If this explanation is correct for human dihydrofolate reductase, this reactant activation is a particularly striking example of the power of a steric effect because NADPH differs from $NADP^+$ by only a hydrogen. In the case of dihydrofolate reductase from *E. coli* (25% identity; 3.9 gap percent), the association of NADPH enhances the dissociation of tetrahydrofolate by a factor of 350.[1162] Results from both crystallography and relaxation dispersion of hydrogen-1 in nuclear magnetic resonance spectra[1162,1163] are consistent with the adenylyl portion of NADPH initially associating on the surface of the complex between the enzyme and tetrahydrofolate and the nicotinamide portion then swinging into the active site at a rate of 21 s^{-1} before tetrahydrofolate dissociates into the solution with a rate constant of 1000 s^{-1}. The relaxation dispersion spectra also suggest that, in concert with the nicotinamide swinging into the active site, the 2-amino-4-oxo-5,6,7,8-tetrahydro-1*H*-pteridinyl group is displaced from its original position, coincident with a conformational change in the active site, but that even though it is displaced, the pteridinyl group remains associated with the active site for a short time until the entire molecule of tetrahydrofolate fully dissociates. Whether the conformational change or the extra hydrogen is responsible for the initial displacement was not determined. In the case of dihydrofolate reductase from *M. tuberculosis* (23% identity; 2.2 gap percent), the association of NADPH accelerates the dissociation of tetrahydrofolate by a factor of 2, but there is a conformational change in the active site prior to dissociation of the products that prevents this acceleration from increasing the overall rate of the reaction.[1164]

The displacement of products by reactants at the active site seems so unavoidable that it may occur far more often than the frequency with which obvious reactant activation is observed in steady-state kinetics. A kinetic mechanism in which dissociation of a product is accelerated by association of a reactant can apply even when obvious deviations from the usual rectangularly hyperbolic kinetic behavior are not observed. For example, mutation of Phenylalanine 31 in human dihydrofolate reductase to leucine produces an enzyme in which the reactant NADPH no longer displays reactant activation in steady-state kinetics. Nevertheless, it could

be shown that the association of NADPH still accelerated the dissociation of tetrahydrofolate by directly measuring rates of dissociation for the product tetrahydrofolate from the active site in the presence and absence of NADPH. The reason that reactant activation is no longer observed in steady-state kinetics of the mutant is that, following the transfer of a hydride from NADPH to 7,8-dihydrofolate (H_2F), the dissociation of 5,6,7,8-tetrahydrofolate (H_4F) from enzyme in which $NADP^+$ occupies the site for nicotinamide-adenine dinucleotide has become 30 times slower than when it is occupied by NADPH rather than only 5 times slower, so the reaction proceeds almost exclusively on the path in which NADPH associates before tetrahydrofolate dissociates

$$\begin{aligned} &\text{E·NADPH} \underset{k_{-1}}{\overset{k_1[\text{H}_2\text{F}]}{\rightleftharpoons}} \text{E·NADPH·H}_2\text{F} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \\ &\text{E·NADP}^+\text{·H}_4\text{F} \xrightarrow{k_3} \text{E·H}_4\text{F} \underset{k_{-4}}{\overset{k_4[\text{NADPH}]}{\rightleftharpoons}} \\ &\text{E·NADPH·H}_4\text{F} \xrightarrow{k_5} \text{E·NADPH} + \text{H}_4\text{F} \end{aligned} \qquad (3\text{–}475)$$

a kinetic mechanism that displays normal rectangularly hyperbolic behavior because there are no longer two kinetically significant paths for dissociation of product.[1165] For dihydrofolate reductase from *E. coli*, however, mutation of Leucine 54 to isoleucine accelerates the dissociation of tetrahydrofolate so that its rate becomes the same whether NADPH or $NADP^+$ is bound. The reactant activation is also lost,[1166] but for the opposite reason: namely, that dissociation of tetrahydrofolate has increased so much that association of NADPH no longer makes a difference and the reaction proceeds almost exclusively on the path in which tetrahydrofolate dissociates before NADPH can associate.

Porcine aconitate hydratase (see Equation 3–423),[1167] which catalyzes the three reactions

$$\begin{array}{ccc} \text{citrate} & \rightleftharpoons & \text{isocitrate} \\ & \rightleftharpoons & \\ \textit{cis}\text{-aconitate} + \text{H}_2\text{O} & & \end{array} \qquad (3\text{–}476)$$

is another example of such a **direct measurement of the rate of dissociation of a product**. The enzyme displays linear and uncomplicated initial rates with each of its three substrates as reactants.[1168] The unassisted release of [^{14}C]citrate from the active site of bovine aconitate hydratase in the absence of any other substrates is far too slow, however, for it to be a step in the conversion of *cis*-aconitate to citrate. If the release of [^{14}C]citrate is measured in the presence of unlabeled citrate, however, its release becomes fast enough. In addition, the effects of pH on the rate of the enzymatically catalyzed reaction are inconsistent with the effects of pH on the inhibition shown by analogues for the substrates. It has been concluded that as any one of the three carboxylato arms of a molecule of any one of the three products bound at the active site of aconitate hydratase momentarily pulls away from its subsite on the active site, either that carboxylato group can be trapped by a hydron or the subsite can be seized by the respective carboxylato arm of a molecule of the respective reactant entering the active site from the solution. Either event would prevent the carboxylato arm of the product from reassociating and would hasten the rate of dissociation of the product. If this is the case, aconitate hydratase would be an example of another enzyme the kinetics of which are unremarkable but that nevertheless uses reactants to displace products.

In other situations, the requirement for one of the reactants to associate before one of the products dissociates has been demonstrated in other ways. For example, protein farnesyltransferase from *R. norvegicus* catalyzes the reaction

$$\begin{aligned} &(2E,6E)\text{-farnesyl diphosphate} + \text{CVIM} \rightleftharpoons \\ &\qquad (2E,6E)\text{-farnesyl-CVIM} + \text{diphosphate} \end{aligned} \qquad (3\text{–}477)$$

where (2*E*,6*E*)-farnesyl-CVIM is the tetrapeptide CVIM farnesylated on the sulfanyl group of its cysteine. In a crystallographic molecular model of a complex between the enzyme and both the reactant (2*E*,6*E*)-farnesyl diphosphate and the product (2*E*,6*E*)-farnesyl-CVIM, the (2*E*,6*E*)-farnesyl group of the reactant has displaced the (2*E*,6*E*)-farnesyl group of the product from the farnesyl subsite while the tetrapeptide portion of the product remains bound at its subsite. This observation suggests that the reactant (2*E*,6*E*)-farnesyl diphosphate must associate with the active site before the product (2*E*,6*E*)-farnesyl-CVIM can dissociate,[562] even though (2*E*,6*E*)-farnesyl diphosphate does not display reactant activation.[1169]

There are **several factors that would limit the effectiveness of such mechanisms** for acceleration of the dissociation of product and hence the rate of the enzymatic reaction. First, in the conformation in which only a portion of the product has dissociated, there will likely remain considerable steric hindrance to the approach of the displacing ligand. This steric hindrance will be particularly acute if the displacing ligand is large and can associate with the momentarily exposed portion of the active site in only one particular conformation. In the case of protein farnesyltransferase, however, even though reactant and product are large, the entire (2*E*,6*E*)-farnesyl group in the farnesylated peptide that is its product can swing out of the active site while its tetrapeptide remains bound so that the (2*E*,6*E*)-farnesyl diphosphate that is its reactant can associate unhindered. Second, a rigid molecule like the pyranose of D-glucose acting as a reactant may be able to associate with an active site in only one specific orientation that could not be accommodated if any portion of the product was still bound. Third, not only such steric effects but also charge repulsion could prevent a molecule of the displacing ligand from associating even partially before the entire molecule of product has dissociated. Fourth, if the mechanism of the enzyme involves induced fit, the active site may be continuously changing its conformation as the product dissociates, and this plasticity might preclude the association of any other ligand until the active site was completely vacated. Finally, ligand-promoted dissociations of products are often observed only at high, unphysiological concentrations of the displacing ligand, and such examples could be irrelevant biologically. In spite of these difficulties, promotion of the dissociation of a molecule of product from the active site by a molecule of reactant or another ligand may still be a common feature of enzymatically catalyzed reactions.

