those not occupied by oxamate, are fully occupied or fully unoccupied, and each of the two quaternary conformations found in the same crystal are fully symmetric. No molecules of enzyme in intermediate partially occupied, asymmetric conformations are present in these crystals.

As is the case with hemoglobin (Figure 6–1) and aspartate carbamoyltransferase (Figure 6–2), the quaternary conformational changes accompanying allosteric conformational changes that are observed crystallographically can usually be described as the **reorientation of somewhat rigid bodies around rotational axes or around screw axes of symmetry**. The quaternary conformational change in porcine fructose-bisphosphatase is accomplished by a 17° rotation of one of the dimers in the homotetramer around one of the twofold rotational axes of symmetry in the rotationally symmetric homotetramer.[37] The quaternary conformational change in 6-phosphofructokinase from *G. stearothermophilus*[28] can be described as a 7° rotation of one of the dimers in the homotetramer relative to the other about one of the rotational axes of symmetry in the molecule (Figure 6–9).[43] The quaternary conformational change in L-lactate dehydrogenase from *G. stearothermophilus*, however, can be described as rotation of one dimer in the homotetramer relative to the other around three rotational axes, each parallel to a respective molecular rotational axis of symmetry but only one of which coincides with one of these molecular rotational axes of symmetry.[42] Glycogen phosphor-

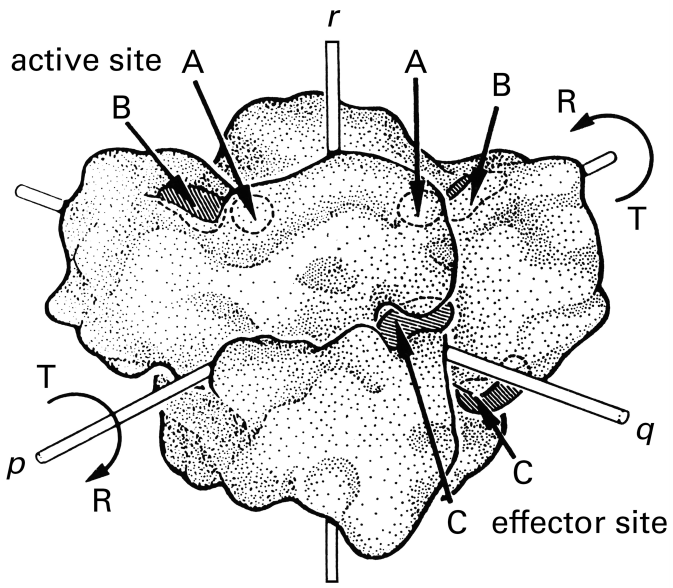

Figure 6–9: Schematic view of the crystallographic molecular model of the tetramer of 6-phosphofructokinase from *E. coli* in the unliganded T conformation.[43] 6-Phosphofructokinase, in the absence of ligands and substrates, was crystallized from 14% poly(ethylene glycol) and 1.0 M NaCl at pH 7.9. The crystals belonged to space group *C*2. Reflections were gathered to Bragg spacing of 0.24 nm. An available refined crystallographic molecular model of the liganded enzyme was used to phase the reflections by molecular replacement, and the initial molecular model of the unliganded enzyme was refined against the data set. A drawing was made of the van der Waals surface of the final molecular model. The four elongated subunits are arranged around the three orthogonal molecular axes of symmetry, *p*, *q*, and *r*. From other maps of electron density of the enzyme complexed with substrates, sites A that bind fructose 6-phosphate and sites B that bind $MgATP^{2-}$ and that together form the active sites could be identified. In the same way, sites C, with which the heterotropic allosteric activators ADP^{3-} and GDP^{3-} or the heterotropic allosteric inhibitor phospho*enol*pyruvate associate, were identified. Both heterotropic allosteric activators and heterotropic allosteric inhibitors in turn occupy the same allosteric site. In comparisons of this crystallographic molecular model of the T conformation with crystallographic molecular models of the enzyme in the R conformation, it could be seen that the conformational change between these two conformations involves a clockwise rotation of one of the dimers through which the *p* molecular axis of symmetry passes relative to the other dimer in the tetramer. ylase *b* from *O. cuniculus* is a homodimer, and the allosteric, quaternary conformational change it undergoes cannot be described as a rotation about its only rotational axis of symmetry but can be described as a rotation of 10° of one monomer with respect to the other about a rotational axis, which cannot be a rotational axis of symmetry but is normal to the rotational axis of symmetry.[44] In the case of human pyruvate kinase, the allosteric, quaternary conformational change can be described as the rotation of two of the monomers in the homotetramer in a clockwise direction and two of the monomers in a counterclockwise direction, around identically located rotational axes in each monomer parallel to one of the molecular rotational axes of symmetry.[31] Regardless of the complexity of the rotations describing the quaternary conformational changes, both conformations of each protein are themselves rotationally symmetric.

It was pointed out by Monod, Wyman, and Changeux that if ligand-linked quaternary conformational changes in oligomeric proteins actually do occur with conservation of molecular symmetry, then the homotropic cooperativity often observed in association of ligands to homooligomeric proteins can be readily explained.[15] Consider the simplest case, that of an α_2 dimer that has one site for ligand L on each subunit and that displays a ligand-linked quaternary conformational change that occurs with conservation of symmetry. The dominant quaternary conformation in the population of unoccupied, fully symmetric dimers is designated as T·T, where T stands for the T conformation, and the dominant quaternary conformation in the population of fully occupied, fully symmetric dimers is designated as R·R, where R stands for the R conformation.[15] These are the two quaternary conformations that would usually be examined crystallographically. Because the quaternary conformational change occurs with conservation of symmetry, only two quaternary conformations of the protein itself are present, T·T and R·R. The accessible states are

$$\begin{array}{ccccc} \mathrm{R{\cdot}R} + 2\mathrm{L} & \xleftarrow[1/2\,K_{\mathrm{dL}}]{} & \mathrm{L{\cdot}R{\cdot}R} + \mathrm{L} & \xleftarrow[2\,K_{\mathrm{dL}}]{} & \mathrm{L{\cdot}R{\cdot}R{\cdot}L} \\ \Big\downarrow L_0 & & \Big\downarrow L_0 \dfrac{K_{\mathrm{dL}}}{K'_{\mathrm{dL}}} & & \Big\downarrow L_{\mathrm{L}} \\ \mathrm{T{\cdot}T} + 2\mathrm{L} & \xleftarrow[1/2\,K'_{\mathrm{dL}}]{} & \mathrm{L{\cdot}T{\cdot}T} + \mathrm{L} & \xleftarrow[2\,K'_{\mathrm{dL}}]{} & \mathrm{L{\cdot}T{\cdot}T{\cdot}L} \end{array} \qquad (6\text{–}30)$$

where K_{dL} and K'_{dL} are the intrinsic dissociation constants for ligand L from a site in the T and the R conformations, respectively. Sites in the two quaternary conformations associate with ligand L independently, so the usual statistical corrections (Equation 6–20) for multiple independent sites apply to the microscopic dissociation constants. The equilibrium constant for conversion of the R·R conformation to the T·T conformation when no site is occupied with ligand L

$$L_0 = \frac{[\mathrm{T{\cdot}T}]_{eq}}{[\mathrm{R{\cdot}R}]_{eq}} \qquad (6\text{–}31)$$

and the equilibrium constant for conversion of the L·R·R·T conformation to the L·T·T·T conformation, in both of which sites are fully occupied with ligand L

$$L_L = \frac{[\mathrm{L{\cdot}T{\cdot}T{\cdot}T}]_{eq}}{[\mathrm{L{\cdot}R{\cdot}R{\cdot}T}]_{eq}} \qquad (6\text{–}32)$$

If the mechanism of Equation 6–30 is to explain cooperativity, the observed fact that association with the ligand L is cooperative requires that a molecule of the unoccupied protein in the T·T conformation, on average, has a lower affinity for ligand L than the affinity of a molecule of the protein with one site occupied and the other unoccupied, when that affinity is averaged over the population of L·R·R and L·T·T. The equilibrium between **the quaternary conformations of the enzyme must shift significantly in the direction of the R conformation** after the first ligand has been bound but before the second is bound. For this change in quaternary conformation to be caused by association of the first ligand, K_{dL} must be less than K'_{dL} by a sufficient amount. If it is, then equilibrium will shift from favoring the T conformation in the absence of ligand L to favoring the R conformation when it is occupied by one ligand L, and the second ligand L, on average, will bind more tightly than the first. Consequently, as long as symmetry is conserved during the quaternary conformational change, this difference in the affinity of the two quaternary conformations for ligand L is all that is necessary for the shift in the quaternary conformational equilibrium to produce homotropic cooperativity.

The appeal of this hypothesis is that the same property that tips the conformational equilibrium—the fact that $K_{dL} < K'_{dL}$—also causes the second ligand to bind more tightly than the first once the equilibrium between the quaternary conformations has shifted. The requirement that symmetry be conserved during the quaternary conformational change is responsible for homotropic cooperativity because it necessitates that, during the quaternary conformational change, the dissociation constant of the unoccupied active site decreases in concert with the dissociation constant for the occupied active site.

The simple model of a homodimer can be **expanded to a homooligomer of any number of subunits**. Suppose that a homooligomeric protein has only two symmetric quaternary conformations, T and R, and that each conformation has as many sites for association of a ligand as there are subunits. Suppose also that, in each quaternary conformation, the respective binding sites are formed by the same respective constellations of side chains but in orientations altered by the quaternary conformational change. It is unlikely that the dissociation constants for the ligand from the binding sites will be the same in these two quaternary conformations. Suppose also, for the moment, that the equilibrium constant, L_0, between the R and T conformations is greater than 1 so that the concentration of the latter is greater than the concentration of the former in the absence of the ligand and that the dissociation constant for the ligand from a binding site in the R conformation is smaller than it is for the ligand from a binding site in the T conformation. Because the dissociation constant for the ligand from the R conformation is smaller that that from the T conformation, as the concentration of ligand is increased, association of the ligand with each binding site in turn will shift the equilibrium between the T and R conformations by the same amount of standard free energy in favor of the latter. As the ligand occupies one or more binding sites on each molecule of protein and the level of occupancy reaches **the point at which the quaternary conformation of the majority of the molecules of protein changes** from the T to the R conformation, the dissociation constant for binding of the final few ligands to the protein decreases, and cooperativity will be observed in the binding of the ligand.

A general equation, based on the proposal that the homooligomer undergoes a quaternary conformational change in which symmetry is conserved, has been derived.[15] If the system has the structure

$$\begin{array}{ccccccccccc}
R_n + nL & \xleftarrow{{}^{1}/_{n}K_{dL}} & R_n{\cdot}L + (n-1)L & \xleftarrow{{}^{2}/_{(n-1)}K_{dL}} & R_n{\cdot}L_2 + (n-2)L & \cdots\cdots & R_n{\cdot}L_{(n-1)} + L & \xleftarrow{nK_{dL}} & R_n{\cdot}L_n \\
\Big\downarrow L_0 & & \Big\downarrow L_0\dfrac{K_{dL}}{K'_{dL}} & & \Big\downarrow L_0\left(\dfrac{K_{dL}}{K'_{dL}}\right)^2 & & \Big\downarrow L_0\left(\dfrac{K_{dL}}{K'_{dL}}\right)^{n-1} & & \Big\downarrow L_0\left(\dfrac{K_{dL}}{K'_{dL}}\right)^{n} \\
T_n + nL & \xleftarrow{{}^{1}/_{n}K'_{dL}} & T_n{\cdot}L + (n-1)L & \xleftarrow{{}^{2}/_{(n-1)}K'_{dL}} & T_n{\cdot}L_2 + (n-2)L & \cdots\cdots & T_n{\cdot}L_{(n-1)} + L & \xleftarrow{nK'_{dL}} & T_n{\cdot}L_n
\end{array} \tag{6–33}$$

where n is the number of protomers in the homooligomer, and only quaternary conformational changes that conserve symmetry [$T_n{\cdot}L_i \rightleftharpoons R_n{\cdot}L_i$] are permitted, and if the fraction of sites occupied (see Equation 3–293)

$$Y \equiv \frac{[ST{\cdot}L]}{[ST]_t} = \frac{\left([R_n{\cdot}L] + 2[R_n{\cdot}L_2] + \ldots + n[R_n{\cdot}L_n]\right) + \left([T_n{\cdot}L] + 2[T_n{\cdot}L_2] + \ldots + n[T_n{\cdot}L_n]\right)}{n\left([R_n] + [R_n{\cdot}L] + [R_n{\cdot}L_2] + \ldots + [R_n{\cdot}L_n]\right) + n\left([T_n] + [T_n{\cdot}L] + [T_n{\cdot}L_2] + \ldots + [T_n{\cdot}L_n]\right)} \tag{6–34}$$

then

$$Y = \frac{[ST]_t\left\{L_0\dfrac{[L]}{K'_{dL}}\left(1+\dfrac{[L]}{K'_{dL}}\right)^{n-1} + \dfrac{[L]}{K_{dL}}\left(1+\dfrac{[L]}{K_{dL}}\right)^{n-1}\right\}}{L_0\left(1+\dfrac{[L]}{K'_{dL}}\right)^{n} + \left(1+\dfrac{[L]}{K_{dL}}\right)^{n}} =$$

$$\frac{[ST]_t\left\{L_0[L]K_{dL}{}^n\left(K'_{dL}+[L]\right)^{n-1} + [L]K'_{dL}{}^n\left(K_{dL}+[L]\right)^{n-1}\right\}}{L_0K_{dL}{}^n\left(K'_{dL}+[L]\right)^n + K'_{dL}{}^n\left(K_{dL}+[L]\right)^n} \tag{6–35}$$

This equation is the **Monod–Wyman–Changeux equation** (MWC equation), in keeping with the biochemical habit of naming equations, methods, and ways to present data, even if trivial, after their originators.

If the **initial rate of an enzymatic reaction** as a function of reactant A is being followed and if it can be assumed with reason that the reactant associates with and dissociates from the active site much more rapidly than it is turned over—in other words, its dissociation constant at equilibrium is the same as its Michaelis constant for each quaternary conformation of the enzyme—then

$$\frac{v_0}{[E]_t} = \frac{k_{0,T}L_0\dfrac{[A]}{K'_{dA}}\left(1+\dfrac{[A]}{K'_{dA}}\right)^{n-1} + k_{0,R}\dfrac{[A]}{K_{dA}}\left(1+\dfrac{[A]}{K_{dA}}\right)^{n-1}}{L_0\left(1+\dfrac{[A]}{K'_{dA}}\right)^{n} + \left(1+\dfrac{[A]}{K_{dA}}\right)^{n}} =$$

$$\frac{k_{0,T}L_0[A]K_{dA}{}^n\left(K'_{dA}+[A]\right)^{n-1} + k_{0,R}[A]K'_{dA}{}^n\left(K_{dA}+[A]\right)^{n-1}}{L_0K_{dA}{}^n\left(K'_{dA}+[A]\right)^n + K'_{dA}{}^n\left(K_{dA}+[A]\right)^n} \tag{6–36}$$

where $k_{0,T}$ is the catalytic constant of the T conformation and $k_{0,R}$ is that of the R conformation.

Most, if not all, instances of homotropic cooperativity examined so far can be quantitatively described by the MWC equation, either for binding (Equation 6–35) or for steady-state kinetics (Equation 6–36).

This ability perhaps is not surprising because these equations have three or five adjustable parameters, respectively. For example, curves generated with the MWC equation fit the data for the binding of O_2 to hemoglobin (Figure 6–7B) as well as do curves generated with the Adair equation, even though the MWC equation has only three adjustable parameters while the Adair equation has four adjustable parameters or coefficients. This instance is perhaps the most stringent test of the ability of this equation to fit sigmoid behavior because the data span a wider range of concentrations of ligand than any other extant set of observations of sigmoid behavior. For the binding of O_2, values for the parameters are $L_0 = 1700 \pm 300$, $K'_{dO_2} = 22 \pm 1$ matm, and $K_{dO_2} = 0.49 \pm 0.02$ matm. As expected, the dissociation constant for O_2 from the R conformation is significantly smaller than that from the T conformation, and L_0 is greater than 1 so that, in the absence of O_2, the T conformation predominates.*

There are **informative limits to the MWC equation**.

First, suppose that $L_0 < 1$ so that the R conformation predominates in the absence of ligand but that it is still the case that the R conformation has a greater affinity for the ligand than the T conformation so that $K_{dL} < K'_{dL}$. In this instance, as the concentration of the ligand increases, the equilibrium shifts even more in favor of the R conformation. For all values K_{dL} and K'_{dL}

$$Y \cong \frac{[L]}{K_{dL} + [L]} \tag{6–37}$$

Association of the ligand behaves as if all sites are the same and independent of each other, which is a result of the fact that the T conformation is never present in solution in significant concentration, and association is only with the R conformation, in which all sites are the same.

Second, suppose that $L_0 > 1$ so that the T conformation predominates in the absence of ligand and that $K'_{dL} > K_{dL}$ so that the ligand shifts the equilibrium in favor of the R conformation but that $L_0 > K'_{dL}{}^2 (K_{dL}{}^2)^{-1} > 1$. In this instance, the ligand will be unable to shift the equilibrium sufficiently (Equation 6–33), and the homooligomer will remain in the T conformation at all concentrations of ligand and

$$Y \cong \frac{[L]}{K'_{dL} + [L]} \tag{6–38}$$

Association of the ligand behaves as if all sites are the same and independent of each other, which is a result of the fact that the R conformation is never present in solution in significant concentration, and association is only with the T conformation.

Third, suppose that $L_0 > 1$ so that the T conformation predominates in the absence of ligand but that $K_{dL} (K'_{dL})^{-1}$ is so small that $L_0 K_{dL} (K'_{dL})^{-1} < 1$. In this instance, because $L_0 (K'_{dL})^{-1} < K_{dL}{}^{-1}$, when $K_{dL} < [L] < K'_{dL}$

$$Y \cong \frac{[L]^n}{L_0 K_{dL}{}^n + [L]^n} \tag{6–39}$$

As long as the concentration of ligand is in the stipulated range, association will be defined by the Hill equation, and the Hill coefficient, n, will be equal to the number of symmetric sites on the homooligomer. Since the stipulated range is quite large because $K_{dL} (K'_{dL})^{-1}$ is so small, this behavior should be expected if the other criteria are met. In this situation, as one molecule of ligand associates with an empty site on an unoccupied molecule of the protein, the quaternary conformation of that molecule of protein shifts from the T to the R conformation and the remaining sites are immediately occupied. In other words, it is as if all the ligands were required to associate with each molecule of protein simultaneously, the requirement that produces the Hill equation. As noted earlier, however, the Hill coefficient is almost never equal to the number of sites. The exercise simply demonstrates that the MWC equation can produce the Hill equation. It can also produce the Adair equation.

The MWC equation rests on a specific assumption about the behavior of the protein under consideration: namely, that this behavior the result of the ability of the protein to undergo, within the range of measurements, a quaternary conformational change that proceeds with conservation of symmetry. Consequently, **the MWC equation is an explanation of**

*There is no correspondence between the structural characteristics of the quaternary conformational change and whether it has high affinity for a ligand or low affinity. For example, the quaternary conformation of hemoglobin with the higher affinity for oxygen, the conformation observed in the crystallographic molecular models of the fully liganded conformation, involves an expansion of the molecule from its dimensions in the conformation of lower affinity observed in crystallographic molecular models of the unliganded protein (Figure 6–1). The opposite is true of aspartate carbamoyltransferase (Figure 6–2).

the observations. The intention is to explain observations of sigmoid behavior in molecular terms. Because sigmoid behavior can almost always be fit with an Adair equation even at the extremes, it follows that the general MWC equation and the general Adair equation must be the same if the explanation is to be consistent with observations.* The general form of the Adair equation (Equation 6–13) can be trivially rearranged to give

$$Y = \frac{\left\{\sum_{i=1}^{n-1} \frac{i}{n}\left(\prod_{i+1}^{n} K_{di}\right)[\mathrm{L}]^i\right\} + [\mathrm{L}]^n}{\left\{\sum_{i=0}^{n-1}\left(\prod_{i+1}^{n} K_{di}\right)[\mathrm{L}]^i\right\} + [\mathrm{L}]^n} \tag{6–40}$$

and the four binomials of the general MWC equation, two in the numerator and two in the denominator, can be expanded by the binomial theorem and the terms with the concentration of ligand to the same power can be combined to obtain

$$Y = \frac{\left\{\sum_{i=1}^{n-1}\binom{n-1}{i-1}\frac{L_0 K_{\mathrm{dL}}{}^i + K'_{\mathrm{dL}}{}^i}{(K'_{\mathrm{dL}}K_{\mathrm{dL}})^i}[\mathrm{L}]^i\right\} + \frac{L_0 K_{\mathrm{dL}}{}^n + K'_{\mathrm{dL}}{}^n}{(K'_{\mathrm{dL}}K_{\mathrm{dL}})^n}[\mathrm{L}]^n}{\left\{\sum_{i=0}^{n-1}\binom{n}{i}\frac{L_0 K_{\mathrm{dL}}{}^i + K'_{\mathrm{dL}}{}^i}{(K'_{\mathrm{dL}}K_{\mathrm{dL}})^i}[\mathrm{L}]^i\right\} + \frac{L_0 K_{\mathrm{dL}}{}^n + K'_{\mathrm{dL}}{}^n}{(K'_{\mathrm{dL}}K_{\mathrm{dL}})^n}[\mathrm{L}]^n} \tag{6–41}$$

where the integers within the parentheses are the usual binomial coefficients. Equation 6–41 can be rearranged to give

$$Y = \frac{\frac{(K'_{\mathrm{dL}}K_{\mathrm{dL}})^n}{L_0 K_{\mathrm{dL}}{}^n + K'_{\mathrm{dL}}{}^n}\left\{\sum_{i=1}^{n-1}\binom{n-1}{i-1}\frac{L_0 K_{\mathrm{dL}}{}^i + K'_{\mathrm{dL}}{}^i}{(K'_{\mathrm{dL}}K_{\mathrm{dL}})^i}[\mathrm{L}]^i\right\} + [\mathrm{L}]^n}{\frac{(K'_{\mathrm{dL}}K_{\mathrm{dL}})^n}{L_0 K_{\mathrm{dL}}{}^n + K'_{\mathrm{dL}}{}^n}\left\{\sum_{i=0}^{n-1}\binom{n}{i}\frac{L_0 K_{\mathrm{dL}}{}^i + K'_{\mathrm{dL}}{}^i}{(K'_{\mathrm{dL}}K_{\mathrm{dL}})^i}[\mathrm{L}]^i\right\} + [\mathrm{L}]^n} \tag{6–42}$$

It can be seen that both the general Adair equation and the general MWC equation have the same form. If each coefficient in the general Adair equation is set equal to each coefficient in the binomial expansion of the general MWC equation for the same power of the concentration of ligand, both those in the numerator and those in the denominator, then it can be seen that for all the coefficients

$$(K'_{\mathrm{dL}}K_{\mathrm{dL}})^{n-i}\binom{n}{i}\frac{L_0 K_{\mathrm{dL}}{}^i + K'_{\mathrm{dL}}{}^i}{L_0 K_{\mathrm{dL}}{}^n + K'_{\mathrm{dL}}{}^n} = \prod_{i+1}^{n} K_{di} \tag{6–43}$$

because

$$\frac{n}{i}\binom{n-1}{i-1} = \binom{n}{i} \tag{6–44}$$

Consequently, for every unique coefficient in an Adair equation, there is a unique coefficient in the corresponding MWC equation; and any behavior that can be described by an Adair equation can also be described by an MWC equation. Unlike an Adair equation, however, an MWC equation provides an explanation for the observations.

There are two important mathematical distinctions between an Adair equation and the corresponding MWC equation. First, because the series of coefficients in an MWC equation is a power series of a number that is always greater than 1, the coefficients that precede each power of the concentration of ligand must increase monotonically while the coefficients in the corresponding Adair equation that precede each power of the concentration, although they are always required to be greater than 0, are not required to increase monotonically but can take on any value. Second, an Adair equation has the same number of coefficients, K_{di}, as n, in addition to the value for n chosen.* In other words the number of coefficients increases as n increases. In an MWC equation there are only three parameters, L_0, K_{dL}, and K'_{dL}, in addition to the value for n, which is independently determined by the number of asymmetric units in the protein and consequently not a parameter. It follows that, for both reasons, an MWC equation is more constrained than the corresponding Adair equation if n is greater than 3, and it does not follow from the equality of Equation 6–43 that any behavior that can be described by an Adair equation can also be described by an MWC

*The following development was provided to the author by Stuart Edelstein.

*Recall that the value chosen for n can be arbitrary if nothing is known about the quaternary structure of the protein or if it is not known whether or not each subunit in a protein of known quaternary structure has a functional site for binding the ligand. For example, L-lactate dehydrogenase from *B. longum* is a tetramer of identical subunits, but each tetramer has only two binding sites for D-fructose 1,6-bisphosphate.[41]

equation. Consequently, there could be situations in which the data could be satisfactorily fit by an Adair equation but not by an MWC equation. The fact that this failure seldom if ever occurs might be an argument in favor of the validity of the general MWC equation and its assumptions, were the data always of high precision and over a large range of concentration for the ligand, which they almost always are not.

The major quaternary conformational change of an oligomeric protein that involves reorientation of the protomers in a homooligomer and that permits it in this way to display homotropic cooperative behavior among its widely separated sites should be distinguished from the local conformational changes that occur in the vicinity of the sites themselves as they are occupied by the ligand. These local conformational changes are those described earlier when changes around the active site upon association of a substrate were discussed. They include shifts in the positions of side chains of amino acids (Figures 3–56 and 3–57), the closing of a lid over the active site (Figure 3–58), and even the closing of structural domains around reactants (Figure 3–55), if this closing of structural domains does not always, by itself, precipitate the quaternary conformational change.

When aspartate carbamoyltransferase from *E. coli* is dissociated into its regulatory β_2 dimers and catalytic α_3 trimers, the resulting catalytic trimers are enzymatically active but display no cooperativity. Modification of these isolated, enzymatically active catalytic α_3 trimers with tetranitromethane converts tyrosines in the protein to *o*-nitrotyrosines. The maximum of absorbance for *o*-nitrotyrosine[45] is 430 nm for the anionic phenolate and 355 nm for the neutral phenol, and the pK_a of nitrotyrosine is 7.5. Consequently, any shift in pK_a owing to a change in the environment surrounding a nitrotyrosine will cause a change in its absorbance when the pH of the solution is well-buffered and in the neutral range. When the active site in such a modified catalytic α_3 trimer is first occupied with carbamoyl phosphate, the binding of succinate, a competitive inhibitor of the enzymatic activity, causes a significant decrease in the absorbance at 430 nm, a change expected from an increase in values of pK_a for some of the nitrotyrosines. This decrease in absorbance can be used to monitor directly the proportion of active sites occupied by the succinate,[46] from which it follows that the decrease is monitoring a local change in conformation.

When these nitrated catalytic α subunits are reconstituted with dimers of regulatory β subunits to produce the intact $(\alpha\beta)_6$ hexamer of aspartate carbamoyltransferase, to which succinate binds cooperatively (Figure 6–3), the same change in absorbance upon occupation of the active site persists.[47] It still monitors directly the binding of the succinate rather than the quaternary conformational change involved in homotropic cooperativity. For this reason, it can be assumed that whatever local conformational change leads to the change of absorbance of the nitrotyrosines in these α subunits is not propagated globally.

Comparisons of the crystallographic molecular model of the isolated, unoccupied catalytic α_3 trimer and the catalytic α_3 trimer of intact $(\alpha_3)_2(\beta_2)_3$ aspartate carbamoyltransferase in the R conformation occupied by *N*-(phosphonacetyl)-L-aspartate (Figure 6–2) demonstrate that an induced fit, in which the amino-terminal structural domain of a catalytic protomer closes upon its carboxy-terminal structural domain by a 10° pivot upon a hinge, closes the active site following the assembly of reactants,[48,49] much as the active site of hexokinase closes around its reactants (Figure 3–55).* It may well be that this conformational change is the local conformational change detected by the nitrotyrosines. The local conformational change that closes off the active site could be a significant contributor to the change in free energy shifting the equilibrium between the T and R conformations even though its progress does not coincide with the progress of the quaternary conformational change.

In addition, in aspartate carbamoyltransferase, a short loop of polypeptide, comprising amino acids 80–87 of an adjacent catalytic α subunit in an α_3 trimer, lies over the closed, occupied active site in the crystallographic molecular model of the R conformation fully occupied with substrates or analogues of substrates, but this loop is shifted away to open the active site in the model of the unoccupied, T conformation (Figure 6–10).[6,50-52] Because the active site is shut off from the solution when this loop covers it, it must be the case that the loop closes over the active site after substrates or analogues of substrates have been bound. Therefore, each rearrangement in each catalytic α subunit must be a local conformational change that occurs

*It should be recalled that, just as is the case with quaternary conformational changes, induced fit relies upon the existence of an equilibrium between two local conformations—in the case of hexokinase, open and closed—that is shifted upon the association of a ligand—in the case of hexokinase, D-glucose.

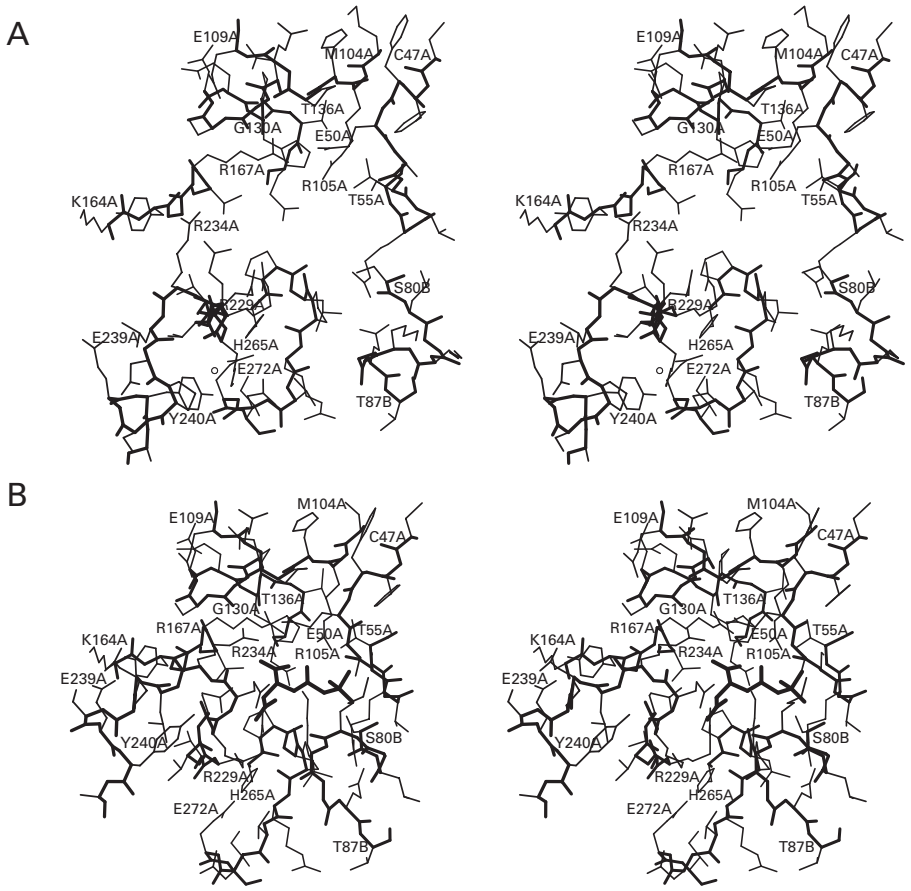

Figure 6–10: Stereodrawings[485] of crystallographic molecular models of the closing of the active site around the bisubstrate analogue *N*-(phosphonacetyl)-L-aspartate during its association with aspartate carbamoyltransferase from *E. coli*. (**A**) Crystals of the enzyme in the T conformation, the regulatory sites of which were occupied by CTP^{4-}, were formed by dialysis of a solution of the enzyme at 18 mg mL^{-1} against a solution of 1 mM cytidine 5′-triphosphate, 3 mM sodium azide, 1 mM 2-sulfanylethanol, 0.2 mM ethylenediamine tetraacetate, and 40 mM sodium citrate at pH 5.7. Crystals of space group *P*321 were obtained. Reflections from the crystals were collected to Bragg spacing of 0.22 nm.[52] (**B**) Crystals of the enzyme in the R conformation, the active sites of which were occupied by *N*-(phosphonacetyl)-L-aspartate (**6–1**), were produced by dialyzing the enzyme at high concentration into 1 mM *N*-(phosphonacetyl)-L-aspartate and 50 mM *N*-ethylmorpholinium maleate at pH 6.9 and 21 °C.[51] Isomorphous crystals of the space group *P*321 were obtained. Reflections were collected from these crystals to Bragg spacing of 0.21 nm.[50] The segments of polypeptide surrounding the active site in each drawing are from Threonine 228A to Alanine 241A, Lysine 164A to Threonine 168A, Cysteine 47A to Threonine 55A, Methionine 104A to Glutamate 109A, Aspartate 129A to Glutamine 137A, and Histidine 265A to Isoleucine 273A from one of the α catalytic polypeptides and a segment from Serine 80B to Threonine 87B from the other. In Panel B, *N*-(phosphonacetyl)-L-aspartate (thickest lines) is seen within the active site surrounded by the catalytic side chains. It has been trapped within the active site by the closing of a lid formed from a loop of polypeptide from Serine 80B to Threonine 87B. In Panel A, the active site in the unliganded crystallographic molecular model is open to the solvent because this lid has swung away, and the active site is much wider (compare the distances between the side chains of Glutamate 50 and Arginine 234) because the two hinged domains forming its top and bottom have swung open.

coincident with association of substrates with the active site and not during the quaternary conformational change because the quaternary conformational change occurs at concentrations of ligands well below saturation. If the closing of the lid were strongly coupled to the quaternary conformational change, then the last ligands, rather than binding with high affinity as a result of the quaternary conformational change, could not bind at all because the lids would be closed. There are also dramatic local changes in conformation of the regulatory β subunits in aspartate carbamoyltransferase upon association of the various nucleotides that act as heterotropic allosteric effectors, but these are local conformational changes that occur within the otherwise unaffected quaternary T and R conformations.[9,53]

Local changes in conformation can be distinguished from quaternary conformational changes by nuclear magnetic resonance spectroscopy.

Cells of *E. coli* were grown in a medium prepared in ^2H_2O with fully deuterated D-glucose as the main source of carbon. Also present in the medium was 2-oxo-[3,3-$^2H_2$,4-^{13}C]butyrate, which during the growth of the bacteria was converted by its metabolic pathways into [2,3,3′,3′,3′,4,4-$^2H_7$,5-$^{13}C^1H_3$]-L-isoleucine. This cellularly created [2,3,3′,3′,3′,4,4-$^2H_7$, 5-$^{13}C^1H_3$]-L-isoleucine was incorporated by the bacteria into the otherwise fully deuterated aspartate carbamoyltransferase. In two-dimensional transverse relaxation-optimized spectroscopy (TROSY) nuclear magnetic resonance spectra, cross peaks arise from through-bond dipolar coupling between carbon-13 and protium atoms in the 5-[$^{13}C^1H_3$]methyl groups of the labeled isoleucines in purified aspartate carbamoyltransferase. From changes in the amplitudes of many of these cross peaks in response to various ligands, it was concluded that these cross peaks come in pairs, each pair arising from one of the isoleucines in the enzyme. One cross peak in each pair arises from this one isoleucine in the T conformation of the enzyme, and the other cross peak from the same isoleucine arises from that isoleucine in the R conformation. It was also concluded that these two conformations were those previously described crystallographically (Figure 6–2).

In the two-dimensional TROSY nuclear magnetic resonance spectra of intact, fully deuterated $(\alpha_3)_2(\beta_2)_3$ aspartate carbamoyltransferase containing [2,3,3′,3′,3′,4,4-$^2H_7$, 5-$^{13}C^1H_3$]isoleucyl groups when it is in the unliganded T conformation, there are several cross peaks the positions of which shift monotonically as phosphonoacetamide, an analogue of the substrate carbamoyl phosphate, occupies the active site as its concentration is increased (Figure 6–11A).[54] Each shifting cross peak has a partner when the enzyme is in the R conformation. The two cross peaks in the respective pair, one from a particular isoleucine in the T conformation (Figure 6–11B) and one from the same isoleucine in the R conformation (Figure 6–11C), both shift as the concentration of phosphonoacetamide increases. These shifts are independent of the reciprocal decrease in amplitude of the former cross peak and the increase in amplitude of the latter that are registering the change from the quaternary T to the quaternary R conformation. The monotonic shifts in position of the peaks on the two-dimensional field are registering local conformational changes that occur upon occupation of each active site in turn, while the reciprocal changes in amplitudes of the two members of each pair of cross peaks are registering the quaternary conformational change from the T to the R conformation.

In two-dimensional TROSY nuclear magnetic resonance spectra of 6-phosphofructokinase from *G. stearothermophilus* labeled in the same way, there are cross peaks from methyl groups of isoleucines in the protein that shift from one position in the T conformation to an adjacent position in the R conformation as the concentration of the substrate D-fructose 6-phosphate, which displays cooperativity in steady-state kinetics,[27] is increased.[55] At intermediate concentrations of D-fructose 6-phosphate, the cross peaks display contributions from each quaternary conformation and monitor the transition from the T to the R conformation, but the positions of the cross peaks for each conformation shift continuously as do those of aspartate carbamoyltransferase (Figure 6–11) as the concentration of D-fructose 6-phosphate is increased. These continuous shifts are monitoring local conformational changes resulting from occupation of the active sites by the D-fructose 6-phosphate.

The closely related enzyme 6-phosphofructokinase (Equation 6–28) from *E. coli* (55% identity; 0.3 gap percent) has been crystallized in two active symmetric conformations, each with the same quaternary R conformation but differing in occupation of the site for the heterotropic allosteric activator, $MgADP^-$. Extensive local changes in conformation around the site for a heterotropic allosteric effector to which $MgADP^-$ binds (Figure 6–9) are observed when the two molecular models are compared, but these conformational changes are not widespread enough to produce any change in the quaternary conformation.[43] Presumably these are local changes

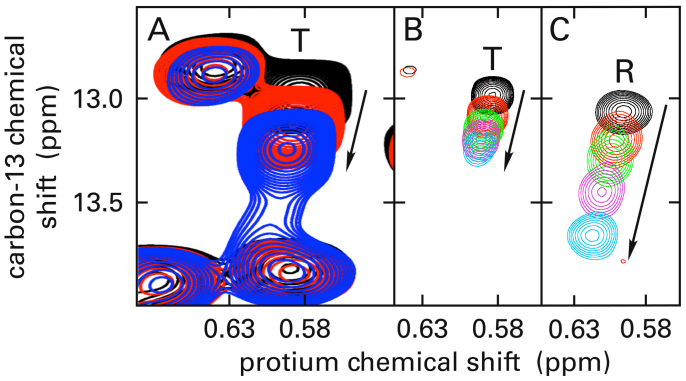

Figure 6–11: Changes in chemical shift caused by local conformational changes resulting from association of phosphonoacetamide with aspartate carbamoyltransferase from *E. coli*.[54] The enzyme was labeled as described in the text. The resulting, fully deuterated enzyme containing one carbon-13 and three protiums in the methyl group at position 5 in each isoleucine was dissolved at concentrations of asparate carbamoyltransferase from 0.3 to 0.9 mM in active sites in deuterium oxide with 50 mM KCl, 20 mM 2-sulfanylethanol, and 20 mM 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonic acid at pH 7.5. The coupling that gives rise to the observed cross peaks is that between carbon-13 and protiums in each methyl group. The cross peak for each methyl group in each isoleucine at a particular position in the two sequences of amino acids for the enzyme occupies a unique position on the field of the two-dimensional spectrum that is determined by the chemical shifts of its carbon-13 and protiums. Because each cross peak arises from a methyl group, all 27 cross peaks from the 27 isoleucines in the protein are confined to a range of carbon-13 chemical shift between 9 and 17 ppm and a range of protium chemical shift between 0.2 and 1.2 ppm. As the concentration of phosphonoacetamide was increased, it was observed that several of the cross peaks in the individual complete spectra shifted monotonically. (**A**) Complete spectra. Portions of three complete spectra obtained at different concentrations of phosphonoacetamide are drawn. The ranges of the chemical shifts are noted on the axes. One of the peaks in the three spectra (labeled T) shifted down and to the left as phosphonoacetamide was added. The spectrum of the unliganded enzyme is in black, the spectrum for a saturating concentration of phosphonoacetamide is in blue, and the spectrum for an intermediate concentration of phosphonoacetamide is in red. (**B**) Peak that registers association of phosphonoacetamide with the T conformation. The peak that shifts significantly in the complete spectrum of Panel A could be emphasized because it was the most intense peak in its vicinity. When the contour levels were given a high setting, the titrating peak dominated the field. This presentation made it easier to quantify the distance over which each shift occurs. Five separate peaks from five complete spectra, each from this same isoleucine, are shown: one for the unliganded enzyme (black), one for the enzyme saturated with phosphonoacetamide (cyan), and three for intermediate concentrations of phosphonoacetamide (red, green, and lavender). (**C**) Peak that registers association of phosphonoacetamide with the R conformation. The mutant in which Lysine 164 and Glutamate 239 in the α catalytic subunit have been changed to glutamate and lysine, respectively, is entirely in the R conformation. The peak corresponding to absorbance of the same methyl group on the same isoleucine as that producing the peak in Panel B could be identified in the complete spectra. The peak for that isoleucine was again emphasized. This peak also shifted when phosphonoacetamide was added to the solutions. Five separate peaks are shown: one for the unliganded enzyme (black), one for the enzyme saturated with phosphonoacetamide (cyan), and three for intermediate concentrations of phosphonoacetamide (red, green, and lavender). in conformation that again may or may not affect the free energy of the equilibrium between the quaternary conformations of the enzyme.

There are many disparate observations that can be explained by the proposal that enzymes displaying cooperativity exist in two rotationally symmetric conformations, the equilibrium between which is linked to association of substrates or heterotropic allosteric effectors. For example, when the initial rate of the reaction catalyzed by aspartate carbamoyltransferase was measured in the direction from *N*-carbamoyl-L-aspartate and phosphate[56] to carbamoyl phosphate and L-aspartate,* ***N*-(phosphonacetyl)-L-aspartate was a potent activator** (Figure 6–12).[57] One explanation for this observation is that the T conformation has low enzymatic activity and neither reactant, unlike the reactants for the reaction in the opposite direction, can shift the conformational equilibrium in favor of the more active R conformation. *N*-(Phosphonacetyl)-L-aspartate, however, can shift the equilibrium in favor of the R conformation. When *N*-(phosphonacetyl)-L-aspartate occupies one or more active sites on a molecule of the enzyme, the distribution of conformations shifts in favor of the R conformation, and the enzymatic activity at the other empty active sites increases dramatically.

Site-directed mutations of amino acids, the side chains of which appear in a crystallographic molecular model to be involved in interactions that change as the quaternary conformations change, can be consistent with the conclusion that shifts in the equilibrium between T and R conformations are responsible for observed allosteric effects. For example, Tyrosine 240 in a catalytic α subunit of aspartate carbamoyltransferase participates in a

*This is the direction of the approach to equilibrium catalyzed by the enzyme that is not usually chosen.

hydrogen bond with a fixed molecule of water that also participates in a hydrogen bond with Glutamate 272 in the crystallographic molecular model of the T conformation but not in the R conformation. The breaking of this cluster of hydrogen bonds, among many other changes, permits contacts to occur between loops in the space between the trimers of catalytic α subunits in the R conformation (Figures 6–2 and 6–8). When Tyrosine 240 is mutated to phenylalanine, so the cluster of hydrogen bonds can no longer form, the apparent affinity of the enzyme for L-aspartate increases.[58] This change is consistent with a destabilization of the T conformation relative to the R conformation, in which each of these two side chains have hydrogen bonds with water in the solvent. Glutamate 50 in a catalytic α subunit of aspartate carbamoyltransferase forms a hydrogen bond with Arginine 105 in the T conformation[6] but forms hydrogen bonds with both Arginines 167 and 234 in the R conformation, one at each of its oxygens (Figure 6–10). When Arginine 105 is mutated to glutamine, so that one of these latter arginines necessarily lacks an acceptor, the apparent affinity of the enzyme for L-aspartate decreases, as well as the cooperativity ($n_H = 1.0$); and these decreases are consistent with a destabilization of the R conformation relative to the T conformation.[59] When both Tyrosine 240 and Glutamate 50 are mutated, the enzyme displays a higher affinity for L-aspartate than when only Glutamate 50 is mutated,[58] consistent with a destabilization of both the R and T conformations. These results suggest that the changes in hydrogen bonds involving these amino acids observed crystallographically are indeed involved in the quaternary conformational change responsible for cooperativity.

When the R and T conformations of hemoglobin were immobilized in silica gel so that the quaternary conformational change was prevented, association of carbon monoxide with the hemes showed two kinetic phases. Various ligands shifted reciprocally the amplitudes of these phases in molecules of hemoglobin trapped in each quaternary conformation. These shifts in amplitude could be explained by assuming that the ligands shifted the equilibrium constants between two or more local conformations that can be achieved by the individual subunits regardless of the quaternary conformation in which they are located.[60]

Following the publication of the explanation of Monod, Wyman, and Changeux, it was pointed out that if a simple model involving only two quaternary conformations of the protein satisfactorily explains homotropic cooperativity, then a model involving more than two quaternary conformations must also be as satisfactory.[61] It has already been pointed out in the discussion of steady-state kinetics that if an explanation based on a particular number of intermediates is consistent with observations, then it necessarily follows that an explanation involving additional intermediates must also be consistent. Therefore, to establish the central hypothesis that, because of the conservation of symmetry, there are only two quaternary conformations, results other than measurements of the binding of a ligand or the behavior of the initial rate of the enzymatic reaction as a function of the concentrations of reactants must be obtained. Experiments addressing this point seek to

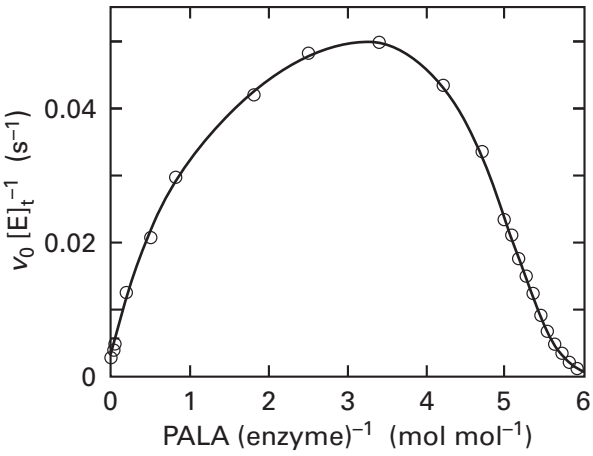

Figure 6–12: Activation of the arsenolysis of *N*-carbamoyl-L-aspartate catalyzed by aspartate carbamoyltransferase from *E. coli* by the binding of *N*-(phosphonacetyl)-L-aspartate stoichiometrically to active sites on the enzyme.[57] The enzymatic reaction was assayed in the direction from *N*-carbamoyl-L-aspartate to L-aspartate by using arsenate in place of phosphate so that the carbamoyl arsenate formed in the reaction would hydrolyze immediately upon formation and drive the reaction in its usually unfavorable direction. The enzyme (70 μM final concentration of active sites) was added to final concentrations of 3 mM arsenate and 5 mM *N*-carbamoyl-L-aspartate at pH 7.0 and 30 °C to initiate the reaction. Production of L-aspartate was monitored continuously by coupling it to oxidation of NADH with aspartate transaminase and malate dehydrogenase. As a result, the reaction mixture contained these two enzymes as well as 0.5 mM 2-oxoglutarate and 0.16 mM NADH. The rate of decrease in the absorbance at 340 nm was used to calculate directly the initial rate of the enzymatic reaction (micromolar second^{-1}). After division by the concentration of active sites, each initial rate (second^{-1}) is plotted as a function of the respective molar ratio of *N*-(phosphonacetyl)-L-aspartate (PALA) to aspartate carbamoyltransferase [moles of PALA (mole of enzyme)$^{-1}$]. At these concentrations of enzyme and *N*-(phosphonacetyl)-L-aspartate, all (>99%) of the *N*-(phosphonacetyl)-L-aspartate is bound by the enzyme ($K_d^{PALA} = 25$ nM) until the concentration of *N*-(phosphonacetyl)-L-aspartate becomes greater than 98% of the concentration of active sites.

demonstrate that only two quaternary conformations of the protein exist over the complete range of concentrations of a ligand that displays cooperativity. Then, because two quaternary conformations have been observed crystallographically, those conformations must be the only two.

In this search for more than two quaternary conformations, it becomes even more important to distinguish local conformational changes from quaternary conformational changes. For example, the closing of the two hinged domains of the α subunits of aspartate carbamoyltransferase upon its assembled reactants is a significant local conformational change. Whether the enzyme is in the T or R conformation, active sites with which reactants have associated will be closed and active sites with which reactants have not associated will be open. Consequently, partially occupied T and R conformations will not actually be rotationally symmetric. On the quaternary level, however, these two partially occupied conformations will be rotationally pseudosymmetric about all four rotational axes of pseudosymmetry. The partially occupied T conformations can still be distinguished from partially occupied R conformations by expansion of the space between the α_3 trimers, rotation of one α_3 trimer relative to the other, and the change in the tilt of the regulatory β_2 dimers (Figure 6–2). Effectively, the partially occupied T or R conformations are formally equivalent to the partially occupied, pseudosymmetric conformations of any rotationally symmetric homooligomer, such as L-lactate dehydrogenase or fumarate hydratase, that does not have different quaternary conformations but, when partially occupied, must be pseudosymmetric rather than symmetric, if only because some of the active sites are occupied.

The most extensive examination of whether or not more than two quaternary conformations exist during the cooperative association of a ligand to a protein has been performed with aspartate carbamoyltransferase from *E. coli*. It should be recalled that association of both carbamoyl phosphate[16] and succinate (Figure 6–4) with aspartate carbamoyltransferase and the behavior of the initial rate of the enzymatic reaction as a function of the concentration of L-aspartate (Figure 6–3) are all cooperative.

Crystals of aspartate carbamoyltransferase of the space group *R*32 form in solutions of the enzyme in the T conformation in the absence of ligands, and the crystallographic asymmetric unit is one folded catalytic polypeptide and one folded regulatory polypeptide. All molecular axes of symmetry coincide with crystallographic axes of symmetry, and the protein in the crystals is necessarily precisely symmetric.[13] Crystals of the protein in which all six catalytic sites are occupied by the bisubstrate analogue *N*-(phosphonacetyl)-L-aspartate (**6–1**) have the space group *P*321, and the crystallographic asymmetric unit is two folded catalytic polypeptides and two folded regulatory polypeptides.[5] The threefold molecular rotational axis of symmetry coincides with the threefold crystallographic rotational axis of symmetry and is precise. Although the twofold molecular axes of symmetry do not coincide with crystallographic axes of symmetry, only small, insignificant deviations from exact symmetry are observed.[6] When a heterotropic allosteric site on the T conformation is occupied with CTP^{4-}, the enzyme also crystallizes in the space group *P*321, with two folded catalytic polypeptides and two folded regulatory polypeptides in the asymmetric unit. Superposition of the folded polypeptides around the twofold noncrystallographic rotational axis of symmetry detects a number of violations of exact symmetry, but almost entirely they are alternative conformations of the side chains of amino acids,[62] rather than significant asymmetry of the polypeptide backbones or orientation of the subunits. There is a crystalline form of the R conformation occupied with *N*-(phosphonacetyl)-L-aspartate in the space group $P2_12_12_1$ in which the entire $(\alpha\beta)_6$ hexamer is the asymmetric unit. Although the folded catalytic α polypeptides superpose closely around the molecular threefold rotational axis of symmetry, the unoccupied, β regulatory polypeptides, which usually display much greater disorder than the folded catalytic polypeptides,[50] superpose poorly around the molecular twofold rotational axis of symmetry (0.15–0.31 nm root mean square deviation).[63] Nevertheless, the conclusion that can be drawn from all these observations taken together is that **both quaternary conformations, the T and R conformations, of aspartate carbamoyltransferase observed crystallographically are rotationally symmetric oligomers** even though they differ dramatically from each other in conformation (Figure 6–2).

Association of *N*-(phosphonacetyl)-L-aspartate with the active sites of aspartate carbamoyltransferase shifts the equilibrium between these two quaternary conformations in favor of the R conformation. In two-dimensional TROSY nuclear magnetic resonance spectra of purified aspartate carbamoyltransferase labeled in the manner described above, several well-resolved cross peaks that monitored conformational

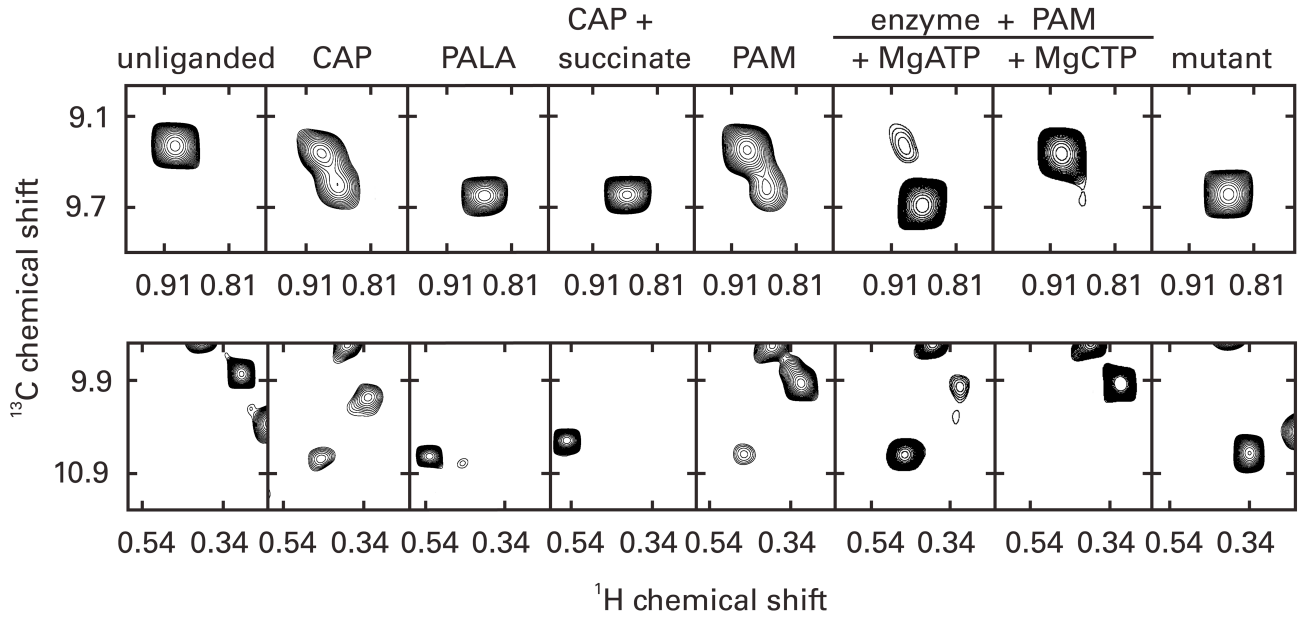

Figure 6–13: Two-dimensional methyl-TROSY (^{1}H–^{13}C) nuclear magnetic resonance spectra of aspartate carbamoyltransferase from *E. coli*.[54] The enzyme was labeled as described in the text and dissolved as described in the legend for Figure 6–11. Only two portions (top row and bottom row) of each complete spectrum are presented in the ranges noted on the respective axes. Further additions to solutions for the respective spectra (from left to right) were as follows: none (unliganded); carbamoyl phosphate (CAP) at a molar ratio of 30 relative to the concentration of active sites; *N*-(phosphonacetyl)-L-aspartate (PALA) at a molar ratio of 1.5; carbamoyl phosphate and succinate (CAP + succinate) at molar ratios of 30 and 75, respectively; phosphonoacetamide (PAM) at a molar ratio of 58; phosphonoacetamide and $MgATP^{2-}$ (enzyme + PAM + MgATP) at molar ratios of 58 and 46, respectively; and phosphonoacetamide and $MgCTP^{2-}$ (enzyme + PAM + MgCTP) at molar ratios of 58 and 32, respectively. Shown in the last column (mutant) are the same regions from a spectrum for a mutant of aspartate carbamoyltransferase in which Lysine 164 and Glutamate 239 in the α catalytic subunit have been changed to glutamate and lysine, respectively. Peaks arising from isoleucines in the R conformation are labeled, and those arising from the same isoleucines in the T conformation are also labeled. Adapted with permission from reference 54. Copyright 2007 National Academy of Sciences. https://doi.org/10.1073/pnas.0703347104

changes could be observed.[54] Many of the isoleucyl 5-methyl groups produced two cross peaks in the spectra, the amplitudes of which were inversely related to each other and changed as the conformation of the enzyme was changed by adding ligands (Figure 6–13). From changes in the amplitudes of each cross peak in response to various ligands, it was concluded that one cross peak from one of these isoleucines arises from the T conformation and the other cross peak from the same isoleucine arises from the R conformation. It was also concluded that these two conformations were those previously described crystallographically. In the presence of *N*-(phosphonacetyl)-L-aspartate, the bisubstrate analogue, only one of these two cross peaks from each isoleucine is observed; and in the absence of ligands, only the other cross peak is observed (Figure 6–13). These observations led to the conclusion that, in each of these two situations, the equilibrium between the R and T conformations was shifted completely to one or the other, as suggested by the crystallographic molecular models (Figure 6–2). In the presence of carbamoyl phosphate, however, about equal amounts of T and R conformations are in equilibrium with each other, but when succinate, an analogue of L-aspartate, is then added, all the molecules of enzyme assume the R conformation. In the presence of 2-phosphonoacetamide, an analogue of carbamoyl phosphate that is stable to hydrolysis, amounts of R and T conformations in a ratio of about 1:3 are present.

The cross peaks of a significant percentage of the isoleucyl 5-methyl groups in the enzyme could be resolved in the spectra. In many of these cases, the cross peaks from a particular methyl group came in pairs that were assumed to represent the T and R conformations. In most of these instances, the ratios of the amplitudes of the cross peaks in each pair were affected in the same way by the association of one or more of the ligands just mentioned. These observations are consistent with the conclusion that under all these circumstances there were **only**

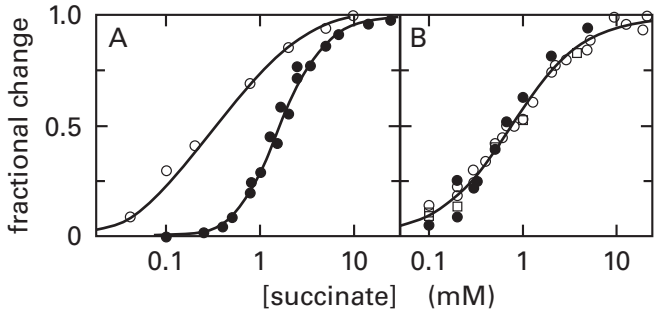

Figure 6–14: Relation between the change in quaternary conformation of *E. coli* aspartate carbamoyltransferase—as monitored by sedimentation velocity, changes in absorbance of nitrotyrosines, or rate of mercuration of cysteines—and the change in occupation of the active sites by succinate—as monitored spectrophotometrically. (**A**) Comparison of the binding of succinate to aspartate carbamoyltransferase and the resulting change in conformation.[47] Catalytic α_3 trimers, made from purified $(\alpha\beta)_6$ hexamers of aspartate carbamoyltransferase, were nitrated with tetranitromethane in the presence of carbamoyl phosphate and succinate so that 0.7 nitrotyrosine was formed for every catalytic α polypeptide and 85% of the enzymatic activity remained. These nitrated (ntr) catalytic α_3 trimers were reconstituted with unmodified regulatory β_2 dimers to form $(\alpha^{ntr}\beta)_6$ hexamers that were enzymatically active and displayed homotropic cooperativity. A change in the spectrum of nitrotyrosines at 430 nm was shown to be directly proportional to the concentration of succinate bound to active sites of the enzyme when carbamoyl phosphate was present at saturating concentration. The fraction of active sites occupied by succinate (●), where 0 is unoccupied and 1.0 is fully occupied with six succinates for each $(\alpha^{ntr}\beta)_6$ hexamer, is plotted as a function of the common logarithm of the succinate concentration (millimolar). The fractional change in sedimentation coefficient ($\Delta s_{max} = -2.9\%$) of these reconstituted $(\alpha^{ntr}\beta)_6$ hexamers (○) was also followed as a function of the molar concentrations of succinate at saturating carbamoyl phosphate under the same conditions. (**B**) Coincidence of three measures of the change in conformation.[67] Nitrated catalytic α_3 trimers, $\alpha_{3,ntr}$, were covalently inactivated by modifying their active sites with pyridoxal phosphate (PLP) and $NaBH_4$. These inactive, nitrated catalytic α_3 trimers, $\alpha_{3,ntr,PLP}$, were then modified with 3,4,5,6-tetrahydrophthalic anhydride to increase their negative charge number. The resulting triply modified catalytic α_3 trimers were reconstituted with native, unmodified catalytic α_3 trimers and regulatory β_2 dimers. The $(\alpha_{3,ntr,PLP}\alpha_{3,native}\beta_6)$ heterohexamers resulting from this reconstitution were isolated by anion-exchange chromatography followed by removal of the phthalyl groups. A nitrated catalytic α_3 trimer in this hybrid could not bind succinate but nevertheless registered the quaternary conformational change of the hexamer through a difference spectrum with a maximum at 450 nm. The quaternary conformation change was monitored by this change in absorbance at 450 nm (○), by the change in sedimentation coefficient (●), and by the change in the rate at which the enzyme was modified by 4-hydroxymercuribenzoate (□). All assays were performed at saturating carbamoyl phosphate (CAP) and at 20 °C. The fractional change in each of these three properties is plotted as a function of the concentration of succinate (molar). The smooth curve is that for Equation 6–48 with $n = 3$, $K_{d,succ} = 0.5$ mM, $K'_{d,succ} = 1.3$ mM, and $L_{CAP} = 3.4$.

two quaternary conformations of aspartate carbamoyltransferase present in the solution and that it is only the ratio between these two conformations that changed. These shifts in the equilibrium between the two conformatations caused the shifts in the ratios of the amplitudes.

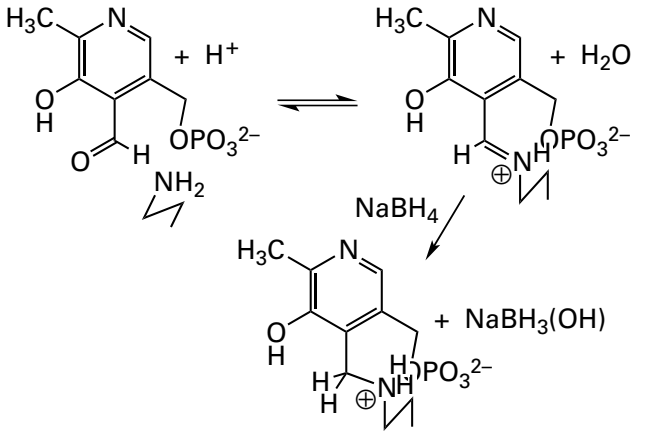
The **change in the distribution of quaternary conformations** that occurs in a solution of aspartate carbamoyltransferase upon addition of a ligand can be **monitored by sedimentation velocity**.[64] The sedimentation coefficient of native aspartate carbamoyltransferase decreases by 3.5% as the unliganded enzyme becomes fully occupied either with carbamoyl phosphate and succinate[64,65] or with *N*-(phosphonacetyl)-L-aspartate.[66] This decrease in the sedimentation coefficient is consistent with a change in the frictional coefficient resulting from expansion of the molecule observed crystallographically (Figure 6–2), and it monitors directly the shift in the equilibrium between quaternary conformational states of the enzyme. The cooperative binding of succinate to aspartate carbamoyltransferase (Figure 6–4) can be monitored directly by the change in absorbance at 430 nm in intact aspartate carbamoyltransferase that has been reconstituted from nitrated catalytic α subunits. The absorbance of this modified enzyme changes in direct proportion to the fraction of active sites occupied by succinate.[47] When the change in sedimentation coefficient as a function of the concentration of succinate is compared to the occupation of the active sites as a function of the concentration of succinate, both at saturating carbamoyl phosphate (Figure 6–14A),[47,67] it can be seen that the majority of the shift in the distribution of conformations has occurred significantly before most of the active sites are occupied.[64] This sequence of events is as expected because the last succinates must associate with high affinity in order to explain homotropic cooperativity. Therefore, if the change from the T to R conformation is to explain the cooperativity, then the quaternary conformation must change before the last succinates are bound.

This observation, that completion of the **quaternary conformational change in the protein precedes full occupation of the active sites**, is a commonly observed property of proteins that display homotropic cooperativity. For example, the heterotropic allosteric activator AMP^{2-} binds to tetrameric glycogen phosphorylase *a* with homotropic cooperativity. Its occupation of the binding sites can be followed directly by equilibrium dialysis, and the change in the distribution of quaternary conformations it promotes can be followed separately by monitoring

changes in the electron paramagnetic resonance spectrum of a covalently bound, stable radical, 1-oxyl-2,2,6,6-tetramethylpiperidine. When the distribution of quaternary conformations is displayed as a function of the fraction of sites occupied (Figure 6–15),[68] the quaternary conformational change is also seen to precede occupation of the sites.

This observation, however, is the expected result regardless of the theory used to explain homotropic cooperativity. The last ligands to bind must bind to the quaternary conformations of high affinity stabilized by the binding of the first ligands to the conformations of low affinity. For this requirement to be fulfilled, the population of the quaternary conformations of high affinity must become dominant before all the ligands have been bound by the protein. The more important issue is whether there are only two quaternary conformations populated to any significant degree in these ligand-promoted transitions or more than two quaternary conformations.

Catalytic α_3 subunits of aspartate carbamoyltransferase, nitrated with tetranitromethane to give them a visible absorption spectrum, were then fully and permanently inactivated by modification of a lysine in their active sites with pyridoxal 5′-phosphate and sodium borohydride



(6–45)

The inactive, modified α_3 subunits were then made more negatively charged by reversible modification of their remaining lysines, which are mostly on the surface of the enzyme, with 3,4,5,6-tetrahydrophthalic anhydride[67,69]

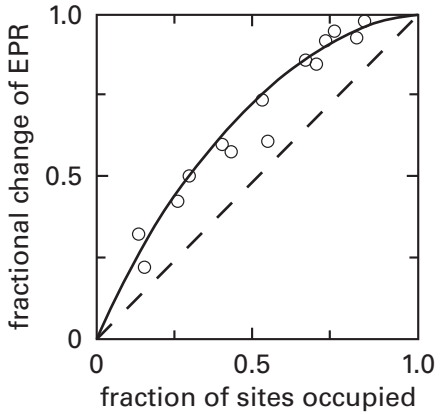


Figure 6–15: Plot of the extent of conformational change[68] of spin-labeled glycogen phosphorylase *a* from *O. cuniculus* as a function of the fraction of sites occupied by the heterotropic allosteric effector AMP^{2-}. Phosphorylase *a* was modified with *N*-(1-oxyl-2,2,6,6-tetramethyl-4-piperidinyl)iodoacetamide to introduce one stable nitroxyl radical into each subunit of the protein. Binding of AMP^{2-} was followed by equilibrium dialysis by measuring at equilibrium the molar concentrations of [U-^{14}C]adenosine 5′-monophosphate in the two chambers, one containing 4 μM phosphorylase *a* and one lacking phosphorylase *a*, for a series of concentrations of the ligand. The binding displayed positive deviation from ideal behavior and could be fit with Equation 6–35 with $L_0 = 3$, $K_{dAMP} = 2$ μM, $K'_{dAMP} = 10$ μM, and $n = 4$. As the occupation of the enzyme by AMP^{2-} was increased by increasing the free concentration of the ligand, the electron paramagnetic resonance (EPR) spectrum changed as the result of broadening of the outer two absorbances of the triplet. The binding of AMP^{2-} was measured and the electron paramagnetic resonance spectra were recorded for a series of samples with the same free concentrations of AMP^{2-}. For each free concentration of AMP^{2-}, the broadening of the spectra observed at that concentration, as a fraction of the broadening observed at saturation with AMP^{2-} [○; fractional change of EPR], is plotted as a function of the respective fraction of sites for AMP^{2-} that were occupied at the same free concentrations of AMP^{2-}. The solid curve is not a fit to the data. It is instead the curve for the function of Equation 6–49 using values for the fraction of the enzyme in the R conformation calculated with Equation 6–48 with $L_0 = 3$, $K_{dAMP} = 2$ μM, $K'_{dAMP} = 10$ μM, and $n = 4$ that were established from the binding of [U-^{14}C]adenosine 5′-monophosphate to the enzyme.

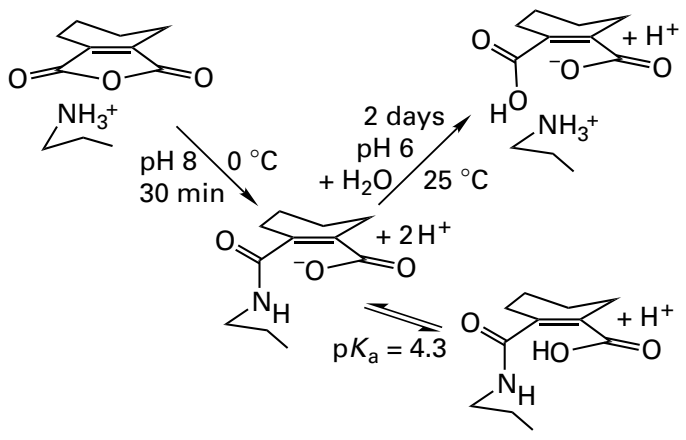

(6–46)

These yellow, inactive, negatively charged subunits were mixed with an equal amount of native unmodified catalytic α_3 subunits, and regulatory β_2 subunits were added to reconstitute $(\alpha\beta)_6$ hexamers. $(\alpha\beta)_6$ Hexamers with **one native catalytic α_3 subunit and one yellow, inactive catalytic α_3 subunit** could be purified by ion-exchange chromatography on a solid phase to which diethylaminoethyl groups are attached, and the tetrahydrophthalyl groups necessary for this separation could then be removed by hydrolysis at pH 6 under intramolecular general base catalysis. When succinate was added to these hybrid molecules saturated with carbamoyl phosphate, an increase in their absorbance at 450 nm was observed. Because neither succinate nor carbamoyl phosphate could bind to the active sites of the yellow, nitrated, inactivated catalytic α_3 subunit in a hexamer, the change in absorbance must have been monitoring a shift in the distribution of quaternary conformations of the nitrated catalytic α_3 subunit brought about by the binding of succinate to the other, unnitrated catalytic α_3 subunit across the twofold rotational axes of pseudosymmetry in the hybrid $(\alpha\beta)_6$ hexamer. The change in absorbance of this hybrid hexamer at 450 nm coincided precisely with the change in sedimentation coefficient. It was also found that the change in **rate constant for the reaction of cysteines in the protein with 4-hydroxymercuribenzoate** coincided with the other two changes (Figure 6–14B) when each of these **three independent monitors of the distribution of quaternary conformations** of the protein was followed as a function of the concentration of succinate.[64,67]

At sufficiently low concentrations of aspartate carbamoyltransferase, the bisubstrate analogue *N*-(phosphonacetyl)-L-aspartate (**6–1**) binds with homotropic cooperativity to the enzyme. The analogue, however, binds so tightly to the active site that it can be used as a stoichiometric ligand at high concentrations of enzyme. For example, when occupation of the active site is followed by ultraviolet difference spectroscopy as a function of moles of *N*-(phosphonacetyl)-L-aspartate added for every mole of hexameric enzyme, a clean titration that inflects at 6 mol mol^{-1} is observed (Figure 6–16A).[66,70,71] When the sedimentation coefficient was followed over the same range of stoichiometries, it was again observed that the change in the distribution of quaternary conformations monitored by sedimentation preceded occupation of the active sites, as expected for a quaternary conformational change producing homotropic cooperativity.

When catalytic α subunits of aspartate carbamoyltransferase were reconstituted with **nitrated regulatory β subunits**, an increase in absorbance at 445 nm and a corresponding decrease in absorbance at 380 nm, arising from a decrease in values of pK_a for some of the *o*-nitrotyrosyl groups in the regulatory β subunits, was observed when *N*-(phosphonacetyl)-L-aspartate was bound to the active sites in the catalytic α subunits of the reconstituted enzyme.[70] As the nitrotyrosines were on the regulatory β subunits, well removed from the active sites,[5] they must have been responding to a quaternary conformational change in the intact enzyme. The changes in absorbance of the *o*-nitrotyrosyl groups at either 380 or 445 nm coincided with the change in sedimentation coefficient when presented as a function of the stoichiometry between *N*-(phosphonacetyl)-L-aspartate and enzyme (Figure 6–16B).[70]

A Zn^{2+} coordinated by four cysteines from a regulatory β subunit is located at the interface between each folded regulatory and catalytic polypeptide in crystallographic molecular models of aspartate carbamoyltransferase.[13] The **zinc can be replaced by nickel**. Bound nickel displays absorption maxima[72] at 360, 440, 660, and 720 nm as well as maxima and minima in the difference circular dichroic spectrum[71] at 360, 405, and 460 nm. Both the absorption spectrum[72] and the difference circular dichroic spectrum[71] of a solution of aspartate carbamoyltransferase display significant changes as the active sites of the modified enzyme are occupied by *N*-(phosphonacetyl)-L-aspartate. The progress of these changes as a function of the stoichiometry of binding of the bisubstrate analogue coincides with the progress of the change in the distribution of quaternary conformations detected by sedimentation (Figure 6–16C).[71]

It follows from all the results just described (Figures 6–14 and 6–16) that the changes in the distribution of quaternary conformations detected by sedimentation, by nitrotyrosines in the inactive catalytic α subunits, by the rate at which the enzyme was modified by 4-hydroxymercuribenzoate, by nitrotyrosines in the regulatory β subunits, and at metallic ions distant from the active sites **all occur in concert** as the active sites of the enzyme become occupied. One explanation for these coincidences is that all these physical measurements are monitoring the same single quaternary conformational change between only two quaternary conformations. In other words, **no combination of these observations was able to detect more than one quaternary conformational change involving only two quaternary conformations**

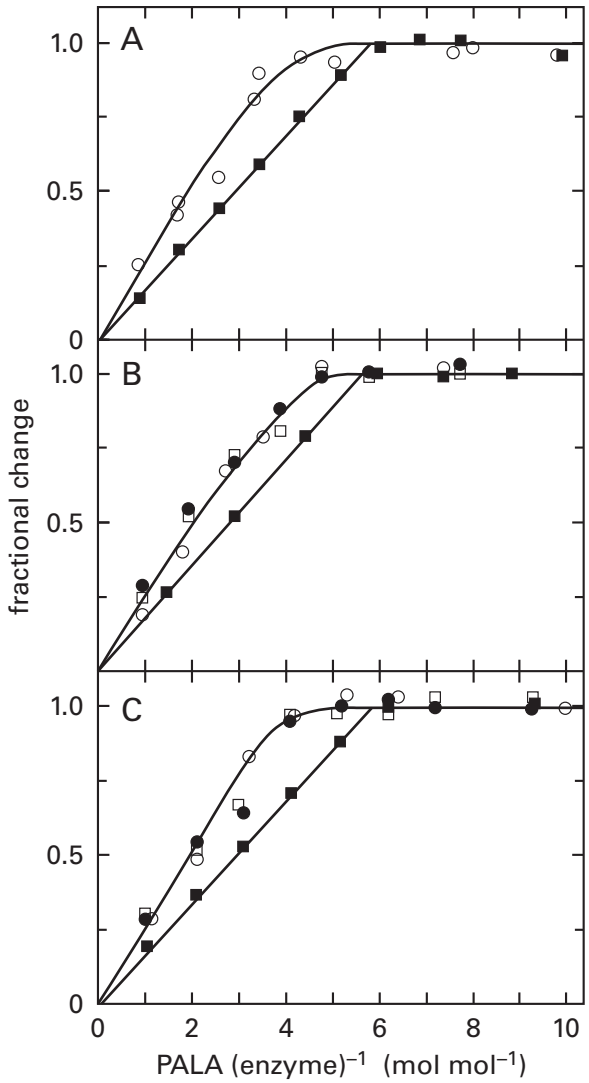

Figure 6–16: Coincidence of several physical measurements monitoring the quaternary conformational change in aspartate carbamoyltransferase from *E. coli* produced by *N*-(phosphonacetyl)-L-aspartate. In all panels, *N*-(phosphonacetyl)-L-aspartate was used to occupy the active sites on the enzyme to varying degrees. This bisubstrate analogue displays homotropic cooperative behavior. In all panels, the change in sedimentation coefficient (○) at various levels of occupation of the active site, measured at 3–4 mg of protein mL^{-1}, was used as the common monitor of the change in quaternary conformation of the enzyme. Association of *N*-(phosphonacetyl)-L-aspartate with aspartate carbamoyltransferase (2.4 mg mL^{-1} in Panel A, 2.1 mg mL^{-1} in Panel B, and 5 mg mL^{-1} in Panel C) was measured directly by following either the difference spectrum of the enzyme at 290 and 286 nm (Panels A and B, ■) or the circular dichroism at 360 nm (Panel C, ■), each of which registers only occupation of the active site with ligand. Each measurement is plotted as the fraction of the respective change (fractional change), relative to the total change between unliganded and fully saturated enzyme, as a function of the respective molar ratio of added *N*-(phosphonacetyl)-L-aspartate (PALA) to aspartate transcarbamoylase [moles of PALA (mole of enzyme)$^{-1}$]. (**A**) Solutions of native protein were monitored at pH 7.0 and 20 °C.[66] (**B**) The protein used for these experiments was reconstituted from native catalytic α_3 subunits and regulatory β_2 subunits modified with tetranitromethane [0.9 nitro group (polypeptide)$^{-1}$]. The change in absorbance (at 17 mg of protein mL^{-1}) at 380 nm (□) or 445 nm (●), both of which are due to absorbance of nitrotyrosines in the regulatory β_2 subunits, as a fraction of the total change between unliganded and fully saturated enzyme, is plotted. The changes were monitored at pH 7.0 and 25 °C.[70] (**C**) The protein used for these experiments was reconstituted from native catalytic and regulatory subunits. stripped of their Zn^{2+}, in the presence of $Ni(NO_3)_2$ (10-fold molar excess over sites) to replace the Zn^{2+} of the native enzyme with Ni^{2+}. The change in circular dichroism (at 5 mg of protein mL^{-1}) at 405 nm (□) or 460 nm (●), arising from absorption bands of complexed Ni^{2+}, as a fraction of the change between unoccupied enzyme and enzyme saturated with *N*-(phosphonacetyl)-L-aspartate, is plotted as a function of the respective molar ratio of *N*-(phosphonacetyl)-L-aspartate to enzyme. Measurements were made at pH 7.0.[71]

of the enzyme. If there were a third quaternary conformation present at significant concentration, the only way that all observations could coincide is if the changes in each observed quantity in the third quaternary conformation were in the same proportion relative to the respective changes in these observed quantities between the T and R conformations, which seems unlikely.

Formally, the coincidence of all these physical measurements is equivalent to observing an isosbestic point in a series of spectra, an observation that has always been accepted as evidence for only two states. If there is only one quaternary conformational change between unoccupied and fully occupied aspartate carbamoyltransferase, then the quaternary conformational change must occur with conservation of symmetry because both unoccupied and fully occupied aspartate carbamoyltransferase are symmetric oligomers.

When the concentration of aspartate carbamoyltransferase is in sufficient excess over the concentration of *N*-(phosphonacetyl)-L-aspartate, each molecule of enzyme to which the inhibitor is bound will have only one molecule of inhibitor bound. The increase in activity in this range of low concentrations of *N*-(phosphonacetyl)-L-aspartate (<0.05 mol mol^{-1}) will then be a function only of the number of active sites converted to the R conformation by one molecule of *N*-(phosphonacetyl)-L-aspartate.[57] Several conditions were chosen in which the equilibrium constant between the T and R conformations was shifted by other ligands sufficiently toward the R conformation that the binding of only one molecule of *N*-(phosphonacetyl)-L-aspartate would convert the T to the R conformation almost quantitatively. Under these conditions, the experimental value for the number of active sites converted to high enzymatic activity was between 4 and 5. Therefore, under these conditions,

association of one, or perhaps two, molecules of *N*-(phosphonacetyl)-L-aspartate at one, or perhaps two. active sites on the enzyme is able to convert the remaining five, or perhaps four, active sites to the R conformation. This result suggests that the conformational change is highly concerted and that only two conformations can exist in significant concentrations.

The curve for the scattering of X-rays at small angles by the R conformation of aspartate carbamoyltransferase, measured with saturating *N*-(phosphonacetyl)-L-aspartate, and the curve for the scattering of X-rays at small angles by the T conformation, measured in the absence of ligands, are significantly different. A molecule of aspartate carbamoyltransferase was constructed with **five mutated, inactive active sites and one normal active site,** and the quaternary conformation of the enzyme was monitored by the scattering of X-rays at small angles. Association of *N*-(phosphonacetyl)-L-aspartate with that one unmutated active site converted this enzyme from the T to the R conformation, and no other conformations could by detected by the measurement.[73]

Crystals of aspartate carbamoyltransferase of the space group *P*321, in the T conformation with its active sites occupied with phosphonoacetamide, were transferred to a solution of 8 mM malonate, which is an analogue of L-aspartate. The T conformation was converted, in the crystals, to the R conformation as the malonate occupied the active sites.[74] The crystals remained in the space group *P*321 with the usual asymmetric unit of two catalytic α subunits and two catalytic β subunits arrayed around the crystallographic threefold rotational axis of symmetry.

The same values for the equilibrium constants between R and T conformations can fit both independently measured changes in the distribution of quaternary conformations of an enzyme and observed cooperativities. From the mechanism of Equation 6–33, the fraction of the enzyme in the R conformation[15]

$$\bar{R} = \frac{[R_n] + [R_n{\cdot}L] + [R_n{\cdot}L_2] + \ldots + [R_n{\cdot}L_n]}{\left([R_n] + [R_n{\cdot}L] + [R_n{\cdot}L_2] + \ldots + [R_n{\cdot}L_n]\right) + \left([T_n] + [T_n{\cdot}L] + [T_n{\cdot}L_2] + \ldots + [T_n{\cdot}L_n]\right)} \quad (6\text{–}47)$$

and

$$\bar{R} = \frac{\left(1 + \frac{[L]}{K_{dL}}\right)^n}{L_0\left(1 + \frac{[L]}{K'_{dL}}\right)^n + \left(1 + \frac{[L]}{K_{dL}}\right)^n} \quad (6\text{–}48)$$

The fractional change (f_ξ) in any property (ξ), such as absorbance, fluorescence, rate of reaction of sulfanyl groups, scattering of X-rays, or sedimentation coefficient, that changes in direct proportion to the fraction of the enzyme in the R conformation is

$$f_\xi = \frac{\bar{R} - \bar{R}_0}{\bar{R}_\infty - \bar{R}_0} \quad (6\text{–}49)$$

where

$$\bar{R}_0 = \lim_{[L] \to 0} \bar{R} = \frac{1}{L_0 + 1} \quad (6\text{–}50)$$

and

$$\bar{R}_\infty = \lim_{[L] \to \infty} \bar{R} = \frac{{K'_{dL}}^n}{L_0 {K_{dL}}^n + {K'_{dL}}^n} \quad (6\text{–}51)$$

The observed behavior of the distribution of conformations of spin-labeled glycogen phosphorylase *a* from *O. cuniculus* as a function of the occupation of the heterotropic allosteric sites in the enzyme by AMP^{2-} could also be described by Equations 6–48 and 6–49 (smooth curve in Figure 6–15),[68] with a value for L_0 of 3. When the MWC equation (Equation 6–35) was constrained by setting the value for L_0 at 3, this constrained equation could fit the data for cooperative binding of AMP^{2-} to the enzyme.

As the concentration of *N*-(phosphonacetyl)-L-aspartate is increased, the fractional changes in sedimentation coefficient of aspartate carbamoyltransferase coincide with those in the rate at which the enzyme is modified at its sulfanyl groups by 4-hydroxymercuribenzoate. It has already been noted that these fractional changes coincide with those in the absorbance of nitrotyrosines in the inactive catalytic α subunits or in the regulatory β subunits and those in the distribution of quaternary conformations detected at metallic ions distant from the active sites (Figures 6–14 and 6–16). The fractional changes in sedimentation coefficient and those in the rate at which the enzyme is modified by 4-hydroxymercuribenzoate can be fit with Equations 6–48 and 6–49.[75] All these observations taken together are consistent with the conclusion that each fractional change is equal to f_ξ, the fraction of the enzyme that has changed from the T conformation into the R conformation, The value for L_0 from this fit is 250, and this value can be inserted into the MWC equation for two reactants that each have a higher affinity for the R conformation than the T conformation. The resulting equation, constrained by fixing L_0, is able to fit both the cooperativity for the initial rate of the enzymatic reaction as a function of the concentration of L-aspartate at saturating concentrations of carbamoyl phosphate and the cooperativity for the initial rate of the enzymatic reaction as a function of the concentration of carbamoyl phosphate at saturating concentrations of L-aspartate. The equation also fits stimulation of the enzymatic activity by succinate (see Problem 6–5 for stimulation by maleate, an analogue of succinate), an effect that is a result of the cooperativity displayed by the enzyme.

As the active sites of fully deuterated aspartate carbamoyltransferase containing [2,3,3′,3′,3′,4,4-$^2H_7$, 5-$^{13}C^1H_3$]isoleucyl groups are filled with phosphonoacetamide, an analogue of carbamoyl phosphate, each pair of cross peaks in the two-dimensional **methyl-TROSY nuclear magnetic resonance spectra** either records only the transition from the T to the R conformation (Figure 6–13) or records both the transition from the T to the R conformation (a reciprocal change in amplitude) and the local conformational changes that accompany the occupation of the active sites (a change in chemical shift).[54] The changes in chemical shift (δ) of nine pairs of cross peaks in the nuclear magnetic resonance spectra that record the local conformational changes accompanying the occupation of the active site by phosphonoacetamide in the R and T conformations, respectively (Figure 6–11B,C), were measured. From the magnitudes of these changes in chemical shift, dissociation constants for phosphonoacetamide from the active sites of the R conformation (K_{dPAM} = 1.8 + 0.1 mM) and the T conformation (K'_{dPAM} = 3.8 + 0.3 mM) could be calculated (see Equations 3–297 and 3–303)

$$Y_{lig} = \frac{\delta_{obs} - \delta_{uo}}{\delta_{sat} - \delta_{uo}} = \frac{\Delta\delta}{\Delta\delta_t} = \frac{[ST]_{eq}}{K_{dL} + [ST]_{eq}} \tag{6–52}$$

These measurements are direct determinations of the dissociation constants that are independent of each other and do not rely on the MWC equation in any way. None of the titration curves for occupation of the active sites by phosphonoacetamide in the R conformation by itself or the T conformation by itself displays cooperativity, which is one of the assumptions in the derivation of the MWC equation. The value for L_{PAM}, the equilibrium constant for the conformational equilibrium when the active site of aspartate carbamoyltransferase occupied by phosphonoacetamide (PAM), estimated from the two-dimensional TROSY nuclear magnetic resonance spectra (Figure 6–13) is 3.4 ± 1.2. From K_{dPAM}, K'_{dPAM}, and L_{PAM} (see Equation 6–33), the equilibrium constant

$$L_0 = L_{PAM}\left(\frac{K'_{d,PAM}}{K_{d,PAM}}\right)^6 \tag{6–53}$$

can be estimated to be 300 ± 190, which is consistent with estimates of L_0 by sedimentation velocity (250).[75] The value for L_{PAM} (3.4 ± 1.2) also agrees, within the errors of measurement, with the value for L_{CAP} (6.8 ± 2.4)[76] derived from a titration of the enzyme saturated with carbamoyl phosphate (CAP) with succinate (Figure 6–4).

The conformations of aspartate carbamoyltransferase were followed by scattering of X-rays at small angles as the active enzyme consumed several different saturating concentrations of L-aspartate and carbamoyl phosphate until equilibrium was reached. Each individual time-resolved scattering curve could be fit by a linear combination of only the scattering curve of the R conformation and the scattering curve of the T conformation, which shift in their relative concentrations as the reaction progresses and the reactants decrease in concentration. There was **no indication of any other conformations**

throughout the course of the reaction.[77] This result is an actual observation of isosbestic behavior. A value for L_0 of 70 was determined by fitting measurements of the scattering of X-rays at small angles as a function of the concentration of *N*-(phosphonacetyl)-L-aspartate to Equations 6–48 and 6–49.[78]

All the foregoing observations demonstrate that, at least in the case of aspartate carbamoyltransferase from *E. coli*, the **cooperativity observed in its association with substrates and analogues of its substrates arises from the existence of two and only two quaternary conformations** that are in equilibrium with each other. They also demonstrate that the equilibrium between these conformations is shifted by thermodynamic linkage because the dissociation constants for both carbamoyl phosphate and L-aspartate from the R conformation are smaller than those from the T conformation. Aside from hemoglobin—where observations are complicated by the fact that it is an asymmetric $(\alpha\beta)_2$ tetramer—in no other protein that displays cooperativity have the correlations between quaternary conformations and cooperativity in its associations with ligands been examined so extensively as in aspartate carbamoyltransferase. It is still possible that there will be one, several, or many proteins that assume several asymmetric quaternary conformations and that the equilibrium among those several conformations will explain the cooperative behavior. At the moment, however, no other protein has been examined extensively enough to draw this conclusion.

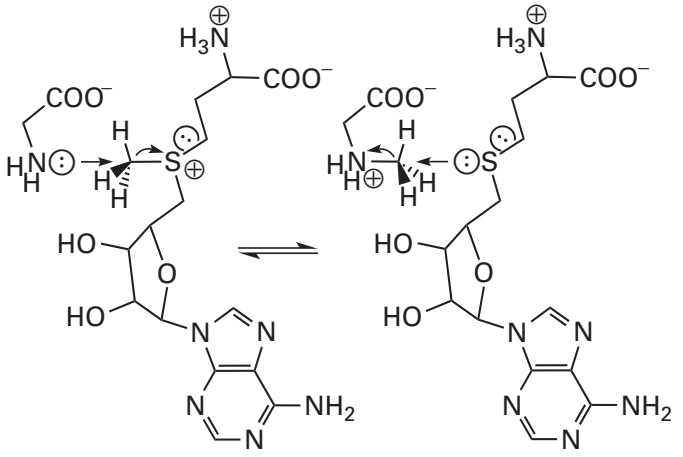
Cooperativity observed in measurements of the initial rate of a particular enzymatic reaction also can be explained by the existence of two rotationally symmetric quaternary conformations of the enzyme that differ in their affinity for substrate. The most unambiguous cases in which the explanation of cooperativity provided by the MWC equation can be applied are those in which cooperativity in the binding of ligands, such as molecular oxygen to hemoglobin (Figures 6–5 and 6–7) or succinate to aspartate carbamoyltransferase (Figures 6–4 and 6–14), rather than cooperativity in steady-state kinetics, is observed. This unambiguity results from the fact that differences in the dissociation constants for the binding of ligands to the T and R conformations produce the shift in the equilibrium constant between them. Consequently, cooperativity in these cases is not complicated by the effect of conformational changes on both rate constants and equilibrium constants. There are, however, far fewer measurements of cooperative association of a ligand than there are of cooperativity in the effects of the concentration of a reactant on the initial rates of enzymatic reactions, so some attention must be paid to these measurements of steady-state kinetics.

Suppose that a homooligomeric enzyme has two quaternary conformations and that each conformation has as many active sites as there are subunits. In each conformation, the respective active sites are formed by the same respective constellations of side chains, albeit in orientations altered by the conformational change. It is unlikely that the dissociation constants, the catalytic constants, and the specificity constants for reactants at the active sites will be the same in the two quaternary conformations of the enzyme. Suppose also, for the moment, that the equilibrium constant, L_0, between the R and T conformations is greater than 1 so that the concentration of the latter is greater than the concentration of the former in the absence of reactants; that the dissociation constant for one reactant is smaller in the R conformation than in the T conformation; and that the concentration of only that one reactant is varied. Because the dissociation constant from an active site in the R conformation for the one reactant that is being varied is smaller than that from an active site in the T conformation, as the concentration of that reactant is increased, its association with active sites on the enzyme will shift the equilibrium between the T and R conformations in favor of the latter. As that reactant occupies one or more active sites on each molecule of enzyme and the level of occupancy reaches the point at which most molecules have changed from the T to the R conformation, the catalytic constants and the specificity constants of the remaining active sites will be those of the R conformation.

The problem with assessing the behavior of the initial rate of the enzymatic reaction as a function of the concentration of that reactant is that even though the dissociation constant of the reactant must decrease upon the change in conformation, **the catalytic constants and the specificity constants for that reactant in the two conformations of the active site determine the initial rate for the enzymatic reaction at steady state, not its dissociation constant.** If association and dissociation of that reactant with the active site in both conformations are so rapid that the dissociation constant for that reactant from each conformation is its Michaelis constant, K_m, for that conformation and if the catalytic constant for both active sites is the same, then the initial rate of the enzymatic reaction as a function of the concentration of reactant will be directly proportional to

the occupation of the active site at equilibrium and will simply reflect the cooperative association of reactant. It has already been mentioned that, even with enzymes that do not have two different quaternary conformations, the Michaelis constant for a reactant is rarely its dissociation constant from an active site. Consequently, even though the cooperativity observed in the initial rate of the enzymatic reaction as a function of the concentration of reactant can be fit with Equation 6–36, this fact alone does not permit values to be assigned to the intrinsic dissociation constants and the catalytic constants for that reactant to two conformations of the enzyme from this fit, just as the value for a Michaelis constant in a situation in which cooperativity is not displayed cannot be assigned to the dissociation constant for reactant[79] even though it usually seems to the observer that it should be so and regardless of the units on the Michaelis constant. Nevertheless, cooperative behavior in the initial rate as a function of the concentrations of reactants requires that association of reactants be cooperative and that the cooperative association of reactant be manifest, even if indirectly, as the cooperative effect of its concentration on the enzymatic reaction. It is possible that cooperativity in enzymatic kinetics is so advantageous that natural selection promotes such a manifestation.

In a few instances, the cooperative **binding of a reactant to the otherwise unoccupied active site correlates satisfactorily with the cooperative effect** that its concentration has on the initial rate of the enzymatic reaction. For example, cooperative binding (Hill coefficient = 2.3) of *S*-adenosyl-L-methionine as a function of its concentration to the unoccupied active site of glycine *N*-methyltransferase (previously Equation 1–19)



(6–54)

from *Rattus norvegicus* corresponds within the error of measurement with the cooperative effect ($n_H = 2.3$) of its concentration on the initial rate of the enzymatic reaction at 2.0 mM glycine. The concentration of *S*-adenosylmethionine at which half the sites are occupied (50 μM) in the measurement of binding is also indistinguishable from the concentration (43 μM) at which the initial rate is half the limiting rate.[80] In this instance, the initial rate does seem to be registering only association of reactant with the active site.

Fructose 6-phosphate, in the absence of $MgATP^{2-}$, binds cooperatively to the active site of 6-phosphofructokinase (Equation 6–28) from *Saccharomyces cerevisiae*,[81] and the effect of the concentration of fructose 6-phosphate on the initial rate of the enzymatic reaction[82] also displays cooperativity (Figure 6–17C). The value for L_0 (12 ± 3) from a fit of the data for the binding of fructose 6-phosphate in the absence of $MgATP^{2-}$ (○) with the MWC equation and the value for L_{ATP} (20 ± 10) from a fit of the data for the initial rate of the enzymatic reaction (□) as a function of the concentration of fructose 6-phosphate in the presence of a subsaturating concentration of $MgATP^{2-}$ (0.15 mM) with the kinetic version of the MWC equation (Equation 6–36) are indistinguishable, within the margin of error, which may be due to the fact that $MgATP^{2-}$ does not bind cooperatively.[82] The value for the dissociation constant (0.1 ± 0.01 mM) of fructose 6-phosphate from the otherwise unoccupied R conformation of the enzyme obtained by the fit of the MWC equation to the data is somewhat smaller than the dissociation constant (0.25 ± 0.05 mM) for fructose 6-phosphate from the active site of the R conformation occupied by $MgATP^{2-}$ obtained from the fit of Equation 6–36 to the data, as might be expected from steric effects when the two reactants together occupy the active site.

In most instances, however, **the correlation between the cooperative binding of a reactant and the cooperative effect of its concentration on the enzymatic reaction is poor**. For example, the initial rate of 2-dehydropantoate 2-reductase

$$\text{NADPH} + \text{2-dehydropantoate} + \text{H}^+ \rightleftharpoons (R)\text{-pantoate} + \text{NADP}^+ \qquad (6\text{–}55)$$

from *Staphylococcus aureus* as a function of the concentration of NADPH displays cooperativity with a Hill coefficient of 2.5 ± 0.2, even though the enzyme

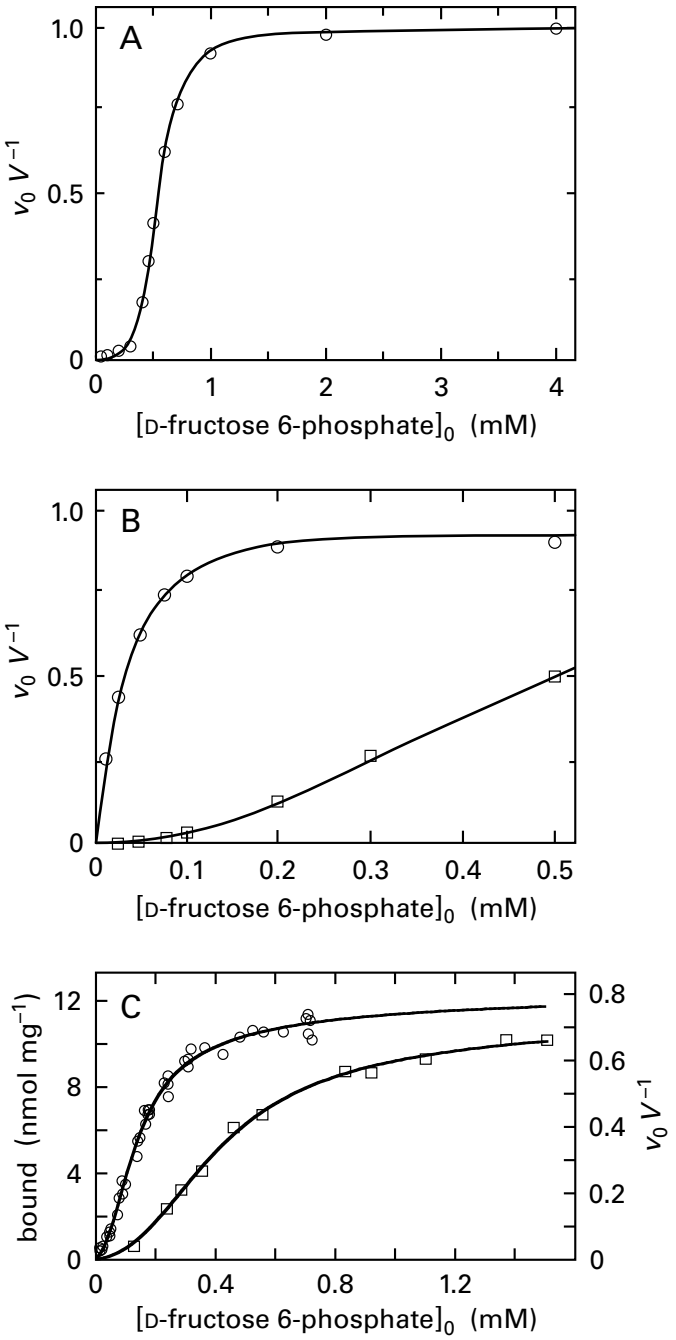


Figure 6–17: Cooperativity in the initial rates as a function of the concentration of D-fructose 6-phosphate and cooperativity in the binding of D-fructose 6-phosphate for 6-phosphofructokinase. (**A**) Cooperativity in the kinetics of 6-phosphofructokinase from *E. coli*.[84] The purified enzyme was assayed in 1 mM $MgATP^{2-}$, 10 mM $MgCl_2$, and 0.1 M 2-amino-2-hydroxymethylpropane-1,3-diol at pH 8.2 and 25 °C and at the noted concentrations of D-fructose 6-phosphate. Each initial rate of the reaction as a fraction of the limiting rate ($v_0\ V^{-1}$) is plotted as a function of the respective initial concentration of D-fructose 6-phosphate (millimolar). (**B**) Lack of cooperativity and induction of cooperativity by a heterotropic allosteric inhibitor in the kinetics of 6-phosphofructokinase from *G. stearothermophilus*.[26] The purified enzyme was assayed in 1 mM $MgATP^{2-}$, 10 mM $MgCl_2$, 5 mM NH_4Cl, 0.2 mM NADH, 10 μg mL^{-1} fructose-bisphosphate aldolase, 18 μg mL^{-1} triose-phosphate isomerase, 2.4 μg mL^{-1} glycerol-3-phosphate dehydrogenase, and 0.1 M 2-amino-2-hydroxymethylpropane-1,3-diol at pH 8.2 and at the noted concentrations of D-fructose 6-phosphate by coupling production of D-fructose 1,6-bisphosphate to the enzymatic reactions catalyzed by fructose-bisphosphate aldolase, triose-phosphate isomerase, and glycerol-3-phosphate dehydrogenase. The initial rates (v_0) of the reaction as a fraction of the limiting rate ($v_0\ V^{-1}$) are plotted as a function of the initial concentrations of D-fructose 6-phosphate (millimolar). Each initial rate was measured in either the absence (○) or presence (□) of 0.5 mM phospho*enol*-pyruvate, a heterotropic allosteric inhibitor of the enzyme. (**C**) Binding of D-fructose 6-phosphate to 6-phosphofructokinase from *S. cerevisiae* (left axis)[81] and the initial rate of the enzymatic reaction as a function of the initial concentration of D-fructose 6-phosphate (right axis).[82] The binding of D-fructose 6-[^{32}P]phosphate to the enzyme (○) was determined by equilibrating enzyme and substrate in 5 mM $MgSO_4$ and 50 mM imidazolium chloride at pH 7.2 and 20 °C and then forcing a portion of the solution through a membrane impermeant to the enzyme. The free concentration of D-fructose 6-[^{32}P]phosphate (F6P) was determined in the fluid passing through the membrane, and the total concentration was determined in the fluid that did not pass through. Each determination of bound D-fructose 6-[^{32}P]phosphate [nanomoles bound (milligram of protein)$^{-1}$] is plotted as a function of the respective free concentration of D-fructose 6-[^{32}P]phosphate, and the curve is a fit of Equation 6–35 to the data with $L_0 = 12 \pm 3$; $K_{dF6P} = 0.1 \pm 0.01$ mM; and $K'_{dF6P} > 10$ mM. The initial rates of the enzymatic reaction (□) were determined in 5 mM $MgCl_2$ at pH 7.1 with the concentration of $MgATP^{2-}$ fixed at 0.15 mM and the concentration of D-fructose 6-phosphate (F6P) varied. "Activity was normalized with respect to the calculated maximum activity." Each normalized activity is plotted as a function of the respective concentration of D-fructose 6-phosphate. The curve is a fit of Equation 6–36 to the data with $L_0 = 20 \pm 10$; $K_{dF6P} = 0.25 \pm 0.05$ mM; and $K'_{dF6P} > 100$ mM.

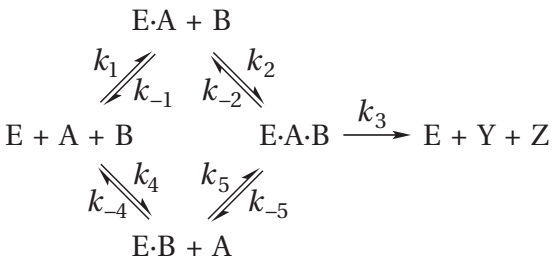
is an α_2 dimer in which each subunit has only one active site. Association of NADPH with the enzyme at equilibrium, in the absence of 2-dehydropantoate, is cooperative, but it has a Hill coefficient of only 1.3 ± 0.05. This discrepancy could be explained by a kinetic mechanism for the steady-state random bimolecular association of the two reactants (previously Equation 3–136)



(6–56)

in which the individual associations are not rapid enough to reach equilibrium as the reaction progresses. The rate equation for this mechanism (previously Equation 3–137)

$$v_0 = \frac{a[\mathrm{A}]_0[\mathrm{B}]_0 + b[\mathrm{A}]_0[\mathrm{B}]_0^2 + c[\mathrm{A}]_0^2[\mathrm{B}]_0}{d + e[\mathrm{B}]_0 + f[\mathrm{B}]_0^2 + g[\mathrm{A}]_0 + h[\mathrm{A}]_0^2 + i[\mathrm{A}]_0[\mathrm{B}]_0 + j[\mathrm{A}]_0[\mathrm{B}]_0^2 + l[\mathrm{A}]_0^2[\mathrm{B}]_0} \quad (6\text{–}57)$$

has terms in which the concentrations of reactants are squared, which can explain the greater cooperativity that is observed in the steady-state kinetics.[83]

At pH 8.2, 6-phosphofructokinase (Equation 6–28) from *E. coli* displays cooperativity in the effect of the concentration of the reactant fructose 6-phosphate on the initial rate of the enzymatic reaction at a fixed, saturating concentration of its other reactant, $MgATP^{2-}$ (Figure 6–17A).[19,84] This cooperativity, however, decreases to a Hill coefficient of 1 as the concentration of $MgATP^{2-}$ is decreased, a trend that is consistent with the fact that, in the absence of $MgATP^{2-}$, the binding of fructose 6-phosphate to the active site of the enzyme is not cooperative,[85] unlike the binding of fructose 6-phosphate to the active site of 6-phosphofructokinase from *S. cerevisiae* (Figure 6–17C). At pH 8.2, however, 6-phosphofructokinase from *G. stearothermophilus*, although it is quite similar to that of *E. coli* (55% identity; 0.3 gap percent), displays cooperativity in the effects of the concentration of fructose 6-phosphate on the initial rate of the enzymatic reaction only when phospho*enol*pyruvate, a heterotropic allosteric inhibitor of the enzyme,[28,86] is present as well as saturating concentration of $MgATP^{2-}$ (Figure 6–17B).[26] At pH 7.5, however, the enzyme displays cooperativity in the effects of fructose 6-phosphate on the initial rate in the absence of phospho*enol*pyruvate.[27]

Most enzymes have two or more reactants, and usually, as in the case of aspartate carbamoyltransferase or 6-phosphofructokinase from *E. coli,* **each reactant exerts an effect on the equilibrium** between the T and R conformations (Figure 6–13). As a result, it is difficult to correlate cooperativity in the binding of one reactant to the active site, in the absence of the other reactant or reactants, to the cooperativity observed in the kinetics.

In cases in which the Hill coefficient for the effect of the concentration of reactant on the initial rate of an enzymatic reaction is greater than the number of subunits in a homooligomer,[87] a reasonable explanation would be that rate-limiting steps for the reaction as it occurs on the T conformation are different from those for the reaction on the R conformation.

In the absence of a demonstration that the kinetics are governed only by dissociation constants of the reactants, the function describing the binding of reactant is the same as the function describing the effect of the concentration of that reactant on the initial rate of the enzymatic reaction. Dissociation constants derived from fitting Equation 6–36 to the data are probably illusory because the equation was derived on the assumption that the associations of reactants at steady state are always rapid enough to be at equilibrium. Nevertheless, **any cooperativity observed in kinetic measurements almost always arises, albeit indirectly, from differences in dissociation constants** of reactant from two or more quaternary conformations of the enzyme. Otherwise, reactants would have no effect on the conformation of the enzyme, and noncooperative, rectangularly hyperbolic kinetics would be observed.

In a few exceptional cases, cooperativity or apparent cooperativity in the effect of the concentration of reactant on the initial rate of an enzymatic reaction **arises from causes other than a homotropic allosteric mechanism resulting from changes in quaternary conformations.** For example, L-tryptophan is both a substrate and a heterotropic allosteric activator of tryptophan 2,3-dioxygenase from *Delftia acidovorans* because the reaction is the first step in the catabolism of this amino acid. The two roles of L-tryptophan were distinguished by using analogues. The competitive inhibitor 5-fluorotryptophan binds only at the active site,[88] while 2-methyltryptophan cannot bind at the active site but acts as a heterotropic allosteric activator at a separate site.[89] When a heterotropic allosteric site is saturated with 2-methyltryptophan, the initial rate of the enzymatic reaction is a rectangularly hyperbolic function of the concentration of L-tryptophan; and in the absence of 2-methyltryptophan, the binding of 5-fluorotryptophan to the active site is a rectangularly hyperbolic function of its concentration. In the absence of either 5-fluorotryptophan or 2-methyltryptophan,

however, the initial rate of the enzymatic reaction as a function of the concentration of L-tryptophan displays positive deviation from hyperbolic behavior. An explanation for this behavior consistent with all the facts is that the positive deviation arises because, as the active sites become occupied, heterotropic allosteric sites also become occupied. As a result, the initial rate at higher concentrations of L-tryptophan is greater than those predicted from the initial slope of the curve at concentrations of L-tryptophan where the site for the activator is vacant. This explanation does not invoke homotropic cooperativity among active sites, only a heterotropic allosteric effect between the active site and the site for binding the effector.

In the case of glucokinase from *R. norvegicus*, which is a monomeric enzyme, the apparent cooperativity in the effect of the concentration of D-glucose on the enzymatic reaction arises from the fact that there is a transition from an inactive to an active form of the enzyme that is slower (2–10 min) than the period of time over which the initial rates were measured. Because this transition is accelerated by high concentrations of D-glucose, the initial rate of the enzymatic reaction increases more than it should have if it were only association of D-glucose with one form of the singular active site that was governing the initial rate. When the enzyme is preincubated with high concentrations of D-glucose or with the simple competitive inhibitor *N*-acetylglucosamine, the cooperativity is eliminated.[90] When association of D-glucose with the enzyme is measured under conditions in which each measurement at each concentration of D-glucose is made only after equilibrium is achieved, the association shows no cooperativity.[91] The slow conformational change responsible for the aberrant behavior has been assigned to a loop of 30 amino acids that closes over the active site. In the unoccupied enzyme, the loop is disordered, and the transition between the disordered and ordered states is slow as D-glucose associates with the active site and the loop closes over it. A mutant of the enzyme in which four amino acids in this loop have been switched no longer displays cooperativity in its initial rate as a function of the concentration of D-glucose.[91]

An actual artifact is observed with glycine hydroxymethyltransferase (see Equation 2–10)

$$\text{tetrahydrofolate} + \text{L-serine} \rightleftharpoons H_2O + \text{glycine} + \text{5,10-methylenetetrahydrofolate} \quad (6\text{–}58)$$

from *O. cuniculus*. Originally, it was observed that the initial rate of the enzymatic reaction, as a function of the concentration of the reactant tetrahydrofolate, appeared to display cooperativity. It was later demonstrated that this observation was artifactual and arose from instability of the tetrahydrofolate at low concentrations.[92] As a result, the actual concentrations of reactant in the lower range were less than the nominal concentrations, causing the initial rates measured in this range to be lower than they should have been. At higher concentrations, the tetrahydrofolate was stable, and the initial rates measured in this range were accurate but higher relative to those at the lower concentrations.

Most instances of positive deviations from ideal behavior in association of reactants during measurements of initial rate of an enzymatic reaction, however, probably do involve homotropic allosteric processes.

As the kinetics of the enzymatic reaction catalyzed by phosphofructokinase (Equation 6–28) from *G. stearothermophilus* (Figure 6–17B) illustrate, heterotropic allosteric effectors often cause cooperativity in the effects of the concentration of a reaction to appear, and heterotropic allosteric effectors can also cause cooperativity to disappear (Figure 6–3). As might be expected, these materializations and dematerializations result from the ability of heterotropic allosteric effectors to shift the equilibrium between two or more conformations of the protein. This behavior begs the question of how homotropic and heterotropic allosteric effects are related to each other and whether or not the same conformational changes are responsible for both effects. As might be expected, the answer to these questions depends on the enzyme being examined.

Problem 6–1: Derive Equation 6–5 from Equation 6–3 and the conservation of protein.

$$[P] + [P{\cdot}L_n] = [P]_t$$

Problem 6–2: Derive Equation 6–11 from Equation 6–10 and the conservation of protein.

Problem 6–3: Derive Equation 6–42 from Equation 6–35 and the binomial theorem.

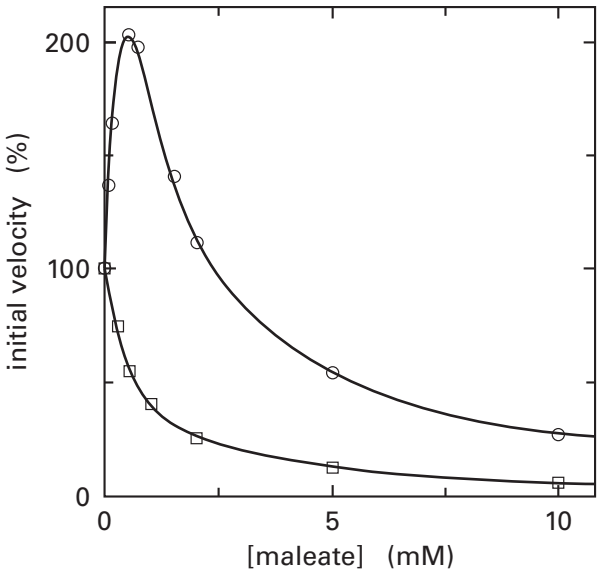
Problem 6–4: The mean hemoglobin concentration in the blood of adult human males is 157 g L^{-1}.

(A) Find the molar masses of human α polypeptide, human β polypeptide, and heme B, and calculate the molar concentration of sites for binding of molecular oxygen in the blood of an average adult male.
(B) The capacity of the blood used in the measurements of Figure 6–5 for binding O_2 at saturation, by extrapolation, is 191 mL of O_2 (liter of blood)$^{-1}$. Calculate the capacity of this blood from C. G. Douglas in units of moles of O_2 (mole of heme)$^{-1}$.
(C) What percent of the hemes are binding O_2 if the hemoglobin concentration of the blood of C. G. Douglas were that of the average male?
(D) What might cause this number to be different from 100%?

Problem 6–5: The enzymatic rate of the reaction catalyzed by aspartate carbamoyltransferase is a sigmoid function of the L-aspartate concentration at saturating carbamoyl phosphate (Figure 6–3).

(A) Write a series of linkage boxes to describe the binding of each of the six aspartates to the enzyme and to explain the observed cooperativity. Remember to indicate the statistical corrections.

Maleate is an inhibitor of aspartate carbamoyltransferase that is competitive with L-aspartate. The following behavior was observed when maleate was added to the enzyme along with L-aspartate.



Activation and inhibition of aspartate carbamoyltransferase from *E. coli* by maleate, an analogue of L-aspartate.[93] The reaction mixtures contained 3.6 mM carbamoyl phosphate, 1.0 mM L-aspartate, 0.04 M potassium phosphate at pH 7.0, maleate at the concentrations indicated, and 0.4 μg mL^{-1} native aspartate carbamoyltransferase (○) or 0.2 μg mL^{-1} heated aspartate carbamoyltransferase (□). Heated aspartate carbamoyltransferase was prepared by heating native aspartate carbamoyltransferase at a concentration of 20 μg mL^{-1} in 4 mM potassium phosphate buffer at pH 7.0 and 60 °C for 4 min, followed by rapid cooling in an ice–water bath. The initial rates of enzymatic assays (percent of control) are presented as a function of the concentrations of maleate (millimolar). Note the concentration of L-aspartate and where this concentration falls on the curve in Figure 6–3.

(B) Where approximately is the enzyme in the linkage boxes before maleate is added?
(C) Why does the maleate first stimulate enzymatic activity?
(D) Why does it eventually inhibit enzymatic activity?
(E) What has happened during the heat treatment described in the legend to the figure?

Heterotropic Allosteric Control

A heterotropic allosteric effector is a ligand that acts by associating with a protein or enzyme at a site different from a site for binding another ligand or an active site and altering association of ligands or substrates with this other site or its steady-state kinetics. Consequently, the ultimate decision on whether or not a ligand is a heterotropic allosteric effector is **made crystallographically**. For example, 6-phosphofructokinase (Equation 6–28) from *E. coli* is activated by $MgADP^-$ and $MgGDP^-$ so that, as levels of nucleoside diphosphates rise, glycolysis will accelerate to replenish the levels of nucleoside triphosphates. The enzyme is inhibited by phospho-

*enol*pyruvate[19] so that as levels of this indicator of glycolytic flux rise, the flow of D-fructose 6-phosphate into glycolysis will decrease. The enzyme is an α_4 homotetramer that has been examined extensively by crystallography. The four symmetrically arrayed active sites with which the reactants $MgATP^{2-}$ and D-fructose 6-phosphate associate are distinct and well-separated from the four symmetrically arrayed sites with which heterotropic allosteric effectors associate (Figure 6–9). There is little doubt that both the activation and the inhibition of the enzyme are allosteric.

The enzymatic activity of aspartate carbamoyltransferase (Equation 6–1) from *E. coli* is modulated by nucleoside triphosphates (Figure 6–3). When both $MgCTP^{2-}$ and $MgUTP^{2-}$ are present in solution, the enzyme is inhibited,[94-96] and when both $MgATP^{2-}$ and $MgGTP^{2-}$ are present in solution, the enzyme is activated. That $MgATP^{2-}$ and $MgGTP^{2-}$ are heterotropic allosteric effectors of aspartate carbamoyltransferase follows from the fact that the allosteric site to which they bind is on a different subunit from the one on which the active site resides. Because $MgCTP^{2-}$ and $MgUTP^{2-}$ bind to the same allosteric site at which $MgATP^{2-}$ and $MgGTP^{2-}$ bind,[9] they are also heterotropic allosteric effectors of the enzyme.

When an inhibitor of an enzymatic reaction competes with one of its reactants, a crystallographic decision on whether or not it is a heterotropic allosteric inhibitor is even more important. In particular, in situations where the end product of a metabolic pathway is a competitive inhibitor that does not seem to resemble the reactant with which it competes, the usual impulse is to assume that heterotropic allosteric inhibition is occurring. The dissimilarity of the inhibitor from the substrates, however, cannot be used as an argument that it is a heterotropic allosteric inhibitor. Nor can a decision that the inhibitor is acting at the active site be made from steady-state kinetic measurements demonstrating that the inhibitor is a competitive inhibitor, which would normally be taken as evidence that the inhibitor is competing with the reactant for occupation of the active site. The **definitive decision whether the observed competitive inhibition results from association of the inhibitor with the active site or from heterotropic allosteric inhibition** is also ultimately made by crystallography. Such decisions have been made for a number of inhibitors. For example, mevalonate kinase

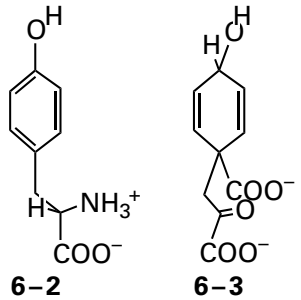
$$MgATP^{2-} + (R)\text{-mevalonate} \rightleftharpoons H^+ + (R)\text{-5-phosphomevalonate} + MgADP^- \quad (6\text{–}59)$$

catalyzes an early step in the metabolic pathway for biosynthesis of (2*Z*,6*Z*)-farnesyl diphosphate. In crystallographic molecular models of the enzyme from *R. norvegicus*, it has been observed that farnesyl diphosphate, which is a competitive inhibitor of the human enzyme[97] with respect to $MgATP^{2-}$, which it does not resemble very closely, nevertheless associates with the active site of the enzyme. The diphosphate of (2*Z*,6*Z*)-farnesyl diphosphate overlaps the subsite with which the triphosphate of $MgATP^{2-}$ associates, and the triisoprenoid portion of (2*Z*,6*Z*)-farnesyl diphosphate overlaps the subsite with which the adenosyl group of $MgATP^{2-}$ associates.[98] Consequently, farnesyl diphosphate is not a heterotropic allosteric inhibitor.

L-Lysine is a competitive inhibitor of homocitrate synthase from *S. cerevisiae* with respect to 2-oxoglutarate[99]

$$\text{acetyl-SCoA} + H_2O + \text{2-oxoglutarate} \rightleftharpoons H^+ + \text{HSCoA} + (R)\text{-2-hydroxybutane-1,2,4-tricarboxylate} \quad (6\text{–}60)$$

which it does not resemble very closely. The enzyme catalyzes the first committed step in biosynthesis of L-lysine. L-Lysine associates with the active site of the enzyme from *Schizosaccharomyces pombe* (72% identity; 0 gap percent) at a location that almost completely overlaps that occupied by 2-oxoglutarate.[100] L-Tyrosine (**6–2**) inhibits prephenate dehydrogenase from *Aquifex aeolicus*, the first committed step in its biosynthesis, by occupying the same location in the active site occupied by the reactant prephenate (**6–3**)



6–2 **6–3**

which it does resemble.[101]

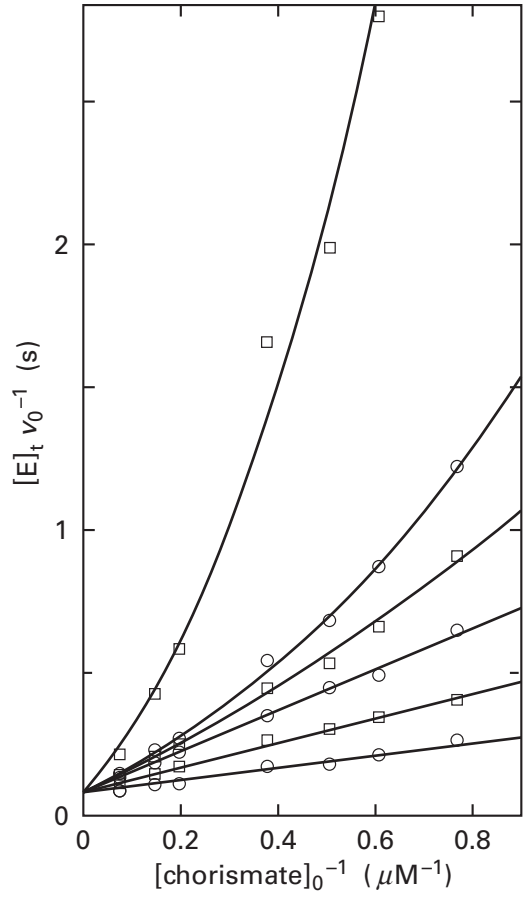


Figure 6–18: Competitive heterotropic allosteric inhibition of anthranilate synthase from *S. typhimurium* by L-tryptophan.[104,105] Solutions contained 20 mM L-glutamine, 10 mM MgCl, various concentrations of chorismate, various concentrations of L-tryptophan, and 0.1 M potassium phosphate at pH 7.0 and 25 °C. The reaction was initiated by adding anthranilate synthase, and the rate of production of anthranilate was followed fluorometrically (λ_{ex} = 308 nm; λ_{em} = 388 nm) over the first few minutes to obtain initial rates. The initial rates were converted to unit of second^{-1}. The reciprocal of each initial rate (v_0^{-1} in seconds) is plotted as a function of the respective reciprocal of the initial concentration of chorismate (micromolar^{-1}) at six fixed concentrations of L-tryptophan: in ascending order of the curves, 0, 2.5, 5.0, 7.5, 10, and 20 μM. The lines and curves are drawn by hand.

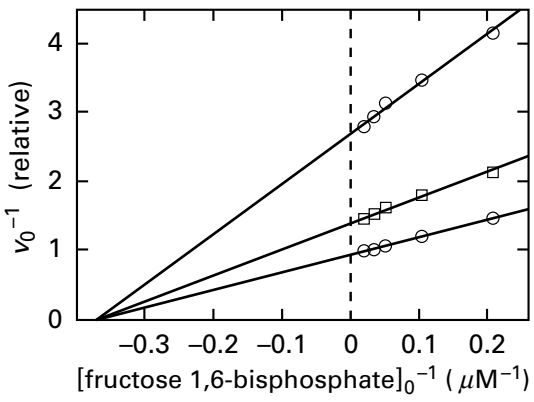
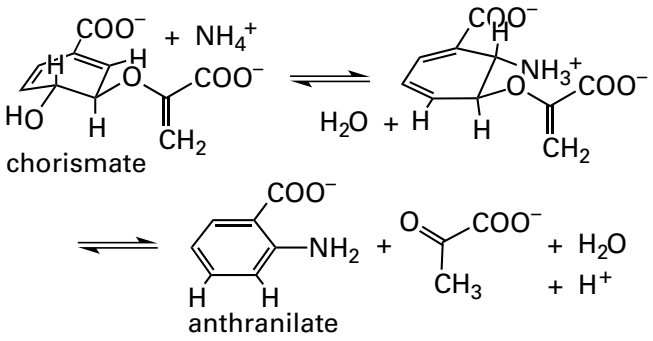


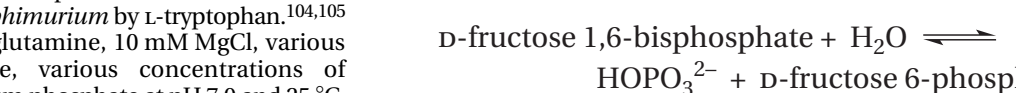
Contrariwise, **a heterotropic allosteric inhibitor is often a competitive inhibitor** even though the site with which it associates is well-removed from the active site. For example, the inhibition of anthranilate synthase (previously Equation 5–85)



(6–61)

from *Salmonella typhimurium* by L-tryptophan, which is known from crystallographic observations to be a heterotropic allosteric inhibitor,[102,103] is competitive with respect to chorismate (Figure 6–18).[104,105]

When acting to control metabolism, **direct competitive inhibition at an active site and heterotropic allosteric inhibition are not mutually exclusive.** For example, fructose 2,6-bisphosphate inhibits fructose-bisphosphatase



(6–62)

Figure 6–19: Noncompetitive heterotropic allosteric inhibition of fructose-bisphosphatase from *R. norvegicus* by AMP^{2-} with respect to the reactant D-fructose 1,6-bisphosphate.[108] Solutions contained 0.15 mM $NADP^+$, 20 mM 2-sulfanylethanol, 10 mM $MgSO_4$, 2 μmol min^{-1} mL^{-1} D-glucose-6-phosphate isomerase, 0.3 μmol min^{-1} mL^{-1} D-glucose-6-phosphate dehydrogenase ($NADP^+$), fructose-bisphosphatase, and 50 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol chloride at pH 7.5 and 30 °C. Each reaction was initiated by adding one of several concentrations of D-fructose 1,6-bisphosphate, and the rate of production of D-fructose 6-phosphate was followed by coupling it to production of NADPH (λ_{max} = 339 nm) by the use of D-glucose-6-phosphate isomerase and D-glucose-6-phosphate dehydrogenase ($NADP^+$). The reciprocal of each initial rate (v_0^{-1} relative to the limiting rate of the enzymatic reaction in the absence of inhibitor) is plotted as a function of the respective reciprocal of the initial concentration of D-fructose 1,6-bisphosphate (micromolar^{-1}) at three fixed concentrations of the heterotropic allosteric inhibitor AMP^{2-}: in ascending order of the curves, 0, 80, and 160 μM. The lines are drawn by hand, so as to converge at a point on the axis of the abscissa.

from *R. norvegicus*[106] by associating with the active site in place of the reactant D-fructose 1,6-bisphosphate[107] while AMP^{2-}, a noncompetitive inhibitor of the enzyme (Figure 6–19),[108,109] associates at a heterotropic allosteric site.

Crystallographic observations have shown that heterotropic allosteric sites can be located almost anywhere in an enzyme relative to its active site. They can be well within the same subunit in which the active site is located, as is the case for glycogen phosphorylase *b* from *O. cuniculus* (Figure 6–20)[110,111] and anthranilate synthase (Equation 6–61) from *Serratia marcescens*.[103] They can be adjacent to or within the symmetrically arrayed interfaces between the subunits of a homooligomer, as is the case for

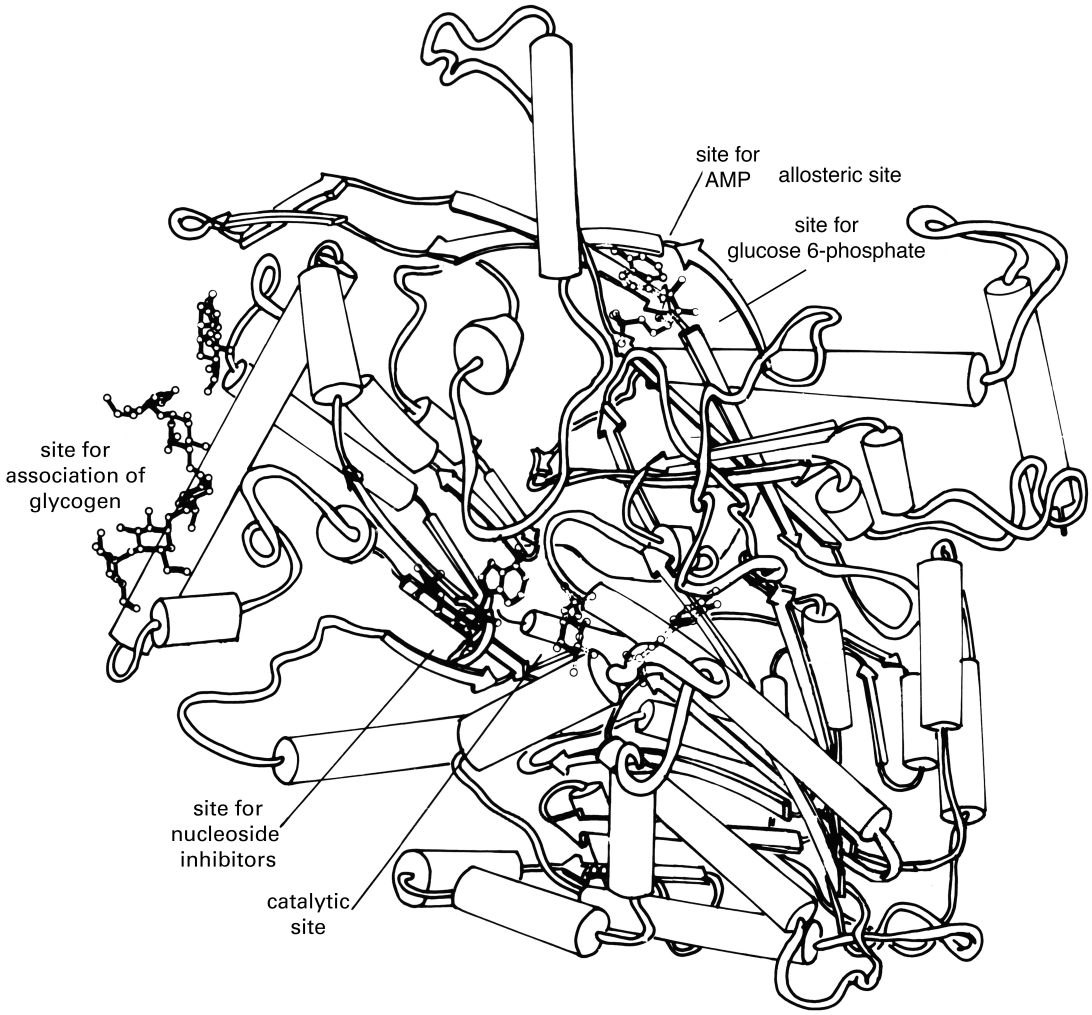


Figure 6–20: Schematic drawing of the crystallographic molecular model of one subunit of glycogen phosphorylase *b* from *O. cuniculus*, indicating all sites for the various heterotropic allosteric effectors.[110] The drawing summarizes a large number of crystallographic studies in which data sets from various liganded forms of the crystalline enzyme were used to provide maps of electron density or difference electron density. In these studies, the crystals were often stabilized by crosslinking to prevent them from shattering as a result of the conformational changes promoted by the binding of certain ligands. Although this shortcut placed in question whether the observed changes in conformation were indicative, it did allow the various binding sites for ligands to be identified. In the drawing, AMP^{2-} is shown bound at the site for heterotropic allosteric effectors. D-Glucose 6-phosphate (not drawn), an allosteric inhibitor, binds next to AMP^{2-} in the site for allosteric effectors. Maltoheptaose, portions of which were not resolved in the respective map of electron density, is shown bound at the site for association of glycogen. D-Glucose 1-phosphate and pyridoxal phosphate are shown bound at the catalytic site. The site for nucleoside inhibitors is occupied by AMP^{2-}. Reprinted with permission from reference 110. Copyright 1984 Portland Press, Ltd. https://doi.org/10.1042/bj2180045

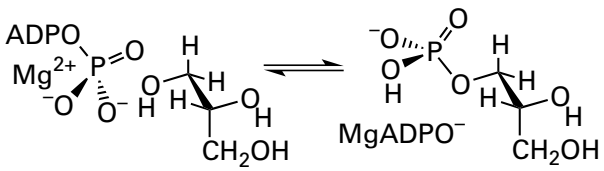
glycogen synthase from *S. cerevisiae*,[112] acetylglutamate kinase from *Thermotoga maritima*,[113] and 6-phosphofructokinase (Figure 6–9). They can reside upon a twofold rotational axis of symmetry within a homooligomer* as do the sites for the pseudosymmetric molecule fructose 1,6-bisphosphate in both L-lactate dehydrogenase from *B. longum*[42] and glycerol kinase (previously Equation 4–283)



(6–63)

from *E. coli*.[114]

Heterotropic allosteric sites can be located on a regulatory domain within the subunit comprising a homooligomer, distinct from the catalytic domain in which the active site is located, but in the same folded polypeptide, as is the case for sulfate adenylyltransferase from *Penicillium chrysogenum*,[115] porcine fructose-1,6-bisphosphatase,[36] and phosphoglycerate dehydrogenase from *E. coli*.[116,117] In fructose-1,6-bisphosphatase, the regulatory domain (201 aa) is larger than the catalytic domain (137 aa); but in phosphoglycerate dehydrogenase, the regulatory domain (92 aa) is smaller than the catalytic domain (300 aa). Heterotropic allosteric sites can be located on regulatory β subunits in an $(\alpha\beta)_n$ heterooligomer in which the active sites are on the catalytic α subunits, as is the case for aspartate carbamoyltransferase (Figure 6–2) and ATP phosphoribosyltransferase from *Psychrobacter arcticus*.[118] In the former instance, the regulatory subunit (153 aa) is smaller than the catalytic subunit (311 aa); in the latter, the regulatory subunit (387 aa) is larger than the catalytic subunit (231 aa).

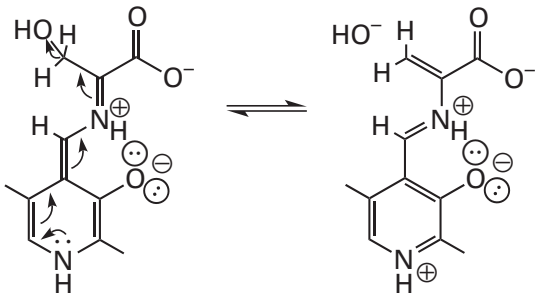
Finally, catalytic α subunits and regulatory β subunits can be loosely associated rather than tightly associated. Each can comprise a separate homooligomeric protein, and these two distinct homooligomers can be unassociated with each other in some circumstances but form an allosterically regulated heterooligomer in other circumstances, as is the case for acetolactate synthase[119-121] and bovine cyclic-AMP-dependent non-specific serine/threonine protein kinase.[122,123] In the case of acetolactate synthase from *S. cerevisiae*, the regulatory protein is a β_8 homooctamer with 422(D_4) rotational symmetry with which four catalytic α_2 homodimers can associate to form the regulated $(\alpha_2)_4\beta_8$ heterohexadecamer. Each twofold rotational axis of symmetry in the four catalytic homodimers coincides with a pair of perpendicular twofold rotational axes of symmetry in the homooctamer.[124]

In heterooligomers containing equal numbers of two different subunits, in which one type of subunit contains the active site for an enzymatic activity and the other contains the active site for a different enzymatic activity rather than a site with which a heterotropic allosteric effector can associate, the progress of catalysis in one active site can be coordinated with that in the other by a heterotropic allosteric effect. For example, in tryptophan synthase (previously Equation 3–523)

1-*C*-(indol-3-yl)glycerol 3-phosphate + L-serine $\rightleftharpoons$ L-tryptophan + D-glyceraldehyde 3-phosphate + H_2O

(6–64)

the indole-3-glycerol-phosphate lyase activity, catalyzed by the active site on an α subunit, must be coordinated with the tryptophan synthase (indole-salvaging) activity, catalyzed by the active site on the β subunit to which it is connected, because the former produces the indole that passes through the tunnel between them before it can used by the latter. One way in which this coordination is accomplished is that formation of the pyridoximines of 2-aminoacrylate from serine (see Equation 2–13)



(6–65)

at the active site for tryptophan synthase (indole-scavenging) on a β subunit increases the rate for production of indole at the active site for indole 3-glycerol-phosphate lyase on the α subunit to which it is connected 150-fold.[125] It has been demonstrated crystallographically[126] and by nuclear magnetic resonance spectroscopy of fluorinated analogues of substrates for indole-3-glycerol-phosphate lyase[127] that formation of the pyridoxime of 2-aminoacrylate

*In such instances, there are half as many sites for binding the allosteric ligand as there are subunits in the oligomer.

promotes a quaternary conformational change of the heterooligomer, closing both the active site for tryptophan synthase (indole-scavenging) and the active site for indole-3-glycerol-phosphate lyase around their respective reactants, which leads to an increase in overall enzymatic activity. Another way the coordination is accomplished is that association of substrates and analogues of substrates with an active site for indole-3-glycerol-phosphate lyase on an α subunit increases the affinity for L-serine for the active site for tryptophan synthase (indole-scavenging) on the β subunit to which it is connected and shifts the equilibria among the intermediates at this active site in favor of the pyridoximine of 2-aminoacrylate.[128-130] The quaternary conformational change that accomplishes this heterotropic allosteric effect has also been described crystallographically.[131]

One of the more surprising crystallographic observations is that **the same allosteric site can associate in turn with both a heterotropic allosteric activator and a heterotropic allosteric inhibitor of the enzyme.** In such instances, both heterotropic allosteric inhibition and heterotropic allosteric activation originate from the same site. For example, in the case of aspartate carbamoyltransferase, the same site on a regulatory β subunit associates at the same location with a complex of one CTP^{4-}, one UTP^{4-}, and one Mg^{2+} ($CTP{\cdot}Mg{\cdot}UTP^{6-}$), which leads to heterotropic allosteric inhibition, and with a complex of two ATP^{4-} and one Mg^{2+}($ATP{\cdot}Mg{\cdot}ATP^{6-}$), which leads to heterotropic allosteric activation (Figure 6–3). In both instances, the Mg(ribosyl 5′-triphosphate)$_2^{6-}$ portion of the respective complex occupies exactly the same location in the allosteric site while the bases occupy slightly different locations that nevertheless overlap.[9] In chorismate mutase from *S. cerevisiae*, the heterotropic allosteric inhibitor L-tyrosine and the heterotropic allosteric activator L-tryptophan associate with the same allosteric site. Their carboxy groups, their amino groups, and their α and β carbons occupy identical locations, but the locations occupied by the 4-hydroxyphenyl group and the indolyl group, respectively, only partially overlap (Figure 6–21).[132,133]

A heterotropic allosteric inhibitor and a heterotropic allosteric activator can occupy the same allosteric site even when the inhibitor and activator are much **less similar to each other**. For example, the allosteric site in glycogen phosphorylase (previously Equation 5–122)

$$[(1\rightarrow4)\text{-}\alpha\text{-D-glucosyl}]_n + HOPO_3^{2-} \rightleftharpoons [(1\rightarrow4)\text{-}\alpha\text{-D-glucosyl}]_{n-1} + \alpha\text{-D-glucose 1-phosphate} \quad (6\text{–}66)$$

from *O. cuniculus* binds both AMP^{2-}, a heterotropic allosteric activator of the enzyme, and D-glucose 6-phosphate, a heterotropic allosteric inhibitor. Phospho groups of the effectors occupy the same location in the site, so their association is mutually exclusive, but the glucosyl and adenosyl groups occupy different locations in the respective complexes.[110] In the case of 6-phosphofructokinase from *G. stearothermophilus* (see Figure 6–9),[28,86] the heterotropic allosteric inhibitor phospho*enol*pyruvate associates with the same site as the heterotropic allosteric activator $MgADP^-$. The phospho group of phospho*enol*pyruvate occupies the same location as the β-phospho group of $MgADP^-$, and the carboxylato group of phospho*enol*pyruvate, occupies the same location as the α-phospho group of $MgADP^-$.

In ribonucleoside-diphosphate reductase, $dATP^{4-}$, ATP^{4-}, $dGTP^{4-}$, and $dTTP^{4-}$, as heterotropic allosteric inhibitors and heterotropic allosteric activators, bind to two distinct allosteric sites on the protein.[134] Depending upon what nucleotides are in which sites, the catalytic constant for the enzyme is increased or decreased and the relative values of the specificity constants for the reactants, ADP^{3-}, GDP^{3-}, UDP^{3-}, and CDP^{3-} are determined.[135] In this way, the concentrations in the cytoplasm of the four deoxyribonucleotides, which are the precursors of DNA, are balanced.

So far, the only explanation of heterotropic allosteric effects that can reproduce the observed behavior and explain how association of an effector at a distant site is able to affect catalysis at the active site is that there are two or more conformations of the enzyme, each of which has different steady-state rate constants for the enzymatic reaction and each of which has different dissociation constants for heterotropic allosteric effectors. The fact that each heterotropic allosteric effector for a particular enzyme can shift the equilibrium between the two or more conformations by thermodynamic linkage is the reason that the steady-state kinetics of the enzyme change in the presence of that effector.

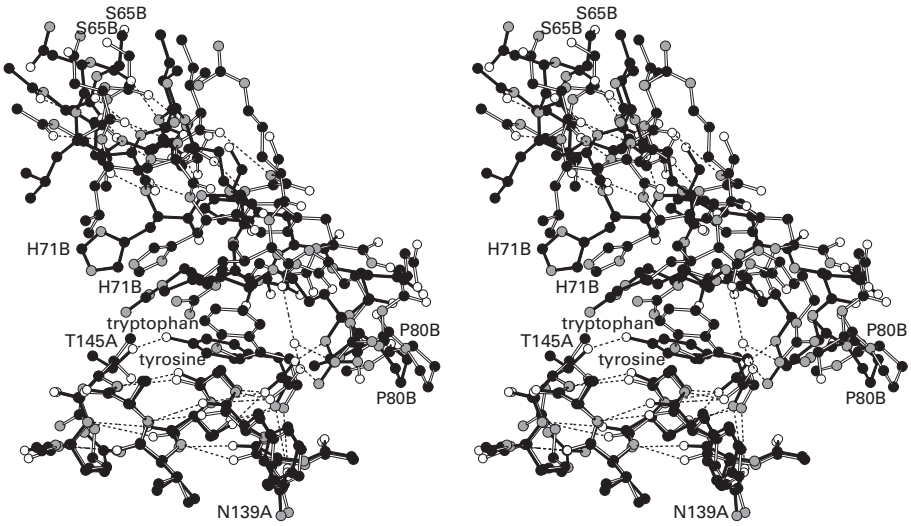


Figure 6–21: Stereodrawings[485] of crystallographic molecular models of the allosteric site on chorismate mutase from *S. cerevisiae* that associates with both the heterotropic allosteric inhibitor L-tyrosine and the heterotropic allosteric activator L-tryptophan.[132,133] Black atoms are carbons, white atoms are oxygens, and gray atoms are nitrogens. The portion of the molecular model with L-tryptophan bound in the site is designated by white bonds, and the portion of the molecular model of the enzyme with L-tyrosine bound in the site is designated by black bonds. The two sites in each dimer of the enzyme both lie in the interface between its two subunits, and they are related to each other by a twofold rotational axis of symmetry running through the interface. Amino acids from Asparagine 139 to Arginine 146 comprise the portion of the lower subunit in the drawing and are labeled with the letter A. Amino acids from Leucine 64 to Proline 80 comprise the portion of the upper subunit in the drawing and are labeled with the letter B. Because the heterotropic allosteric activator L-tryptophan associates preferentially with the R conformation and the heterotropic allosteric inhibitor L-tyrosine associates preferentially with the T conformation, the enzyme crystallized in the R conformation when L-tryptophan was present in the solution but in the T conformation when L-tyrosine was present in the solution. The two different crystallographic molecular models, those of the R and T conformations, were aligned by superposing the α helices formed by Asparagine 139A to Arginine 146A from the two models. When these α helices are superposed, it can be seen that the upper subunit, both its α helix and the loop following the α helix, shifts back and to the left when the conformation changes from the R to the T conformation. Only hydrogen bonds that lie within the α helices are drawn in order to highlight those α helices. The many hydrogen bonds cementing the α-amino group and the carboxy group of each bound amino acid in the site are also drawn. It can be seen that the same amino acids supply those hydrogen bonds in each conformation, with the exception of the intercession of a molecule of water between the side chain of Arginine 75B and the carboxy group of L-tryptophan in the R conformation.

Each of the two or more distinct conformations of an enzyme, the equilibrium among which is being controlled by the differences in dissociation constants for association of a heterotropic allosteric effector, usually is a **rotationally symmetric quaternary conformation**. The control exerted by a heterotropic allosteric effector arises from its association in turn with as many identical heterotropic allosteric sites as there are asymmetric units in the symmetric homo-oligomer of a particular quaternary conformation. Both the control of conformational changes by the thermodynamic linkage between the conformational equilibrium and association of heterotropic allosteric effectors and the multimolecularity of the various associations of both effectors and reactants for the enzyme often cause the binding of several molecules of effector or reactant to be cooperative and display sigmoid behavior. This cooperativity, however, that usually accompanies heterotropic allosteric inhibition and activation complicates the explanation of the observed heterotropic allosteric effects in isolation.

For the moment, it will be assumed that there are only two conformations of the enzyme controlled by heterotropic allosteric effectors. Historically, the conformation from which a heterotropic allosteric inhibitor has the smaller dissociation constant has been designated T and the conformation from which a heterotropic allosteric activator has the smaller dissociation constant has been designated R.[133] These designations, perhaps by design and often in the absence of any experimental validation, conflate the symmetric quaternary conformational changes responsible for cooperativity in the behavior of association of substrates and cooperativity of the initial rate of the enzymatic reaction as a function of the concentration of a reactant with the two conformations responsible for heterotropic allosteric effects. There is, however, no necessary connection between heterotropic allosteric effects and cooperative effects. To avoid this conflation, for the moment, even though it may seem strange to those used to it, the inhibited conformation from which a heterotropic allosteric inhibitor has the smaller dissociation constant will designated the **H conformation**, the in**H**ibited conformation, and the activated conformation from which a heterotropic allosteric activator has the smaller dissociation constant will be designated the **V conformation**, the acti**V**ated conformation.

The fact that, in many cases, a heterotropic allosteric inhibitor and a heterotropic allosteric activator associate with the same site is inconsequential to their ultimate effects on the equilibrium between the H and V conformations. The consequential facts are that the inhibitor has a higher affinity for that site when the enzyme is in the H conformation than when it is in the V conformation and that the activator has a higher affinity for that site when the enzyme is in the V conformation than when it is in the H conformation. All that is necessary is for the activator and inhibitor to be different enough from each other that the affinity of the site for activator increases and the affinity of the site for inhibitor decreases when the H changes to the V conformation. The structure of the allosteric site in chorismate mutase from *S. cerevisiae* in the H conformation when the heterotropic allosteric inhibitor L-tyrosine is associated with it and the structure of the same site in the V conformation when the heterotropic allosteric activator L-tryptophan is associated with it (Figure 6–21) comprise an example of this principle. The conformational change in the structure of the allosteric site when the H becomes the V conformation is able to increase significantly the dissociation constant of L-tyrosine, the heterotropic allosteric inhibitor, and decrease significantly the dissociation constant of L-tryptophan, the heterotropic allosteric activator, and vice versa. In this instance, the only ligands associated with the conformations in the respective crystals were L-tyrosine and L-tryptophan, so the situation is not complicated by the presence of any substrates for the enzyme.

One explanation is that heterotropic allosteric inhibition is based on the ability of a heterotropic allosteric inhibitor to shift the equilibrium from a V to an H conformation and that heterotropic allosteric activation is based on the ability of a heterotropic allosteric activator to shift the equilibrium from an H to a V conformation. If this explanation is to apply to the general case of heterotropic allosteric inhibition and activation,[136] then it must be assumed that the **V conformation of the enzyme has either a larger specificity constant for the reactant affected by the allosteric modulation, or a larger catalytic constant** relative to the H conformation, or both properties. If a heterotropic allosteric inhibitor has a smaller dissociation constant for the H than the V conformation, its association with the enzyme will shift the equilibrium in favor of the H conformation and either decrease the catalytic constant, decrease the specificity constant, or have both effects. For example, both effects are observed when $MgCTP^{2-}$ and $MgUTP^{2-}$ are present and aspartate carbamoyltransferase is catalyzing its reaction (Figure 6–3). If a heterotropic allosteric activator has a smaller dissociation constant for the V than for the H conformation, its association with the enzyme should shift the equilibrium

in favor of the V conformation and increase the catalytic constant, increase the specificity constant, or have both effects. For example, both effects are observed when $MgATP^{2-}$ and $MgGTP^{2-}$ are present and aspartate carbamoyltransferase is catalyzing its reaction. In this way, by controlling the equilibria between the two conformations of the enzyme, heterotropic allosteric effectors are able to control enzymatic reactions.

There are situations in which the V conformation has a larger catalytic constant for reactant than the H conformation, a larger specificity constant for reactant than the H conformation, or both properties. In such situations, when a heterotropic allosteric activator is present in solution, the initial rate of the enzymatic reaction at all concentrations of the varied reactant below saturation is usually greater than or equal to the initial rate in the absence of the activator. In such situations, when a heterotropic allosteric inhibitor is present in solution, the initial rate of the enzymatic reaction at concentrations of the varied reactant below saturation is usually less than or equal to the initial rate in the absence of inhibitor. In other words, the curves for the initial rate as a function of the concentration of reactant in the presence of a heterotropic allosteric activator, in the absence of activators and inhibitors, and in the presence of a heterotropic allosteric inhibitor do not cross each other, as is the case in Figure 6–3.

There is no reason, however, other than perhaps the effects of natural selection, that the catalytic constant of the H conformation cannot be larger than that of the V conformation while the specificity constant for reactant is smaller for the H conformation. Similarly, there is no reason that the specificity constant for reactant of the H conformation cannot be larger than that of the V conformation while the catalytic constant is smaller for the H conformation. In such an instance, at a particular set of concentrations of reactants—usually those in the normal cytoplasmic ranges—a heterotropic allosteric activator can still activate the enzymatic reaction and a heterotropic allosteric inhibitor can still inhibit the enzymatic reaction. Suppose that a heterotropic allosteric effector has a higher affinity for the H conformation than the V conformation. Suppose also that the catalytic constant is larger and the specificity constant is smaller for the H conformation than those for the V conformation. In the presence of a high enough concentration of heterotropic allosteric effector, the limiting rate of the enzymatic reaction will be greater in the presence of the effector than in its absence while the specificity constant will be smaller in its presence than in its absence. The curve for the initial rate for the enzymatic reaction in the presence of effector will cross that for the initial rate in its absence. At low concentrations of heterotropic allosteric effector, it will be an inhibitor; and at high concentrations, it will be an activator.

It is possible that behavior resulting from this rarely observed possibility applies when a combination of L-phenylalanine and L-tyrosine act as heterotropic allosteric inhibitors of 3-deoxy-7-phosphoheptulonate synthase[137] from *Mycobacterium tuberculosis* when the reactant, D-erythrose 4-phosphate, is varied (Figure 6–26B).* In this instance, the curves do cross. Even in this case, however, the difference in maximal rates is small and perhaps not statistically significant. In the case of 6-phosphofructokinase (Equation 6–28) from *E. coli*, the heterotropic allosteric effector $MgADP^-$ increases the specificity constant and decreases the concentration at which the initial rate of the enzymatic reaction as a function of the concentration of D-fructose 6-phosphate is half its limiting rate, but $MgADP^-$ also decreases the limiting rate of the reaction itself as its concentration is increased. Consequently, $MgADP^-$ is both an activator and an inhibitor at the same time, and the curves cross. It could be shown, however, that $MgADP^-$ acts at the active site as a competitive inhibitor of the other reactant $MgATP^{2-}$. When $MgGDP^-$ is used as a heterotropic allosteric activator rather than $MgADP^-$, the limiting rate of the reaction does not decrease as the concentration of $MgGDP^-$ is increased, and the curves do not cross.[19] In almost all cases, the **curve of the initial rate of an enzymatic reaction in the presence of a heterotropic allosteric inhibitor does not cross the curve of the initial rate in the presence of a heterotropic allosteric activator**, and neither curve crosses the curve for the initial rate in the absence of inhibitors or activators.

Rather than controlling the rate of its catalytic reaction, **a heterotropic allosteric conformational change can change the reaction** itself. For example, [glutamate—ammonia-ligase] adenylyltransferase from *E. coli* is responsible for both adenylation and deadenylation of glutamate–ammonia ligase (previously Equation 3–405)

$$\text{L-glutamate} + NH_3 + MgATP^{2-} \rightleftharpoons MgADP^- + HOPO_3^{2-} + \text{L-glutamine} \qquad (6\text{–}67)$$

*This figure is on page 1734.

from *E. coli*. The active site of [glutamate—ammonia-ligase] adenylyltransferase uses $MgATP^{2-}$ as a reactant to adenylate glutamate–ammonia ligase at Tyrosine 397 in a covalent modification that alters its enzymatic activity.[138] [Glutamate—ammonia-ligase] adenylyltransferase can exist in six different conformations, two of which are inactive, three of which catalyze adenylation, and one of which catalyzes deadenylation of glutamate—ammonia ligase. L-Glutamine, acting as a heterotropic allosteric effector of the adenylyltransferase, shifts the equilibrium among the conformations of adenylyltransferase in favor of the three conformations that catalyze adenylation. As a result, L-glutamine is a heterotropic allosteric effector of adenylyltransferase that converts it from an enzyme that deadenylates the ligase to one that adenylates the ligase.[139] The latter reaction is the transfer of an adenylyl group from diphosphate to the 4-hydroxy group of a tyrosine in the ligase, and the former reaction is hydrolysis of that adenylated tyrosine. Both are nucleophilic substitutions at phosphorus, but the leaving group in the adenylation and the nucleophile in the deadenylation are quite different.

The result of a shift in the equilibrium between the conformations of an enzyme accomplished by associations of heterotropic allosteric effectors at its heterotropic allosteric sites is manifested in the steady-state kinetics. Because an enzyme operates within its organism at steady state, these manifestations observed in the experimental steady-state kinetics define the abilities of heterotropic allosteric inhibitors and activators to control the enzymatic activity in the native environment of the enzyme.

As is the case with all kinetic discussions, a distinction must be made between **observations** and explanations for the observed behavior. Heterotropic allosteric inhibitors display properties reminiscent of classical enzymatic inhibitors. In a few instances, **noncompetitive heterotropic allosteric inhibition** is observed. For example, heterotropic allosteric inhibition[36] of fructose-bisphosphatase (Equation 6–62) from *R. norvegicus* at its active sites by AMP^{2-} associating with its allosteric sites is noncompetitive with respect to the reactant D-fructose 1,6-bisphosphate (Figure 6–19). This noncompetitive heterotropic allosteric inhibition is distinguished, as is classical nonallosteric noncompetitive inhibition (previously Equation 3–178)

$$v_0 = \frac{k_{0,A,app}\left(\frac{K_{inI}}{[I] + K_{inI}}\right)[E]_t\,[A]_0}{K_{mA,app} + [A]_0} \tag{6–68}$$

by the fact that the Michaelis constant is unaffected by the inhibitor as the limiting rate of the enzymatic reaction is decreased.

A far more common observation, however, is **competitive heterotropic allosteric inhibition**. For example, heterotropic allosteric inhibition[102,103] of anthranilate synthase (Equation 6–61) from *S. typhimurium* by L-tryptophan is competitive with respect to the reactant chorismate (Figure 6–18). As with classical nonallosteric competitive inhibition (previously Equation 3–170)

$$v_0 = \frac{k_{0,A,app}[E]_t[A]_0}{K_{mA,app}\left(\frac{[I] + K_{icI}}{K_{icI}}\right) + [A]_0} \tag{6–69}$$

competitive heterotropic allosteric inhibition is distinguished by two facts. First, the limiting rate of the enzymatic reaction, at least within the range of concentrations of inhibitor that are chosen, is invariant. Second, the concentration of reactant at which half the limiting rate is attained increases and the specificity constant for reactant decreases.

Finally, there are instances of **mixed heterotropic allosteric inhibition** in which both the limiting rate decreases and the concentration of reactant at which half the limiting rate is attained increases as in the case of the inhibition of aspartate carbamoyltransferase by $MgCTP^{2-}$ and $MgUTP^{2-}$ (Figure 6–3).

One feature of heterotropic allosteric inhibition that distinguishes it from classical inhibition is that there are often **certain limits beyond which the inhibition fails to conform to classical expectations**. For example, heterotropic allosteric inhibition[140] of 4-hydroxy-tetrahydrodipicolinate synthase

$$\text{L-aspartate-4-semialdehyde} + \text{pyruvate} \rightleftharpoons H^+ + H_2O + (2S,4S)\text{-4-hydroxy-2,3,4,5-tetrahydropicolinate} \tag{6–70}$$

from *Campylobacter jejuni* by L-lysine is competitive with respect to the reactant L-aspartate-4-semialdehyde at concentrations less than 0.06 mM, but

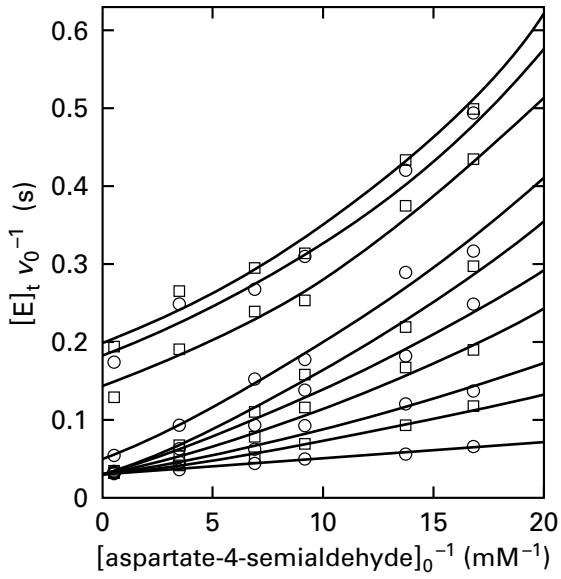

Figure 6–22: Heterotropic allosteric inhibition of 4-hydroxy-tetrahydrodipicolinate synthase from *C. jejuni* by L-lysine.[141] Solutions contained 0.35 mM pyruvate, 0.16 mM NADH, 0.25 μM active sites for 4-hydroxy-tetrahydrodipicolinate reductase, various concentrations of L-aspartate-4-semialdehyde, various concentrations of L-lysine, and 0.1 M 2-[4-(2-hydroxyethyl)-piperazin-1-yl]ethanesulfonic acid at pH 8.0 and 25 °C. The reaction was initiated by adding active sites for 4-hydroxy-tetrahydrodipicolinate synthase to a final concentration of 11 nM, and the rate of production of (2*S*,4*S*)-4-hydroxy-2,3,4,5-tetrahydrodipicolinate was followed by coupling it to the consumption of NADH (λ_{max} = 339 nm) during reduction of (2*S*,4*S*)-4-hydroxy-2,3,4,5-tetrahydrodipicolinate by 4-hydroxy-tetrahydrodipicolinate reductase. The observed initial rates were converted to units of second^{-1}. The reciprocal of each initial rate (v_0^{-1} in seconds) is plotted as a function of the respective reciprocal of the initial concentration of L-aspartate-4-semialdehyde (millimolar^{-1}) at 10 fixed concentrations of L-lysine: in ascending order of the curves, 0, 40, 50, 60, 70, 80, 100, 200, 500, and 1000 μM. The line and the curves are drawn by hand through the data.

the inhibition is no longer competitive at higher concentrations (Figure 6–22).[141] In heterotropic allosteric inhibition of amino-acid *N*-acetyltransferase from *Neisseria gonorrhoeae* by L-arginine, the inhibitor displays mixed inhibition with respect to L-glutamate. L-Arginine decreases the limiting rate of the enzymatic reaction and increases the concentration of L-glutamate at which the initial rate of the enzymatic reaction is half the limiting rate (Figure 6–23A).[142] In this instance, however, at saturating concentrations of the two reactants, L-glutamate and acetyl-SCoA, increasing the concentration of the heterotropic allosteric inhibitor L-arginine decreases the rate of the enzymatic reaction until a plateau is reached at which the enzyme retains 14% of the activity it has in the absence of L-arginine (Figure 6–23B).

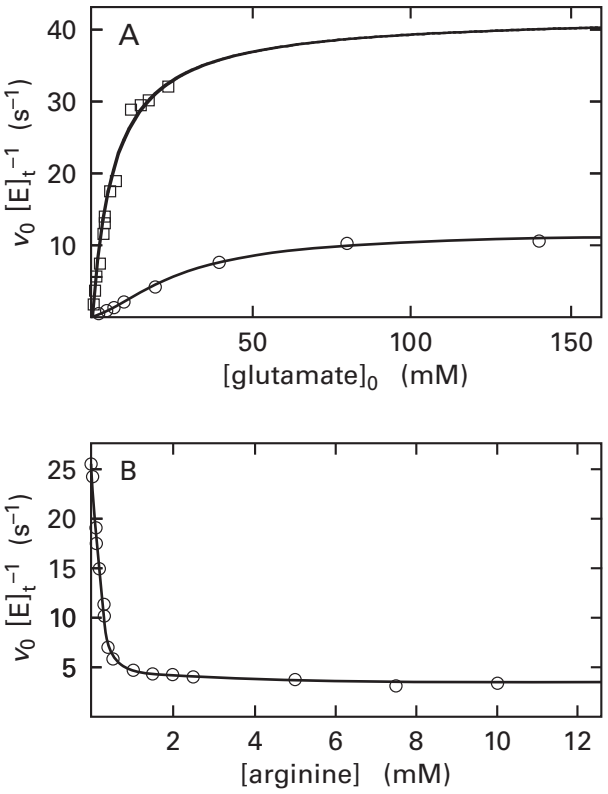

Figure 6–23: Heterotropic allosteric inhibition of amino-acid *N*-acetyltransferase from *N. gonorrhoeae* by L-arginine.[142] The reaction was carried out in 100 μL of 100 mM NaCl, 4 mM acetyl-SCoA, various concentrations of L-glutamate, various concentrations of L-arginine, and 50 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol chloride at pH 8.5 and 30 °C. The reaction was initiated by adding 4 nmol of active sites, and the mixtures were quenched after 1 or 5 min with 100 μL of 30% trichloroacetic acid. The product, *N*-acetyl L-glutamate, was quantified by using liquid chromatography and mass spectrometry. The observed initial rates were converted to units of second^{-1} by dividing by the molar mass of protein for each mole of active sites. (**A**) Each initial rate ($v_0\ [E]_t^{-1}$ in second^{-1}) is plotted as a function of the respective initial concentration of L-glutamate (millimolar) in the presence of (□) 0.1 mM or (○) 1.0 mM L-arginine. (**B**) Each initial rate ($v_0\ [E]_t^{-1}$ in second^{-1}) at 15 mM L-glutamate is plotted as a function of the respective concentration of L-arginine (millimolar^{-1}). The curves are drawn by hand through the data.

A heterotropic allosteric activator almost always decreases the concentration of reactant A required to produce an enzymatic rate that is half the limiting rate and increases the specificity constant for reactant. This is the behavior observed for the activation of aspartate carbamoyltransferase in the presence of the heterotropic allosteric activators $MgATP^{2-}$ and $MgGTP^{2-}$ (Figure 6–3) and for the activation of dCMP deaminase

$$dCMP + H_2O + H^+ \rightleftharpoons NH_4^+ + dUMP \qquad (6\text{–}71)$$

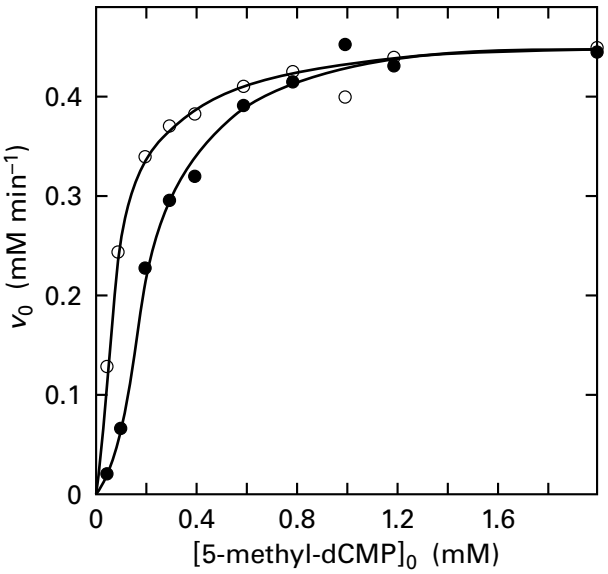

Figure 6–24: Heterotropic allosteric activation of dCMP deaminase from *E. asinus* by MgdCTP^{2-}.[143] The reaction was carried out in 5 mM 2-sulfanylethanol, 1 mM $MgCl_2$, various concentrations of 5-methyldeoxycytidine monophosphate, and 50 mM imidazolium chloride at pH 7.5 and 38 °C. The reaction was initiated by adding dCMP deaminase. The rate of decrease in the concentration of 5-methyldeoxycytidine monophosphate was followed by monitoring its absorbance at 295 nm. Each observed initial rate (micromolar minute^{-1}) is plotted as a function of the respective initial concentration of 5-methyldeoxycytidine monophosphate ([5-methyl-dCMP]$_0$ in millimolar) in the absence of heterotropic allosteric activator (●) and in the presence of 0.3 μM MgdCTP^{2-} (○).

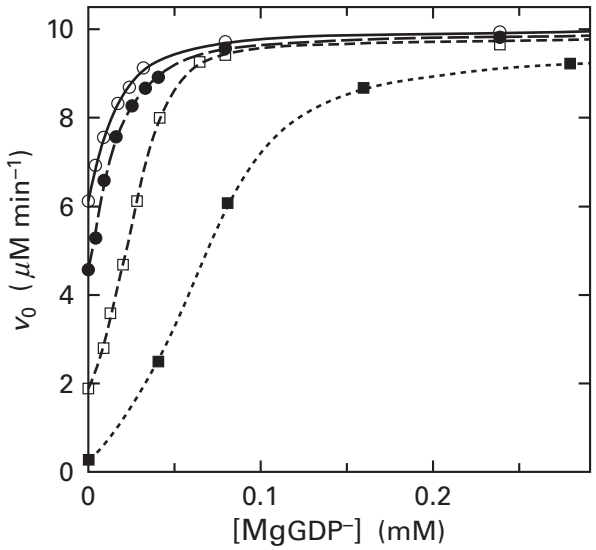

Figure 6–25: Heterotropic allosteric activation of 6-phosphofructokinase from *E. coli* by MgGDP$^-$.[19] The reaction was carried out in 0.1 mM MgATP^{2-}, 0.9 mM $MgCl_2$, various concentrations of D-fructose 6-phosphate, various concentrations of MgGDP$^-$, 0.2 mM NADH, 120 μg mL^{-1} fructose-bisphosphate aldolase, 30 μg mL^{-1} triose-phosphate isomerase, 30 μg mL^{-1} glycerol-3-phosphate dehydrogenase (NAD$^+$), 1 M creatine phosphate, 10 μg mL^{-1} creatine kinase, and 35 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol chloride at pH 8.5 and 28 °C. The reaction was initiated by adding 6-phosphofructokinase. The rate of production of D-fructose 1,6-bisphosphate was followed by coupling it to oxidation of NADH (λ_{max} = 339 nm) by glycerol-3-phosphate dehydrogenase (NAD$^+$) and the glycerone phosphate produced from D-fructose 1,6-bisphosphate by fructose-bisphosphate aldolase and triose-phosphate isomerase. Creatine kinase and phosphocreatine were present to regenerate MgATP^{2-} from the MgADP$^-$ produced during the reaction so that the initial rates remained linear. Each observed initial rate (micromolar minute^{-1}) is plotted as a function of the respective concentration of MgGDP$^-$ (millimolar) at concentrations of D-fructose 6-phosphate of 0.22 mM (■), 0.44 mM (□), 0.7 mM (●), and 1 mM (○).

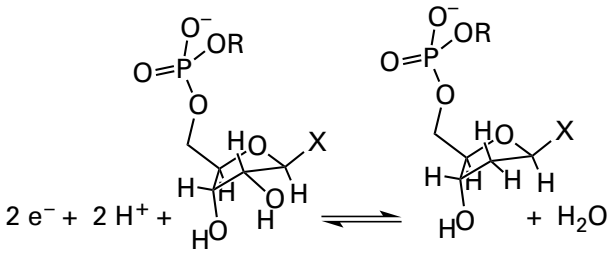
from *Equus asinus* in the presence of the heterotropic allosteric activator MgCTP^{2-} (Figure 6–24).[143] Were these enzymatic reactions noncooperative in initial rate as a function of the concentration of reactant, this effect would be described as a decrease in the Michaelis constant. In the case of an enzymatic reaction that shows sigmoid behavior, however, there is no longer a Michaelis constant because, by definition, a Michaelis constant is only a parameter of a rectangular hyperbola defining noncooperative kinetics.