The product of an enzymatic reaction in one direction is a reactant in the other direction, and by the principle of microscopic reversibility, if the dissociation of a product proceeds through multiple, reversible detachments, the **association of that same substrate as a reactant must proceed through multiple, reversible attachments.** In solution, most reactants for enzymes have internal rotational degrees of freedom around their single bonds and randomly assume many different conformations. When reactants are bound to an active site, however, only one of those conformations that can be achieved in solution is usually assumed on the site. While it is unlikely, a particular active site may pick only that one conformation out of the solution. It seems more reasonable, however, that an active site is able to **associate partially with the incorrect conformers of its reactant and promote the conformational change to the correct conformer**. In this strategy, following the association of only a portion of the reactant in a subsite of the active site, the sequential, reversible formation of the multiple attachments that are precisely positioned by that active site would cause any one of the many conformations of the reactant existing in solution to assume gradually the specific conformation it adopts when it is completely pinned down. As each attachment is formed and rotation about intervening single bonds then aligns the next set of noncovalent donors and acceptors, the next noncovalent interaction is completed, and so forth until all the attachments have formed, and the reactant has assumed the unique, bound conformation. For example, a small protein that has no detectable secondary structure in solution is a physiological inhibitor of aspartic endopeptidase A from *S. cerevisiae*. In a crystallographic molecular model of the inhibitor bound to the enzyme, the portion of the inhibitor occupying the active site is an α helix.[1170] One can imagine a sequence of properly aligned, noncovalent interactions, completed in a random order, that would guide the structureless inhibitor gradually into an α helix as opposed to the active site binding only the vanishingly small concentration of α helix in the solution.*

A similar issue arises in situations in which **a particular ionization state of a reactant is required for an enzymatic reaction**. For example, Arginine 381 forms a hydrogen bond with the phenoxy oxygen of the L-tyrosine that is a reactant for tyrosine phenol-lyase

$$\text{L-tyrosine} + H_2O \rightleftharpoons \text{phenol} + \text{pyruvate} + NH_4^+ \qquad (3\text{–}478)$$

from *C. freundii*, which uses pyridoxal 5′-phosphate as a prosthetic group. This hydrogen bond stabilizes the phenolate that is required in the elimination of the 1-oxo-2,5-cyclohexadien-4-yl group catalyzed by the enzyme.[1171] Does the enzyme associate only with the conjugate base of the 4-hydroxyphenyl

*It should be recalled that an isolated α helix is always unstable in solution, again because of the competition of molecules of water for the donors and acceptors of hydrogen bonds.

group of L-tyrosine, the phenolate, which is present in the solution at a low concentration relative to the conjugate acid, the phenol? Or does the 4-hydroxyphenyl group of L-tyrosine associate with the active site and does its hydron dissociate as the hydrogen bond forms with this arginine? The increase in the observed specificity constant for L-tyrosine, k_{tyr}, with increasing pH, from 65 M^{-1} s^{-1} at pH 6.6 to 1.3×10^4 M^{-1} s^{-1} at pH 8.4, suggests that the actual reactant for tyrosine phenol-lyase is the phenolate.

As do substrates, active sites change conformations during association and dissociation of substrates. It is usually assumed that the conformation of the enzyme from which the products dissociate is the same conformation with which the next set of reactants associate. There are instances, however, in which this is not the case.[1172,1173] In such an instance, **the conformation of the active site from which the product dissociates is different from the conformation with which the reactant associates**. For example, the conformation of triose-phosphate isomerase from *G. gallus* (Equation 3–384) from which glycerone phosphate has just dissociated as a product or with which glycerone phosphate must associate as a reactant is different from the conformation with which glyceraldehyde 3-phosphate must associate as a reactant or from which it has just dissociated as a product.[1174] In the case of proline racemase from *Clostridium stricklandii*

$$\text{L-proline} \rightleftharpoons \text{D-proline} \qquad (3\text{–}479)$$

the two forms of the enzyme, one specific for L-proline and the other for D-proline, are not different conformations but different tautomers in which the hydron just removed from the reactant still sits on the base that removed it and the conjugate base of the acid that just added a hydron to the reactant remains unhydronated.[1175] The hydron must be removed from the former and another hydron added to the latter before the next reactant can associate with the enzyme for the next catalytic cycle. The two forms of fumarate hydratase (Equation 3–1) from *S. cerevisiae*, however, are tautomers that also differ in conformation.[1176]

The simplest kinetic mechanism for these enzymes is

$$\mathrm{E} + \mathrm{A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}A} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{E'{\cdot}Z} \xrightarrow{k_3} \mathrm{E'} + \mathrm{Z} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \mathrm{E} + \mathrm{Z} \qquad (3\text{–}480)$$

In most cases, the conversion between the two conformations or two tautomers of the unliganded enzyme (E and E′) is so fast (0.1–10 μs^{-1})[1174] that it does not limit the catalytic constant of the enzyme, but a rate-affecting conversion can be detected by measuring flux ratios[1177] with isotopic tracers.[1172]

A large number of enzymes have substrates that are not solutes in free solution in an aqueous phase. One major group of such enzymes is those that catalyze reactions in which the substrates are **lipids**. Lipids such as fats, oils, polyisoprenoids, phospholipids, and sphingolipids are almost always dissolved in a separate amphipathic phase composed of either the lipid itself or a mixture of the lipid with other fats, oils, polyisoprenoids, phospholipids, or sphingolipids. These separate amphipathic phases can be fat droplets, lipoproteins, micelles, or membranes. There are some enzymes that are embedded permanently in one or the other of these separate amphipathic phases with their active sites immersed in that nonpolar phase, so their reactants can enter the active site from that phase and their products leave the active site into that phase by simple diffusion, just as reactants enter an active site from the aqueous solution by simple diffusion. Examples of such enzymes are bovine quinol—cytochrome-*c* reductase (Figure 2–32), an enzyme spanning the inner mitochondrial membrane that oxidizes ubiquinol, and the two related enzymes found in membranes of the endoplasmic reticulum: diacylglycerol *O*-acyltransferase,[1178] the enzyme responsible for the synthesis of triacylglycerols, and sterol *O*-acyltransferase,[1179] the enzyme responsible for acylating the 3-hydroxy group of cholesterol. Many enzymes that have substrates sequestered in a separate amphipathic phase, however, remain in the aqueous phase almost completely surrounded by water, but nevertheless their substrates in the amphipathic phase must associate with and dissociate from their active sites.

Phospholipase A_2 catalyzes the hydrolysis of phosphatidylcholine, which is 1,2-diacyl-*sn*-glycero-3-phosphocholine

1,2-diacyl-*sn*-glycero-3-phosphocholine
+ H_2O $\rightleftharpoons$ a carboxylic acid
+ 1-acyl-*sn*-glycero-3-phosphocholine
(3–481)

As was originally demonstrated with porcine triacylglycerol lipase,[1180] although phospholipase A_2 free in solution will hydrolyze soluble, unaggregated short-chain 1,2-diacyl-*sn*-glycero-3-phosphocholine, its activity increases dramatically when a particular 1,2-diacyl-*sn*-glycero-3-phosphocholine aggregates into micelles or bilayers[1181] or is dispersed into micelles of detergent.[1182] These observations demonstrate that the enzyme is most efficient when **operating at an interface** between the aqueous phase and a separate **amphipathic phase** in which the reactant is dissolved.