The decrease in the concentration of reactant required to produce an enzymatic rate that is half the limiting rate can be far more dramatic that those observed with dCMP deaminase and aspartate carbamoyltransferase. For example, D-fructose 1,6-bisphosphate, a heterotropic allosteric activator of L-lactate dehydrogenase from *Thermus caldophilus*, decreases the concentration of pyruvate required to produce half the limiting rate[144] by a factor of 1000 ± 200.

A heterotropic allosteric activator can either have no **effect on the limiting rate** (Figure 6–24) or increase the limiting rate (Figure 6–3). If, however, a heterotropic allosteric activator does increase the limiting rate of the reaction, there will usually be a concentration of reactant above which the activator, when present at a saturating concentration, will no longer increase the limiting rate. For example, when 6-phosphofructokinase (Equation 6–28) from *E. coli* is catalyzing its reaction at pH 8.5 and at concentrations of D-fructose 6-phosphate of 0.22 mM and greater, addition of increasing concentrations of the heterotropic allosteric activator MgGDP$^-$ increases the steady-state rate to the same level regardless of the concentration of D-fructose-6-phosphate (Figure 6–25).[19]

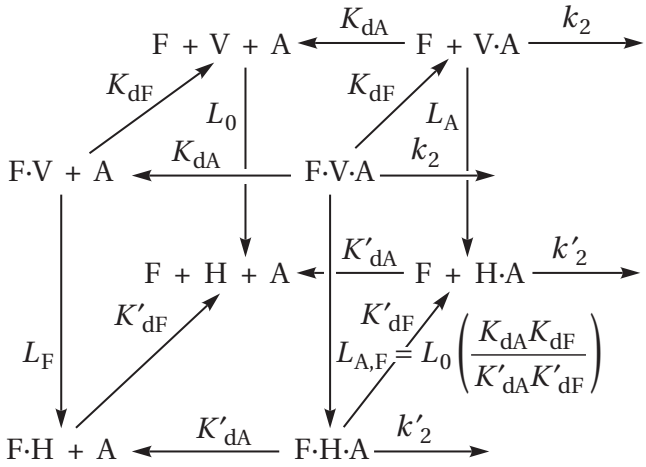
To avoid the complication of sigmoid behavior while still providing an explanation of heterotropic allosteric inhibition and activation, at least qualitatively, it is useful to derive a kinetic equation for an allosteric monomer. Allosteric enzymes are not homooligomers because they are allosteric but because almost all molecules of protein, allosteric or not, are homooligomers. In fact, it is not necessary for an enzyme to be a homooligomer to display allosteric behavior. For example, the enzymatic activity of ribonucleoside-triphosphate reductase (previously Equation 5–139)



(6–72)

from *Lactobacillus leichmannii* is allosterically[145] activated by deoxyribonucleoside triphosphates,[146-148] even though the enzyme is a monomer of only one folded polypeptide.[145,149] When glycogen phosphorylase *b* (Equation 6–66), which is allosterically activated by AMP^{2-}, is treated with sodium borohydride and then transferred to 7% formamide, it dissociates into monomers. Although the cooperativity of the effect of the concentration of AMP^{2-} on enzymatic activity is lost, AMP^{2-} remains a heterotropic allosteric activator of the enzyme.[150]

If an enzyme were monomeric, were allosterically inhibited or allosterically activated, and association of its reactant and association of a heterotropic allosteric inhibitor or activator were both to reach equilibrium rapidly before the subsequent catalytic steps commence, then the **linkage cube**



(6–73)

would explain its behavior. The two conformations of the enzyme are designated as the V and H conformations because $K_{dA} < K'_{dA}$, or $k_2 > k'_2$, or both inequalities hold. In this kinetic mechanism the arrows indicate the direction of each equilibrium. Ligand A is the reactant being varied in the measurement, usually while all the other reactants are maintained at saturating concentrations; and ligand F is a heterotropic allosteric effector, either an inhibitor or an activator. The allosteric constants L_0, L_A, L_F, and $L_{A,F}$ are equilibrium constants for the respective equilibria between the V and H conformations when the enzyme is unoccupied, fully occupied by reactant A, fully occupied by heterotropic allosteric effector F, and fully occupied by both A and F, respectively. The latter three are conditional allosteric constants for enzyme occupied by ligands. For the sake of simplicity, dissociation constants for reactant A, K_{dA} and K'_{dA}, and effector F, K_{dF} and K'_{dF}, from the same conformation, H or V, are assumed to be independent of the occupancy of the other site

$$K_{dA} = \frac{[V][A]}{[V{\cdot}A]} = \frac{[F{\cdot}V][A]}{[F{\cdot}V{\cdot}A]} \tag{6–74}$$

$$K'_{dA} = \frac{[H][A]}{[H{\cdot}A]} = \frac{[F{\cdot}H][A]}{[F{\cdot}H{\cdot}A]} \tag{6–75}$$

$$K_{dF} = \frac{[F][V]}{[F{\cdot}V]} = \frac{[F][V{\cdot}A]}{[F{\cdot}V{\cdot}A]} \tag{6–76}$$

$$K'_{dF} = \frac{[F][H]}{[F{\cdot}H]} = \frac{[F][H{\cdot}A]}{[F{\cdot}H{\cdot}A]} \tag{6–77}$$

These assumptions are reasonable because a heterotropic allosteric effector associates at a site separated from the active site and because only the conformational change between the V and H conformations alters the affinity of each site for its ligands and communicates the fact that the other site is occupied by its ligand. By linkage

$$K_{dA} L_0 = L_A K'_{dA} \tag{6–78}$$

$$K_{dF} L_0 = L_F K'_{dF} \tag{6–79}$$

$$K_{dA} L_F = L_{A,F} K'_{dA} \tag{6–80}$$

$$K_{dF} L_A = L_{A,F} K'_{dF} \tag{6–81}$$

The steady-state rate equation derived from this kinetic mechanism has the usual rectangularly hyperbolic form

$$\frac{v_0}{[E]_t} = \frac{k_0[A]_0}{K_{mA} + [A]_0} = \frac{k_0 k_A [A]_0}{k_0 + k_A [A]_0} \tag{6–82}$$

where

$$k_0 = \frac{k_2 K'_{dA} K'_{dF} (K_{dF} + [F]) + k'_2 L_0 K_{dA} K_{dF} (K'_{dF} + [F])}{K'_{dA} K'_{dF} (K_{dF} + [F]) + L_0 K_{dA} K_{dF} (K'_{dF} + [F])} \tag{6–83}$$

$$K_{mA} = K_{dA}\left\{\frac{K'_{dA} K'_{dF} (K_{dF} + [F]) + L_0 K'_{dA} K_{dF} (K'_{dF} + [F])}{K'_{dA} K'_{dF} (K_{dF} + [F]) + L_0 K_{dA} K_{dF} (K'_{dF} + [F])}\right\} \tag{6–84}$$

and

$$k_A = \frac{k_2 K'_{dA} K'_{dF} (K_{dF} + [F]) + k'_2 L_0 K_{dA} K_{dF} (K'_{dF} + [F])}{K_{dA} K'_{dA} K'_{dF} (K_{dF} + [F]) + L_0 K_{dA} K'_{dA} K_{dF} (K'_{dF} + [F])} \tag{6–85}$$

At any fixed concentration of heterotropic allosteric effector, the initial rate for the enzymatic reaction is a rectangularly hyperbolic function of the concentration of reactant A because the enzyme is monomeric. These equations are **in qualitative agreement with the behavior** of heterotropic allosteric effectors.

Given the definitions of the two conformations, it must follow that a heterotropic allosteric inhibitor shifts the equilibrium constant between the two conformations in the direction of the less enzymatically active H conformation. Consequently, for that inhibitor, $K'_{dF} < K_{dF}$. By the same definitions, it must follow that a heterotropic allosteric activator shifts the equilibrium constant between the two conformations in the direction of the more enzymatically active V conformation. Consequently, for that activator, $K'_{dF} > K_{dF}$.

As was the case with cooperativity, there are **limits that apply to the ability of a heterotropic allosteric effector to affect the steady-state kinetics.** If $L_0 < 1$, so that the V conformation predominates in the absence of any ligands, and if $K'_{dF} < K_{dF}$, so that ligand F is a heterotropic allosteric inhibitor that shifts the equilibrium in favor of the H conformation, but $L_0 < K'_{dF} K'_{dA} (K_{dF} K_{dA})^{-1} < 1$, then the inhibitor will be unable to shift the equilibrium (Equation 6–73) sufficiently in favor of the H conformation. The enzyme will remain in the V conformation at all concentrations of inhibitor and reactant, and no inhibition will occur. Because the enzyme is always in the V conformation, it cannot be activated by a heterotropic allosteric activator either. If $L_0 > 1$, so that the H conformation predominates in the absence of any ligands, and if $K'_{dF} > K_{dF}$, so that ligand F is a heterotropic allosteric activator that shifts the equilibrium in favor of the V conformation, but $L_0 > K'_{dF} K'_{dA} (K_{dF} K_{dA})^{-1} > 1$, then the activator will be unable to shift the equilibrium (Equation 6–73) sufficiently in favor of the V conformation. The enzyme will remain in the H conformation at all concentrations of activator and reactant, and no activation will occur. Because the enzyme is always in the H conformation, it cannot be inhibited by a heterotropic allosteric inhibitor either. Such situations have no selective advantage.

To explain noncompetitive heterotropic allosteric inhibition, such as that displayed by the inhibition of fructose-bisphosphatase from *R. norvegicus* by AMP^{2-} (Figure 6–19), $L_0 < 1$, $K_{dA} = K'_{dA}$, $K'_{dF} < K_{dF}$, and $k'_2 < k_2$. With these designations, it can be seen (Equation 6–84) that $K_{mA} = K_{dA}$ for all values of [A] and [F], and it can also be seen (Equation 6–83) that k_0 decreases as [F] increases. Because $K_{dA} = K'_{dA}$,

reactant A cannot affect the equilibrium between the H and V conformations, and the dissociation constant of reactant from the enzyme is always the same regardless of the ratio between the two conformations established by a heterotropic allosteric inhibitor. The decrease in k_0 as [F] increases, however, is significant only if

$$\frac{K'_{dF}}{K_{dF}} < L_0 < \frac{k_2}{k'_2} \tag{6–86}$$

Because $K_{dA} = K'_{dA}$, if L_0 is less than $K'_{dF}\,(K_{dF})^{-1}$, then the ligand will be unable to shift the equilibrium sufficiently and the enzyme will remain in the V conformation. If L_0 is greater than $k_2\,(k'_2)^{-1}$, then the amount of H conformation in the absence of F would be so great that its enzymatic activity would be greater than that of the smaller amount of V conformation present, and no significant decrease in enzymatic activity would be observed as the heterotropic allosteric inhibitor F was added.

Because, as one might expect, the dissociation constant for a reactant is rarely unaffected by the change from the V to the H conformation, noncompetitive heterotropic allosteric inhibition is rarely observed. Competitive heterotropic allosteric inhibition, such as that observed with anthranilate synthase (Figure 6–18), is more common.

There are two **simple explanations for competitive heterotropic allosteric inhibition**. First, from the equation for the catalytic constant k_0 (Equation 6–83), it can be seen that if heterotropic allosteric inhibitor F cannot associate with the V conformation of the enzyme ($K_{dF} = \infty$) and reactant A cannot associate with the H conformation ($K_{dA}' = \infty$), then heterotropic allosteric inhibition will be competitive at all finite concentrations of inhibitor F and k_0 will be equal to k_2 because reactant, when it is at saturation, will always be able to shift the equilibrium entirely to the V conformation because the concentration of inhibitor must always be finite. Second, if the catalytic constant for the V conformation, k_2, is equal to the catalytic constant for the H conformation, k'_2, then heterotropic allosteric inhibition will be competitive because $k_0 = k_2 = k'_2$ at all concentrations of heterotropic allosteric inhibitor (Equation 6–83). The behavior of the initial rate of the enzymatic reaction in each situation mimics classical competitive inhibition, so neither of these simplifications can explain the unique properties of allosteric competitive inhibition, and neither seems likely anyway.

It has already been demonstrated that competitive heterotropic allosteric inhibition has several unique properties that distinguish it from classical competitive inhibition. If the preceding simple conditions do not hold and the kinetic mechanism of Equation 6–73 is the proper explanation, then competitive heterotropic allosteric inhibition can still occur, and the peculiarities that distinguish it from classical competitive inhibition can be explained.

In **classical competitive inhibition**, no matter how high the concentration of inhibitor, increasing the concentration of reactant can always completely overcome the inhibition. The simplest way to understand this fact is to suppose that two ligands, A and B, occupy the same site (ST) on a protein and sterically exclude each other

$$\text{ST·B} + \text{A} \xrightarrow{K_{dB}} \text{B} + \text{ST} + \text{A} \xleftarrow[K_{dA}]{} \text{B} + \text{ST·A} \tag{6–87}$$

The concentration of the complex between the site and ligand A

$$[\text{ST·A}] = \frac{K_{dB}[\text{ST}]_t[\text{A}]}{K_{dA}K_{dB} + K_{dB}[\text{A}] + K_{dA}[\text{B}]} \tag{6–88}$$

The equation states that no matter what the concentration is for ligand B—for example, when B is an inhibitor of the enzymatic activity—if the concentration of ligand A—for example, when A is a reactant for the enzyme—is made large enough, the site will be completely occupied by ligand A. In classical competitive inhibition, at saturating concentrations of reactant, the active sites are fully occupied by molecules of reactant sterically excluding molecules of inhibitor, and thereby the enzyme achieves the same limiting rate as is achieved in the absence of inhibitor. The defining property of classical competitive inhibition is the fact that the same limiting rate is reached at saturating concentrations of reactant regardless of the concentration of inhibitor.

Another signature of classical competitive inhibition with respect to reactant A is that when the concentration of inhibitor is increased, **the Michaelis constant** for reactant A, K_{mA}, increases. The specificity constant for reactant decreases by the same factor because the catalytic constant k_0 does not change (Equation 6–69). If the observed Michaelis constant for the hypothetical heterotropic allosteric monomer is to increase as the concentration of a competitive

heterotropic allosteric inhibitor F increases, then the derivative of Equation 6–84 with respect to the concentration of inhibitor must be greater than 0. By taking the derivative, it can be determined that if that derivative is to be greater than 0*

$$(K'_{dF} - K_{dF})(K_{dA} - K'_{dA}) > 0 \qquad (6–89)$$

If it is stipulated, by definition, that the dissociation constant for a heterotropic allosteric inhibitor is smaller for the H conformation than it is for the V conformation ($K'_{dF} < K_{dF}$), then the Michaelis constant for reactant A will increase upon addition of a competitive heterotropic allosteric inhibitor F only when $K_{dA} < K'_{dA}$. For the increase in K_{mA} to be significant, however, $L_0 K_{dA} < K'_{dA}$. If $L_0 K_{dA}$ were greater than K'_{dA}, the enzyme would always be almost entirely in the H conformation regardless of how much reactant A was present, even in the absence of a heterotropic allosteric inhibitor, because the difference in dissociation constants for reactant A from the two conformations would not be great enough to shift the equilibrium significantly from the H to the V conformation. Consequently, even if $K'_{dF} < K_{dF}$, no inhibition of the reaction would be observed and this discussion would not be occurring.

If the following two limits on the expression for **the catalytic constant** k_0 for heterotropic allosteric inhibition (Equation 6–83) are taken

$$\lim_{[F] \to 0} k_0 = \frac{k_2 K'_{dA} + k'_2 L_0 K_{dA}}{K'_{dA} + L_0 K_{dA}} \qquad (6–90)$$

$$\lim_{[F] \to \infty} k_0 = \frac{k_2 K'_{dA} K'_{dF} + k'_2 L_0 K_{dA} K_{dF}}{K'_{dA} K'_{dF} + L_0 K_{dA} K_{dF}} \qquad (6–91)$$

it can be seen that if $K'_{dF} < K_{dF}$, $K_{dA} < K'_{dA}$, $k'_2 < k_2$, and $L_0 K_{dA} K_{dF} > K'_{dA} K'_{dF}$, then the catalytic constant k_0 will decrease as [F] approaches saturation, regardless of the concentration of reactant. It can also be seen, however, that if Equation 6–83 is factored into terms that depend on [F], then the catalytic constant is always invariant when

$$[F] < K'_{dF} \left\{ \frac{K'_{dA} K_{dF} + L_0 K_{dA} K_{dF}}{K'_{dA} K'_{dF} + L_0 K_{dA} K_{dF}} \right\} \qquad (6–92)$$

This inequality states that in certain situations there is a concentration of heterotropic allosteric inhibitor below which it will appear to be competitive, but that the inhibition observed will no longer be competitive but mixed when the concentration of inhibitor becomes greater than the concentration defined by the inequality.

In other words, unlike classical competitive inhibition, **competitive heterotropic allosteric inhibition can be conditional**. Usually all concentrations of inhibitor chosen for the measurements, by chance, are greater than this limit so that the inhibition appears to be mixed (Figures 6–3 and 6–24) or all concentrations chosen, by chance, are less than this limit so that the inhibition appears to be competitive (Figure 6–18). Occasionally, however, there are situations in which the range of concentrations chosen spans this limit, as is probably the case for heterotropic allosteric inhibition of 4-hydroxy-tetrahydrodipicolinate synthase by L-lysine (Figure 6–22), and **the inhibition can be both mixed and competitive** in different ranges of concentration for a heterotropic allosteric inhibitor.

The various limits on the properties of heterotropic allosteric inhibition of the steady-state kinetics of an enzymatic reaction, which are not observed with classical inhibition and which distinguish heterotropic behavior from classical behavior, are more easily understood by examining the state of the allosteric enzyme when the active site is saturated with reactant and the allosteric site is saturated with a heterotropic allosteric inhibitor (Equation 6–73). **At saturation with both heterotropic allosteric inhibitor and reactant, an allosteric enzyme attains a particular limiting rate that can either be that of the V conformation, that of the H conformation, or a value between** these two limiting rates. Which of these three possiblities will pertain depends on the value of the allosteric equilibrium constant $L_{A,F}$ between the fully occupied V conformation and the fully occupied H conformation.

*This inequality illustrates the fact that the kinetic mechanism of Equation 6–73 and the steady-state kinetic mechanism derived from it do not stipulate anything about the properties of the two conformations of the enzyme. It is only when the properties of the two conformations are defined in terms of their dissociation constants for one of their ligands that the inequality requires a particular inequality between the dissociation constants for another ligand.

Suppose that when the concentrations of both the heterotropic allosteric inhibitor and the reactant are at saturation, and both sites are fully occupied, the V conformation dominates ($L_{A,F} << 1$). In this instance, inhibition by a heterotropic allosteric inhibitor will be competitive at all concentrations of inhibitor because at saturation with reactant, regardless of the concentration of inhibitor, the limiting rate will always be that of the V conformation, which accounts for all of the enzyme when it is fully occupied by reactant and inhibitor.

Suppose, however, that when the concentrations of both the heterotropic allosteric inhibitor and the reactant are at saturation, and both sites are fully occupied, the H conformation predominates either partially ($L_{A,F} > 1$) or fully ($L_{A,F} >> 1$). If the H conformation has a lower catalytic constant, then competitive inhibition can be observed at low concentrations of inhibitor if the saturation by the reactant shifts the equilibrium from the H conformation promoted by the inhibitor in the absence of reactant completely to the V conformation. These low concentrations of inhibitor are unable to shift the equilibrium away from the V conformation when reactant is at saturation. At higher concentrations of the heterotropic allosteric inhibitor, however, the limiting rate must begin to decrease, as it does in the case of inhibition of 4-hydroxy-tetrahydrodipicolinate synthase by L-lysine (Figure 6–22), because saturation by the reactant is no longer able to shift the equilibrium completely to the V conformation. At high enough concentrations of inhibitor to saturate its binding site, the catalytic constant will come closer to or equal that of the H conformation (k'_2 in Equation 6–73) than that of the V conformation. How close depends on the value of $L_{A,F}$.

The inhibition of amino-acid *N*-acetyltransferase by L-arginine (Figure 6–23B) is a clearer example of this behavior. At saturating concentrations of L-arginine, the catalytic constant reaches a constant value, which is probably that of either the H conformation itself (right lower front corner of Equation 6–73) or the weighted average established by the equilibrium ratio of the V and H conformations when the concentration of L-arginine is sufficient to saturate the allosteric sites on the V conformation and the concentration of L-glutamate is sufficient to saturate the active sites on the H conformation (right lower front and right upper front corners in Equation 6–73). The inability of L-arginine to completely inhibit the reaction at any concentration is in contrast to the behavior of classical enzymatic inhibitors.

The inability of a reactant at all concentrations of inhibitor to reach the same limiting rate as its concentration is increased to infinity (Figure 6–22) and the inability of a heterotropic allosteric inhibitor at all concentrations of reactant to decrease the limiting rate of an enzymatic reaction to 0 as its concentration is increased to infinity (Figure 6–23B)—both properties of classical competitive inhibition—are consequences of the same property of heterotropic allosteric inhibition: the fact that the equilibrium constant between the fully saturated V conformation and the fully saturated H conformation, $L_{A,F}$, alone determines the limiting rate.

If, however, the H conformation has the same catalytic constant as the V conformation and only differs by having a larger dissociation constant for reactant, which is one of the simple, but unlikely, explanations for competitive heterotropic allosteric inhibition, then even if the V conformation predominates at saturation with both heterotropic allosteric inhibitor and reactant, competitive inhibition will be observed (Figure 6–18). This explanation may describe the behavior of 6-phosphofructokinase from *E. coli* for which phospho*enol*pyruvate is a competitive heterotropic allosteric inhibitor at concentrations even in the range of its dissociation constant for the V conformation.[19,151]

There are instances in which **two heterotropic allosteric inhibitors reinforce their effects** on a steady-state rate of the reaction. In the case of aspartate carbamoyltransferase, the inhibition caused by $MgUTP^{2-}$ and $MgCTP^{2-}$ together (Figure 6–3) is more effective than that of either alone.[9,94] In has already been noted that one CTP^{4-}, one UTP^{4-}, and one Mg^{2+} are accommodated by the site on each regulatory subunit of the enzyme, an unusual property that explains this behavior. The enzymatic activity of 3-deoxy-7-phosphoheptulonate synthase (see Equation 3–17)

D-erythrose 4-phosphate + phospho*enol*pyruvate + $H_2O \rightleftharpoons HOPO_3^{2-}$ + 3-deoxy-D-*arabino*-hept-2-ulosonate 7-phosphate (6–93)

from *M. tuberculosis* is inhibited allosterically[152] by the aromatic amino acids, L-tryptophan, L-phenylalanine, and L-tyrosine,[137] which are products of the respective metabolic pathways that all begin with this enzymatic reaction. Each aromatic amino acid has its own site on the enzyme so that all three can

bind simultaneously.[152] Combinations of these amino acids are more effective inhibitors than each is alone (Figure 6–26). Although the combination of L-phenylalanine and L-tyrosine (Figure 6–26B) is no more effective than either alone (Figure 6–26A), the combinations of L-tryptophan and L-tyrosine and of L-tryptophan and L-phenylalanine are more effective than either alone, and the combination of all three is more effective than any combination of two.[152] An explanation for this behavior is that each inhibitor has a dissociation constant from the H conformation that is smaller than its dissociation constant from the V conformation. The consequence of these differences is that the equilibrium constant $L_{F1,F2}$ between the V and H conformations in the absence of reactant but at saturation with two inhibitors, F1 and F2, is now $L_0K_{dF1}K_{dF2}\,(K'_{dF1}K'_{dF2})^{-1}$ instead of $L_0K_{dF}\,(K'_{dF})^{-1}$ as it is for a single heterotropic allosteric inhibitor (Equation 6–79), and the equilibrium constant at saturation with reactant and both inhibitors is $L_0K_{dF1}K_{dF2}K_{dA}\,(K'_{dF1}K'_{dF2}K'_{dA})^{-1}$ instead of $L_0K_{df}K_{dA}\,(K_{dF}'K_{dA}')^{-1}$. The differences in dissociation constants multiply together because the differences in standard free energy add together.

Heterotropic allosteric activators almost always decrease the concentration of reactant A required to produce an initial rate for an enzymatic reaction that is half the limiting rate, and they often increase the catalytic constant for the enzymatic reaction (Figure 6–3). Almost all heterotropic allosteric activation are complicated by sigmoid saturation curves resulting from the fact that each enzyme is a symmetric homooligomer that has several identical sites for binding reactants and several identical sites for binding heterotropic allosteric activators. Equations 6–82 to 6–85, however, based on the assumption that the enzyme is a monomer, can provide **qualitative explanations of the increase in the concentration of reactant required to achieve half the limiting rate and any increase in the catalytic constant**. Again, the fact that the enzyme is assumed to be a monomer eliminates the cooperativity that almost always accompanies the steady-state kinetics of an allosteric enzyme. Consequently, there is a Michaelis constant in this hypothetical case because the initial rate is always a rectangularly hyperbolic function of the concentration of reactant.

If the observed Michaelis constant is to decrease as the concentration of a heterotropic allosteric activator F increases, as is almost always observed, then the derivative of Equation 6–84 with respect to

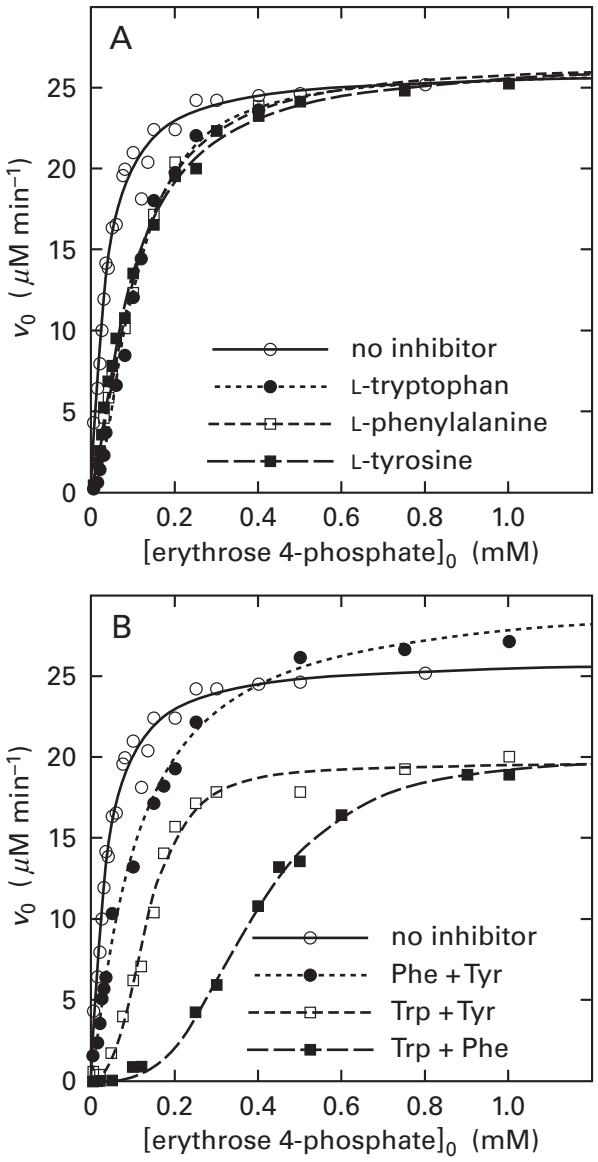


Figure 6–26: Additive heterotropic allosteric inhibition of 3-deoxy-7-phosphoheptulonate synthase from *M, tuberculosis* by L-tryptophan, L-phenylalanine, and L-tyrosine.[137] The reaction was carried out in 0.3 mM phospho*enol*pyruvate, 0.1 mM $MnSO_4$, 3,3′,3″-phosphanetriyltripropanoic acid, various concentrations of D-erythrose 4-phosphate, and 50 mM 2-[bis(2-hydroxyethyl)-amino]-2-(hydroxymethyl)propane-1,3-diol chloride at pH 7.5 and 30 °C. The reaction was initiated by adding 0.09 nmol of active sites. The decrease in the concentration of phospho*enol*-pyruvate was followed by the loss of absorbance at 232 nm. Each observed initial rate (micromolar minute^{-1}) is plotted as a function of the respective initial concentration of D-erythrose 4-phosphate (millimolar). (**A**) Initial rates in the absence of inhibitor (○) and in the presence of 200 μM L-tryptophan (●), 200 μM L-phenylalanine (□), or 200 μM L-tyrosine (■). (**B**) Initial rates in the absence of inhibitor (○) and in the presence of 100 μM L-phenylalanine and 100 μM L-tyrosine (●), 100 μM L-tryptophan and 100 μM L-tyrosine (□), or 100 μM L-tryptophan and 100 μM L-phenylalanine (■). The curves are fits of Equation 3–44 or 6–36, as appropriate, to the data.

the concentration of the activator must be less than 0. For the derivative to be negative, it must be the case that

$$(K'_{dF} - K_{dF})(K_{dA} - K'_{dA}) < 0 \qquad (6\text{–}94)$$

If $K_{dA} < K'_{dA}$, it follows that if the Michaelis constant is to decrease in the presence of a heterotropic allosteric activator, which requires the derivative to be less than 0, then $K_{dF} < K'_{dF}$. As expected, **a heterotropic allosteric activator must have a greater affinity for the V conformation than for the H conformation**.

Because the curves for heterotropic allosteric activation rarely if ever cross, the **limiting rate of the enzymatic reaction** in the presence of a heterotropic allosteric activator must be greater than or equal to the limiting rate in its absence. If the observed catalytic constant is to increase or stay the same as the concentration of a heterotropic allosteric activator F increases, as is almost always observed, then the derivative of Equation 6–83 with respect to the concentration of effector must be equal to or greater than 0. For this to be so, it must be the case that

$$0 \le (k'_2 - k_2)(K_{dF} - K'_{dF}) \qquad (6\text{–}95)$$

Because $K_{dF} < K'_{dF}$, it follows that if the catalytic constant is to stay the same or increase in the presence of a heterotropic allosteric activator, which requires the derivative to be equal to or greater than 0, then it must be the case that $k'_2 \le k_2$.

By examining Equation 6–83, however, it can be seen that if $k'_2 < k_2$, $K_{dA} < K'_{dA}$, and $K_{dF} < K'_{dF}$, so that a heterotropic allosteric activator increases the catalytic constant, then the increase will be significant only if $L_0K_{dA} < K'_{dA}$. If $L_0K_{dA} < K'_{dA}$, then the enzyme will be almost completely in the V conformation at saturation with reactant A in the absence of heterotropic allosteric activator, and addition of the activator can have little effect on k_0 and hence the limiting rate of the enzymatic reaction (Figure 6–24).* If, however, $L_0K_{dA} > K'_{dA}$, then **saturating concentrations of reactant A alone will be unable to shift the equilibrium completely in favor of the V conformation** (Equation 6–73), and addition of a heterotropic allosteric activator will increase the catalytic constant. For example, the fact that $MgATP^{2-}$ and $MgGTP^{2-}$ increase the initial rate of the reaction catalyzed by aspartate carbamoyltransferase even at saturation with L-aspartate (Figure 6–3) indicates that, under these conditions, saturating concentrations of L-aspartate are insufficient to draw the enzyme completely into the V conformation. Another explanation for such an observation would be that there was a third conformation into which the activator could draw the enzyme with an even greater limiting rate than that of the V conformation.

Finally, by taking the limit of Equation 6–83 at which the concentration of heterotropic allosteric activator goes to infinity, it can be seen that if $L_0K_{dA}K_{dF} < K'_{dA}K'_{dF}$ and

$$[A] > K_{dA}\left(\frac{K'_{dF} + L_0K_{dF}}{K'_{dF}}\right) \qquad (6\text{–}96)$$

then the catalytic constant will be equal to k_2. Above this concentration of reactant A, a saturating concentration of reactant is able to shift the equilibrium completely in favor of the V conformation, which has a catalytic constant of k_2 (Figure 6–25) regardless of the concentration of heterotropic allosteric activator. In this case, a heterotropic allosteric activator will be unable to increase the catalytic constant.

In enzymes that do not display heterotropic allosteric behavior, reactants often inhibit the enzymatic activity at higher concentrations (previously Equation 3–256)

$$v_0 = \frac{k_0[E]_t k_A[E]_t[A]_0}{k_0[E]_t + k_A[E]_t[A]_0\left(\frac{K_{iA} + [A]_0}{K_{iA}}\right)} \qquad (6\text{–}97)$$

but are rarely, if ever, able to activate an enzymatic reaction by associating at the active site. **Reactants, however, can activate the enzymatic reaction in which they participate by associating with a heterotropic allosteric site**. For example, L-phenylalanine activates phenylalanine 4-monooxygenase by associating with an allosteric site distinct from the active site in which L-phenylalanine is hydroxylated,[153,154] and pyruvate heterotropically activates pyruvate decarboxylase from *S. cerevisiae*[155] by associating with an allosteric site[156] distinct from the active site in which pyruvate is decarboxylated.

*Again, a trivial, but unlikely, explanation for the invariance of k_0 as the concentration of allosteric activator is increased is that $k_2 = k'_2$.

So far, only the effects of heterotropic allosteric inhibitors or activators on the steady-state kinetics of the overall enzymatic reaction have been examined, again with the caveat that association of reactant must be at equilibrium during its turnover and the enzymatic reaction be occurring at steady state. This latter requirement is met in the cytoplasm where the control of metabolism occurs, but a more comprehensive understanding of the actual mechanism of inhibition or activation can be gained by identifying the **steps in the kinetic mechanism controlled by a heterotropic allosteric effector**. For example, by following the pre-steady-state kinetics of 2-isopropylmalate synthase from *M. tuberculosis* by quenched flow, it could be shown that the heterotropic allosteric inhibitor L-leucine[157] decreases the rates of chemical steps transforming the reactants, acetyl-SCoA and 3-methyl-2-oxobutanoate, into the products, (2*S*)-2-isopropylmalate and coenzyme A. Consequently, the rate-limiting step of the enzymatic reaction, which is the release of products in the absence of inhibitor, becomes the production of the undissociated products on the active site in the presence of inhibitor, and the inhibitor acts by changing the rate-limiting step in the enzymatic reaction.[158] In the case of pyruvate carboxylase (previously Equation 5–229)

$$\text{pyruvate} + HOCO_2^- + MgATP^{2-} \rightleftharpoons HOPO_3^{2-} + MgADP^- + H^+ + \text{oxaloacetate} \quad (6\text{–}98)$$

from *Gallus gallus*, it could be shown by quenched flow that the heterotropic allosteric activator acetyl-SCoA[159] increases the rate of formation of 1-(*N*-carboxy)biotin on the active site by a factor of 200.[160]

To this point, qualitative explanations of heterotropic allosteric inhibition have been provided by examining the behavior of an allosteric monomer. It is possible, however, to derive a kinetic equation that describes heterotropic allosteric behavior of an allosteric oligomer as well as cooperativity of association of heterotropic allosteric effectors and substrates or reactants.

The kinetic mechanism for allosteric effects (Equation 6–73) can be combined with the equilibrium mechanism for cooperativity (Equation 6–33) to obtain an expanded rate equation that can be fit to experimental results in which both heterotropic allosteric effects and cooperativity are observed. This expansion, however, assumes that the **same symmetric quaternary conformational change** between only two conformations that is responsible for cooperativity is the same one that causes heterotropic allosteric inhibition. Consequently, by the usual convention, these two conformations will now be designated the R and T conformations. It should be kept in mind, however, that if this particular explanation of the observed behavior is consistent with a set of observations of the steady-state kinetics of an enzymatic reaction, then explanations involving more than two quaternary conformations must also be consistent.

Pyruvate kinase (Equation 6–29) from *O. cuniculus* is allosterically inhibited by L-phenylalanine (Figure 6–27A).[30] This inhibition regulates the concentration of phospho*enol*pyruvate, a precursor of the aromatic amino acids. Its carbon skeleton eventually becomes the carboxy carbon, the α carbon, and the β carbon of L-phenylalanine and L-tyrosine. Formally, in the range of concentrations examined, L-phenylalanine (Phe) is a competitive inhibitor with respect to phospho*enol*pyruvate (PEP) because it changes only the apparent specificity constant k_{PEP} for phospho*enol*pyruvate and the concentration of phospho*enol*pyruvate at which the enzymatic rate is half the limiting rate, but it does not change the limiting rate of the enzymatic reaction.[161]

Pyruvate kinase is a homotetramer, rather than a monomer; and in the presence of sufficient concentrations of the heterotropic allosteric inhibitor L-phenylalanine, the initial rate of the enzymatic reaction is a cooperative function of the concentration of the reactant phospho*enol*pyruvate (Figure 6–27A). It has been demonstrated, by direct measurement of the binding of phospho*enol*pyruvate to pyruvate kinase (Figure 6–27B), that the observed Michaelis constant for this reactant is equal to its observed dissociation constant in the absence of L-phenylalanine.* In the presence of L-phenylalanine, the concentration of phospho*enol*pyruvate at which the initial rate of the enzymatic reaction is half the limiting rate is also the same as the concentration at which half the active sites are occupied.[161] Consequently, the initial rate of the enzymatic reaction was assumed to be directly proportional to the occupation of the active sites by phospho*enol*pyruvate and determined only by its dissociation constant and its concentration, as required by the kinetic mechanism of Equation 6–73.

*In the absence of L-phenylalanine, the initial rate as a function of phospho*enol*pyruvate is rectangularly hyperbolic and has a Michaelis constant.

Because pyruvate kinase is a symmetric homotetramer of four identical subunits, each of which can bind a molecule of L-phenylalanine and each of which has an active site, the kinetic mechanism of Equation 6–73 must be expanded to account for association of four molecules of L-phenylalanine to four identical heterotropic allosteric sites and four molecules of phospho*enol*pyruvate to four identical active sites on each molecule of pyruvate kinase in both the T and R conformations. Equation 6–73 has been **expanded to include all 25 states of occupation for the tetramer in the R conformation and all 25 states of occupation for the tetramer in the T conformation**, and the states of occupation were connected by 25 allosteric constants and 32 dissociation constants to produce a $2\times5\times5$ linkage network, which is too large to reproduce here. In effect, the kinetic mechanism of Equation 6–73 was multiplied by the linkage relation for association of both reactant and inhibitor of Equation 6–33 to produce the expanded kinetic mechanism.[30]

It has been shown that such a multiplication produces, as the equation for dependence of the initial rate for an enzymatic reaction as a function of the concentration of reactant A

$$\frac{v_0}{[\mathrm{E}]_t} = \frac{k_{0,\mathrm{T}}\,L\,\dfrac{[\mathrm{A}]}{K'_{\mathrm{dA}}}\left(1+\dfrac{[\mathrm{A}]}{K'_{\mathrm{dA}}}\right)^{n-1} + k_{0,\mathrm{R}}\,\dfrac{[\mathrm{A}]}{K_{\mathrm{dA}}}\left(1+\dfrac{[\mathrm{A}]}{K_{\mathrm{dA}}}\right)^{n-1}}{L\left(1+\dfrac{[\mathrm{A}]}{K'_{\mathrm{dA}}}\right)^{n} + \left(1+\dfrac{[\mathrm{A}]}{K_{\mathrm{dA}}}\right)^{n}} \qquad (6\text{–}99)$$

where

$$L = L_0\,\frac{\left(1+\dfrac{[\mathrm{F_{inh}}]}{K'_{\mathrm{d,inh}}}\right)^{n}\left(1+\dfrac{[\mathrm{F_{act}}]}{K'_{\mathrm{d,act}}}\right)^{n}}{\left(1+\dfrac{[\mathrm{F_{inh}}]}{K_{\mathrm{d,inh}}}\right)^{n}\left(1+\dfrac{[\mathrm{F_{act}}]}{K_{\mathrm{d,act}}}\right)^{n}} \qquad (6\text{–}100)$$

where $\mathrm{F_{inh}}$ is a heterotropic allosteric inhibitor, $\mathrm{F_{act}}$ is a heterotropic allosteric activator, and the dissociation constants are as follows: $K_{\mathrm{d,inh}}$ is for inhibitor $\mathrm{F_{inh}}$ from the R conformation, $K'_{\mathrm{d,inh}}$ is for inhibitor $\mathrm{F_{inh}}$ from the T conformation, $K_{\mathrm{d,act}}$ is for activator $\mathrm{F_{act}}$ from the R conformation, and $K'_{\mathrm{d,act}}$ is for activator $\mathrm{F_{act}}$ from the T conformation.[19] Notice that, mathematically, no distinction is made between a heterotropic allosteric inhibitor and a heterotropic allosteric activator. Only when the dissociation constant of the effector is smaller for the T conformation than for the R conformation will the effector be a heterotropic allosteric inhibitor. and only when its dissociation constant is smaller for the R conformation than the T conformation will the effector be a heterotropic allosteric activator. In effect, because their concentrations are constant, because none is chemically altered by the reaction, and because their association with the allosteric sites is always at equilibrium, the presence of heterotropic allosteric effectors simply shifts the value for the equilibrium constant between the R and T conformations. This shifted equilibrium constant then governs the cooperative association of reactant A. Again the assumption behind all these equations is that associations of reactants are always at equilibrium, irrespective of the progress of the enzymatic reaction.

Table 6–1: Equilibrium Constants and Rate Constants for Pyruvate Kinase[30]

equilibrium constant or rate constant[a]	numerical value
L_0	0.094 ± 0.03
K_{dPEP}	$44 \pm 2\ \mu$M
K'_{dPEP}	$440 \pm 40\ \mu$M
$K_{\mathrm{d,Phe}}$	14 ± 3 mM
$K'_{\mathrm{d,Phe}}$	0.6 ± 0.07 mM
k_2	$920 \pm 110\ \mathrm{s^{-1}}$
k'_2	$90 \pm 70\ \mathrm{s^{-1}}$

[a]The numerical values listed are from fits of the expanded MWC equation to the values of the observed initial rates in steady-state kinetics. The dissociation constants are for phospho*enol*pyruvate (PEP) from the active site and L-phenylalanine (Phe) from the heterotropic allosteric site.

The rate equation derived from this expanded kinetic mechanism, where there is only the heterotropic allosteric inhibitor L-phenylalanine ($[\mathrm{F_{act}}] = 0$), could be fit satisfactorily to the observations (Figure 6–27A). From these fits, values for the equilibrium constant L_0 and the various dissociation constants in the proposed kinetic mechanism (Equation 6–73) were obtained (Table 6–1).[30] The fit of the equations to the data was satisfactory even though it was assumed that association of phospho*enol*pyruvate

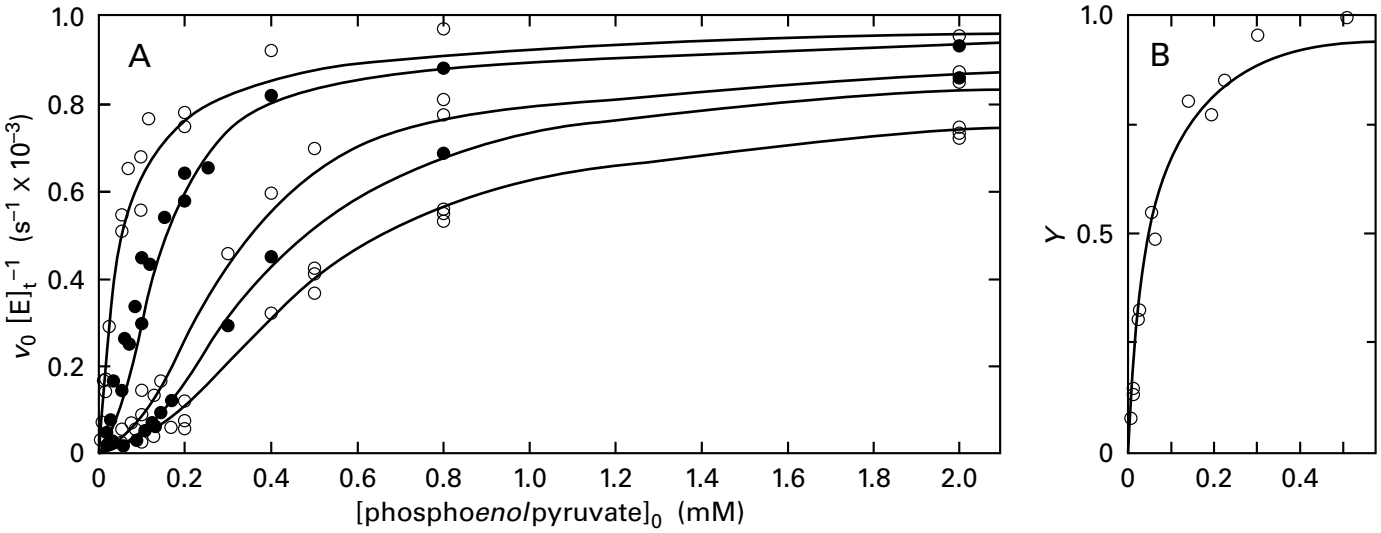

Figure 6–27: Heterotropic allosteric inhibition of pyruvate kinase from *O. cuniculus* by L-phenylalanine and a demonstration that the Michaelis constant and the dissociation constant of phospho*enol*pyruvate from the enzyme are the same.[30] (**A**) Heterotropic allosteric inhibition. Solutions contained 72 mM KCl, 7.2 mM $MgSO_4$, 2.0 mM ADP^{3-}, 0.3 mM NADH, 0.3 μM in active sites of L-lactate dehydrogenase, variable amounts of phospho*enol*pyruvate, variable amounts of L-phenylalanine, and 50 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol chloride, pH 7.5 and 23 °C. Each reaction was initiated by adding pyruvate kinase, and the rate of production of pyruvate was followed by coupling its consumption to the consumption of NADH (λ_{max} = 339 nm) by L-lactate dehydrogenase. Initial rates were calculated from the decrease in absorbance at 340 nm. Each initial rate was divided by the concentration of active sites of pyruvate kinase in the assay ($v_0\,[E]_t^{-1}$ in second^{-1}), and each of these initial rate constants is plotted as a function of the respective initial concentration of phospho*enol*pyruvate (millimolar). Each set of assays had, in descending order 0, 3, 7, 9, or 12 mM L-phenylalanine. The curves are fits of a rate equation for the kinetic mechanism of Equation 6–73 that has been expanded to account for association of four molecules of L-phenylalanine and four molecules of phospho*enol*pyruvate to four identical heterotropic allosteric sites and four identical active sites, respectively, on each molecule of pyruvate kinase in both the T and R conformations. (**B**) Binding of phospho*enol*pyruvate to pyruvate kinase. Binding was measured by molecular exclusion at pH 7.5 and 23 °C. Solutions (0.55 mL) containing pyruvate kinase (150–350 μM in active sites) and various concentrations of [^{14}C]phospho*enol*pyruvate were mixed with 50 mg of dehydrated beads of Sephadex G-50. The Sephadex imbibed a certain amount of the fluid. It was assumed that the free phospho*enol*pyruvate equilibrated between the fluid in the interior of the beads and solution surrounding the beads while the protein remained entirely outside the beads. From the volume of fluid added, the total amount of protein added, the total amount of phospho*enol*pyruvate added, the molar concentration of phospho*enol*pyruvate in the fluid outside the beads (as determined by scintillation counting) and the molar concentration of protein in the fluid outside the beads (as determined by the absorbance at 280 nm), the moles of phospho*enol*pyruvate bound to each mole of active sites could be calculated as a function of the free concentration of phospho*enol*pyruvate (millimolar). The points are the experimental determinations. The line is drawn on the basis of the assumption that the dissociation constant for phospho*enol*pyruvate is the same as the numerical value (0.44 mM) for the Michaelis constant observed kinetically in Panel A. The scale of the axis of the abscissa is the same as the scale in Panel A to facilitate comparison.

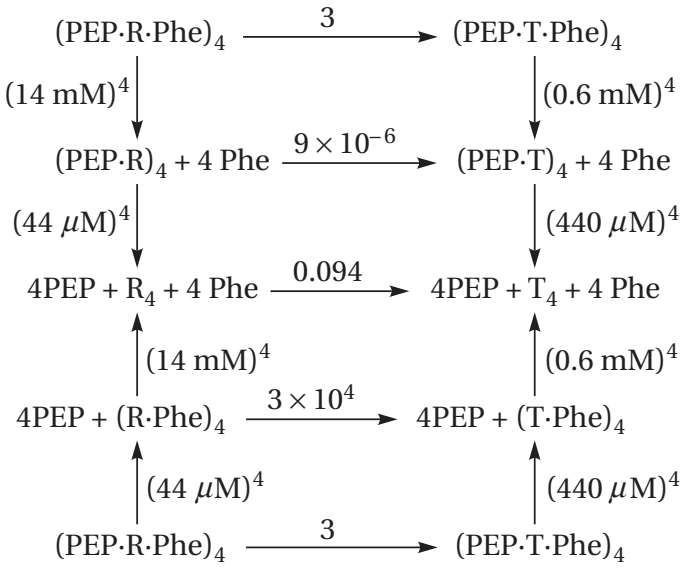
to either the R or the T conformation is unaffected by association of L-phenylalanine and that association of L-phenylalanine to either the R or the T conformation is unaffected by association of phospho*enol*pyruvate, as should be the case for this explanation of heterotropic allosteric inhibition (see Equations 6–74 to 6–77).

Both homotropic cooperativity of the initial rate of the reaction catalyzed by pyruvate kinase as a function of the concentration of phospho*enol*pyruvate (PEP) in the presence of sufficient concentrations of L-phenylalanine (Phe) and heterotropic inhibition of the activity of the enzyme by L-phenylalanine (Figure 6–27A) can be **explained simultaneously by the expanded kinetic mechanism based on the existence of only two symmetric quaternary conformations of the enzyme**, R and T, the equilibrium between which is shifted in one direction by phospho*enol*pyruvate and in the other direction by L-phenylalanine. L-Phenylalanine inhibits pyruvate kinase by shifting the conformational equilibrium in favor of the T conformation, which has a lower affinity for phospho*enol*pyruvate (K'_{dPEP} = 440 μM and K_{dPEP} = 44 μM) and a lower catalytic constant (k'_2 = 90 s^{-1} and k_2 = 920 s^{-1}). This shift is accomplished because L-phenylalanine has a greater affinity for the T conformation ($K'_{d,Phe}$ = 0.6 mM and $K_{d,Phe}$ = 14 mM) than it does for the R conformation.

The fundamental allosteric constant is less than 1($L_0 = 0.094$), so pyruvate kinase, unlike aspartate carbamoyltransferase (Figure 6–13), is already mostly in the R conformation in the absence of L-phenylalanine and phospho*enol*pyruvate. Consequently, the initial rate of the enzymatic reaction, in the absence of L-phenylalanine, is a rectangularly hyperbolic function of the concentration of phospho*enol*pyruvate (Figure 6–27A) because association of phospho*enol*-pyruvate can only increase the predominance of the R conformation. At concentrations of L-phenylalanine sufficient to shift the conformational equilibrium in favor of the T conformation, **association of phospho*enol*pyruvate becomes cooperative** because its dissociation constant from the R conformation is smaller than its dissociation constant from the T conformation. Because the binding of L-phenylalanine shifts the conformational equilibrium from one in favor of the R conformation in the absence of ligands to one in favor of the T conformation, its association with the otherwise unoccupied enzyme is cooperative (Figure 6–28).

If only a manageable portion of the expanded $2 \times 5 \times 5$ linkage network[30] is examined



(6–101)

it can be seen that as L-phenylalanine is added to the solution, the equilibrium between the two conformations shifts in favor of the T conformation; and as phospho*enol*pyruvate is added to the solution, it shifts in favor of the R conformation. When the concentration of L-phenylalanine is high enough to saturate the R conformation, pyruvate kinase exists primarily ($L_{\text{Phe,PEP}} = 3$) in the T conformation regardless of how high the concentration of phospho*enol*-pyruvate is. Unlike the case of classical steric competition, saturating concentrations of phospho*enol*pyruvate cannot drive L-phenylalanine off the enzyme because the active site is distant from the heterotropic allosteric site. If $L_{\text{Phe,PEP}} = 3$, competitive inhibition should be observed at low concentrations of inhibitor, as is observed (Figure 6–27A); but as the concentration of heterotropic allosteric inhibitor increases, the limiting rate should begin to decrease; and at high enough concentrations of inhibitor, the limiting rate should be closer to that of the T conformation (K'_2 in Equation 6–73) than that of the R conformation. Unfortunately, in the case of pyruvate kinase, high enough concentrations of L-phenylalanine to observe the decrease in limiting rate ([Phe] > 14 mM), which would have been a further justification of the procedure, simply were not used in the measurements (Figure 6–27A), although an examination of the graph at the highest concentrations of L-phenylalanine used (12 mM) suggests that the inhibition is not competitive.

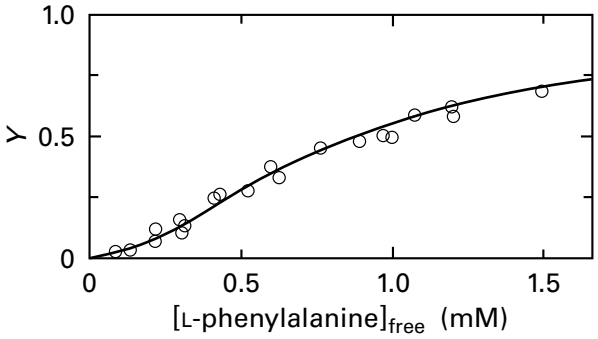


Figure 6–28: Binding of L-phenylalanine to pyruvate kinase from *O. cuniculus*.[30] The binding of [^{3}H]-L-phenylalanine to the enzyme was measured by equilibrium dialysis at pH 7.5 and 23 °C. A solution containing 210 μM pyruvate kinase was placed in one compartment, and a solution of [^{3}H]-L-phenylalanine of an appropriate molar concentration was placed in the other compartment. After equilibrium had been reached (20 h), the final concentration of the protein in its compartment (as determined by absorbance at 280 nm) and the final concentrations of L-phenylalanine in each compartment (as determined by scintillation counting) in each compartment were assessed. From these concentrations, the free concentration of L-phenylalanine as well as the moles of L-phenylalanine bound for each mole of the tetrameric enzyme could be calculated for each measurement. The fractional saturation (Y) is plotted as a function of the free concentration of L-phenylalanine (millimolar). The smooth curve was a fit of Equation 6–35 to the data using the conformational equilibrium constant and the dissociation constants for L-phenylalanine from the R conformation, $K_{\text{d,Phe}}$, and the T conformation, $K'_{\text{d,Phe}}$, of the enzyme that were obtained from the curves in Figure 6–27A (Table 6–1).

The sum of all the conformational changes that produce both cooperativity and heterotropic allosteric effects is observed crystallographically. It should now be clear from the foregoing discussion that there are **several levels of conformational changes** that usually occur in such an enzyme that displays both heterotropic allosteric behavior and cooperativity. First, there are the **local conformational changes** that occur upon association of a heterotropic allosteric effector or association of one or more substrates for the enzyme and are confined to the immediate vicinity of the respective site. Second, there are conformational **changes that occur within the individual subunits** that could be responsible for the observed heterotropic allosteric behavior but may not elicit a quaternary conformational change. Third, there are the **quaternary conformational changes** that are responsible for cooperativity. These quaternary conformational changes could also be responsible for heterotropic allosteric behavior because, as these changes occur, the affinities of the symmetrically displayed heterotropic allosteric sites as well as the active sites change.

One might believe, and many do, that molecular details of the conformational changes that enable heterotropic allosteric behavior to occur should be able to be gathered from examination of crystallographic molecular models of the two or more conformations involved. For example, significant changes occur around the allosteric site in the two conformations of chorismate mutase from *S. cerevisiae*: the V conformation, crystallized with the heterotropic allosteric activator L-tryptophan bound in the allosteric site, and the H conformation, crystallized with the heterotropic allosteric inhibitor L-tyrosine in the allosteric site (Figure 6–21). In addition to a number of reorientations of the side chains in the vicinity of the site, two α helices surrounding the site have shifted in their relative orientation. The enzyme, however, also undergoes a quaternary conformational change between the H and V conformations that involves the entire α_2 dimer.[133] The conformation of an enzyme with high affinity for a particular ligand that is studied crystallographically is usually produced by fully occupying sites on the protein with that ligand, as was the case with chorismate mutase, and it is usually also rotationally symmetric. In such a situation, the local conformational changes, the conformational changes that might be confined to an individual subunit, and the quaternary conformational change have all occurred together and have all been completed. In such a situation, local conformational changes that occur around sites for ligands and substrates and that result only from the binding of the ligand itself are **difficult, if not impossible, to distinguish** from conformational changes confined to an individual subunit and from quaternary conformational changes.

Although crystallographic observations are necessary to define the sum of all the various conformational changes in atomic detail, **other methods are often used to detect particular conformational changes while an enzyme is in solution.** Many examples of these chemical and physical methods normally used to study the structure of native proteins were presented when the cooperativity of aspartate carbamoyltransferase was discussed earlier, but the same physical methods can be used to monitor the conformational changes that mediate heterotropic allosteric effects. For example, isopropyl β-D-thiogalactoside, an analogue of a natural heterotropic allosteric activator, is bound by *lac* repressor from *E. coli* (an α_4 homotetramer) in the absence of DNA. Upon binding, a change in the optical spectrum of *lac* repressor is observed, which indicates alterations in the environments around its tyrosines. Changes in the circular dichroic spectrum and sedimentation coefficient of the protein are also observed.[65,162] In another example, changes in the conformation of hemoglobin documented crystallographically can be followed by observing changes in nuclear magnetic resonance spectra.[163]

The rate of deuteration of the amido nitrogens in segments of the folded polypeptide comprising 4-hydroxy-tetrahydrodipicolinate synthase from *C. jejuni* could be followed by mixing the enzyme with deuterium oxide, removing samples at various times, quenching the deuterium exchange with acid, digesting the unfolded polypeptide with pepsin at low pH, separating the resulting peptic peptides chromatographically, and determining their mass by mass spectrometry. It was found that segments of polypeptide surrounding the active site became less susceptible to deuterium exchange in the presence of L-lysine, a heterotropic allosteric inhibitor (Figure 6–22) of the enzyme. These results suggested that the inhibitor was decreasing the conformational dynamics around the active site because the T conformation was more rigid in this region than the R conformation.[164] Because the active site in the crystallographic molecular model of the enzyme, an α_4 homotetramer, is buried and access to it appears limited,[165] it was proposed that the increase in rigidity observed for the T conformation decreases the rate for association of the reactant L-aspartate-4-semialdehyde with the active site when the enzyme is in

this conformation. At high enough concentrations of L-lysine to cause the T conformation to predominate even in the presence of saturating concentrations of L-aspartate-4-semialdehyde, the limiting rate of the enzymatic reaction decreases (Figure 6–22) because of this rigidification.

In 6-phosphofructokinase (Equation 6–28) from *O. cuniculus*, an α_4 homotetramer, there is a side chain of cysteine in each subunit that reacts preferentially with fluorodinitrobenzene. When a heterotropic allosteric activator of the enzymatic reaction, such as AMP^{2-}, is bound to the enzyme, the rate of this arylation increases. When a heterotropic allosteric inhibitor, such as citrate, is bound, however, the rate decreases.[166] It was assumed that the rate of this reaction responds to shifts in the orientation of amino acids surrounding the cysteine that result from a conformational change in the protein the equilibrium for which is shifted by association of the effectors.

Glycogen phosphorylase *a* (Equation 6–66) from *O. cuniculus*, an α_4 homotetramer, can be modified at a cysteine in each of its subunits by *N*-(1-oxyl-2,2,6,6-tetramethyl-4-piperidinyl)iodoacetamide to introduce a stable radical into the protein. The electron paramagnetic resonance spectrum of this radical shifts, presumably in response to a conformational change in the protein, when AMP^{2-}, a heterotropic allosteric activator of the enzymatic activity, is bound by the enzyme.[68]

If the shifts in equilibria between particular quaternary conformations of an enzyme, brought about by association of ligands and accomplished by thermodynamic linkage, produce a heterotropic allosteric effect and also cooperativity, then it must be the case that these equilibria exist in both the presence and the absence of ligands. For example, in the case of chorismate mutase from *S. cerevisiae*, it seems reasonable to assume that in the absence of ligands there are two conformations of the enzyme: one in which the allosteric site fits L-tryptophan and one in which the allosteric site fits L-tyrosine. From the atomic details of the two respective conformations of the allosteric site when they are occupied in turn by these heterotropic allosteric ligands (Figure 6–21), it can be seen that each conformation would almost exclude the other ligand and that the equilibrium between them would surely be shifted by thermodynamic linkage in one direction by L-tryptophan and in the other direction by L-tyrosine.

That such an equilibrium exists between two conformations in the presence of ligands is clear from results such as those displayed in Figures 6–13 and 6–21.[167,168] It has been far more **difficult to prove** that equilibria between allosteric conformations of a protein exist in the absence of ligands. The reason for this difficulty is that the equilibrium constants are usually significantly different from 1. For example, it can be estimated that, in the absence of ligands, the equilibrium constant L_0 (Equation 6–24) for conversion of the R conformation into the T conformation for aspartate carbamoyltransferase from *E. coli*[54] is around 200 and that for 6-phosphofructokinase from *E. coli*[19] is around 4×10^6. In such situations, it is impossible to measure the small amount of R conformation that should be present in solution in the absence of ligands. In many instances, the equilibrium favors the R conformation in the absence of ligands,[37,142,169,170] but the equilibrium constant in these cases is usually much less than 1.

Serendipitously, in at least one of these latter cases, that of pyruvate kinase (Equation 6–29) from *O. cuniculus*, the equilibrium constant L_0 has been estimated to be 0.1 (Equations 6–100 and 6–101). If this is so, in the absence of ligands, even though the R conformation predominates, about 9% of the enzyme should be in the T conformation. L-Phenylalanine is a heterotropic allosteric inhibitor of pyruvate kinase. Therefore, L-phenylalanine alone should be able to shift the equilibrium distribution between the two conformations in one direction while phospho*enol*pyruvate alone, a reactant that displays cooperativity,[30] should be able to shift it in the other. L-Phenylalanine decreases the sedimentation velocity of pyruvate kinase relative to that when the enzyme is unoccupied ($\Delta s_{20,w} = -0.24$ S), and phospho*enol*pyruvate increases the sedimentation velocity relative to that when the enzyme is unoccupied ($\Delta s_{20,w} = +0.11$ S).[161] From scattering of neutrons at low angles, it can be calculated that association of L-phenylalanine with unliganded pyruvate kinase increases its radius of gyration by 0.08 ± 0.02 nm, and association of phospho*enol*pyruvate with the unliganded enzyme decreases its radius of gyration by 0.06 ± 0.02 nm.[171] L-Phenylalanine increases by 10-fold the rate of reaction of cysteines in the protein with dithiobis(2-nitrobenzoate), and phospho*enol*pyruvate decreases this rate by 5-fold.[161] Each physical and chemical property should be monitoring the average of the two conformations at equilibrium in the absence of either ligand. These observations are consistent with the two respective ligands pulling by linkage in opposite

directions on **a conformational equilibrium that exists in the absence of any ligand**, but they cannot exclude the possibility that the conformations present in the absence of the ligands are only the two that are assumed by the enzyme in the presence of heterotropic allosteric inhibitors and activators.[172]

In another serendipitous instance, the R conformation of 6-phosphofructokinase (Equation 6–28) from *E. coli* crystallized from a solution of the enzyme that did not contain any of its substrates or heterotropic allosteric effectors even though, as has been noted, the equilibrium constant L_0 between the T and R conformations has been estimated to be heavily in favor (4×10^6) of the T conformation in this situation.[43] This outcome certainly suggests that, in this case, the R conformation is present in solution and in equilibrium with the T conformation and that the crystallization itself pulled this equilibrium in the direction of the R conformation by mass action. In every other case with other proteins, however, the T conformation is expected to predominate in a solution that crystallizes in the absence of substrate and heterotropic allosteric effectors.

One approach to this problem of demonstrating that the equilibrium exists in the absence of ligands is to discover a **mutant of the enzyme in which the equilibrium in the absence of ligands has been altered** so that it is in a measurable range. For example, mutation of Lysine 143 in the regulatory β subunits of aspartate carbamoyltransferase to alanine shifts the equilibrium constant between the R and T conformation to a value of 2.7 ± 0.8, a range in which the equilibrium can be monitored by sedimentation velocity.[173] Addition of $MgCTP^{2-}$ shifts the equilibrium constant to 30 ± 20, and addition of $MgATP^{2-}$ shifts the equilibrium constant to 0.2 ± 0.1. When Aspartate 236 in the catalytic α subunit of aspartate carbamoyltransferase from *E. coli* is mutated to alanine, an equilibrium between at least two conformations of the mutant enzyme with an equilibrium constant or constants in the range 0.5–2 can be observed by scattering of X-rays at small angles.[174] This equilibrium shifts to a scattering profile resembling that of the R conformation of the wild-type enzyme upon addition of *N*-(phosphonacetyl)-L-aspartate, and it shifts to a scattering profile closely resembling that of the T conformation of the wild-type enzyme upon addition of $MgCTP^{2-}$.

In spite of the few instances in which the equilibrium between two unoccupied conformations of a heterotropic allosteric enzyme have been directly observed, the possibility must be considered that the conformation or conformations that predominate when the allosteric sites or active sites are occupied cannot exist when these sites are unoccupied.

Crystallographers often succumb to the temptation to identify a "path of conformational changes [that] transmit the inhibitory signal"[175] from an allosteric site to the active site of the enzyme.[118,133] For example, in the case of ATP phosphoribosyltransferase from *P. arcticus*, a detailed, linear mechanical explanation was provided for the allosteric inhibition of the enzyme by histidine.[118] The idea is that there is a concerted set of shifts in the positions and orientations of side chains, polypeptide backbone, and portions of interfaces between subunits, usually chosen by the crystallographer to lie directly between the allosteric site and the active site, that mechanically conveys the information that an effector resides in the allosteric site to the active site without relying on preexisting conformational changes of the protein.[176] One difficulty with such an explanation is that there is no way to validate it. For example, if amino acids participating in such a path are mutated to interfere with the changes observed, the fact that such mutations interfere with a heterotropic allosteric effect is not a validation because such mutations must affect the equilibrium between the two quaternary conformations one way or the other, if that equilibrium actually exists, to the same extent that they disrupt the particular region around the mutation itself, and this effect on the equilibrium would explain the interference of the allosteric effect.

When aspartate carbamoyltransferase from *E. coli* is locked in the R conformation by disulfides between cysteines inserted in place of its Alanines 241 (Figure 6–8), the enzyme, although it is fully active, no longer displays heterotropic allosteric inhibition by $MgCTP^{2-}$ or heterotropic allosteric activation by $MgATP^{2-}$, even though any mechanical path for communication between the allosteric site and active site should not be affected by the alteration. When these disulfides are eliminated by thiol–disulfide exchange with an added thiol, heterotropic allosteric inhibition and activation are restored to the normal levels.[24] Locking of the enzyme in the R conformation prevented the allosteric communication, not some interference in a path between the sites.* The fact that association of either $MgCTP^{2-}$

*In a related example, malate dehydrogenase ($NADP^+$) from *Sorghum bicolor* is allosterically activated by light. In the dark, a disulfide between two cysteines in the enzyme locks it in an inactive T conformation. Illumination activates photosynthesis, producing reduced ferredoxin that ultimately leads to reduction of the disulfide and enables the equilibrium between the inactive T and active R conformations to be established.[178]

or $MgATP^{2-}$ with the allosteric sites on the regulatory β subunits of aspartate carbamoyltransferase in the R conformation has no effect on the chemical shifts of protons on the methyl groups of isoleucines, valines, and leucines in the catalytic α subunits is also consistent with the conclusion that there is no path of conformational changes mechanically altering the active site upon association of the effectors.[179]

Nevertheless, in this view, the ligands themselves mechanically induce the protein to assume the respective conformation or conformations. Large quaternary conformational changes are observed upon association of molecular oxygen with hemoglobin (Figure 6–1), association of *N*-(phosphonacetyl)-L-aspartate with aspartate carbamoyltransferase (Figure 6–2), association of magnesium 5′-adenylic imidodiphosphonic anhydride ($MgAMPPNP^{2-}$) with aspartate kinase (Figure 6–29),[177] and association of AMP^{2-} with fructose-bisphosphatase.[37] It is difficult to believe that association of such small ligands, which upon association are only minor players in the structures of each complex, can somehow physically induce such significant changes in the structures of such large proteins when those changes in structure do not already preexist in a conformation in equilibrium with the unoccupied conformation. Furthermore, if the ligand were able to perform this feat, there would have to be no significant steric or electronic interaction preventing this purportedly sterically enforced rearrangement of the structure. Consequently, there would be no reason that this conformation of the protein could not be achieved in the absence of the ligand.

All these considerations suggest that an equilibrium between the quaternary conformations observed crystallographically exists in the absence of the ligands. If so, the entire quaternary conformational change between the two conformations defined crystallographically or by a set of physical measurements produces the communication. It is counterproductive to focus attention on only one small portion of that overall conformational change, in particular changes that occur in a line between the two sites.

The question that now arises is whether a conformational change between only two quaternary conformations is responsible for both heterotropic allosteric effects and homotropic cooperativity displayed by many enzymes or whether there must be more than two conformations to explain all heterotropic allosteric effects observed. This question is more complicated in situations where there are heterotropic allosteric effectors in addition to cooperatively associating substrates. Most of the peculiar effects of heterotropic allosteric inhibitors and activators can be explained qualitatively by the kinetic mechanism of Equation 6–73, but that explanation is irrelevant to this question because a monomer, which is unable to display cooperative behavior was chosen for the quaternary structure to avoid the complication of cooperativity.

Monod, Wyman, and Changeux pointed out that most enzymes displaying heterotropic allosteric effects also display homotropic cooperativity in association of substrates and in the initial rates as a function of the concentrations of reactants.[15] They proposed that the two properties are usually present together because both require the enzyme to be able to adopt at least two conformations the relative stabilities of which are linked to the binding of ligands. Most proteins are oligomeric for reasons unrelated to cooperativity, but the fact that they are oligomeric is required for homotropic cooperativity to be manifested. When a particular oligomeric enzyme is able to adopt two symmetric quaternary conformations, both heterotropic allosteric behavior and homotropic cooperativity can exploit this quaternary conformational change. The argument is that heterotropic allosteric inhibition and activation and homotropic cooperativity occur simultaneously because the conformational change used for communicating heterotropic allosteric effects is the same one used for communicating homotropic cooperativity. In such a case, the conformational equilibrium is shifted in favor of the less active T conformation by a heterotropic allosteric inhibitor and in favor of the more active R conformation by substrates, reactants, and heterotropic allosteric activators. In effect, this argument is an application of Occam's razor to the question.

Nevertheless, even though they often occur together, there is **no necessary connection between heterotropic allosteric effects and cooperative effects**. For example, α_2 homodimeric phosphoserine phosphatase from *M. tuberculosis*, which hydrolyzes *O*-phospho-L-serine, is allosterically inhibited by L-serine from an allosteric site distinct from the active site. None of the measurements, however, of initial rate of the enzymatic reaction as a function of the reactant *O*-phospho-L-serine in the presence or absence of L-serine display cooperativity, as one might expect were there only two symmetric quaternary conformations responsible for heterotropic allosteric

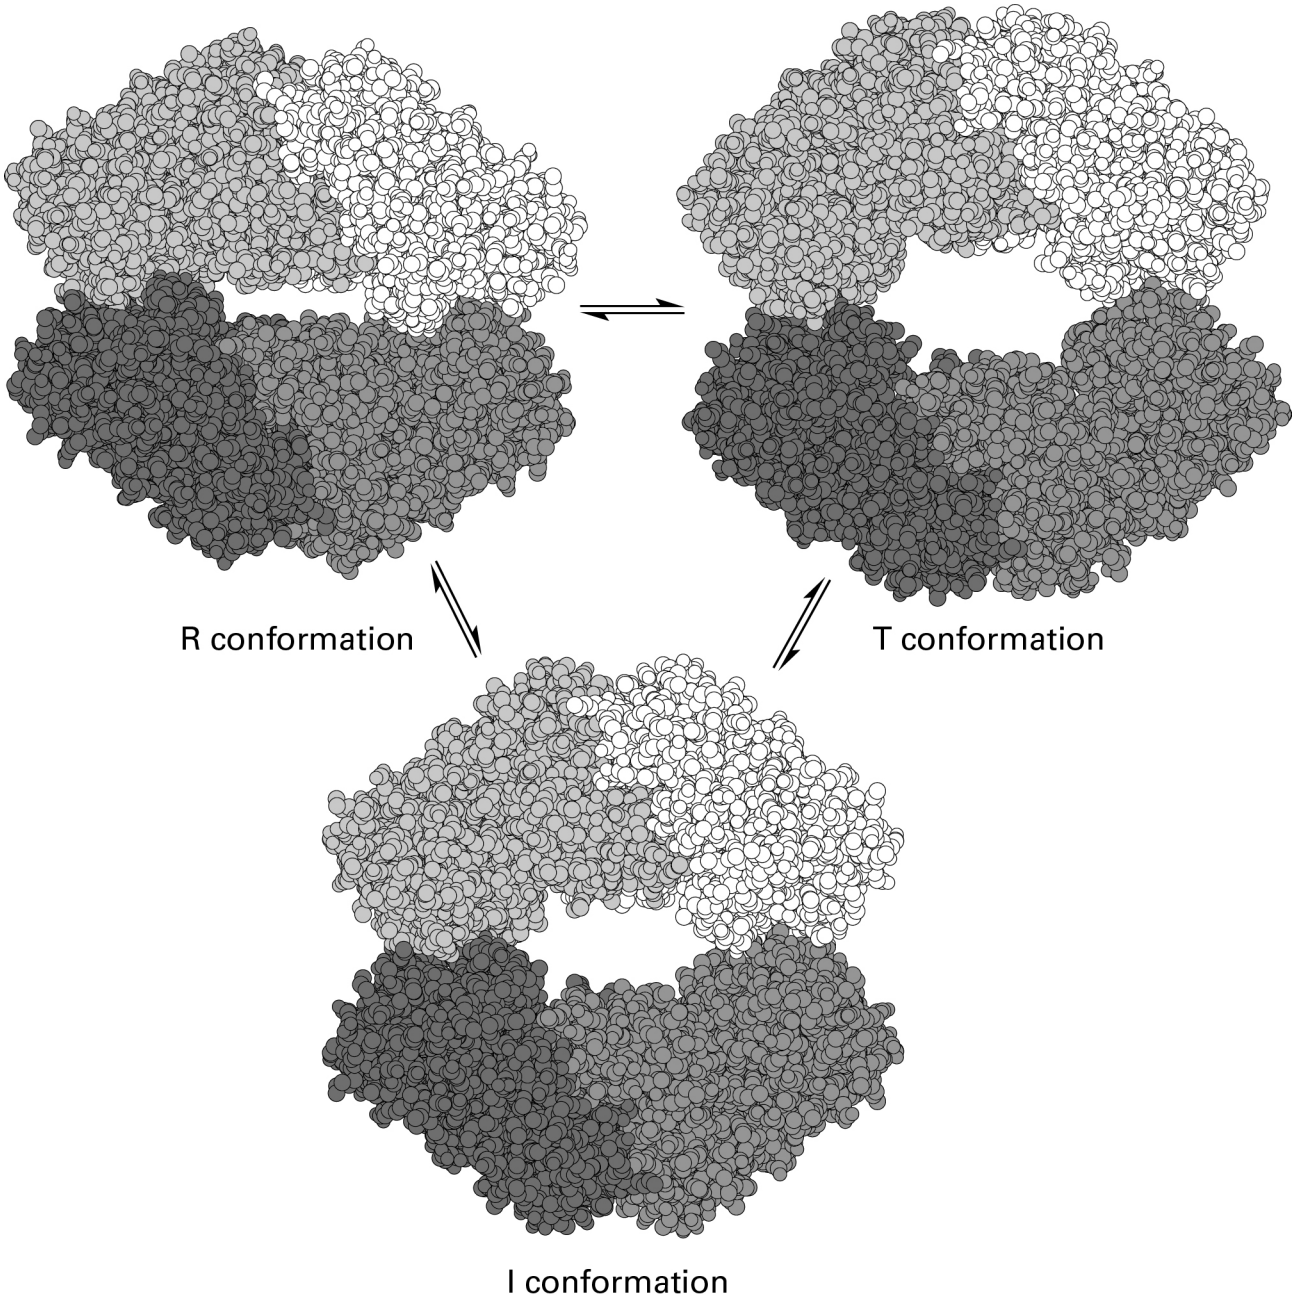

Figure 6–29: Stereodrawings[485] of crystallographic molecular models of aspartate kinase from *M. jannaschii* in its three conformations.[177] Each subunit of the α_4 tetramer is drawn in a different shade of gray. Aspartate kinase was poised in the R conformation, the active sites of which were occupied by L-aspartate and $MgAMPPNP^{2-}$, by dissolving the enzyme (12 mg mL^{-1}) in 5 mM $MgAMPPNP^{2-}$ and 30 mM L-aspartate. Crystals were then grown in 800 mM ammonium formate, 100 mM 2-[bis(2-hydroxyethyl)amino]-2-(hydroxymethyl)propane-1,3-diol at pH 8.0 with 13–15% poly(ethylene glycol) 4000 as the precipitant. Crystals of the space group $P2_12_12_1$ were obtained. Reflections were collected from these crystals to Bragg spacing of 0.23 nm. Aspartate kinase was poised in the T conformation, the active sites of which were occupied by L-threonine, by dissolving the enzyme (12 mg mL^{-1}) in 6 mM L-threonine and 30 mM L-aspartate. Crystals were then grown in 0.2 M KI with 1.4–1.6 M ammonium sulfate as the precipitant. Crystals of the space group $P2_12_12_1$ were obtained. Reflections were collected from these crystals to Bragg spacing of 0.27 nm. After a week at 4 °C, crystals of the enzyme in a third conformation, the active sites of which were occupied only by L-aspartate, appeared in the batches of crystals of the enzyme in the R conformation. These new crystals had the space group $C222_1$. Reflections were collected from these crystals to Bragg spacing of 0.27 nm. It was found that the enzyme in these crystals had a distinct conformation, which can be designated the I conformation. The equilibrium between the R conformation (left), the I conformation (below), and the T conformation (right) is represented with space-filling drawings of the three refined, complete crystallographic molecular models. Noncrystallographic rotational axes of symmetry are vertical and horizontal in the plane of the page and normal to the plane of the page.

inhibition.[180] Consequently, the proposal that an enzyme can exist in a symmetric quaternary T conformation with which, by definition, a heterotropic allosteric inhibitor preferentially associates and a symmetric quaternary R conformation with which, by definition, a substrate or a heterotropic allosteric activator preferentially associates is able to explain heterotropic allosteric effects. This fact, however, does not mean that these are the same T and R conformations that explain homotropic cooperativity in the absence of heterotropic allosteric effectors or that the existence of these two conformations requires the enzyme to display cooperative behavior.

In the case of aspartate carbamoyltransferase, however, most, if not all, experimental observations suggest that the conformations responsible for heterotropic allosteric effects and homotropic cooperativity are the same two symmetric quaternary conformations. Aspartate carbamoyltransferase can exist in R and T conformations. Because $MgATP^{2-}$ shifts the equilibrium between the R and T conformations in favor of the R conformation (Figure 6–13), $MgATP^{2-}$ must have a smaller dissociation constant from the R than it does from the T conformation. Presumably, $MgGTP^{2-}$ does also. Because $MgCTP^{2-}$ shifts the equilibrium between the R and T conformations in favor of the T conformation (Figure 6–13), $MgCTP^{2-}$ must have a smaller dissociation constant from the T than it does from the R conformation. Presumably, $MgUTP^{2-}$ does also. L-Aspartate has a smaller dissociation constant from the R conformation occupied by carbamoyl phosphate than it does from the T conformation occupied by carbamoyl phosphate. As is observed (Figure 6–3), $MgATP^{2-}$ and $MgGTP^{2-}$ should decrease the concentration of L-aspartate required for the initial rate of the enzymatic reaction to reach half its limiting value, and $MgCTP^{2-}$ and $MgUTP^{2-}$ should increase that concentration. If the R conformation of aspartate carbamoyltransferase has a larger catalytic constant than the T conformation, then $MgATP^{2-}$ and $MgGTP^{2-}$ should increase the apparent catalytic constant for the enzymatic reaction, and $MgCTP^{2-}$ and $MgUTP^{2-}$ should decrease the apparent catalytic constant of the enzymatic reaction, as is also observed (Figure 6–3).

A feature of noncompetitive heterotropic allosteric inhibition, albeit a rare one, can support the conclusion that the same two symmetric quaternary conformations responsible for heterotropic allosteric effects are the same two that are responsible for homotropic cooperativity. Association of substrates with the active sites of enzymes, the steady-state kinetics of which display noncompetitive heterotropic allosteric inhibition, is usually not cooperative. One explanation for the fact that **noncompetitive heterotropic allosteric inhibition**, by definition, does not alter the Michaelis constant for reactant is that $K_{dA} = K'_{dA}$. If this equality holds, then the concentration of reactant A cannot affect the equilibrium between the R and T conformations. Consequently, even when the enzyme is homooligomeric, association of reactant cannot be cooperative, nor can the initial rate of the enzymatic reaction as a function of its concentration display cooperativity. For example, fructose-bisphosphatase from *R. norvegicus* is a homotetramer, yet the initial rate of the enzymatic reaction as a function of the concentration of D-fructose 1,6-bisphosphate (Figure 6–19) does not display cooperativity at any of the concentrations of AMP^{2-}, a noncompetitive heterotropic allosteric inhibitor, as expected. In the absence of ligands, fructose-bisphosphatase is in the R conformation,[36,38] and AMP^{2-} shifts the equilibrium in favor of the T conformation, which has a lower catalytic constant for the enzymatic reaction. This shift in the equilibrium constant between the R conformation, with high activity, and the T conformation, with low activity ($k'_2 < k_2$) produced by the inhibitor, which is unaffected by the concentration of D-fructose 1,6-bisphosphate, is the reason for the decrease in the catalytic constant k_0.

In many cases, **only two quaternary conformations have been observed crystallographically**, a fact reinforcing the almost universal convention of the T and R conformations. For example, aspartate carbamoyltransferase from *E. coli* has been examined crystallographically with many different heterotropic allosteric effectors. Although there are significant local conformational changes within the constituent folded polypeptides around the binding sites being occupied when different ligands associate with the same quaternary conformation,[9,48,49,53] all the complexes between ligands and enzyme assume either the T or R conformation when crystallized from solution. The results from nuclear magnetic resonance spectroscopy are also unable to detect any quaternary conformations other than the T and R conformations the equilibrium between which is shifted both by heterotropic allosteric effectors and by homotropic allosteric ligands and substrates (Figure 6–13). The crystallographic molecular models of glycogen phosphorylase *b* (Equation 6–66 and Figure 6–20) from *O. cuniculus*, activated either by association of AMP^{2-} or by covalent phosphorylation at distinct sites, are both in the same quaternary R conformation,[181,182] which is distinct from the

quaternary T conformation observed when the heterotropic allosteric inhibitor D-glucose 6-phosphate is bound in the allosteric site or in the absence of ligands.[183]

In instances in which an enzyme is simply inhibited allosterically by the final product of a metabolic pathway and there are no as-yet-recognized heterotropic allosteric activators, it is less surprising that only T and R conformations are observed crystallographically. Examples of such situations are phosphoglycerate dehydrogenase from *E. coli*, which is allosterically inhibited by L-serine, the final product of the pathway;[117] anthranilate synthase (Equation 6–61) from *S. marcescens*, which is allosterically inhibited by L-tryptophan, the final product of the pathway;[103] 4-hydroxy-tetrahydrodipicolinate synthase from *Nicotiana sylvestris*, which is allosterically inhibited by L-lysine, the final product of the pathway;[184] sulfate adenylyltransferase

$$MgATP^{2-} + \text{sulfate} + Mg^{2+} \rightleftharpoons MgOPO_3PO_3^{2-} + \text{magnesium adenosine 5′-phosphosulfate} \quad (6\text{–}102)$$

from *P. chrysogenum*, which is allosterically inhibited by 3′-phosphoadenylyl sulfate, the final product of the pathway;[115] and 3-deoxy-7-phosphoheptulonate synthase (Equation 6–93) from *E. coli*, which is allosterically inhibited by L-phenylalanine, the final product of the pathway.[175]

There are, however, examples of allosterically controlled enzymes that can assume **at least three distinct quaternary conformations**, the equilibria among which are shifted by association of substrates and heterotropic allosteric effectors. For example, aspartate kinase

$$MgATP^{2-} + \text{L-aspartate} \rightleftharpoons \text{4-phospho-L-aspartate} + MgADP^{-} \quad (6\text{–}103)$$

from *Methanocaldococcus jannaschii* crystallizes in three distinct quaternary conformations (Figure 6–29): one that crystallizes from a solution of the substrate L-aspartate; one that crystallizes from a solution of L-aspartate and $MgAMPPNP^{2-}$; and one that crystallizes from a solution of L-threonine, a heterotropic allosteric inhibitor of the enzyme. Each conformation differs significantly from the others in the disposition of its subunits, and each has the noted ligands bound in all the active sites or allosteric sites on the enzyme. Each of the three quaternary conformations is symmetric, but in the conformation stabilized by association of L-threonine, the symmetrically distributed sites for association of L-threonine are not symmetrically occupied, a fact that suggests there may be subtle asymmetries in the structure of this conformation.

It may also be the case that in some instances in which only two conformations of an allosteric enzyme have been defined crystallographically, **a third may yet be discovered**. The quaternary conformations of porcine fructose-bisphosphatase (Equation 6–62) in crystallographic molecular models of a number of different complexes with heterotropic allosteric inhibitors, substrates, analogues of substrates, and a physiological competitive inhibitor could all be clearly identified as one of two quaternary conformations designated the T and R conformations.[36,37,176,185] It was then later reported that a third, distinct quaternary conformation of the same enzyme crystallized from solution under different conditions.[186] As has already been noted, there is no reason that a molecule of protein should exist in only one conformation or only two conformations in equilibrium with each other. Heterotropic allosteric inhibition and activation would still be a consequence of the existence of three globally symmetric conformations if, for example, there is a quaternary T conformation of low enzymatic activity that is most stable in the presence of saturating concentrations of heterotropic allosteric inhibitor, another quaternary conformation that is most stable in the absence of ligands or in the presence of only one substrate, and a quaternary R conformation of high enzymatic activity stabilized by association of both reactants and heterotropic allosteric activators. Certainly, in the case of aspartate kinase from *M. jannaschii* (Figure 6–29), one could imagine that the equilibrium between the conformation observed at saturating concentrations of L-threonine, a heterotropic allosteric inhibitor of the enzyme,[187] and the conformation observed in the presence of saturating L-aspartate could be responsible for heterotropic allosteric inhibition while the equilibrium between the conformation in the presence of saturating L-aspartate and $MgAMPPNP^{2-}$ could be responsible for homotropic cooperativity.

Contrariwise, at one time, several observations suggested that the heterotropic allosteric effects and the cooperativity observed for aspartate carbamoyltransferase from *E. coli* (Figure 6–3) could be the result of separate conformational changes.[188,189]

The nuclear magnetic resonance spectra (Figure 6–13), however, demonstrate that heterotropic allosteric effectors and reactants and analogues of reactants shift the equilibrium between only two conformations, the R and T conformations. Aspartate carbamoyltransferase was reconstituted from regulatory subunits and nitrated catalytic subunits, and the active sites were saturated with carbamoyl phosphate. Both the homotropic cooperativity observed with L-aspartate as a reactant and the change in sedimentation coefficient upon adding *N*-(phosphonacetyl)-L-aspartate were those expected if the modified protein saturated with carbamoyl phosphate (CAP) was 60% in the T conformation and 40% in the R conformation ($L_{CAP} = 1.5$).[190] This significant shift in the equilibrium constant in favor of the R conformation resulted from nitration as well as from saturation with carbamoyl phosphate. When the heterotropic allosteric inhibitor $MgCTP^{2-}$ was added to the solution, the absorbance of the nitrated enzyme at 450 nm decreased; and when the heterotropic allosteric activator $MgATP^{2-}$ was added, the absorbance increased. These changes were in the directions expected for an increase in the concentration of the less active T conformation or the more active R conformation, respectively. In the presence of $MgCTP^{2-}$, the percentage of T conformation, calculated from both the homotropic cooperativity displayed by L-aspartate and the change in sedimentation coefficient produced by *N*-(phosphonacetyl)-L-aspartate, increased to 80% ($L_{CTP,CAP} = 4$); and in the presence of $MgATP^{2-}$, it decreased to 40% ($L_{ATP,CAP} = 0.7$). These are the changes expected if the heterotropic allosteric effects are coupled to the same quaternary conformational change as homotropic cooperativity.

It has already been noted that the simplest solution to implementing both heterotropic allosteric effects and homotropic cooperativity is to tie them to the same quaternary conformational change and that this solution seems to have been hit upon by natural selection in many instances. There are, however, observations of physical properties of allosteric enzymes for which no more than two quaternary conformations have been observed crystallographically that are presented as **evidence for the existence of more than two quaternary conformations involved in their heterotropic and homotropic allosteric effects**. For example, changes in fluorescence of the single tryptophan in pyruvate kinase from *G. stearothermophilus*, which is distant from both the active sites and the site at which the heterotropic allosteric activator D-ribose 5-phosphate binds, indicate that association of the reactant phospho*enol*pyruvate, the concentration of which affects the initial rate of the enzymatic reaction cooperatively, produces an R conformation that is distinct from the conformation produced by association of D-ribose 5-phosphate.[191]

Ten of the cross peaks that shifted the most in two-dimensional TROSY nuclear magnetic resonance spectra of the methyl groups of isoleucines in 6-phosphofructokinase from *G. stearothermophilus* were observed in solutions containing no ligands, saturating concentrations of the substrate D-fructose-6-phosphate, saturating concentrations of the heterotropic allosteric inhibitor phospho*enol*pyruvate, and saturating concentrations of both D-fructose-6-phosphate and phospho*enol*pyruvate. The shifts observed in these 10 cross peaks indicated that there were more than just two quaternary conformations of the enzyme under all these conditions.[55]

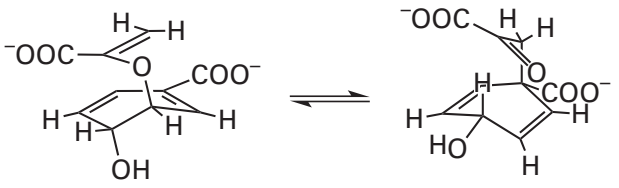
Such observations, however, could be consistent with the existence of only two quaternary conformations of the enzyme if local conformational changes were clearly distinguished from quaternary conformational changes, as was done with aspartate carbamoyltransferase.

At first glance, **mutations of an allosteric enzyme that eliminate cooperativity without eliminating heterotropic allosteric inhibition**[192-194] would seem to suggest that different conformational equilibria are responsible for cooperativity and heterotropic allosteric inhibition. For example, when Arginine 234 in the catalytic subunit of aspartate carbamoyltransferase is mutated to serine, the Hill coefficient describing the effect of the concentration of L-aspartate on the enzymatic activity decreases from 2.3 to a value indistinguishable from 1.0. Another explanation of such an observation, however, is that the mutation has changed the rate-limiting step in the enzymatic reaction so that the initial rate of the enzymatic reaction is no longer directly proportional to the occupation of the active site by reactant. Consequently, the underlying cooperativity in association of reactant with the active site is no longer manifest in the effect of the concentration of reactant on the initial rate. In fact, mutation of Arginine 234 decreases the value for the catalytic proficiency of the enzyme, $k_0\,K_{m,asp}^{-1}$, by a factor of 2000, and it would not be surprising if such a large change were due to a change in rate-limiting step for the enzymatic reaction. The concentration of L-serine, a heterotropic allosteric inhibitor of phosphoglycerate dehydrogenase from *E. coli*, affects the initial rate of the enzymatic reaction

cooperatively (Hill coefficient = 2.0 ± 0.07), but mutation of Glycine 294 to valine eliminates this cooperativity (Hill coefficient = 1.08 ± 0.04) on its effect on the initial rate, even though L-serine binds to its allosteric site on the mutant enzyme with the same degree of cooperativity (Hill coefficient = 2.0) with which it binds to the wild-type enzyme.[195,196]

Unfortunately, in instances in which a mutation eliminates cooperativity in the steady-state kinetics as a function of the concentration of a reactant but does not eliminate heterotropic allosteric effects, a threefold demonstration that the mutation eliminates the cooperativity of the actual association of reactant with the active site, that the mutation does not alter the ability of a heterotropic allosteric inhibitor to inhibit the binding of reactant to the active site, and that, for the mutant, the binding of reactant remains noncooperative even in the presence of inhibitor has not been presented. These three observations would be necessary to conclude that the conformational equilibrium responsible for cooperativity of a reactant is different from the conformational equilibrium responsible for heterotropic allosteric inhibition.

When Glutamate 23 in chorismate mutase (previously Equation 1–161)



(6–104)

from *S. cerevisiae*, which is a homodimer, is mutated to aspartate, the Hill coefficient describing the effect of the concentration of chorismate on enzymatic activity decreases from 1.5 to a value indistinguishable from 1.0 in the absence of L-tyrosine, its heterotropic allosteric inhibitor, and from 1.7 to a value indistinguishable from 1.0 in the presence of 100 μM L-tyrosine. The concentration of chorismate at which the initial rate of the enzymatic reaction is half the limiting rate, however, is still increased by L-tyrosine from 4.5 to 9.5 mM, a change similar to the increase observed in the wild type (from 4.0 to 6.7 mM).[197] Furthermore, association of L-tyrosine with one heterotropic allosteric site in the homodimer increases the microscopic dissociation constant of L-tryptophan from the other site by a factor of 3, and association of L-tryptophan with one heterotropic allosteric site increases the microscopic dissociation constant of L-tyrosine from the other site by a factor of 3. These two facts would be consistent with their competition for the two quaternary conformations observed crystallographically, but neither L-tyrosine nor L-tryptophan binds to the enzyme cooperatively,* which is inconsistent with the existence of only those two quaternary rotationally symmetric quaternary conformations.[198] If there were only those two conformations, either the heterotropic allosteric inhibitor L-tyrosine or the heterotropic allosteric activator L-tryptophan would have to associate cooperatively with the unoccupied enzyme. These results suggest that heterotropic allosteric effects are confined to the individual subunits, even though the cooperativity in the effect of the concentration of chorismate on the enzymatic activity would seem to require that its association with the active site be linked to the quaternary conformational change between the two rotationally symmetric conformations. These considerations suggest that homotropic cooperativity and heterotropic allosteric behavior in the case of chorismate mutase are not linked to the same conformational change and that there exists at least a third quaternary conformation in which one subunit has assumed an H conformation and the other a V conformation.

Although the simplest strategy for a protein that displays both homotropic cooperativity and heterotropic allosteric behavior is to link these two processes to the same conformational change between two quaternary conformations at equilibrium with each other, it appears that natural selection has produced at least some proteins if not many that have **the ability to assume more than two quaternary conformations**, the conformational changes among which are linked arbitrarily to the binding of the various ligands. The stable radical 1-oxyl-2,2,6,6-tetramethylpiperidine, when it is covalently bound to glycogen phosphorylase from *O. cuniculus* (Figure 6–20), detects changes in the distribution of conformations in solutions of the protein (Figure 6–15). The changes detected by the radical when the heterotropic allosteric activator AMP^{2-} is bound by glycogen phosphorylase *b* differ significantly from those caused by the substrate D-glucose 1-phosphate. The complete set of results suggests that the enzyme can assume four distinct conformations variously linked to the binding of ligands.[199] A distinction between quaternary conformations and local conformations was

*In fact, association of the first L-tyrosine (K_{dY} = 70 μM) seems to increase the microscopic dissociation constant for association of the second (K_{dY} = 180 μM).

not made. The existence, however, of enzymes in which the conformational change responsible for heterotropic allosteric effects is different from that responsible for homotropic cooperativity is irrelevant to the issue of whether or not homotropic cooperativity arises from the ability of an oligomeric protein to exist in only quaternary conformations in which symmetry is conserved that was discussed earlier.

The argument to this point has emphasized, albeit not exclusively, an explanation of heterotropic allosteric effects as a result of the ability of the effector to shift an equilibrium between two or more symmetric quaternary conformations. This argument follows from the principle that symmetry is conserved in the conformational changes of a homooligomeric protein. This view seems to be held by a majority of investigators, given the wide use of the terms T conformation and R conformation. As has been already mentioned, however, there are heterotropic allosteric effects that cannot be explained satisfactorily in this way. The failure of such an explanation often results in cases in which there are a large number of heterotropic allosteric effects on association of a ligand or the kinetics of an enzymatic reaction. For example, there are heterotropic allosteric effects on association of molecular oxygen with hemoglobin caused by changes in pH, as well as heterotropic allosteric effects on the kinetics of association of oxygen, that do not seem to be linked to the quaternary conformational equilibria that conserve symmetry.* In this instance, it has been shown that local conformational changes within the subunits of hemoglobin that do not exert significant influence on the well-established quaternary conformational changes of the protein (Figure 6–1) can explain these effects that cannot be explained solely by a shift in the equilibrium between these quaternary conformations.[200] In a sense, the fact that these allosteric conformational changes that take place entirely within the individual subunits is a corollary to the conclusion that heterotropic allosteric effects can be linked to a conformational change in a monomeric protein. It is still a conformational explanation of heterotropic allosteric effects that relies on the linkage of association of a ligand on a conformational equilibrium, only it is a local conformational equilibrium between two or more conformations confined within each subunit.

*It should be noted that hemoglobin is a weak example of the principle of conservation of symmetry because it is an $(\alpha\beta)_2$ heterodimer. Nevertheless, the issue is the existence of local conformational equilibria unlinked to quaternary conformational equilibria.

Heterotropic allosteric effectors usually alter the cooperativity of association of substrates and reactants with an active site. Such changes are to be expected. Assume for the moment that there are only two symmetric quaternary conformations of the enzyme, the T conformation that predominates in the presence of saturating concentrations of a heterotropic allosteric inhibitor and the R conformation that predominates in the presence of saturating concentrations of reactants for the enzyme or heterotropic allosteric activators. Assume also that cooperativity of the steady-state kinetics mirrors the cooperativity of association of reactants with the active site. If the effects manifested by a heterotropic allosteric effector are exerted through the same quaternary conformational change as that controlled by homotropically cooperative reactant or reactants, then the change in cooperativity of the initial rate as a function of the concentration of a reactant will **depend on which conformation of the enzyme is favored in the absence of heterotropic allosteric ligands.**

If the effect of the concentration of a reactant on the initial rate of the enzymatic reaction or the binding of a substrate to the otherwise unoccupied enzyme is homotropically cooperative, then the T conformation dominates in the absence of all ligands. Because a heterotropic allosteric inhibitor increases the stability of the T conformation and increases the value for the allosteric constant L (Equation 6–100), it should increase the degree of homotropic cooperativity and increase the sigmoidicity, up to the point at which the reactant can no longer significantly shift the equilibrium from the T to the R conformation. For example, the heterotropic allosteric inhibitor L-isoleucine increases the Hill coefficient, n_H, for the initial rate of threonine ammonia-lyase from *Mycolicibacterium smegmatis* as a function of L-threonine[201] from 2.4 to 3.1; the heterotropic allosteric inhibitor phospho*enol*pyruvate increases the Hill coefficient for the initial rate of 6-phosphofructokinase from *Thermus thermophilus* as a function of D-fructose 6-phosphate[202] from 1.5 to 2.5; and the sigmoidicity of the initial rate of aspartate carbamoyltransferase as a function of the concentration of L-aspartate (Figure 6–3) is greater in the presence of $MgCTP^{2-}$ and $MgUTP^{2-}$ ($n_H = 2.7$) than in their absence ($n_H = 2.0$). In the case of aspartate transcarbamoylase, the allosteric constant in the absence of heterotropic allosteric inhibitors, L_0, is greater than 1, but heterotropic allosteric inhibitors increase this conformational equilibrium constant.

Suppose that either the initial rate of the enzymatic reaction as a function of the concentration of a reactant or the association of a reactant for an otherwise unoccupied enzyme that can exist in both T and R conformations is not cooperative but rectangularly hyperbolic. There are two possible explanations for this observation. First, in the absence of substrate or reactant and the absence of heterotropic allosteric effectors, the R conformation is dominant ($L_0 < 1$). Second, the T conformation is so dominant ($L_0 K_{dA} > K'_{dA}$) that neither substrate nor reactant at saturation can shift the equilibrium between the R and T conformations significantly. If the former explanation applies, because the reactant associates only with the dominant R conformation and the allosteric constant L becomes even smaller upon its association, then both binding and transformation of the reactant are noncooperative, rectangularly hyperbolic functions of its concentration. When a heterotropic allosteric inhibitor is added, however, it shifts the conformational equilibrium in favor of the T conformation by increasing the allosteric constant L. If its presence shifts the equilibrium so that the allosteric constant is greater than 1, then homotropic cooperativity of association of reactant or the initial rate as a function of the concentration of reactant will be observed where none was in the absence of inhibitor.

It is frequently observed that **a heterotropic allosteric inhibitor can cause a rectangularly hyperbolic effect of the concentration of a reactant on the initial rate of an enzymatic reaction to become cooperative**.[203,204] For example, the presence of the heterotropic allosteric inhibitor L-lysine causes the effect of L-aspartate-4-semialdehyde on the initial rate of the reaction catalyzed by 4-hydroxy-tetrahydrodipicolinate synthase from from *C. jejuni*, which is rectangularly hyperbolic in the absence of inhibitor, to become cooperative (Figure 6–22). The fact that, in the absence of L-lysine, the enzyme is predominantly in the R conformation, which would explain the absence of cooperativity in this situation, is consistent with the fact that inhibition of the enzyme is a significantly cooperative function ($n_H = 2.0$) of the concentration of L-lysine.[205] L-Arginine, a heterotropic allosteric inhibitor, also converts the effect of the concentration of L-glutamate on the initial rate of amino-acid *N*-acetyltransferase from *N. gonorrhoeae* from rectangularly hyperbolic to cooperative (Figure 6–23).[142] Combinations of the three heterotropic allosteric inhibitors L-tryptophan, L-tyrosine, and L-phenylalanine convert the effect of the concentration of D-erythrose 4-phosphate on the initial rate of 3-deoxy-7-phosphoheptulonate synthase from *M.tuberculosis* from rectangularly hyperbolic to cooperative (Figure 6–26). Phospho*enol*pyruvate, a heterotropic allosteric inhibitor, converts the effect of the concentration of D-fructose 6-phosphate on the initial rate of 6-phosphofructokinase from *G. stearothermophilus* from rectangularly hyperbolic to cooperative (Figure 6–17B).

The most obvious explanation for such behavior is that, in the absence of heterotropic allosteric inhibitor, the allosteric constant L_0 is less than 1, so **the enzyme is almost completely in the R conformation at all concentrations of reactant**. As has already been noted, L-phenylalanine causes the effect of phospho*enol*pyruvate on the initial rate of the reaction catalyzed by pyruvate kinase from *O. cuniculus*, which is rectangularly hyperbolic in the absence of heterotropic allosteric inhibitor, to become cooperative (Figure 6–27A). The fact that the binding of the heterotropic allosteric inhibitor L-phenylalanine with unoccupied pyruvate kinase is cooperative (Figure 6–28)[30] is consistent with the proposal that L_0 is less than 1 for this enzyme, that the R conformation predominates in the absence of ligands, and that L-phenylalanine has a smaller dissociation constant from the T conformation than it does from the R conformation so that association of L-phenylalanine with the otherwise unoccupied enzyme is cooperative. In a situation where L_0 is less than 1, association of reactant with the R conformation would be the same as association of any ligand to a homooligomer with only one quaternary conformation, which is always rectangularly hyperbolic, while association of a heterotropic allosteric inhibitor, by shifting the equilibrium in favor of the T conformation, will be cooperative. Only when a heterotropic allosteric inhibitor shifts the equilibrium between the T and the R conformations so that the T conformation is present in high enough concentration in the absence of reactant will the reactant associate with the enzyme cooperatively. This explanation, however, requires that both heterotropic allosteric inhibitor and reactant shift the same equilibrium between the same two conformations.

Mutations of an allosterically regulated enzyme can also convert the effect of the concentration of a reactant on the initial rate of the enzymatic reaction from rectangularly hyperbolic to cooperative.[206] Again, the explanation is that before the mutation the allosteric equilibrium constant favors the R conformation and after the mutation it favors the T conformation.

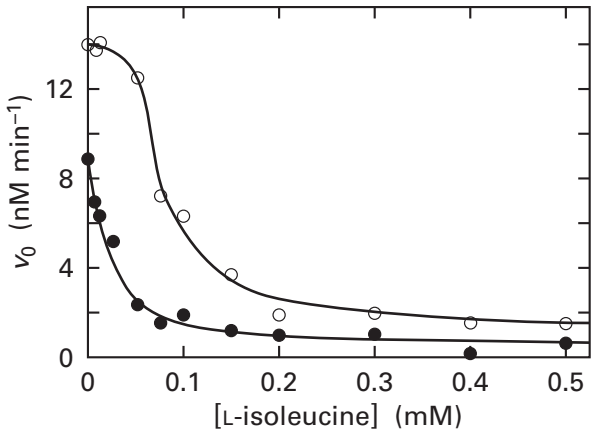


Figure 6–30: Heterotropic allosteric inhibition of threonine ammonia-lyase from *E. coli* by L-isoleucine.[15] Solutions contained 0.4 μM pyridoxal phosphate, 0.1 mM $MgCl_2$, various concentrations of L-isoleucine, various concentrations of L-threonine, and 0.1 M potassium phosphate at pH 8.05 and 27 °C. The reaction was initiated by adding a sample from a partially purified preparation of threonine ammonia-lyase. After suitable intervals, the samples were quenched by adding acid. The concentration of 2-oxobutanoate in each sample was determined by adding 2,4-dinitrophenylhydrazine, extracting the 2,4-dinitrophenylhydrazone of 2-oxobutanoate with ethyl acetate, and measuring the absorbance of the extract at 360 nm. Each initial rate (v_0 in nanomolar minute^{-1}) is plotted as a function of the respective concentration of L-isoleucine (millimolar) at two initial concentrations of L-threonine: 5 mM (●) and 20 mM (○).

Reciprocally, it has also been observed that **a reactant that displays cooperativity in its association with the active site can cause a rectangularly hyperbolic effect of the concentration of a heterotropic allosteric inhibitor on the initial rate of an enzymatic reaction to become cooperative.** For example, the inhibition of threonine ammonia-lyase from *E. coli* by the heterotropic allosteric inhibitor L-isoleucine is rectangularly hyperbolic at low concentrations of the reactant L-threonine but becomes cooperative at higher concentrations (Figure 6–30).[15] An explanation for this behavior is that, at low concentrations of L-threonine, L_0 is greater than 1 and the T conformation predominates. Consequently, L-isoleucine associates noncooperatively with this dominant T conformation, from which it has a smaller dissociation constant than it does from the R conformation, and it simply shifts the equilibrium constant more in favor of the T conformation. The reactant L-threonine, however, has a smaller dissociation constant from the R conformation than from the T conformation, and at high enough concentrations, it shifts the equilibrium in favor of the R conformation. When it does, association of L-isoleucine then becomes cooperative. Again, this explanation requires the same equilibrium between the same two conformations to produce both heterotropic allosteric inhibition and cooperativity; in this case, cooperativity in association of inhibitor rather than in association of reactant.

Because it must increase the stability of the R conformation and decrease the value for the allosteric constant L, a **heterotropic allosteric activator should decrease the degree of homotropic cooperativity** displayed by a reactant. For example, L-valine, a heterotropic allosteric activator of threonine ammonia-lyase from *M. smegmatis*, decreases the Hill coefficient, n_H, of the initial rate of the enzymatic reaction as a function of the concentration of the reactant L-threonine[201] from 2.4 to 1.1. In the extreme, where the difference in affinity of the two conformations for heterotropic allosteric activator is sufficient to invert the value for the equilibrium constant for conformational change in the absence of reactant, the protein will be mostly in the R conformation in the presence of saturating concentrations of the activator even in the absence of other ligands. This latter limit is reached in the activation of aspartate carbamoyltransferase in the presence of $MgATP^{2-}$ and $MgGTP^{2-}$, which activate aspartate carbamoyltransferase from *E. coli* by decreasing both k_0 and k_{asp} and also eliminate cooperativity in the dependence of the initial rate of the enzyme on L-aspartate (Figure 6–3).

Reactants that normally display homotropic cooperativity often no longer display this behavior in the presence of a heterotropic allosteric activator.[15,191,207-209] Acetyl-SCoA is a heterotropic allosteric activator of phospho*enol*pyruvate carboxylase. In this way, flow through the Krebs cycle is increased when levels of acetyl-SCoA are high. Acetyl-SCoA, in its role as heterotropic allosteric activator, eliminates the cooperativity of the initial rate of phospho*enol*pyruvate carboxylase from *S. typhimurium* as a function of the concentration of phospho*enol*pyruvate.[210]

Magnesium ADP^-, a heterotropic allosteric activator of 6-phosphofructokinase from *E. coli*, increases the specificity constant, k_{F6P}, for D-fructose 6-phosphate (F6P) while phospho*enol*pyruvate, a heterotropic allosteric inhibitor, decreases it, yet both $MgADP^-$ and phospho*enol*pyruvate decrease cooperativity in the dependence of the initial rate of the enzyme on the initial concentration of D-fructose 6-phosphate.[19] An explanation for this observation is that the activator shifts the equilibrium between the conformations so that the R conformation dominates in the absence of reactant while the inhibitor shifts the equilibrium so heavily

in the direction of the T conformation that even saturating concentrations of reactant cannot shift it sufficiently in the direction of the R conformation to overcome the shift caused by the inhibitor.

Such situations, however, in which either an activator or an inhibitor decreases cooperativity or both do, **cannot provide evidence for the existence of only one equilibrium between two conformations** of the enzyme. Although this behavior can be explained by the existence of only two conformations, it can also be explained as readily by the existence of separate conformational equilibria, one for heterotropic allosteric effects and another for cooperativity. In this case, a heterotropic allosteric effector would shift the enzyme into the third quaternary conformation, which would simply associate with reactant as would a normal homooligomer in which there is no quaternary conformational change linked to the association. Consequently, such behavior provides no evidence in favor of the effectors and reactants controlling the equilibrium between the same two conformations. Likewise, the observation that a heterotropic allosteric inhibitor causes the effects of a heterotropic allosteric activator to become cooperative[15] can be just as consistent with separate equilibria responsible for heterotropic allosteric effects and for cooperativity. Again this ambiguity is a consequence of the fact that any explanation for observed behavior of equilibria or observed kinetics can always be expanded by adding additional participants and remain consistent with the observations. Nevertheless, these effects of ligands on the observed cooperativity are those expected from the existence of only two quaternary conformations that are responsible for them.

There are many examples of simple heterotropic allosteric inhibition by a single inhibitor, simple heterotropic allosteric activation by a single activator, and even simple heterotropic allosteric inhibition and activation by a single inhibitor and a single activator. Many enzymes, however, are controlled by complicated combinations of classical competitive inhibition, heterotropic allosteric inhibition, and heterotropic allosteric activation exerted by several inhibitors and activators associating both with the active site and with more than one allosteric site.

Glycogen phosphorylase (Equation 6–66) releases D-glucose, the primary source of immediate metabolic energy in an animal, from glycogen. Glycogen phosphorylase *b* from *O. cuniculus* is controlled, as might be expected, by a large collection of different heterotropic allosteric effectors (Table 6–2) that associate with one or more of five distinct sites (Figure 6–20) and affect the equilibrium or equilibria between two or more conformations of the enzyme. The site for heterotropic allosteric effectors (AE) binds AMP^{2-}, a heterotropic allosteric activator of the enzyme that signals a need for metabolic energy,[211,212] but the enzyme is inhibited when this site is occupied by $MgATP^{2-}$.[213] It was proposed that opposite effects from the same site can occur because AMP^{2-} binds more tightly to only one conformation while $MgATP^{2-}$ prevents the binding of AMP^{2-} but has no effect on the conformational equilibria. A similar situation occurs in the catalytic (C) site. D-Glucose 1-phosphate, acting as a reactant, shifts the conformational equilibrium in favor of a more active conformation,[213] while D-glucose, also binding at the active site as a simple competitive inhibitor,[214] shifts it in favor of a less active or inactive conformation to shut down glycogen utilization when levels of D-glucose are high.[215]

Table 6–2: Effects of Various Ligands on the Conformational Equilibria between Enzymatically Active and Inactive Conformations of Glycogen Phosphorylase from *O. cuniculus*

ligand	site[a]	conformer
AMP^{-}	AE	active
$MgATP^{2-}$	AE	neither[b]
D-glucose 6-phosphate	G6P	neither
D-glucose 1-phosphate	C	active
D-glucose	C	inactive
adenosine	I	inactive
caffeine	I	inactive[c]
glycogen	G	active

[a]Named as in Figure 6–20. [b]Competes with AMP for nucleotide site. [c]Synergistic with D-glucose. [d]Binds at a site adjacent to the nucleotide site and competes with AMP.

Sandwiched between Phenylalanine 285 and Tyrosine 613 in the enzyme from *O. cuniculus* is another site, the site for nucleoside inhibitors (I), at which planar heterocycles such as those in caffeine, adenine, inosine, adenosine, AMP^{2-}, $MgATP^{2-}$, or flavin mononucleotide can bind.[216] These ligands are all heterotropic allosteric inhibitors of the enzyme. Because either D-glucose, binding to the active site, or any one of these inhibitors, binding to the site for nucleoside inhibitors, shifts the conformational equilibrium in favor of a less active or inactive conformation or conformations of the enzyme, when both D-glucose and one of these other inhibitors are present, they inhibit the enzyme in concert.[216,217] D-Glucose increases the apparent dissociation constant for any one of these inhibitory heterocyclic compounds by independently shifting the conformational equilibrium constant in favor of the R conformation, with which they associate less avidly.

D-Glucose 6-phosphate binds at a site (G6P) that is immediately adjacent to the site for heterotropic allosteric effectors. When it is bound at this site, one of its phosphate oxygens overlaps the location at which one of the phosphate oxygens of AMP^{2-} is bound.[110] Consequently, AMP^{2-} cannot bind to the site and activate the enzyme because of steric exclusion, which explains the inhibition of activation by AMP^{2-} manifested by D-glucose 6-phosphate. This makes sense because glycogenolysis should not be activated when the concentration of a glycolytic intermediate such as D-glucose 6-phosphate is high.

Finally, there is a site at which the enzyme normally binds to glycogen, the glycogen storage site (G). When a polysaccharide occupies this site, in the absence of AMP^{2-}, the conformational equilibrium or equilibria is shifted in favor of the active conformation and the enzymatic reaction is accelerated.[218]

The first-order rate constants for the conformational changes that accompany changes in the affinity of a homooligomer in either the binding of its ligands or its enzymatic activity have a wide range of values. These conformational changes are unimolecular isomerizations of the folded polypeptides within the oligomer that can lead to alterations in the orientations of its subunits.

The kinetics of isomerizations that occur when carbon monoxide is photodissociated from the four hemes in fully occupied human **hemoglobin** have been studied extensively. Upon complete and almost instantaneous dissociation of bound carbon monoxides, the molecules of hemoglobin are almost all in the R conformation, which then converts to the T conformation (Figure 6–1). A **rapid change** in the scattering of X-rays at small angles, which monitors directly the quaternary conformational change,[219] occurs with a rate constant of approximately 0.5 μs^{-1} at 20° C. This rate constant is indistinguishable from the rate constant of approximately 2 μs^{-1} for a change in circular dichroic absorption at 340 nm, arising from tryptophan and tyrosines in the interfaces between the subunits,[220] and from the rate constant of 1.3 μs^{-1} for a change in absorption between 400 and 480 nm, the region in which the heme absorbs.[221] These coincidences are consistent with the conclusion that these changes all monitor the **rapid global quaternary conformational change** from the R to the T conformation. Less rapid changes in infrared signals in Raman spectra are thought also to arise from the interfaces between the subunits.[222] Less rapid changes in the circular dichroic spectrum at 340 nm[220] occur with rate constants between 0.05 and 0.1 μs^{-1} and may be monitoring final readjustments in the R conformation. There are also more rapid changes in absorption of the heme and in the resonance Raman infrared spectrum that have been assigned to local conformational changes around the heme in response to its unoccupation. The rate constant for the conformational relaxation[223] that occurs after aspartate carbamoyltransferase in the R conformation associates with $MgCTP^{2-}$ is 0.01 μs^{-1} at pH 7.0 and 25 °C. All these processes are quite rapid when compared to catalytic constants of enzymes. The opening and closing of the active sites of enzymes such as hexokinase (Figure 3–55) and citrate synthase must also proceed at rates greater than or equal to the turnover numbers for these enzymes.

There are, however, many **conformational changes that have slow rates**. When 6-phosphofructokinase (Equation 6–28) from *O. cuniculus* is preincubated with heterotropic allosteric activators and then diluted for enzymatic assay, its enzymatic activity is quite high at first but then decreases slowly to the steady-state rate.[224] When the enzyme is preincubated with heterotropic allosteric inhibitors and then diluted for assay, its enzymatic activity is low at first but then increases slowly to the steady-state rate. These decreases and increases in enzymatic activity reflect the slow rate constant for the conformational changes responsible for heterotropic allosteric effects. The first-order rate constants for these relaxations are between 0.003 and 0.03 s^{-1}

at pH 7.5 and 25 °C. Very similar behavior is also observed[225] with human amidophosphoribosyltransferase (previously Equation 4–313)

$$\text{manganese 5-phospho-}\alpha\text{-D-ribose 1-diphosphate} + \text{L-glutamine} + H_2O \rightleftharpoons \text{L-glutamate} + H^+ + MnOPO_3PO_3^{2-} + \text{5-phospho-}\beta\text{-D-ribosylamine} \quad (6\text{–}105)$$

The slow conformational change in this instance has a rate constant of about 0.005 s^{-1} at 25 °C. Formally, there is no distinction except in magnitude between a rapid and a slow conformational relaxation. It may, however, be the case that the rate of conformational change has evolved to match the rates of the particular fluctuations in concentration of effectors to which the enzyme is adapted to respond.

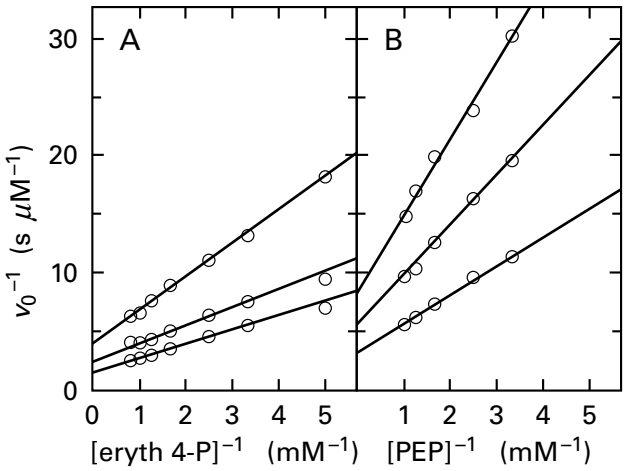
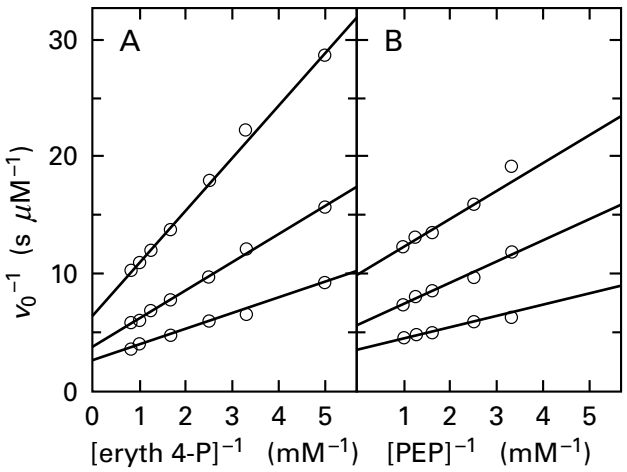
Problem 6–6: The reaction catalyzed by 3-deoxy-7-phosphoheptulonate synthase (see Equation 3–17)

$$\text{phospho}\textit{enol}\text{pyruvate} + H_2O + \text{D-erythrose 4-phosphate} \rightleftharpoons HOPO_3^{2-} + \text{3-deoxy-D-}\textit{arabino}\text{-hept-2-ulosonate 7-phosphate}$$

is the first committed reaction in the biosynthesis of L-phenylalanine and L-tyrosine. The reaction of the enzyme from *E. coli* is allosterically inhibited[175] by both L-phenylalanine and L-tyrosine. Below are some of the kinetic results that describe this heterotropic allosteric inhibition.



Inhibition of 3-deoxy-7-phosphoheptulonate synthase by L-tyrosine.[226] The reaction mixtures for the observations in Panel A contained 2 mM phospho*enol*pyruvate, D-erythrose 4-phosphate as indicated, 0.13 mg of protein mL^{-1}, and 0.1 M potassium phosphate at pH 6.4. The reaction mixtures for the observations in Panel B contained 2 mM D-erythrose 4-phosphate, phospho*enol*pyruvate as indicated, 0.1 mg of protein mL^{-1}, and 0.1 M potassium phosphate at pH 6.4. All reaction mixtures were incubated for 10 min at 37 °C, and the amount of 3-deoxy-D-*arabino*-hept-2-ulosonate 7-phosphate formed was determined. Each reciprocal of the initial rate of the enzymatic reaction (v_0 in micromolar of 3-deoxy-D-*arabino*-hept-2-ulosonate 7-phosphate produced second^{-1}) is plotted as a function of the reciprocal of the concentrations of reactant, either (A) erythrose 4-phosphate (eryth 4-P; millimolar) or (B) phospho*enol*pyruvate (PEP; millimolar). The concentrations of L-tyrosine in the reaction mixtures for each line were, in each panel in ascending order, 0, 20, and 40 μM.



Inhibition of 3-deoxy-7-phosphoheptulonate synthase by L-phenylalanine.[226] The procedure was the same as described above, with the exceptions that L-phenylalanine was used to inhibit the enzyme rather than L-tyrosine and that the reaction mixtures contained 0.13 mg of protein mL^{-1} (Panel A) or 0.09 mg of protein mL^{-1} (Panel B). The concentrations of L-phenylalanine in the reaction mixtures for each line were, in each panel in ascending order, 0, 20, and, 40 μM.

(A) Do the heterotropic allosteric inhibitors L-phenylalanine and L-tyrosine compete with any reactant?
(B) Extend the lines in each figure and decide whether the heterotropic allosteric inhibitors might affect dissociation constants for D-erythrose 4-phosphate (eryth 4-P) from the enzyme.
(C) What kinetic parameter of the enzymatic reaction is affected by association of inhibitors with the enzyme?
(D) Assume that there are two conformations of the enzyme, R and T, in equilibrium with each other and that L-phenylalanine affects this equilibrium. Draw the linkage relation between binding of L-phenylalanine and the conformational equilibrium of the enzyme.
(E) If

$$L_0 = [\mathrm{T}]\,[\mathrm{R}]^{-1}$$
$$K_{\mathrm{dPhe}} = [\mathrm{R}][\mathrm{Phe}]\,[\mathrm{R{\cdot}Phe}]^{-1}$$
$$K'_{\mathrm{dPhe}} = [\mathrm{T}][\mathrm{Phe}]\,[\mathrm{T{\cdot}Phe}]^{-1}$$
$$L_{\mathrm{Phe}} = [\mathrm{T{\cdot}Phe}]\,[\mathrm{R{\cdot}Phe}]^{-1}$$

what is the relation between these four equilibrium constants?
(F) To explain the effect of L-phenylalanine on the properties of the enzyme, what probably are values for L_0 and L_{Phe} with respect to 1 if $K'_{\mathrm{dPhe}} << K_{\mathrm{dPhe}}$?

Problem 6–7: The Bohr effect of hemoglobin is the change in the affinity of hemoglobin (Hb) for molecular oxygen with a change in pH. It is due to a heterotropic allosteric interaction between hydrons (H^+) and molecular oxygen (O_2). The main experimental facts can be approximated in the following way. An approximation is made to simplify the situation and elucidate underlying principles. The main simplification is to ignore homotropic cooperativity.

(a) The reaction between Hb and O_2 can be described by the following equilibrium.

$$\mathrm{HbO_2} \rightleftharpoons \mathrm{Hb} + \mathrm{O_2}$$

(b) At pH 7, the apparent dissociation constant $K_{\mathrm{dO_2,app}}$ for this reaction is 18 μM.

(c) The apparent dissociation constant changes with pH, reaching a constant minimum value of 2.5 μM above pH 9.5 and a constant maximum value of 50 μM below pH 6.0.

(d) If a 0.1 mM solution of oxygenated hemoglobin ($Hb{\cdot}O_2$) in unbuffered 0.2 M NaCl at pH 7 is deoxygenated by bubbling with N_2, the pH of the resulting solution increases by 0.26 pH unit.

(e) Assume that the reaction of interest between hemoglobin and hydronium can be considered a consequence of the ionization of a single amino acid side chain in each $\alpha\beta$ dimer.

(f) The curves for the binding of molecular oxygen by Hb have been determined at several different values of pH. The reaction measured experimentally is

$$\mathrm{HbO_{2,t}} \overset{K_{\mathrm{d,O_2,app}}}{\rightleftharpoons} \mathrm{Hb_t} + \mathrm{O_2}$$

where $[\mathrm{HbO_{2,t}}] = [\mathrm{Hb{\cdot}O_2}] + [\mathrm{Hb{\cdot}H^+{\cdot}O_2}]$, $[\mathrm{Hb_t}] = [\mathrm{Hb}] + [\mathrm{Hb{\cdot}H^+}]$, and $K_{\mathrm{dO_2,app}} = [\mathrm{Hb_t}][\mathrm{O_2}]\,[\mathrm{Hb{\cdot}O_{2,t}}]^{-1}$.

Values of the apparent dissociation constants for molecular oxygen from hemoglobin are as follows.

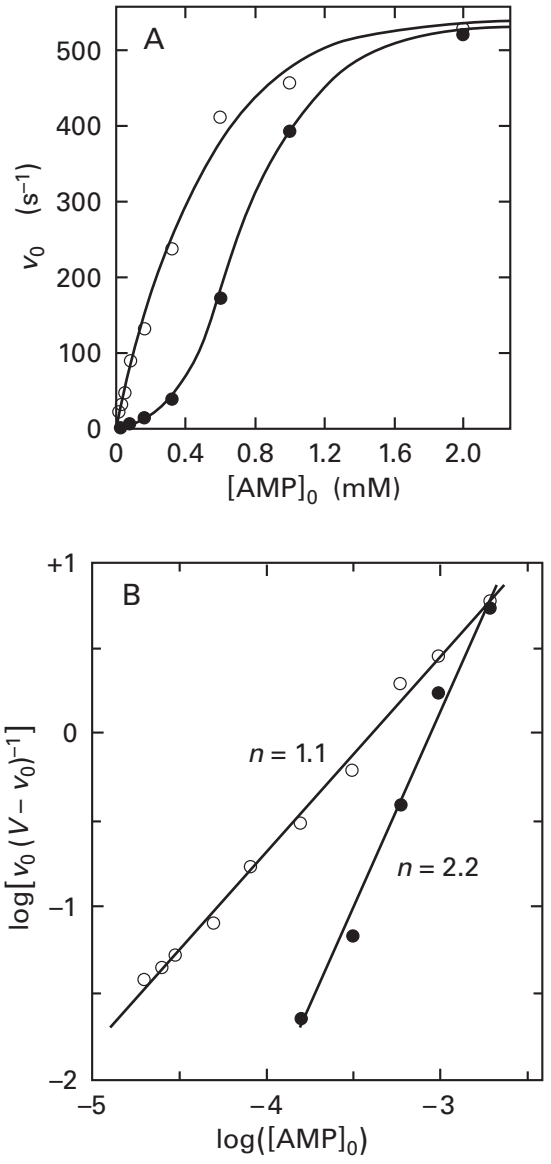
pH	$K_{\mathrm{dO_2,app}}$ (μM)	pH	$K_{\mathrm{dO_2,app}}$ (μM)
10.0	2.5	7.0	25
9.0	3.0	6.5	37
8.25	4.8	6.0	45
7.6	13	5.0	50

(A) Define the four microscopic equilibrium constants: $K_{\mathrm{dO_2}}$, $K_{\mathrm{dO_2,H^+}}$, K_{aHb}, and $K_{\mathrm{aHb{\cdot}O_2}}$. Write the reactions to which they refer.
(B) Show that $K_{\mathrm{dO_2}}K_{\mathrm{aHbO_2}} = K_{\mathrm{dO_2,H^+}}K_{\mathrm{aHb}}$.
(C) How many equilibrium constants are independent ones?
(D) By using the relations between the equilibrium constants derived above, show that $K_{\mathrm{dO_2,app}}$ is a function of only $[H^+]$ and give the mathematical relation.
(E) Plot log $K_{\mathrm{dO_2,app}}$ against pH. Explain the shape of the curve in terms of the equation in part D.
(F) If the pK_a for the oxygen-linked group in deoxyhemoglobin (pK_{aHb}) were 8.5, what would be the pK_a of this group in oxyhemoglobin, p$K_{\mathrm{aHbO_2}}$?
(G) Explain observation d.

Problem 6–8: The enzyme AMP deaminase from *O. cuniculus* catalyzes the following reaction:

$$AMP^{2-} + H^+ + H_2O \rightleftharpoons IMP^{2-} + NH_4^+$$

The enzyme is a tetramer and is activated by K^+. The kinetics of this activation, with respect to the concentration of AMP^{2-}, are displayed in Panel A of the following figure. Open circles are the data gathered in the presence of a nonactivating cation (tetramethylammonium); filled circles are the data gathered in the presence of K^+. Panel B of the figure is simply a replot of the data by the Hill equation.



Effect of the concentration of AMP^{2-} on the initial rate of AMP deaminase[227] in the presence and absence of K^+. Assays were run at various concentrations of AMP, 0.15 M tetramethylammonium chloride (●) or 0.15 M KCl (○), and 50 mM imidazolium chloride at pH 6.5 and 30 °C. (A) Initial rate (v_0, in second^{-1}) with respect to the initial concentration of AMP^{2-} ($[AMP]_0$; millimolar). (B) Plots of data from Panel A in the format of the Hill equation (Equation 6–9).

Potassium ion activates the enzyme by increasing its apparent affinity for AMP^{2-} without altering its limiting rate and by eliminating the cooperativity for the effect of AMP^{2-} on enzymatic rate.

(A) Assume that there are two forms of the enzyme, R and T, in equilibrium with each other and that both K^+ and AMP^{2-} can shift that equilibrium. Draw the two linkage relations that connect the binding of either K^+ or the first AMP^{2-} to the conformational equilibrium of the enzyme. Abbreviate K^+ as K and AMP^{2-} as AMP.

(B) By definition

$$L_0 = [T]\,[R]^{-1}$$
$$L_K = [K{\cdot}T]\,[K{\cdot}R]^{-1}$$
$$L_{AMP} = [T{\cdot}AMP]\,[R{\cdot}AMP]^{-1}$$
$$K_{dAMP} = [R][AMP]\,[R{\cdot}AMP]^{-1}$$
$$K'_{dAMP} = [T][AMP]\,[T{\cdot}AMP]^{-1}$$
$$K_{dK} = [K][R]\,[K{\cdot}R]^{-1}$$
$$K'_{dK} = [K][T]\,[K{\cdot}T]^{-1}$$

Write two fundamental equalities relating some of these equilibrium constants with others.

(C) Assume that the R conformation has a higher affinity for AMP^{2-} than the T conformation; in other words, $K_{dAMP} < K'_{dAMP}$. What must be true for the value of L_0 to explain the cooperativity of the enzyme in the absence of K^+?

(D) What must be true for values of L_0 and L_K to explain K^+ activation?

(E) Why does activation by K^+ result in the loss of cooperativity?

(F) Why does K^+ affect only the Michaelis constant for AMP^{2-} rather than the limiting rate, V?

Interfaces and Oligomeric Associations

The quaternary conformational changes controlled by ligands, substrates, and heterotropic allosteric effectors involve reorientations of the folded polypeptides that constitute the oligomer with respect to each other. These reorientations occur at the interfaces between the subunits. Within each interface there are two faces, and it is these faces that reorient relative to each other. For these reorientations to proceed, changes in the molecular **contacts within the interfaces** that hold the oligomer together must occur. These contacts within the interface are between amino acid side chains and portions of the polypeptide backbones that are in the two faces. These changes in orientation can be seen at the interfaces in hemoglobin as their faces shift during the quaternary conformational change.

Crystallographic molecular models are available for human hemoglobin both in its unliganded, deoxy (T) conformation[228] and in its liganded, oxy (R) conformation. The latter hemoglobin is either in a complex with molecular oxygen,[229] its physiological ligand, or in a complex with carbon monoxide,[230] a congener of molecular oxygen. The more extensive[231] identical interfaces between subunits $\alpha 1$ and $\beta 1$ and between subunits $\alpha 2$ and $\beta 2$ (Figure 6–1) remain the same in each quaternary conformation. The two interfaces that change—namely, the less extensive interfaces between subunits $\alpha 1$ and $\beta 2$ (Figure 6–31)[1] and between subunits $\alpha 2$ and $\beta 1$—are also identical to each other both before and after the conformational change because of the twofold rotational axis of symmetry relating the two $\alpha\beta$ dimers. Passing through the center of each identical interface, $\alpha 1\beta 2$ and $\alpha 2\beta 1$, is a twofold rotational axis of pseudosymmetry (normal to the page in Figure 6–31), so each interface has two similar pairs of contacts related by this axis. These two pseudosymmetric pairs of contacts are formed by the third α helix (helix C) of one subunit interdigitating with a loop of polypeptide (the FG corner) between the sixth and seventh α helices of the other subunit and the third α helix (helix C) of the other subunit interdigitating with the loop of polypeptide (the FG corner) between the sixth and seventh α helices of the first subunit.

Because the axis, however, is a rotational axis of pseudosymmetry, these two sets of contacts related by it adjust differently to the conformational change. Within the juxtaposition of the FG corner of subunit $\alpha 1$ and helix C of subunit $\beta 2$ (Figure 6–31), the arrangement of the interlocking contacts among the three amino acids from subunit $\alpha 1$ and the two amino acids from subunit $\beta 2$ remain the same during the conformational change, and the shift in the orientations of the subunits is accommodated by plastically shifting the conformations and atomic contacts among these five amino acids.[1] Within the juxtaposition of the FG corner of subunit $\beta 2$ and helix C of subunit $\alpha 1$ (Figure 6–31), however, which are in the same interface between subunits $\alpha 1$ and $\beta 2$, the order of the amino acids in the interdigitations shifts to accommodate the new orientation as the two faces of this interface slide across each other.

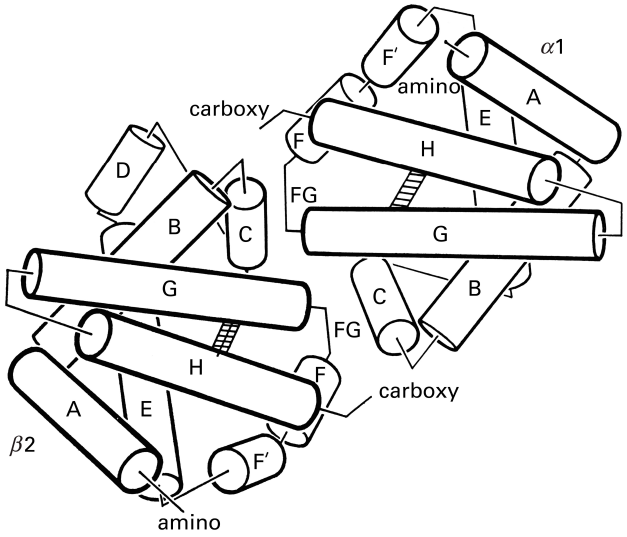


Figure 6–31: Schematic diagram of the arrangement of an $\alpha 1$ subunit and a $\beta 2$ subunit that forms the $\alpha 1\beta 2$ interface in the crystallographic molecular model of hemoglobin.[1] The crystallographic molecular models of deoxyhemoglobin and carbonmonoxyhemoglobin described in Figure 6–1 were used to draw the diagram and provide the disposition of an $\alpha 1$ subunit and a $\beta 2$ subunit. Because the $\alpha 1\beta 2$ interface shown here rearranges significantly during the conformational change, the diagram represents neither model but is an average structure that is intended simply to display the disposition of secondary structures at the interface in both molecular models. The hemes are seen side-on in this view as hatched trapezoids. The α helices that form the majority of the protein are labeled consecutively A–H from the amino terminus (labeled "amino") to the carboxy terminus (labeled "carboxy") of each subunit. The $\alpha 1\beta 2$ interface is formed from the FG corners and the C α helices. The twofold rotational axis of pseudosymmetry is normal to the page and passes through the center of the structure. Reprinted with permission from reference 1. Copyright 1979 Elsevier. https://doi.org/10.1016/0022-2836(79)90277-8

For example, Histidine 97 from the FG corner of the β2 subunit packs between Threonine 41 and Proline 44 from the C helix of subunit α1 in the deoxy conformation, but it shifts over to pack between Threonines 38 and 41 in the oxy conformation. It has been proposed that this alternation between only **two discrete accessible and stable interdigitations** within this second juxtaposition is the reason that there are only two conformations of the oligomer.[1]

At the hemes, the difference in affinity for oxygen between the deoxy and oxy conformations arises from a shift in the position of the sixth helix (helix F) that causes the iron to be pulled out of the plane of the heme in the deoxy conformation but to reside within the plane of the heme in the oxy conformation (Figure 2–53). The connection between this shift and the quaternary conformational change can be thought of in two equivalent ways. On the one hand, it could be concluded that a change in quaternary conformation causes the interfaces involving the FG corners to change their structure, pushing or pulling the covalently connected helix F across the heme and changing the affinity for oxygen. On the other hand, it could be concluded that the binding of oxygen pulls the iron into the plane of the heme, which in turn pulls on helix F and lowers the stability of the deoxy conformation because the shifted helix can be accommodated most effectively in the oxy conformation. These two views of the conformational change are not mutually exclusive; in fact, they are probably two sides of the same coin. The most important point is that the change in conformation be coupled indivisibly to the change in affinity of the hemes for oxygen. This coupling of a conformational change to a functional change is the reason that conformational changes permit cooperativity and heterotropic allosteric control, as well as the conformational conversion of chemical and mechanical energy.

Crystallographic molecular models are available for aspartate carbamoyltransferase in the T conformation, to which $MgCTP^{2-}$ is bound,[62] and in the R conformation, to which *N*-(phosphonacetyl)-L-aspartate is bound.[6,51] During the quaternary conformational change (Figure 6–2)—which involves rotation of the catalytic α subunits relative to each other, opening up of the space between them, and tilting of the regulatory β subunits—several **changes occur in the interfaces** among the subunits.[6] An extensive interface between each catalytic α subunit and the regulatory β subunit immediately adjacent to it but in the other half of the oligomer is present in the T conformation but not in the R conformation because the expansion of the space between the two catalytic trimers sunders it. An interface between each catalytic α subunit and the catalytic α subunit adjacent to it in the other half of the oligomer that is present in the T conformation (Figure 6–8) is also drastically altered and almost eliminated during the conformational change as the α_3 trimers move apart. These two interfaces presumably would act to stabilize the T conformation relative to the R conformation. The interface between adjacent subunits in each trimer of catalytic α subunits, however, becomes more extensive in the R conformation than in the T conformation, which would operate in the opposite direction. The main interface between a catalytic α subunit and a regulatory β subunit, which acts as one of the six identical, symmetrically displayed pivots during the quaternary conformational change, sustains a significant number of changes in atomic contacts, as might be expected during such a rotation of β subunits relative to α subunits. Overall, however, the number of contacts in that interface also increases upon the change from the T to the R conformation.

When **atomic contacts across the various interfaces** are examined in detail, 31 are lost and 25 different ones are gained for each of the six asymmetric units, comprising one catalytic α subunit and one regulatory β subunit, upon the transition from the T to the R conformation. This accounting, however, is a deceptive tally because large changes in the number of contacts (34 lost and 48 gained for each asymmetric unit) also occur within the folded polypeptides themselves, and there is no reason to focus on only one category of changes to explain the overall differences in stability between the two quaternary conformations. In addition, there was no distinction made between the contacts lost and gained within each subunit as a result of local conformational changes and those lost or gained as a result of the quaternary conformational change.

One of the more remarkable aspects of the structure of many of **the interfaces the faces of which shift during the conformational changes** producing allosteric behavior, such as the two in human hemoglobin, is their **relatively small extent**. For example, the homotetramer of porcine fructose-bisphosphatase (Equation 6–62) is held together by four interfaces between the four subunits. Because of the 222(D_2) symmetry of the molecule, the four interfaces consist of two identical pairs. The quaternary conformational change between the T and R conformations includes a reorientation of the subunits that involves only one pair of interfaces. Within each of these two symmetrically identical

interfaces that are involved in the quaternary conformational change, there are two faces, one from each subunit across the interface. It is these faces that reorient, and it is changes in the structures of these faces that cause the reorientation. As a result of these changes, the two faces shift relative to each other, causing the two dimers to rotate by 17° around the twofold rotational axis of symmetry relative to each other.[37] The symmetrically identical interfaces in the other pair are more extensive, and they do not experience a shift in the orientation of their two constituent faces during the quaternary conformational change. In the pair in which the faces reorient, each symmetrically identical interface is formed by contacts among only 20 amino acids from one face and 24 amino acids from the other. In the pair in which the faces do not reorient, each interface is formed by contacts among 48 amino acids from one face and 52 amino acids from the other.[232] In this instance, the interfaces within which the faces shift during the allosteric quaternary conformational change are less extensive by a significant margin.

Each pair of symmetrically related interfaces within which the faces reorient when the deoxy conformation of hemoglobin turns into the oxy conformation (Figure 6–31) involves only 11 amino acids from each subunit.[231] The interface between two subunits in glycogen phosphorylase from *O. cuniculus* is at a neck connecting the two much wider globular subunits (Figure 6–32).[214,486] The twofold rotational axis of symmetry passes through the center of the neck, which is formed from several loops of polypeptide that interdigitate symmetrically around the axis (Figure 6–32). The narrow cross section of the neck relative to the centers of the two subunits causes this interface to be less extensive than those usually encountered in oligomers that do not display allostery.

It is within such **interfaces in which the faces shift** that the changes in orientation among the folded polypeptides occur. Most enzymes (85%) are either dimers or tetramers with 222(D_2) symmetry formed from identical folded polypeptides.[233] **Twofold rotational axes of symmetry** run through the centers of the interfaces holding together such homooligomers, and **an overall change in structure within one of these rotationally symmetric interfaces includes a pair of identical reorientations of its faces**. These interfaces are related to each other by the twofold rotational axis of symmetry. That these pairs of structural changes, because they are identical to each other, are required to occur simultaneously is the reason the symmetry is maintained. The binding of ligand to one subunit causes local conformational changes that destabilize the quaternary conformation. The interfaces, however, remain symmetric and in the unliganded conformation until the number of ligands bound is sufficient to shift the equilibrium constant for the quaternary conformational change of the oligomer to the other side of unity. Then, as the quaternary conformational change of the oligomer commences, it cannot stop at some intermediate asymmetric state because the interfaces among the subunits do not mesh properly until a symmetrical oligomer of the other conformation is formed.[15] The difference of a few kilojoules mole^{-1} of standard free energy between the imprecise fit at the interfaces in an asymmetrical oligomer and the precise fit in a symmetrical oligomer dictates that the ligand-linked quaternary conformational changes built into the sequence of amino acids for each subunit occur in concert during the quaternary conformational change of the oligomer.

When the faces within less extensive interfaces shift relative to each other during a quaternary conformational change, the dissociation constant between the two folded polypeptides on the two sides of the interface necessarily changes. Because these interfaces are often puny, the larger homooligomer in which these puny interfaces are located sometimes dissociates into smaller homooligomers when it associates with or dissociates from its ligands, substrates, or heterotropic allosteric effectors. Dissociation occurs because the dissociation constant for the symmetric interfaces increases as the result of reorientation of its faces that occurs during the quaternary conformational change. In a dimer, there is only one interface with identical halves holding the oligomer together, as with the dimer of glycogen phosphorylase (Figure 6–32). When the dissociation constant for this interface increases, the dimer can split into two monomers. In a tetramer, there are four or six interfaces holding the oligomer together—two or three symmetrically arrayed pairs of identical interfaces—through each of which passes a molecular twofold rotational axis of symmetry. Usually one pair of identical interfaces in a homotetramer is stronger than the other pair or pairs and is much less affected by the quaternary conformational change, as is the case in fructose-bisphosphatase. When dissociation constants for the weaker pair or pairs of interfaces increase during the change in quaternary conformation, whether the change occurs by association or dissociation of ligands, the tetramer

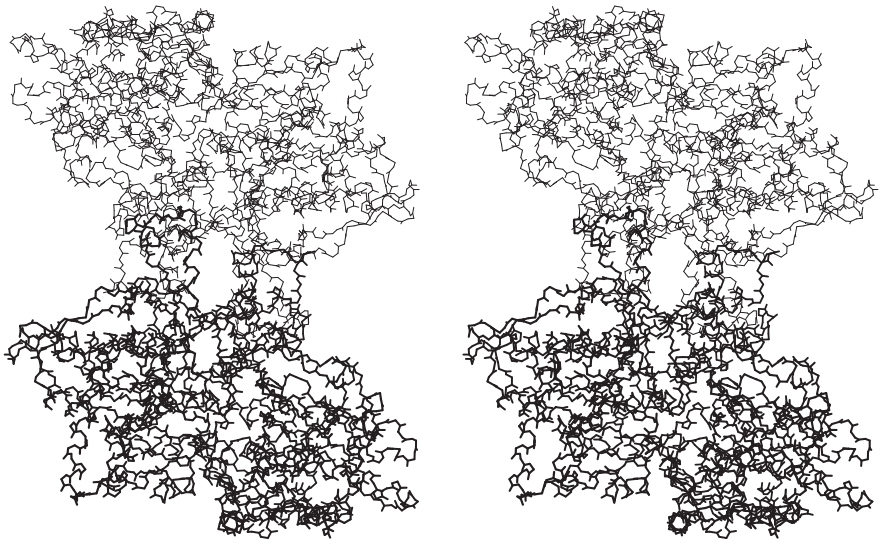

Figure 6–32: Stereodrawing[485] of the two polypeptide backbones in the crystallographic molecular model[486] of the α_2 dimer of glycogen phosphorylase *b* from *O. cuniculus*. The crystals were of space group $P4_32_12$, and a single subunit (841 aa) occupied the asymmetric unit. The only ligand observed in the map of electron density was the prosthetic pyridoxal phosphate. In the figure, the two subunits (thick and thin lines) of the α_2 dimer are displayed around the crystallographic twofold rotational axes of symmetry, which in this view is normal to the page. The interface between the subunits is peculiar in that it is formed by interdigitating strands that create a neck between the two globular structures.

can split into two dimers, each of which retains the strong interface unaffected by the conformational change

A **reactant, heterotropic allosteric activator, or heterotropic allosteric inhibitor can change one or the other of these dissociation constants** and either effect such a dissociation or, in reverse, promote association of the halves that are products of such a dissociation.* The isoenzyme of aspartate kinase (Equation 6–103) in *E. coli* that is inhibited allosterically by L-lysine is a homodimer.[234] Two of these homodimers exist in equilibrium with a tetrameric dimer of dimers within a particular range of concentration of protein. Addition of L-lysine shifts the equilibrium in favor of the tetramer.[235] Human amidophosphoribosyltransferase (Equation 6–105) is a homotetramer that exists in equilibrium with its two dimers. Addition of AMP^{2-}, a heterotropic allosteric inhibitor,[236] also shifts the equilibrium in favor of the tetramer.[237]

In the two previous examples, the binding of a heterotropic allosteric inhibitor promoted association of dimers to a tetramer, but association of **a substrate, heterotropic allosteric inhibitor, or heterotropic activator can promote either association or dissociation of an oligomer**. The heterotropic allosteric inhibitor phospho*enol*pyruvate shifts the equilibrium between dimers and tetramers in favor of dimers of 6-phosphofructokinase from *G. stearothermophilus*, promoting dissociation of the tetramer (Figure 6–9) into dimers, which occurs at the pair of identical symmetrically displayed interfaces in which the faces shift in their relative orientation during the quaternary conformational change.[27,238] In the case of threonine ammonia-lyase from *Arabidopsis thaliana*, the heterotropic allosteric inhibitor L-isoleucine[239] also shifts the equilibrium between dimers and tetramers in favor of dimers.[240] The binding of either molecular oxygen or carbon monoxide, each a homologue of a substrate for an enzyme, promotes dissociation of the stable $(\alpha\beta)_2$ tetramer of human deoxyhemoglobin (Figure 6–1) into $\alpha\beta$ dimers.[241] The heterotropic allosteric activator[242] $MgGTP^{2-}$ shifts the equilibrium between dimers and tetramers in favor of tetramers of uracil phosphoribosyltransferase from *Toxoplasma gondii*.[243] And D-ribulose 5-phosphate, a cooperative substrate, promotes association of two monomers of human ribulose-phosphate 3-epimerase to form a dimer, which is the more enzymatically active quaternary form of the enzyme.[244,245]

In a few instances, dimers of a particular enzyme are in equilibrium with an oligomer larger than a tetramer, and the equilibrium is affected by a substrate or heterotropic allosteric effector.[246] For example, rotationally symmetric dimers of a rare allele of human porphobilinogen synthase are in equilibrium with octamers and also in equilibrium with hexamers.[247] Each octamer is a tetramer of the dimers arrayed around a fourfold rotational axis of symmetry. There are eight identical interfaces among the four dimers, not counting those that hold the dimers together, and these interfaces are symmetrically related by the fourfold rotational axis of symmetry. Each hexamer of dimers is arrayed around a threefold rotational axis of symmetry, and there are six identical interfaces among the dimers, distinct from the eight that produce the octamer, arrayed around the threefold axis of symmetry. In both the octamer and the hexamer, however, none of these interfaces connecting the homodimers—eight in the octamer and six in the hexamer—has a twofold rotational axis running through it because the individual subunits participating in these interfaces are arranged about the threefold and fourfold axes of symmetry, respectively, as are the catalytic subunits in aspartate carbamoyltranferase (Figure 6–2), head to tail. The interface within a dimer is the strong one while the eight and the six interfaces holding together each octamer and hexamer, respectively, are weak. Association of the substrate, 5-aminolevulinate, shifts the equilibrium from one in favor of hexamers to one in favor of octamers.[248] Association of substrate alters the conformation of the surface of each subunit in a dimer in such a way that the two faces on the surface of each subunit that participates in formation of the hexamer no longer can do so and the two faces on each subunit that participates in formation of the octamer can now do so.

So far, all but one of the examples of oligomeric enzymes in which an equilibrium between monomer and dimer or between dimer and tetramer, hexamer, or octamer is shifted by heterotropic allosteric effectors and substrates are cases in which the **active site is removed from or distant from the interface** or interfaces that dissociate or the faces that associate.[234,245,247,249-252] In these instances, a direct effect of dissociation of the interface or association of the faces in the oligomer on the enzymatic activity cannot occur, even though there could well be indirect effects,

*By microscopic reversibility, the removal of any ligand that causes dissociation of a homooligomer must cause its reassociation, and the removal of any ligand that promotes the association of the halves of a homooligomer must cause its dissociation.

which would be difficult to dissect from the global conformational change itself.

In the case of 6-phosphofructokinase from *G. stearothermophilus*, however, **a portion of the active site is in the interface** the faces of which shift upon the quaternary conformational change (Figure 6–9). In the crystallographic molecular model of the homotetramer, the active site of which is occupied by fructose 6-phosphate and $MgADP^-$, it can be seen that fructose 6-phosphate occupies a subsite in which two of the eight side chains forming the subsite are from the subunit opposite the one that provides the other six.[27,253] Both 6-phosphofructokinase from *G. stearothermophilus*[238] and 6-phosphofructokinase from *S. aureus* (59% identity; 0.6 gap percent) are homotetramers that exist in equilibrium with the respective two homodimers. Each tetramer is enzymatically active, and the dimer is inactive. Addition of phospho*enol*pyruvate, a heterotropic allosteric inhibitor, shifts the equilibrium between tetramer and dimers of 6-phosphofructokinase from *G. stearothermophilus* in favor of the enzymatically inactive dimer. Addition of $MgATP^{2-}$, an inhibitor as well as being a substrate, shifts the equilibrium between tetramer and dimers of 6-phosphofructokinase from *S. aureus*[27] in favor of the enzymatically inactive dimer. Because the subsite for fructose 6-phosphate is in the interface, there is no complete active site in the dimer, and it is only formed when the tetramer forms. Consequently, the tetramerization has **a direct effect on the enzymatic activity**, and it seems reasonable to assume that dissociation of the tetramer, at least in part, explains the inhibition. In most cases, however, there cannot be a direct effect because of the usual remove of the active site from the interface.

The observed effect of a substrate or heterotropic allosteric effector on the molar concentrations of monomers and dimers, or of dimers and tetramers, in equilibrium with each other in a particular solution depends on both the dissociation constant for the oligomer and the concentration of the protein in solution. For the moment, define dimer D as either a homodimer of monomers or a homodimer of homodimers, which is by definition a homotetramer of $222(D_2)$ symmetry, and define monomer M as the monomer forming that homodimer or the homodimer forming that homotetramer with $222(D_2)$ symmetry. Also assume, as has been noted, that a homotetramer of $222(D_2)$ symmetry almost always or always dissociates into two homodimers. The equation for the equilibrium between dimer D and monomer M is

$$2\,\mathrm{M} \xleftarrow[K_{d2}]{} \mathrm{D} \tag{6–106}$$

and the dissociation constant for dimer D is

$$K_{d2} = \frac{[\mathrm{M}]^2}{[\mathrm{D}]} \tag{6–107}$$

Because the dissociation constant is the quotient of the square of the concentration of monomer M and the unsquared concentration of dimer D, the observed concentrations of monomers and dimers, respectively, depends on the total concentration of the protein. If

$$[\mathrm{M}]_t = [\mathrm{M}] + 2[\mathrm{D}] \tag{6–108}$$

is the equation for conservation of mass, where $[M]_t$ is the total concentration of monomers in solution, both those present as free monomers M and those present as dimers D, then the fraction of total monomers that are free monomers*

$$f_M = \frac{[\mathrm{M}]}{[\mathrm{M}]_t} = \frac{\left(K_{d2}^2 + 8K_{d2}[\mathrm{M}]_t\right)^{1/2} - K_{d2}}{4[\mathrm{M}]_t} \tag{6–109}$$

and the fraction of total monomers that comprise dimers

$$f_D = \frac{2[\mathrm{D}]}{[\mathrm{M}]_t} = \frac{4[\mathrm{M}]_t + K_{d2} - \left(K_{d2}^2 + 8K_{d2}[\mathrm{M}]_t\right)^{1/2}}{4[\mathrm{M}]_t} \tag{6–110}$$

From these two equations, it can be seen that, when the concentrations of all other components remain the same, as the total concentration of monomers—and hence the concentration of the protein—is increased, the concentration of monomers decreases and the concentration of dimers increases. The equations apply to dissociation of any oligomer, not just homodimers and homotetramers, into two equal parts—for example, dissociation of the hetero-tetramer of hemoglobin.

*This equation differs from that in Yu and Pettigrew[254] only in the definition of what constitutes a subunit.

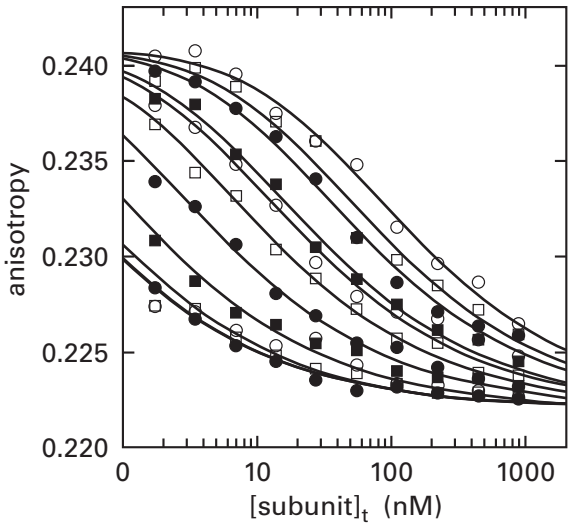

Figure 6–33: Dissociation of glycerol kinase from *E. coli* that occurs when the protein is diluted.[254] Glutamate 478, which is on the surface of glycerol kinase, was mutated to cysteine. Although there are five cysteines in the native protein, none is accessible for reaction when the protein is in a solution containing 2 mM glycerol and 2 mM $MgATP^{2-}$. The mutant protein was modified with 5-(iodoacetamido)-2′,7′-difluorofluorescein in 2 mM glycerol, 2 mM ATP^{4-}, and 0.1 M triethanolammonium chloride at pH 8.0. At the completion of the reaction, 0.35 mole of 2′,7′-difluorofluorescein was incorporated for every mole of subunit. The anisotropy of fluorescence ($\lambda_{excitation}$ = 485 nm; $\lambda_{emission}$ = 515 nm) was assessed in a solution of 2 mM glycerol, 0.1 mM ethylenediaminetetraacetate, 0.1 mM 2-sulfanylethanol, various concentrations of the heterotropic allosteric inhibitor D-fructose 1,6-bisphosphate, and 0.1 M triethylammonium chloride at pH 7.0. The anisotropy is plotted as a function of the total concentration of subunits of glycerol kinase in the solution (nanomolar). The axis of the abscissa is in a common logarithmic scale. The concentrations of D-fructose 1,6-bisphosphate, in descending order, were 0, 0.05, 0.1, 0.2, 0.3, 0.5, 1, 5, 10, 20, and 50 mM. Each curve is a fit of Equations 6–109, 6–110, and 6–112 to the data.

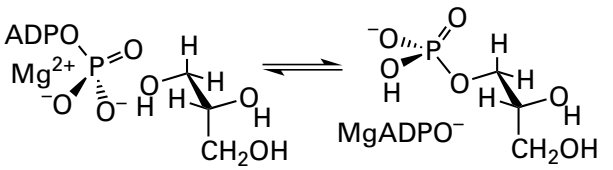
Glycerol kinase (previously Equation 4–283)



(6–111)

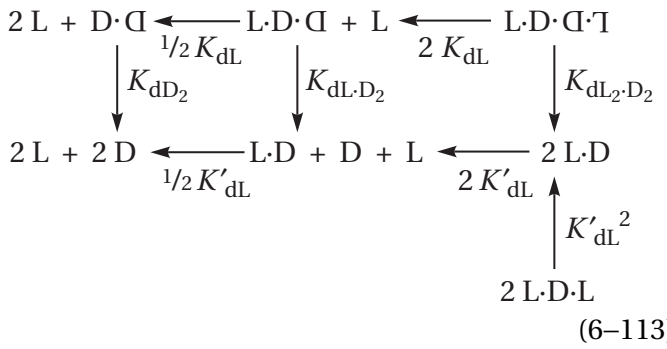
from *E. coli* can be a homodimer or a homotetramer of 222(D_2) symmetry, and these two oligomers are in rapid equilibrium with each other. The active sites are distant from the interfaces involved in dissociation and association.[255] The enzyme was modified with 5-(iodoacetamido)-2′,7′-difluorofluorescein at a cysteine in each of its polypeptides. The steady-state fluorescent anisotropy of the fluorophore, which is a function of rotational diffusion of the oligomer to which it is attached, depends on whether it is attached to a subunit in a dimer or a subunit in a tetramer. The tetramer has lower anisotropy than the dimer because its rotational diffusion is less. Consequently, it is possible to follow, by fluorescent anisotropy, the equilibrium concentrations of dimers and tetramers of glycerol kinase in equilibrium with each other as a function of the total concentration of dimers in solution (Figure 6–33).[254] If the monomer in this dissociation is defined as the homodimer and the dimer in this dissociation is defined as the homotetramer, then the observed steady-state anisotropy

$$\bar{r} = \bar{r}_M f_M + \bar{r}_D f_D \qquad (6–112)$$

where $\bar{r}_M$ is the steady-state anisotropy of the monomer and $\bar{r}_D$ is the steady-state anisotropy of the dimer, and the fractions of monomer and dimer are defined by Equations 6–109 and 6–110. As the total concentration of monomers is increased, the ratio between the concentration of monomers and the concentration of dimers decreases, as expected.

D-Fructose 1,6-bisphosphate is a heterotropic allosteric inhibitor of glycerol kinase from *E. coli*. Its two sites for binding are in two of the interfaces between the subunits in the tetramer of glycerol kinase, and both sites sit upon the same twofold rotational axis of symmetry passing through these two interfaces. Consequently, the site for binding of D-fructose 1,6-bisphosphate is formed from the same side chains on each subunit, which are related by the local twofold rotational axis of symmetry, and there are only two sites on each tetramer.[114] As might be predicted, D-fructose 1,6-bisphosphate binds more tightly to the tetramer, so as the concentration of D-fructose 1,6-bisphosphate is increased, the tetramer becomes more stable (Figure 6–33), and its apparent dissociation constant becomes smaller. The curves in the figure are all fits of Equations 6–109, 6–110, and 6–112 to the data, and the apparent dissociation constant, $K_{d4,app}$, obtained from these fits decreases as the concentration of fructose 1,6-bisphosphate increases.

An equation for the dissociation constant of the tetramer was derived from a simple set of linked equilibria



(6–113)

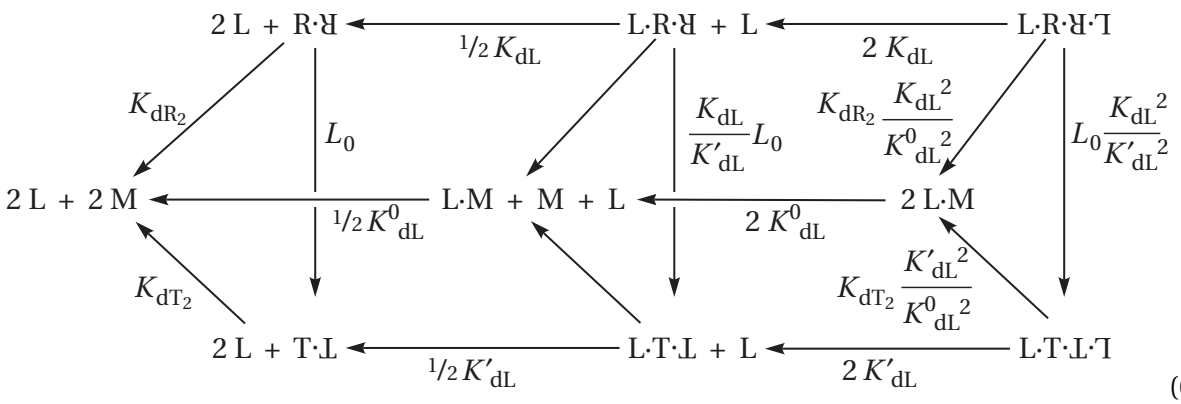
In this equation, the intrinsic dissociation constants of fructose 1,6-bisphosphate from the dimer, K'_{dL}, and from the tetramer, K_{dL}, differ. Consequently, the linked dissociation constants of the unoccupied tetramer, K'_{dD_2}, the tetramer occupied by one fructose 1,6-bisphosphate, $K'_{dL\cdot D_2}$ and the tetramer occupied by two fructose 1,6-bisphosphates, $K'_{dL_2\cdot D_2}$, also must differ from each other. Association of a second fructose 1,6-bisphosphate with the dimer prevents that doubly occupied dimer from associating with another occupied dimer. The decrease in the apparent dissociation constant for the tetramer as the concentration of fructose 1,6-bisphosphate is increased (Figure 6–33) could be fit with the equation derived from these linked equilibria and the intrinsic dissociation constants of $K_{dL} = 0.1$ mM and $K'_{dL} = 20$ mM. As expected, the dissociation constant for fructose 1,6-bisphosphate is smaller for the tetramer than for the dimer.

It is clear, from a consideration of the horizontal asymptotes for the lines in Figure 6–33, that if the dissociation constant for the tetramer of glycerol kinase were large enough, then only dimers of the enzyme would be observed at all concentrations of enzyme and all concentrations of D-fructose 1,6-bisphosphate. It is also clear that if the dissociation constant were small enough, then only tetramers would be observed. Consequently, if concentrations of enzyme that were too small had been chosen, no association of dimers would have been observed, or if concentrations of enzyme that were too large had been chosen, no dissociation of tetramers would have been observed, yet the binding of heterotropic allosteric inhibitor would still be changing the dissociation constant of the tetramer.

In the case of association of fructose 1,6-bisphosphate with glycerol kinase, there was no consideration of the fact that it is a heterotropic allosteric inhibitor of the enzyme, only that it is a ligand that happens to associate within the interface between the dimers in the tetramer, and hence its association is linked to dissociation of the tetramer. The **ability of substrates, heterotropic allosteric effectors, and other ligands to change the dissociation constant for a dimer into two monomers**, or for a dimer of dimers into two dimers, when sites with which they associate are distant from the interfaces that dissociate is also a consequence of linkage. In addition, because the faces in the interface in a dimer or the faces in the two weak interfaces in a dimer of dimers shift during the quaternary conformational changes that are responsible for cooperativity, the same linkage that produces cooperativity is also responsible for changing the dissociation constants for those interfaces.

Assume that the protein is a dimer but remember that the same derivation applies to a tetramer of 222(D_2) symmetry that dissociates into homodimers at the weakest pair or pairs of interfaces. Assume that sites for association of a particular ligand, L, are not within the interface that dissociates so that their effect on dissociation of the dimer is solely the result of their effect on the equilibrium between two quaternary conformations, T and R. Since the allosteric interface between the two monomers in the dimer must differ between the two quaternary conformations and this difference must result in a change in the dissociation constant of the interface, the effect of the ligand on the equilibrium constant between the two conformations results in a linked effect on the dissociation constant for the dimer. Remember also that the allosteric interfaces in an allosteric tetramer of 222(D_2) symmetry change both their structure and the orientation of their two faces upon association of ligand and that they are almost always the weak interfaces that dissociate.

Consider the following **linkage relation** for an allosteric dimer associating with ligand L



(6–114)

where

$$K_{dT_2} = \frac{[M]^2}{[T{\cdot}T]} \tag{6–115}$$

and

$$K_{dR_2} = \frac{[M]^2}{[R{\cdot}R]} \tag{6–116}$$

The dissociation constant for ligand L from the monomer

$$K^0_{dL} = \frac{[L][M]}{[L{\cdot}M]} \tag{6–117}$$

The rest of the equilibrium constants have their usual definition. The **apparent dissociation constant for the dimer**

$$K_{dD,app} = \frac{([M] + [L{\cdot}M])^2}{[T{\cdot}T] + [L{\cdot}T{\cdot}T] + [L{\cdot}T{\cdot}T{\cdot}L] + [R{\cdot}R] + [L{\cdot}R{\cdot}R] + [L{\cdot}R{\cdot}R{\cdot}L]} \tag{6–118}$$

With the above definitions

$$K_{dD,app} = K_{dR_2} \frac{\left(1 + \frac{[L]}{K^0_{dL}}\right)^2}{\left(1 + \frac{[L]}{K_{dL}}\right)^2 + L_0 \left(1 + \frac{[L]}{K'_{dL}}\right)^2}$$

$$= K_{dR_2} \frac{K_{dL}^2 K'^2_{dL} \left(K^0_{dL} + [L]\right)^2}{K^0_{dL}{}^2 K'^2_{dL} (K_{dL} + [L])^2 + L_0 K^0_{dL}{}^2 K_{dL}^2 (K'_{dL} + [L])^2} \tag{6–119}$$

with the following limits

$$\lim_{[L] \to 0} K_{dD,app} = K_{dR_2} \frac{1}{1 + L_0} \tag{6–120}$$

$$\lim_{[L] \to \infty} K_{dD,app} = K_{dR_2} \frac{K_{dL}^2 K'^2_{dL}}{K^0_{dL}{}^2 (K'^2_{dL} + L_0 K_{dL}^2)} \tag{6–121}$$

When $L_0 > 1$, the T conformation predominates in the absence of ligand. If $K'_{dL} > K_{dL}$, then the ligand shifts the equilibrium in favor of the R conformation. In this situation, in the absence of ligand, the apparent dissociation constant of the dimer into two monomers is $K_{dR_2} L_0^{-1}$, which is simply K_{dT_2}, the dissociation constant for the dimer in the T conformation. In the presence of saturating concentrations of ligand, however, the apparent dissociation constant for the dimer is $K_{dT} K'^2_{dL} (K^0_{dL}{}^2)^{-1}$, which is the dissociation

constant of the dimer in the T conformation shifted by the difference in dissociation constants for the ligand from the T conformation and from the monomer, respectively, just as any dissociation of a dimer is shifted by a difference in the dissociation constant for the ligand between dimer and monomer. If $K'_{dL}{}^2\ (K^0_{dL}{}^2)^{-1} < 1$, then the apparent dissociation constant for the dimer will decrease at all concentrations of ligand L until saturation because the dissociation constant of ligand from the monomer is larger than that from the dimer. If $K'_{dL}{}^2\ (K^0_{dL}{}^2)^{-1} > 1$, then the dissociation constant for the dimer will increase at all concentrations of ligand L until saturation.

When $L_0 < 1$, the R conformation predominates in the absence of ligand. If $K'_{dL} < K_{dL}$, then the ligand shifts the equilibrium in favor of the T conformation. In the absence of ligand, the apparent dissociation constant is K_{dR_2}, the dissociation constant for the R conformation. In the presence of saturating concentrations of ligand, however, the apparent dissociation constant is $K_{dR}K_{dL}{}^2\ (K^0_{dL}{}^2)^{-1}$, which is the dissociation constant of the dimer in the R conformation shifted by the difference in dissociation constants for the ligand from the R conformation and from the monomer. If $K_{dL}{}^2\ (K^0_{dL}{}^2)^{-1} < 1$, then the dissociation constant for the dimer will decrease at all concentrations of ligand L until saturation. If $K_{dL}{}^2\ (K^0_{dL}{}^2)^{-1} > 1$, then the dissociation constant for the dimer will increase at all concentrations of ligand L until saturation.