Phospholipase A_2 accomplishes its catalysis of the hydrolysis of its reactant phosphatidylcholine by associating with the surface of the amphipathic phase in which phosphatidylcholine is dissolved and, **while remaining bound to the surface, hydrolyzing many molecules of phosphatidylcholine** by diffusing in two dimensions or scooting over the surface to reach them one after the other.[1183] Such two-dimensional diffusion on a surface is the equivalent of the three-dimensional diffusion of the usual enzyme through the cytoplasm. Phospholipase A_2 from *N. atra* associates firmly with the surface of the amphipathic phase, in part through hydrophobic interactions between that surface and a ring of hydrophobic amino acids on the surface of the enzyme surrounding its active site,[1184] but human 1-alkyl-2-acetylglycerophosphocholine esterase, which also acts as a phospholipase on the surface of the amphipathic phase of a lipoprotein, has an amphipathic α helix 11 amino acids long that associates with the lipids and holds the enzyme on the surface.[1185] A molecule of phosphatidylcholine, when it is encountered by either of these scooting enzymes, rises by simple diffusion out of the surface into the active site.[1184] A similar ring of hydrophobic amino acids surrounds the active site of triacylglycerol lipase,[958,1186] which hydrolyzes triacylglycerides by a similar interfacial mechanism. The hydrophobic patch on the surface of human sphingomyelin phosphodiesterase, however, that mediates its association with a membrane does not surround the active site but is adjacent to it.[1187] In addition to the ring of hydrophobic amino acids that associate nonspecifically with the surface of the amphipathic phase, there is a separate site on phospholipase A_2 for binding tightly to the head groups of anionic phospholipids such as phosphatidic acid and phosphatidylserine in a biological membrane.[1188] This other site provides selection for biological membranes, which usually contain one of these anionic phospholipids, rather than any other amphipathic phase.

There are several observations consistent with this **scooting mechanism**. The initial rate of hydrolysis of phosphatidylcholine catalyzed by phospholipase A_2 increases as a rectangularly hyperbolic function of the concentration of micelles of phosphatidylcholine[1189] or the concentration of micelles of detergent containing a particular molar ratio of phosphatidylcholine.[1190] These results are consistent with the reversible association between the enzyme and a micelle and the dissociation constant being greater than 0. When the concentration of micelles of detergent is held at saturation so that all the phospholipase A_2 from *Naja naja* is bound to micelles at a given instant, the initial rate of hydrolysis increases as a rectangularly hyperbolic function of the mole fraction of phosphatidylcholine in the micelles.[1191,1192] This result is consistent with a normal enzymatic reaction proceeding through the collision and association of reactant with the active site as a result of diffusion of enzyme and phosphatidylcholine over the surface of each occupied micelle. When porcine phospholipase A_2 hydrolyzes 1,2-ditetradecanoyl-*sn*-glycero-3-phosphomethanol in the form of an aqueous suspension of small bilayer vesicles, the amount of hydrolysis achieved at the completion of the reaction increases nonlinearly with the concentration of phospholipase A_2.[1193] This result is consistent with a situation in which each molecule of enzyme, under these circumstances, participates in a kinetically irreversible association with a vesicle so that it can hydrolyze the phospholipid only by scooting over the surface of that one vesicle during the course of the reaction. If these small vesicles are fused into larger vesicles after the reaction has ceased, hydrolysis resumes as each molecule of enzyme encounters unhydrolyzed reactant that has fused with the vesicle to which it is bound. When the mole fraction of the diester 1,2-ditetradecanoyl-*sn*-glycero-3-phosphomethanol is increased in vesicles of the inert diether 1,2-ditetradecyl-*sn*-glycero-3-phosphomethanol, the initial rate of hydrolysis of the diester by porcine phospholipase A_2 increases.[1194] This result is again consistent with a normal enzymatic reaction proceeding through the collision and association of reactant with the active site as a

result of diffusion of enzyme and reactant over the surface of the vesicle.

Cellulose is a **solid** that is secreted by the cells of plants and bacteria. Individual long molecules of $[(\beta 1,4)\text{-D-glucose}]_n$ are the strands of polymer that comprise the solid. Each type of cellulose consists of a particular distribution of amorphous cellulose, in which the strands are randomly arrayed, and crystalline cellulose, in which the strands are aligned parallel to each other in a crystalline array. Crystalline cellulose is an impenetrable solid, so cellulases, the purpose of which is to hydrolyze cellulose, must operate on the surface of the solid. The holoenzyme of cellulose 1,4-β-cellobiosidase (reducing end) Cbh1, a cellulase from *Hypocrea jecorina*, associates with the surface of solid crystalline cellulose from *Cladophora* and diffuses over the surface at random at a rate of 30 nm s^{-1} until it encounters the reducing end of a strand of $[(\beta 1,4)\text{-D-glucose}]_n$ protruding from the surface. If it successfully associates with the end of the strand, it then digests the strand at a rate of 9 nm s^{-1}, successively releasing molecules of the disaccharide cellobiose, (β1,4)-D-glucosyl-D-glucose, from the reducing end of the polymer. The cellulase spends, on average, about 8 s digesting the polymer of $[(\beta 1,4)\text{-D-glucose}]_n$ with which it is associated before it dissociates, releasing over the interval about 70 molecules of cellobiose.[1195]

Some reactants are incorporated into linear polymers rather than separate phases with two-dimensional interfaces such as biological membranes. In such instances, enzymes searching the polymer for a specific reactant are often able to **diffuse along the polymer in one dimension**. As is the case with diffusion in solution or diffusion of an enzyme over a surface, diffusion of a protein along a linear polymer is usually an unbiased random walk in which motion in either direction has an equal probability, and the molecule of protein moves back and forth at random. A fibril of collagen is a linear cable formed by polymerization of individual collagen monomers.[1196] Interstitial collagenase cleaves fibrils of collagen into fragments by hydrolyzing a specific peptide bond in each collagen monomer in the fibril. This single peptide bond is the reactant that the enzyme has to find in the linear polymer. To accomplish this goal, a molecule of interstitial collagenase diffuses back and forth in a random walk along a collagen fibril, cleaving monomers at the specific peptide bond as it encounters each site of hydrolysis.[1197]

Double-stranded and single-stranded DNA are also linear polymers. A number of enzymes are able to diffuse along a strand of DNA searching for a particular reactant within the polymer.[1198] Examples of such proteins are *lac* repressor from *E. coli*,[1199] type II site-specific deoxyribonuclease BamHI from *Bacillus amyloliquefaciens*,[1200] DNA-(apurinic or apyrimidinic site) lyase V encoded by Escherichia phage T4,[1201] DNA (cytosine-5-)-methyltransferase from *E. coli*,[1202,1203] late enhancer complex for DNA-directed DNA polymerase encoded by Escherichia phage T4,[1204] and RNA-directed DNA polymerase encoded by human immunodeficiency virus.[1205]

The paradigm for diffusing along duplex DNA is type II site-specific deoxyribonuclease EcoRI from *E. coli*.[1206] The enzyme cleaves double-stranded DNA at the restriction site with the palindromic sequence GAATTC that is unmethylated on the two cytosines. The enzyme must find this sequence of nucleotides in long stretches of DNA before it cleaves it between guanine and adenine on each strand. To find the reactant, the enzyme associates with duplex DNA and diffuses along the DNA until it encounters the palindrome. When two fragments of duplex DNA, one 4316 base pairs long and the other 34 base pairs long, each with a restriction site approximately in their center, are mixed at equimolar concentrations, type II site-specific deoxyribonuclease is added for various times, and the rates at which the two fragments are cleaved at the respective restriction site are assessed, the apparent association of the enzyme with the longer fragment is about 7 times more rapid than with the shorter.[1206] The explanation is that, even though the molar concentration of the two restriction sites is the same, the likelihood of the enzyme encountering a portion of the longer DNA, associating with it, and diffusing to the restriction site is far greater than the likelihood of it encountering a portion of the shorter DNA and associating with it. Once it encounters any portion of duplex DNA, the enzyme associates and then diffuses along the duplex in a random walk to the restriction site.

When a fragment of 1027 base pairs containing two restriction sites in the middle separated by 51 base pairs was mixed at 100-fold molar excess with type II site-specific deoxyribonuclease from *E. coli* at an ionic strength of 0.13 M, the initial rate at which two cleavages were made in the fragment exceeds the initial rate at which only a single cleavage was made[1207] by a factor of 1.7. This observation suggests that the enzyme can associate with the duplex DNA, diffuse along it, and most times, but not always, make two consecutive cleavages before

dissociating. If the enzyme always cleaved the second restriction site once it had cleaved the first, no fragments that had been cleaved at only one site would have been observed. Six separate fragments of duplex DNA were then constructed in which two restriction sites were placed at distances from each other of 42, 134, 234, 335, 482, and 605 base pairs while on each side of each of the six pairs the length of DNA was the same. When each fragment was mixed in 400-fold molar excess with type II site-specific deoxyribonuclease at an ionic strength of 0.07 M, the ratio between the initial rate at which two cleavages were made by the enzyme in a fragment and the initial rate at which only a single cleavage was made declined as the distance between the two restriction sites was increased. From the ratio of these rates, it could be calculated that the first-order rate constant for diffusive movement of the enzyme from one base pair to an adjacent base pair in a random walk is 300,000 times greater than the first-order rate constant for dissociation of the enzyme from the DNA.[1208] Even for the two fragments in which the two restriction sites are separated by the shortest distances (42 base pairs and 135 base pairs), however, the rate constant at which a second cleavage occurs after the first is only 1.5 times the rate constant at which the first cleavage occurs. The fact that, on average, the protein walks at random from one base pair to one next door 300,000 times before it dissociates and yet often does not cover such short linear distances before it dissociates is simply a consequence of diffusing between two points in an unbiased random walk along a linear polymer.