The **usual limits to cooperative and heterotropic allosteric behavior** apply. If $L_0 > K'_{dL}{}^2\ (K_{dL}{}^2)^{-1} > 1$, then the ligand will be unable to shift the equilibrium sufficiently (Equation 6–114), and almost all the dimer will remain in the T conformation at all concentrations of ligand, and no change in its dissociation constant will be observed. If $L_0 < K'_{dL}{}^2\ (K_{dL}{}^2)^{-1} < 1$, then the ligand will be unable to shift the equilibrium sufficiently to produce significant concentrations of the T conformation, almost all of the dimer will remain in the R conformation at all concentrations of ligand, and no change in its dissociation constant will be observed.

D-Fructose 1,6-bisphosphate is a heterotropic allosteric inhibitor of glycerol kinase, and its inhibition of enzymatic activity shows a degree of cooperativity ($n_H = 1.5$). In the absence of substrates, however, the enzyme is probably in the T conformation and remains in the T conformation as D-fructose 1,6-bisphosphate associates because it is a heterotropic allosteric inhibitor. Consequently, the decrease in dissociation constant observed with increasing concentration of D-fructose 1,6-bisphosphate (Figure 6–33) most likely represents only the fact that the dissociation constant for D-fructose 1,6-bisphosphate from the dimer (the monomer in Equation 6–114) is significantly larger than its dissociation constant from the tetramer in the T conformation (the dimer in the T conformation in Equation 6–114) without the complication of the allosteric conformational change.*

If the ligand is a heterotropic allosteric inhibitor and the inhibitor alone shifts the allosteric equilibrium from the R conformation in its absence to the T conformation at saturating concentrations, then $K'_{dL} < K_{dL}$ and $K'_{dL}{}^2\ (K_{dL}{}^2)^{-1} < L_0 < 1$. In the absence of inhibitor, the apparent dissociation constant of the dimer is

$$\lim_{[L] \to 0} K_{dD,app} \cong K_{dR_2} \tag{6–122}$$

and at saturating concentrations of inhibitor, it is

$$\lim_{[L] \to \infty} K_{dD,app} \cong \frac{K_{dR_2}K'_{dL}{}^2}{L_0 K^0_{dL}{}^2} = K_{dT_2}\frac{K'_{dL}{}^2}{K^0_{dL}{}^2} \tag{6–123}$$

In the absence of inhibitor, the apparent dissociation constant is that of the R conformation; and at saturating concentrations of inhibitor, the apparent dissociation constant is that of the dimer in the T conformation **shifted by the difference in dissociation constants for the ligand** from the T conformation and from the monomer (Equation 6–114).

If $K'_{dL}{}^2\ (L_0 K^0_{dL}{}^2)^{-1} < 1$, then the dissociation constant for the dimer at saturating concentrations of heterotropic allosteric inhibitor will be less than that in the absence of inhibitor. In the case of aspartate kinase from *E. coli*, dimers of the enzyme associate to form dimers of dimers upon binding of the heterotropic allosteric inhibitor L-lysine.[234]

If $K'_{dL}{}^2\ (L_0 K^0_{dL}{}^2)^{-1} > 1$, then the dissociation constant for the dimer at saturating concentrations of heterotropic allosteric inhibitor will be greater than that in the absence of ligand. In the case of 6-phosphofructokinase from *G. stearothermophilus*, the dimer of dimers dissociates into two dimers upon binding of the heterotropic allosteric inhibitor phospho*enol*pyruvate.[238]

*With, however, the already noted complication of the inhibition of association of the dimers caused by the association of two D-fructose 1,6-bisphosphates with the dimer.

If the ligand is a heterotropic allosteric activator or substrate and the ligand alone shifts the allosteric equilibrium from the T conformation in its absence to the R conformation at saturating concentrations, then $K'_{dL} > K_{dL}$ and $K'_{dL}{}^2\ (K_{dL}{}^2)^{-1} > L_0 > 1$. In the absence of activator or substrate, the apparent dissociation constant of the dimer is

$$\lim_{[L] \to 0} K_{dD,app} \cong \frac{K_{dR_2}}{L_0} = K_{dT_2} \qquad (6\text{–}124)$$

and at saturating concentrations of activator or substrate, it is

$$\lim_{[L] \to \infty} K_{dD,app} \cong K_{dR_2} \frac{K_{dL}{}^2}{K^0_{dL}{}^2} = K_{dT_2} L_0 \frac{K_{dL}{}^2}{K^0_{dL}{}^2} \qquad (6\text{–}125)$$

In the absence of ligand, the apparent dissociation constant is that for the T conformation; and at saturating concentrations of ligand, the apparent dissociation constant is that for the dimer in the R conformation shifted by the difference in dissociation constants for the ligand from the R conformation and from the monomer (Equation 6–114).

If $L_0 K_{dL}{}^2\ (K^0_{dL}{}^2)^{-1} < 1$, then the dissociation constant for the dimer at saturating concentrations of activator or substrate will be less than that in the absence of activator or substrate. For example, association of the substrate D-ribulose 5-phosphate with human ribulose-phosphate 3-epimerase causes monomers of the enzyme to dimerize.[244,245]

If $L_0 K_{dL}{}^2\ (K^0_{dL}{}^2)^{-1} > 1$, then the dissociation constant for the dimer at saturating concentrations of activator or substrate will be greater than that in the absence of activator or substrate. For example, $(\alpha\beta)_2$ tetramers of human hemoglobin dissociate to $\alpha\beta$ dimers upon association with molecular oxygen,[241] its substrate.

There is one peculiarity of Equation 6–119. If one examines its behavior as a function of the concentration of ligand when there is no ligand present and when there is a saturating concentration of ligand, the decrease to a smaller value for the apparent dissociation constant at saturation or the increase to a larger value at saturation is not necessarily monotonic. There can be inflections and inversions in the value before saturation is reached. These inflections can be disconcerting.

For the moment, consider the two following, perhaps unlikely, situations. For one particular protein, if a ligand is observed to be a heterotropic allosteric inhibitor and the dissociation constant for that ligand from the dimer in the T conformation is the same as its dissociation constant from the monomer, then the dissociation constant for the dimer at saturation with inhibitor (Equation 6–123) would have to be greater than its dissociation constant in the absence of inhibitor (Equation 6–122) because $L_0 < 1$ or heterotropic allosteric inhibition would not be observed. For a different protein, if a ligand is observed to be a heterotropic allosteric activator and the dissociation constant for that ligand from the dimer in the R conformation is the same as its dissociation constant from the monomer, then the dissociation constant for the dimer at saturation with inhibitor (Equation 6–125) would have to be greater than its dissociation constant in the absence of inhibitor (Equation 6–124) because $L_0 > 1$ or heterotropic allosteric activation would not be observed. These considerations suggest, counterintuitively, that if these equalities and inequalities describe these two different situations, then association of an observed heterotropic allosteric inhibitor to the first protein and association of an observed heterotropic allosteric activator to the second protein **biases each equilibrium between dimer and monomer in favor of the monomer**.

Suppose that the apparent dissociation constant of the dimer is larger when either a heterotropic allosteric inhibitor or activator is present at saturation than in their absence. In this case, addition of the inhibitor or activator could cause dissociation of the dimer, which would diminish and eventually eliminate cooperativity and any further heterotropic allosteric effects because the monomer can display neither of these properties. To avoid this possibility, the quotient of the dissociation constant for the inhibitor from the T conformation and its dissociation constant from the monomer or the quotient of the dissociation constant for the activator from the R conformation and its dissociation constant from the monomer must be small enough to prevent this dissociation of the dimer from occurring.

Nevertheless, it follows from all the foregoing considerations that **the effect of a substrate, heterotropic allosteric inhibitor, or heterotropic allosteric activator on the equilibrium between dimers and**

monomers or between dimers of dimers and dimers bears no relation to its effect on the equilibrium between or among the allosteric quaternary conformations of the dimers or the dimers of dimers that are responsible for the cooperativity and heterotropic allosteric effects that these ligands display. Consequently, any outcome is possible with any ligand that affects the equilibrium between two quaternary conformations. Addition of a heterotropic allosteric inhibitor or activator or a substrate can lead to dissociation of the dimer or the dimer of dimers. Addition of a heterotropic allosteric inhibitor or activator or a substrate can lead to association of monomers into a dimer or to association of dimers into a dimer of dimers.*

All the arguments leading to this conclusion are equally valid for dissociation of any oligomeric protein or enzyme for which an allosteric ligand alters its quaternary conformation and hence the dissociation constants of some or all of its interfaces, even heterooligomers or oligomers with greater than twofold rotational axes of symmetry. An example of both these latter peculiarities would be aspartate carbamoyltransferase, an $(\alpha_3)_2(\beta_2)_3$ heterohexamer with a threefold rotational axis of symmetry. In this instance, however, the $(\alpha_3)_2(\beta_2)_3$ heterohexamer has not yet been observed to dissociate into its parts when any ligand is added, and its dissociation requires either heating or addition of agents that chemically modify the protein. Ligands, however, are able to interconvert dimers, hexamers, and octamers of human porphobilinogen synthase.

It is unlikely that the dissociation constant between dimer and monomer, between tetramer and dimer, or between any other types of oligomers will be unaffected by a change in the quaternary conformation of the protein such as occurs in aspartate carbamoyltransferase because changes in the interfaces that accompany a change in quaternary conformation almost always occur in the weakest interfaces in the oligomer. If, however, the concentration of enzyme is high enough or low enough, these changes in dissociation constant, even though they must occur upon a particular conformational change, **will not cause any measurable change in the state of aggregation of the oligomer**. The question that is far more difficult to answer with any certainty is whether or not changes in the aggregation state of the oligomer at the cytoplasmic concentration of a particular enzyme have any advantageous or disadvantageous effect that might influence natural selection.* These changes in the state of aggregation, if and when they occur, may simply be unavoidable and inconsequential results of the fact that the dissociation constants must change as an allosterically linked quaternary conformational change rearranges the interfaces holding together the dimers, the dimers of dimers, or any other oligomer. This conclusion is valid whether there are only two quaternary conformations of the protein or there are many.

Factors influencing the lysine-mediated association reaction and their relationship to the cooperativity of lysine inhibition, *J. Biol. Chem. 249*, 5478–5484. https://doi.org/10.1016/S0021-9258(20)79753-X

Yu, P., and Pettigrew, D. W. (2003) Linkage between fructose 1,6-bisphosphate binding and the dimer–tetramer equilibrium of *Escherichia coli* glycerol kinase: Critical behavior arising from change of ligand stoichiometry, *Biochemistry 42*, 4243–4252. https://doi.org/10.1021/bi027142l

Problem 6–9: Because 2,3-bisphosphoglycerate binds to a site created by the two β subunits in tetrameric hemoglobin, its dissociation constant from the dissociated $\alpha\beta$ dimers must be much larger than that from the intact $(\alpha\beta)_2$ tetramer.

(A) Draw a relation between the binding of 2,3-bisphosphoglycerate and dissociation of deoxyhemoglobin into dimers.

(B) How would the presence of 2,3-bisphosphoglycerate affect the apparent dissociation constant between dimers and tetramers of deoxyhemoglobin?

(C) Derive formulas that relate the dissociation constant of the oligomer to the molar concentration of 2,3-bisphosphoglycerate.

*This consideration causes the historical origins of the names "tight" (T) and "relaxed" (R) to be even more ambiguous.

*There is a slight increase in the osmotic pressure of the cytoplasm when a dimer of protein or a dimer of dimers dissociates.

Conformational Conversion of Energy

A significant portion of the $MgATP^{2-}$ that is consumed in an animal by hydrolysis to $MgADP^{-}$ and $HOPO_3^{2-}$ is consumed by Na^+/K^+-exchanging ATPase, and the majority of the $MgATP^{2-}$ produced in an animal from $MgADP^{-}$ and $HOPO_3^{2-}$ is produced by H^+-transporting two-sector ATPase. Both enzymes convert the chemical standard free energy available from hydrolysis of $MgATP^{2-}$ into **conformational changes that perform work**; or, in reverse, work is performed upon the protein to drive conformational changes that reverse hydrolysis and create $MgATP^{2-}$. As with all enzymes, these two enzymes catalyze approaches to equilibrium, and in each case the outcome, whether it is the net hydrolysis of $MgATP^{2-}$ or the net formation of $MgATP^{2-}$, depends entirely on the activity of the substrates. Both enzymes either hydrolyze $MgATP^{2-}$ or create $MgATP^{2-}$ when the proper concentrations of substrates are imposed. Although these two enzymes are dramatically different in structure and do not share a common ancestor, the strategy that they employ to couple free energy of hydrolysis of $MgATP^{2-}$ to work that they perform or work that is performed upon them is based on their ability to proceed through several conformational changes that are forced by the protein to occur in a particular order.

The work performed by these enzymes or that is performed upon them is the **movement of ions across membranes**. A **gradient** is the change in a quantity—such as temperature, electric potential, or the concentration or chemical activity of a substance—with distance, expressed as a ratio or differential ratio of the quantity. A **chemical gradient** is a gradient in chemical potential established when the molar concentration of uncharged substance A, such as D-glucose, is greater on one side of a biological membrane than on the other side An **electric gradient** is a gradient in electric potential established when the molar concentration of ionically charged substance A, such as sodium ion, is greater on one side of a biological membrane than on the other side. An **electrochemical gradient** is a gradient in chemical activity of a substance, caused by the combination of its chemical and electric gradients. When these enzymes transport ions across membranes, the ions move across an electrochemical gradient in their concentration. Because of microscopic reversibility, if one of these enzymes is able to move its ions against their concentration gradients, it must also be able to move the ions in the other direction with their concentration gradients.

When the concentrations of an neutral molecule, such as D-glucose, are the same on the two sides of membrane, which is the situation at equilibrium, the change in standard free energy, ΔG°, for moving a molecule of that uncharged substance from one side of the membrane (side a) to the other (side b) is 0 by definition. When the concentrations are different on the two sides, however, the usual equation for situational free energy applies

$$\Delta G = \Delta G^\circ + RT \ln \frac{[A]_b}{[A]_a} = RT \ln \frac{[A]_b}{[A]_a} \quad (6\text{–}126)$$

where $[A]_a$ and $[A]_b$ are the molar concentrations of substance A on side a of the membrane, the side from which it is removed, and on side b of the membrane, the side to which it is added. If substance A is charged—for the sake of argument, it has a positive charge of charge number n, A^{n+}—then the difference in electric potential, ΔV_{ab}, between the two sides must be considered

$$\begin{aligned} \Delta G &= RT \ln \frac{[A^{n+}]_b}{[A^{n+}]_a} + zF\Delta V_{ab} \\ &= RT \ln \frac{[A^{n+}]_b}{[A^{n+}]_a} + nF\Delta V_{ab} \end{aligned} \quad (6\text{–}127)$$

where ΔV_{ab} is the electric potential on side b minus the electric potential on side a, z is the charge number of substance A—which in this case is equal to n—and F is the Faraday constant (96.5 kJ V^{-1} mol^{-1}). This equation defines an **electrochemical gradient of the ions**. The first term is the chemical gradient and the second term is the **electric gradient**, the electric potential across the membrane caused by the imbalance of ionic charge.

To move a positively charged ion from a solution with an electrochemical potential that is negative relative to that of the solution to which it is moved requires work and results in an increase in free energy. To accomplish its intended purpose, Na^+/K^+-exchanging ATPase uses the free energy from hydrolysis of $MgATP^{2-}$ to move Na^+ and K^+ across the plasma membrane of animal cells against electrochemical gradients of Na^+ and K^+. The situational free energy, ΔG, for the movement of the ions in these circumstances is positive.

To move a positively charged ion from a solution with an electrochemical potential that is positive relative to that of the solution to which it is moved results in a decrease in free energy that can be used to perform work. To accomplish its intended purpose, H^+-transporting two-sector ATPase moves hydrons down an electrochemical gradient of hydrons across a membrane in mitochondria, chloroplasts, or a bacterium to provide the free energy necessary to reverse hydrolysis and synthesize $MgATP^{2-}$ instead. The situational free energy, ΔG, for the movement of the ions in these circumstances is negative.

The strategy that each enzyme uses is its own particular form of **conformational coupling**. Hydrolysis or, in reverse, creation of $MgATP^{2-}$ is divided by each enzyme into a sequence of steps. The work ultimately accomplished or used by each enzyme is also divided into the same number of steps, which are forced to occur in concert with steps for the hydrolysis.[256] At the same time that each step in the hydrolysis and synthesis of $MgATP^{2-}$ occurs, the corresponding step in the physical transformation performing work or using work is forced to occur. The site at which the $MgATP^{2-}$ is hydrolyzed and, in reverse, created in each case is in a different location in the enzyme from the location at which the physical transformation performing work and, in reverse, having work performed on it is effected. Consequently, the obligation that particular steps for hydrolysis or creation coincide with particular steps for the physical transformation is enforced by accompanying global conformational changes in the enzyme. Each step involves a global conformational change that includes particular local conformational changes both at the hydrolytic site and at the location where the physical transformation is being accomplished. Each global conformational change proceeds only when both the closely circumscribed step in hydrolysis and creation of $MgATP^{2-}$ and the closely circumscribed step in the physical transformation proceed together. As in heterotropic allostery, global conformational changes dependably couple what occurs in one location on the enzyme with what occurs at another, usually distant location on the enzyme. Whenever the two processes are not forced by the conformational changes to occur simultaneously, energy is wasted. Natural selection has naturally minimized such failures. A paradigm of this strategy of conformational coupling is the reaction catalyzed by Na^+/K^+-exchanging ATPase and its close relatives.

Na^+/K^+-Exchanging ATPase[257] catalyzes the reaction

$$2\,K^+_e + MgATP^{2-}_c + 3\,Na^+_c + H_2O \rightleftharpoons 2\,K^+_c + MgADP^-_c + H^+ + 3\,Na^+_e + HOPO_3{}^{2-}_c \quad (6\text{–}128)$$

where the subscripts c and e refer to the cytoplasm and the extracytoplasmic space, respectively.[258,259] It is a protein spanning the plasma membranes[260-262] of all animal cells and catalyzing the active transport of the alkali metallic cations Na^+ and K^+ across itself.

Na^+/K^+-Exchanging ATPase is a member of **a family of enzymes**, the P-type ATPases, each of which spans a bilayer of phospholipids and catalyzes the primary active transport of particular inorganic cations across the plasma membrane or the endoplasmic reticular membranes of a cell between the cytoplasm and an extracytoplasmic space. The particular reactions catalyzed by these enzymes serve to introduce the members of the family (Table 6–3).[257-279] Each couples hydrolysis of $MgATP^{2-}$ to the movement of cations across a membrane up their electrochemical gradients, but the identity and stoichiometry of the cations moving out of and into the cytoplasm differs. A compelling verification that all the enzymes in this family are closely related is that most of the portions of Na^+/K^+-exchanging ATPase in the globular regions outside the membrane, as well as the four of its membrane-spanning α helices peripheral to the central six that create the compartment for cations, can be replaced by homologous segments from H^+/K^+-exchanging ATPase without affecting its ability to transport Na^+ and K^+ across the membrane.[280]

Mammalian Na^+/K^+-exchanging ATPase is composed of two subunits,[281] α (1020 aa)[282,283] and β (300 aa),[284] each present in the active complex in one copy.[285,286] The β subunit is a cell surface glycoprotein uninvolved in catalysis, and the α catalytic subunit performs the active transport. The α subunit is a protein that spans the plasma membrane, and it is so large that it dwarfs the bilayer of the membrane.[287] Each enzyme in the family contains a polypeptide homologous (Table 6–3) to the catalytic α polypeptide of Na^+/K^+-exchanging ATPase[277,288,289] but no glycoprotein homologous to the β subunit of Na^+/K^+-exchanging ATPase. The large **catalytic polypeptide** is fixed in the bilayer, as are all membrane-spanning proteins, and it catalyzes transport not by moving back and forth across the membrane but by **passing the cations back and forth through itself**.[290] In this regard, active transport is not transport through a membrane but transport through a protein.

Table 6–3: Family of P-type ATPases[a]

name[b]	homology	where found	function
Na^+/K^+-exchanging ATPase[257-262]		plasma membranes of animal cells	transports three Na^+ out of the cytoplasm in exchange for two K^+
H^+/K^+-exchanging ATPase[264-266]	62% identity 0 gap percent	plasma membranes of gastric mucosa	transports one or two[c] H^+ out of the cytoplasm in exchange for two K^+
P-type Ca^{2+} transporter[267-269]	27% identity 1.7 gap percent	sarcoplasmic reticulum	transports two Ca^{2+} out of the cytoplasm in exchange for two or three H^+
calmodulin-dependent[270-273] P-type Ca^{2+} transporter	27% identity 2.7 gap percent	plasma membranes of animal cells	transports one Ca^{2+} out of the cytoplasm in exchange for two H^+
P-type H^+ exporting[274-277] transporter	23% identity 2.2 gap percent	plasma membranes of fungi and plants	transports H^+ out of the cytoplasm
P-type Ca^{2+} transporter[278]	29% identity 1.4 gap percent	plasma membranes of fungi	transports Ca^{2+} out of the cytoplasm
P-type Zn^{2+} transporter[279]	23% identity 2.1 gap percent	plasma membranes of bacteria and plants	transports excess[d] Zn^{2+}, as well as Cd^{2+} and Pb^{2+}, out of the cytoplasm

[a]Relative to Na^+/K^+-exchanging ATPase. [b]The names of the enzymes in this family differ significantly from each other because the name of an enzyme is based on the participants in the equilibrium that it catalyzes rather than any ancestral relationships, which usually makes sense. [c]Stoichiometry depends on the gradient of pH. [d]Zn^{2+} is an essential trace metallic ion but is toxic at high concentrations.

The fact that all the sequences of amino acids for all these catalytic polypeptides are homologous to each other (Table 6–3) requires that they have descended from a common ancestor, that they all fold respectively to produce superposable structures, and that they all catalyze active transport by the same stepwise mechanism.

During catalysis of the active transport of the respective cations, each member of this family passes through a homologous sequence of steps coupling hydrolysis of $MgATP^{2-}$ to the movement of the cations. A fundamental aspect of this scheme is the existence of at least four distinct global conformations of the enzyme. These four conformations differ in structure from each other both at the site where the $MgATP^{2-}$ is hydrolyzed and at a compartment that has access alternately to each side of the membrane and through which the transported cations pass. The hydrolytic site in each enzyme is 5 nm away from the compartment through which the respective cations pass (Figure 6–34).[291,292] Consequently, the conformational changes that are responsible for active transport are typical heterotropic allosteric conformational changes that link changes in the structure of the hydrolytic site to distant changes in the structure of the compartment for the cations. Each hydrolytic site is located in a large globular portion of the respective enzyme that comprises more than half its mass and is located on the cytoplasmic side of the membrane. Only on the cytoplasmic side of each membrane in which these enzymes are located is a significant concentration of $MgATP^{2-}$ available. The compartment for the cations is in the middle of a bundle of ten α helices that span the bilayer of the membrane in which the enzyme is found (Figure 6–35).[282,287,291,293-295]

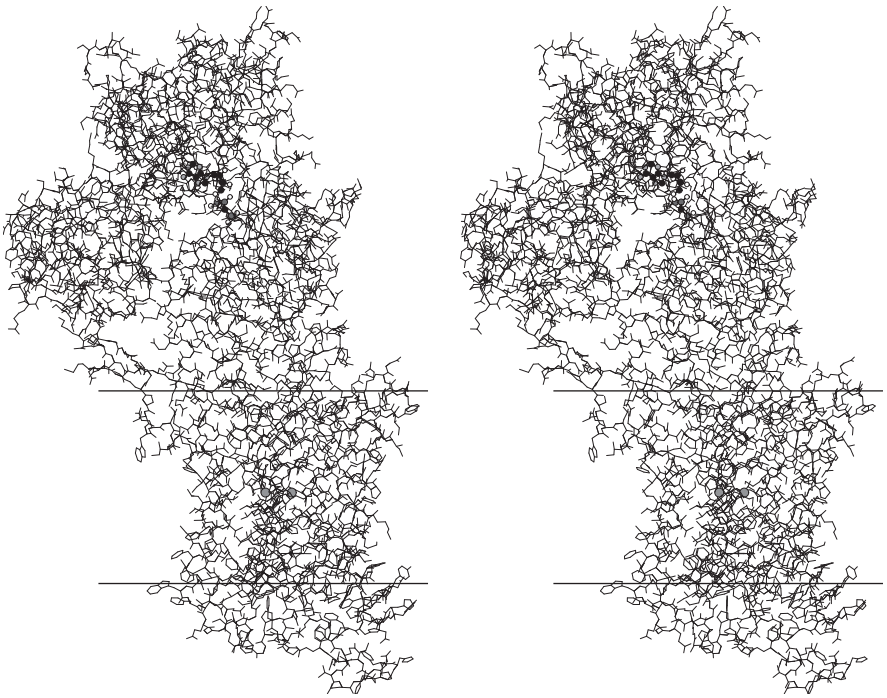

Figure 6–34: Stereodrawing[485] of a crystallographic molecular model of P-type Ca^{2+} transporter from *O. cuniculus* in which the hydrolytic site of the enzyme is occupied by magnesium 5′-adenylic methylenediphosphonic anhydride ($MgAMPPCP^{2-}$) and the compartment for the transported cations is occupied by two Ca^{2+}.[291] Membranes of sarcoplasmic reticulum enriched in P-type Ca^{2+} transporter, isolated from the white muscle of the hind legs of *O. cuniculus,* were dissolved in a 2% solution of the detergent 3,6,9,12,15,18,21,24,27-nonaoxanonatriacontan-1-ol, and P-type Ca^{2+} transporter was purified by nonspecific adsorption to a solid phase of agarose to which the dye reactive red 120 had been covalently attached and then by selective elution of the enzyme from the solid phase by a solution containing 0.4 mM $MgAMPPCP^{2-}$. The purified enzyme was then crystallized from a 2% solution of the detergent 3,6,9,12,15,18,21,24-octaoxahexatriacontan-1-ol containing an undisclosed amount of phosphatidylcholine, 0.5 mM $MgAMPPCP^{2-}$, 5 mM $MgCl_2$, and 10 mM $CaCl_2$. The entire structure of the enzyme is drawn in skeletal format. The polypeptide backbone is shown in thick line segments and the side chains in thin line segments. The $MgAMPPCP^{2-}$ occupying the hydrolytic site is drawn in ball-and-stick format. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large dark gray atoms are the three atoms of phosphorus. The two Ca^{2+} occupying the compartment for cations are the two large gray spheres in the center of the portion of the enzyme that spans the membrane. Although there is no phospholipid bilayer in the map of electron density, presumably because the enzyme is in an unresolved micelle of detergent and phospholipid, the location of the bilayer in the structure (parallel horizontal lines) was assigned by the authors. The cytoplasmic portion of the enzyme is above the membrane, and the extracytoplasmic portion is below the membrane.[287] The enzyme seems to have crystallized in an intermediate conformation between the $E1{\cdot}MgATP^{2-}$ and $[Ca^{2+}]_2{\cdot}E1{\sim}P$ conformations in which the two Ca^{2+} are occluded from both the cytoplasmic and extracytoplasmic solutions in the compartment in the middle of the membrane.[291] Presumably the full conformational change to the $[Ca^{2+}]_2{\cdot}E1{\sim}P$ conformation has been arrested because the $MgAMPPCP^{2-}$ is unable to phosphorylate the aspartate in the hydrolytic site.

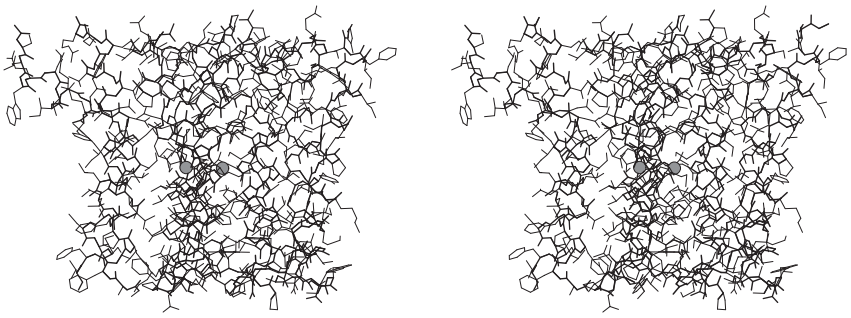

Figure 6–35: Stereodrawing[485] of the ten α helices that span the membrane in P-type Ca^{2+} transporter and form the compartment through which the two Ca^{2+} pass. The two Ca^{2+} occupying the compartment for the cations are the two large gray spheres in the center of the drawing. The portion of the drawing in Figure 6–34 within the volume designated by the authors as spanning the sarcoplasmic reticulum has been magnified to make it easier to observe the individual α helices surrounding the two Ca^{2+}. The ten α helices include amino acids 44–74, 85–115, 249–278, 291–318, 753–782, 783–813, 824–856, 893–922, 926–954, and 960–990, respectively, from the complete sequence of amino acids. Only the α helices that include amino acids 291–318, 753–782, 783–813, and 893–922 provide ligands to the Ca^{2+}. In addition, the two α helices that include amino acids 44–74 and 85–115, which do not provide ligands, form the wall of the compartment for the cations on the left-hand side of the drawing. The two α helices including amino acids 753–782 and 893–922, in addition to providing ligands for the cations, form the wall of the compartment on the right-hand side of the drawing. The α helix including amino acids 783–813 is in the center of the wall in front of the compartment, and the α helix including amino acids 291–318 is in the center of the wall in back of the compartment.

Figure 6–36: Stereodrawings[485] of crystallographic molecular models of the ligands chelating the hard cations Ca^{2+}, Na^+, and K^+ when they are occluded in the compartments through which they pass in the respective enzymes. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. The large coordinated gray spheres are the respective metallic cations. (**A**) Two Ca^{2+} occluded within the compartment in P-type Ca^{2+} transporter from *O. cuniculus*.[291] The portion of the crystallographic molecular model of P-type Ca^{2+} transporter drawn in Figure 6–35 was rotated 90° about a horizontal axis in the plane of the page to obtain a view down into the compartment from the cytoplasmic side of the membrane. Only segments from the four α helices that include amino acids 291–318, 753–782, 783–813, and 893–922 and that provide ligands to the two Ca^{2+} are included in the drawing. Each side chain that provides a ligand to a cation is labeled with its identity and its number in the overall sequence of amino acids. (**B**) Three Na^+ occluded within the compartment through which they pass in Na^+/K^+-exchanging ATPase.[292] Membranes from the outer medullae of porcine kidneys enriched in Na^+/K^+-exchanging ATPase[487] were dissolved in a solution of the detergent 3,6,9,12,15,18,21,24-octaoxahexatriacontan-1-ol at a ratio of 1.3 g of detergent (g of protein)$^{-1}$ to obtain a monodisperse solution of the enzyme.[285] The enzyme was then crystallized from a solution containing 150 mM NaCl, 3 mM $MgADP^-$, 1 mM $AlCl_3$, and 0.25 mM oligomycin A. The $MgADP^-$ and $AlCl_3$ formed a complex in the hydrolytic site of the enzyme that promotes formation of the conformation in which three Na^+ are occluded in the compartment for the cations. The drawing was prepared in the same orientation as that in Panel A by superposing only those segments of the crystallographic molecular model of Na^+/K^+-exchanging ATPase that included sequences of amino acids homologous (Figure 6–37) to those comprising the segments from P-type Ca^{2+} transporter represented in Panel A. (**C**) Two K^+ occluded within the compartment through which they pass in Na^+/K^+-exchanging ATPase.[299] Membranes from the rectal glands of *S. acanthias* enriched in Na^+/K^+-exchanging ATPase[302] were dissolved in a solution of the detergent 3,6,9,12,15,18,21,24-octaoxahexatriacontan-1-ol at a ratio of 4 g of detergent (g of protein)$^{-1}$. The enzyme (2.1 mg mL^{-1}) was then crystallized from a 1.5% solution of 3,6,9,12,15,18,21,24-octaoxahexatriacontan-1-ol containing 100 mM KCl, 4 mM MgF_2, and 2.5 mg mL^{-1} phosphatidylcholine. In the presence of K^+ and the absence of nucleotide, the enzyme assumes the E2·$[K^+]_2$ conformation with the two K^+ occluded within the compartment for the cations. The drawing was prepared in the same orientation as that in Panel B by superposing only those segments of the molecular model of Na^+/K^+-exchanging ATPase from *S. acanthias* that included sequences of amino acids homologous (Figure 6–37) to those comprising the segments from porcine Na^+/K^+-exchanging ATPase represented in Panel B. In all three drawings, the ligands are connected to the cations by thick dotted lines, and the thinner dotted lines designate hydrogen bonds. There are two molecules of water (small white solitary spheres) in the drawing in Panel A, one molecule of water in the drawing in Panel B, and six molecules of water in the drawing in Panel C. These molecules of water are fixed by hydrogen bonds to the protein and by coordination to the cations. All of them are within the membrane. There are more in the drawing in Panel C only because there are almost no molecules of water anywhere in the maps of electron density for the other two molecular models. There are empty spaces scattered throughout the membrane-spanning portions of all these molecular models, probably occupied by molecules of water that are simply unobserved.

The compartment through which the cations pass is formed by six of the ten membrane-spanning α helices, but only four of these six α helices provide direct ligands to the cations. The compartment is located in the middle of the bundle at a position that is close to or within the plane defined by the center of the bilayer of phospholipids surrounding the enzyme (Figure 6–35). In each enzyme, this compartment is a **site for binding hard cations, Ca^{2+}, Na^+, or K^+**. Consequently, the ligands are exclusively oxygens: amido oxygens from the polypeptide backbone and oxygens from the side chains of amino acids. Each side chain provides one or two **oxygens as inner-sphere ligands** to the respective cation. Six of the side chains in P-type Ca^{2+} transporter from *O. cuniculus* that provide ligands to the two Ca^{2+} when they occupy the compartment were identified by site-directed mutation,[296] and their assignment was later verified by crystallography.[294] It was then demonstrated by site-directed mutation that the homologous side chains in Na^+/K^+-exchanging ATPase from *S. cerevisiae*[297] as well as three others in the porcine enzyme[298] were involved as ligands to the two K^+ and three Na^+, respectively. These latter assignments were also verified crystallographically.[292,295,299]

When the compartment in the middle of P-type Ca^{2+} transporter from *O. cuniculus* is **occupied by two Ca^{2+}** on their way across the protein, the ligands to the cations can be identified in crystallographic molecular models (Figure 6–36A).[300] The site in the compartment chelating the first Ca^{2+} (to the left in the figure) consists of both oxygens from the carboxylato group of Glutamate 309, the acyl oxygen from the carbamoyl group of Asparagine 796, three amido oxygens from the backbone of the same α helix in the polypeptide, and one oxygen from the carboxylato group of Aspartate 800. The other oxygen from the carboxylato group of Aspartate 800 is a ligand to the second Ca^{2+} (to the right in the figure). The other ligands chelating this second Ca^{2+} are the acyl oxygen from the carbamoyl group of Asparagine 768, the hydroxy oxygen of Threonine 799, two buried molecules of water, one of the carboxylato oxygens of Glutamate 771, and both oxygens from the carboxylato group of Glutamate 908. These are all paradigmatic ligands for Ca^{2+} bound to sites in enzymes (Figure 4–53, **4–156**, and Problem 4–46).

Figure 6–37: Alignment of the sequences of amino acids for the segments of P-type Ca^{2+} transporter from *O. cuniculus*, porcine (*Sus scrofa*) Na^+/K^+-exchanging ATPase, and Na^+/K^+-exchanging ATPase from *S. acanthias* in the drawings of Figure 6–36. The alignments of the first three segments are obvious by inspection, but the alignment of the last segments of the two Na^+/K^+-exchanging ATPases with the segment from P-type Ca^{2+} transporter was made by structural superposition. The amino acids providing ligands to the respective cations are shown in boldface.

When the compartment in the middle of porcine Na^+/K^+-exchanging ATPase is **occupied by three*** **Na^+** on their way across the protein, the ligands to these three Na^+ can again be identified in crystallographic molecular models (Figure 6–36B).[285,292] The site chelating the first Na^+ (to the left in the figure) consists of one oxygen from each carboxylato group of Aspartate 804 and Glutamate 327, a buried molecule of water, and three amido oxygens from the backbone of an α helix in the polypeptide. Both the α helix and the amido oxygens themselves are homologous to the α helix and the three amido oxygens from the polypeptide, respectively, that chelate the homologously situated Ca^{2+} in P-type Ca^{2+} transporter (Figure 6–37), and the two carboxylato groups providing two of the other ligands to the Na^+ are also on side chains of amino acids in homologous positions in the sequence of amino acids to two of the carboxylato groups chelating the same Ca^{2+}. The second Na^+ (in the middle in the figure) shares one of the amido oxygens from the polypeptide with the first Na^+. Ir is also chelated by two carboxylato oxygens, one from Glutamate 779 and one from Aspartate 808, the acyl oxygen of the carbamoyl group of Asparagine 776, the hydroxy oxygen of Serine 775, and a buried molecule of water. The two carboxylato groups and the carbamoyl group are on side chains in homologous positions in the sequence of amino acids, respectively, to the two carboxylato groups and the carbamoyl group that chelates the homologously situated Ca^{2+} in P-type Ca^{2+} transporter (Figure 6–37). Finally, the site chelating the third Na^+ (to the right in the figure) consists of the other oxygen from the carboxylato group of Aspartate 808 that also coordinates the second Na^+, an amido oxygen from the polypeptide, the acyl oxygen of the carbamoyl group of Glutamine 923, the hydroxy group of Threonine 774, and the π system of Tyrosine 771, in an example of a π–cation interaction.[301]

When the compartment in the middle of Na^+/K^+-exchanging ATPase from *Squalus acanthias* is **occupied by two K^+** on their way across the protein (Figure 6–36C),[299,302] the site chelating the first K^+ (to the left in the figure) consists of an oxygen from each of the carboxylato groups of Aspartate 811 and Glutamate 334, which are homologous to Aspartate 804 and Glutamate 327 in the porcine enzyme, and the same three amido oxygens from the same α helix in the polypeptide as are used for the similarly coordinated Na^+ when Na^+ ions are occupying the compartment (Figure 6–37), as well as an oxygen from the carboxylato group of Glutamate 786, homologous to Glutamate 779 in the porcine enzyme. The second K^+ (to the right in the figure) shares the same oxygen of Aspartate 811 coordinating the first K^+ as well as the hydroxy group of Serine 782 and the carbamoyl oxygen of Asparagine 783, which are homologous to the oxygens of Serine 775 and Asparagine 776 used for the similarly coordinated Na^+ when Na^+ ions are occupying the compartment in the porcine enzyme. In addition, this second K^+ is coordinated by an amido oxygen from the backbone of the polypeptide and a molecule of water. All these oxygens that are ligands are typical of those coor-

*Oligomycin A is bound to the enzyme in the crystals used to produce this crystallographic molecular model to stabilize the complex between the protein and the three Na^+.

dinating K^+ in sites in other enzymes (**4–154** and Figure 4–52).

It is clear from the drawings of the crystallographic molecular models and the foregoing description detailing the homology in the ligands used to coordinate the ions that P-type Ca^{2+} transporter (Figure 6–37) and Na^+/K^+-exchanging ATPase are closely related enzymes.

In the site to the left in the drawings of Na^+/K^+-exchanging ATPase, the same five homologous ligands coordinate Na^+ (Figure 6–36B) or K^+ (Figure 6–36C) while only the sixth ligand differs. The only chemical difference between these two alkali metallic ions that the site can recognize is the **difference in their respective ionic radii**, and the consequent difference in density of charge. The ionic radius of Na^+ with six ligands is 0.102 nm, and the ionic radius of K^+ with six ligands is 0.138 nm, a difference in diameters of only 0.072 nm. It is clear, however, from the role of the enzyme in metabolism, that natural selection was able to exert significant influence on making this discrimination as exclusive as possible because any mistakes would uselessly waste $MgATP^{2-}$.

That almost the same set of ligands make this distinction unerringly is another demonstration of the fundamental rigidity of the positions assumed by the functional groups in an active site. If the protein surrounding this site for one or the other of the two cations were actually soft and able to flex significantly, even though the two global conformations to which the respective cation are bound are different from each other, the ligands would not be able to distinguish between Na^+ and K^+. The rigidity with which the ligands assume their positions is essential to this distinction. The site must be rigid enough to enforce a contraction of the ligands by the necessary 0.07 nm when its specificity for K^+ is changed to its specificity for Na^+.

Each enzyme in the family other than Na^+/K^+-exchanging ATPase transports **hydrons** in one direction in exchange for the K^+ or Ca^{2+} that are transported in the other direction. In some instances, hydrons are actively transported out of the cytoplasm, while in other instances, they are actively transported into the cytoplasm as if they were simply convenient replacements on carboxylato groups for the hard cations. Further complicating the situation is the observation that the stoichiometry for the hydrons that are transported appears to vary with the pH of the solution into which they depart or from which they enter. Such a variation in stoichiometry would be expected if, during the passage of these hydrons through the compartment, they reside, as they must, on one, two, or three of the carboxylato groups that form the sites for the Ca^{2+} or K^+ when those cations are travelling in the opposite direction from the hydrons. Differences in values of pK_a for these carboxy groups dictate the relation between the pH of the solution and the stoichiometry of the occupation.

Hydrons are ubiquitous, so it is difficult to distinguish those hydrons being transported from all the other hydrons both in the enzyme and in the solution. Na^+/K^+-exchanging ATPase, however, transports Na^+ in one direction and K^+ in the other direction, and these cations are easily identified. Consequently, the earliest and most informative observations defining the mechanism of active transport were obtained in studies of Na^+/K^+-exchanging ATPase because the strokes of the pump in the two directions could be distinguished and followed independently by varying the concentrations of the alkali metallic ions.

The global conformational changes responsible for active transport of Na^+, Ca^{2+}, or H^+ in one direction and K^+ or H^+ in the other direction across a membrane couple changes in the accessibility of the compartment for cations to changes at the site for hydrolysis of $MgATP^{2-}$. For Na^+/K^+-exchanging ATPase, the **four major global conformations** that the enzyme assumes during catalysis can be designated as $E2{\cdot}[K^+]_2$, $E1{\cdot}MgATP^{2-}$, $[Na^+]_3{\cdot}E1{\sim}P$, and E2–P (Figure 6–38).[303,304] The mechanism for actively transporting three Na^+ and two K^+ is the same as the respective mechanisms used by other members of the family. Consequently, to maintain consistency, the four conformations can be designated $E2{\cdot}[H^+]_2$, $E1{\cdot}MgATP^{2-}$, $[Ca^{2+}]_2{\cdot}E1{\sim}P$, and E2–P for P-type Ca^{2+} transporter; $E2{\cdot}[K^+]_2$, $E1{\cdot}MgATP^{2-}$, $[H^+]_2{\cdot}E1{\sim}P$, and E2–P for H^+/K^+-exchanging ATPase; and so forth, with the reminder that the stoichiometry for H^+ is usually variable because they are carried by carboxy groups as simple acidic hydrons.

Detailed measurements of the **steady-state kinetics** of purified porcine Na^+/K^+-exchanging ATPase are consistent with this mechanism for the enzymatic reaction.[305] The initial rate as a function of the concentration of Na^+ displays positive deviation

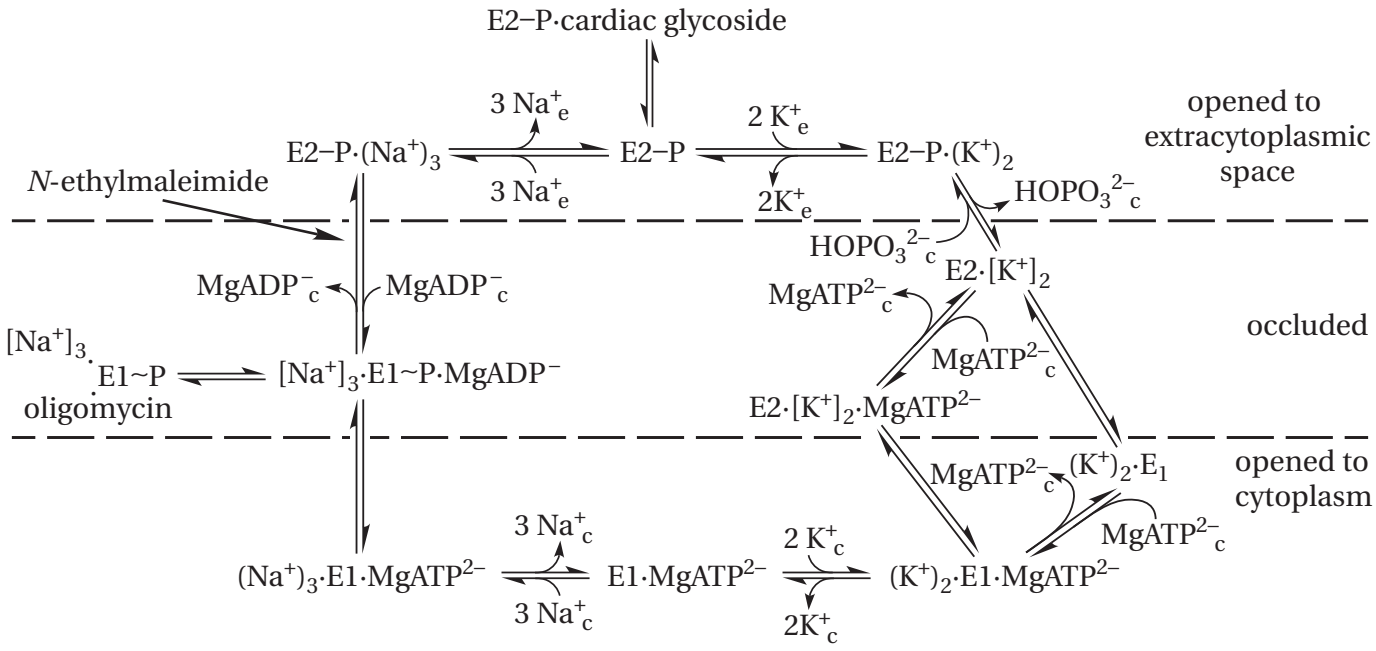

Figure 6–38: Kinetic mechanism for active transport of Na^+ and K^+ catalyzed by Na^+/K^+-exchanging ATPase. The four major conformations of the enzyme are E2·[K+], E1·$MgATP^{2-}$, $[Na^+]_3$·E1~P, and E2–P. Changes at the active site for hydrolysis of $MgATP^{2-}$ are indicated by association of $MgATP^{2-}$, release of $MgADP^-$, formation of the phosphorylated form E1~P and its transformation to the phosphorylated form E2–P, and dephosphorylation of E2–P. Changes in occupation and accessibility of the compartment for cations are indicated by association and dissociation of K^+ and Na^+. The major shifts between the conformation opened to the cytoplasm (E1·$MgATP^{2-}$), the two occluded conformations ($[Na^+]_3$·E1~P and E2·[K+]), and the conformation opened outward (E2–P) are designated by their locations with respect to the dashed lines representing the bilayer. The inhibitor oligomycin is noncovalently bound by a specific conformation, $[Na^+]_3$·E1~P, and modification of the enzyme with *N*-ethylmaleimide prevents the conformational change from E1~P to E2–P. The cardiac glycosides, such as ouabain, and cardiac aglycons, such as strophanthidin, are a set of natural products that inhibit Na^+/K^+-exchanging ATPase by binding from the extracytoplasmic solution[488] and fill the wide channel opening into the empty compartment for cations in the E2–P conformation.[303,304]

from rectangularly hyperbolic behavior. This positive deviation is not due to cooperativity but due to the molecularity of the reaction: three Na^+ together are reactants. In fact, the Michaelis constant for the third Na^+ to associate with the enzyme is greater than the Michaelis constant for the first two rather than smaller, as would be the case if Na^+ were associating cooperatively.

The easiest and least complicated place to start (Figure 6–38) is with Na^+/K^+-exchanging ATPase in the **E2·$[K^+]_2$ conformation** in which two K^+ are enclosed in the compartment for cations and the compartment is occluded, or inaccessible, to the solutions on either side of the membrane. In this conformation, porcine Na^+/K^+-exchanging ATPase encloses two tightly bound $^{86}Rb^+$—which are congeners of two K^+, are transported as efficiently as two K^+, and are also radioactive*—when no other substrates are bound to the enzyme.[306-308] This ability to occlude these Rb^+ is the defining feature of this conformation. In the usual situation, the occluded cations are the two K^+ that have entered the compartment from the extracytoplasmic solution during the normal sequence of events and are in transit to the cytoplasmic solution. In crystallographic molecular models of the E2·$[K^+]_2$ conformation of porcine Na^+/K^+-exchanging ATPase, the two K^+ are occupying their ligands in the compartment for cations

*There are several radioactive isotopes of the alkali metal ions and alkaline earth metal ions, such as $^{86}Rb^+$, $^{42}K^+$, $^{22}Na^+$, $^{45}Ca^{2+}$, and $^{89}Sr^{2+}$ that are used to examine the association of the ions with these enzymes. Their radioactivity allows them to be detected at the low stoichiometric concentrations at which these large, membrane-bound, often impure enzymes must be studied. They are a sensitive method for ascertaining whether or not cations are in the compartment when the enzyme is in one of its conformations.

(Figure 6–36C), and there are no obvious paths on which they can leave the compartment, a fact consistent with their occlusion.[295,299] In the corresponding crystallographic molecular model of P-type Ca^{2+} transporter from *O. cuniculus*, the compartment for cations is vacant but presumably the H^+ passing through it, which are homologues of the K^+ passing through Na^+/K^+-exchanging ATPase, are invisible occupants of several of the carboxy groups that will chelate the Ca^{2+} as carboxylato groups on the return trip,[300,309,310] and the compartment is also occluded. The behavior of the steady-state concentration of occluded $^{86}Rb^+$ as a function of the concentration of Na^+ while porcine Na^+/K^+-exchanging ATPase is hydrolyzing $MgATP^{2-}$ is consistent with its participation in the normal enzymatic reaction and with the kinetic mechanism of Figure 6–38.[305]

During a conformational change, which can be detected in mammalian Na^+/K^+-exchanging ATPase by following either the intrinsic fluorescence of its tryptophans[311] or the response of fluorescent, covalently attached groups that do not otherwise affect the enzyme,[312] the compartment then opens to the cytoplasmic surface. This **E1·MgATP^{2-} conformation** is open to the cytoplasmic solution. Two previously occluded $^{42}K^+$ have been shown to depart from this conformation in canine Na^+/K^+-exchanging ATPase,[313] and three Na^+ bind to it during the normal cycle. In crystallographic molecular models of P-type Ca^{2+} transporter from *O. cuniculus* in this E1·$MgATP^{2-}$ conformation, in which the compartment for cations is vacant (Figure 6–39A),[309,314,315] there are two hydrophilic channels that connect the cytoplasmic solution to the compartment. One of these channels is formed by a dramatic sinking into the bilayer of one of the α helices that span the membrane (arrow in Figure 6–39B).[316] The shift in the position of this α helix opens a wide funnel into one side of the compartment. Passing out from the opposite side of the compartment for the cations in this conformation is a channel, again into the cytoplasm, filled with molecules of water, that meanders among four of the other α helices that span the membrane. This latter channel is neither wide nor obvious, and its opening does not involve any dramatic rearrangement of the α helices,[315] so it may not be an alternative exit from or entrance to the compartment.

In the reaction catalyzed by P-type Ca^{2+} transporter, the two hydrons leaving the compartment, which are homologues of the two K^+ leaving the compartment from Na^+/K^+-exchanging ATPase, and the two Ca^{2+} entering the compartment, which are homologues of the three Na^+, pass through one or the other or both of these hydrophilic channels.[315] The departure of two K^+ and the arrival of three Na^+ through the homologous hydrophilic channels in the E1·$MgATP^{2-}$ conformation of Na^+/K^+-exchanging ATPase produces the competition between these cations both at the cytoplasmic surface of the human enzyme[317] and in the steady-state kinetics of human Na^+/K^+-exchanging ATPase[318] and Na^+/K^+-exchanging ATPase from *Carcinus maenas*.[257] Potassium ion is a competitive product inhibitor of Na^+ in its role as a reactant. In P-type Ca^{2+} transporter from *O. cuniculus*, the two Ca^{2+} that associate with the compartment for cations when it is open to the cytoplasm in the E1·$MgATP^{2-}$ conformation bind sequentially and can be distinguished kinetically.[319] This distinction results from the fact that one of them is deeper in the compartment than the other (Figure 6–39B).

When two K^+ have left and three Na^+ have entered the compartment through one or both of the openings to the cytoplasm, the compartment again closes, and three radioactive $^{22}Na^+$ become locked within the compartment of porcine Na^+/K^+-exchanging ATPase in a different occluded state[320] that defines in part the **[Na^+]$_3$·E1~P conformation**.* In crystallographic molecular models of porcine Na^+/K^+-exchanging ATPase[292,321] occupied by three Na^+ (Figure 6–36B) and P-type Ca^{2+} transporter from *O. cuniculus*[291,315,316] occupied by two Ca^{2+} (Figure 6–36A), which are homologues of the three Na^+, the cytoplasmic entrances to the compartment for cations have closed and the cations are now occluded (Figure 6–39B).

The conformational change in Na^+/K^+-exchanging ATPase that then occurs between the [Na^+]$_3$·E1~P conformation and the **E2–P conformation** can also be followed by covalently attaching fluorescent reporters of the structure of the protein to the canine enzyme.[312] This conformational change opens the compartment for cations to the extracytoplasmic side (Figure 6–40).[291,294] In the crystallographic molecular model of P-type Ca^{2+} transporter from *O. cuniculus* in this conformation, there is a wide hydrophilic channel, open to the extracytoplasmic side of the bilayer and ending in the compartment for cations (Figure 6–40B).[322,323] The opening of this channel, which provides an unobstructed path connecting the compartment with the extracytoplasmic solution, is accomplished by movement of the extracytoplasmic portions of four of the membrane-spanning α helices away from the other six.[315]

*In this instance, the enzyme was modified by *N*-ethylmaleimide (Figure 6–38) to stabilize the occluded state.

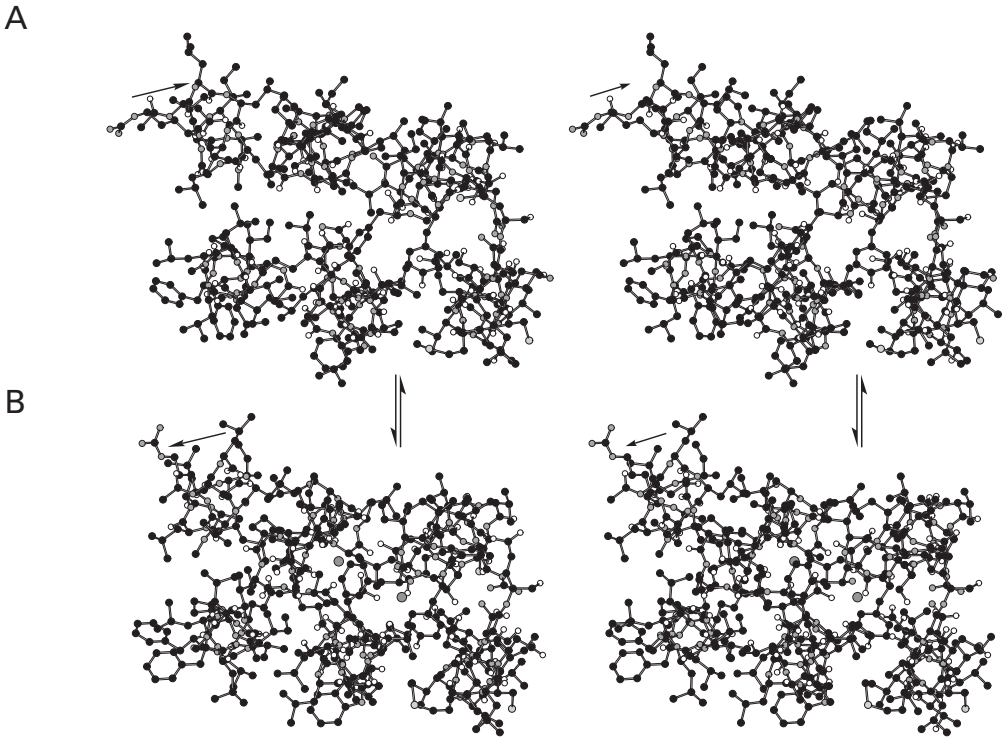

Figure 6–39: Stereodrawings[485] of crystallographic molecular models representing the closing of the cytoplasmic entrance to the compartment for Ca^{2+} in P-type Ca^{2+} transporter from *O. cuniculus* around the two Ca^{2+}. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. (**A**) Crystallographic molecular model of the compartment when the door is open to the cytoplasmic solution in the E1·MgATP^{2-} conformation and the compartment is ready to associate with Ca^{2+} that have entered the compartment from the cytoplasmic solution.[314] Membranes of sarcoplasmic reticulum enriched in P-type Ca^{2+} transporter were isolated from white muscle of the hind legs of *O. cuniculus*. The membranes (12 mg mL^{-1}) were dissolved in a solution (18 mg mL^{-1}) of the detergent 3,6,9,12,15,18,21,24,27-nonaoxanonatriacontan-1-ol. The dissolved enzyme was then crystallized in the presence of 80 mM KCl, 3 mM $MgCl_2$, and 3.9 mM ethylene glycol bis(2-aminoethyl ether)-*N,N,N′,N′*-tetraacetate to sequester any calcium in solution and prevent it from associating with sites in the compartment. Reflections were collected to Bragg spacing of 0.31 nm. The peptide sarcolipin was also added to stabilize the E1·MgATP^{2-} conformation. The enzyme adopts an α-helical conformation that spans the membrane and lies below the two α helices at the lower left and center left of the drawing. (**B**) Crystallographic molecular model[316] of the closed, occluded compartment in the $[Ca^{2+}]_2$·E1~P conformation occupied by two Ca^{2+}, drawn as large gray spheres. Membranes of sarcoplasmic reticulum enriched in P-type Ca^{2+} transporter were isolated from white muscle of the hind legs of *O. cuniculus*. The membranes were suspended in 0.5 mg mL^{-1} deoxycholate, 0.3 M sucrose, 0.5 M KCI, 1 mM ethylenediaminetetraacetate, 1.25 mM $MgCl_2$, and 10 μM $CaCl_2$ at pH 7.9 to remove any loosely attached protein. The washed membranes at 3.0 mg mL^{-1} were then dissolved in 2.0 mg mL^{-1} deoxycholate, 0.3 M sucrose, 0.5 M KCI, 1 mM ethylenediaminetetraacetate, 1.5 mM $MgCl_2$, and 20 μM $CaCl_2$ at pH 8.0. The supernatant was dialyzed against 0.3 M sucrose, 0.5 M KCI, 1 mM ethylenediaminetetraacetate, 1.5 mM $MgCl_2$, and 20 μM $CaCl_2$ at pH 8.0. The re-formed membranes, which contained only P-type Ca^{2+} transporter, were then dissolved in 30 mM 3,6,9,12,15,18,21,24-octaoxatetratriacontan-1-ol, 20% glycerol, 80 mM KCl, 10 mM $CaCl_2$, 2 mM $MgCl_2$, and 1 mM magnesium 5′-adenylic methylenediphosphonic anhydride (MgAMPPCP^{2-}) at 12 mg mL^{-1} final protein concentration. The solution was mixed with an equal volume of 8% poly(ethylene glycol), 4% *tert*-butanol, 15% glycerol, 5 mM 2-sulfanylethanol, and 200 mM sodium acetate to form crystals. Reflections were collected to Bragg spacing of 0.26 nm. The view in both drawings is from the cytoplasmic side of the membrane into the interior down several of the membrane-spanning α helices. The view is also in the same orientation as in Figure 6–36A. In the present instance, however, the two α helices that form the wall of the compartment on the left in the drawing are included. They were not included in the drawing of Figure 6–36A because they do not provide ligands to the Ca^{2+}. All six of the α helices that form the walls of the compartment were extended up to the cytoplasmic surface of the membrane, to include the door to the compartment from that side. Each stereodrawing includes the same segments of polypeptide from each of these six α helices. In the drawing of the occluded compartment in Panel B, the two Ca^{2+} can be seen at the bottom of the drawing in the same orientation as in Figure 6–36A. This equivalence can be verified by looking for Asparagine 768 and Aspartate 800. The door to the compartment is the α helix in the upper left-hand corner of the two drawings. In the open conformation (Panel A), a large entrance to the compartment can be seen. In the occluded conformation (Panel B), the door has been closed. Opening of the compartment involves a sinking of the upper left-hand α helix into the membrane away from the viewer and movement away from the other five α helices (arrow in Panel B). Closing of the compartment around the two Ca^{2+} involves movement of the α helix in the opposite direction (arrow in Panel A).

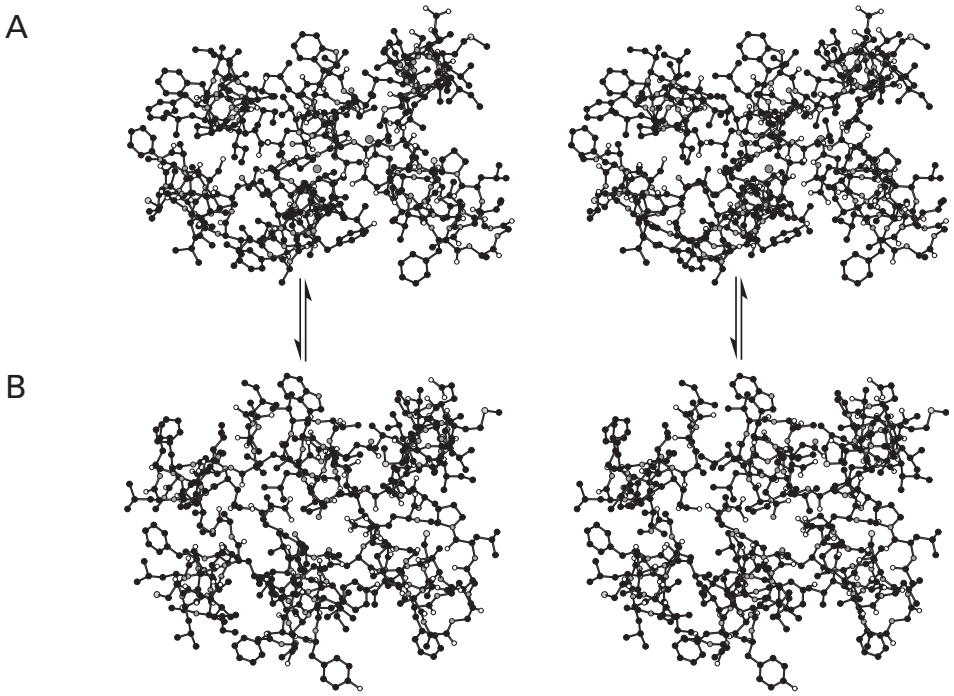

Figure 6–40: Stereodrawings[485] of crystallographic molecular models representing the opening of the extracytoplasmic entrance to the compartment for Ca^{2+} in P-type Ca^{2+} transporter from *O. cuniculus*. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. (**A**) Crystallographic molecular model of the closed, occluded compartment in the $[Ca^{2+}]_2$·E1~P conformation occupied by two Ca^{2+} (Figure 6–36A), drawn as large gray spheres. The view is from the extracytoplasmic surface of the membrane rather than the cytoplasmic surface. To obtain this view, the molecular model drawn in Figure 6–35 was rotated 90° about a horizontal axis in the plane of the page in the opposite direction from the rotation used to obtain the view in Figure 6–36A. (**B**) Crystallographic molecular model of the compartment when the door is open to the extracytoplasmic solution in the E2–P conformation and the Ca^{2+} have dissociated into the extracytoplasmic solution. To obtain this molecular model of the open compartment,[323] the same preparation of P-type Ca^{2+} transporter described in the legend of Figure 6–34 was used. The enzyme, however, was crystallized from a solution of 2 mM BeF_2, 4 mM NaF, 10 mM $MgCl_2$, and 3 mM ethylene glycol bis(2-aminoethyl ether)-*N,N,N′,N′*-tetraacetate to sequester any calcium in solution and prevent it from associating with sites in the compartment. The beryllium atom in BeF_2 forms a covalent bond (0.16 nm) with one oxygen of the carboxylato group of Aspartate 351 in the hydrolytic site to produce an acyloxy beryllium trifluoride that mimics the phosphorylated intermediate in the E2–P conformation, and there is no free Ca^{2+} in solution to associate with the ligands in the compartment. These two strategies ensure formation of the E2–P conformation. The view in both drawings is from the extracytoplasmic side of the membrane. All six α helices that form the wall of the compartment are included and were extended from the ligands to the Ca^{2+} up to the extracytoplasmic surface of the membrane, to include the door to the compartment from that side. Each drawing includes the same segments of polypeptide from these six α helices. The fact that the drawing is in an orientation that results from a 180° rotation about a horizontal axis in the plane of the page in Figure 6–36A can be verified by finding the two Ca^{2+} in Panel A and looking for Asparagine 768 and Aspartate 800. Although there are significant changes in the orientation and alignments of four or five of the six α helices between the drawings in Panels A and B, the α helix in the middle of the bottom row swings open most dramatically (arrow in Panel A) to produce an open path out of the compartment that allows the Ca^{2+} to dissociate into the extracytoplasmic solution.

This wide funnel opened to the extracytoplasmic side of the enzyme is occupied in its entirety and completely blocked by a molecule of cardiac glycoside in crystallographic molecular models of complexes between cardiac glycoside and Na^+/K^+-exchanging ATPase[303,304,324-326] in this conformation. This fact explains why cardiac glycosides, which are strong inhibitors of the enzyme, associate with only this conformation (Figure 6–38). In P-type Ca^{2+} transporter, two Ca^{2+} depart from this E2–P conformation to be replaced by two or three H^+. In Na^+/K^+-exchanging ATPase, three Na^+ depart from this E2–P conformation to be replaced by two K^+. During this exchange, Na^+ acts as a competitive product inhibitor of K^+ in its role as a reactant in the steady-state kinetics of the enzyme.[257,318]

When the conformational change between the occluded $[Na^+]_3$·E1~P conformation and the open $(Na^+)_3$·E2–P conformation in Na^+/K^+-exchanging ATPase is initiated by a large and rapid voltage change across the plasma membrane of axons from *Doryteuthis pealeii*, there are three movements of positive charge[327] that have been assigned to the individual dissociations of three Na^+ at rates of 1, 10, and >1000 ms^{-1}. In the case of P-type Ca^{2+} transporter from *O. cuniculus*, the conformational change between $[Ca^{2+}]_2$·E1~P and $(Ca^{2+})_2$·E2–P is slow (0.03 ms^{-1} at 25° C) and the subsequent dissociation of the two Ca^{2+} into the extracytoplasmic solution is rapid (>10^2 ms^{-1}) so that the two Ca^{2+} that dissociate cannot be kinetically distinguished.[319,328] These rapid rates for dissociation of the cations from both Na^+/K^+-exchanging ATPase and P-type Ca^{2+} transporter are consistent with the large size of the opening to the compartment for cations from the extracytoplasmic solution in crystallographic molecular models of the E2–P conformation (Figure 6–40B).[322,323]

In the final step in the mechanism, the protein closes around the two K^+ to regenerate the E2·$[K^+]_2$ conformation.[308] During this final step in P-type Ca^{2+} transporter, the protein closes around two or three hydrons to regenerate the occluded E2·$[H^+]_n$ conformation. A mutant of P-type Ca^{2+} transporter from *O. cuniculus*, in which Glutamate 309, one of the glutamates in the compartment, has been mutated to glutamine to simulate its hydronation, crystallizes in a conformation that was proposed to be an intermediate between the E2–P and E2·$[H^+]_n$ conformations as the compartment is closing around the hydrons.[329]

The Michaelis constants for Na^+ and K^+ in the steady-state kinetics of Na^+/K^+-exchanging ATPase are assumed to be the dissociation constants for the respective ions when they are reactants because they are such small, uncomplicated ions that they probably associate and dissociate from their sites in the compartment rapidly. The inhibition constants in steady-state kinetics for Na^+ and K^+ are assumed to be for Na^+ as a product competing with K^+ as reactant for occupation of the compartment when it is open to the extracellular surface of the enzyme and for K^+ as a product competing with Na^+ as reactant for occupation of the compartment when it is open to at the cytoplasmic surface of the enzyme. In steady-state kinetics, the Michaelis constant for Na^+ entering the compartment for cations in human Na^+/K^+-exchanging ATPase[318] and Na^+/K^+-exchanging ATPase from *C. maenas*[257] as a reactant from the cytoplasmic solution and the Michaelis constant for K^+ entering the compartment for cations as a reactant from the extracytoplasmic solution, respectively, are significantly smaller than the inhibition constants for Na^+ as a product when it is leaving the compartment for cations into the extracytoplasmic solution or K^+ leaving the compartment for cations as a product into the cytoplasmic solution.

Although these differences in dissociation constant are not necessary for active transport to occur by this mechanism (Figure 6–38), in this way, the rates of exchange of two K^+ for three Na^+ in the E1·$MgATP^{2-}$ conformation and three Na^+ for two K^+ in the E2–P conformation are accelerated. The time between the opening to one side of the membrane of the compartment loaded with the proper number of one type of cation (the cationic products) and the closing of the compartment around the proper number of the other type of cation (the cationic reactants) can be viewed as the time it takes for the cationic products to vacate and the cationic reactants to occupy the compartment. As these exchanges proceed by random collisions of cations with the open compartment, the probability that cationic reactants will be bound in the correct number and in the absence of bound cationic products increases as the dissociation constant for cationic products from the site increases and the dissociation constant for cationic reactants from the site decreases. Furthermore, under normal circumstances, when the enzyme is actively transporting cations against their electrochemical gradients, the concentrations of cationic products are always greater than the concentrations of cationic reactants on the respective sites of the membrane. For example, at the cytoplasmic side, K^+ is the cationic

product and Na^+ is the cationic reactant, but the concentration of K^+ is significantly greater than the concentration of Na^+.

The existence of the four discrete global conformations assumed by Na^+/K^+-exchanging ATPase—$E2{\cdot}[K^+]_2$, $E1{\cdot}MgATP^{2-}$, $[Na^+]_3{\cdot}E1{\sim}P$, and E2–P—has been established in several ways other than their ability to occlude particular cations. There are several short segments of the native folded catalytic α polypeptide of Na^+/K^+-exchanging ATPase from *O. cuniculus*[330] and porcine H^+/K^+-exchanging ATPase[331] that are susceptible to cleavage by endopeptidases, presumably because they form exposed loops on the surface of the native enzyme, and the accessibilities of these segments to endopeptidases change dramatically as the conformations change.[332] The affinity of the different conformations of Na^+/K^+-exchanging ATPase for ligands such as $MgATP^{2-}$ and cardiac glycosides are dramatically different.[311,333] Finally, in addition to the observations described above, a number of fluorescent molecules have been covalently attached to various locations in canine and porcine Na^+/K^+-exchanging ATPase, and their fluorescence emission changes as changes are made in the conformation of the enzyme.[312,334] Because these various reporters of the structure of the protein are scattered over its surface, it is assumed that each change in structure being detected is a global conformational change.

Steps in the mechanism for hydrolysis of $MgATP^{2-}$ at the hydrolytic site of Na^+/K^+-exchanging ATPase are connected by global conformational changes to each change in access to the compartment through which the cations pass.

When the enzyme is in the $E2{\cdot}[K^+]_2$ conformation, two K^+ are occluded within the compartment, and the hydrolytic site is unoccupied by substrates. There are two parallel paths that the mechanism can take from this point (Figure 6–38), each of which opens the compartment to the cytoplasmic side of the enzyme. The conformational change of mammalian Na^+/K^+-exchanging ATPase from the $E2{\cdot}[K^+]_2$ conformation to the $(K^+)_2{\cdot}E1$ conformation, in which the enzyme is open to the cytoplasmic surface is slow and has an unfavorable equilibrium constant, but when it happens to occur, $MgATP^{2-}$ at low concentration can bind rapidly and with high affinity to the hydrolytic site, locking in the open $(K^+)_2{\cdot}E1$ conformation. The hydrolytic site, however, does have a large dissociation constant for $MgATP^{2-}$ in the $E2{\cdot}[K^+]_2$ conformation. If $MgATP^{2-}$ is at a high enough concentration, then it can bind before the conformational change occurs. When it binds, the enzyme opens to the cytoplasm in a fast step leading to release of the K^+.[311,335] The product of both paths is the conformation $E1{\cdot}MgATP^{2-}$. Normal cytoplasmic concentrations of $MgATP^{2-}$ are sufficient to saturate the hydrolytic site when the enzyme is in the $E2{\cdot}[K^+]_2$ conformation, even though it displays low affinity for $MgATP^{2-}$ in this conformation; and when it is in the plasma membrane of a cell, the **binding of $MgATP^{2-}$ accelerates the opening of the compartment to the cytoplasm**.[312] In addition, steady-state kinetic measurements of porcine Na^+/K^+-exchanging ATPase, when correlated to the rate at which $^{86}Rb^+$ is deoccluded in the absence of $MgATP^{2-}$, lead to the conclusion that high concentrations of Na^+ ($K_{d,app}$ = 40 mM), presumably associating with a site other than the compartment in which the two Rb^+ are occluded, also accelerate their deocclusion,[305] but the side of the membrane on which this site is located was not determined. Because $MgATP^{2-}$ can bind to the hydrolytic site by either of these two paths, the steady-state kinetics of P-type Ca^{2+} transporter from *O. cuniculus* as the concentration of $MgATP^{2-}$ is varied display positive deviations from linear behavior that appear to be cooperative,[336] although they are not because the enzyme is a monomer with only one active site for hydrolysis of $MgATP^{2-}$ and no other sites with which $MgATP^{2-}$ associates.

From a comparison of a crystallographic molecular model of P-type Ca^{2+} transporter from *O. cuniculus* in which the site for hydrolysis of $MgATP^{2-}$ is empty with one of the enzyme in which the same site is occupied by magnesium 5′-adenylic methylenediphosphonic anhydride ($MgAMPPCP^{2-}$), it can be concluded that association of $MgATP^{2-}$ with the $E2{\cdot}[H^+]_2$ conformation of the enzyme proceeds with a **major local conformational change** (Figure 6–41).[291,294,316] Three **hinged domains**, formed by 110, 160, and 240 amino acids (upper left, upper middle, and upper right, respectively, in Figure 6–41A) comprise the majority of the large portion of P-type Ca^{2+} transporter that resides in the cytoplasm. In the absence of nucleotide, these domains are splayed apart. After $MgAMPPCP^{2-}$ has been bound by the open hydrolytic site, and presumably after $MgATP^{2-}$ has been bound during normal turnover as well, these three domains have closed around the nucleotide (Figure 6–41B) and merged into a large, compact globular structure. The same hinged domains and the same conformational change are observed in Na^+/K^+-exchanging ATPase.[292,295,304,321]

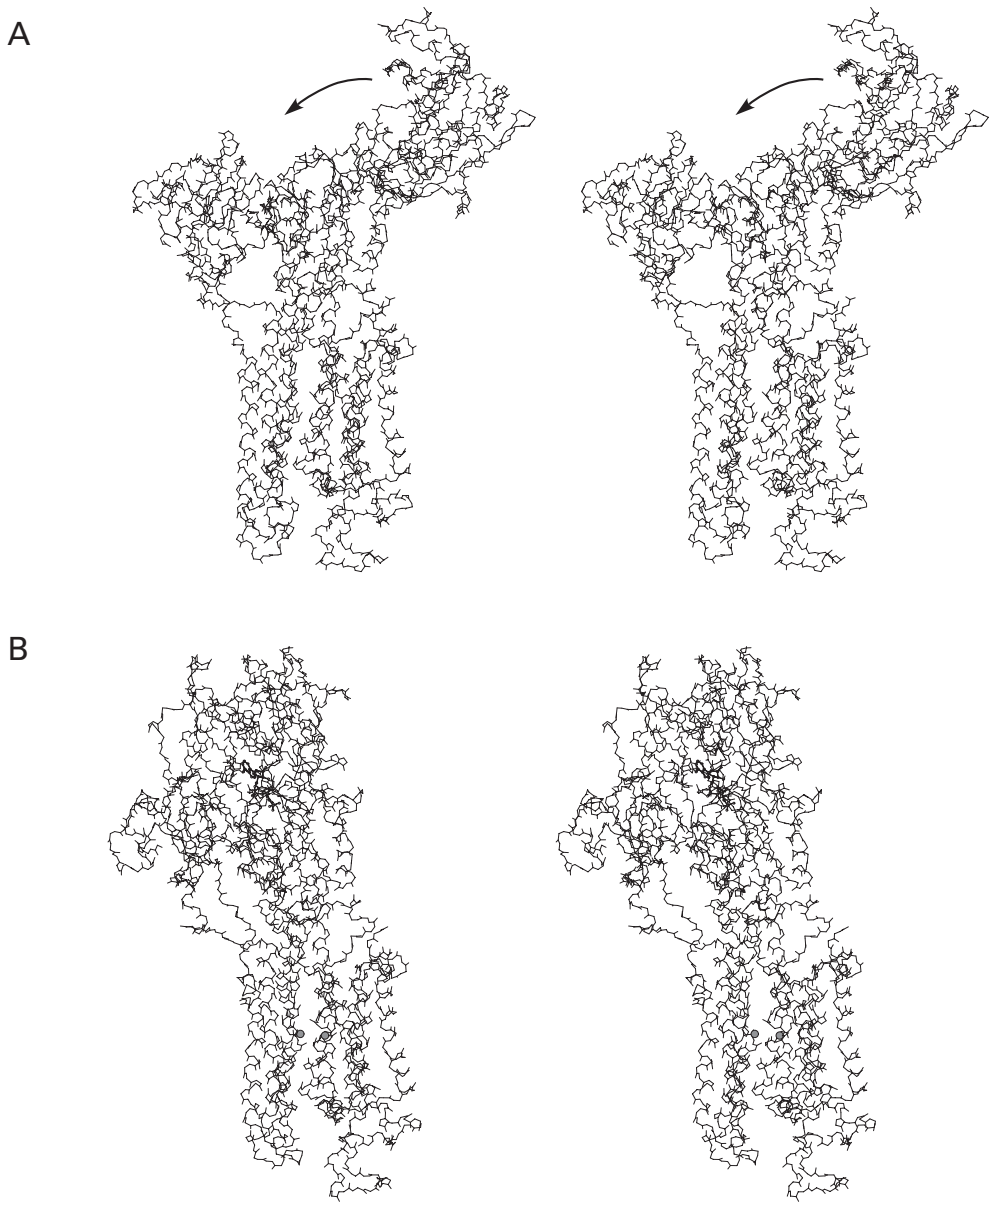

Figure 6–41: Stereodrawings[485] of crystallographic molecular models showing the local change in conformation that results when the structural domains of P-type Ca^{2+} transporter from *O. cuniculus* close around a molecule of $MgATP^{2-}$ to produce the occupied hydrolytic site. (**A**) Open hydrolytic site. To obtain this crystallographic molecular model,[294] the same preparation of P-type Ca^{2+} transporter described in the legend of Figure 6–34 was used. The enzyme, however, was crystallized from a solution of 10 mM $CaCl_2$ and 3 mM $MgCl_2$ in the absence of any nucleotide, phosphate, or compound that could produce a mimic of the phosphorylated intermediate. (**B**) Closed hydrolytic site. The same crystallographic molecular model was used to make this drawing of the enzyme with its hydrolytic site occupied by $MgAMPPCP^{2-}$ as was used for the drawing in Figure 6–34. Again, black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large dark gray atoms are the three atoms of phosphorus. Only the atoms in the complete polypeptide backbones are included in the two skeletal drawings. The two Ca^{2+} occupying the compartment for cations are drawn as large gray spheres. To give the best view of the three domains that are splayed open in the drawing of the local conformation in which the hydrolytic site is open and unoccupied (Panel A), an orientation that is produced by a 40° rotation about a vertical axis in the plane of the page in Figure 6–34 was chosen. The drawing of the enzyme occupied by $MgAMPPCP^{2-}$ is in the same orientation. The major motion producing the closing of the structural domains is the pivot to the left (arrow) of the large structural domain on the right of the cytoplasmic portion of the enzyme in Panel A.

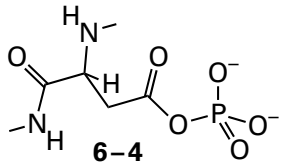
This large local change in conformation is probably what biases the conformational change from the $E2\cdot[K^+]_2$ to the $E1\cdot MgATP^{2-}$ conformation upon association of $MgATP^{2-}$.

In the resulting $E1\cdot MgATP^{2-}$ conformation, the hydrolytic site has closed around $MgATP^{2-}$ and the compartment for cations has opened to the cytoplasmic solution. Once the compartment for cations in Na^+/K^+-exchanging ATPase is open to the cytoplasm, two K^+ are eventually replaced by three Na^+ while the $MgATP^{2-}$ remains in the hydrolytic site that has closed around it. Once three Na^+ have replaced two K^+ in the compartment for cations in Na^+/K^+-exchanging ATPase, the global conformation changes, occluding the three Na^+. Alternatively, once two Ca^{2+} have replaced several H^+ in the compartment for cations of P-type Ca^{2+} transporter, the global conformation changes, occluding the two Ca^{2+}. During this conformational change in Na^+/K^+-exchanging ATPase from the $E1\cdot MgATP^{2-}$ to the $[Na^+]_3\cdot E1\sim P$ conformation, the compartment closes around three Na^+ and the γ-phosphate of $MgATP^{2-}$ is transferred simultaneously to an aspartate in the hydrolytic site to produce an aspartyl phosphate, which is a mixed anhydride[337]



6–4

Peptides have been isolated from streptogrisin digests of Na^+/K^+-exchanging ATPase from *Cavia porcellus* and digests of P-type Ca^{2+} transporter from *O. cuniculus*, respectively, that contain this **intermediate aspartyl phosphate**.[338]

Kinetic studies of the phosphorylation that occurs during the conformational change from the $(Na^+)_3E1\cdot MgATP^{2-}$ to the $[Na^+]_3\cdot E1\sim P$ conformation demonstrate that a slower step ($500\ s^{-1}$ at 24° C), presumably the global conformational change occluding the cations, has to occur before the rapid phosphorylation ($>3000\ s^{-1}$) of the aspartate in the hydrolytic site of the enzyme and that the $MgADP^-$ that is produced at the hydrolytic site during phosphorylation of the aspartate is immediately in rapid equilibrium with $MgADP^-$ in solution.[339] In the crystallographic molecular model of the complex between P-type Ca^{2+} transporter from *O. cuniculus* and $MgAMPPCP^{2-}$, the compartment is occupied by two Ca^{2+} (Figures 6–34 and 6–41B), and it has already been occluded. This molecular model is consistent with the conclusion that the global conformational change from the $E1\cdot MgATP^{2-}$ to the E1~P conformation that occludes the compartment occurs before the aspartate is phosphorylated during the conformational change. Magnesium 5′-adenylic methylenediphosphonic anhydride cannot phosphorylate the aspartate, yet the two Ca^{2+} are occluded.

In the $[Na^+]_3\cdot E1\sim P$ conformation, the aspartyl phosphate (**6–4**) in mammalian Na^+/K^+-exchanging ATPase is in an environment causing it to have a large negative standard free energy of hydrolysis because the aspartyl phosphate and $MgADP^-$ are in rapid equilibrium with $MgATP^{2-}$ free in solution[340,341]

$$E_1COO\sim PO_3^{2-}\cdot MgADP^- \rightleftharpoons E_1COO^-\cdot MgATP^{2-} \qquad (6\text{–}129)$$

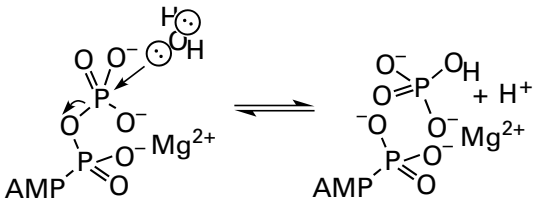
as would be expected from the large negative standard free energy of hydrolysis for acyl phosphates in solution (Table 1–3). If the next conformational change in the mechanism is blocked by binding of the inhibitor oligomycin to the enzyme or by covalent modification of the enzyme with *N*-ethylmaleimide (Figure 6–38), then this rapid equilibrium in the hydrolytic site is manifested in a rapid isotopic exchange[342] of $Mg[^{14}C]ADP^-$ with $Mg[^{12}C]ATP^{2-}$.