One solution to this drawback of a random walk is to bias the diffusion. Biasing diffusion, however, requires an expenditure of standard free energy. DNA Helicase is an enzyme that unwinds duplex DNA into its component single strands. The energy necessary to perform the unwinding catalyzed by DNA helicase is provided by the hydrolysis of $MgATP^{2-}$. When it unwinds DNA the enzyme is a homodimer, but the monomer is able to diffuse along single-stranded DNA with a bias in the direction from the 3′ end to the 5′ end, and this bias is also established by hydrolyzing $MgATP^{2-}$. A molecule of $MgATP^{2-}$ is hydrolyzed each time DNA helicase PcrA from *G. stearothermophilus*[1209,1210] or the related (42% identity; 1.1 gap percent) DNA helicase UvrD from *E. coli*[1211] moves from one nucleotide in a single strand of DNA to the nucleotide on its 5′ side. A fragment of single-stranded DNA covalently labeled at its 5′ end with a fluorescent dye was preincubated at a 2-fold molar excess with monomers of DNA helicase UvrD from *E. coli*. After a monomer associated at random on a fragment of single-stranded DNA, its diffusion was initiated by adding $MgATP^{2-}$, and quenching of the fluorescence of the dye as a function of time was measured.[1212] If it is assumed that each monomer associated at random with the single-stranded DNA and then began to move toward the 5′ end when the $MgATP^{2-}$ was added, from the time course of the quenching, it could be calculated that the rate at which the monomer slides in one direction is 200 nucleotides s^{-1} at 25 °C. No movement of the protein could be detected in the absence of $MgATP^{2-}$.

In this instance, the stepping of the enzyme from one nucleotide to the one on its 5′ side, coincident with the hydrolysis of one molecule of $MgATP^{2-}$, can be considered to be a catalytic turnover of the monomer acting as an enzyme. In this view, the nucleotide in the active site, the nucleotide to its 5′ side, $MgATP^{2-}$, $MgADP^{-}$, and phosphate are the substrates for the enzyme, and the enzymatic reaction is the transfer of the active site from the nucleotide to the nucleotide to its 5′ side, or in other words, the transfer of the nucleotide on the 5′ side into the active site upon dissociation of the nucleotide on the 3′ side.

Problem 3–38: Draw the hydron wire in 4-hydroxytetrahydrodipicolinate synthase in the reset configuration by making the rotations indicated in **3–129** while replacing the water in the solution with a hydronium and rotating the hydroxy group on the substrate to offer a lone pair of electrons to the hydron wire. Then draw the configuration after the hydron is transferred as in Figure 3–60.

Problem 3–39: Nonspecific protein-tyrosine kinase v-Fps from Fujinami sarcoma virus catalyzes the transfer of the γ-phospho group from $MgATP^{2-}$ to a tyrosine in another protein. Its steady-state rate constants were measured in solutions containing various concentrations of glycerol or sucrose to produce different relative viscosities.[1213] The slope of the line for the ratio of its specificity constants as a function of the relative microviscosity of the solution, $k_{pep}\ k_{pep,\eta}^{-1}$, where pep refers to a tyrosyl-peptide used as a reactant for the enzyme in place of one of the proteins that are the natural reactants for the enzyme, is indistinguishable from 0 when measurements of the rate constant k_{pep} are made at saturating concentrations of $MgATP^{2-}$. Because $MgATP^{2-}$ can associate with the enzyme in the absence of the peptide, because $MgATP^{2-}$ is at saturation, and because the change in standard free energy for the overall reaction is significantly exergonic, it has been assumed that this observation of the effect of microviscosity means that the kinetic mechanism for the reaction is

$$\text{E·MgATP} + \text{pep} \underset{K_{d,pep,ATP}}{\rightleftharpoons} \text{E·MgATP·pep} \xrightarrow{k_6} \text{E·MgADP·Ppep} \xrightarrow[+\,\text{MgATP}]{k_7} \text{E·MgATP} + \text{MgADP} + \text{Ppep}$$

where Ppep is the peptide phosphorylated on its tyrosine.

(A) Why was it assumed that the association of the peptide with the enzyme can be described by a simple dissociation constant?

(B) Show that the rate equation for this mechanism is

$$v_0 = \frac{\left(\frac{k_6 k_7}{k_6 + k_7}\right)\left(\frac{k_6}{K_{d,pep,ATP}}\right)[E]_t[pep]_0}{\frac{k_6 k_7}{k_6 + k_7} + \left(\frac{k_6}{K_{d,pep,ATP}}\right)[pep]_0} = \frac{k_0\, k_{pep}[E]_t[pep]_0}{k_0 + k_{pep}[pep]_0}$$

(see Equation 3–40).

The observed slope of the line for the ratio of catalytic constants, $k_0\ k_{0\eta}^{-1}$, as a function of the relative microviscosity is 0.63 ± 0.072. In the absence of microviscogens, when the relative microviscosity of the solution is 1 by definition, the steady-state rate constant $k_{pep} = 35 \pm 7\ mM^{-1}\ s^{-1}$ and the catalytic constant $k_0 = 14 \pm 1\ s^{-1}$.

(C) Derive an expression for the slope of the line for $k_0\ k_{0\eta}^{-1}$ as a function of the relative microviscosity based on the assumed kinetic mechanism and rate equation. Assume that $k_7\ k_{7\eta}^{-1}$ is equal to η_{rel} (Equation 3–460) and that k_6 is unaffected by the microviscosity of the solution.

(D) What are the values of $K_{d,pep,ATP}$, k_6, and k_7 in the assumed mechanism?

Problem 3–40: Show that the mechanism in Equation 3–475 gives the rate equation

$$v_0 = \frac{k_0\, k_{NPH}\, k_{H_2F}[E]_t[NPH]_0[H_2F]_0}{k_0\, k_{NPH}[NPH]_0 + k_0\, k_{H_2F}[H_2F]_0 + k_{NPH}\, k_{H_2F}[NPH]_0[H_2F]_0}$$

where NPH is NADPH and H_2F is dihydrofolate.

(A) Show how this rate equation requires hyperbolic behavior when v_0 is measured as a function of $[NPH]_0$ at a fixed concentration of dihydrofolate.

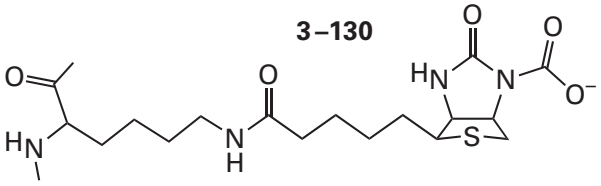
(B) If v_0^{-1} is plotted as a function of $[NPH]_0^{-1}$ at several fixed concentrations of dihydrofolate, what should be observed if the enzymatic reaction has the kinetic mechanism of Equation 3–475?

Transfer of Substrates among Active Sites

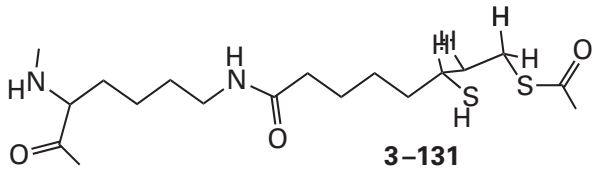
In most reactions that occur sequentially within a metabolic pathway, the product of the preceding reaction in the pathway is released into the cytoplasm from the active site of one enzyme; it diffuses freely and randomly; and upon fortuitous collision, it associates with the active site on the next enzyme. There are, however, situations in which the active sites for two or more different, consecutive reactions in a metabolic pathway are assembled into a **multienzymatic complex**.