If, however, the next conformational change proceeds spontaneously (Figure 6–38), as it normally does, then the $[Na^+]_3\cdot E1\sim P$ conformation converts rapidly to the $E2\text{–}P\cdot(Na^+)_3$ conformation, in which the compartment for the Na^+ being transported has opened to the extracytoplasmic surface. The acyl phosphate, although still at the same aspartate in Na^+/K^+-exchanging ATPase from *Electrophorus electricus*,[343] has **changed from one with a large negative standard free energy of hydrolysis to one with a small standard free energy of hydrolysis** because in this conformation it is in rapid equilibrium with phosphate in solution[344]

$$E_2COO\text{–}PO_3^{2-} + H_2O \rightleftharpoons E_2COO^- + H^+ + HOPO_3^{2-} \qquad (6\text{–}130)$$

in Na^+/K^+-exchanging ATPase from *E. electricus* as well as the feline enzyme. In other words, in this conformation, phosphate in solution is able to easily phosphorylate the aspartate in the hydrolytic site. This phosphorylation is analogous to what occurs on the active site of myosin ATPase in the absence of actin, where $MgADP^-$ and $HOPO_3^{2-}$ are in rapid

equilibrium with $MgATP^{2-}$ (see Equation 5–259 and Figure 5–18)



(6–131)

which at the time was an unexpected observation. In the case of Na^+/K^+-exchanging ATPase, an acyl phosphate is in equilibrium with H_2O and $HOPO_3^{2-}$, also contrary to expectation. The structure of the hydrolytic site in this conformation has dramatically shifted the value for an equilibrium constant relative to what it would be in free solution, a feat that will be duplicated by the active site of H^+-transporting two-sector ATPase.

Once three Na^+ in the compartment for cations in Na^+/K^+-exchanging ATPase have been replaced by two K^+, or in the case of P-type Ca^{2+} transporter, two Ca^{2+} by two or three H^+, the conformational change from the E2–P conformation in which two K^+ occupy the open compartment to the E2·$[K^+]_2$ conformation occurs. Coincident with the closing of the compartment to occlude the two K^+, the **acyl phosphate is hydrolyzed** to regenerate the empty hydrolytic site.[341,345] This conformational change can be followed by observing the effect of the concentration of K^+ on the rate of hydrolysis of the aspartyl phosphate (**6–4**) in the active site of bovine Na^+/K^+-exchanging ATPase[346] that has been formed from [γ-^{32}P]$MgATP^{2-}$ in the presence of Na^+. Because the aspartyl phosphate in the E2–P conformation hydrolyzes rapidly, but only upon addition of K^+, while the aspartyl phosphate in the $[Na^+]_3$·E1~P conformation rapidly transfers its phosphate to $MgADP^-$, the relative amounts of these two conformations, and hence the equilibrium constant between them, can be determined under any set of circumstances.[341] The phosphate produced by hydrolysis of the aspartyl phosphate in the E2–P conformation seems to remain associated with the hydrolytic site during the transition from the E2–P conformation to the E2·$[K^+]_2$ conformation, as there is a crystallographic molecular model of Na^+/K^+-exchanging ATPase from *S. acanthias* in which the hydrolytic site is closed around an analogue of phosphate that cannot phosphorylate the aspartate and the two K^+ are occluded.[299]

The steps in the mechanism of active transport at which standard free energy changes that represent the standard free energy of hydrolysis of $MgATP^{2-}$ are manifested are not the steps in which the covalent bonds are made and broken. The steps in which covalent bonds are made and broken are the transitions between E1·$MgATP^{2-}$ and $[Na^+]_3$·E1~PO_3^{2-}·$MgADP^-$ and E2–P and E2·$[K^+]_2$. The **steps in which the change in standard free energy are manifest** are those in which only conformational changes of the enzyme occur, which are in the spontaneous transition between $(Na^+)_3$·E1~P and E2–P and the transition between E2·$[K^+]_2$ and E1·$MgATP^{2-}$ that is strongly promoted by association of $MgATP^{2-}$. Yet again, these observations seem counterintuitive.

Active transport occurs because specific events that take place at the site where the $MgATP^{2-}$ is hydrolyzed are coupled to distinct, but also specific, events that take place in the compartment through which the cations pass into and out of the cytoplasm. This compartment is defined by its ability to occlude the cations. The distance between this compartment and the hydrolytic site is 5 nm (Figure 6–34), and the only reasonable strategy for this rigid coupling of events is through extensive global conformational changes in the enzyme.

Each global conformation through which the coupling is accomplished must be solid enough to unerringly transfer information about the status of the active site and the status of the compartment for the ions over such a long distance. The protein in each conformation cannot be soft. Because there is nothing special about the protein in these enzymes, this necessity yet again demonstrates that **proteins cannot be soft**.

Because the occluded forms, in which the cations are stationary occupants in the compartment through which they pass, exist, the actual transport of the cations involves closing of the compartment at one side, after they are bound, before it opens to the other side. Because the barrier at the closed end of an open compartment is at that instant the only barrier between the cytoplasmic and extracytoplasmic solutions, it follows that, as they are transported, **it is not the cations that move but the barrier between cytoplasm and extracytoplasmic solution that moves.**

Several drawings have been presented in which four of the crystallographic molecular models of P-type Ca^{2+} transporter have been proposed to be representatives of the four respective global conformations of the enzyme that accomplish the active transport of Ca^{2+} and H^+.[322,347] There are several problems with these presentations that make them

premature. First, there is no agreement among the crystallographers as to which molecular models represent the four conformations. Second, in many of the molecular models chosen, rather large perturbants of the structure—such as sarcolipin,[314] a peptide of 31 amino acids that forms a membrane-spanning α helix adjacent to the α helices forming the compartment for Ca^{2+} and H^+, or thapsigargin,[300,309,315,348,349] a rather large molecule, $C_{34}H_{50}O_{12}$, that binds within the compartment for cations—were bound to P-type Ca^{2+} transporter in the crystals and were present in the molecular model. In fact, the only molecular models in which the compartment is open to the cytoplasm have these perturbants associated with them.

Finally, there has been no attempt to distinguish between **local conformational changes**, which are dramatic, and global conformational changes, which are probably more subtle but are key to the process. For example, the induced fit upon association of adenine nucleotides with the active site of P-type Ca^{2+} transporter or Na^+/K^+-exchanging ATPase is a significant conformational change. It seems, however, to be associated only with occupation of the active site by an adenine nucleotide, normally the substrates $MgATP^{2-}$ or $MgADP^-$. If so, this conformational change may be a local conformational change similar to the one that occurs upon association of carbamoyl phosphate and L-aspartate with the active sites of aspartate carbamoyltransferase. Nevertheless, even if it is only a local conformational change, it probably promotes the respective global conformational changes from the $E2{\cdot}[H^+]_n$ to the $(H^+)_n{\cdot}E1{\cdot}MgATP^{2-}$ conformation and from the $E2{\cdot}[K^+]_2$ to the $(K^+)_2{\cdot}E1{\cdot}MgATP^{2-}$ conformation that follow association of $MgATP^{2-}$ at normal cellular concentrations. In another example, whenever the compartment for cations in P-type Ca^{2+} transporter is occupied by Ca^{2+}, it is in an occluded local conformation,[316] but during the catalytic cycle, Ca^{2+} must associate with and dissociate from the compartment when it is open on each side of the membrane. Nevertheless, even if closing of the compartment around the Ca^{2+} to occlude them is a local conformational change, it promotes the next global conformational change, in the sequence linking the events in the compartment with the events in the active site.

The entire process (Equation 6–128) of **active transport is reversible**, as are all enzymatic reactions. The rapid reversibility of the two halves of the mechanism, that in which Na^+ is transported and that in which K^+ is transported, can be demonstrated. The enzyme in an intact, resealed human erythrocyte in the absence of K^+ catalyzes a rapid three-for-three exchange of cytoplasmic, radioactive $^{24}Na^+$ for extracytoplasmic, nonradioactive $^{23}Na^+$ that requires the presence of both cytoplasmic $MgATP^{2-}$ and cytoplasmic $MgADP^-$ as expected if the mechanism is as described (Figure 6–38).[350,351] The enzyme in resealed human erythrocytes also catalyzes, in the absence of Na^+, a rapid two-for-two exchange of cytoplasmic, radioactive $^{42}K^+$ for extracytoplasmic, nonradioactive $^{39}K^+$ that requires[352] the presence of cytoplasmic $HOPO_3^{2-}$ as expected (Figure 6–38) but also the presence of cytoplasmic $MgATP^{2-}$. The latter requirement results from the fact that the binding of $MgATP^{2-}$ at the hydrolytic site accelerates the rate-limiting step in the K^+/K^+ exchange, that of opening the compartment to the cytoplasm to release the occluded K^+. Finally, if sufficient concentration gradients of Na^+ and K^+ are created across the plasma membranes of erythrocytes from *C. porcellus* and the concentrations of $MgADP^-$ and $HOPO_3^{2-}$ in the cytoplasm are high and the concentration of $MgATP^{2-}$ is low, then Na^+/K^+-exchanging ATPase will synthesize[353] $MgATP^{2-}$.

H^+-Transporting two-sector ATPase is an unrelated enzyme that normally, but also reversibly, catalyzes the synthesis of $MgATP^{2-}$ from $MgADP^-$ and $HOPO_3^{2-}$ by coupling that synthesis to the transport of cations.

H^+-Transporting two-sector ATPase[354]

$$MgADP^-_{neg} + HOPO_3{}^{2-}_{neg} + n\,H^+_{pos} + H^+_{neg} \rightleftharpoons n\,H^+_{neg} + MgATP^{2-}_{neg} + H_2O_{neg} \quad (6\text{–}132)$$

is responsible for most of the synthesis of $MgATP^{2-}$ in aerobic living organisms.* H^+-Transporting two-sector ATPase is embedded in and spans the inner membrane of a mitochondrion, the membrane of the thylakoid of a chloroplast, or the plasma membrane of a bacterium. The subscripts indicate that the hydrons are transported across the membrane of the organelle or cell during catalysis from the space on the side of the membrane that normally has a more positive electric potential into the space

*The hydron to the right on the first line of the equation is referred to as a "scalar" hydron. A scalar hydron is a hydron that is a reactant or product of the chemical transformation catalyzed by the enzyme, that appears on the side of the membrane where that transformation occurs, and that is not involved in the net transport of hydrons from one side of the membrane to the other.

that nomally has a more negative electric potential.* Depending on the species of the organism and the organelle in which the enzyme is located, the effective stoichiometry† of the hydrons transported, *n*, is between 8/3 and 15/3.[355] For example, the stoichiometry for mammalian mitochondria is 8/3 while that for cells of *E. coli* is 10/3. A related enzyme[356] from certain bacteria uses a gradient of Na^+ from the exterior to the interior of the bacterium to synthesize $MgATP^{2-}$. This ability is another example of Na^+ substituting for H^+, as is observed in the cation ATPases just discussed, but it does not mean that the H^+-transporting two-sector ATPases and the cation ATPases are in any way related to each other—far from it.

Under normal circumstances when there is a large **electrochemical gradient of hydrons** from the exterior intramembrane space of a mitochondrion to the matrix in its interior, from the exterior of a bacterial cell to the cytoplasm in its interior, or from the interior lumen of a thylakoid to the stroma on its exterior surface,†† H^+-transporting two-sector ATPase synthesizes $MgATP^{2-}$ from $MgADP^-$ and $HOPO_3^{2-}$, just as Na^+/K^+-exchanging ATPase will synthesize $MgATP^{2-}$ when there are large electrochemical gradients of Na^+ and K^+ across the membrane. If, however, the electrochemical gradient decreases sufficiently, H^+-transporting two-sector ATPase will then catalyze the net transport of hydrons in reverse from the interior to the exterior of a mitochondrion or bacterial cell or from the exterior to the interior of a thylakoid against the electrochemical gradient of hydrons at the expense of hydrolysis of $MgATP^{2-}$. Under these circumstances, the enzyme catalyzes the active transport of hydrons. In fact, there are related enzymes,[357] commonly referred to as V-type proton ATPases, the sole purpose of which is to transport hydrons actively across a membrane, in this instance from the cytoplasm of a eukaryotic cell into internal membrane-enclosed spaces such as lysosomes, endosomes, and the Golgi apparatus, to acidify their interior. Because the transport is from cytoplasm into the interior of these enclosed spaces, the V-type proton ATPases are presumably, as are chloroplasts, the descendants, by invagination, of an ancestral H^+-transporting two-sector ATPase in the plasma membrane of the bacterial cells that became the cells of eukaryotes rather than their mitochondria, which are the descendants of invasive bacteria. This origin places the active sites at which $MgATP^{2-}$ is hydrolyzed on the cytoplasmic surface of the respective organelles, which is where the $MgATP^{2-}$ is found.

As is the case with P-type Ca^{2+} transporter (Figure 6–34) and Na^+/K^+-exchanging ATPase, H^+-transporting two-sector ATPase is embedded in a membrane with most of its mass in the aqueous solution on one side of that membrane. In the case of H^+-transporting two-sector ATPase, however, the **majority of its mass is in the space that normally has the more negative electric potential**. As with P-type Ca^{2+} transporter and Na^+/K^+-exchanging ATPase, the **portion of the enzyme embedded in the bilayer of the membrane** is also constructed almost entirely of α helices that span or almost span that membrane. P-Type Ca^{2+} transporter, however, is composed of only one folded polypeptide while H^+-transporting two-sector ATPase is composed of many different subunits,[358] the exact number in most species still to be determined. In addition, several of these subunits are present in multiple copies. As a result, H^+-transporting two-sector ATPase is much larger than P-type Ca^{2+} transporter and Na^+/K^+-exchanging ATPase.

The major portion of the large structure located in the aqueous solution on the side of the membrane with a more negative electric potential can

*The terms cytoplasmic and extracytoplasmic or even interior or exterior are useless in this instance because the mitochondria and chloroplasts in which H^+-transporting two-sector ATPase is found are both the progeny of bacterial cells in which the enzyme is also found. The inner membrane of a mitochondrion is the plasma membrane of the ancestral bacterium so the ancient cytoplasmic space, now the matrix of the mitochondrion, is on the side of the inner membrane opposite the cytoplasm of the eukaryotic cell. A thylakoid is the progeny of an invagination in the plasma membrane of the ancestral bacterium that pinched off. Consequently, the interior of the thylakoid is the ancient extracytoplasmic space, and the ancient cytoplasmic space is on the same side of the membrane of the thylakoid as the cytoplasm of the eukaryotic cell in which it is found. The enzyme is unaware of its change of venue and is still transporting hydrons into bacterial cells, into the matrix of the mitochondion, and out of the interior of the thylakoid when $MgATP^{2-}$ is being synthesized. Consequently, positive (pos) and negative (neg) indicate the spaces that have, under normal cytoplasmic circumstances, positive and negative electric potential relative to each other.

†The stoichiometries noted are those for H^+-transporting two-sector ATPase when it is operating at its highest efficiency. Because there is not a direct chemical connection between the current of hydrons and the synthesis of $MgATP^{2-}$, the actual stochiometry is probably less than the ideal, depending on the circumstances.

††There is a "large electrochemical gradient of hydrons" from the exterior to the interior when the pH is sufficiently lower ($\Delta pH = 0.5–1.5$) in the solution on the positive, acidic side of the membrane than in the solution on the negative, basic side, and the electric potential is sufficiently more positive ($\triangle V = -50$ to -220 mV) in the solution on the positive, acidic side than in the solution on the negative, basic side.[355]

be dissociated from the rest of H⁺-transporting two-sector ATPase and purified.[359] For historical reasons,* this soluble sector of H⁺-transporting two-sector ATPase is called F_1-ATPase, and the portion that is left behind within the membrane is called the F_o sector. Together these comprise the two sectors of H⁺-transporting *two-sector* ATPase. The sector that is **F_1-ATPase contains the active sites** at which $MgATP^{2-}$ is either synthesized from or hydrolyzed to $MgADP^-$ and $HOPO_3^{2-}$. When it is detached from the F_o sector of the intact enzyme, F_1-ATPase is no longer coupled to the electrochemical gradient because it is no longer attached to the F_o sector, which is the portion of the enzyme that spans the membrane and transports hydrons across it. For H⁺-transporting two-sector ATPase to synthesize $MgATP^{2-}$, the reversible hydrolysis of $MgATP^{2-}$, which is catalyzed by the active sites on F_1-ATPase, must be coupled to the movement of hydrons down the usual electrochemical gradient, and this transport of hydrons takes place through the F_o sector. Consequently, F_1-ATPase on its own can only hydrolyze $MgATP^{2-}$, which it does quite efficiently. It follows that, under normal circumstances when they are associated with each other, the coupling between the two sectors must, necessarily, be tight.

Five different folded polypeptides comprise F_1-ATPase from bovine mitochondria.[360,361] These five folded polypeptides, of lengths 510 amino acids (α), 480 amino acids (β), 273 amino acids (γ), 146 amino acids (δ), and 50 amino acids (ε), are present in the stoichiometry $\alpha_3\beta_3\gamma\delta\varepsilon$. In the crystallographic molecular model of bovine F_1-ATPase (Figure 6–42),[362-366] the three α subunits and the three β subunits, the sequences of which are homologous to each other (23% identity; 3.2 gap percent) and the tertiary structures of which are superposable,[363] form a ring with a **sixfold rotational axis of pseudosymmetry**. Because the α and β subunits alternate around the ring (Figure 6–42), it is a heterohexamer composed of three $\alpha\beta$ dimers, and all six subunits are assembled head-to-tail.[363,364] The γ subunit, in addition to folding into a small globular domain (150 aa) below this $(\alpha\beta)_3$ ring, also forms a shaft,† composed of a long (48 aa) continuous α helix from its amino terminus and a long (73 aa) continuous α helix from its carboxy terminus. These two α helices twist around each other in half a turn of a coiled coil (Figure 6–43B).[364] The folded δ and ε polypeptides are two small globular subunits (not shown in Figures 6–42 and 6–43) attached to the protruding globular base of the γ subunit on the surface of that globular domain opposite the location of the $(\alpha\beta)_3$ heterohexameric ring. These small subunits are not involved directly in the synthesis of $MgATP^{2-}$, but they function to connect and couple, in part, the γ subunit of the F_1-ATPase to the F_o sector.

In intact F_1-ATPase from every species examined, **the three $\alpha\beta$ dimers assume different conformations**, so the central axis is a threefold rotational axis of pseudosymmetry[363] rather than, as in most trimeric proteins, a threefold rotational axis of symmetry. The $(\alpha\beta)_3$ heterohexameric ring from *Bacillus* sp. PS3 (α subunit, 59% identity; 0.4 gap percent and β subunit, 76% identity; 0.8 gap percent relative to the respective bovine subunits), in the absence of any other subunits of its F_1-ATPase, has been crystallized, and there is a crystallographic threefold rotational axis of symmetry relating the three $\alpha\beta$ heterodimers.[367] From this observation it follows that the $(\alpha\beta)_3$ heterohexameric ring from *Bacillus* sp. PS3 on its own has an exact threefold rotational axis of symmetry, as would be expected, and the conformations of its $\alpha\beta$ subunits must be identical. In the crystallographic molecular model of the intact $(\alpha\beta)_3\gamma\delta\varepsilon$ complex from *Bacillus* sp. PS3, however, the three $\alpha\beta$ heterodimers around the ring adopt the three different conformations observed in the bovine $(\alpha\beta)_3\gamma\delta\varepsilon$ complex.[368] Consequently, the asymmetry in the $(\alpha\beta)_3\gamma\delta\varepsilon$ complex of F_1-ATPase from *Bacillus* sp. PS3, and presumably in all the other F_1-ATPases, is induced by the dramatic asymmetry of the γ subunit (Figure 6–43) upon which the $(\alpha\beta)_3$ heterohexameric ring is snugly impaled. The asymmetry among the three $\alpha\beta$ heterodimers in the intact enzyme is crucial to the ability of H⁺-transporting two-sector ATPase to synthesize $MgATP^{2-}$.

As might be expected, the **active sites at which $MgATP^{2-}$ is synthesized** or hydrolyzed are located in the $(\alpha\beta)_3$ heterohexamer of F_1-ATPase. There are six sites at which either $MgATP^{2-}$ or $MgADP^-$ and $HOPO_3^{2-}$ can be bound simultaneously in the heterohexamer,[365,369] and these six sites are related by the sixfold rotational axis of pseudosymmetry, rotation around which superposes the six homologous subunits, three α subunits and three β subunits. The six sites are located within the six interfaces between α and β subunits (Figure 6–42A,B), one in each interface, and side chains from both the α and β subunits comprising a given interface form each binding site.

Figure 6–42: Space-filling drawings and stereodrawings[485] of a crystallographic molecular model of the $(\alpha\beta)_3\gamma$ portion of bovine F_1-ATPase.[365] Mitochondria were isolated by differential centrifugation from a homogenate of bovine heart, and these mitochondria were then sonicated to produce submitochondrial particles. During this procedure, the majority of the intramitochondrial soluble proteins were released into solution and could be removed by pelleting the submitochondrial particles. The washed submitochondrial particles in aqueous buffer were shaken with 0.5 volume of chloroform, the emulsion was broken, and the yellowish, clear aqueous phase was concentrated. The concentrate was then submitted to chromatography by molecular exclusion, and the fractions containing F_1-ATPase were concentrated and passed over a solid phase to which Cibacron Blue F3GA was covalently attached. The adsorbant removed the remaining impurities to produce a solution of purified F_1-ATPase, which was precipitated with ammonium sulfate.[362] The enzyme was redissolved and crystallized with poly(ethylene glycol) 6000 as a precipitant in 0.2 M NaCl, 3 mM sodium azide, 20 mM $MgSO_4$, 0.25 mM $MgAMPPNP^{2-}$, 5 μM $MgADP^{-}$, and 50 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol at pH 8.2. Reflections from crystals were collected to Bragg spacing of 0.19 nm. The portion of the resulting refined crystallographic molecular model containing the complete polypeptides of the three α subunits, the three β subunits, and the γ subunit is presented to the left in space-filling models (γ subunit in black, α subunits in gray, and β subunits in white) and to the right as stereo line drawings of only the polypeptide backbones (γ subunit in thick lines, α subunits in lines of intermediate thickness, and β subunits in thin lines) in the same orientation as the space-filling models. The four molecules of $MgAMPPNP^{2-}$, the single molecule of $MgADP^{-}$, and the single molecule of $HOPO_3^{2-}$, which are associated one in each of the six occupied sites in the $(\alpha\beta)_3$ ring in the crystallographic molecular model, are drawn in ball-and-stick format. Again, black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large dark gray atoms are atoms of phosphorus. (**A**) Side-on views with the γ subunit protruding from the top. (**B**) View from the surface of the enzyme from which the γ subunit protrudes. This orientation defines clockwise (negative rotation) and counterclockwise (positive rotation). (**C**) Stereo line drawing of the polypeptide backbones of the γ subunit and only the three catalytic β subunits with their active sites occupied. The site labeled MgATP, normally occupied by $MgATP^{2-}$, is occupied here by the analogue $MgAMPPNP^{2-}$. The site labeled MgADP, normally occupied by $MgADP^{-}$ and $HOPO_3^{2-}$ in equilibrium with $MgATP^{2-}$ and a molecule of water, is occupied here by $MgADP^{-}$ and azide ion in place of $HOPO_3^{2-}$. The site labeled $HOPO_3^{2-}$, normally occupied by various substrates associating and dissociating, is occupied here by $HOPO_3^{2-}$.

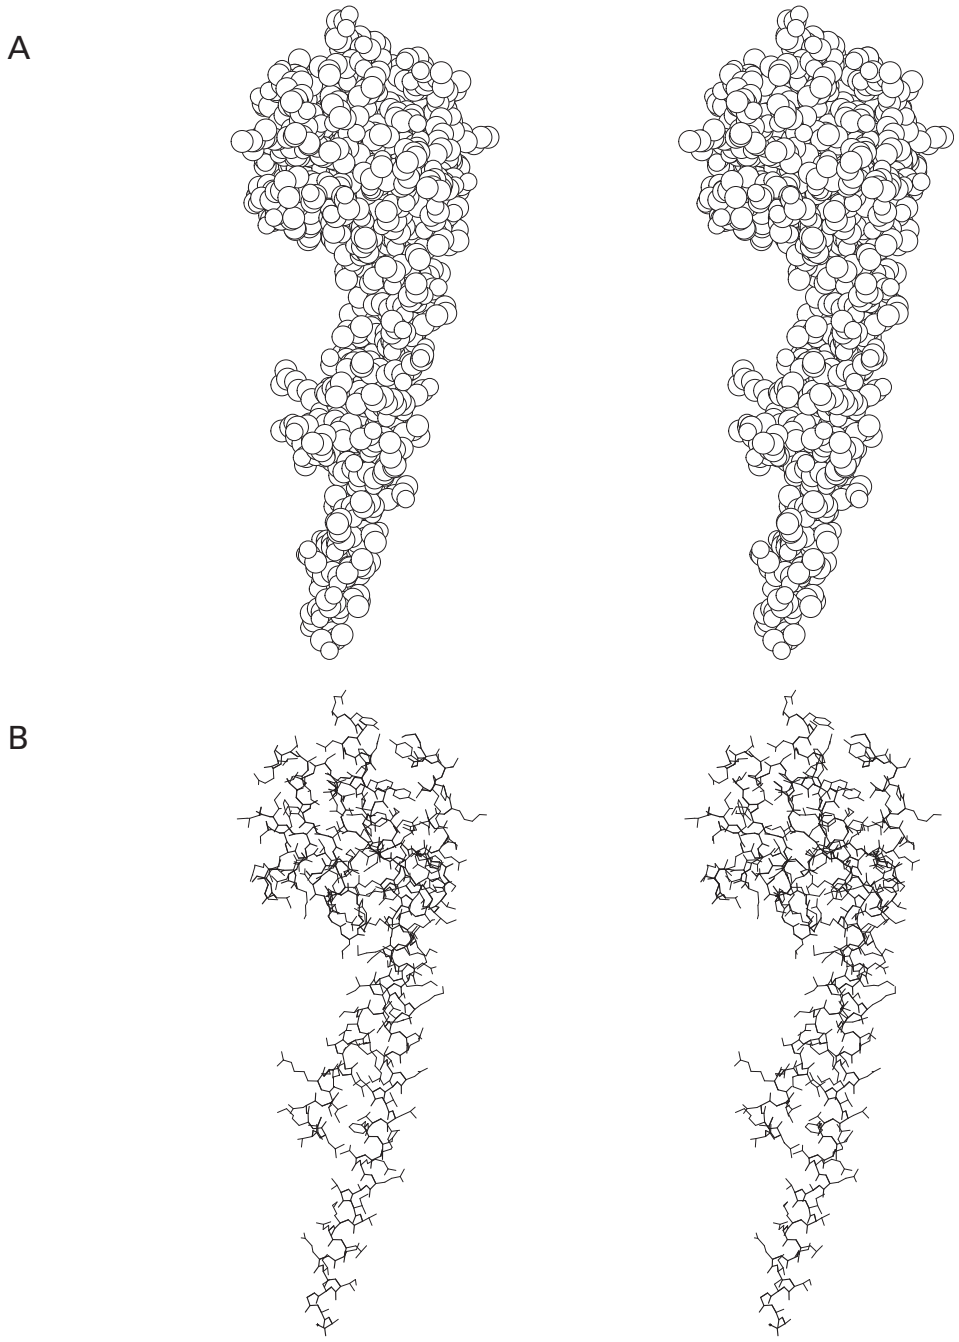

Figure 6–43: Stereodrawings[485] of a crystallographic molecular model of the γsubunit of bovine F_1-ATPase. The γsubunit is from the same crystallographic molecular model as that of Figure 6–42. (**A**) Stereo space-filling drawing of the complete γsubunit. (**B**) Stereo line drawing of all amino acids and their side chains in the complete γsubunit .

Figure 6–44: Stereodrawings[485] of crystallographic molecular models of the two active sites of bovine F_1-ATPase that are occupied by nucleotides. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, large light gray atoms are sulfurs, and large dark gray atoms are atoms of phosphorus. The segments of polypeptide drawn are identified by naming and numbering the amino acids at their amino-terminal and carboxy-terminal ends. The majority of the segments are from the β subunit, and the numbers of their amino acids are unadorned. The two segments from the α subunit are designated by adding an α to the end of each number. (**A**) Active site on the β subunit in the same crystallographic molecular model as that of Figure 6–42 occupied by $MgADP^-$ (black bonds) and N_3^- ion and in the D conformation.[365] A molecule of water on Mg^{2+}, the N_3^- ion, and a second molecule of water, however, have been replaced by a drawing of $HOPO_3^{2-}$ (black bonds). This drawing is positioned in the active site so that its phosphorus is 0.31 nm from the oxygen of the $MgADP^-$ that is to become the bridging oxygen in $MgATP^{2-}$, a distance that is slightly within the sum of the van der Waals radii (0.33 nm). This position of its phosphorus places its apical oxygen in the same location as the molecule of water that is forming hydrogen bonds with Arginine β264 and Glutamate β192 and the amido oxygen of Serine α344 in the unaltered crystallographic molecular model. One of the equatorial oxygens of $HOPO_3^{2-}$ is oriented toward the Mg^{2+} in as close an approach as possible, which leaves the two other equatorial oxygens occupying positions close the two peripheral negatively charged nitrogens of N_3^-, each with a formal charge number of –0.5. This drawing represents the D conformation occupied by the two substrates $MgADP^-$ and $HOPO_3^{2-}$. (**B**) Active site of Panel A occupied instead by a molecule of $MgAMPPNP^{2-}$ (black bonds) in a different crystallographic molecular model[366] of bovine F_1-ATPase. For this molecular model, the enzyme was crystallized with poly(ethylene glycol) 6000 as a precipitant in 0.2 M NaCl, 20 mM $MgSO_4$, 0.25 mM $MgAMPPNP^{2-}$, 5 μM $MgADP^-$, and 50 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol at pH 8.2. In the absence of N_3^-, this active site is occupied by $MgAMPPNP^{2-}$. Consequently, this molecular model represents the active site in the D conformation occupied by the substrates $MgATP^{2-}$ and H_2O. The molecule of H_2O that is the other substrate forms hydrogen bonds with Arginine β264 and Glutamate β192 and the amido oxygen of Serine α344; and it is in the same location as the molecule of water that was replaced by the apical oxygen of $HOPO_3^{2-}$ to draw the active site in Panel A. (**C**) Active site on the β subunit in the same crystallographic molecular model as that of Figure 6–42, occupied by $MgAMPPNP^{2-}$ (black bonds) and consequently in the T conformation. Arrows between the three panels indicate that the active site in the D conformation is the catalytic site in which the substrates $MgADP^-$ and $HOPO_3^{2-}$ and $MgATP^{2-}$ and H_2O come to equilibrium and that, at an instant in which it is occupied by $MgATP^{2-}$ and H_2O, its conformation is changed to the T conformation by rotation of the γ subunit.

Each site for binding adenine nucleotides, however, is formed mainly (85%) by side chains from only one subunit. Consequently, there are three sites formed mainly by side chains from an α subunit, and there are three sites formed mainly by side chains from a β subunit.

The three sites for the binding of adenine nucleotides formed mainly from each of the three β subunits and pseudosymmetrically arranged in the asymmetric $(\alpha\beta)_3$ heterohexamer (Figure 6–42C) are the active sites at which $MgATP^{2-}$ is synthesized and hydrolyzed.[366] This conclusion follows in part from **covalent labeling of the active sites**. A large number of reagents, both nonspecific electrophiles[370-372] and photoactive reagents[373,374] and electrophilic[375-381] and photolytically reactive[382] derivatives of adenine nucleotides, inactivate the enzymatic hydrolysis of $MgATP^{2-}$ by modifying the side chains of amino acids in a β subunit of F_1-ATPase.

Magnesium 2-azidoATP^{2-}, upon photolysis, covalently modifies Tyrosine β349 of bovine F_1-ATPase[383] and this single modification inactivates the enzyme.[384] The same tyrosine in bovine F_1-ATPase or its homologue in the F_1-ATPase from thermophilic *Bacillus* sp. PS3 is also modified by the nonspecific electrophilic reagent 7-chloro-4-nitrobenzofuran, and this exclusive modification also inactivates the enzymatic activity.[385-389] 5′-[4-Fluorosulfonylbenzoyl]inosine, an electrophilic derivative of a purine nucleoside, also inactivates the enzyme by modifying this same tyrosine in bovine F_1-ATPase.[390] Upon photolysis of 3′-*O*-(4-benzoyl)benzoyladenosine 5′-diphosphate bound in the active site of bovine F_1-ATPase, a triplet state of the carbonyl of benzophenone is formed that abstracts a hydrogen from a nearby amino acid, and the resulting radical on the benzophenone then colligates with the resulting radical on that amino acid to insert into the protein. The amino acid modified is in a tryptic nonadecapeptide containing Tyrosine β349.[382] Tyrosine β349 is in the site that was subsequently identified crystallographically (Figure 6–44)[363,365,366] as the active site of the enzyme. Its phenyl ring lies flat against the adenine of $MgATP^{2-}$ or ADP^{3-}.

Dicyclohexylcarbodiimide modifies exclusively a glutamate in F_1-ATPase from *E. coli* that is homologous to Glutamate β192 of bovine F_1-ATPase,[391,392] and this modification inactivates the ATPase activity of the enzyme.[393] Glutamate β192 is the sole catalytic acid–base in the active site (Figure 6–44).

In at least one instance, however, a reagent, in this case 2-oxo-2-phenylacetaldehyde, modifies an amino acid, the arginine in F_1-ATPase from chloroplasts of *Spinacia oleracea* that is in the homologous position of Arginine β299 in bovine F_1-ATPase. The modification inactivates the enzyme even though

this amino acid is distant (2.4 nm) from the nearest atom in $MgATP^{2-}$ when it is bound in the active site.[372]

In each instance cited above, with the informative exception of the case of Arginine β299, the **modification of only one amino acid side chain in one β subunit** in the $(\alpha\beta)_3\gamma\delta\varepsilon$ complex that is F_1-ATPase is sufficient to completely inactivate the ATPase activity.* The conclusion that has been drawn from these results is that the three active sites on the enzyme do not act independently of each other during hydrolysis of $MgATP^{2-}$ and, by microscopic reversibility, during synthesis of $MgATP^{2-}$. A number of other observations also suggest that the three active sites are required to act together in concert to hydrolyze a molecule of $MgATP^{2-}$.[394]

There are kinetic measurements and isotopic exchanges that suggest a mechanism for hydrolysis of $MgATP^{2-}$ and, in reverse, for the synthesis of $MgATP^{2-}$. When hydrolysis of $MgATP^{2-}$ by bovine F_1-ATPase is monitored under **conditions in which catalysis can occur at only one active site** on each $(\alpha\beta)_3$ heterohexamer, the reaction is dramatically different from the situation in which all three sites are hydrolyzing $MgATP^{2-}$ together.[395] When 1 μM bovine F_1-ATPase is mixed with 0.3 μM $MgATP^{2-}$ so that only one site in each $(\alpha\beta)_3$ heterohexamer can be occupied, hydrolysis of $MgATP^{2-}$ and release of $MgADP^-$, and $HOPO_3^{2-}$ into solution is extremely slow (5 h^{-1}).[396]

The reason for this slow rate is not that hydrolysis of $MgATP^{2-}$ on the active site is slow. In fact, on an active site of the enzyme in this situation, the equilibrium

$$ECOO^-\cdot MgATP^{2-}\cdot H_2O \rightleftharpoons ECOOH\cdot MgADP^-\cdot HOPO_3^{2-} \quad (6\text{–}133)$$

with an equilibrium constant of 0.5, is established rapidly. The magnitude of this **equilibrium constant for the reaction on this single active site** is another example of the ability of an active site to dramatically change the equilibrium constant observed for reactants and products in solution. Steady-state and stopped-flow kinetic measurements are consistent with this equilibrium being established even when F_1-ATPase from *E. coli* is continuously hydrolyzing $MgATP^{2-}$ in its normal steady state.[397]

Reactants and products in this equilibrium interconvert on an active site with rate constants* k_2 and k_{-2} of 12 and 24 s^{-1}, respectively.[396] Rather, as in the case of myosin ATPase, it is the **release of products that is rate-limiting** when only one site on the $(\alpha\beta)_3$ heterohexamer is catalyzing the hydrolysis. Both ADP^{3-} and $HOPO_3^{2-}$ are released into solution at the same slow rate (14 h^{-1}).[398] If, however, excess $MgATP^{2-}$ is added before the products have dissociated, the rate of dissociation of ADP^{3-} and $HOPO_3^{2-}$ increases more than 100,000-fold to a rate equal to the rate of hydrolysis of $MgATP^{2-}$ at the higher concentrations of reactant.[398-401] Consequently, association of $MgATP^{2-}$ with another of the active sites on the $(\alpha\beta)_3$ heterohexamer accelerates the dissociation of products from the active site in which they were in equilibrium with reactant.

The equilibrium between $MgATP^{2-}$ and $MgADP^-$ and $HOPO_3^{2-}$ on an active site in F_1-ATPase can also be established from the other direction. When $MgADP^-$ and $H_2PO_4^-$ are added to F_1-ATPase from chloroplasts of *S. oleracea*, the enzyme forms, on one of its active sites, 0.25 mol of $MgATP^{2-}$ for every mole of $(\alpha\beta)_3\gamma\delta\varepsilon$ F_1-ATPase.[402]

The fact that both ADP^{3-} and $HOPO_3^{2-}$ are released from the active site of bovine F_1-ATPase with the same rate constant in the absence of excess $MgATP^{2-}$ suggests that a slow rate-limiting conformational change opens the active site to the solution. Once the active site has opened, both products dissociate so rapidly that the observed rates of their dissociations are simply equal to the rate of the conformational change opening the site. If so, then association of $MgATP^{2-}$ at another site, presumably another of the three active sites, dramatically accelerates this conformational change.

The rate at which $MgATP^{2-}$ associates with this second site (6×10^6 M^{-1} s^{-1}) to enhance the rate of dissociation of products from the first active site is equal to the rate at which $MgATP^{2-}$ associates with a single active site in the unoccupied $(\alpha\beta)_3$ heterohexamer.[396,401] This equality suggests that the site to

*The truncated version of F_1-ATPase from *Bacillus* sp. PS3, which contains only α and β subunits in the stoichiometry $(\alpha\beta)_3$ and which hydrolyzes $MgATP^{2-}$, is completely inactivated by incorporation of the reagent 7-chloro-4-nitrobenzofuran into only one-third of the β subunits. This observation suggested that the $(\alpha\beta)_3$ ring in the absence of the γ subunit is asymmetric.[389] As has already been noted, however, this $(\alpha\beta)_3$ subcomplex of F_1-ATPase, in the absence of nucleotides, crystallizes in the space group $P2_13$ with an $\alpha\beta$ dimer in the asymmetric unit, a fact requiring that the $(\alpha\beta)_3$ heterohexamer in this particular crystal be threefold rotationally symmetric.[367]

*Note that, in the active site of the enzyme while it is hydrolyzing $MgATP^{2-}$, the synthesis of $MgATP^{2-}$ is nevertheless 2 times faster than its hydrolysis.

which the $MgATP^{2-}$ binds to accelerate the release of products has the same conformation as the active site to which it binds when the enzyme is completely unoccupied and that this site to which it binds is another of the three active sites. **Association of $MgATP^{2-}$ with a site in this conformation produces the conformational change** at the site at which $MgATP^{2-}$ and $MgADP^{-}$ and $HOPO_3^{2-}$ are in equilibrium, opening that active site to the solution and releasing ADP^{3-} and $HOPO_3^{2-}$ when $MgATP^{2-}$ is being hydrolyzed.

These kinetic measurements of the reaction catalyzed by F_1-ATPase clarify previous **observations of intermediate isotopic exchange**.[394] In fact, it was these earlier observations of isotopic exchange that inspired the kinetic observations just described. When $Mg[\gamma\text{-}^{18}O_3P]ATP^{2-}$ is hydrolyzed in $H_2{}^{16}O$ or $Mg[\gamma\text{-}^{16}O_3P]ATP^{2-}$ is hydrolyzed in $H_2{}^{18}O$ by bovine F_1-ATPase, as the concentration of $MgATP^{2-}$ in solution is lowered systematically, the number of oxygens from water incorporated by intermediate isotopic exchange into the $H_2PO_4^{-}$ that is the product of the enzymatic reaction increases from the stoichiometric value of 1 to greater than 3.[399,403] The explanation for these observations of intermediate isotopic exchange is that association of $MgATP^{2-}$ with one of the three catalytic sites on the $(\alpha\beta)_3\gamma\delta\varepsilon$ oligomer accelerates the release of the products of hydrolysis of $MgATP^{2-}$ at one of the other sites, as was documented in the later kinetic experiments. If this is so, then the lower the concentration of $MgATP^{2-}$, the longer the reactants and products of the reaction (Equation 6–133) between $MgATP^{2-}$ and H_2O and $MgADP^{-}$ and $HOPO_3^{2-}$ will sit at equilibrium. As the reaction sits at equilibrium, the nucleotides and $HOPO_3^{2-}$ are constantly exchanging oxygens with molecules of water. If molecules of water can enter and leave the active site but $MgATP^{2-}$, $MgADP^{-}$, and $HOPO_3^{2-}$ cannot or if there are several molecules of water locked in the active site that can participate in the isotopic exchange, then the longer reactant and product remain locked in the active site, the more exchange will be observed. From the observed rates for incorporation of oxygen from water during this intermediate isotopic exchange, it could be calculated[404] that, on the active site, the rate of the back reaction for synthesis of $MgATP^{2-}$ from $MgADP^{-}$ and $HOPO_3^{2-}$ is 60 s^{-1}, which is indistinguishable, within the margin of error, from the 24 s^{-1} measured in the experiments that were described earlier.[396]

When intact H^+-transporting two-sector ATPase embedded in its membrane is hydrolyzing $MgATP^{2-}$ in the absence of an electrochemical gradient of hydrons, it also catalyzes the intermediate isotopic exchange of $H_2{}^{18}O$ into the $H^{16}OP^{16}O_3^{2-}$ that is its product.[405-407] In reverse, when the enzyme is synthesizing $MgATP^{2-}$ from $MgADP^{-}$ and $HOPO_3^{2-}$ in the presence of a sufficient electrochemical gradient of hydrons, incorporation of oxygen-16 from $H_2{}^{16}O$ into the $Mg[\gamma\text{-}^{18}O_3P]ATP^{2-}$ formed from $H^{18}OP^{18}O_3^{2-}$ as a result of intermediate isotopic exchange is observed. This intermediate exchange during the synthesis of $MgATP^{2-}$ is accelerated when the concentration of $MgADP^{-}$ in solution is decreased by adding pyruvate kinase and phospho*enol*pyruvate[408] or by simply decreasing the initial concentration of $MgADP^{-}$.[409] Decreasing the concentration of $HOPO_3^{2-}$ also leads to an increase in this intermediate isotopic exchange.[409] The same results were observed with H^+-transporting two-sector ATPase from *S. oleracea*.[410] These observations can be explained by assuming that, in order for newly synthesized $MgATP^{2-}$ to be released into solution from the active site in which it is in equilibrium with $MgADP^{-}$ and $HOPO_3^{2-}$, both $MgADP^{-}$ and $HOPO_3^{2-}$ must occupy one of the two other active sites in the $(\alpha\beta)_3$ heterohexamer. The longer it takes for the other active site be occupied, the longer the $MgADP^{-}$ and $HOPO_3^{2-}$ and the $MgATP^{2-}$ and the molecule of water remain at equilibrium in the catalytic active site and the more intermediate isotopic exchange occurs.

All the results presented so far suggest that at least two of the three active sites on the $(\alpha\beta)_3$ heterohexamer in a molecule of F_1-ATPase must cooperate during hydrolysis of $MgATP^{2-}$. The fact, however, that a hybrid $(\alpha\beta)_2\alpha\beta'\gamma\delta\varepsilon$ oligomer of F_1-ATPase with one mutant, inactive β subunit (β') and two unmutated β subunits, one with a presumably normal active site and the other with a presumably normal site for binding of $MgATP^{2-}$, is unable to catalyze hydrolysis of $MgATP^{2-}$ at normal rates implies that **all three of the active sites on the β subunits must cooperate** under normal circumstances.[411]

An explanation for all these observations of kinetics and intermediate isotopic exchange has been provided.[408,412] It has been updated (Figure 6–45) by consideration of the crystallographic molecular models of the three active sites (Figure 6–44) and of the conformations of the three $\alpha\beta$ heterodimers (Figure 6–46).[363,365]

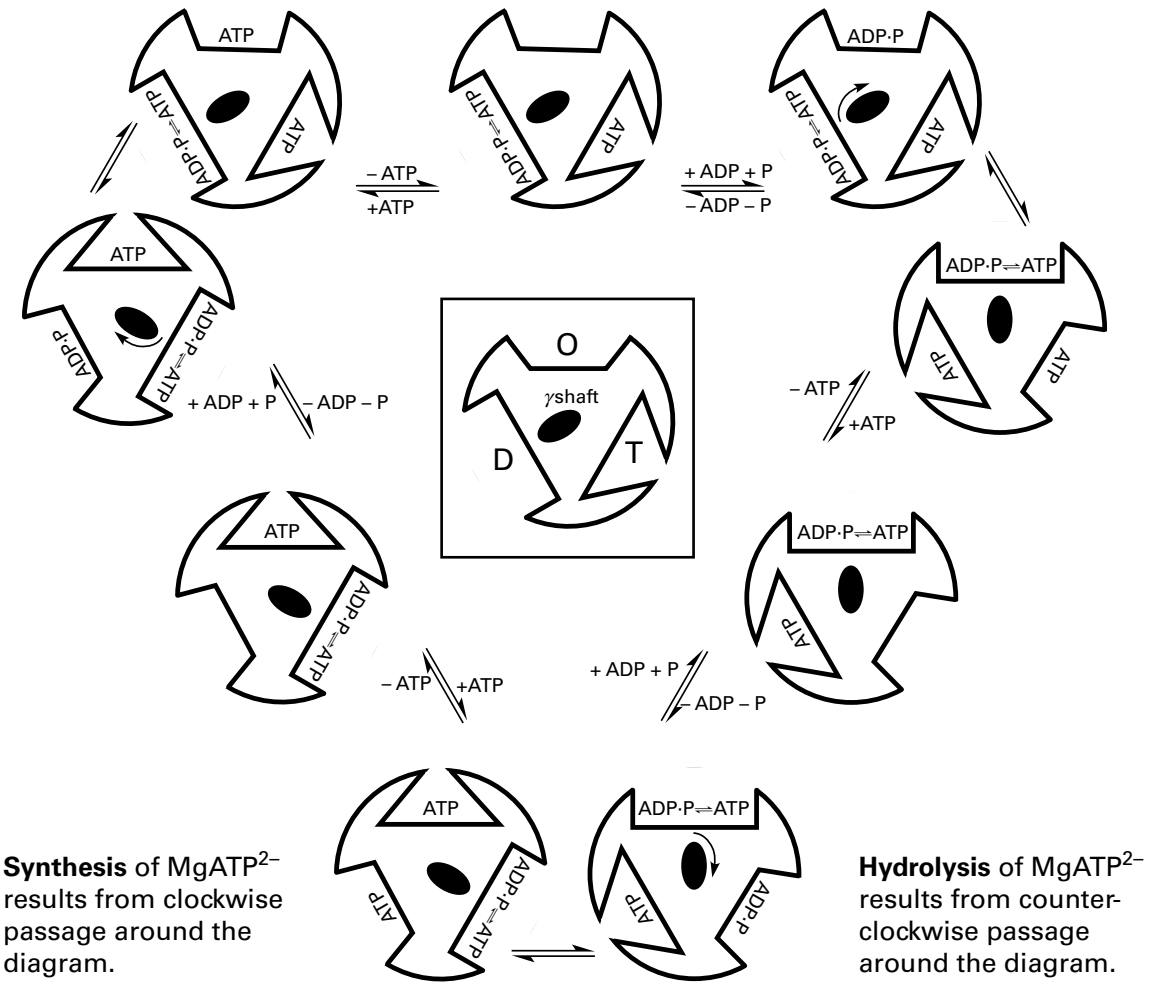

Figure 6–45: Diagrams[408,412] of a proposal for the quaternary conformational changes through which F_1-ATPase passes during the consecutive synthesis of three molecules of MgATP^{2-} from three molecules of MgADP^{-} and $HOPO_3^{2-}$. The diagramatic representations for each of the three conformations of the $\alpha\beta$ heterodimer are defined within the box in the center. The original proposal for the conformational mechanism has been updated by considering the results of the foregoing crystallographic molecular models and the conclusion that the active site in which catalysis occurs is the active site in the D conformation,[366,414] which is represented in the diagrams by the equilibria. The three conformations that each active site adopts—O, D and T—are identified in the central drawing. The reactions along each side of the equilateral triangle are dissociation of MgATP^{2-} and association of MgADP^{-} and $HOPO_3^{2-}$. The steps at the three vertices are the quaternary conformational changes produced by clockwise rotation in steps of –120° of the γ subunit, represented by the black ellipse.

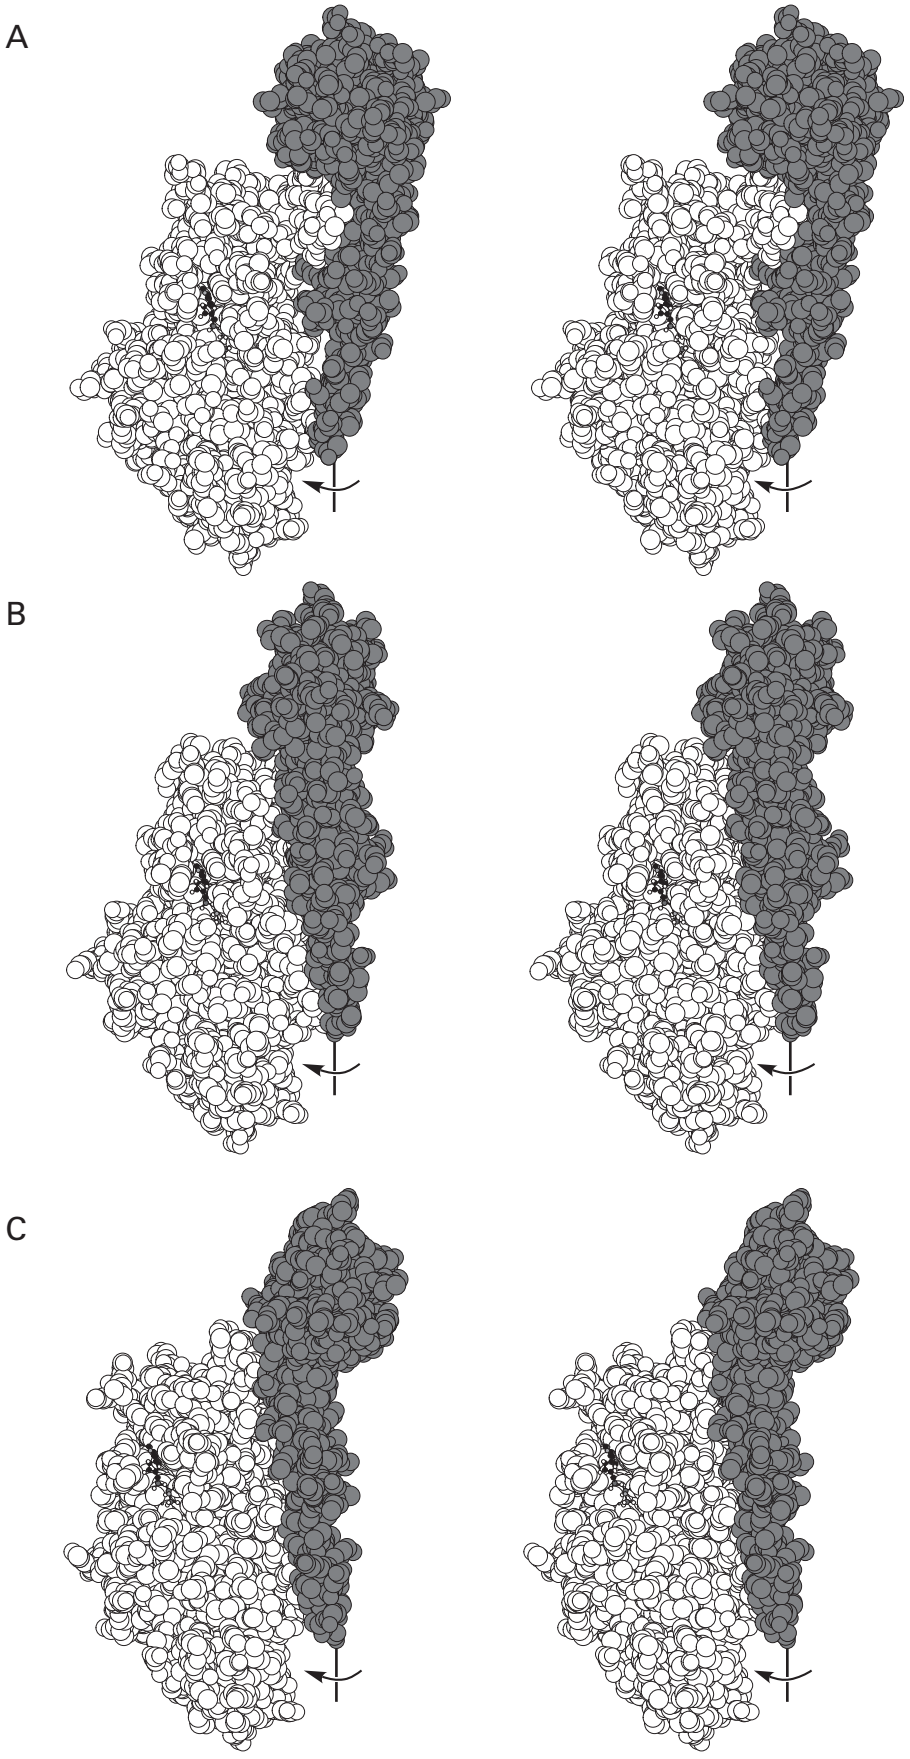
Figure 6–46: Stereodrawings[485] of changes in the conformation of the β subunit of F_1-ATPase promoted by rotation of the γ subunit. Protein is presented in space-filling stereodrawings, and the ligands in each panel are portrayed in ball-and-stick format in which black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large dark gray atoms are atoms of phosphorus. Drawings of the three β subunits in the crystallographic molecular model of Figure 6–42 are each presented in the same orientation, with the γ subunit in its orientation relative to that particular β subunit. In this way, the drawings reproduce the consecutive changes in one of the β subunits expected upon two consecutive –120° rotations of the γ subunit. The rotation of the γ subunit depicted is clockwise (arrow), the direction in which MgATP^{2-} is synthesized. (**A**) The β subunit in the D conformation. Here the active site is occupied by the MgADP^{-} in the crystallographic molecular model, and a drawing of $HOPO_3^{2-}$, which is not present in the crystallographic molecular model, has been added. This drawing represents the active site in which substrates are in catalytic equilibrium. (**B**) The β subunit in the T conformation. Here the active site is occupied by the MgAMPPNP^{2-} in the crystallographic molecular model. This drawing represents the active site in which the eventual product, MgATP^{2-}, is protected from hydrolysis. (**C**) The β subunit in the O conformation. This drawing represents the active site that has been thrown open. A molecule of MgATP^{2-}, which is not present in the crystallographic molecular model, has been placed in its approximate location in the T conformation to illustrate the opening of the active site that precedes dissociation of product. Notice how the two segments of polypeptide above the substrates that clasp them in the D and T conformations have spread apart to open the active site to the solution.



A
B
C

At any instant, the three $\alpha\beta$ heterodimers in the entire $(\alpha\beta)_3\gamma\delta\varepsilon$ complex, each of which contains one of the three active sites, are in **three different conformations.** In the O conformation, **the active site in the $\alpha\beta$ heterodimer is open to the solution**, and the substrates $MgADP^-$ and $HOPO_3^{2-}$ or the substrates $MgATP^{2-}$ and a molecule of water can associate with or dissociate from this conformation. In the D conformation, in which in a given instant the **active site in the $\alpha\beta$ heterodimer is closed around the substrates**, $MgADP^-$ and $HOPO_3^{2-}$ or $MgATP^{2-}$ and a molecule of water, these four substrates are in rapid equilibrium with each other (Equation 6–133), which by chance or design seems to favor $MgATP^{2-}$ slightly. In the T conformation, the active site is closed around $MgATP^{2-}$ but the $MgATP^{2-}$ and the molecule of water are no longer in equilibrium with $MgADP^-$ and $HOPO_3^{2-}$. The D conformation contains the only active site that is catalytically active. In the T conformation, catalysis of the equilibrium has been suspended, and instead the **active site in the $\alpha\beta$ heterodimer protects the molecule of $MgATP^{2-}$** that occupies it from adventitious hydrolysis.

This explanation is consistent with and **explains the available crystallographic molecular models.** In crystallographic molecular models of bovine F_1-ATPase (Figure 6–42), these three different conformations are easily distinguished and have been identified by the ligands that occupy their active sites.[363] The enzyme has been crystallized from a solution containing $MgADP^-$; magnesium 5′-adenylic imidodiphosphonic anhydride ($MgAMPPNP^{2-}$), a stable analogue of $MgATP^{2-}$; and azide (N_3^-), an analogue of $HOPO_3^{2-}$. In these crystals, the active site in the T conformation of the $\alpha\beta$ heterodimer is occupied by a molecule of $MgAMPPNP^{2-}$, and the active site in the D conformation of the $\alpha\beta$ heterodimer is occupied by $MgADP^-$ and azide.[365] The latter fact indicates that the D conformation of the active site has a preference for $MgADP^-$ and N_3^- over the $MgAMPPNP^{2-}$ that is also in solution because the concentration of $MgAMPPNP^{2-}$ is 50 times higher than that of $MgADP^-$. The active site in the O conformation of the $\alpha\beta$ heterodimer in this crystallographic molecular model is occupied by one $HOPO_3^{2-}$, and it is significantly distorted relative to the other two active sites into a conformation open to the solution. In two other crystallographic molecular models of F_1-ATPase, from *R. norvegicus*[369] and from *Bos taurus*,[413] both crystallized in the absence of Mg^{2+}, the O site is occupied by ADP^{3-} and has partially closed around it. When the $(\alpha\beta)_3$ ring in the molecular model of the bovine enzyme is viewed from the surface from which the γ subunit protrudes (Figure 6–42C), the conformations in counterclockwise* order are O, D, and T.

The **catalytic active site** in which $MgATP^{2-}$ and a molecule of water and $MgADP^-$ and $HOPO_3^{2-}$ are in equilibrium with each other during the normal catalysis performed by F_1-ATPase (Equation 6–133) has been identified as the active site in the D conformation (Figure 6–44A,B).[366,414] In a crystallographic molecular model[366] in which the active site in the D conformation is occupied by $MgAMPPNP^{2-}$ (Figure 6–44B), the molecule of water that is the reactant in hydrolysis of $MgATP^{2-}$ is compressed against the γ-phosphorus of $MgAMPPNP^{2-}$. The distance between the oxygen of this molecule of water and the γ-phosphorus (0.31 nm) is less than the sum of their van der Waals radii (0.335 nm), and the distance between this oxygen and one oxygen on the γ-phosphorus (0.28 nm) is also within the sum of the van der Waals radii (0.30 nm). The distance (0.48 nm) between the oxygen of this molecule of water and an oxygen on the β-phosphorus of $MgADP^-$ in the active site in the D conformation occupied by $MgADP^-$ and N_3^- (Figure 6–44A), when it is not compressed against a phosphorus atom, is the same (±0.004 nm) as that between this oxygen and the bridging nitrogen in $MgAMPPNP^{2-}$ when it is occupying the active site in the D conformation and it is compressed against the γ-phosphorus. From these indistinguishable distances, it follows that this molecule of water is rigidly held in this exact location regardless of the occupants of the active site. The α-phospho and β-phospho groups of either $MgADP^-$ or $MgATP^{2-}$ are also rigidly held. In fact, there are six donors for hydrogen bonds in addition to the Mg^{2+} anchoring firmly just the β-phospho group, the phospho group containing the oxygen that is the nucleophile in the nucleophilic substitution at the phosphorus in $HOPO_3^{2-}$ that has $MgATP^{2-}$ as its product. Consequently, when the phospho group of $HOPO_3^{2-}$, the axial oxygen of which replaces this molecule of water, is transferred to the nucleophilic oxygen on the β-phospho group of the $MgADP^-$, the phosphorus of $HOPO_3^{2-}$ must also be forced up against the nucleophilic oxygen on the β-phospho group, again within the sum of the two van der Waals radii.

When $MgAMPPNP^{2-}$ is occupying the active site in the T conformation (Figure 6–44C) rather than the D conformation, however, the molecule of

*For reasons that will become apparent later, the accepted view of F_1-ATPase for determining clockwise and counterclockwise rotation of the γ subunit is from the surface from which it protrudes, the top surface in the drawing in Figure 6–42A.

water that was a participant in the equilibrium between $MgATP^{2-}$ and $MgADP^{-}$ and $HOPO_3^{2-}$ in the active site in the D conformation, has been pulled away from the γ-phosphorus of $MgAMPPNP^{2-}$ (0.37 nm) by the conformational change (Figure 6–44). In addition, the two lone pairs of electrons on this molecule of water are occupied by donors for hydrogen bonds from Arginine β264 and one of the molecules of water on Mg^{2+}, and its two hydrogens are occupied by acceptors for hydrogen bonds from Glutamate β192 and the amido oxygen of Serine α344.[415] Consequently, this molecule of water in the active site in the T conformation is too far from the γ-phosphorus atom, and it no longer has one of its lone pairs of electrons directed at the γ-phosphorus atom. Therefore, it cannot participate in a nucleophilic substitution at the γ-phosphorus atom leading to hydrolysis of the $MgATP^{2-}$ that, under normal circumstances, would occupy this site in the T conformation. Calculations are consistent with the proposal that, in the active site in the T conformation, $MgATP^{2-}$ is thermodynamically stabilized as well as kinetically stabilized relative to $MgADP^{-}$ and $HOPO_3^{2-}$.[416] Although it seems strange, the only obvious significant difference between the active sites in the D and T conformations is the position and nucleophilicity of this molecule of water,[414] yet this **shift in the position of the molecule of water** seems to be all that is required to protect the $MgATP^{2-}$. It seems that the way this enzyme achieves one of the most important synthetic reactions in a living organism is to use a conformational change to move a molecule of water a tenth of a nanometer away from an atom of phosphorus and hold it there.

C**atalysis that is provided by the active site in the D conformation** to promote equilibration is straightforward. Three hydrogen bonds, by holding its axial oxygen firmly, compress the phosphorus of $HOPO_3^{2-}$ against the nucleophilic oxygen on the β-phospho group of $MgADP^{-}$ (Figure 6–44A) as well as compressing the molecule of water formed from the axial oxygen against the phosphorus of the γ-phospho group of $MgATP^{2-}$ (Figure 6–44B). The most important of the three groups participating in these hydrogen bonds is the amido oxygen of Serine α344 because it is in a polypeptide backbone and consequently significantly more rigidly positioned than either the guanidinio group of Arginine β264 or the carboxy group of Glutamic Acid β192. The amido oxygen of Serine α344 also has the advantage that it can only accept a hydrogen bond, thereby ensuring that the hydron on $HOPO_3^{2-}$ is on the oxygen of the hydroxy group that becomes the water that is the required leaving group in the nucleophilic substitution at phosphorus. The amido oxygen of Serine α344 also ends up as one of the four hydrogen bonds that prevent the molecule of water from being a nucleophile in the active site when it has changed to the T conformation. To convert the hydroxy group on $HOPO_3^{2-}$ into the molecule of water that is the required leaving group in the conversion of $MgADP^{-}$ and $HOPO_3^{2-}$ into $MgATP^{2-}$, the necessary hydron is provided by the catalytic carboxy group of Glutamic Acid β192, which forms a hydrogen bond with the hydroxy group on $HOPO_3^{2-}$ in the ground state.

In free solution at pH 7 and 25 °C and a concentration of Mg^{2+} of 1 mM, which are the nominal conditions of cytoplasm, the equilibrium constant is 1×10^{-4} for the reaction*

$$ADP_t + phosphate_t \rightleftharpoons ATP_t + H_2O \qquad (6\text{–}134)$$

where ADP_t is adenosine diphosphate in all its forms (about 45% $MgADP^{-}$ and 45% ADP^{3-}), ATP_t is adenosine triphosphate in all its forms (>80% $MgATP^{2-}$), and $phosphate_t$ is phosphate in all its states of hydronation (60% $HOPO_3^{2-}$).[417] In the active site of F_1-ATPase in the D conformation, the value for the equilibrium constant for the equivalent reaction is 2. This **dramatic shift in the equilibrium constant** must result from the fact that the active site has a higher affinity for $MgATP^{2-}$ and water than for $MgADP^{-}$ and $HOPO_3^{2-}$. In contrast to the fact that $MgATP^{2-}$ must associate with the active site of F_1-ATPase in the catalytic D conformation with high affinity, the Michaelis constant for $MgATP^{2-}$ as a reactant for the hydrolysis catalyzed by the enzyme from *R. norvegicus* is in the range of 0.1 mM.[418] This observation is consistent with a requirement for the binding of $MgATP^{2-}$ at an active site other than the catalytic active site on a molecule of F_1-ATPase with a dissociation constant around 0.1 mM to promote the release of products during hydrolysis of $MgATP^{2-}$.

The reason that the active site in the catalytic D conformation has a **higher affinity for $MgATP^{2-}$ than for $MgADP^{-}$ and $HOPO_3^{2-}$** can be understood

*The equilibrium constant cited[417] does not include the concentration of water in the numerator. In the present instance, it has been included so that a comparison can be made with the reaction in the active site, in which the product water is a pre-positioned, isolated molecule of water.

by placing $HOPO_3^{2-}$ in the crystallographic molecular model of the active site in the D conformation that is occupied by $MgADP^-$ and N_3^- (Figure 6–44A) after removing the N_3^- and two molecules of water that together occupy the usual positions of the four oxygens of $HOPO_3^{2-}$ in its absence.[365] The most inescapable requirement for this insertion is that the phosphorus atom of $HOPO_3^{2-}$ cannot be less than 0.31 nm away from the oxygen on the β-phospho group that acts as the nucleophile because of the van der Waals radii of the phosphorus atom (0.18 nm) and the oxygen atom (0.15 nm). Placing these two atoms at a distance of 0.31 nm also places the apical oxygen of $HOPO_3^{2-}$ in almost the exact position of the molecule of water that forms paradigmatic hydrogen bonds with Arginine β264 and Glutamate β192 and the amido oxygen of Serine α344 in the active site in the D conformation when it is occupied either by $MgADP^-$ and N_3^- or by $MgAMPPNP^{2-}$ (Figure 6–44B) and positions the bond between phosphorus and the apical oxygen of $HOPO_3^{2-}$ in the proper orientation for the nucleophilic substitution at phosphorus. The three equatorial oxygens of $HOPO_3^{2-}$ can then be positioned in the same orientation as three equatorial oxygens on the γ-phospho group in the active site in the D conformation when it is occupied by $MgAMPPNP^{2-}$.

There are several disadvantages, however, to this inescapable position for $HOPO_3^{2-}$ in the active site in the D conformation when it is also occupied by $MgADP^-$ relative to the same active site when it is occupied by $MgAMPPNP^{2-}$ and the molecule of water that is the other product of the nucleophilic substitution at phosphorus. A hydrogen bond cannot form between Lysine β166 and one of the equatorial oxygens on $HOPO_3^{2-}$, and a hydrogen bond cannot form between Arginine α373 and another of the equatorial oxygens on $HOPO_3^{2-}$ because the distances (0.33 nm) between the respective nitrogens that are donors and oxygens that are acceptors are too long (Figure 6–44A). Both hydrogen bonds (0.29 nm), however, form when $MgADP^-$ and $HOPO_3^{2-}$ become $MgATP^{2-}$ and a molecule of water (Figure 6–44B). The closest oxygen on $HOPO_3^{2-}$ is a marginal ligand to Mg^{2+} because the distance between it and Mg^{2+} is too long and its oxygen is not in an octahedral position, which is the preferred geometry of coordination for Mg^{2+}. The closest oxygen on $HOPO_3^{2-}$ to Mg^{2+} also must push aside one of the molecules of water that is a ligand to Mg^{2+} because of a steric clash, and this steric effect distorts the coordination at this position as well. When $MgADP^-$ and $HOPO_3^{2-}$ become $MgATP^{2-}$ and a molecule of water, an oxygen on the β-phospho group of $MgATP^{2-}$ and this same oxygen, which was the closest oxygen to Mg^{2+} in $HOPO_3^{2-}$ and is now on the γ-phospho group of $MgATP^{2-}$, are undistorted octahedral ligands for Mg^{2+}. This undistorted coordination is the same as that between Mg^{2+} and ATP^{4-} when $MgATP^{2-}$ is in solution. Nor can the Mg^{2+} be readily reoriented to adjust to these distortions caused by this oxygen on $HOPO_3^{2-}$ when the active site in the D conformation is occupied by $MgADP^-$ because the Mg^{2+} is coordinated by the oxygen of Threonine β167, by a molecule of water between it and one of the nonbridging oxygens of the α-phospho group of $MgADP^-$, and by an oxygen from the β-phospho group of $MgADP^-$, which is rigidly held and cannot move any closer to $HOPO_3^{2-}$ because of the steric hindrance of the van der Waals radii. For all these reasons, it seems apparent that the active site of the enzyme should have a higher affinity for $MgATP^{2-}$ and the molecule of water than for $MgADP^-$ and $HOPO_3^{2-}$.

The **structure of the opened active site** in the $\alpha\beta$ heterodimer in the O conformation is dramatically different from that of the active site of an $\alpha\beta$ heterodimer in either the D or T conformation (Figure 6–47).[363,365,366] The door that closed over the $MgADP^-$ and $HOPO_3^{2-}$ formed by the segment of polypeptide containing Phenylalanine β422 to Threonine α429 has opened to the solution, permitting dissociation of $MgATP^{2-}$ in the direction of synthesis. The cup for the β-phospho group of $MgATP^{2-}$ and $MgADP^-$, however, is still in almost the same conformation, although somewhat tilted, and is holding $HOPO_3^{2-}$ in the crystallographic molecular model, presumably ready to cup the β-phospho group of the reactant $MgADP^-$ rather than $HOPO_3^{2-}$ following dissociation of $MgATP^{2-}$ in the direction of synthesis. The methyl group of Alanine β425 and the phenyl ring of Tyrosine β349, which clamp the pyrimidinyl groups of both adenine nucleotides (0.8 nm apart) in the D and T conformations (Figure 6–44), are still opposite each other (0.95 nm apart) and ready to clamp down again. The phenyl group of Phenylalanine β422, into the π molecular orbital system of which the exocyclic amido group buries its two hydrogens (Figure 6–44) and which distinguishes adenine from guanine by electron repulsion, is ready to swing outward to perform its function. All these features prepare the site to associate with ADP^{3-}.

Figure 6–47: Stereodrawings[485] of changes in the conformation of one of the active sites in F_1-ATPase upon changes in the quaternary conformation of enzyme. The polypeptide backbones of the segments of polypeptide surrounding the active sites in the crystallographic molecular model of Figure 6–42 are shown as stereo line drawings, and the adenine nucleotides and $HOPO_3^{2-}$ are shown as ball-and-stick stereodrawings in which black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large dark gray atoms are atoms of phosphorus. (**A**) Superposition of the segments of polypeptide and $MgADP^-$ and $HOPO_3^{2-}$ from the active site in the D conformation (gray lines) upon the same segments of polypeptide and $MgAMPPNP^{2-}$ from the active site in the T conformation (black lines). (**B**) Superposition of the segments of polypeptide and $MgAMPPNP^{2-}$ from the active site in the T conformation (black lines) upon the same segments of polypeptide and the adventitious $HOPO_3^{2-}$ from the active site in the O conformation. (**C**) Active site in the O conformation in the crystallographic molecular model of Figure 6–42 occupied by $HOPO_3^{2-}$, labeled as in Figure 6–44. Again, the majority of the segments are from the β subunit, the numbers of their amino acids are unadorned, and the two segments from the α subunit are designated by adding an α to the end of each number. Two oxygens of $HOPO_3^{2-}$ occupy the cup that had been and will be occupied by one of the nonbridging oxygens of the β-phospho groups of $MgATP^{2-}$ and $MgADP^-$ (Figure 6–44).

In another crystallographic molecular model in which the O conformation is occupied by $HOPO_2S^{2-}$ ($pK_a = 5.4$), in which the hydron is on one of the oxygens,[419] there are hydrogen bonds between one or the other oxygen and Arginine β264, Arginine β193, and Lysine β166 and between sulfur and Arginine β264 and Arginine β193. Each side chain forms hydrogen bonds to the oxygens of $HOPO_3^{2-}$ or the γ-phospho group of $MgATP^{2-}$ in the catalytic D conformation (Figure 6–44A,B). From these facts, it has been concluded that $HOPO_2S^{2-}$ in this molecular model occupies the subsite with which the substrate $HOPO_3^{2-}$ associates in the O conformation.[420]

The **proposal for the synthesis of $MgATP^{2-}$** (Figure 6–45) includes the following sequence of events.[363,394] The reactants $MgADP^-$ and $HOPO_3^{2-}$ associate with an active site in an $\alpha\beta$ heterodimer in the O conformation, and the conformation of that active site changes from the O to the D conformation. On the basis of the crystallographic molecular model of the enzyme from *R. norvegicus* crystallized in the absence of Mg^{2+}, in which ADP^{3-} occupies the active site in the O conformation, it has been proposed that ADP^{3-} can bind to the active site of the β subunit in the O conformation, inducing a partial closing around itself before $HOPO_3^{2-}$ associates with the active site and its conformation changes completely to the D conformation,[369,413] but the arrangement of the side chains holding the $MgADP^-$ in the active site in this complex is somewhat different from that in the D conformation (Figure 6–44). However they came to be there, once Mg^{2+}, ADP^{3-}, and $HOPO_3^{2-}$ are bound to the active site in the O conformation, its conformation changes to the catalytic D conformation and the equilibrium between $MgATP^{2-}$ and a molecule of water and $MgADP^-$ and $HOPO_3^{2-}$ is established. Following establishment of this equilibrium, the active site on the same $\alpha\beta$ heterodimer undergoes its second conformational change into the T conformation at an instant when it happens to be occupied by $MgATP^{2-}$ and the molecule of water rather than by $MgADP^-$ and $HOPO_3^{2-}$. The T conformation protects $MgATP^{2-}$ from hydrolysis. This active site on the same $\alpha\beta$ heterodimer occupied by this stable molecule of $MgATP^{2-}$ then undergoes a third and final change back to the O conformation. The change from the D to the T conformation is undramatic, but the change from the T to the O conformation is dramatic (Figure 6–47). The active site swings open to the solution, and $MgATP^{2-}$, around which there are definitely no longer any catalytic groups, simply dissociates into solution. The abrupt conformational change of the active site in the T conformation, in which $MgATP^{2-}$ is enclosed and protected from catalytic hydrolysis, to the O conformation site, from which $MgATP^{2-}$ readily dissociates, is the key to the synthesis of $MgATP^{2-}$ by H^+-transporting two-sector ATPase.[405]

The reason that each of the three active sites on a molecule of F_1-ATPase passes through these three conformations during the synthesis of $MgATP^{2-}$ is the same reason that there are three conformations in the enzyme at rest: the γ subunit. When the enzyme is not at rest but synthesizing $MgATP^{2-}$, the **γ subunit rotates** clockwise in steps of -120° (Figures 6–45 and 6–46). Because the three conformations of the $\alpha\beta$ heterodimers within the $(\alpha\beta)_3$ ring are created by the asymmetry of the γ subunit, the **conformational changes must proceed in concert** with strict conservation of the global asymmetry (Figures 6–42 and 6–45) as the γ subunit rotates.[365,366] At each step, when one of the $\alpha\beta$ heterodimers changes from the O to the D conformation, its clockwise neighbor is required to change from the T to the O conformation, and its counterclockwise neighbor is required to change from the D to the T conformation. The clockwise rotation of the γ subunit cannot occur until the active site in an $\alpha\beta$ heterodimer changing from the O to the D conformation is occupied by $MgADP^-$ and $HOPO_3^{2-}$ and the active site in an $\alpha\beta$ heterodimer changing from

the D to the T conformation is occupied by $MgATP^{2-}$. The former of these two requirements explains why the incorporation of oxygen-16 from $H_2{}^{16}O$ into the $Mg[\gamma\text{-}{}^{18}O_3P]ATP^{2-}$ formed from $H^{18}OP^{18}O_3{}^{2-}$ as a result of intermediate isotopic exchange while the enzyme is synthesizing $MgATP^{2-}$ increases as the concentration of either $MgADP^-$ or $HOPO_3{}^{2-}$ is decreased.

If this is the mechanism by which F_1-ATPase synthesizes $MgATP^{2-}$, then it must be the case, by **microscopic reversibility**, that the enzyme proceeds through the same sequence of steps in reverse when it is hydrolyzing $MgATP^{2-}$. A molecule of the reactant $MgATP^{2-}$ associates with the active site in an $\alpha\beta$ heterodimer in the O conformation. During the change from the O to the T conformation caused by a counterclockwise rotation of the γsubunit, the active site closes upon the $MgATP^{2-}$ and the molecule of water. Because the key to the synthesis of $MgATP^{2-}$ is the absolute control of this molecule of water, it is engaged in four hydrogen bonds, and at this point, it is too distant to participate in hydrolysis, so the molecule of $MgATP^{2-}$ is at rest. A counterclockwise rotation of the γsubunit causes the conformation of the active site in the same $\alpha\beta$ heterodimer to change to the D conformation, in which $MgATP^{2-}$ and the molecule of water can now equilibrate rapidly with $MgADP^-$ and $HOPO_3{}^{2-}$. At an instant when $MgADP^-$ and $HOPO_3{}^{2-}$ occupy the active site in the D conformation, a counterclockwise rotation of the γsubunit causes the $\alpha\beta$ heterodimer to change from the D to the O conformation, but this can happen only if a molecule of $MgATP^{2-}$ is occupying the active site in the O conformation before the change in conformation occurs. The products of hydrolysis, $MgADP^-$ and $HOPO_3{}^{2-}$, dissociate from the open active site as products. These requirements for occupation, in addition to those for the sequence of conformational changes, follow from microscopic reversibility.

Observations that have been made of hydrolysis of $MgATP^{2-}$ by the enzyme are all consistent with this mechanism. Consequently, those observations are also evidence that it is the mechanism for the synthesis of $MgATP^{2-}$. During hydrolysis of $MgATP^{2-}$, there is an active site on the enzyme in which $MgATP^{2-}$ and a molecule of water and $MgADP^-$ and $HOPO_3{}^{2-}$ reach an equilibrium in favor of the former. The equilibrium persists until a second molecule of $MgATP^{2-}$ associates with the enzyme, after which $MgADP^-$ and $HOPO_3{}^{2-}$ dissociate from the enzyme. The second molecule of $MgATP^{2-}$ terminates the equilibration by associating at the active site in the $(\alpha\beta)_3$ trimer that is in the O conformation because the γsubunit cannot rotate until that site is occupied by a molecule of $MgATP^{2-}$. When the γsubunit is then able to rotate, the active site in the D conformation changes to the O conformation and the $MgADP^-$ and $HOPO_3{}^{2-}$ dissociate while the conformation of the active site with which $MgATP^{2-}$ has just associated changes to the T conformation. The active site previously in the T conformation, which must have been occupied by $MgATP^{2-}$, just as the three uninvolved sites in the three α subunits are always occupied by $MgATP^{2-}$, shifts in concert to the D conformation.

The **requirements for occupancy of the active sites before rotation can occur** during the synthesis of $MgATP^{2-}$ by this proposed mechanism are obvious. If the transformation from the O to the D conformation could occur when the active site in the O conformation is occupied by $MgATP^{2-}$, when the active site is occupied by only $MgADP^-$ or only $HOPO_3{}^{2-}$, or when the active site is empty, then no synthesis of $MgATP^{2-}$ at that particular active site would occur during that cycle. If the transformation from the D to the T conformation could occur at an instant when the active site is occupied with $MgADP^-$ and $HOPO_3{}^{2-}$ rather than $MgATP^{2-}$, then no synthesis of $MgATP^{2-}$ at that site would occur during that cycle. Such mistakes are made, but the more that are made, the less efficient becomes the synthesis of $MgATP^{2-}$, the normal purpose of the enzyme. Natural selection must have minimized the frequency of those mistakes. The requirements for occupancy during hydrolysis of $MgATP^{2-}$ are simply the result of microscopic reversibility. An obvious structural explanation for the requirement that the active site in the D conformation must be occupied by $MgATP^{2-}$ before the conformational change to the T conformation can occur during the synthesis of $MgATP^{2-}$ would be that it should be impossible to pull $HOPO_3{}^{2-}$ by its apical oxygen 0.06 nm away from its location in the D conformation to the location it would have to occupy in the T conformation to retain the three hydrogen bonds to this apical oxygen while a molecule of water could easily be pulled away.

There are two ways to explain the sequence of global conformational changes coincident with the rotation of the γsubunit during the synthesis of $MgATP^{2-}$.

The first explanation is an **equilibrium explanation**. The sequences of amino acids for the α and β subunits together encode all three conformations, O, D, and T, which are able to equilibrate with each other at the level of the conformation of each $\alpha\beta$ heterodimer. When the global conformation of

the $(\alpha\beta)_3$ ring in the O,D,T global conformation is occupied in turn by the proper substrates at its three active sites and then assumes the D,T,O global conformation as a result of these more local equilibrations, the γ subunit is able to rotate in the clockwise direction and sterically stabilize this D,T,O conformation. This explanation is equivalent to the explanation given for the ability of allosteric ligands to change the conformation of an allosterically controlled and cooperative enzyme such as aspartate carbamoyltransferase. The problem is that the three $\alpha\beta$ heterodimers together have to change their individual conformations coincident with the required local conformational changes in each of them, and all these conformational changes have to occur in concert before the O,D,T global conformation becomes the D,T,O global conformation that permits rotation of the γ subunit. Another way to view this explanation, however, is to consider the three conformations represented schematically in Figure 6–45 to be three global conformations that the $(\alpha\beta)_3$ heterohexameric ring can assume and that are in equilibrium with each other. When the global conformation of the moment changes to one that is adjacent in the cycle represented in the figure in either direction, synthesis of $MgATP^{2-}$ or hydrolysis of $MgATP^{2-}$, the shaft of the γ subunit rotates clockwise or counterclockwise, respectively, to fit this new global conformation, temporarily locking that conformation in place.

The second explanation is a **mechanical explanation**. The γ subunit is a camshaft on which there are two principal cams (Figure 6–43), the bulge along its length formed by the bend of the longer of the two α helices and the overhang at the top that is formed from the globular domain of the γ subunit as it emerges from its seat and perhaps a portion of the ε subunit, which rotates with the γ subunit.[421,422] As the camshaft turns, it sterically distorts the conformation of each $\alpha\beta$ heterodimer in turn into the O, the D, and then the T conformation. This explanation appeals to an observer who is familiar with machines, and the metaphor of a machine will become even more compelling as the discussion proceeds. The problem is that, as has already been noted, proteins of the size of an $\alpha\beta$ heterodimer are hard, not soft, and cannot be distorted readily.

As usual, the two explanations are not mutually exclusive. In the first case, it is reasonable that steric forces engendered by a powered rotation of the γ subunit dramatically hasten and bias the equilibration of the different permitted global conformations. In the second case, the distortion produced by the rotating γ subunit must produce only conformations that are allowed by the sequences of amino acids for the α and β subunits and hence can be achieved by them in the absence of steric forces applied by the γ subunit. The steric forces simply stabilize one of these encoded conformations at each $\alpha\beta$ heterodimer.

There are experimental observations demonstrating that the γ subunit does rotate in its seat as $MgATP^{2-}$ is hydrolyzed. That rotation of the γ subunit of some kind must occur was demonstrated by forming an $(\alpha\beta'_{rad})_2\alpha\beta'\gamma\delta\varepsilon$ hybrid of F_1-ATPase from *E. coli* with β' subunits in which Aspartate β380, which is immediately adjacent in the crystallographic molecular model to Cysteine γ87 in the γ subunit, was mutated to cysteine and in which only two of these mutated β subunits were radioactive (rad). A cystine was formed between a nonradioactive, mutant β' subunit and the γ subunit, and this crosslinked β'–γ was reconstituted with three α subunits, two radioactive, mutant β'_{rad} subunits, a δ subunit, and an ε subunit. This complex was inactive in hydrolysis of $MgATP^{2-}$ until the cystine was reduced to two cysteines. Reduction of the complex allowed it to hydrolyze $MgATP^{2-}$, after which the cystines were re-formed. Some of the γ subunits, which initially were crosslinked only to nonradioactive β' subunits, were found now to be crosslinked to radioactive β'_{rad} subunits.[423]

The γ subunit in F_1-ATPase from *S. oleracea* was modified exclusively at Cysteine 322 with eosin-5-maleimide, and this modified F_1-ATPase was immobilized on beads of crosslinked agarose. It was found that, immediately after photobleaching of the eosin with an intense flash of polarized light, the absorption of bound eosin was anisotropic. If $MgATP^{2-}$ was present, the anisotropy decayed ($k = 7\ s^{-1}$ at 37° C) as the γ subunit rotated, but no decay of anisotropy was observed when $MgAMPPNP^{2-}$ was used[424] instead of $MgATP^{2-}$.

The most convincing verification, however, of rotation of the γ subunit within its seat in the $(\alpha\beta)_3$ ring during hydrolysis of $MgATP^{2-}$ by F_1-ATPase has been **watching it rotate**.[425,426] For the explanation of the synthesis of $MgATP^{2-}$ to be correct, when F_1-ATPase is hydrolyzing $MgATP^{2-}$, the upper right subunit in Figure 6–42 converts in turn from the O to the T and then to the D conformation. These conformational changes require the γ subunit to rotate in

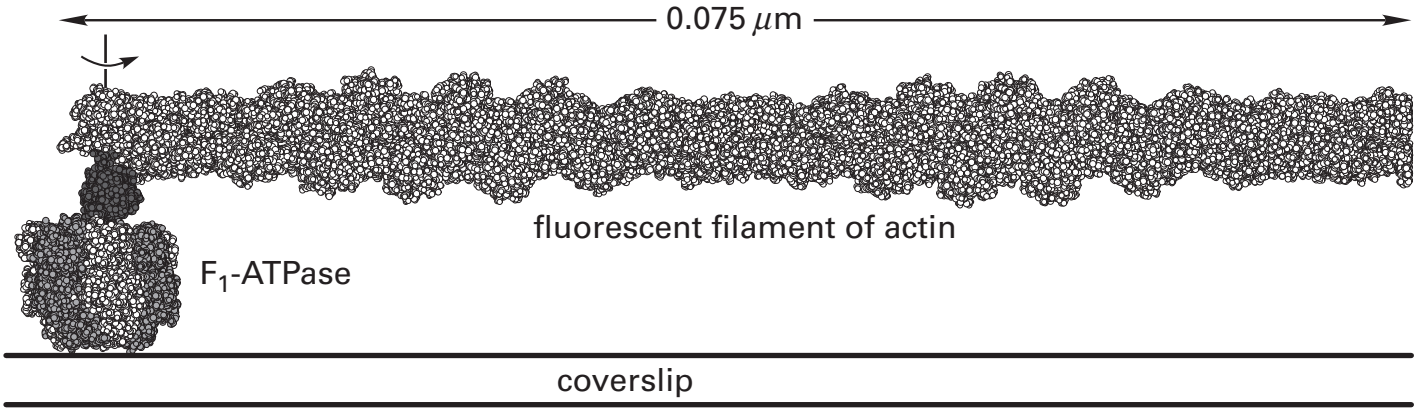

Figure 6–48: Drawing[485] of a filament of actin bound to the γsubunit of F_1-ATPase. The portion of the crystallographic molecular model of F_1-ATPase containing the complete polypeptides of the three αsubunits, the three βsubunits, and the γsubunit (Figure 6–42) is presented as a space-filling model (γsubunit in dark gray, αsubunits in light gray, and βsubunits in white). The molecular model of a filament of actin from *O. cuniculus* was constructed from a map of electron scattering density derived from 63,000 images in electron micrographs of filaments of actin frozen in amorphous ice. Crystallographic molecular models of actin monomer were then inserted into this map of electron scattering density to obtain a molecular model of the helical filament. This molecular model, in space-filling representation and at the same scale, was placed so that one end impinged upon the γsubunit of bovine F_1-ATPase (Figure 6–42). The point of attachment was arbitrarily chosen to be at one end of the filament because most of the rotating fluorescent filaments of actin had their rotation axis at one end of the filament. The filament of actin in the drawing was truncated at the other end because the actual filaments observed rotating were about 1 μm long, about 15 times longer than the segment drawn.

a counterclockwise direction when viewed on the side of the $(\alpha\beta)_3$ ring from which it protrudes (Figure 6–45). The $(\alpha\beta)_3$ ring of the $(\alpha\beta)_3\gamma F_1$-ATPase subcomplex from *Bacillus* sp. PS3 was firmly affixed to a glass coverslip through its surface opposite that from which the γsubunit protrudes. A filament of fluorescent actin was then attached to the γsubunit protruding from the affixed $(\alpha\beta)_3$ ring (Figure 6–48). Because fluorescent filaments of actin are large enough to be observed in a fluorescence microscope, individual filaments of the fluorescent actin could be observed directly. When $MgATP^{2-}$ was added, many of the filaments, which were being viewed from below the coverslip and hence from the side opposite that from which the γsubunit protrudes, rotated in a clockwise direction, as predicted. When the filament of actin was 1 μm long (13 times longer than the portion of the filament of actin depicted in Figure 6–48), rotations as rapid as 5 s^{-1} were observed.

As one might expect from the dimensions (Figure 6–48), when the actin filament turns through the solution while $MgATP^{2-}$ is being hydrolyzed, it encounters significant **frictional resistance to its rotational motion**. At a saturating concentration of 2 mM $MgATP^{2-}$, the rotational rate is a function of the length of the actin filament. The longer the filament, the slower is the rotation. From this relation, the torque exerted on the actin filament by the γsubunit within the $(\alpha\beta)_3$ ring of F_1-ATPase from *Bacillus* sp. PS3[426] or the γsubunit within the $(\alpha\beta)_3$ ring of F_1-ATPase from *E. coli*[427] can be estimated. The estimate of the **torque generated** is 50 pN nm (5×10^{-20} J rad^{-1}) when [$MgATP^{2-}$] is 2 mM, [$MgADP^{-}$] is 10 μM, and [phosphate] is 0.1 mM at pH 7.0. If a complete rotation (2π rad) requires hydrolysis of three molecules of $MgATP^{2-}$, the free energy of hydrolysis at these concentrations of $MgATP^{2-}$, $MgADP^{-}$, and phosphate should be able to generate a torque of 5.4×10^{-20} J rad^{-1}, which is the torque observed. An even more direct measurement of the torque generated on a magnetic bead attached to the γsubunit within the $(\alpha\beta)_3$ ring of F_1-ATPase from *Bacillus* sp. PS3 in an applied magnetic field as a function of the standard free energy of hydrolysis of $MgATP^{2-}$ showed the same equivalence[428] over a range of free energies of hydrolysis from −70 to −110 kJ mol^{-1}. This **equivalence between generated torque and standard free energy of hydrolysis** supports the conclusion that hydrolysis of the $MgATP^{2-}$ at three sites for every revolution is driving the rotation of the filament of actin or the magnetic bead.

That these measurements are consistent with the conclusion that the torque generated during this step is roughly equivalent to the standard free energy of hydrolysis of the molecule of $MgATP^{2-}$ suggests that rotation must be tightly coupled to hydrolysis. It necessarily follows, from microscopic

reversibility, that if a clockwise torque is applied to the γsubunit that is equal to or greater than the counterclockwise torque generated during its hydrolysis, then molecules of $MgATP^{2-}$ must be synthesized from molecules of $MgADP^{-}$ and $HOPO_3^{2-}$. This enforced synthesis has been observed. When magnetic beads are attached to γsubunits of F_1-ATPase from *Bacillus* sp. PS3 such that they are tilted off the central axis of the $(\alpha\beta)_3\gamma$subcomplex, and the subcomplex is attached to a glass slide, the bead can be forced to **drive the rotation of the γsubunit clockwise** by a rotating magnetic field. When the γsubunit is forced to rotate clockwise* within the $(\alpha\beta)_3$ ring, $MgATP^{2-}$ is synthesized[429,430] from $MgADP^{-}$ and $HOPO_3^{2-}$.

At low enough concentrations (2 μM) of $MgATP^{2-}$, so that the rate of rotation of the filament of actin is slow enough that the generation of torque does not limit the rate, its rotation is resolved into **discrete steps of +120°**.[426] If a spherical 40 nm bead of colloidal gold is used rather than a fluorescent filament of actin to visualize the rotation, then the viscous drag on the rotating γsubunit, and hence the generation of torque, is decreased dramatically. The bead is attached to the γsubunit of the $(\alpha\beta)_3\gamma$complex of F_1-ATPase from *Bacillus* sp. PS3 off-axis so that the oscillation as the bead rotates can be observed. The bead rotates when a saturating concentration of $MgATP^{2-}$ (2 mM) is present, and its rotation proceeds in discrete +120° steps (Figure 6–49),[431] as expected if the rotation is the result of discrete global conformational changes of the $(\alpha\beta)_3$ ring (Figure 6–45). Furthermore, the rate of rotation under these conditions of low torque is equal to one-third the rate of hydrolysis of $MgATP^{2-}$ in a range of concentrations of $MgATP^{2-}$ that encompasses rates over a span of 1000.

When one of the β subunits in the $(\alpha\beta)_3$ ring is replaced with a mutant β' subunit, the active site of which binds $MgATP^{2-}$ slowly, association of $MgATP^{2-}$ with just this one active site in the open conformation becomes the rate-limiting step in the overall hydrolysis of $MgATP^{2-}$,[432] and the rotation of beads

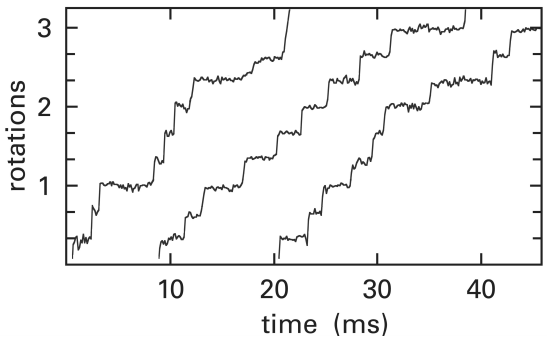

Figure 6–49: Rotation of the γsubunit of F_1-ATPase[431] in steps of +120°. A mutant of the $(\alpha\beta)_3\gamma$complex of F_1-ATPase from *Bacillus* PS3 in which Cysteine 193 in the α subunit had been mutated to serine and Serine 107 and Isoleucine 210 in the γsubunit had both been mutated to cysteines was prepared by site-directed mutation. These two cysteines introduced into the complex were then modified with 6-*N*′-[2-(*N*-maleimido)-ethyl]-*N*-piperazinylamidohexyl-D-biotinamide to attach biotinyl groups covalently to the protein. The protein was then mixed with streptavidin, a homotetrameric protein (4 × 183 aa) from *Streptomyces avidinii* with four symmetrically arranged sites for the binding of biotin (k_{diss} = 0.009 h^{-1}). The protein to which streptavidin had bound was then mixed with spheres of colloidal gold (diameter 40 nm) coated with bovine serum albumin that had been modified with with sulfosuccinimidyl-*N*-[*N*′-(D-biotinyl)-6-aminohexanoyl]-6′-aminohexanoate. The open sites on the streptavidin bound to the mutant F_1-ATPase associated with biotinyl groups on the serum albumin adsorbed to the beads, and beads became attached to γsubunits of F_1-ATPase. Molecules of F_1-ATPase to which beads were attached were adsorbed to a glass coverslip at the surface opposite that from which the γsubunit protrudes (Figures 6–42 and 6–48). When a solution containing 2 mM $MgATP^{2-}$ was introduced, some of the beads attached to the coverslip through molecules of F_1-ATPase were observed to rotate. These rotating beads ended up attached to the γsubunit with their centers displaced about 10 nm from the axis of rotation of the γsubunit so that the spheres themselves could be seen to rotate around that axis. The rotation was observed with a high-speed digital motion picture camera at 2 frames ms^{-1}. For analysis, a rotating bead in the field was chosen and placed within the transparent circle of a digital mask, and an algorithm was used to follow the rotation of that bead and convert each image into a rotational position for the centroid of the bead relative to the axis of rotation. Rotational position is plotted continuously in units of full rotation as a function of time. It can be seen that the rotation is discontinuous and occurs in steps of a third of a rotation (+120°). of colloidal gold attached to γsubunits of the $(\alpha\beta)_2\alpha\beta'\gamma$subcomplex occurs in discrete steps of +360° rather than steps of +120°. When the active site of the unmutated $\alpha\beta$ heterodimer counterclockwise to the mutant $\alpha\beta'$ heterodimer is in the D conformation, occupied by the equilibrating mixture of $MgATP^{2-}$ and $MgADP^{-}$ and $HOPO_3^{2-}$, the rotation of +120° cannot occur until the reactant $MgATP^{2-}$ binds to the active site of the mutant $\alpha\beta'$ heterodimer. Association of $MgATP^{2-}$ with the

*As previouly noted, the accepted view of F_1-ATPase for determining clockwise and counterclockwise rotation of the γsubunit is the view of the surface from which the γsubunit protrudes (Figure 6–42). From here on, angles of rotation will be given the signs appropriate for rotation when viewed from this side of F_1-ATPase. From this side, during synthesis of $MgATP^{2-}$, the rotation of the γsubunit is clockwise; and during hydrolysis of $MgATP^{2-}$, its rotation is counterclockwise. By accepted convention (sinister, righteous), clockwise or left-handed rotation is given a negative sign, and counterclockwise or right-handed rotation is given a positive sign.

mutant is slow. As soon as it associates, the first rotation of +120° and its accompanying conformational changes occur, followed by two rapid unresolved rotations of +120° as $MgATP^{2-}$ binds rapidly, in succession, to the unmutated $\alpha\beta$ heterodimers consecutively during the rapid hydrolysis of two molecules of $MgATP^{2-}$.

The individual steps of +120° during hydrolysis of $MgATP^{2-}$ can be **resolved into two steps**. Rotation of native, unmutated $(\alpha\beta)_3\gamma$ subcomplex of F_1-ATPase from *Bacillus* sp. PS3, while hydrolyzing $MgATP^{2-}$, was followed as a function of the concentration of $MgATP^{2-}$. At 2 mM $MgATP^{2-}$, the rotation occurs in discrete steps of +120°, but at 20 μM $MgATP^{2-}$, discrete **steps of +80° and +40°** could be observed.[431] It has been concluded that the reason for these intermediate steps is that there are two global conformations through which F_1-ATPase passes while hydrolyzing or, by microscopic reversibility, while synthesizing each molecule of $MgATP^{2-}$. One conformation precedes the +80° step, and the other precedes the +40° step when the enzyme is hydrolyzing $MgATP^{2-}$. The requirements for these two conformational changes to occur have been examined.

When F_1-ATPase from *Bacillus* sp. PS3 is hydrolyzing $MgATP^{2-}$ in the intermediate range of concentrations at which the rotation takes alternating steps of +40° and +80°, the dwell time between a +40° step and an +80° step increases as the concentration of $MgATP^{2-}$ is decreased, while the dwell time between an +80° step and a +40° step does not.[431] This result suggests that the global conformation of the $(\alpha\beta)_3$ ring that precedes a +80° step and follows a +40° step cannot undergo the next conformational change that is to occur during the +80° step until $MgATP^{2-}$, the reactant for hydrolysis, associates with one of the active sites. This global conformation, during hydrolysis of $MgATP^{2-}$, is **waiting for the reactant $MgATP^{2-}$ to associate**.

When F_1-ATPase from *Bacillus* sp. PS3 is hydrolyzing magnesium adenosine 5′-[γ-thio]triphosphate, a slow reactant, or when a mutant of the enzyme in which the glutamic acid homologous to Glutamic Acid β192 in bovine F_1-ATPase has been mutated to aspartic acid is hydrolyzing $MgATP^{2-}$, the steady-state rate of hydrolysis is decreased significantly relative to the rate of hydrolysis of unmodified $MgATP^{2-}$ by the native enzyme. In each instance, the dwell time between the +80° step and the +40° step increases.[433] This result suggests that the global conformation of the $(\alpha\beta)_3$ ring that precedes a +40° step and follows a +80° step cannot undergo the next conformational change that is to occur during the +40° step **until the equilibrium between $MgATP^{2-}$ and H_2O and $MgADP^-$ and $HOPO_3^{2-}$ has been established**.

At 2 mM $MgATP^{2-}$ the rotation occurs in discrete steps of +120°; when the concentration of $MgATP^{2-}$ is decreased to 20 μM, the rotation occurs in steps of +80° and +40°; and when the concentration of $MgATP^{2-}$ is decreased further to 2 μM, the rotation again occurs in discrete steps of +120°. It follows from these observations that as the concentration of $MgATP^{2-}$ is decreased from 2 mM to 2 μM, a **change in rate-limiting step** occurs. At 2 μM $MgATP^{2-}$, the rate-limiting step is association of $MgATP^{2-}$ while at 2 mM $MgATP^{2-}$, the rate-limiting step is the establishment of the equilibrium between $MgATP^{2-}$ and H_2O and $MgADP^-$ and $HOPO_3^{2-}$. As the concentration of $MgATP^{2-}$ is decreased from 20 μM to 2 μM, the rate-limiting step becomes association of $MgATP^{2-}$ with an active site in an $\alpha\beta$ heterodimer, and the +40° step becomes rapid relative to the slow, rate-limiting +80° step. As a result, the +40° step cannot be resolved, and only +120° steps are observed. When the concentration of $MgATP^{2-}$ is increased from 20 μM to 2 mM, association of $MgATP^{2-}$ with an active site in an $\alpha\beta$ heterodimer increases, and the +80° step becomes rapid relative to the slow, rate-limiting +40° step. As a result, the +80° step cannot be resolved and only +120° steps are observed.

Measurements have been made of the orientation of a fluorophore rigidly and covalently attached to two neighboring cysteines introduced by site-directed mutation into each β subunit of F_1-ATPase from *Bacillus* sp. PS3.[434] Molecular distances have been estimated from fluorescence resonance energy transfer[435] among three fluorescent sulfoindocyanine dyes attached to three cysteines that had been inserted into the three β subunits of F_1-ATPase from *Bacillus* sp. PS3 in place of Leucines 398 by site-directed mutation.[436] These observations are consistent with the conclusion that, when $MgATP^{2-}$ is being hydrolyzed, **the conformation that precedes the +40° step is the conformation usually observed in crystallographic molecular models** (Figures 6–42, 6–44, and 6–46). In addition, fluorescence resonance energy transfer between a fluorophore attached to Cysteine γ5 and a fluorophore attached to Cysteine β3 is consistent with the orientation of the γ subunit in the conformation preceding the +80° step during hydrolysis of $MgATP^{2-}$, which proceeds with counterclockwise rotation of the γ subunit, being +40° from its rotational orientation usually observed in crystallographic molecular models.[437] This observation is

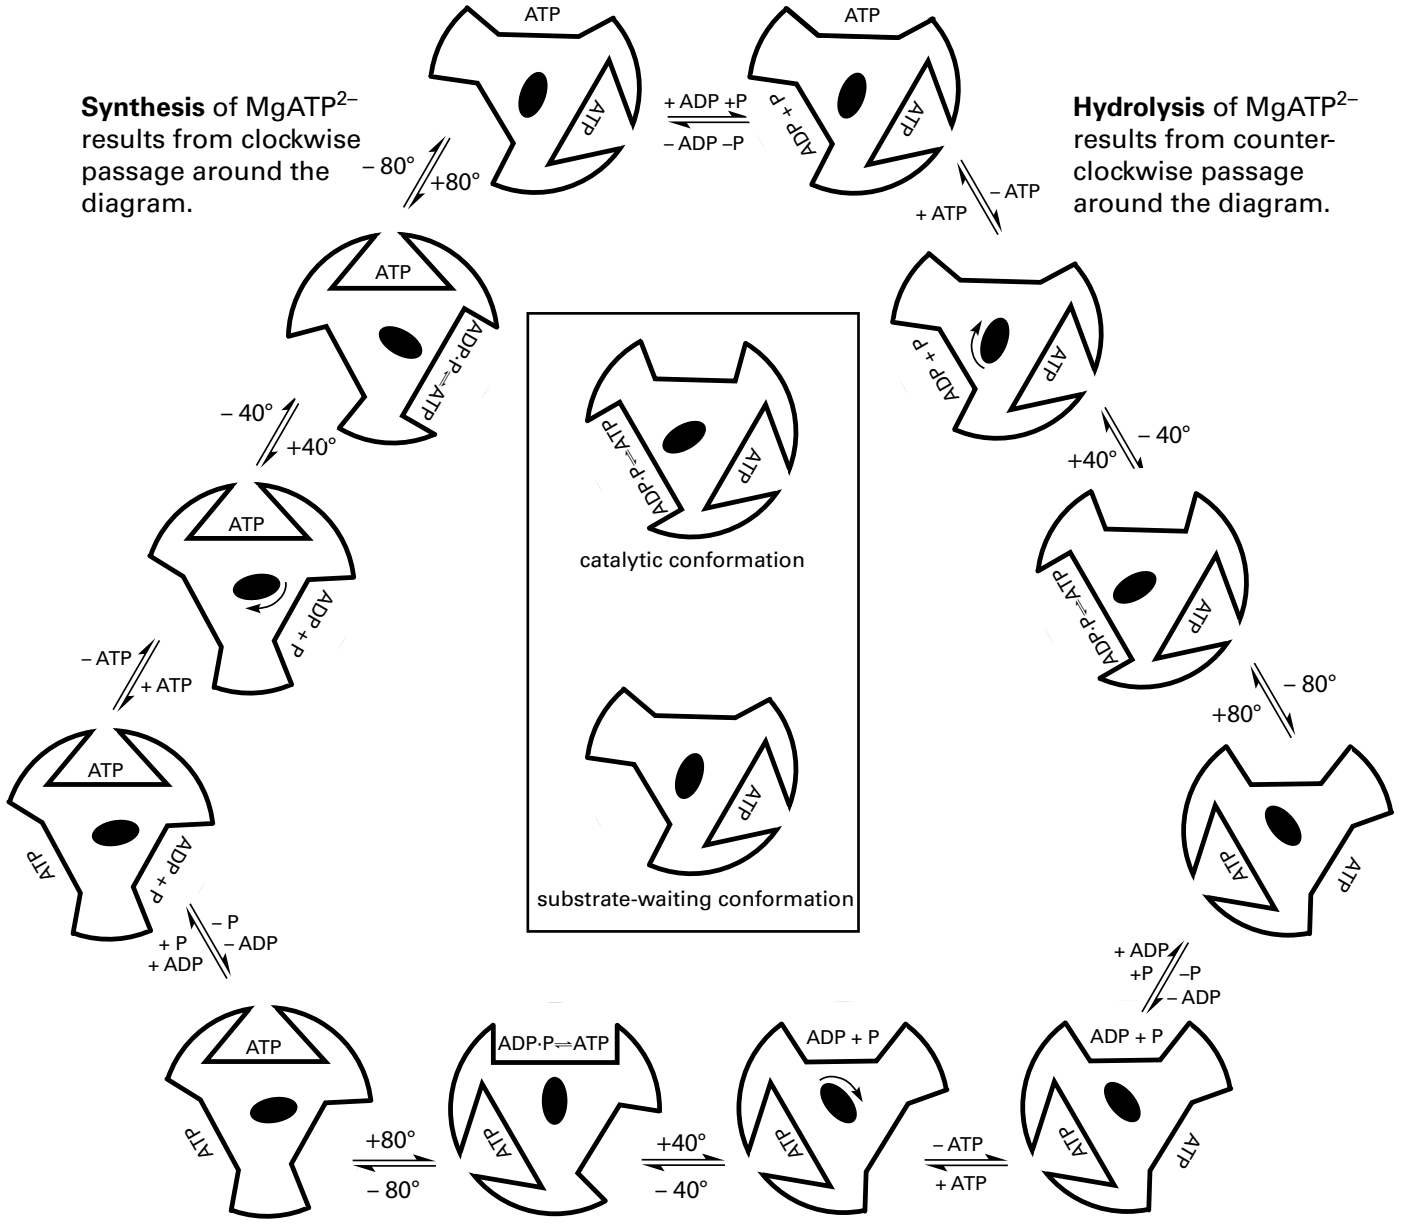

Figure 6–50: Revision of the diagram of Figure 6–45 to incorporate the properties of the intermediate conformation that, during hydrolysis of $MgATP^{2-}$, follows a discontinuous rotation of –80° and precedes a discontinuous rotation of –40° to complete a step of –120° (Figure 6–49). The diagramatic representations for each of the three conformations of the $\alpha\beta$ heterodimer in the two different global conformations are defined within the box in the center. In this diagram, the two intermediate rotations comprise the sides of the equilateral triangle with the catalytic global conformation observed in the crystallographic molecular model of Figure 6–42 in the center of each side. The quaternary conformations at the vertices are the intermediate conformations, the ATP-waiting conformations, from which the substrate $MgATP^{2-}$ dissociates in the direction of synthesis and associates in the direction of hydrolysis. The points in the sequence at which $MgADP^-$ and $HOPO_3^{2-}$ associate or dissociate, respectively, are not clear, so in the diagram, they are shown associating during the rotation of –80°, a choice for which there is some evidence.

consistent with the conclusion that **the conformation of the $(\alpha\beta)_3$ ring preceding the +80° step is different** from its crystallographic conformation.

All these observations suggest that there are two different global conformations of the $(\alpha\beta)_3$ ring in F_1-ATPase that are adopted while the enzyme is hydrolyzing $MgATP^{2-}$, or in reverse synthesizing $MgATP^{2-}$, rather than just the conformation observed crystallographically. These two conformations (Figure 6–50) are the catalytic conformation and the subtrate-waiting conformation. The crystallograph-

ically observed global conformation is the **catalytic global conformation**, the one preceding the counterclockwise step of +40° during hydrolysis of $MgATP^{2-}$**.** In this global conformation, a molecule of the reactant $MgATP^{2-}$ is protected within the active site of the $\alpha\beta$ heterodimer in the T conformation; the reactants, $MgATP^{2-}$ and the molecule of water, and the products, $MgADP^{-}$ and $HOPO_3^{2-}$, are coming to equilibrium within the active site of the $\alpha\beta$ heterodimer in the D conformation; and all the explanations of these two conformations in these two different β subunits drawn from the crystallographic molecular models are still valid. The second conformation, which results from the +40° rotation and precedes the +80° rotation during hydrolysis of $MgATP^{2-}$, is the **substrate-waiting global conformation**. The substrate-waiting global conformation is also intrinsically asymmetric, with asymmetry determined again by the γ subunit. In the substrate-waiting global conformation, in the direction of hydrolysis, one of the active sites in the $\alpha\beta$ heterodimer is open to the solution and waiting for association of $MgATP^{2-}$.

During hydrolysis, the catalytic global conformation is in a **catalytic dwell** until the reactants, $MgATP^{2-}$ and the molecule of water, and the products, $MgADP^{-}$ and $HOPO_3^{2-}$, reach equilibrium or at least until an instant in which the active site in the D conformation is occupied by the products of hydrolysis, $MgADP^{-}$ and $HOPO_3^{2-}$, at which point the counterclockwise rotation of +40° occurs. If these two conformations alternate while F_1-ATPase is hydrolyzing $MgATP^{2-}$, then they must also alternate while it is synthesizing $MgATP^{2-}$. If the rotation of +40° during hydrolysis is required to take place only when $MgADP^{-}$ and $HOPO_3^{2-}$ are occupying the $\alpha\beta$ heterodimer in the D conformation—so that they end up as products ready to dissociate from the same $\alpha\beta$ heterodimer in the open conformation produced by the rotation—then it follows, by microscopic reversibility, that the rotation of –40° during synthesis is required to take place only when $MgADP^{-}$ and $HOPO_3^{2-}$ are occupying an $\alpha\beta$ heterodimer in the same open conformation. Consequently, in the direction of synthesis, the essential purpose of this $\alpha\beta$ heterodimer in the open conformation within the substrate-waiting global conformation is to wait until the reactants $MgADP^{-}$ and $HOPO_3^{2-}$ associate and occupy their proper places before it converts to the D conformation within the catalytic global conformation.

While the magnitudes of fluorescence resonance energy transfer within the catalytic global conformation are consistent with the conclusion that it is the one observed crystallographically, the magnitudes of fluorescence resonance energy transfer within the substrate-waiting global conformation, which has not been observed crystallographically, provide some information about its structure. One of the active sites in an $\alpha\beta$ heterodimer is in a conformation that is indistinguishable by physical measurements from the T conformation in the crystallographic molecular model, and this active site is assumed to be occupied by a protected molecule of $MgATP^{2-}$. The other two active sites, although distinguishable in their resonance transfer, are about as open as the O conformation in the crystallographic molecular model, but in one of those, the interface between α and β subunits is even more open than in the O conformation.[436]

There is a problem with the original proposal for the synthesis of $MgATP^{2-}$ (Figure 6–45). There are **two essential discriminations** that H^+-transporting two-sector ATPase must make in order to synthesize $MgATP^{2-}$ by a conformational mechanism. First, the global conformation of the enzyme must change only when $MgATP^{2-}$ and the molecule of water are occupying the active site of the $\alpha\beta$ heterodimer in the D conformation in order to withdraw the molecule of water and enclose the $MgATP^{2-}$ in the T conformation. Second, the global conformation of the enzyme must change only when $MgADP^{-}$ and $HOPO_3^{2-}$ are occupying the site of the $\alpha\beta$ heterodimer in a conformation open to the solution to capture these two reactants in the D conformation. At both sites, the circumstances are changing rapidly. In the site in the D conformation, the equilibrium between $MgATP^{2-}$ and the molecule of water and $MgADP^{-}$ and $HOPO_3^{2-}$ is constantly interconverting the participants. Dissociations and associations of $MgADP^{-}$ and $HOPO_3^{2-}$ into and from solution are constantly proceeding at the open site with which they associate. It is unlikely that $MgATP^{2-}$ will be momentarily situated in the active site in the D conformation at the same time that $MgADP^{-}$ and $HOPO_3^{2-}$ will be momentarily situated in the site with which they associate.

The solution that natural selection seems to have chosen to this problem is to have two conformations that alternate with each other as the overall rotation proceeds. In the synthesis of $MgATP^{2-}$, when $MgADP^{-}$ and $HOPO_3^{2-}$ are occupying the open site in the substrate-waiting conformation, the –40° rotation occurs, trapping them in the active site of that same $\alpha\beta$ heterodimer in the D conformation. When the equilibrium between $MgADP^{-}$ and $HOPO_3^{2-}$ and $MgATP^{2-}$ and a molecule of water has

been established and at an instant when $MgATP^{2-}$ is occupying the catalytic site in the D conformation, the –80° rotation occurs, trapping the $MgATP^{2-}$ in the T conformation.

All these conclusions lead to a **revision of the earlier conformational explanation** for the synthesis of $MgATP^{2-}$. This revision (Figure 6–50)[436] attempts to assign the status of each active site and its occupants in each of the two conformations, but the overall strategy[363,394]—associating with only $MgADP^{-}$ and only $HOPO_3^{2-}$, setting them in equilibrium with each other, trapping and protecting the $MgATP^{2-}$ that has been formed before it can be unformed in this equilibrium, and opening to release the $MgATP^{2-}$ that was trapped into solution—has not been revised.

As before, during synthesis of $MgATP^{2-}$, in the catalytic global conformation a molecule of the product $MgATP^{2-}$ is at rest, withdrawn from the molecule of water, and protected within the active site of the $\alpha\beta$ heterodimer in the T conformation. The enzyme is waiting for the equilibrium within the active site of the $\alpha\beta$ heterodimer in the D conformation to be established between the reactants, $MgADP^{-}$ and $HOPO_3^{2-}$, and the products, $MgATP^{2-}$ and the molecule of water, and also waiting in the catalytic dwell for an instant in which it is occupied only by the products, $MgATP^{2-}$ and the molecule of water. In that instant, when only the products are present, the γsubunit rotates –80° to produce the also-asymmetric, substrate-waiting global conformation, in which the $MgATP^{2-}$ that was just formed and selected by the change in conformation is protected in the same $\alpha\beta$ heterodimer in a closed conformation that is indistinguishable by physical measurements from the T conformation within the catalytic global conformation. During hydrolysis of $MgATP^{2-}$, the substrate-waiting global conformation is the one with which the reactant $MgATP^{2-}$ associates. Microscopic reversibility requires that, during the synthesis of $MgATP^{2-}$, the substrate-waiting conformation is the one in which the $MgATP^{2-}$—formed and trapped in the preceding cycle and waiting in the $\alpha\beta$ heterodimer in the preceding T conformation within the catalytic global conformation—has now become untrapped. This $MgATP^{2-}$ finds itself in the same $\alpha\beta$ heterodimer that is now in an open conformation and dissociates.

The only way, however, to have the reactants $MgADP^{-}$ and $HOPO_3^{2-}$ associate with an open active site in the substrate-waiting global conformation and end up in the active site of the $\alpha\beta$ heterodimer in the D conformation within the catalytic global conformation after the rotation of –40° is for them to associate with the other open conformation within the substrate-waiting global conformation (Figure 6–50), not the one from which $MgATP^{2-}$ dissociates. It so happens that this other active site is the one that, preceding the rotation of –40°, was in the O conformation within the catalytic global conformation that is occupied by ADP^{3-} in several crystallographic molecular models. The conformation of the $\alpha\beta$ heterodimer in the O conformation within the catalytic global conformation may change very little upon the –80° rotation.*

There is no reason for association and dissociation of reactants and products in either the direction of synthesis or the direction of hydrolysis to occur in a special order because the two open active sites within the substrate-waiting conformation are on different $\alpha\beta$ heterodimers, and the physical measurements suggest that neither of them is the same as the one in the O conformation within the crytallographic molecular model of the catalytic global conformation. There are measurements of occupation of the active sites by nucleotides in the substrate-waiting conformation in the direction of hydrolysis that use a derivative of $MgATP^{2-}$ to which a fluorescent sulfoindocyanine dye has been covalently attached at the 3′-oxygen.[438] Measurements of fluorescence intensity indicate that this derivative associates with the substrate-waiting conformation when it is already occupied by two other nucleotides. These results imply that, in the direction of hydrolysis, the reactant $MgATP^{2-}$ associates before the product $MgADP^{-}$ dissociates. After association, the substrate-waiting complex has three nucleotides associated with it: the protected $MgATP^{2-}$, the just-bound $MgATP^{2-}$ in the $\alpha\beta$ heterodimer in one open conformation, and the product $MgADP^{-}$ in the $\alpha\beta$ heterodimer in the other open conformation. These observations are consistent with the conclusion that there must be an open site for $MgATP^{2-}$ and an open site for $MgADP^{-}$ in the substrate-waiting conformation. They are also consistent with the possibility of $MgADP^{-}$ associating with the active site of the $\alpha\beta$ heterodimer in the O conformation even before the rotation of –80° occurs. Other measurements, however, of the effects of the product $MgADP^{-}$ on rotation of the γsubunit during hydrolysis of $MgATP^{2-}$ are consistent with the conclusion that $MgADP^{-}$ must dissociate during or just prior to the conformational change between the substrate-waiting and catalytic global conformations.[439] Because of these observations, the order of

*In the drawing, a slight change was introduced in the region with which $HOPO_3^{2-}$ associates, although even that change may be unwarranted.

association and dissociation in Figure 6–50 was chosen even though it is not exclusive.

The maximum rate at which $MgATP^{2-}$ can be synthesized by bovine H^+-transporting two-sector ATPase[440] at 30 °C is 440 s^{-1}, which is the same as the maximum rate at which the enzyme hydrolyzes $MgATP^{2-}$ in the absence of a gradient of hydrons. The equivalence of these rates suggests that, when neither catalysis nor association nor dissociation of reactants is rate-limiting, the rotation of the γ subunit in each direction encounters equivalent barriers.

A molecular model of intact porcine H^+-transporting two-sector ATPase (Figure 6–51)[441] has been constructed from a map of electron-scattering density derived from image reconstruction of electron micrographs of molecules of the intact enzyme frozen in amorphous ice. Alignments of the sequences of amino acids for the known subunits of the porcine enzyme are 83%–99% identical to those of the bovine enzyme and contain no gaps, so the structures of the two intact enzymes must be essentially identical. In the molecular model, the shaft composed of the γ, δ, and ε subunits protruding from the $(\alpha\beta)_3$ ring of F_1-ATPase (Figure 6–42) is attached, through its flat top, to a **cylinder composed of eight c subunits** (Figure 6–52B).[441,442] There is a globular protein, formed from segments of nine of the subunits of the intact enzyme, completely within the membrane on one side of the cylinder of c subunits (Figure 6–52C). A coiled coil of α helices, beginning at the surface of the membrane, connects this globular protein within the membrane to the top of the $(\alpha\beta)_3$ ring of F_1-ATPase (Figure 6–51). The complete structure of H^+-transporting two-sector ATPase is one of the strangest structures of a protein that has been observed.

Each of the eight identical c subunits forming the cylinder is a **hairpin of two α helices**,[443] each one 20 amino acids long, arranged in such a way that one α helix in each c subunit is on the external surface of the cylinder and the other is in the interior of the cylinder. The eight c subunits are arrayed around an eightfold rotational axis of symmetry normal to the plane of the bilayer of phospholipids* forming the inner mitochondrial membrane.[442] There is a single α helix of unknown provenance with an unknown sequence of amino acids on this rotational axis of symmetry that plugs what would otherwise be a hole filled with a chain of molecules of water comprising a hydron wire. The rotational axis of symmetry of the cylinder of c subunits is coaxial with the rotational axis of pseudosymmetry in the center of the $(\alpha\beta)_3$ ring, on which axis sits the asymmetric α-helical doubly coiled coil of the γ subunit (Figures 6–42 and 6–43).

Subunit a of porcine H^+-transporting two-sector ATPase also spans the membrane (Figure 6–52A), and its entire folded polypeptide (226 aa) is within the membrane in the multisubunit globular protein, to the side of the cylinder of c subunits. Subunit a consists of seven, mostly hydrophobic, α helices of different lengths.[444] **Subunit a is flush against the cylinder of eight c subunits**, and two of its α helices come in intimate contact with four of the separate exterior α helices of four of the c subunits. The longest α helix, the fifth one in subunit a, even curves to fit flush against the cylinder (Figure 6–52B).[445-448]

The net **clockwise rotation of the cylinder of c subunits** past subunit a drives the rotation of the shaft of the γ subunit within the $(\alpha\beta)_3$ ring in F_1-ATPase during the synthesis of $MgATP^{2-}$. The $(\alpha\beta)_3$ ring of F_1-ATPase in turn is rigidly connected to subunit a by the coiled coil of α helices to prevent it from rotating relative to subunit a. This rotation of the cylinder of c subunits in concert with rotation of the γ subunit of F_1-ATPase has been directly observed[449-455] when intact H^+-transporting two-sector ATPase in a membrane is hydrolyzing $MgATP^{2-}$.

There are mutants of H^+-transporting two-sector ATPase in which a cystine has been introduced, crosslinking a c subunit to a segment of polypeptide in the globular protein within the membrane adjacent to the cylinder of c subunits (Figure 6–52C). These mutant enzymes are unable to transport hydrons into vesicles of membrane in which they had been incorporated when $MgATP^{2-}$ was added to the outside, but they are able to do so at the same rate as unmutated enzyme when the cystine is eliminated by thiol–disulfide exchange with 1,4-bis(sulfanyl)butane-2,3-diol.[456] This observation requires that the cylinder of c subunits rotate relative to the globular protein.

*Unlike a plasma membrane, which contains a significant concentration of cholesterol, the bilayer of the inner mitochondrial membrane is formed almost completely from phospholipids and also contains cardiolipin, a phospholipid unique to mitochondria.

Figure 6–51: Stereodrawing[485] of a molecular model of porcine H^+-transporting two-sector ATPase from a reconstruction of images in electron micrographs.[441] Mitochondria were obtained from a homogenate of fresh porcine hearts by differential centrifugation. These mitochondria were suspended in 75 mM sorbitol, 75 mM sucrose, 20 mM KCl, 5 mM $MgCl_2$, and 10 mM 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate at pH 7.5, and a mass of the detergent digitonin equal to 4 times the mass of the protein in the suspension was added to dissolve the mitochondria. Undissolved material was removed by centrifugation. H^+-Transporting two-sector ATPase was purified by centrifugation on a gradient of 0.4–2.0 M sucrose in a buffer containing 0.1% digitonin. Its location on the gradient was determined by electrophoresis on gels of poly(acrylamide) cast in a solution of dodecyl sulfate. The fractions collected from the gradient were concentrated and further purified by molecular-exclusion chromatography, again in a buffer containing 0.1% digitonin. Samples of an aqueous solution containing the purified enzyme were applied to grids for electron microscopy, and the grids were rapidly frozen to turn the thin film of solution into amorphous ice. High-resolution images of about 350,000 molecules of a tetrameric complex of H^+-transporting two-sector ATPase were chosen for further analysis, during which the most informative 114,103 particles were selected for the final reconstruction. The rotational orientation of each tetrameric complex was determined algorithmically, and from these assigned orientations and the individual images to which they were assigned, a three-dimensional map of electron-scattering density was computed to a nominal resolution of 0.44 nm. A crystallographic molecular model of bovine F_1-ATPase was inserted into the map of electron scattering density, and with molecular models of H^+-transporting two-sector ATPase from other species as guides, molecular models with sequences of amino acids for the polypeptides of known subunits in the porcine F_o sector were inserted into the map. Electron densities from several segments of polypeptide of unknown provenance that were left were filled with models of polypeptide backbone without side chains. The final model was then submitted to refinement. (**A**) Stereo line drawing of just the polypeptide backbones of the known subunits of the enzyme as well as the unknown segments in the final refined molecular model of porcine H^+-transporting two-sector ATPase. The $(\alpha\beta)_3\gamma$ portion of F_1-ATPase is drawn with thinner lines, and all the other polypeptide backbones, including the δ and ε subunits of F_1-ATPase, are drawn with thicker lines. The three noncatalytic sites on the $(\alpha\beta)_3$ heterohexamer are occupied by the usual molecules of $MgATP^{2-}$. The active sites in the D and T conformations are occupied by ADP^{3-}, which was included in the solution in which the enzyme was suspended when added to the grid. These five nucleotides are drawn in ball-and-stick format. Again, black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large dark gray atoms are atoms of phosphorus. (**B**) Cellular orientation of H^+-transporting two-sector ATPase and its position in the bilayer. The approximate location of the bilayer of phospholipids is indicated in a line drawing of the polypeptide backbones of the final molecular model, and the various parts of H^+-transporting two-sector ATPase are labeled as if it were an appliance for making $MgATP^{2-}$, driven by the shaft of a motor.

Figure 6–52: Stereodrawings[485] of portions of the complete molecular model of porcine H^+-transporting two-sector ATPase[441] drawn in Figure 6–51. (**A**) Stereo line drawing, viewed from within the plane of the membrane. The complete polypeptide backbones in the cylinder of the eight α-helical hairpins of the eight c subunits are drawn with thin lines. The lone α helix, of unknown provenance with an unknown sequence of amino acids, in the center of the cylinder and the complete polypeptide backbone of subunit a (to the right in the drawing) are drawn with thick lines. (**B**) Stereo line drawing, viewed from the positive, acidic side of the membrane. Participants and designations are the same as in Panel A but viewed from the upper side of the drawing in Panel A. (**C**) Stereo line drawing from within the plane of the membrane and including additional segments of polypeptide. The complete polypeptide backbones in the cylinder of the eight α-helical hairpins of the eight c subunits are drawn with thin lines. The lone α helix in its center and the complete polypeptide backbones from subunit a, subunit f, and subunit DAPIT; those segments of the polypeptides of subunit B1, subunit d, and protein 8 that are in the membrane; and the complete or partial polypeptide backbones of three unknown polypeptides observed in the map of electron scattering density are drawn with thick lines (to the right in the drawing). All these latter segments of polypeptide are within the membrane and form a compact globular protein.

When the connection between the cylinder of c subunits and the shaft of the γsubunit in H^+-transporting two-sector ATPase from *S. cerevisiae* is disrupted by eliminating the δ subunit by site-directed mutation, mitochondria containing the mutated enzyme could no longer synthesize $MgATP^{2-}$ and were also unable to maintain an electrochemical gradient of hydrons because a leak for hydrons is present where one was not before.[457] Presumably, the cylinder of c subunits, no longer connected to the shaft of the γsubunit and no longer experiencing significant resistance to rotation from the synthesis of $MgATP^{2-}$, simply rotates in a net clockwise direction at will, shuttling hydrons until the electrochemical gradient is dissipated while no $MgATP^{2-}$ can be synthesized.

Within the membrane, five stretches of polypeptide from five identified and sequenced subunits of porcine H^+-transporting two-sector ATPase and three stretches of polypeptide from three unknown and hence unsequenced subunits form the structure surrounding subunit a (Figure 6–52C). Together with the entire subunit a, they form the compact globular protein to one side of the cylinder of c subunits. The other segments of polypeptide in the globular protein firmly attach subunit a to the triply coiled coil of α helices that emerges from the membrane on its negative, basic side and connects to the $(\alpha\beta)_3$ ring of the F_1-ATPase, which is within the majority of the protein on the negative, basic side of the membrane. These other eight segments of polypeptide within the membrane also act as **booms to push the bilayer of phospholipid away** from the extensive interface between subunit a and the ring of eight c subunits so that the two opposite edges of this interface are in unimpeded contact with solutions on the positive, acidic side and the negative, basic side of the membrane.

The majority of the surface of the cylinder of c subunits—those portions not in contact with subunit a and the other segments of polypeptide, in particular the majority of its midsection—is immersed within the hydrocarbon in the center of the bilayer of phospholipids, as if it were dissolved in clear machine oil bounded by the phosphoglyceroyl head groups on either side of the bilayer at its top and bottom.

The carboxy group of each Glutamic Acid 58, located on the outer α helix of each of the eight c subunits, carries one of the hydrons flowing across the membrane. Related by the eightfold rotational axis of symmetry, each Glutamate 58 around the exterior of the cylinder is located in the middle of an outer α helix and in the very middle of the membrane. During the rotation of the cylinder past subunit a, each carboxylato group of the eight Glutamates 58 in turn is loaded with a hydron from the solution on the positive, acidic side of the membrane, and then that hydron is unloaded by dissociation into the solution on the negative, basic side of the membrane. Consequently a complete rotation of the cylinder of c subunits can be divided into a number of identical steps equal to the number of c subunits in the ring. In the case of porcine H^+-transporting two-sector ATPase there are eight steps, each involving a -45° clockwise rotation of the cylinder during the synthesis of $MgATP^{2-}$.

When hydrons pass across the membrane from the solution on the positive, acidic side to the solution on the negative, basic side of the membrane during the synthesis of $MgATP^{2-}$, while the cylinder turns in a net clockwise direction relative to the position of subunit a, they pass across the interface between subunit a and the exterior α helices of the cylinder of c subunits (Figures 6–52A,B). In the middle of its journey, each hydron is carried on a Glutamate 58 as a neutral carboxy group, rotating through the hydrocarbon of the membrane. The hydron cannot dissociate in this solvent, so it remains on the carboxy group. Between the single subunit a and the cylinder of c subunits, there are **two half channels**, one between the solution on the positive, acidic side of the membrane and a location in the center of the membrane that is accessible to the carboxy group on a Glutamate 58 and the other between the solution on the negative, basic side of the membrane and a different, but nearby, location in the center of the membrane that is also accessible to a Glutamate 58.[458] Each channel is a gap in the interface between subunit a and the cylinder of c subunits.[357,441,459-467]

In porcine H^+-transporting two-sector ATPase during the synthesis of $MgATP^{2-}$, a hydron from the solution on the positive, acidic side of the membrane enters the interface between subunit a and the c subunits (Figure 6–53A).[441] There is a fairly **wide gap in the interface lined with hydrophilic side chains** from Threonines 161 and 165, Asparagine 163, and Glutamine 97 in subunit a that connects the positive, acidic solution to the space between the guanidinio group of Arginine 159 in subunit a and the carboxylato group of Glutamate 58B in the c subunit labeled B in Figure 6–53 when it is in position to accept a hydron (Figure 6–53A).

Figure 6–53: Stereodrawings[485] of the half channel in the gap on the positive, acidic side of the membrane where transfer of a hydron to the carboxylato group of a Glutamate 58 in the cylinder of c subunits occurs during synthesis of $MgATP^{2-}$. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. The drawing shows a portion of the molecular model of porcine H^+-transporting two-sector ATPase[441] drawn in Figure 6–51 that includes the interface between subunit a and the cylinder of c subunits in which the gap that forms the channel from the positive, acidic solution is located. The segments of subunit a that line the gap forming the half channel (Isoleucine 10–Proline 18, Asparagine 83–Isoleucine 106, Isoleucine 147–Leucine 170, and Threonine 200–Serine 219) are drawn, to the right in each panel of the figure. Glutamine 97, Threonine 161, Asparagine 163, and Threonine 165, the hydrophilic side chains of which are located in the wall of the channel, are labeled. During synthesis of $MgATP^{2-}$, hydrons pass through the enzyme from the positive, acidic solution to the negative, basic solution. (**A**) Segments of two external α helices, on the positive, acidic half of the cylinder c subunits (in both cases Glycine 53–Phenylalanine 73), labeled A and B. The point at which a hydron is transferred to Glutamate 58B in the α helix of c subunit B is thought to be adjacent to Arginine 159, at the bottom of the channel and at the end of a hydron wire. It is also thought that the side chain of Glutamate 58B rotates around its β carbon–γ carbon bond to approach the guanidino group more closely before the hydron in the half channel from the positive, acidic side associates with the carboxylato group. Glutamic Acid 58A in the α helix of c subunit B is moving toward the hydrocarbon of the bilayer. (**B**) Coordinates of the molecular model for the same segments from c subunits A and B, submitted to a clockwise rotation of –20° around the axis of symmetry running through the cylinder of c subunits. Rotation of the cylinder was perfomed before the respective atoms in those segments were added to the drawing. The segments of subunit a, however, were drawn in the same orientation as in the drawing in Panel A. The clockwise rotation of –20° moves the carboxy group of Glutamic Acid 58B away from the gap to the positive, acidic side of the membrane, but only when it is the conjugate acid carrying the hydron. Glutamic Acid 58A in in the α helix of c subunit A has entered the hydrocarbon of the bilayer. (**C**) Coordinates of the molecular model for the segments of c subunit, submitted to a further clockwise rotation of –25° to complete a full step of –45°. The drawing is the same as that in Panel A, with the exception that the labels of the α helices were changed from A to B and from B to C because, upon completion of a –45° step, Glutamate 58C in the α helix of c subunit C has rotated into the loading zone for a hydron in the same position that Glutamate 58B in the α helix of c subunit B did in Panel A, and the α helix of c subunit B occupies the same position that the α helix of c subunit A did in Panel A. In this drawing, Glutamate 58C has arrived at the point at which a hydron in the half channel from the positive, acidic side is transferred to its carboxylato group. In Panel B, Glutamic Acid 58C in the α helix of c subunit C was in the unloading zone in the bottom of the channel from the negative, basic side of the membrane and its hydron had to dissociate into that channel before the rotation of –25° could occur, bringing it into the loading zone for a hydron from the positive, acidic side of the membrane. The curved arrows in Panels A and B indicate clockwise rotations. The curved arrow in Panel C, which indicates a counterclockwise rotation of the cylinder +20° in reverse, emphasizes the equilibrium between the rotational orientations, in this case returning Glutamate 58C to the channel from the negative, basic side of the membrane.

Figure 6–54: Stereodrawings[485] of the half channel in the gap on the negative, basic side of the membrane where transfer of a hydron from the carboxy group of a Glutamatic Acid 58 in the cylinder of c subunits occurs during synthesis of $MgATP^{2-}$. Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. The drawing shows a portion of the molecular model of porcine H^+-transporting two-sector ATPase[441] that includes the interface between subunit a and the cylinder of c subunits in which the gap that forms the channel from the negative, basic solution is located. Each panel is a drawing of a portion of the same molecular model, portions of which are drawn in Figure 6–53, but it is viewed from the opposite side of the membrane. The segments of subunit a that line the gap forming the half channel (Leucine 49–Leucine 75, Methionine 100–Phenylalanine 114, Threonine 123–Leucine 160, and Leucine 208–Aspartate 224) are drawn, again to the right in each panel of the figure. Histidine 127, Glutamate 145, and Glutamine 152, the hydrophilic side chains of which are located in the wall of the channel, are labeled. (**A**) Segments of three external α helices, on the negative, basic half of the cylinder c subunits (in all three cases Leucine 46–Leucine 62) with the same labels, A, B and C, used in Figure 6–53. As in Figure 6–53A, a hydron in the gap on the positive, acidic side is associating with the carboxylato group of Glutamate 58B, and Glutamatic Acid 58A is on its way into the hydrocarbon as it was before. (**B**) Coordinates of the molecular model for the same segments from c subunits B and C, submitted to a clockwise rotation of –20° around the axis of symmetry running through the cylinder of c subunits. Recall that a clockwise rotation appears to be a counterclockwise rotation from this vantage point. The α helix from c subunit A has departed into the hydrocarbon. The segments of subunit a, however, are drawn in the same orientation as in the drawing in Panel A. The point at which hydrons dissociate from the carboxy groups of Glutamic Acids 58 is adjacent to Serine 148, at the bottom of the gap. Arginine 159 is also labeled to show the bottom of the half channel from the positive, acidic side of the membrane relative to the bottom of the half channel from the negative, basic solution. The carboxy group of Glutamic Acid 58C in c subunit C, counterclockwise to the α helix in c subunit B, has just completed its transit of the hydrocarbon. The clockwise rotation of –20° has brought this carboxy group into alignment with Serine 148, where its hydron dissociates. The clockwise rotation of –20° moves the carboxy group of Glutamic Acid 58B away from the gap to the positive, acidic side of the membrane on its way into the hydrocarbon. Glutamic Acid 58A has entered the hydrocarbon of the bilayer. (**C**) Coordinates of the molecular model for the segments of c subunit, submitted to a further clockwise rotation of –25° to complete a full step of –45°. The drawing is the same as that in Panel A, with the exception that the labels of the α helices were changed from A to B and from B to C, and the α helix of c subunit D, which has just entered from the hydrocarbon and is not yet in the unloading zone for its hydron, has been added. Glutamate 58C, from which a hydron dissociated in Panel B, has arrived at the point at which a hydron in the half channel from the positive, acidic side associates with its carboxylato group. The curved arrows in Panels A and B indicate the respective clockwise rotations. The curved arrow in Panel C, which indicates a counterclockwise rotation of the cylinder +20° in reverse, emphasizes the equilibrium between the rotational orientations, in this case returning Glutamate 58C to the channel from the negative, basic side of the membrane. Between the two orientations in this equilibrium, Glutamate 58C passes through a gap of 25°. Within this gap, it must remain unhydronated.

The empty space in the molecular model between the van der Waals surfaces of the carboxyato group of Glutamate 58B and the guanidinio group of Arginine 159 is about 0.3 nm wide. The resolution of the model of porcine H^+-transporting two-sector ATPase derived from image reconstruction from electron micrographs is insufficient to observe **fixed molecules of water**, but the space between these two side chains must contain at least one molecule of water, forming a hydrogen bond to the carboxylato group or a hydrogen bond to the guanidinio group or bridging them. In a higher-resolution molecular model from image reconstruction of electron micrographs of H^+-transporting two-sector ATPase from *Polytomella*,[462] a molecule of water can be observed forming a hydrogen bond to the guanidinio group of the homologous arginine in subunit a (28% identity; 2.2 gap percent).

Because there is no significant empty space in a molecule of protein, the entire hydrophilic gap in the interface between subunit a and two adjacent c subunits (labeled A and B in Figure 6–53A) must also contain molecules of water, some fixed in place by donors and acceptors for hydrogen bonds on the side chains of Threonines 161 and 165, Asparagine 163, and Glutamine 97 as well as the amido groups of the polypeptide backbone. There must also be some disordered molecules of water in less confined regions within the gap. Presumably the fixed molecules of water and the hydroxy groups on Threonines 161 and 165 provide a **hydron wire** through which the **hydron moves from the intrusion of the positive, acidic solution into the gap** to the carboxylato group of Glutamate 58B in the middle of the external α helix in c subunit B (Figure 6–53A).

During the synthesis of $MgATP^{2-}$, once the carboxylato group of Glutamate 58B has been hydronated, the cylinder, and hence its α helix, rotates clockwise to remove the now-neutral carboxy group of Glutamic Acid 58B from the hydron wire (Figure 6–53B) on its way around the circle through the hydrocarbon of the phospholipids to the half channel opening to the negative, basic solution. After a further rotation of –25°, the unhydronated carboxylato group of Glutamate 58C in the α helix in c subunit C (Figure 6–53C), on the counterclockwise side of the c subunit B, arrives at the hydron wire from the positive, acidic solution and the delivery of a hydron is repeated to begin the next step.

After the hydron from the positive, acidic surface has associated with Glutamate 58B (Figure 6–53A) and the cylinder has rotated in a clockwise direction by only about –20° (the –20° rotation from Panel A to Panel B in Figure 6–53 is the same as the –20° rotation from Panel A to Panel B in Figure 6–54 but viewed from the other side of the membrane), a hydron dissociates from the carboxy group of Glutamic Acid 58C to the counterclockwise side of c subunit B. At this point, Glutamic Acid 58C has just completed its circumnavigation through the hydrocarbon carrying its hydron. That hydron then passes into the negative, basic solution on the other side of the membrane through a fairly wide gap in the interface between subunit a and the cylinder of c subunits (Figure 6–54B).[441] This gap is about +25° counterclockwise from the gap on the positive, acidic side, and it is lined with hydrophilic side chains from Histidine 127, Glutamate 145, and Glutamine 152 in subunit a. When Glutamate 58C arrives from the hydrocarbon, this gap connects the negative, basic solution to the space between the carboxy group of Glutamic Acid 58C and the hydroxy group of Serine 148 in subunit a (Figure 6–54B). The space between Serine 148 and Glutamic Acid 58C probably contains one or more fixed molecules of water. The entire gap between subunit a and two adjacent c subunits (those labeled B and C in Figure 6–54B) must also contain molecules of water, some fixed in place by donors and acceptors for hydrogen bonds on the side chains of Histidine 127, Glutamate 145, and Glutamine 152 as well as the amido groups of the polypeptide backbone and some in disordered regions.

Presumably the fixed molecules of water and the carboxy group of Glutamic Acid 145 from subunit a provide a hydron wire through which the hydron moves from the carboxy group of Glutamic Acid 58C **into the intrusion of the negative, basic solution into the gap**, and hence into the solution on the negative, basic side. In the higher-resolution molecular model of H^+-transporting two-sector ATPase from *Polytomella*, single molecules of water and pairs of molecules of water can be observed in this gap, and some of these molecules of water are probably participants in a hydron wire,[462] the complete structure of which is not resolved. In the portion of subunit a in H^+-transporting two-sector ATPase from *T. thermophilus* that is structurally homologous to subunit a in the porcine enzyme, the hydrophilic side chains projecting into this gap on the negative, basic side of the membrane, organizing the molecules of water, and participating in the hydron wire are more numerous and their alignment is more exact.[463]

During the synthesis of $MgATP^{2-}$, after the hydron dissociates from the carboxy group on Glutamic Acid 58C, the now-carboxylato group on Glutamate 58C rotates about –25° with the cylinder in the clockwise direction (Figure 6–54B,C) to arrive next to Arginine 159 at the bottom of the gap in the interface between the cylinder of c subunits and subunit a that opens to the positive, acidic side to begin the next step.

To couple the clockwise rotation of the cylinder of c subunits to the movement of hydrons down the electrochemical gradient from the positive, acidic solution to the negative, basic solution with complete stoichiometry and hence maximum efficiency, the –335° clockwise rotation between the half channel from the positive, acidic solution and the half channel to the negative, basic solution must proceed only when the carboxy group of Glutamic Acid 58 has been hydronated, and the hydron cannot dissociate between the the two half channels. In addition, the –25° clockwise rotation between the half channel to the negative, basic solution and the half channel from the positive, acidic solution must proceed only when the carboxylato group of Glutamate 58 has been unhydronated, and it must remain unhydronated. If these requirements are completely satisfied, then **the movement of each hydron from the positive, acidic solution to the negative, basic solution is coupled stoichiometrically to a clockwise rotation of 45° by the cylinder of c subunits.**[468,469]

The requirement that the carboxy group of Glutamic Acid 58 remain hydronated during the clockwise rotation between the channels is satisfied by the hydrocarbon, which provides an ingenious solution to keeping it hydronated over an arc of about –335°. More critically, however, the requirement that the clockwise rotation of only about –25° between the two channels (Figure 6–54B,C) must proceed only when the carboxylato group of Glutamate 58 has been unhydronated and the requirement that it must remain unhydronated are far more difficult to achieve because it must move through an interface between two subunits of the protein. Furthermore, because all these rotations are reversible, the movement through this small gap may actually reverse several times before proceeding forward. When the carboxylato group of Glutamate 58 returns to the gap leading to the negative, basic solution during a momentary reversal, it must also traverse the intervening space unhydrated, or an unproductive hydron leak from the positive, acidic side to the negative, basic side would occur.

Consequently, the key to accomplishing the proper stoichiometry for the clockwise and counterclockwise rotations of 25° between the negative, basic half channel on the one side of the membrane and the positive, acidic half channel on the other is the properties of the **short gap between the two half channels.** This gap sits between the channel to the negative, basic solution, at which a hydron dissociates from Glutamic Acid 58 when it is adjacent to Serine 148 on subunit a (Figure 6–54B), and the channel to the positive, acidic solution, at which a hydron associates with the same Glutamate 58 when it is adjacent to Arginine 159 on subunit a (Figure 6–54C). Every time one of the Glutamic Acids 58 moves through that gap in a clockwise or counterclockwise direction as the hydronated conjugate acid, the free energy that must be captured from the electrochemical gradient of hydrons by H^+-transporting two-sector ATPase is lost. How the protein within this short gap solves this requirement is still unclear and may require elucidation of the exact positions of the side chains and the fixed molecules of water present in that short gap. Nevertheless, the structure of this short gap must have been under significant selective presure.

For H^+-transporting two-sector ATPase to function properly, subunit a must be affixed to the $(\alpha\beta)_3$ ring so that, every time the cylinder of c subunits completes a full revolution past subunit a within the membrane, the shaft of the γ subunit completes a full revolution within the $(\alpha\beta)_3$ ring. When the cylinder of c subunits in intact H^+-transporting two-sector ATPase from *E. coli* was attached firmly to a glass coverslip and filaments of actin were attached either to a β subunit or to subunit a, the respective filaments rotated at the same rate, and the rates at which they rotated changed in concert as the viscous drag was increased.[450] This observation is consistent with the β subunit and subunit a being connected tightly together within H^+-transporting two-sector ATPase. This connection is achieved by the triply coiled coil of α helices.

All H^+-transporting two-sector ATPases have an $(\alpha\beta)_3$ ring, a $\gamma\delta\varepsilon$ shaft, a rotationally symmetric ring of c subunits, and subunit a or its equivalent, and each is homologous in its sequence of amino acids, or at the least structurally homologous, to its respective siblings in the various species of animals, plants, fungi, and bacteria.[358] The **segments of H^+-transporting two-sector ATPase that connect subunit a to the $(\alpha\beta)_3$ ring**, however, differ among animals, plants, fungi, and bacteria. In the case of

porcine H^+-transporting two-sector ATPase (Figure 6–51), the connection is made by a triply coiled coil of α helices anchored at one end in the globular protein within the membrane containing subunit a and at the other end entwined within a structure formed from subunit O and affixed tightly to the $(\alpha\beta)_3$ ring. In H^+-transporting two-sector ATPase from *Polytomella*, the connection is made by a much wider, kinked rope of five and sometimes six α helices along its length and some strands of random meander.[462] Regardless of the differences among the different species, a connection is made[445,446,448,470-474] with one or two separate α-helical coiled coils providing straps and various subunits, which differ among species, gluing these straps to the $(\alpha\beta)_3$ ring.

In addition to the differences in the number and identity of subunits forming the connection between subunit a and the $(\alpha\beta)_3$ ring among the H^+-transporting two-sector ATPases from different species is the difference in the **number of c subunits in the cylindrical ring**.[442] Bovine and porcine H^+-transporting two-sector ATPase have 8 c subunits in the ring,[442] the enzyme from *S. cerevisiae* has 10 c subunits in the ring,[475] the enzyme from *E. coli* also has 10 c subunits in the ring,[476] the enzyme from *S. oleracea* has 14 c subunits in the ring,[477] Na^+-transporting two-sector ATPase from *Ilyobacter tartaricus* has the equivalent of 11 c subunits in the ring,[478,479] and Na^+-transporting two-sector ATPase from *Enterococcus hirae* has the equivalent of 10 c subunits in the ring.[480] The number of c subunits in the cylinder from Na^+-transporting two-sector ATPase from *I. tartaricus* can be varied from 10 to 15 by site-directed mutation without affecting its function.[481] Although this relation has not been accurately validated, it usually is assumed[442] that the ratio between the number of hydrons transported down the electrochemical gradient and the number of $MgATP^{2-}$ synthesized, when the enzyme is operating at maximum efficiency and stoichiometry, is simply the ratio between the number of c subunits in the cylinder for a particular species divided by the number of active sites (3). Nothing, however, operates at maximum efficiency.

The strange aspect of this ratio is that it is usually not an integer, as it would be if the number of c subunits were usually 9 or 12.* The rotational offsets for the steps in the two distant and independent rotors are not the same as they would be if there were only 3 c subunits in the cylinder to match the 3 subunits the $(\alpha\beta)_3$ ring, or if there were 9 c subunits in the cylinder to match the alternating rotations of 80° and 40° of the γ subunit. It has been assumed that the mismatch between the number of c subunits and the number of active sites in F_1-ATPase requires that either the connection between subunit a and the $(\alpha\beta)_3$ ring or the connection between the ring of c subunits and the shaft of the γ subunit in H^+-transporting two-sector ATPase be **flexible enough to permit effective coordination** between steps in rotation of the cylinder of c subunits relative to subunit a and steps in the rotation of the γ subunit within the $(\alpha\beta)_3$ ring. Were the connection absolutely rigid, neither rotor could proceed through its steps because of the mismatch in their stoichiometry. Nevertheless, the coiled coils and their attachments ensure that every complete rotation of the cylinder of c subunits over the course of several complete rotations is always accompanied by the same number of complete rotations of the γ subunit within the $(\alpha\beta)_3$ ring.

Various global conformations of H^+-transporting two-sector ATPase from *Polytomella* have been observed in image reconstructions of electron micrographs. In the molecular models derived from these reconstructions, the connection between the $(\alpha\beta)_3$ ring and the strap of the coiled coil has flexed to accommodate different rotational orientations of the cylinder of c subunits relative to the rotational orientation of the $(\alpha\beta)_3$ ring. The only difference among these global conformations seems to be these relative rotational orientations. It has been proposed that these different global conformations permit the necessary coordination between the rotary motions.[462]

A different conclusion was reached when the stiffness of the connections between subunit a and the $(\alpha\beta)_3$ ring and the stiffness of the connection between the cylinder of c subunits and the shaft of the γ subunit were measured. Actin filaments or magnetic beads were attached to either the cylinder of c subunits or the globular structure within the membrane containing subunit a in wild-type H^+-transporting two-sector ATPase from *E. coli* or mutants of the enzyme in which cystines crosslink the γ subunit to a β subunit or a c subunit to subunit a. When these variously modified H^+-transporting two-sector ATPases were attached through the surface of their F_1-ATPase opposite the shaft of the γ subunit (Figure 6–48), measurements of the torque required to rotate the bead magnetically or the observed displacements of the bead or the filament of actin caused by random Brownian displacements for each

*This lack of an integral relationship defied expectations, much as the fact that the number of amino acids in a complete turn of a helix formed by a polypeptide defied expectations.[482]

modified form of enzyme could be used to determine the stiffness of either the connection between subunit a and the $(\alpha\beta)_3$ ring or the connection between the cylinder of c subunits and the shaft of the γsubunit. Counterintuitively, it was concluded that the stiffness between subunit a and the $(\alpha\beta)_3$ ring was about 10 times greater than the stiffness between the cylinder of c subunits and the shaft of the γsubunit and that the flexions required to coordinate the rotary motions of the γsubunit and those of the c subunit occur mostly in the connection between the cylinder of c subunits and the shaft of the γsubunit,[453,483] an interface that seems upon inspection to be rather inflexible (Figure 6–51).

In contradiction to this conclusion that the flexions occur in the connection between the cylinder of c subunits and the shaft of the γsubunit, when cystines were introduced in turn between several of the subunits that form the interfaces in the $\gamma\delta\varepsilon c_{12}$ rotor in H^+-transporting two-sector ATPase from *E. coli*, no effect was observed on the ability of each mutated and stitched enzyme to transport hydrons into vesicles into which it was incorporated or to synthesize $MgATP^{2-}$ when a large enough gradient of hydrons was established across the membranes of the vesicles.[484]

The temptation to compare H^+-transporting two-sector ATPase to an electrical appliance in which the shaft of a motor drives machinery accomplishing its purpose has been irresistible (Figure 6–51B). The $(\alpha\beta)_3$ ring of F_1-ATPase accomplishes the purpose of the appliance, that of synthesizing $MgATP^{2-}$. The $\gamma\delta\varepsilon$ shaft connects this machinery to the motor that turns the shaft. The motor is not the usual induction motor of an electric appliance, but a motor that employs a current directly without magnetic induction. The cylinder of c subunits is most analogous to a commutator ring in an induction motor and subunit a to one of its brushes. The subunits that grasp the $(\alpha\beta)_3$ ring, the α-helical coiled coils, and the segments of polypeptide surrounding subunit a in the membrane together form a rigid housing that ensures that the brush and the machinery accomplishing the purpose of the appliance are firmly fixed in a constant orientation as the shaft turns.

Given this irresistible impulse, much attention has been devoted to mechanical explanations of how the free energy in the electrochemical gradient of hydrons is converted stereochemically into the conformational changes that are responsible for the synthesis of $MgATP^{2-}$. As was the case with Na^+/K^+-exchanging ATPase, however, the only relevant chemical fact is that when eight hydrons, one after the other, move through the cylinder of c subunits in porcine H^+-transporting two-sector ATPase from the positive, acidic solution to the negative, basic solution, three molecules of $MgATP^{2-}$ are produced from three molecules of $MgADP^-$ and three molecules of $HOPO_3^{2-}$ by F_1-ATPase. If this **coupling is effectively enforced** and there is a sufficient electrochemical gradient of hydrons from the positive, acidic solution to the negative, basic solution, it necessarily follows that the equilibrium in Equation 6–132 will be in favor of the synthesis of $MgATP^{2-}$.

This consideration brings up another point that often seems to be ignored. As is the case with all enzymes, H^+-transporting two-sector ATPase catalyzes its reaction in both directions and every step is a reversible step. Although throughout this discussion preference has been given to the direction of the reaction in which $MgATP^{2-}$ is synthesized, this preference is personal and only due to the fact that this synthesis is what the enzyme usually does. The enzyme, however, also catalyzes hydrolysis of $MgATP^{2-}$, and the net direction of the reaction in a given set of circumstances depends on the change in situational free energy for Equation 6–132 under those circumstance. It follows that any molecular explanation of the role of any of the catalytic functional groups that implies that it assists the reaction in only one direction should be read with the fact that the reaction is reversible always in mind. The basis of microscopic reversibility is that any effect that lowers the standard free energy of a transition state increases the rate in each direction of the equilibrium governed by that transition state.

One is left with the impression that H^+-transporting two-sector ATPase, the source of most of the $MgATP^{2-}$ responsible for all the kinetic energy in living organisms, is one of the most bizarre enzymes in the collection, and a fit place to conclude this disquisition. The question of how it works seems to have been answered. The question of how it came to exist in the first place may never be answered.

Glossary

Acid Acidic hydron and the atom to which it is attached.

Acid dissociation constant Equilibrium constant that relates the concentration of hydronium ion and the concentration of the conjugate base of an acid to the concentration of the acid.

Activator Ligand that binds to an enzyme and forms a dead-end complex that has a greater rate of catalysis than normal.

Active site Unique location on the surface or in the interior of one of the subunits in an enzyme molecule where the reaction catalyzed by that enzyme takes place.

Active-site label Reagent that has been designed to associate specifically, noncovalently, and in a defined orientation within the active site of a particular enzyme at the location normally occupied by a substrate and then modify covalently a particular catalytic acid–base or particular side chain that participates in association of a substrate with the active site.

Active transport of hydrons Movement of hydrons against an electrochemical gradient through the portion of an enzyme that spans the membrane, which requires that there be a continuous path for the hydrons to follow from one side of the enzyme to the other and a physical mechanism to couple the expenditure of energy, in the form of a favorable oxidation–reduction or the hydrolysis of $MgATP^{2-}$, to the unfavorable transport of the hydrons. See also *formal transport of hydrons*.

Actual reactant Reactant in an enzymatic reaction that is formed nonenzymatically from a compound originally thought to be the reactant.

Acyl oxidation state Oxidation state for a carbon that has three bonds, either σ bonds or a mixture of σ bonds and π bonds, to heteroatoms and only one σ bond to carbon or hydrogen. See *oxidation states of carbon*.

Adair equation One of two equations that are used to fit sigmoid behavior and that involve no explanation for sigmoid behavior. See also *Hill equation*, *Monod–Wyman–Changeux equation*, and *sigmoid behavior*.

Additional substrate Substrate that is not part of the formal stoichiometric equation for an enzymatic reaction because it is regenerated during the reaction but that must be present in solution for the enzymatic reaction to occur.

Affinity label Compound that contains a reactive center and that is designed to resemble the substrate of an enzyme or ligand for a protein so closely that it will bind specifically to the active site or binding site, and while it is bound the reactive center will covalently modify an amino acid in or near the site.

Agonist Ligand that binds to a protein and, upon binding, produces a measurable change in the characteristic physiological function of that protein.

Aldol condensation Nucleophilic addition of the α carbon of an enolate or enamine to a carbonyl group or imine to form a carbon–carbon bond and give an alcohol or amine.

Alkyl migration Transfer of an alkyl group, usually intramolecularly and often between two adjacent atoms (as in a 1,2-alkyl migration), during the course of a molecular rearrangement. See also *hydride migration*.

Allosteric constant Constant for the equilibrium between two conformations of an enzyme or protein that displays allosteric behavior. See also *conditional allosteric constant* and *fundamental allosteric constant*.

Allosteric effect Indirect interaction between distinct, spatially separated sites on a protein during which the conformation of the protein is altered by association of a ligand at one or more of the sites, causing a change at one or more of the other sites. See also *heterotropic allosteric effect* and *homotropic allosteric effect*.

Amphipathic molecule Extended molecule that has a hydrophilic region, usually one end, and a hydrophobic region, usually the other end.

Antagonist Ligand that binds to a protein and blocks the ability of an agonist to accomplish its normal function.

Antenna Large structure in a photosystem the prosthetic chromophores of which are responsible for absorbing photons of incident light and in which the resulting electronic excitation, an exciton, is transferring to the special pair of the reaction center.

Anti elimination Elimination in which the leaving group and the hydron or electrophile dissociate on opposite sides of a plane containing the carbons in a carbon–carbon bond to which they are attached. See also *syn elimination*.

Antiperiplanar conformation Arrangement in which two periplanar substituents of interest are oriented at a dihedral angle of $180^\circ \pm 30^\circ$ from one another. See also *synperiplanar conformation*.

Antiperiplanar push Push exerted by a lone pair of electrons in the antiperiplanar conformation to a leaving group. See also *synperiplanar push*.

Apical position Position of the substituents or ligands in a trigonal bipyramid that are collinear or almost collinear with the central atom above and below an equatorial plane, or the position in a pyramidal arrangement that is at or near the apex of the pyramid. See also *equatorial position*.

Apparent rate constant Rate constant in a rate equation that is not a function of the concentration of a reactant but that varies as the concentration of another reactant is varied.

Aromatic transition state Transition state in which there is a continuous, conjugated ring of atoms with atomic orbitals, each of which overlaps in sequence around the ring with its two nearest neighbors, so that they together form a complete cyclic molecular orbital system containing $4n + 2$ electrons.

Associative exchange Mechanism for the exchange of ligands to a metallic cation in which the entering ligand associates with the metallic cation, expanding its coordination, and then the leaving ligand dissociates. See also *dissociative exchange*.

Associative nucleophilic substitution Nucleophilic substitution that proceeds through a tetrahedral intermediate, in which the bond between the electrophile and the nucleophile has fully formed before the bond between the leaving group and the electrophile begins to break. See also *concerted nucleophilic substitution* and *dissociative nucleophilic substitution*.

Base Basic lone pair of electrons and the atom with which it is associated.

Bifurcation of two electrons Situation in which the two electrons of a two-electron reductant are required to travel singly through two different paths of electron transfer or, in reverse, two electrons that have traveled singly through two different paths are combined and transferred together to a two-electron oxidant.

Bilin Linear tetrapyrrole, derived ultimately from heme *b*, that is extensively conjugated and is one of the prosthetic chromophores found in certain antennae of photosystems.

Biochemical standard reduction potential, $E^{\circ\prime}$ Reduction potential, relative to a standard hydrogen electrode, observed when the two members of the redox couple are present at equal activity at a pH of 7.

Bisubstrate analogue Molecule composed of portions from two reactants for an enzyme.

Bond dissociation energy Enthalpy (kilojoules mole^{-1}) required to break the bond homolytically between a hydrogen and the rest of the particular molecule to form a radical, regardless of whether or not that radical was formed by the abstraction of a hydrogen.

Bond order Theoretical index of the degree of bonding between two atoms relative to that of a single bond containing a localized electron pair, which is equal to the often nonintegral difference between the population of electrons in bonding orbitals and the population in antibonding orbitals in the region between the two atoms, divided by 2.

Brønsted coefficient, β Slope of a linear Brønsted plot.

Brønsted coefficient for leaving groups, β_{lg} Slope of a linear Brønsted plot in which rate constants and pK_a values for conjugate acids of the leaving groups are plotted.

Brønsted coefficient for nucleophiles, β_{nuc} Slope of a linear Brønsted plot in which the common logarithms of rate constants for a set of nucleophiles participating in the same nucleophilic substitution are plotted as a function of the values for pK_a of the respective nucleophiles.

Brønsted correlation Any correlation between the common logarithms of a set of rate constants or equilibrium constants for the members of a set of interchangeable participants in a particular reaction—be they reactants, products, or catalysts—and the values of pK_a for the respective participants or for their conjugate acids, corrected for the number of acidic hydrons and basic lone pairs of electrons on the participating atom.

Brønsted plot Graph of a Brønsted correlation in which the common logarithms of a set of equilibrium constants or rate constants are plotted against the respective values of corrected pK_a for the chosen participant or its conjugate acid.

Brønsted relation for general acid–base catalysis Function that relates the rate constants or common logarithms of the rate constants for general acid catalysis to the acid dissociation constants or values of pK_a for the catalysts or that relates the rate constants or common logarithms of the rate constants for general base catalysis to the acid dissociation constants or values of pK_a for the conjugate acids of the catalysts.

Burst of product Rapid appearance of an amount of product equal to the molar concentration of active sites in the solution that can be distinguished kinetically from the much slower accumulation of product that follows the burst and proceeds at the normal steady-state rate.

Cage Complex of molecules of solvent that surrounds two molecules, which entered the cage from solution or formed during a dissociation, and hinders their separation by diffusion.

Cage effect Association of two molecules in a solution within a cage of solvent that permits the molecules to undergo a series of collisions within the cage in quick succession, each known as an encounter.

Caged reactant Photolabile derivative of the reactant for an enzyme that is catalytically inactive but that decomposes upon photolysis to produce the catalytically active reactant.

Captodative effect Effect on the stability of a carbon-centered radical determined by the combined action of an electron-withdrawing substituent (a captor) and an electron-releasing substituent (a dator), both attached to the radical center.

Carbanionic intermediate Diamagnetic, noncovalent intermediate that forms in an active site when a hydron or another electrophile dissociates heterolytically from a carbon in a reactant—usually a carbon adjacent to a carbonyl, imino, or acyl group—and that dissociation produces a carbanion or that forms when a nucleophile associates heterolytically with a carbon in a reactant—usually a carbon conjugated to a carbonyl, imino, or acyl carbon—and that association produces a carbanion.

Carbenium ion Carbocation containing a carbon atom with three substituents and a vacant *p* atomic orbital, generated when the leaving group dissociates from an electrophilic carbon before the nucleophile enters the reaction and having the hybridization *p*, sp^2, sp^2, sp^2 because of electron repulsion among the three occupied molecular orbitals of the three σ bonds to the substituents.

Carbocationic intermediate Diamagnetic, noncovalent intermediate that forms in an active site when a leaving group dissociates heterolytically from a carbon in a reactant and that dissociation produces a carbocation or that forms when a hydron or another electrophile associates heterolytically with carbon in a reactant and that addition produces a carbocation.

Carbonato oxidation state Oxidation state for a carbon that is entirely bonded to heteroatoms. See *oxidation states of carbon*.

μ-Carbonmonoxy group Carbon monoxide that bridges two or more metallic ions and participates in each of the coordinations of those metallic ions.

Carbonyl oxidation state Oxidation state for a carbon that has two σ bonds to either carbon or hydrogen and either two single σ bonds to heteroatoms or a σ bond and a π bond, the two components of a double bond, to a heteroatom. See *oxidation states of carbon*.

Carotenoid Tetraterpenoid formally derived from lycopene that contains 40 carbon atoms and a linear conjugated π molecular orbital system of 22 or 30 carbon atoms that is all trans and fairly rigid throughout its length and that is one of the prosthetic groups in a photosystem responsible for absorption of a photon and transfer of the resulting electronic excitation to the special pair.

Catalytic constant, k_0 Observed rate constant, which is apparently first-order with respect to the total molar concentration of active sites and zero-order with respect to reactants, for the enzymatic reaction at high concentrations of all reactants or at extrapolated infinite concentrations.

Catalytic immunoglobulin Immunoglobulin that is raised against an analogue for either a transition state or an intermediate of high energy in a particular chemical reaction and that, because it binds the corresponding transition state or intermediate of high energy tightly, catalyzes the corresponding reaction.

Channeling efficiency Percentage of initial reactant that is converted to final product intramolecularly within a multienzymatic complex relative to the total amount of initial reactant converted to final product both intramolecularly, by passing from one active site to the next within a molecule of the complex, and intermolecularly, by passing through the solution between active sites on different molecules of the complex.

Charge-transfer complex Complex between a reductant (the electron donor) and an oxidant (the electron acceptor) formed in a reversible equilibrium and characterized by an electronic transition to an excited state in which electronic charge is transferred from the donor to the acceptor.

Chemical gradient Gradient in chemical potential established when the molar concentration of uncharged substance A is greater on one side of a biological membrane than on the other side. See also *electric gradient, electrochemical gradient,* and *gradient*.

Chlorophyll Derivative of a pheophytin in which Mg^{2+} is coordinated in the center of the aromatic ring by lone pairs of electrons from the four central nitrogens.

Chloroplast Organelle in plant cells that is responsible for absorbing light and producing a reductant of low potential, that is descended from a photosynthetic bacterium, and that has an outer membrane corresponding to the plasma membrane of the ancestral photosynthetic bacterial cell within which there are thylakoids descended from chromatophores in the ancestral bacterium.

Chromatography by size exclusion Method that can be used to determine the binding of a ligand to a protein in which the protein is passed through a column of beaded, tightly crosslinked dextran that has been equilibrated with a solution containing a fixed concentration of ligand, and the protein binds ligand as it passes through the beaded dextran until the binding reaches equilibrium.

Chromatophore Cellular structure in a photosynthetic bacterium, either an invagination of the plasma membrane or a separate vesicle in the cytoplasm the interior of which is, or is derived from, the extracytoplasmic solution.

Claisen condensation Substitution of the α carbon of an enolate or enamine for a leaving group, usually an alcohol, amine, or thiolate, at the acyl carbon of the respective derivative of a carboxylic acid to give a carbonyl or the derivative of a carbonyl.

Cobalamin Prosthetic group that contains a coordinated cobalt ion to which four of the ligands are lone pairs of electrons from the four central nitrogens in a corrinoid ring.

Coenzyme Cofactor that is a small molecule relative to the enzyme itself, that associates with and dissociates from the enzyme during each turnover, either at the active site or at another site specific to the coenzyme, and that transfers chemical groups, hydrogens, or electrons among active sites. See also *cofactor* and *prosthetic group*.

Cofactor Any ion, usually a metallic cation, or any organic molecule that is required by an enzyme for its function. See also *coenzyme* and *prosthetic group*.

Col Lowest of all barriers of potential energy along all the paths between reactant and product on a surface of potential energy through which passes the reaction coordinate and, as at a pass in the mountains, at which the curvature is positive along the coordinate perpendicular to the reaction coordinate along which the curvature is negative.

Colligation Formation of a covalent bond by the combination or recombination of two radicals.

Commitment forward, c_f Ratio between the forward elementary rate constant for a specific step in the mechanism of an enzymatically catalyzed reaction and the composite rate constant for the reversal of the reaction from the form of the enzyme immediately preceding this specific step to the point at which the reactant of interest has been released back into the solution.

Commitment in reverse, c_r Ratio between the reverse elementary rate constant for a specific step in the mechanism of an enzymatically catalyzed reaction and the composite rate constant for forward flux from the form of the enzyme immediately following this step through the first kinetically irreversible step in the mechanism.

Competitive inhibition Inhibition produced by a competitive reversible inhibitor. See also *mixed inhibition*, *noncompetitive inhibition*, and *uncompetitive inhibition*.

Competitive reversible inhibitor with respect to reactant A Reversible inhibitor the addition of which to the solution decreases the observed value of the specificity constant or apparent specificity constant for reactant A while having no effect on the value of the catalytic constant or apparent catalytic constant for that reactant.