In many multienzymatic complexes, substrates or portions of substrates are transferred as covalent adducts between active sites on the same multienzymatic complex without being released into the cytoplasm as free solutes.

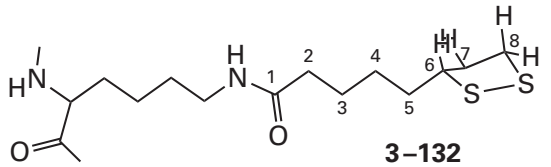
A family of **small, independently folding, detachable domains**[1214,1215] is responsible for transferring either an *N*-carboxybiotinyl group



or the corresponding uncarboxylated biotinyl group or an S^8-acyldihydrolipoyl group



or the corresponding lipoyl group



among the active sites of certain multienzymatic complexes. The *N*-carboxybiotinyl, biotinyl,[1216] S^8-acyldihydrolipoyl, and lipoyl groups[1217] are each covalently incorporated into their respective domains through an amide formed between their carboxy groups and nitrogen 6 of a lysine within the respective sequence of amino acids.* These domains, known as **biotin carboxyl-carrier domains and lipoyl acyl-carrier domains**, respectively, are all about 70 amino acids long, at the lower limit of the number of amino acids necessary to produce a stable folded globular structure in the absence of internal disulfides. Biotin carboxyl-carrier domains and lipoyl acyl-carrier domains are all evolutionarily related to each other (20–25% identity and less than 1 gap percent) and have superposable structures composed of a core of six roughly parallel β strands and often, but not always, a couple of peripheral β strands.[1214,1215,1218] The particular lysines to which the respective biotinyl groups or lipoyl groups are attached are at the same position in the respective sequences of amino acids when they are aligned with each other.

In the α_2 homodimer of **acetyl-CoA carboxylase**

$$\mathrm{MgATP^{2-} + HOCO_2^- + acetyl\text{-}SCoA \rightleftharpoons MgADP^- + HOPO_3^{2-} + H^+ + malonyl\text{-}SCoA} \quad (3\text{–}482)$$

from *S. cerevisiae*, the biotin carboxyl-carrier domain (BCCD) is located between positions 701 and 769 in the middle of the polypeptide (2233 aa) that folds to form each of the two identical subunits in the homodimer.[57] Acetyl-CoA carboxylase is a multienzymatic complex because each subunit contains two **enzymatic domains**. The active site of the amino-terminal enzymatic domain in each subunit catalyzes biotin carboxylase

$$\mathrm{MgATP^{2-} + HOCO_2^- + [BCCD]\text{-}N^6\text{-biotinyl-L-lysine} \rightleftharpoons [BCCD]\text{-}N^6\text{-carboxybiotinyl-L-lysine} + MgADP^- + H^+ + HOPO_3^{2-}} \quad (3\text{–}483)$$

and the active site of the carboxy-terminal enzymatic domain in each subunit catalyzes acetyl-CoA carboxytransferase

$$\mathrm{[BCCD]\text{-}N^6\text{-carboxybiotinyl-L-lysine} + acetyl\text{-}SCoA \rightleftharpoons malonyl\text{-}SCoA + [BCCD]\text{-}N^6\text{-biotinyl-L-lysine}} \quad (3\text{–}484)$$

The biotin carboxyl-carrier domain, which is between these two enzymatic domains in the polypeptide, is responsible for transferring the carboxy group that is covalently attached to nitrogen 6 of biotin (**3–130**) from the active site of biotin carboxylase, where it is added to biotin, to the enolate of acetyl-SCoA within the active site of acetyl-CoA carboxytransferase, where it is added to the enolate.

In the crystallographic molecular model of the complex between acetyl-CoA carboxylase from *S. cerevisiae* and coenzyme A (Figure 3–65),[57] the active site for acetyl-CoA carboxytransferase could be located by inspection because it is occupied by both coenzyme A and the biotinyl group. In this active site, nitrogen 1 of the biotinyl group is 0.43 nm from the sulfur of coenzyme A, an appropriate distance for carboxylation of the enolate of an acetyl group, if it were on the sulfur of the coenzyme A, by a carboxy group, if it were on nitrogen 1 of the biotinyl group.

*Note that the distal sulfur in each prosthetic group is six atoms from the amide and the acyl oxygen in each prosthetic group is 10 atoms from the amide.

Figure 3–65: Stereodrawing[576] of the crystallographic molecular model of one of the two subunits in the homodimer of the complex between acetyl-CoA carboxylase from *S. cerevisiae* and coenzyme A.[57] The enzyme is a dimer of two folded polypeptides, each 2233 amino acids long. A number of disordered segments of polypeptide in the crystal account for gaps in the molecular model. The biotin carboxyl-carrier domain (center right in the drawing), the biotinyl group (BTN) attached to the biotinylated carboxyl-carrier domain through an amide to Lysine 735 (**3–130**), and the molecule of coenzyme A are drawn with thicker lines. The label BTN is adjacent to the bicyclic *N,N′*-dialkylurea of the biotin, and the label CoA is adjacent to the sulfanyl group of coenzyme A. Coenzyme A occupies the active site for acetyl-SCoA, and the biotinyl group is docked in this active site as well. Because it is in the middle of the sequence of amino acids for the polypeptide, the biotinylated carboxyl-carrier domain is attached to the rest of the protein by two leashes. One is a short segment of extended polypeptide, within which are nine single bonds about which rotation of the polypeptide can occur. The other is a long stretch of polypeptide in which there is a disordered region between Proline 772 and Alanine 778 (dashed line in the center of the drawing) for which there is no electron density. The active site of biotin carboxylase (BC) was identified by superposing upon the enzymatic domain for biotin carboxylase the crystallographic molecular model of the ternary complex between $MgADP^-$ and biotin and the homologous (33% identity; 1.6 gap percent) biotin carboxylase from *E. coli*, which is a single enzyme and not part of a multienzymatic complex.

Although the domain in the crystallographic molecular model of acetyl-CoA carboxylase responsible for catalyzing biotin carboxylase could be readily identified by comparison with other biotin carboxylases, the active site within this domain in the crystallographic molecular model was unoccupied by any ligand. Therefore, the active site for biotin carboxylase in this domain was located by superposing on it the crystallographic molecular model of biotin carboxylase from *E. coli* in which the active site was occupied by biotin and $MgADP^-$.

The two active sites in the two enzymatic domains of one subunit of acetyl-CoA carboxylase are 8.0 nm apart. The biotinyl group is attached covalently to the biotin carboxyl-carrier domain by a tether (**3–130**) that, if fully extended, as it essentially is in the crystallographic molecular model (Figure 3–65), has a length of 1.4 nm. The biotin carboxyl-carrier domain is attached covalently to the rest of the subunit at its amino-terminal end by an extended disordered segment of polypeptide with the sequence ENDP and at its carboxy-terminal end by a long disordered leash of polypeptide (dashed line in Figure 3–65) with the sequence DDPSKVKHALPFEGMLPDFGSPVIEGTK. Even though the two active sites are so far apart, it can be seen that the biotinyl group should be able to withdraw from the active site of acetyl-CoA carboxytransferase, the biotin carboxyl-carrier domain should be able to **pivot on the amino-terminal connector while the long disordered carboxy-terminal connector winds around the pivot, and the biotinyl group should then be able t**o associate with the active site of biotin carboxylase. In this instance, it has been concluded that the biotin in the biotinylated carboxyl-carrier domain moves back and forth between the two enzymatic domains on the same subunit in the homodimer.

Pyruvate carboxylase

$$MgATP^{2-} + HOCO_2^- + \text{pyruvate} \rightleftharpoons MgADP^- + HOPO_3^{2-} + H^+ + \text{oxaloacetate} \quad (3\text{–}485)$$

is also a multienzymatic complex. The two enzymatic domains on each subunit in the complex catalyze two reactions analogous to those catalyzed by acetyl-CoA carboxylase: biotin carboxylase (Equation 3–483) and pyruvate carboxytransferase

$$[\text{BCCD}]\text{-}N^6\text{-carboxybiotinyl-L-lysine} + \text{pyruvate} \rightleftharpoons \text{oxaloacetate} + [\text{BCCD}]\text{-}N^6\text{-biotinyl-L-lysine} \quad (3\text{–}486)$$

Pyruvate carboxylase from *Rhizobium etli* is an α_4 homotetramer, and each folded polypeptide contains an amino-terminal enzymatic domain for biotin carboxylase and an enzymatic domain in the middle of the polypeptide for pyruvate carboxytransferase.

Unlike the biotin carboxyl-carrier domain in acetyl-CoA carboxylase from *S. cerevisiae*, which is in the middle of its polypeptide, the biotin carboxyl-carrier domain in pyruvate carboxylase from *R. etli* is at the carboxy-terminal end of its polypeptide. In the crystallographic molecular model,[1219] each of the four biotinylated carboxyl-carrier domains in the rotationally symmetric α_4 homotetramer is connected to the carboxy terminus of the rest of its folded polypeptide by a **structureless leash of polypeptide** with the sequence GATGAAVRRKAEPGNAA.

Unlike the biotinylated carboxyl-carrier domain in acetyl-CoA carboxylase, which transfers the carboxy group between two active sites on the same folded polypeptide in which the biotinylated carboxyl-carrier domain itself is located (Figure 3–65), a biotinylated carboxyl-carrier domain in pyruvate carboxylase on the end of a folded polypeptide in the homotetramer transfers the carboxy group between the active site of biotin carboxylase on another folded polypeptide in the complex and the active site of pyruvate transcarboxylase on yet another of the folded polypeptides. These two active sites, one on the second subunit and the other on the third subunit, are 6.5 nm apart, so the leash has to be long enough to accomplish this feat while remaining attached covalently to the first subunit. Because of the $222(D_2)$ symmetry of the α_4 homotetramer, there are four symmetrically distributed units of biotin carboxylase, pyruvate transcarboxylase, and biotinylated carboxyl-carrier domain in each molecule of the enzyme even though the three domains are each in three different subunits.

The **pyruvate dehydrogenase complex** is responsible for the overall reaction

$$\text{pyruvate} + HSCoA + NAD^+ \rightleftharpoons CO_2 + \text{acetyl-SCoA} + NADH \quad (3\text{–}487)$$

a reaction central to metabolism that connects glycolysis with the citric acid cycle. The homotetracosameric core of the complex from *E. coli* is a symmetric octahedral oligomeric protein[1220] composed of 24 identical, folded polypeptides 630 amino acids long arrayed around six twofold, four threefold, and three fourfold axes of symmetry.[1221] Consequently, the 24 subunits are symmetrically equivalent to each other. By taking advantage of the octahedral symmetry of the protein, a map of scattering density has been produced by reconstructive summation of electron microscopic images of the protein embedded in amorphous ice at a resolution sufficient to insert the 24 polypeptides and construct a molecular model of this homotetracosameric core.[1222]

The 316 amino-terminal amino acids in each of the 24 core polypeptides[1223] comprise **three lipoyl acyl-carrier domains**, each homologous to a biotin carboxyl-carrier domain. As is the case with biotinylated carboxyl-carrier domains, these lipoyl acyl-carrier domains are around 70 amino acids long and folded into a globular structure.[1224,1225] Because all three of the lipoyl acyl-carrier domains in each amino-terminal segment are homologous to each other, they are **internally repeating domains**. Because the three consecutive lipoyl acyl-carrier domains in each subunit of the pyruvate dehydrogenase complex are at the amino-terminal end of the polypeptide forming that subunit, the biotinylated carboxyl-carrier domain in acetyl-CoA carboxylase is found in the middle of its polypeptide, and the biotinylated carboxyl-carrier domain in pyruvate carboxylase is found at the carboxy-terminal end of its polypeptide, these homologous domains are also **evolutionarily shifting domains**.*

In the pyruvate dehydrogenase complex, the acyl group being transferred among the active sites by the lipoyl acyl-carrier domain is an acetyl group. Depending on its place in the catalytic cycle at a given instant, each lipoyl acyl-carrier domain on the homotetracosameric core contains a covalently attached lipoyl group (**3–132**), an S^8-acetyldihydrolipoyl group (**3–131**),[1217] or a dihydrolipoyl group (**3–131** with the acetyl group replaced by a hydron) extending out from its surface the same length as the biotinyl group extends out from the surface in a biotin carboxyl-carrier domain (Figure 3–65). Between the first and second internally repeating domains on each folded polypeptide in the pyruvate dehydrogenase complex from *E. coli* is the sequence ADGAADAAPAQAEEKKEAAPAAAPAAAAAKDVA; between the second and third internally repeating domains is the sequence GEAGAAAPAAKQEAAPAAA-PAPAAG; and between the third internally repeating domain and the rest of the folded polypeptide is the sequence GAAPAAAPAKQEAAAPAPAAKAEAPAAAP-AAKAEG.

The inescapable conclusion from an examination of their sequences alone, in particular considering the high fraction of alanines and prolines, is that each segment is completely disordered and acts as a **flexible leash of random coil**. Consequently, the three consecutive globular lipoyl acyl-carrier domains and their attached N^6-(lipoyl)lysine form **a flexible, triply jointed arm** extending out from each of the 24 protomers in the core.[1226] The purpose of this flexibility is to permit each N^6-(lipoyl)lysine on the arms to gain access consecutively to the three unique active sites in the multienzymatic complex. The individual leashes connecting the domains, if fully extended, are between 10 and 13 nm long, and when the arm is fully extended, it should cover a distance of about 40 nm. In the molecular model from electron microscopy, only the third of these three domains from each subunit, the one closest to the core, is present, presumably because the other two have been frozen in many different locations and orientations and are consequently absent from the reconstruction.[1222] The lipoyl acyl-carrier domain closest to the core seems to assume only one orientation because its lipoyl lysine is inserted into the active site on its subunit and thereby fixed in location.

The pyruvate dehydrogenase complex from *E. coli* can be dissociated and resolved into three separate, discrete proteins: the core and two other proteins.[1227] Each protein carries an active site responsible for one of the three steps in the overall reaction catalyzed by the complex (Equation 3–487). Each of the **three separate enzymes is composed of copies of its own distinct folded polypeptide**, and they are not connected covalently to each other, as are the enzymatic domains in acetyl-CoA carboxylase and pyruvate carboxylase, but associated noncovalently. The core forms the center of the complex. The other two proteins are attached through interfaces between them and the core in the intact complex, but when separated from the core, they are homodimers with the usual twofold rotational axes of symmetry relating

*Evolutionarily shifting domains are domains that are homologous, either in amino acid sequence or because their crystallographic molecular models are superposable, and that appear at different locations in the polypeptides of apparently unrelated proteins. The inference is that natural selection caused them to be inserted adventitiously into already existing proteins.

their respective subunits.[1228,1229] Images of molecules of the entire complex embedded in amorphous ice have also been submitted to reconstruction, but because of the size of the complex, the resulting molecular model is not of sufficient resolution to insert any of the constituent polypeptides. Nevertheless, large globular structures formed from the other two subunits situated on twofold rotational axes of the octahedral core can be observed in the molecular model.[1222]

Pyruvate dehydrogenase (acetyl-transferring)[1229]

$$\text{pyruvate} + \text{protein } N^6\text{-(lipoyl)lysine} + H^+ \rightleftharpoons CO_2 + \text{protein } N^6\text{-(}S\text{-acetyldihydrolipoyl)lysine} \quad (3\text{–}488)$$

is a homodimeric protein (2×887 aa) bound noncovalently to the homotetracosameric core of the pyruvate dehydrogenase complex. Each identical and symmetrically arrayed active site of pyruvate dehydrogenase (acetyl-transferring) uses thiamine diphosphate as a prosthetic group to decarboxylate pyruvate, creating 2-(1-hydroxyethylidene)thiamine diphosphate (Figure 2–6), and then transfers the hydroxyethylidene group of the decarboxylated pyruvate (Figure 2–7) as an acetyl group to an N^6-(lipoyl)lysine (**3–132**) on one of the lipoyl acyl-carrier domains on one of the jointed, flexible arms that happens to be bound to its active site.