Complete kinetic mechanism Kinetic mechanism for a chemical reaction that includes explicitly every elementary step in that reaction and no steps other than elementary steps.

Composite acid–base Network of simple acid–bases, connected by hydrogen bonds, that has several tautomers in equilibrium with each other and from which hydrons can dissociate and associate at the periphery, often accompanied by shifts in the hydrons in the hydrogen bonds of the network.

Composite rate constant Rate constant for a composite reaction, or a step in a kinetic mechanism that is a composite reaction, that can be expressed as a combination of several elementary rate constants for the several constituent elementary steps. It is sometimes called net rate constant. See also *elementary rate constant*.

Composite reaction Chemical reaction, or step in the proposed kinetic mechanism for a reaction, for which the expression for the rate involves rate constants of more than a single elementary reaction and which proceeds through more than one transition state. See also *elementary reaction*.

Concerted elimination–addition Elimination–addition reaction in which there is no carbanionic or carbocationic intermediate because the bond between the one carbon and the leaving group is breaking or forming in concert with the breaking or forming of the bond between the other carbon and the electrophile or hydron in an elementary reaction.

Concerted nucleophilic substitution Nucleophilic substitution in which there is no intermediate because the bond between the leaving group and the electrophile is breaking as the bond between the electrophile and the nucleophile is forming in an elementary reaction. See also *associative nucleophilic substitution* and *dissociative nucleophilic substitution*.

Conditional allosteric constant Allosteric constant for an enzyme in the presence of saturating concentrations of one or more of its ligands. See also *allosteric constant* and *fundamental allosteric constant*.

H conformation Inhibited conformation of an enzyme from which a heterotropic allosteric inhibitor has the smaller dissociation constant. See also *V conformation*.

R conformation Conformation of a protein or enzyme that predominates when a ligand or substrate, the behavior of which is being examined and which displays cooperativity in its association with the protein, is present at saturating concentrations and often only when an allosteric activator or cosubstrate is present. See also *T conformation*.

T conformation Conformation of a protein or enzyme that predominates when a ligand or substrate, the behavior of which is being examined and which displays cooperativity in its association with the protein, is absent and often only when an allosteric inhibitor or cosubstrate is present. See also *R conformation*.

V conformation Activated conformation of an enzyme from which a heterotropic allosteric activator has the smaller dissociation constant. See also *H conformation*.

Conformational selection Sequence of events in which a conformational change occurs in the free enzyme before substrates can associate with the active site. See also *induced fit*.

Conservation of enzyme Principle that the total molar concentration of active sites, which is usually a known quantity but that always remains constant throughout the reaction, must be equal to the sum of the concentrations of all forms of the active site.

Cooperativity Allosteric interaction between two or more identical sites, usually but not always active sites, on an oligomeric protein in which the association of a ligand or substrate at one or more of the sites induces conformational changes in the remaining unoccupied sites, leading to an increase in the affinity of those sites for their ligand or substrate—or an increase in the limiting rate of the remaining active sites—and typically producing sigmoid behavior. See also *sigmoid behavior*.

Corrinoid A macrocyclic tetrapyrrole derived from the porphyrin uroporphyrinogen III in which two of the pyrrolyl groups in the macrocycle are partly reduced and the four pyrrolyl groups are joined by three methine groups and one direct carbon–carbon bond linking their α positions.

Covalent intermediate Intermediate in an enzymatic reaction in which the enzyme itself and the other atoms participating in the intermediate are covalently attached to each other.

Covalent prosthetic intermediate Intermediate in an enzymatic reaction in which the other atoms participating in the intermediate that are derived from the reactants are covalently attached to a prosthetic group that is itself covalently or noncovalently attached to the active site.

Cyclic voltammetry Procedure that can be used to determine the biochemical standard reduction potential of a prosthetic group that participates in a redox couple.

Cycloaddition Pericyclic reaction in which a total of $(2n + 1)$ double bonds from two unsaturated molecules, or two parts of the same unsaturated molecule, participate to produce a cyclic adduct in which the number of π bonds has decreased by two and the number of σ bonds has increased by two, namely, the two σ bonds creating the cyclic adduct.

Cytochrome Visibly colored protein that contains one or more hemes as prosthetic groups and that acts as an electron-transferring coenzyme.

Dead-end inhibition Situation in which a reversible inhibitor forms a complex with an enzyme, either occupied or unoccupied by substrates, that is unable to engage in any further reaction while the inhibitor is bound.

Dead time Interval between the time of mixing and the time at which the flow has ceased completely in an apparatus for stopped flow, during which no observation of changes can be made.

Deshielding Shift of electrons away from the observed nucleus that decreases the shielding those electrons would normally provide.

Desolvation Process during which the layer of solvation surrounding a molecule is stripped away.

Deuterium kinetic isotope effect Change in a rate constant produced by substitution of a deuterium for a protium in a reactant.

Diamagnetic, noncovalent intermediate Intermediate in an enzymatic reaction that forms within the active site, that is noncovalently associated with the active site, and in which all electrons are paired in atomic and molecular orbitals.

Diastereotopic faces Two faces of a trigonal atom with three different functional groups where addition to that atom of a functional group different from the other three would form one of a pair of diastereomers. See also *enantiotopic faces* and *stereoheterotopic faces*.

Diastereotopic functional groups Two identical functional groups on a prochiral atom where replacement of one of the two with a functional group different from the other two on the same atom would form one of a pair of diastereomers. See also *enantiotopic functional groups* and *stereoheterotopic functional groups*.

Diels–Alder reaction Cycloaddition in which four atoms in two adjacent, conjugated double bonds (the diene) form a cyclohexene by combining with a double bond (the dienophile) elsewhere in the same molecule or in another molecule.

Disproportionation Reaction in which two identical molecules are converted to two different molecules and, in a special case, two identical molecules at the same intermediate oxidation state are converted to one molecule at a higher oxidation state and one molecule at a lower oxidation state.

Dissociative exchange Mechanism for the exchange of ligands to a metallic cation in which the leaving ligand dissociates from the metallic cation, contracting its coordination, and then the entering ligand occupies the open site of coordination. See also *associative exchange*.

Dissociative nucleophilic substitution Nucleophilic substitution in which the bond between the leaving group and the electrophile is completely broken before the bond between the electrophile and the nucleophile begins to form and which necessarily involves an intermediate. See also *associative nucleophilic substitution* and *concerted nucleophilic substitution*.

Distributive reaction Situation in which an active site catalyzes a reaction within a particular segment of a linear homopolymer—be it a cleavage of the polymer beyond that segment, the addition of a new segment to that segment, or simply a chemical alteration of that segment—by associating from solution before and dissociating into the solution after the catalytic event within that segment. See also *processive reaction*.

Donnan effect Effect that causes a ligand that is charged to be depleted or enriched in the diffuse layer of dissolved counterions around the protein and that, consequently, decreases or increases, respectively, the measured concentration of bound ligand in the compartment containing the protein.

Double kinetic isotope effect Change in a primary kinetic isotope effect associated with the overall enzymatic reaction that is brought about by substituting a heavier isotope at another position in the molecule at which another bond is formed or broken.

Electric gradient Gradient in electric potential established when the molar concentration of ionically charged substance A is greater on one side of a biological membrane than on the other side. See also *chemical gradient, electrochemical gradient,* and *gradient*.

Electrochemical gradient Gradient in chemical activity of a substance, caused by the combination of chemical and electric gradients. See also *chemical gradient, electric gradient,* and *gradient*.

Electrochemical gradient of hydrons Sum of the free energy stored in the electric potential and the free energy stored in the difference in the concentration of hydrons (the gradient of hydrons) across a membrane.

Electrocyclic reaction Pericyclic reaction in which a σ bond is formed between the termini of a fully conjugated linear π molecular orbital system containing three (or $2n + 3$) π bonds among six (or $4n + 6$) atoms that become a ring with two (or $2n + 2$) π bonds and the σ bond connecting the former termini and in which the number of π bonds has decreased by one and the number of σ bonds has increased by one.

Electron-donating substituent Group that donates electron density to an adjacent atom or π molecular orbital system that is more electron-deficient than the donor.

Electron repulsion Positive, unfavorable free energy that results from overlap between filled orbitals.

Electron-withdrawing substituent Group that withdraws electron density from an adjacent atom or π molecular orbital system that is less electron-deficient.

Electronic matrix element, H_{AB} Term that quantifies the coupling of the electronic state of the donor of an electron with the electronic state of the acceptor of an electron in an outer-sphere electron transfer when both are in the configuration of the transition state. See also *Marcus equation*.

Electrophilic aromatic addition Addition of an electrophile to a carbon in an electron-rich and nucleophilic aromatic system to form a cationic adduct between the electrophile and an atom in the aromatic ring.

Electrophilic aromatic substitution Electrophilic aromatic addition followed by the dissociation of another electrophile from the resulting adduct, usually (but not always) from the same carbon to which the first electrophile added, with the result that one electrophile replaces another electrophile.

Electrostatic catalysis Enhancement of the rate of a reaction that results from the electrostatic field created by the formal elementary charge of one or several nearby functional groups.

Elementary rate constant Rate constant for an elementary reaction. See also *composite rate constant*.

Elementary reaction Reaction for which no reaction intermediates have been detected or need to be postulated in order to describe the chemical reaction on a molecular scale, which occurs in a single step, and which passes through only a single transition state. See also *composite reaction*.

Elimination–addition Reaction in which an acid or electrophile and a base or nucleophile are removed from two adjacent carbons or two carbons separated by one or more double bonds to produce a double bond or an additional double bond, or a reaction in which an acid or electrophile and a base or nucleophile are added to a carbon–carbon double bond or the two ends of a conjugated set of double bonds.

Enamine Vinylic amine, which is the conjugate base resulting from removal of a hydron from the carbon atom α to an iminium.

Enantiotopic faces Two opposite faces of a trigonal atom with three different achiral functional groups where addition to that atom of an achiral functional group different from the other three would form one of a pair of enantiomers. See also *diastereotopic faces* and *stereoheterotopic faces*.

Enantiotopic functional groups Two identical functional groups on a prochiral tetrahedral atom where replacement of one of the two with an achiral functional group different from the other two on the same atom would form one of a pair of enantiomers. See also *diastereotopic functional groups* and *stereoheterotopic functional groups*.

Encounter complex Complex of all the necessary molecular participants in the transition state for the production of an intermediate or product, which have been assembled together at an encounter-controlled rate; most of the time, the participants dissociate before a transition state forms, except in the case of an encounter-controlled reaction.

Encounter-controlled bimolecular rate constant Rate constant for a reaction in which every encounter between the two reactants results in product; also referred to as the "diffusion-controlled rate constant".

Endergonic Description of a reaction for which the overall standard Gibbs energy change ΔG° is positive. See also *exergonic* and *isoergonic*.

End-product inhibition Situation where one or several end products of a metabolic pathway inhibit the first committed reaction in that pathway. See also *first committed reaction*.

Ene reaction Pericyclic reaction in which the distal atom in the double bond adjacent to an allylic hydrogen adds to an atom in a second double bond unconjugated to the first, either in another molecule or within the same molecule, to form a new σ bond while the allylic hydrogen is transferred to the other atom in the second double bond so that the number of π bonds has decreased by one and the number of σ bonds has increased by one during the transfer of the hydrogen.

Enethiolate Vinylic thiolate, which is the conjugate base resulting from removal of a hydron from the carbon atom α to a thiocarbonyl.

Enol tautomer Vinylic tautomer of a ketone, aldehyde, ketimine, aldimine, or acyl derivative in which there is a hydron on the oxygen, nitrogen, or sulfur and a double bond between the carbonyl or acyl carbon and the carbon adjacent to it, and that is the conjugate acid of an enolate. See also *keto tautomer*.

Enolate Conjugate base of a ketone or aldehyde from which the acidic hydrogen on carbon adjacent to the carbonyl group has dissociated.

Enzyme Molecule of protein that acts as a catalyst for a particular chemical reaction by forming a molecular complex with the reactant or reactants and that increases the rate of the reaction, catalyzes only one specific reaction type, operates on only a limited or exclusive set of substrates, controls the regiospecificity of the reaction, and is specific to only one of the enantiomers or diastereomers of its substrates.

Equatorial position Position of the three substituents or ligands in a trigonal bipyramid or the four ligands in a pyramidal arrangement coplanar or almost coplanar with the central atom. See also *apical position*.

Equilibrium dialysis Method that can be used to determine the binding of a ligand to a protein in which the protein is placed on one side of a semipermeable membrane that separates two compartments, ligand is added to both compartments, the system is allowed to reach equilibrium, and the concentration of protein on the one side and the concentrations of the ligand on the two sides are then measured.

Equilibrium isotope effect Change in the equilibrium constant for a reaction produced by isotopic substitution at an atom in the reactant and product.

Equilibrium-ordered mechanism Kinetic mechanism in which it is proposed that the association of reactants is ordered and each association of a reactant is at equilibrium.

Equilibrium-random mechanism Kinetic mechanism in which it is proposed that the association of reactants is random and each association of a reactant is at equilibrium.

Evolutionarily shifting domains Domains that are homologous, either in amino acid sequence or because their crystallographic molecular models are superposable, and appear at different locations in the polypeptides of apparently unrelated proteins.

Exciton Electronic excitation treated as if it were a quasi-particle capable of migrating through a network of chromophores.

Exergonic Description of a reaction for which the overall standard Gibbs energy change ΔG° is negative. See also *endergonic* and *isoergonic*.

Expanded kinetic mechanism Kinetic mechanism for a chemical reaction that expands one or more of the steps in a kinetic mechanism to include additional steps.

Extradiol dioxygenase One of a family of enzymes that can dioxygenate an ortho or para dihydroxyphenyl or aminohydroxyphenyl group to turn it into the respective 6-oxohexa-2,4-dienoate by oxidatively cleaving the carbon–carbon bond adjacent to one of the hydroxy groups but not the carbon–carbon bond between two vicinal ortho hydroxy groups. See also *intradiol dioxygenase*.

Final product Product that dissociates from the active site for the last reaction in a sequence of successive reactions catalyzed by a multienzymatic complex. See also *initial reactant* and *intermediate substrate*.

First committed reaction Earliest step in any metabolic pathway in which a metabolite is produced that can only be used in that pathway. See also *end-product inhibition*.

Fixed molecule of water Molecule of water that has a fixed location in a map of electron density because, at any given instant, that site in the crystal is occupied by a molecule of water.

Fixed reactant Reactant that is held at a constant concentration in a series of experiments to determine the initial rate of an enzymatic reaction. See also *varied reactant*.

Flavin Coenzyme that can be either free in solution or a tightly bound prosthetic group; that has, as its catalytically active portion, a 7,8-dimethylisoalloxazine substituted at nitrogen 10; and that has three stable oxidation states differing sequentially by two one-electron steps between oxidized flavin, flavin semiquinone (a radical), and reduced flavin.

Flavoenzyme Enzyme with a flavin prosthetic group that is either covalently bound or tightly bound noncovalently.

Fluorescent reporter Functional group incorporated into an enzyme that can register, by changes in its fluorescence, changes occurring in the active site as reactants associate and are converted into intermediates.

Formal transport of hydrons Appearance of hydrons in the solution on one side of a membrane, resulting from their dissociation during the oxidation of one or more prosthetic groups on that side of the membrane, and disappearance of an equal number of hydrons from the solution on the other side of the membrane, resulting from their association during the reduction of one or more prosthetic groups on that side of the membrane. See also *active transport of hydrons*.

Fractionation factor Theoretically calculated or observed primary equilibrium isotope effect for transfer of a hydrogen from a particular position in a particular molecule to a reference molecule.

Franck–Condon principle Principle that an electronic transition is most likely to occur without changes in the positions of the nuclei in the molecular entity and its environment or, in other words, that the position and momentum of all nuclei in a system be the same before and after the transfer of an electron.

Free energy change, ΔG, for an oxidation–reduction Change in free energy resulting from the difference between the reduction potential of the redox couple of oxidized reactant and its reduced product in an oxidation–reduction reaction and the reduction potential of the redox couple of reduced reactant and its oxidized product.

Fundamental allosteric constant Allosteric constant for an enzyme in the absence of any of its ligands. See also *allosteric constant* and *conditional allosteric constant*.

Gap percent Number of gaps for every 100 positions that have to be added to obtain the greatest percent identity in two sequences of amino acids being aligned. See also *percent identity*.

General acid–base catalysis Increase in the rate of a reaction due only to an increase in the concentration of an added acid–base.

General acid catalysis Increase in the rate of a reaction due only to an increase in the concentration of the conjugate acid of an added acid–base, which may include hydronium ion and which is expressed as a rate constant multiplied by the concentration of the conjugate acid.

General base catalysis Increase in the rate of a reaction due only to an increase in the concentration of the conjugate base of an added acid–base, which may include hydroxide ion and which is expressed as a rate constant multiplied by the concentration of the conjugate base.

General redox couple Widely used cytoplasmic redox couple—such as NAD^+ and NADH, ubiquinone and ubiquinol, oxidized and reduced electron-transfer flavoprotein, or oxidized and reduced ferredoxin—that participates in an enzymatically catalyzed oxidation–reduction and that connects the particular reaction catalyzed by the enzyme to the overall reduction potential at which the cytoplasm is poised. See also *nominal redox couple*.

Gradient Change in a quantity—such as temperature, electric potential, or the concentration or chemical activity of a substance—with distance, expressed as a ratio or differential ratio of the quantity. See also *chemical gradient*, *electric gradient*, and *electrochemical gradient*.

Haber–Bosch process Industrial method for converting N_2 to NH_4^+ that uses a catalyst produced from a dust of magnetite (Fe_2O_3) that has been partially reduced to form a layer of ferrous oxide surrounded by a layer of porous metallic iron.

Half-reaction Oxidation or reduction of one of the two redox couples that together make up an oxidation–reduction.

Hammond postulate Principle that the transition state between a reactant or reactants and an intermediate of high energy should resemble the intermediate more closely than the reactant or reactants.

Heme Prosthetic complex, surrounded by protein, formed between an octahedrally coordinated iron ion and a porphyrin the four central nitrogens of which act as a tetradentate ligand providing four equatorial lone pairs of electrons as ligands to the iron ion, and the two axial ligands, which are opposite each other across the iron, are provided by the protein, the solvent, or solutes in the solution.

Heme P450 Prosthetic heme that is found in a group of monooxygenases that catalyze several different types of oxidations and that, upon association with carbon monoxide, displays a characteristic absorption at 450 nm in its difference spectra, caused by the presence of a thiolate in an axial position of the heme.

Heterolysis Cleavage of a covalent bond so that both bonding electrons remain with one of the two fragments between which the bond is broken. See also *homolysis*.

Heterolytic reaction Reaction in the mechanism of which covalent bonds are broken by heterolysis or, when bonds are formed, both electrons forming each bond arrive on the same reactant. See also *homolytic reaction*.

Heterotropic allosteric effect Allosteric effect that occurs when the interacting sites bind different ligands. See also *allosteric effect* and *homotropic allosteric effect*.

Heterotropic allosteric effector Ligand that acts by associating with a protein or enzyme at a site different from a site for binding another ligand or an active site and altering association of ligands or substrates with this other site or its steady-state kinetics.

High-potential [4Fe–4S] iron–sulfur cluster Iron–sulfur cluster that participates in the oxidation–reduction between the monoanionic and dianionic states and for which the standard reduction potential lies between 0 and +500 mV.

High-spin state State of the ion of a transition metal in which its $3d$ electrons are distributed so that as many of the $3d$ orbitals as possible, even if they are not degenerate because of the effects of the ligands, contain unpaired electrons of the same spin as dictated by Hund's rule.

High-valent state Formal oxidation state of a transition metal ion that is more positive than the oxidation states of that ion that are usually encountered.

Hill coefficient Slope of a plot of log $[Y\,(1 - Y)^{-1}]$ against log [L], for ligand or substrate L, where Y can be either occupancy or fraction of limiting velocity, which serves as a semiquantitative measure of the degree of cooperativity.

Hill equation One of two equations that are used to fit sigmoid behavior and that involve no explanation for sigmoid behavior. See also *Adair equation, Monod–Wyman–Changeux equation,* and *sigmoid behavior*.

Homolysis Cleavage of a bond so that each of the molecular fragments between which the bond is broken retains one of the bonding electrons. See also *heterolysis*.

Homolytic reaction Reaction in the mechanism of which covalent bonds are broken by homolysis or formed by colligation. See also *heterolytic reaction*.

Homotropic allosteric effect Allosteric effect that occurs when two or more interacting sites are composed of the same respective amino acids within two or more constituent subunits, each formed from a folded polypeptide of the same sequence, and consequently associate with the same ligand or set of ligands. See also *allosteric effect* and *heterotropic allosteric effect*.

Hydride migration Transfer of a hydrogen (formally a hydride), usually intramolecularly and often between two adjacent atoms (as in a 1,2-hydride migration), during the course of a molecular rearrangement. See also *alkyl migration*.

Hydron General name to be used without regard to the nuclear mass of the hydrogen entity, either for hydrogen in its natural abundance or where it is not desired to distinguish between the isotopes. See also *proton*.

Hydron motive force Difference in the free energy of a hydron between the two sides of a cellular membrane across which there is an electrochemical gradient of hydrons.

Hydron wire Chain of hydrogen bonds into one end of which a hydron enters and out of the other end of which a hydron emerges or out of one end of which a hydron is removed and into the other end of which a hydron enters.

Hydronium ion Species unavoidably present in aqueous solution that is composed of one hydron and either four molecules of water ($H_9O_4^+$), six molecules of water ($H_{13}O_6^+$), or 21 molecules of water ($H_{43}O_{21}^+$) in some fluctuating combination for which the mean number of waters is unknown.

Hydrophobic effect Decrease in standard free energy that results from the removal of hydrogen–carbon bonds from contact with water.

Hydroxide ion Species unavoidably present in aqueous solution that can be considered as a hydron hole, shared among the central oxygen and three, or perhaps more, of its nearest neighbors of water, in which there is one hydron fewer than two hydrogens for every oxygen.

α-Hydroxy enamine Enamine in which the nitrogen of thiamine diphosphate participates, that is formed when an electrophile dissociates from the adduct between thiamine diphosphate and an aldehyde or ketone, and that is basic and nucleophilic at its α carbon because of the electron excess usually provided at such a carbon by an enamine.

Hyperconjugation Interaction of the two electrons in a σ bond with the lowest unoccupied molecular orbital (LUMO) or a partially occupied molecular orbital of an adjacent π molecular orbital system or an adjacent unoccupied or partially occupied p atomic orbital.

Induced fit Change in the conformation of an enzyme that is thermodynamically linked to the association of its substrates and that usually produces a more competent active site. See also *conformational selection*.

Inhibition constant, K_i Dissociation constant of an inhibitor from an enzyme.

Inhibitor Chemical substance that, when added to the solution, decreases the initial rate of an enzymatically catalyzed reaction.

Initial rate, v_0 Rate of decrease in the concentration of reactant in an enzymatically catalyzed reaction, or the rate of increase in the concentration of product, observed immediately after the reaction is initiated, either by adding the enzyme or by adding the final reactant necessary to complete the set of reactants; or, if necessary, the rate extrapolated back to zero time.

Initial reactant Reactant that associates with the active site for the first reaction in a sequence of successive reactions catalyzed by a multienzymatic complex. See also *final product* and *intermediate substrate*.

Inner-sphere catalysis Increase in the rate of a reaction due to one or more reactants becoming inner-sphere ligands to a catalytic metallic cation and, during their coordination, participating in the reaction. See also *outer-sphere catalysis*.

Inner-sphere electron transfer Electron transfer, usually between two metal centers sharing a ligand or an atom in their respective coordination shells, that takes place when there is strong electronic coupling (>20 kJ mol^{-1}) between donor (the reductant) and acceptor (the oxidant) in the transition state. See also *outer-sphere electron transfer*.

Interaction coefficient Slope of the line when a series of Brønsted coefficients is plotted as a function of the values of pK_a for the conjugate acids of a series of homologous acids or bases participating in the reaction other than the participants that produced the Brønsted coefficients.

Intermediate Arrangement of atoms in the mechanism of a chemical reaction that has a lifetime longer than the time required for the intramolecular and intermolecular vibrations among those atoms to become established and that is formed from the reactants and reacts further to give the products. See also *transition state*.

Intermediate isotopic exchange Hydrogen or oxygen isotopic exchange observed at a position in one product as the reaction is proceeding in one direction, but the exchanged isotope is not an atom that would have been incorporated into the product from a stoichiometric hydron or a stoichiometric molecule of water during the normal course of the reaction.

Intermediate substrate Product of any of the successive reactions catalyzed by a multienzymatic complex except for the last reaction in the sequence. See also *final product* and *initial reactant*.

Intermolecular, bimolecular reaction Reaction that takes place between two different reactants.

Intradiol dioxygenase One of a family of enzymes that can dioxygenate an ortho dihydroxyphenyl group to turn it into a (2*Z*,4*Z*)-hexa-2,4-dienedioate by oxidatively cleaving the carbon–carbon bond between the two vicinal hydroxy groups. See also *extradiol dioxygenase*.

Intramolecular, unimolecular reaction Reaction in which a bond will be formed between two atoms within the same reactant.

Intrinsic kinetic isotope effect Kinetic isotope effect on a microscopic rate constant for a specific elementary step in the mechanism of an enzymatically catalyzed reaction, not necessarily a step in which the bond at which isotopic substitution has been made is broken.

Inverse kinetic isotope effect Counterintuitive increase in an apparent rate constant that results from substitution of a lighter isotope with a heavier isotope. See also *normal kinetic isotope effect*.

Inversion of configuration Configurational change when a chemical species having a tetrahedral arrangement of bonds to a central atom, such as carbon or phosphorus, is converted into the chemical species having the opposite relative configuration.

Iron–sulfur cluster Array of two or more iron ions, bridging sulfide ions, and nonbridging sulfido groups of cysteines from the protein, in the most common arrangements of which four sulfurs are positioned tetrahedrally around each iron ion.

[2Fe–2S] Iron–sulfur cluster Iron–sulfur cluster that contains two iron ions with two of the tetrahedral positions around each iron ion occupied by sulfide ions and the other two positions occupied by sulfido groups of cysteines in the protein.

[3Fe–4S] Iron–sulfur cluster Iron–sulfur cluster that contains three atoms of iron and that is usually derived from a [4Fe–4S] iron–sulfur cluster in which one of the four irons has dissociated because a cysteine from the protein that would normally form a strong bond with this iron is either absent or unable to do so.

[4Fe–3S] Iron–sulfur cluster Iron–sulfur cluster that is formally a [4Fe–4S] iron–sulfur cluster from which one of the sulfides has been removed.

[4Fe–4S] Iron–sulfur cluster Iron–sulfur cluster that contains four iron ions and four sulfide ions with three of the tetrahedral positions around each iron ion occupied by sulfide ions and the fourth occupied by the sulfido group of a cysteine from the protein.

Isoergonic Description of a reaction for which the overall standard Gibbs energy change ΔG° is close to zero. See also *endergonic and exergonic*.

Isoprenoid Compound formally derived from isoprene, the skeleton of which can generally be discerned in repeated occurrence of isoprenoid units in the molecule but that may differ from strict additivity of isoprene units by loss or shift of a fragment, commonly a methyl group.

Isoprenoid unit Five-carbon building block within a molecule formally, but not necessarily actually, derived from isoprene (2-methylbuta-1,3-diene), found in carotenoids, steroids, and terpenes.

Isotopic exchange Exchange of one isotope of an atom in a reactant for a different isotope of that atom catalyzed by the active site of an enzyme during which the exchanged isotope appears in either the reactant or product.

Isotopic exchange at equilibrium Isotopic exchange within one reactant that is observed when all reactants and products of the enzymatic reaction are present in the solution and the respective concentrations of reactants and products are purposely set so that they satisfy the equation for the equilibrium constant.

Isotopic exchange at initial rate Isotopic exchange that is observed at an atom in one reactant when all the reactants and none of the products are present and the reaction is proceeding only in one direction.

Keto–enol tautomerization Interconversion between keto and enol tautomers of a carbonyl carbon, with the equilibrium constant K_E.

Keto tautomer Tautomer of a ketone, aldehyde, ketimine, aldimine, or acyl derivative in which there is a hydron on the carbon adjacent to the carbonyl or acyl carbon, and the double bond is between the carbonyl or acyl carbon and the oxygen, nitrogen, or sulfur. See also *enol tautomer*.

Kinetic isotope effect Change in a rate constant produced by substitution of the isotope of one or more atoms in a reactant for another isotope. See also *primary kinetic isotope effect* and *secondary kinetic isotope effect*.

Kinetic mechanism Proposal for the steps through which a chemical reaction proceeds between reactants and products, each step of which is associated with one rate constant (if proposed to be kinetically irreversible) or two rate constants (if proposed to be an equilibrium).

Kinetic titration Titration of the sites for an activator, substrate, or inhibitor of an enzyme that is followed by its effect on the kinetics of the enzymatic reaction in a situation in which the ligand has a small enough dissociation constant so that it is stoichiometrically bound by the enzyme. See also *spectrophotometric titration*.

Kinetically irreversible step Step in which the rate of the back reaction is so slow that it has no effect on the kinetics of the overall reaction.

Leaving group Atom or group of atoms that dissociates heterolytically from an electrophilic center, leaving behind the rest of the molecule.

Leffler coefficient Slope of a linear plot in which the changes in standard free energy of activation for a set of reactants participating in the same type of reaction are plotted against the overall changes in standard free energy of each individual reaction.

Ligand Molecule that binds to but is not chemically transformed by a protein.

Light-harvesting prosthetic group Prosthetic group in the antenna of a photosystem that absorbs light and from which the resulting electronically excited state migrates through the network of prosthetic groups in the antenna to a photosynthetic reaction center.

Limiting rate, V Rate of the enzymatic reaction at a given total molar concentration of active sites at high concentrations of all reactants or at extrapolated infinite concentrations.

Local conformational change Conformational change that occurs within the tertiary structure of a single folded polypeptide, that is confined to that folded polypeptide, and that has an insignificant effect on neighboring subunits. See also *quaternary conformational change*.

Low-potential [4Fe–4S] iron–sulfur cluster Iron–sulfur cluster that participates in the oxidation–reduction between the dianionic and trianionic states and for which the standard reduction potential lies between –800 and 0 mV.

Low-spin state State of the ion of a transition metal in which its 3d electrons are distributed so that one or more of its 3d orbitals of low energy contain pairs of electrons of opposite spin while one or more of its 3d orbitals of high energy, as a result of electron repulsion from the ligands, remain vacant.

Macroviscosity Viscosity of a solution. See also *microviscosity*.

Marcus equation Relation that defines the rate constant for the outer-sphere transfer of an electron to be a thermodynamic function of temperature, electronic matrix element (H_{AB}), reorganization energy (λ), and free energy accompanying the transfer (ΔG°). See also *electronic matrix element, H_{AB}*, and *reorganization energy, λ*.

Mechanism-based label Active-site label that must be chemically altered at the active site, in a reaction resembling the one normally catalyzed by the enzyme, before it can modify a catalytic acid–base or side chain in the active site.

Mediator Small molecule that can be rapidly oxidized or reduced by one or two electrons at an electrode and also rapidly reduced or oxidized by the prosthetic group in a protein so that the concentrations of oxidized and reduced prosthetic group in the solution can be conveniently poised at the reduction potential of the electrode.

Metabolism Ensemble of the coordinated sequences of chemical reactions and physical processes that occur within all living cells to provide energy (catabolism) and to accomplish biosynthesis (anabolism).

Michael addition Addition to a carbon–carbon double bond conjugated to a carbonyl, imino, or acyl group in which a nucleophile adds to the carbon in the double bond peripheral to and a hydron or electrophile adds to the carbon distal to the carbonyl, imino, or acyl group.

Michaelis constant for reactant A, K_{mA} Concentration of reactant A at which the rate of the enzymatic reaction at a given total molar concentration of active sites is half the limiting rate when all other reactants for the enzyme are present at high concentrations or have been extrapolated to infinite concentrations.

Microscopic reversibility Principle, which is a corollary of absolute rate theory, stating that any chemical reaction must pass through the same transition states but in opposite order in the forward and reverse directions, so the mechanism in one direction is exactly the reverse of the mechanism in the other direction even though the fluxes through the steps in the two directions differ when the reaction is not at equilibrium.

Microviscosity Viscosity experienced by a molecule in a solution. See also *macroviscosity*.

Midpoint reduction potential, E_m Potential measured under a given set of conditions when the total molar concentration of the reduced participant in a redox couple, $[\text{reduced}]_t$, in all its ionization states and tautomers is equal to the total molar concentration of the oxidized participant in the same redox couple, $[\text{oxidized}]_t$, in all its ionization states and tautomers, and the conditions are such that the activity coefficients cancel, usually because the concentrations of the reactants are small.

Mitochondrion Organelle in all eukaryotic cells that is responsible for producing $MgATP^{2-}$ by oxidative phosphorylation; that is descended from an aerobic, nonphotosynthetic bacterium; and that has an inner membrane corresponding to the plasma membrane of the ancestral bacterial cell.

Mixed inhibition Inhibition produced by a mixed reversible inhibitor. See also *competitive inhibition*, *noncompetitive inhibition*, and *uncompetitive inhibition*.

Mixed reversible inhibitor with respect to reactant A Reversible inhibitor for which the inhibition constant that affects the specificity constant or apparent specificity constant for reactant A is different from the inhibition constant that affects the catalytic constant or apparent catalytic constant for reactant A, and both inhibition constants are finite.

Molecular orbital Wavefunction that describes an electron distribution over the effective field provided by the nuclei and all other electrons of a molecule, that can be expressed as a linear combination of atomic orbitals, and that is usually represented schematically as envelope encompassing a region of space in which there is an arbitrarily fixed high probability of finding the electron occupying the orbital.

π Molecular orbital system Complete set of molecular orbitals—equal to the number of atoms in the system—each orbital of which is a linear combination of p atomic orbitals, one from each of the atoms, which are all adjacent to each other, and that delocalizes the electrons that occupy the constituent molecular orbitals over all the atoms in the system and in which the distribution of electrons can be approximated by examining resonance structures.

σ Molecular orbital system System containing two molecular orbitals that results from the combination of two atomic orbitals from two adjacent atoms, either s orbitals or hybrid orbitals formed from an s orbital and an atomic orbital of higher principal quantum number, and that forms a localized covalent bond between the two atoms.

Molecular orbital system of the transition state Set of atomic and molecular orbitals that are formed by mixing of the atomic and molecular orbitals of the reactant or reactants in a chemical reaction and that can undergo permitted unmixing to generate the atomic and molecular orbitals of the product or products of the chemical reaction.

Molybdoenzyme Enzyme that contains a molybdenum ion coordinated by both sulfanyl groups from one or two molybdopterins. See also *tungstoenzyme*.

Monod–Wyman–Changeux equation General equation that explains sigmoid behavior on the basis of the proposal that the homooligomer involved undergoes a quaternary conformational change in which symmetry is conserved. See also *Adair equation*, *Hill equation*, and *sigmoid behavior*.

Monomeric metaphosphate Planar molecule in which phosphorus is trivalent, hybridized sp^2, forms a σ bond to each of the three oxygens, and contains three pairs of electrons in a π molecular orbital system.

Mononuclear iron–sulfur cluster Iron–sulfur cluster that contains one iron ion with all four tetrahedral positions occupied by the sulfido groups of cysteines from the protein.

Multienzymatic complex Assembly of the active sites for two or more different reactions in the same macromolecular complex.

Nominal redox couple Redox couple that is unique to a particular flavoenzyme and that gives the enzyme its name. See also *general redox couple*.

Noncompetitive inhibition Inhibition produced by a noncompetitive reversible inhibitor. See also *competitive inhibition*, *mixed inhibition*, and *uncompetitive inhibition*.

Noncompetitive reversible inhibitor with respect to reactant A Reversible inhibitor the addition of which to the solution decreases the specificity constant or apparent specificity constant for reactant A and the catalytic constant or apparent catalytic constant for reactant A by the same factor.

Nonprocessive enzyme Enzyme that catalyzes a distributive reaction.

Normal kinetic isotope effect Decrease in a rate constant that results from substitution of a lighter isotope with a heavier isotope. See also *inverse kinetic isotope effect*.

Nuclear Overhauser effect Increase or decrease in the integrated intensity of the absorption of one nucleus in a nuclear magnetic resonance spectrum that occurs when a neighboring nucleus is saturated by applied radio frequency at which it absorbs and that results from the intramolecular transfer of nuclear spin polarization.

Nucleophilic substitution Heterolytic transfer of an electrophile between two lone pairs of electrons, each at a nucleophilic position, by which one nucleophile is replaced by another nucleophile.

Omit map of difference electron density Map of electron density produced when the molecular model of a substrate, ligand, or inhibitor is omitted from a crystallographic molecular model, a data set is calculated from this molecular model, and refinement against the observed reflections is initiated and continued until the positive electron density for these omitted participants in the maps no longer changes.

One-electron oxidation–reduction Oxidation–reduction in which a single electron is transferred to the oxidant from the reductant.

Ordered association Situation in which two or more reactants must add to an active site in a particular order to produce a Michaelis complex between all reactants and the active site. See also *random association*.

Outer-sphere catalysis Increase in the rate of a reaction produced by ligands coordinated to a metallic cation, rather than by the metallic cation itself. See also *inner-sphere catalysis*.

Outer-sphere electron transfer Electron transfer that takes place between a donor and an acceptor, usually separated from each other by several to many atoms, when there is weak or no electronic coupling between them in the transition state. See also *inner-sphere electron transfer*.

Oxidation number Number assigned to an atom that is the charge it would bear if all the ligands were removed, along with the electron pairs that were shared with the atom, and that is largely synonymous with its oxidation state.

Oxidation–reduction Complete balanced reaction that is the sum of two redox couples, in which the oxidant of one couple is reduced by the transfer of one or two electrons from the reductant of the other couple, causing the oxidation number of the reductant to increase and the oxidation number of the oxidant to decrease, and that is usually accompanied by association and dissociation of hydrons from the participants.

Oxidation state Degree of oxidation of an atom.

Oxidation state of an alcohol Oxidation state for a carbon that has one σ bond to a heteroatom and three other σ bonds to either carbon or hydrogen. See *oxidation states of carbon*.

Oxidation state of an alkane Oxidation state for a carbon that has four σ bonds to either carbon or hydrogen. See *oxidation states of carbon*.

Oxidation states of carbon Five configurations defined by the number of bonds—none, one, two, three, or four—between a carbon atom and one or more heteroatoms, the transitions between which are oxidations–reductions that have their own distinct chemistry. See *acyl oxidation state*, *carbonato oxidation state*, *carbonyl oxidation state*, *oxidation state of an alcohol*, and *oxidation state of an alkane*.

Oxidative decarboxylation Oxidation that causes a carboxylato group to dissociate from a molecule as carbon dioxide and that usually involves the formation of a carbonyl or the derivative of a carbonyl at a carbon β to the carboxylato group that dissociates with an enolate intermediate.

Oxocarbenium ion Distinct type of carbenium ion in which one substituent of the carbon atom is an oxygen atom so that the positive charge is delocalized between carbon and oxygen.

μ-Oxo group Oxide dianion or a hydroxide that bridges two or more metallic ions and participates in the coordination of each metallic ion.

Oxyanion hole Arrangement of donors for hydrogen bonds that associates with an oxyanion in a substrate or intermediate in an enzymatic reaction, but usually it stabilizes an oxyanion in an intermediate.

Partition function of the transition state, $^{\ddagger}Q^{0\prime}$ Function calculated from all degrees of freedom available to the transition state except motion along the reaction coordinate.

Patterson map Map of all the vectors between all the atoms in the unit cell of a crystal.

Pentadienyl carbenium ion Intermediate in an electrophilic aromatic substitution on a phenyl group that is produced when the electrophile adds to one of the carbons in the ring, that is formed by mixing the five *p* atomic orbitals remaining in the ring, and that usually delocalizes a positive charge.

Percent identity Percentage of positions in two optimally aligned sequences of amino acids that are occupied by identical amino acids. See also *gap percent*.

Perfectly processive enzyme Processive enzyme that transforms every segment in a particular molecule of a polymer without dissociating from it.

Pericyclic reaction Concerted reorganization of bonding that takes place through a transition state that is a cyclic array of overlapping atomic orbitals and proceeds through an aromatic transition state. See *cycloaddition*, *electrocyclic reaction, ene reaction*, and *sigmatropic rearrangement*.

Periplanarity Location of atoms, bonds, and lone pairs of electrons that are within dihedral angles of ±30° of a plane passing through a σ bond and that allows overlaps of molecular and atomic orbitals to occur among them.

pH–rate profile Plot of the observed rate constants for a reaction as a function of pH at constant temperature and ionic strength in the absence of added general acid–bases that is usually presented as the common logarithms of the observed rate constant for the reaction as a function of pH.

Pheophytin Macrocyclic prosthetic tetrapyrrole, derived from a porphyrin, that has an aromatic ring of 18 atoms over which a single electron can be delocalized, causing it to be capable of participating in one-electron transfer.

Phosphodiester Phosphoric acid that has been esterified with two alcohols, such as two nucleotides.

Phosphomonoester Phosphoric acid that has been esterified with only one alcohol, such as the 6-hydroxy group of glucose.

***N*-(5′-Phosphopyridoxyl)enamine** Structure formed when an electrophile dissociates from the β carbon of an *N*-(5′-phosphopyridoxyl)iminium and that is (as is the case with all enamines) electron-rich, basic, and nucleophilic.

Phosphotriester Phosphoric acid that has been esterified with three alcohols.

Photoisomerization Photochemical process accomplishing an isomerization of a prosthetic group by a bond rotation that causes an initial *E* or *Z* conformation to be changed to the opposite conformation as a result of absorbing a photon of light.

Photosynthetic reaction center Membrane-spanning enzyme that forces an electron to move from a donor of more positive standard reduction potential to an acceptor of more negative standard reduction potential by coupling that movement to the consumption of the energy in a photon of visible light.

Photosystem Complex between a photosynthetic reaction center and a number of proteins containing one or more types of chromophores such as chlorophylls, carotenoids, and bilins that together act as an antenna to absorb quanta of light.

Ping-pong mechanism Kinetic mechanism in which the active site oscillates between two forms, each separated from the other by a respective irreversible step, and each form has the same pattern of rate constants relating it to the other form.

Porphyrin Prosthetic group containing four pyrrolyl groups united through their α positions by four methine groups into a macrocyclic, aromatic ring, the four nitrogens of which can act as equatorial ligands to an octahedrally coordinated transition metallic ion.

Positional isotopic exchange Intramolecular isotopic exchange of one atom in a substrate with another atom, of the same element but a different isotope, in such a way that the product of the isotopic exchange is chemically identical to the reactant except that the two isotopes within the molecule have been interchanged.

Potentiometric titration Procedure in which the reduction potential of a solution, which is monitored by an electrode, is changed while the degree of oxidation–reduction of the molecule that is the subject of the titration is monitored.

Predominantly competitive inhibition with respect to reactant A Type of mixed inhibition where the inhibitor has a greater affinity for the enzyme unoccupied by reactant A than for the active site occupied by reactant A.

Predominantly uncompetitive inhibition with respect to reactant A Type of mixed inhibition where the inhibitor has a greater affinity for the enzyme occupied by reactant A than for the active site unoccupied by reactant A.

Primary equilibrium isotope effect Equilibrium isotope effect for isotopic substitution at a particular atom that is transferred between a reactant and a product during a reaction.

Primary kinetic isotope effect Kinetic isotope effect for a reaction in which the bond between the one atom that has been isotopically substituted and an atom to which it is covalently attached is broken or in which such a bond is formed. See also *kinetic isotope effect and secondary kinetic isotope effect*.

***pro-R* Functional group** Stereoheterotopic functional group on a prochiral atom to which arbitrary assignment of higher priority relative to the other identical functional group generates the *R* configuration at that atom.

***pro-S* Functional group** Stereoheterotopic functional group on a prochiral atom to which arbitrary assignment of higher priority relative to the other identical functional group generates the *S* configuration at that atom.

Processive enzyme Enzyme that catalyzes a processive reaction.

Processive reaction Situation in which an active site catalyzes a reaction within a particular segment of a linear homopolymer—be it a cleavage of the polymer beyond that segment, the addition of a new segment to that segment, or simply a chemical alteration of that segment—and then moves, without dissociating, to an adjacent segment of that polymer to catalyze the same reaction again. See also *distributive reaction*.

Processivity Ratio of the rate at which the active site moves to the next segment of a polymer and completes its catalysis of the reaction at that location to the rate at which the polymer dissociates from the enzyme.

Prochiral carbon Tetrahedral carbon to which are attached two chemically identical functional groups and two other functional groups, each of which is different from the two identical ones and different from each other, and that is capable of becoming chiral if one of the identical functional groups were replaced by a functional group different from the other two or a trigonal carbon to which are attached three different functional groups and that is capable of becoming chiral if an additional functional group, different from the other three, were attached.

Prochiral molecule Molecule that is achiral but that is capable of becoming chiral by a single substitution or addition.

Product Substrate that is being produced in the reaction catalyzed by an enzyme; or substrate that is not present when a solution is prepared to monitor a chemical reaction catalyzed by an enzyme but that is produced during the reaction.

Promoter sequence Sequence of nucleotides in double-stranded DNA that identifies a point at which transcription is to be initiated.

Prosthetic group Molecule, in addition to the amino acids that comprise a protein, that is either covalently attached as a posttranslational modification to the protein or remains tightly bound for an extended period of time (often equal to the lifetime of the protein) and that, when it is acting as a cofactor in an active site, provides a catalytic functional group. See also *coenzyme* and *cofactor*.

Protomers Identical, constituent complexes, between one or several folded polypeptides, each different from the others, that when combined in a fixed stoichiometry form the oligomeric protein.

Proton Nuclear particle of charge number +1 and rest mass of 1.007 276 470(12) unified atomic mass units. See also *hydron*.

Proximal ligand Axial ligand derived from the protein surrounding a heme that has only one ligand from the protein.

Push Interaction with a lone pair of electrons on an adjacent oxygen or nitrogen and the central atom in a nucleophilic dissociation or in the tetrahedral intermediate in a nucleophilic substitution, or the lone pair of electrons on an oxygen or nitrogen that is conjugated to the atom adjacent to the central atom, that results from an overlap between the filled orbital of the lone pair and the unoccupied orbital in the σ bond between the central atom and the leaving group that produces electron repulsion between the lone pair of electrons and the σ bond being broken, and that accelerates the departure of a leaving group.

Pyridoxal 5′-phosphate Prosthetic group that provides an aldehyde as a catalytic functional group and that is usually bound covalently to the resting enzyme as an internal pyridoximine, formed at the aldehyde in a simple nucleophilic substitution with the primary amino group of a lysine in the active site of the enzyme.

Pyridoximine Imine formed between the carbonyl group of pyridoxal 5′-phosphate and the amino group of a lysine within the enzyme (an internal pyridoximine) or an amino group in a substrate (an external pyridoximine).

***N*-Pyruvoyl group** Pyruvoyl group that is covalently attached through an amide between its carboxy group and the amino terminus of an enzyme and that provides a ketone with a catalytic capacity similar to that of the aldehyde in pyridoxal 5′-phosphate for the decarboxylation of α-amino acids.

Q-cycle Explicit series of electron transfers catalyzed by quinol—cytochrome-*c* reductase or plastoquinol—plastocyanin reductase that occur in an obligate order among a Rieske [2Fe–2S] iron–sulfur cluster, two hemes *b*, and a heme *c*.

Quaternary conformational change Conformational change in an oligomer that includes two or more of its subunits (but usually all of them), that usually occurs with retention of the symmetry of the oligomer, and that usually involves a change in the orientation of its constituent folded polypeptides with respect to each other. See also *local conformational change*.

Quenched flow Technique for following the progress of a reaction in an apparatus in which the reaction time can be controlled by connecting the outlet from a rapid mixing chamber to a length of tubing that is connected to a second mixing chamber or that simply ends in a quench solution and varying the time between mixing and the second mixing chamber or the quench solution by changing the flow rate or the length and cross-sectional area of the tubing connecting them and that permits products of the reaction to be assayed chemically rather than only spectroscopically. See also *stopped flow*.

Quinol Cyclic aromatic compound that has two hydroxy groups ortho or para to each other, or otherwise conjugated to each other, including ubiquinols, plastoquinols, menaquinols, and phylloquinol.

Quinone Derivative of a quinol in which the two hydroxy groups have been oxidized to carbonyl groups in a fully conjugated cyclic dione but that is not aromatic.

Quinonoid intermediate Structure formed when an electrophile dissociates from the carbon immediately adjacent to the iminium nitrogen in an external pyridoximine and that, as a result of this dissociation, is basic, nucleophilic, electron-rich, and capable of push.

Radiationless transfer of energy by resonance Formalism that describes the transfer of electronic excitation without photon emission or absorption from the initially excited chromophore (the donor) to another chromophore (the acceptor) as the consequence of a dipole–dipole interaction, the magnitude of which depends on spectral overlap, intermolecular distance, and the relative orientation of the transition dipole moments of the molecules.

Radical clock Compound, such as a methylcyclopropane or *trans*-2-methyl-1-phenylcyclopropane, that rearranges rapidly at a known rate when the respective radical is produced upon abstraction of a hydrogen from its methyl group.

Radical intermediate Paramagnetic, noncovalent intermediate that possesses an unpaired electron and that forms in an active site when a hydrogen atom is abstracted from a reactant, when an electron is added or subtracted from a reactant, or when a reactant dissociates homolytically.

Random association Situation in which the two or more reactants for an enzymatic reaction can add to the active site in any order to produce the same complex between all of them and the active site. See also *ordered association*.

Rate-affecting step Step in the complete kinetic mechanism of a reaction the elementary rate constant of which appears in the kinetic equation governing the rate of a reaction other than the rate-limiting rate constant for that reaction.

Rate equation Mathematical equation, derived from a written kinetic mechanism, that relates the observed initial rate, v_0, of the reaction to the initial concentrations of reactants and total molar concentration of active sites, the only parameters of which are the rate constants in the mechanism.

Rate-limiting step Last step in a series of reaction steps, the rate constant for which appears in the kinetic equation for the multistep reaction.

Rate of dialysis Unidirectional rate at which a ligand passes through a semipermeable membrane, which is directly proportional to the ligand's free concentration.

***Re* face** Stereoheterotopic face of a trigonal atom the functional groups of which, when viewed from that side of the carbon, appear in a clockwise sense in order of priority. See also *Si face*.

Reactant Substrate that is present when a solution is prepared by an investigator to undergo a reaction catalyzed by an enzyme.

Reactant activation Acceleration of the initial rate of an enzymatic reaction by a reactant as its concentration is increased, beyond the usual increase in rate resulting only from its association with the active site.

Reactant antagonism Effect that occurs when one reactant decreases the dissociation constant for another reactant and vice versa.

Reaction coordinate Path from reactant to product on a surface of potential energy that passes through a col on the surface at the transition state.

Redox couple Reduced molecule and oxidized molecule, such as reduced flavin and oxidized flavin, that can be interconverted by subtracting or adding only electrons and hydrons.

Reduction potential, E Driving force, usually expressed as a voltage, that a redox couple, under a given set of conditions, can provide to move electrons from a standard hydrogen electrode to the oxidized molecule of the redox couple to form the reduced molecule.

Relaxation time, τ Reciprocal of the first-order rate constant observed for a given first-order relaxation, formally defined as the time t during which the overall change in concentration falls to e^{-1} of its initial value.

Reorganization energy, λ Difference between the free energy of a Franck–Condon state in which the position and momentum of the nuclei and their respective solvation are the same before and after the transfer of an electron and the sum of the free energies of the equilibrium nuclear configuration of the donor, the equilibrium nuclear configuration of the acceptor, and their respective solvations. See also *Marcus equation*.

Resonance Raman infrared spectrum Raman spectrum observed when a chromophore in the active site is excited by a beam of light from a laser that is perpendicular to the beam of the laser that is registering the spectrum.

Reverse hydronation Situation in which a minor tautomer of either unassociated reactant or unassociated active site, rather than the respective major tautomer, or a minor tautomer of the Michaelis complex of the two, rather than the major tautomer, is the active form of the active site.

Reversible inhibitor Inhibitor that exerts its effect by associating noncovalently and reversibly with the enzyme and that, when associated, decreases or eliminates its ability to catalyze the reaction.

Rieske [2Fe–2S] iron–sulfur cluster [2Fe–2S] iron–sulfur cluster in which there are two histidines from the protein as ligands to one of the irons instead of two cysteines.

Secondary kinetic isotope effect Kinetic isotope effect in which the isotopic substitution occurs at another atom that is attached covalently to an atom participating in the breaking of a bond, other than the two atoms between which the bond is broken. See also *kinetic isotope effect, primary kinetic isotope effect, α-secondary kinetic isotope effect, and β-secondary kinetic isotope effect.*

α-Secondary kinetic isotope effect Secondary kinetic isotope effect in which the isotopic substitution occurs at an atom bonded directly to one atom in a bond being broken during the reaction. See also *kinetic isotope effect, primary kinetic isotope effect, secondary kinetic isotope effect, and β-secondary kinetic isotope effect.*

β-Secondary kinetic isotope effect Secondary kinetic isotope effect in which the isotopic substitution occurs at an atom bonded to an atom that, in turn, is bonded to an atom in the bond being broken during a reaction. See also *kinetic isotope effect, primary kinetic isotope effect, secondary kinetic isotope effect, and α-secondary kinetic isotope effect.*

Selanyl group Selenium analogue (–SeH) of a sulfanyl group.

Selenocysteine Amino acid homologous to serine and cysteine, in which a selenium replaces the oxygen or sulfur, respectively.

Semipermeable membrane Polymer film with pores large enough to permit small molecules to pass through them but too small to permit the passage of macromolecules such as proteins, polysaccharides, or nucleic acids.

Semiquinone Intermediate oxidation state with an unpaired electron that is formed by the removal of one electron from a quinol or other one-electron donor (such as reduced flavin) and from which another electron can be removed to produce the respective quinone or other donor oxidized by removal of two electrons.

Shielding Effect of electrons surrounding the observed nucleus and electrons surrounding neighboring nuclei that causes the local field of the nucleus to be less than the applied external magnetic field.

***Si* face** Stereoheterotopic face of a trigonal atom the functional groups of which, when viewed from that side of the carbon, appear in a counterclockwise sense in order of priority. See also *Re face.*

Sigmatropic rearrangement Pericyclic reaction in which a σ bond allylic to a π bond in the reactant is broken, a new σ bond allylic to a π bond is formed, and two π bonds migrate to adjacent positions in a situation in which both reactant or reactants and product or products together have two (or $2n + 2$) π bonds that are capable of participating in a cyclic, conjugated transition state in which the σ bond of the reactant and the σ bond of the product can also participate.

Sigmoid behavior Deviation from ideal behavior in which the slope of the curve describing occupancy of sites for ligands or substrates or for enzymatic activity increases as the concentration of ligand or substrate is increased before it then decreases as it approaches its rectangularly hyperbolic asymptote at saturation, producing an S-shaped (sigmoid) plot. See also *cooperativity.*

Solvation Interactions, favorable or unfavorable, between a molecule of solute or a transition state and molecules of solvent in the vicinity that modify the behavior of the solvent molecules and which in turn affect the behavior of the molecule of solute or the transition state.

Solvent deuterium kinetic isotope effect Kinetic isotope effect that results from the substitution of a hydron in the molecules of solvent for a deuterium and which, in a biochemical context, is when ^2H_2O is used as solvent instead of ^1H_2O.

Solvent kinetic isotope effect Kinetic isotope effect that results from a change in the isotopic composition of the solvent, usually when another isotopic form of the solvent is substituted for the naturally occurring isotopic form.

Special pair Two chlorophylls that together make up the prosthetic group in a photosynthetic reaction center that undergoes initial excitation either directly from sunlight or indirectly by transfer of an exciton.

Specific acid catalysis Increase in the rate of a reaction due only to an increase in the concentration of hydronium ion.

Specific base catalysis Increase in the rate of a reaction due only to an increase in the concentration of hydroxide ion.

Specificity constant for reactant A, k_A Observed apparent second-order rate constant, which is first-order with respect to the total molar concentration of active sites and first-order with respect to reactant A, for the enzymatic reaction at low concentration of reactant A, or at extrapolated zero concentration, when all other reactants for the enzymatic reaction are present at high concentrations or have been extrapolated to infinite concentrations.

Spectrophotometric titration Titration of the sites for an activator, substrate, or inhibitor of an enzyme that is followed by its effect on the absorbance of the solution due to a change in the absorbance of the ligand or the protein or both of them. See also *kinetic titration*.

Standard entropy of approximation, $\Delta^{\ddagger}S^{\circ}_{\text{approx}}$ Decrease in standard entropy that results when two reactants that are free in solution form a complex within a solvent cage with the alignments required to form the transition state for the reaction in which they participate.

Standard entropy of molecularity, $\Delta^{\ddagger}S^{\circ}_{\text{molec}}$ Change in standard entropy due solely to bringing two separate reactants together into the same solvent cage.

Standard entropy of rotational restraint, $\Delta^{\ddagger}S^{\circ}_{\text{rot}}$ Decrease in standard entropy that is required to freeze rotational motions within a solvent cage enclosing two reactants during the formation of a transition state.

Standard free energy of activation, $\Delta^{\ddagger}G^{\circ\prime}$ Difference between the standard chemical potentials of the reactants in an elementary reaction when they are free in solution and when they are in the transition state.

Standard hydrogen electrode Electrode in which diatomic hydrogen gas at a pressure of 10^5 pascals is poised electrochemically at equilibrium with two hydrons at pH = 0 in aqueous solution.

Standard reduction potential, E° Reduction potential observed when the two members of a redox couple are present at equal activity at a pH of 0.

Steady-state approximation Assumption that, because the concentration of reactant is so much greater than the concentration of enzyme, after the first few molecules of reactant have been turned into product by each molecule of enzyme, the concentration of each species involving the enzyme has reached a constant, steady state.

Stereoelectronic control Control of the identity of products or rate of a reaction by particular rotational alignments among atoms in a reactant that approximate and overlap molecular and atomic orbitals in the ground state preceding a transition state.

Stereoheterotopic faces Two faces that are either enantiotopic or diastereotopic. See also *diastereotopic faces* and *enantiotopic faces*.

Stereoheterotopic functional groups Two identical functional groups that are either enantiotopic or diastereotopic. See also *diastereotopic functional groups* and *enantiotopic functional groups*.

Sticky product Product that dissociates slowly from the active site relative to either the rate of the back reaction to bound reactant or the rate of the forward reaction from bound reactant to bound product.

Sticky reactant Reactant that is converted to products free in solution faster than it can dissociate from the active site.

Stopped flow Technique for following the progress of a reaction in an apparatus where an observation chamber is located as close to a mixing chamber as possible, and rapid flow of two solutions containing reactants through the mixing chamber under high pressure is initiated and then arrested as abruptly as possible so that the progress of the reaction can be monitored in the observation chamber by some method with a rapid response, such as absorbance or fluorescence. See also *quenched flow*.

Structure–activity correlation Effect of changing the functional groups on a particular reactant on the rate of a common reaction.

Substrates All of the molecules that are interconverted by an enzyme as it catalyzes its particular chemical reaction and that appear in the equation for the equilibrium catalyzed by the enzyme.

Swain–Schaad relation Theoretical function that relates the rate constant for a reactant substituted at a particular position with tritium to the ratio of the rate constants for that reactant hydronated and deuterated, respectively, at the same position.

Swain–Scott correlation Plot of common logarithms of observed second-order rate constants for a set of nucleophiles participating in a particular nucleophilic substitution as a function of a set of parameters, also known as nucleophilicities, that are related to the common logarithms of the respective rate constants for nucleophilic substitutions between the same set of nucleophiles and a reference electrophile.

Syn elimination Elimination in which the leaving group and the hydron or electrophile dissociate on the same side of a plane containing the carbons in a carbon–carbon bond to which they are attached. See also *anti elimination*.

Synperiplanar conformation Arrangement in which the two periplanar substituents of interest are oriented at a dihedral angle of $0° \pm 30°$ from one another. See also *antiperiplanar conformation*.

Synperiplanar push Push exerted by a lone pair of electrons in the synperiplanar conformation. See also *antiperiplanar push*.

Tautomerization Dissociation of a hydron from one atom in a molecule before, after, or concurrent with the association of a hydron with another atom in the same molecule.

Temperature jump Relaxation technique in which the temperature of a chemical system is suddenly raised, the system then relaxes to a new state of equilibrium, and analysis of the relaxation process provides rate constants for the step or steps through which the system proceeds to reach the new equilibrium.

Ternary complex Complex between an active site and two reactants.

Terpene Isoprenoid of biological origin that can be designated as a monoterpene (C_{10}), sesquiterpene (C_{15}), diterpene (C_{20}), triterpene (C_{30}), or tetraterpene (C_{40}).

Terpenoid Terpene that has been modifed so that it contains atoms of oxygen.

Tetrahedral intermediate Intermediate in a reaction in which an initially double-bonded carbon atom (typically an acyl carbon atom) has been transformed from trigonal to tetrahedral.

Thiamine diphosphate Prosthetic group tightly, but noncovalently, bound to the active sites of certain enzymes, the functionally important site of which is a carbon sandwiched between the iminium nitrogen and the sulfur in a thiazolium and the conjugate base of which is an ylide.

Thylakoid Flattened vesicle of membrane, inside the outer membrane of a chloroplast in a plant cell or inside the plasma membrane of a cyanobacterium, that corresponds to a chromatophore in the ancestral photosynthetic bacterial cell that gave rise to chloroplasts.

Total molar concentration of active sites, $[E]_t$ Sum of the concentrations of unoccupied active sites and of active sites occupied by substrates and intermediates in the enzymatic reaction.

Transamination Conversion of an amino group into an oxo group at one carbon and conversion of an oxo group into an amino group at another carbon, resulting in the transfer of ammonia or an amine between the two carbons.

Transferred nuclear Overhauser effect Nuclear Overhauser effect caused by the transfer of saturation from the atom in one molecule to the atom in another molecule that results from the two molecules being in intimate contact.

Transimination Conversion of an imine formed with one amino group into an imine formed with another amino group, usually at the same carbon.

Transition state Point of maximum potential energy along the reaction coordinate between reactant and product, which is located at a col, which lasts only as long as is necessary to pass over the col, and which is an assembly of atoms at the col that has an equal probability of forming the reactants or products of the elementary reaction in which it participates. See also *intermediate*.

Transition state theory Theory applied to the rates of elementary reactions that assumes an equilibrium, with an equilibrium constant $^{\ddagger}K'$, exists between the reactants and the sole transition state for the reaction.

Trigonal bipyramid Arrangement in which three of the five substituents on a particular atom or ligands to a particular metallic cation, which are designated equatorial, lie close to or within a plane containing the central atom or metallic cation at approximately 120° angles to each other and the other two substituents or ligands, which are designated apical, are located above and below the equatorial plane, respectively, close to or on a line perpendicular to the plane that passes through the central atom or metallic cation.

Tritium kinetic isotope effect Change in a rate constant produced by substitution of a tritium for a protium in a reactant.

Tungstoenzyme Enzyme that contains a tungsten ion coordinated by both sulfanyl groups from one or two molybdopterins. See also *molybdoenzyme*.

Tunneling Process by which a particle or a set of particles crosses a barrier on a surface of potential energy without having the energy required to surmount this barrier and which is usually revealed in the behavior of isotopes.

Two-electron oxidation–reduction Oxidation–reduction in which two electrons are transferred to the oxidant from the reductant.

Ultrafiltration Method that can be used to determine the binding of a ligand to a protein in which the protein and the ligand are allowed to equilibrate in a solution, a portion of the solution is forced under pressure through a semipermeable membrane, and the concentration of protein on the unfiltered side and the concentrations of the ligand on the filtered and unfiltered sides are then measured.

Uncompetitive inhibition Inhibition produced by an uncompetitive reversible inhibitor. See also *competitive inhibition*, *mixed inhibition*, and *noncompetitive inhibition*.

Uncompetitive reversible inhibitor with respect to reactant A Reversible inhibitor the addition of which to the solution decreases the catalytic constant or apparent catalytic constant for reactant A while having no effect on the specificity constant or apparent specificity constant for reactant A.

Varied reactant Reactant that is varied at several discrete, different concentrations in a series of experiments that determine the initial rate of an enzymatic reaction. See also *fixed reactant*.

Vibrational Stark effect Shift in the frequency of the maximum of absorbance for a vibrational mode produced by an electric field.

Ylide Compound in which an anionic carbon or other anionic atom is attached directly to a heteroatom (usually nitrogen, phosphorus, or sulfur) carrying a fixed formal positive charge, a separation of charge that cannot be neutralized internally by a shift of π electrons in a π molecular orbital system.

Enzymes and Other Proteins Discussed

acetaldehyde dehydrogenase (acetylating)
acetate CoA-transferase
acetate kinase
acetoacetate decarboxylase
acetolactate synthase
acetylcholinesterase
acetyl-CoA *C*-acetyltransferase
acetyl-CoA carboxylase
acetyl-CoA carboxytransferase
acetylene hydratase
N-acetylglucosamine-6-phosphate deacetylase
N^4-(*β*-*N*-acetylglucosaminyl)-L-asparaginase
β-*N*-acetylglucosaminylglycopeptide *β*-1,4-galactosyltransferase
acetylglutamate kinase
β-*N*-acetylhexosaminidase
N-acetylneuraminate synthase
N-acetylneuraminate lyase
acireductone dioxygenase (Ni^{2+}-requiring)
acireductone synthase
aconitate Δ-isomerase
aconitate hydratase
[acyl-carrier-protein] hydrolase
[acyl-carrier-protein] *S*-acetyltransferase
[acyl-carrier-protein] *S*-malonyltransferase
acyl-CoA:acyl-CoA alkyltransferase
acyl-homoserine-lactone synthase
acyl-CoA dehydrogenase
adenine deaminase
adenine phosphoribosyltransferase
adenosine deaminase
adenosine kinase
adenosylhomocysteinase
adenosylmethionine decarboxylase
adenylate kinase
adenylosuccinate lyase
adenylosuccinate synthase
adenylyl-sulfate reductase
ADP-*glyceromanno*-heptose 6-epimerase
ADP-glucose phosphorylase
adrenodoxin-$NADP^+$ reductase
aerobic carbon monoxide dehydrogenase
alanine racemase
alanine—tRNA ligase
alcohol dehydrogenase
aldehyde dehydrogenase (FAD-independent)
aldehyde dehydrogenase (NAD^+)
aldehyde ferredoxin oxidoreductase
aldehyde oxygenase (deformylating)
aldehyde reductase
alginate lyase
aliphatic halogenase
alkaline phosphatase
1-alkyl-2-acetylglycerophosphocholine esterase
alkylglycerone-phosphate synthase
all-trans-8′-apo-*β*-carotenal 15,15′-oxygenase
allantoin racemase
alliin lyase
alliin synthase
allophycocyanin
amicyanin
amidophosphoribosyltransferase
amidoxime reductase
D-amino-acid oxidase
L-amino-acid oxidase
D-amino-acid transaminase
L-aminoadipate-semialdehyde dehydrogenase
2-(3-amino-3-carboxypropyl)histidine synthase
2-amino-4-deoxychorismate synthase
amino-acid *N*-acetyltransferase

butane monooxygenase (soluble)
butyryl-CoA dehydrogenase
calmodulin-dependent P-type Ca^{2+} transporter
cAMP-dependent protein kinase
camphor 5-monooxygenase
carbamoyl-phosphate synthase (ammonia)
carbamoyl-phosphate synthase (glutamine-hydrolyzing)
carbazole 1,9a-dioxygenase
carbide synthase
carbonic anhydrase
carboxy-*S*-adenosyl-L-methionine synthase
5-(carboxyamino)imidazole ribonucleotide mutase
5-(carboxyamino)imidazole ribonucleotide synthase
N^2-(2-carboxyethyl)arginine synthase
(carboxyethyl)arginine β-lactam-synthase
3-carboxyethylcatechol 2,3-dioxygenase
carboxylesterase
3-carboxy-*cis,cis*-muconate cycloisomerase
4-carboxymuconolactone decarboxylase
carboxypeptidase
carboxypeptidase A
carboxypeptidase C
carboxypeptidase D
5-carboxyvanillate decarboxylase
β-carotene 15,15′-dioxygenase
carotenoid oxygenase 1
catalase
catalase-peroxidase
catechol *O*-methyltransferase
catechol oxidase
CDP-4-dehydro-6-deoxyglucose reductase
CDP-6-deoxy-L-*threo*-D-*glycero*-4-hexulose-3-dehydrase
CDP-paratose 2-epimerase
cellobiose dehydrogenase (acceptor)
cellulase
cellulose 1,4-β-cellobiosidase
cellulose 1,4-β-cellobiosidase (reducing end)
cellulose synthase
cellulose synthase (UDP-forming)
cephalosporin synthase
chalcone isomerase
chalcone synthase
chitinase
chloramphenicol *O*-acetyltransferase
chloride peroxidase
chlorite O_2-lyase
4-chlorobenzoate—CoA ligase
4-chlorobenzoyl-CoA dehalogenase
cholest-4-en-3-one 26-monooxygenase [(25*S*)-3-oxocholest-4-en-26-oate forming]
cholesterol monooxygenase (side-chain-cleaving)
cholesterol oxidase
choline oxidase
chondroitin AC lyase
chorismate mutase
chorismate mutase–prephenate dehydratase
chorismate synthase
chymotrypsin
α-chymotrypsin
citrate (*pro*-3*S*)-lyase
citrate (*Re*)-synthase
citrate (*Si*)-synthase
c-Jun amino-terminal protein kinase
coenzyme-B sulfoethylthiotransferase
CO-methylating acetyl-CoA synthase
coronamic acid synthase
creatinase
creatine kinase
creatininase
crotonyl-CoA carboxylase/reductase
cupriplastocyanin
cyanamide hydratase
cyclic-AMP-dependent non-specific serine/threonine protein kinase
cycloartenol synthase
cyclohexanone monooxygenase
cyclomaltodextrin glucanotransferase
cyclopropane-fatty-acyl-phospholipid synthase
cystathionine γ-lyase

dihydropyrimidine dehydrogenase (NADP$^+$)
dihydroxy-acid dehydratase
3,4-dihydroxy-2-butanone-4-phosphate synthase
1,4-dihydroxy-2-naphthoyl-CoA synthase
3,4-dihydroxyphenylacetate 2,3-dioxygenase
dihydroxyacetanilide epoxidase
diiron hydrogenase
dimethyl sulfide:cytochrome c_2 reductase
dimethylallyl*trans*transferase
4-dimethylallyltryptophan synthase
N^1-(1,1-dimethylallyl)tryptophan synthase
dimethylglycine oxidase
N^1-(1,1-dimethylprop-2-enyl)tryptophan synthase
dimethylpropiothetin dethiomethylase
dimethylsulfoxide reductase
dinitrogenase
dinitrogenase reductase
2,6-dioxo-6-phenylhexa-3-enoate hydrolase
diphosphate—fructose-6-phosphate 1-phosphotransferase
diphosphomevalonate decarboxylase
dipicolinate synthase
DNA (cytosine-5-)-methyltransferase
DNA β-glucosyltransferase
DNA helicase
DNA helicase I
DNA helicase PcrA
DNA helicase UvrD
DNA ligase (ATP)
DNA-(apurinic or apyrimidinic site) lyase
DNA-formamidopyrimidine glycosylase
DNA-3-methyladenine glycosylase II
DNA-directed DNA polymerase
DNA-directed DNA polymerase β
DNA-directed RNA polymerase
dopamine β-monooxygenase
double-stranded uracil-DNA glycosylase
dTDP-glucose 4,6-dehydratase
dTMP kinase
dUTP diphosphatase
*Eco*RV endonuclease
elastase
electron-transferring flavoprotein
electron-transferring-flavoprotein dehydrogenase
enamidase
endo-1,4-β-xylanase
endoglucanase CelC
endothiapepsin
2-enoate reductase
enoyl thioester reductase
enoyl-[acyl-carrier-protein] reductase (NADH)
enoyl-[acyl-carrier-protein] reductase (NADPH, *Re*-specific)
enoyl-CoA hydratase
epi-isozizaene synthase
epoxidase
epoxidase AsqJ
epoxide hydrolase
ethanolamine ammonia-lyase
ethylenediamine-*N*,*N*′-disuccinate lyase
ethylmalonyl-CoA mutase
exodeoxyribonuclease (lambda-induced)
exo-(1→4)-α-D-glucan lyase
exoribonuclease II
exo-α-sialidase
F_1-ATPase
(2*E*,6*E*)-farnesyl diphosphate synthase
farnesyl*trans*transferase
fatty acid synthase system
ferredoxin
ferredoxin hydrogenase
ferredoxin reductase
ferredoxin—NADP$^+$ reductase
ferredoxin—nitrite reductase
ferredoxin:CoB-CoM heterodisulfide reductase
ferredoxin:thioredoxin reductase
flavin monooxygenase
flavin prenyltransferase
flavodoxin
flavoenzyme NADPH—hemoprotein reductase
flavoprotein of assimilatory sulfite reductase (NADPH)

glutathione transferase
glutathione-disulfide reductase
glyceraldehyde-3-phosphate dehydrogenase
glycerol dehydrogenase
glycerol kinase
glycine *C*-acetyltransferase
glycine amidinotransferase
glycine dehydrogenase (decarboxylating)
glycine hydroxymethyltransferase
glycine *N*-methyltransferase
glycine oxidase
glycine reductase
glycogen phosphorylase
glycogen synthase
glycoprotein 3-α-L-fucosyltransferase
glyoxylate reductase
GMP synthase (glutamine-hydrolysing)
GTP 3′,8-cyclase
GTP cyclohydrolase
guanidinoacetate *N*-methyltransferase
H^+/K^+-exchanging ATPase
H^+-transporting two-sector ATPase
H_2:CoB-CoM heterodisulfide
haloacetate dehalogenase
haloacid dehalogenase
haloalkane dehalogenase
halohydrin dehalogenase
heme oxygenase (biliverdin-producing, ferredoxin)
heme oxygenase (biliverdin-producing)
hemerythrin
hemocyanin
hemoglobin
hemoperoxidase
hexokinase
3-hexulose-6-phosphate synthase
histidine ammonia-lyase
histidine decarboxylase
histidinol dehydrogenase
histidinol-phosphatase
histidinol-phosphate transaminase
histone acetyltransferase
histone deacetylase
HIV-1 retropepsin
homocitrate synthase
homogentisate 1,2-dioxygenase
homoisocitrate dehydrogenase
homoserine *O*-acetyltransferase
homoserine dehydrogenase
hydrogen peroxide-dependent heme synthase
hydrogenase (acceptor)
[FeFe] hydrogenase H-cluster radical SAM maturase HydG
D-2-hydroxyacid dehydrogenase (NAD^+)
(*S*)-2-hydroxy-acid oxidase
3-hydroxyacyl-[acyl-carrier-protein] dehydratase
3-hydroxyanthranilate 3,4-dioxygenase
3-hydroxybenzoate 4-monooxygenase
3-hydroxybenzoate 6-monooxygenase
4-hydroxybenzoate 3-monooxygenase
4-hydroxybenzoate 3-monooxygenase [NAD(P)H]
4-hydroxybenzoyl-CoA reductase
4-hydroxybutanoyl-CoA dehydratase
3-hydroxybutyryl-CoA epimerase
3-hydroxydecanoyl-[acyl-carrier-protein] dehydratase
3-hydroxyisobutyryl-CoA hydrolase
2-hydroxyethylphosphonate dioxygenase
(*R*)-2-hydroxyisocaproyl-CoA dehydratase
(*R*)-2-hydroxyisocaproyl-CoA dehydratase activator
hydroxylamine dehydrogenase
hydroxylamine reductase
4-hydroxymandelate synthase
hydroxymethylbilane synthase
4-hydroxy-3-methylbut-2-en-1-yl diphosphate reductase
(*E*)-4-hydroxy-3-methylbut-2-enyl-diphosphate synthase (flavodoxin)
hydroxymethylglutaryl-CoA reductase
hydroxymethylglutaryl-CoA reductase (NADPH)
hydroxymethylglutaryl-CoA synthase
3-hydroxy-2-methylpyridinecarboxylate monooxygenase

malate synthase
maleate hydratase
maleate isomerase
mandelate racemase
(*S*)-mandelate dehydrogenase
manganese catalase
manganese peroxidase
mannose-6-phosphate isomerase
mannuronate-specific alginate lyase
medium-chain acyl-CoA dehydrogenase
melilotate 3-monooxygenase
menaquinone reductase
3-mercaptopyruvate sulfurtransferase
mercury(II) reductase
methane monooxygenase (particulate)
methane monooxygenase (soluble)
methanol dehydrogenase (cytochrome *c*)
L-methionine adenosyltransferase
methionine decarboxylase
methionine γ-lyase
L-methionine (*R*)-*S*-oxide reductase
L-methionine (*S*)-*S*-oxide reductase
methionine synthase
methionine—tRNA ligase
methionyl aminopeptidase
2-methylacyl-CoA dehydrogenase
methylamine dehydrogenase (amicyanin)
methylamine—glutamate *N*-methyltransferase
methylamine utilization protein MauG
methylaspartate mutase
methylcrotonyl-CoA carboxylase
methylated-DNA—[protein]-cysteine *S*-methyltransferase
2-methyleneglutarate mutase
methylenetetrahydrofolate dehydrogenase
methylenetetrahydrofolate reductase (NADPH)
methylenetetrahydrofolate reductase [NAD(P)H]
methylenetetrahydrofolate—tRNA-(uracil^{54}-C^5)-methyltransferase [NAD(P)H-oxidizing]
2-*C*-methyl-D-erythritol 4-phosphate cytidylyltransferase
methylglyoxal synthase
3-methyl-2-indolic acid synthase
methylisocitrate lyase
methylmalonyl-CoA carboxytransferase
methylmalonyl-CoA decarboxylase
methylmalonyl-CoA mutase
3-methyl-2-oxobutanoate dehydrogenase (2-methylpropanoyl-transferring)
3-methyl-2-oxobutanoate hydroxymethyltransferase
4-methylphenol dehydrogenase (hydroxylating)
methylphosphonate synthase
5-methyltetrahydropteroyltriglutamate—homocysteine *S*-methyltransferase
mevalonate kinase
micrococcal nuclease
monoamine oxidase
monophenol monooxygenase
morphinone reductase
mRNA interferase toxin RelE
muconate cycloisomerase
muconolactone Δ-isomerase
mycofactocin radical SAM maturase
myeloperoxidase
myoglobin
myosin
myosin II
Na^+/K^+-exchanging ATPase
NADH peroxidase
NADH:ubiquinone reductase (H^+-translocating)
NADPH—hemoprotein reductase
naphthalene 1,2-dioxygenase
neomycin C epimerase
N-formylmethionylaminoacyl-tRNA deformylase
nickel–iron hydrogenase
nicotinamidase
nicotinate dehydrogenase
nicotinate-nucleotide diphosphorylase (carboxylating)
nicotinate-nucleotide—dimethylbenzimidazole phosphoribosyltransferase
nitrate reductase (quinone)

nitric oxide reductase (cytochrome *c*)
nitric oxide reductase (menaquinol)
nitric oxide reductase [NAD(P)$^+$, nitrous oxide-forming]
nitric-oxide synthase
nitric-oxide synthase (flavodoxin)
nitric-oxide synthase (NADPH)
nitrile hydratase
nitrite reductase
nitrite reductase (cytochrome; ammonia-forming)
nitrite reductase (NO-forming)
nitroalkane oxidase
nitrocyanin
nitrogenase
nitrous-oxide reductase
nonspecific protein-tyrosine kinase Csk
nonspecific protein-tyrosine kinase v-Fps
(*S*)-norcoclaurine synthase
nucleoside deoxyribosyltransferase
nucleoside-diphosphate kinase
5′-nucleotidase
octenoyl-CoA reductase/carboxylase
olefin-forming fatty acid decarboxylase
oleoyl-[acyl-carrier-protein] hydrolase
D-ornithine 4,5-aminomutase
ornithine aminotransferase
ornithine carbamoyltransferase
ornithine cyclodeaminase
D-ornithine/D-lysine decarboxylase
L-ornithine N^5-monooxygenase
L-ornithine N^5-monooxygenase (NADPH)
L-ornithine N^5-monooxygenase [NAD(P)H]
orotate phosphoribosyltransferase
orotate reductase (NADH)
orotidine-5′-phosphate decarboxylase
oxalate decarboxylase
oxalate oxidase
oxalate oxidoreductase
3-oxoacid CoA-transferase
3-oxoacyl-[acyl-carrier-protein] synthase
4-oxalocrotonate dehydrogenase
3-oxoacyl-[acyl-carrier-protein] synthase
2-oxo-4-carboxy-3-hexenedioate hydratase
oxoglutarate dehydrogenase (succinyl-transferring)
2-oxo-hept-4-ene-1,7-dioate hydratase
2-oxo-3-hexenedioate decarboxylase
2-oxopropyl-CoM reductase (carboxylating)
palmitoyl-[glycerolipid] 7-desaturase
pancreatic ribonuclease
pectate lyase
penicillopepsin
pentalenene synthase
pepsin
pepsin A
peptide deformylase
peptidyl-glutamate 4-carboxylase
peptidylglycine monooxygenase
peptidylprolyl isomerase
peroxidase
peroxygenase
persulfide dioxygenase
phenacrylate decarboxylase
phenol 2-monooxygenase (NADPH)
phenylalanine aminomutase (D-β-phenylalanine forming)
phenylalanine aminomutase (L-β-phenylalanine forming)
phenylalanine ammonia-lyase
phenylalanine dehydrogenase
phenylalanine 4-monooxygenase
phosphate acetyltransferase
phospho*enol*pyruvate carboxykinase
phospho*enol*pyruvate carboxykinase (ATP)
phospho*enol*pyruvate carboxykinase (GTP)
phospho*enol*pyruvate carboxylase
phospho*enol*pyruvate mutase
6-phosphofructokinase
6-phosphofructo-2-kinase
β-phosphoglucomutase
phosphoglucomutase
phosphoglucomutase (α-D-glucose-1,6-bisphosphate-dependent)

phosphogluconate dehydrogenase (NADP$^+$-dependent, decarboxylating)
6-phospho-β-glucosidase
phosphoglycerate dehydrogenase
phosphoglycerate kinase
phosphoglycerate mutase
phosphoinositide-dependent protein kinase
phosphoinositide phospholipase C
phosphoketolase
phospholipase A_2
phospholipase D
phosphonate dehydrogenase
phosphonoacetaldehyde hydrolase
phosphopantothenate—cysteine ligase (CTP)
phosphopantothenoylcysteine decarboxylase
phosphoprotein phosphatase
phosphopyruvate hydratase
phosphoribosylamine—glycine ligase
phosphoribosylaminoimidazolecarboxamide formyltransferase
phosphoribosylaminoimidazolesuccino-carboxamide synthase
phosphoribosylanthranilate isomerase
phosphoribosylformylglycinamidine synthase
phosphoribosylglycinamide formyltransferase
phosphoribulokinase
phosphoserine phosphatase
O-phosphoserine sulfhydrylase
3-phosphoshikimate 1-carboxyvinyltransferase
phosphotransferase system
phosphotriesterase
photosynthetic reaction center
photosystem II
C-phycocyanin
phycocyanin
phycoerythrin
4-phytase
(+)-α-pinene synthase
L-pipecolate oxidase
pivalyl-CoA mutase
plastocyanin
plastoquinol—plastocyanin reductase
poly(ADP-ribose) glycohydrolase
poly(β-D-mannuronate) C5 epimerase
polysaccharide monooxygenase
polyunsaturated fatty acid isomerase
porphobilinogen synthase
PqqA peptide cyclase
premalbrancheamide halogenase
prephenate dehydratase
prephenate dehydrogenase
preQ1 synthase
primary-amine oxidase
procollagen-lysine 5-dioxygenase
procollagen-proline 4-dioxygenase
proline dehydrogenase
proline racemase
propanediol dehydratase
propionyl-CoA carboxylase
prosolanapyrone-III cycloisomerase
prostaglandin-endoperoxide synthase
protein deglycase DJ-1
protein farnesyltransferase
protein geranylgeranyltransferase
protein O-GlcNAcase
protein-lysine 6-oxidase
protein-tyrosine kinase
protein-tyrosine kinase Csk
protein-tyrosine-phosphatase
protocatechuate 3,4-dioxygenase
pseudouridylate synthase
D-psicose 3-epimerase
D-psicose-6-phosphate 3-epimerase
P-type Ca^{2+} transporter
P-type H^+-exporting transporter
P-type Zn^{2+} transporter
purine nucleosidase
purine-nucleoside phosphorylase
purple acid phosphatase
putidaredoxin—NAD^+ reductase
pyranose oxidase
pyridoxamine—pyruvate transaminase

ulvan lyase
unspecific monooxygenase
uracil phosphoribosyltransferase
uracil-DNA glycosylase
urate hydroxylase
urease
uridine phosphorylase
urocanate hydratase
vanadium nitrogenase
verruculogen synthase
vetispiradiene synthase
xanthine dehydrogenase
xanthine oxidase
xanthine phosphoribosyltransferase
xylose isomerase
D-xylose reductase