The flexible arm then swings around randomly until the resulting N^6-(*S*-acetyldihydrolipoyl)lysine can associate with one of the 24 identical, symmetrically arrayed active sites of dihydrolipoyllysine-residue acetyltransferase

$$\text{protein } N^6\text{-(}S\text{-acetyldihydrolipoyl)lysine} + \text{HSCoA} \rightleftharpoons \text{acetyl-SCoA} + \text{protein } N^6\text{-(dihydrolipoyl)lysine} \quad (3\text{–}489)$$

This enzyme is the homotetracosameric core itself, and the acetyl group arriving on the sulfanyl group in the dihydrolipoyl group of the lipoyl acyl-carrier domain is transferred by the active site to the sulfanyl group of coenzyme A.

The long flexible arm then swings around randomly until the N^6-(dihydrolipoyl)lysine (**3–131**, with the acetyl group replaced by a hydron) on the lipoyl acyl-carrier domain that is the product of the second acetyl transfer can associate with one of the two identical, symmetrically displayed active sites of dihydrolipoyl dehydrogenase[1228]

$$\text{protein } N^6\text{-(dihydrolipoyl)lysine} + NAD^+ \rightleftharpoons NADH + H^+ + \text{protein } N^6\text{-(lipoyl)lysine} \quad (3\text{–}490)$$

another dimeric protein (2×474 aa) bound noncovalently to the homotetracosameric core, and the N^6-(dihydrolipoyl)lysine is oxidized to N^6-(lipoyl)lysine (**3–132**). The long flexible arm then swings around randomly until the N^6-(lipoyl)lysine that is the product of dehydrogenation can associate with an active site for pyruvate dehydrogenase (acetyl-transferring) (Equation 3–488), and the cycle begins again.

In this description, the impression is left that the pyruvate dehydrogenase complex can be divided into 24 independent sectors, each of which is serviced by one of the 24 triply jointed arms and in which these cycles proceed in isolation, much as acetyl-CoA carboxylase seems to be divided into two independent sectors and pyruvate carboxylase can be divided into four independent sectors. It has been demonstrated, however, that the **arms on which the lipoyl acyl-carrier domains are situated are so long and so flexible that a significant fraction of the active sites within a given complex are chemically interconnected**.

A set of pyruvate dehydrogenase complexes from *E. coli*, containing decreasing ratios of the active site for the first enzyme in the sequence, pyruvate dehydrogenase (acetyl-transferring), can be produced either by reconstituting the complex with less than stoichiometric amounts of this particular protein[1230,1231] or by adding an inhibitor of such high affinity that it binds stoichiometrically to a portion of these active sites.[1231] The overall enzymatic activity decreases in direct proportion to the loss of these active sites, and the rate at which N^6-(lipoyl)lysine is acetylated by [2-^{14}C]pyruvate in the absence of coenzyme A and NADH also decreases in direct proportion to the loss of these active sites (Figure 3–66).[1232] All the N^6-(lipoyl)lysines on the lipoyl acyl-carrier domains in the complex, however, still become acetylated in a simple first-order reaction (Figure 3–66), even when as few as five competent active sites for pyruvate dehydrogenase (acetyl-transferring) are present for every homotetracosameric core of dihydrolipoyllysine-residue acetyltransferase.[1231] When, however, fewer than two competent

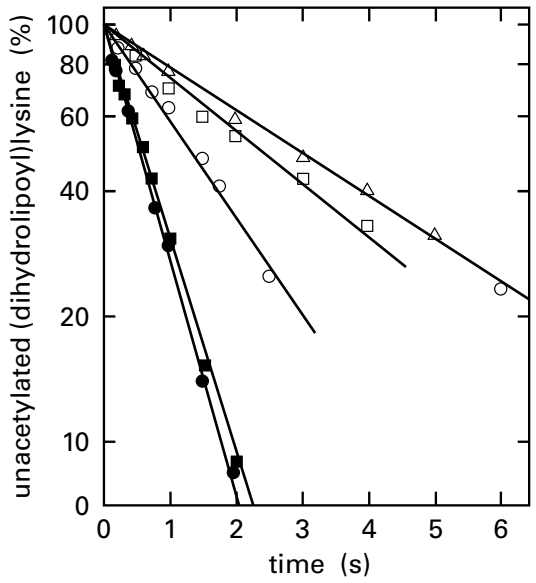


Figure 3–66: Incorporation of [2-^{14}C]pyruvate into a series of partly assembled pyruvate dehydrogenase complexes.[1232] The pyruvate dehydrogenase complexes were reassembled from purified pyruvate decarboxylase and a purified form of the complex between dehydrolipoamide transacetylase and dihydrolipoyl dehydrogenase with a stoichiometry of 0.88 polypeptide of dehydrogenase for every polypeptide of transacetylase. Various ratios of these two purified proteins were mixed and allowed to reassemble, and the products were purified. This procedure produced complexes with 0.21 (△), 0.39 (□), 0.71 (○), and 1.29 (●) polypeptides of decarboxylase for every polypeptide of transacetylase. The native protein (■) has 1.24 polypeptides of decarboxylase for every polypeptide of transacetylase. Transfer of the acetyl moiety from [2-^{14}C]pyruvate (18 μM) to the N^6-(lipoyl)lysines of the transacetylase was monitored as a function of time at 0.7 mM thiamine diphosphate, 10 mM $MgCl_2$, and 1.0 mM NAD^+ at pH 7.0 and 25 °C. The reaction was quenched at various times by mixing with trichloroacetic acid, and the radioactivity bound to protein was assayed. The common logarithm of the percent N^6-(dihydrolipoyl)lysine not acetylated is presented as a function of time (seconds). Notice that the N^6-(lipoyl)lysines became acetylated in each case in a simple first-order reaction.

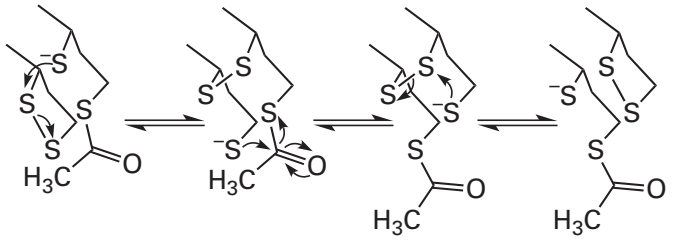
active sites for pyruvate dehydrogenase (acetyl-transferring) are present for every homotetracosameric core of dihydrolipoyllysine-residue acetyltransferase, the acetylation of N^6-(lipoyl)lysines is incomplete, From the final levels of acetylation reached at these low molar ratios of active sites for pyruvate dehydrogenase (acetyl-transferring), it was concluded that each active site in these more incomplete complexes can accomplish the acetylation of only a third to a half of the N^6-(lipoyl)lysines on the homotetracosameric core.[1230,1233]

For steric reasons, a third to a half of the 72 N^6-(lipoyl)lysines on all 72 lipoyl acyl-carrier domains covalently attached to the homotetracosameric core are unable to associate with the same active site on a particular homodimer of pyruvate dehydrogenase (acetyl-transferring). In fact, in the molecular model of the complex, because each globular structure containing dihydrolipoyl dehydrogenase and pyruvate dehydrogenase (acetyl-transferring) sits on one of the twofold axes,[1222] each well removed from the others, the pyruvate dehydrogenase complex can be divided into 12 independent sectors. It must be the case that although the N^6-(lipoyl)lysines on several lipoyl acyl-carrier domains can be acetylated in succession by the same active site of pyruvate dehydrogenase (acetyl-transferring), most of the distribution of acetyl groups over the surface of the homotetracosamer among the 24–36 N^6-(lipoyl)-lysines that can be eventually acetylated by a single active site results from rapid, uncatalyzed exchange of both sulfanyl groups and acetyl groups between sulfanyl groups



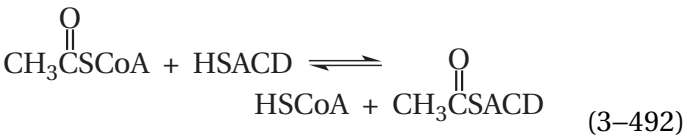
(3–491)

Therefore, acetyl groups are transferred not only among active sites in the complex but also among the N^6-(dihydrolipoyl)lysines attached to the core of the complex. As a result, complexes that are missing up to 80% of their pyruvate dehydrogenase (acetyl-transferring) subunits are still able to function efficiently. This rapid transfer of acetyl groups among all the N^6-(dihydrolipoyl)lysines can still occur unabated in a deletion mutant in which the two amino-terminal lipoyl acyl-carrier domains have been removed, but shortening the leash that is rich in alanines and prolines between the remaining lipoyl acyl-carrier domain and the rest of the protein from 36 amino acids to fewer than 20 amino acids pulls the remaining lipoyl acyl-carrier domain into the central homotetracosamer and decreases its extent significantly.[1234]

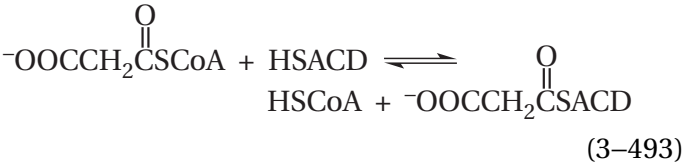
An examination of Equation 3–491 leads to the conclusion that a pyruvate dehydrogenase complex, which, for any reason, is deficient in functional active sites for dihydrolipoyl dehydrogenase, should be able to equilibrate dithio groups among all of its 72 lipoyl acyl-carrier domains just as it equilibrates acetyl groups.

The animal fatty-acid synthase system is a multienzymatic complex that is an α_2 homodimer, in which each of the two identical folded polypeptides contains six globular enzymatic domains and an **acyl-carrier domain** (ACD). The entire length of a constituent human polypeptide is 2511 amino acids. In prokaryotes and plants, the six enzymes that together accomplish the synthesis of fatty acids are six unassociated, separate proteins. The **acyl-carrier protein** that carries the elongating fatty acyl group among them as they diffuse at random through the cytoplasm is also a small separate protein. Several of the six enzymatic domains and the acyl-carrier domain in animal fatty acid synthases are homologous in their sequences of amino acids to the respective proteins of plants and bacteria. All the enzymatic domains can be delineated in the complete sequences of amino acids for the multienzymatic complexes from *G. gallus* and *R. norvegicus* by alignment of these two homologous sequences with those of the plant and bacterial enzymes and the position of peptides within these complete sequences that have been identified as participating in particular active sites of intact animal fatty-acid synthase systems.[1235,1236]

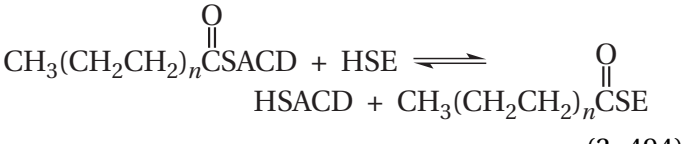
The six enzymatic domains of the animal fatty-acid synthase system catalyze eight reactions[1237]



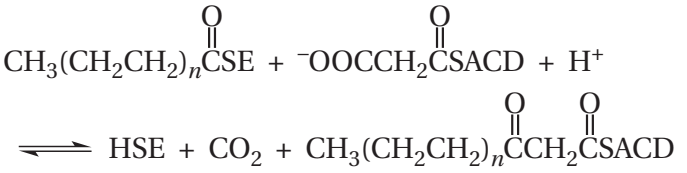
(3–492)



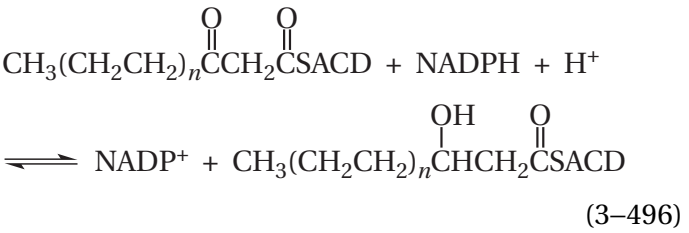
(3–493)



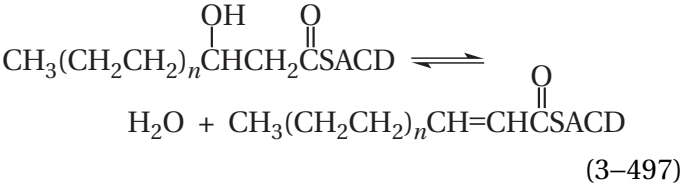
(3–494)



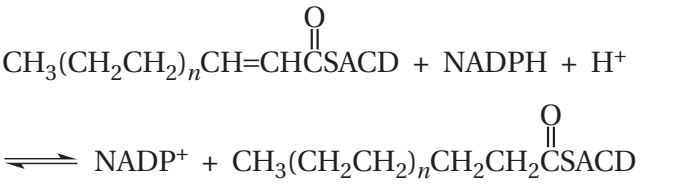
(3–495)



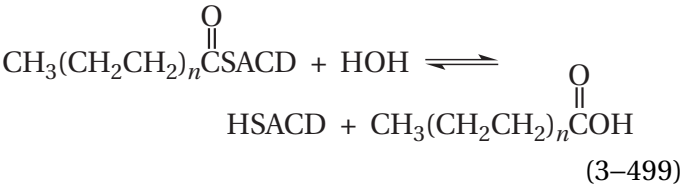
(3–496)



(3–497)



(3–498)



(3–499)

where HSACD is a sulfanyl group on the phosphopantotheinyl group attached as a phosphodiester to a serine in the acyl-carrier domain and HSE is a sulfanyl group on a cysteine in the active site in the domain responsible for β-ketoacyl-[acyl-carrier-protein] synthase I.

The first two reactions, [acyl-carrier-protein] *S*-acetyltransferase (acetyltransferase; Equation 3–492) and [acyl-carrier-protein] *S*-malonyltransferase (malonyltransferase; Equation 3–493), are nucleophilic substitutions of the sulfanyl group of an acyl-carrier domain in the enzyme for the sulfanyl group of coenzyme A at the respective acyl carbon. Both nucleophilic substitutions are catalyzed by the same active site in acyltransferase, one of the enzymatic domains. β-Ketoacyl-[acyl-carrier-protein] synthase I (oxoacyl synthase; sum of Equations 3–494 and 3–495), is carried out by an active site on one of the other enzymatic domains. The final four reactions —3-oxoacyl-[acyl-carrier-protein] reductase (oxoacyl reductase; Equation 3–496), 3-hydroxyacyl-[acyl-carrier-protein] dehydratase (hydroxyacyl dehydratase; Equation 3–497), enoyl-[acyl-carrier-protein] reductase (NADPH, *Re*-specific) (enoyl reductase; Equation 3–498), and oleoyl-[acyl-carrier-protein]

hydrolase (oleoyl hydrolase; Equation 3–499)—are each carried out by one of the other four enzymatic domains in the intact enzyme. The acyl-carrier domain is responsible for carrying the elongating fatty acyl group among the active sites on four of the six enzymatic domains, those catalyzing the reactions of Equations 3–494 through 3–498. When the elongating fatty acid is the proper length, oleoyl hydrolase hydrolyzes it from the sulfanyl on the acyl-carrier domain, and it dissociates into the cytoplasm as a fatty acid.

The acyl-carrier domains, although the same size as the biotinylated carboxyl-carrier domains and the lipoyl acyl-carrier domains, are unrelated to them.* They are instead globular, independently folding, detachable domains that are composed of only α helixes, with no β structure. Each of the two small, globular acyl-carrier domains (70 aa) in an animal fatty-acid synthase system[1238,1239] sits between the five amino-terminal enzymatic domains and a sixth carboxy-terminal enzymatic domain in the sequence of amino acids for each of the two polypeptides that constitute the homodimeric multienzymatic complex.[1237] Consequently, each acyl-carrier domain is in theory attached to the protein by two strands of polypeptide, just as is the biotin carboxyl-carrier domain in acetyl-CoA carboxylase (Figure 3–65). It turns out, however, that the carboxy-terminal enzymatic domain, which is oleoyl hydrolase (Equation 3–499) responsible for only the final step in the synthesis of a fatty acid, is not associated with the large structure formed from the five amino-terminal enzymatic domains (Figure 3–67).[1240] Instead it is a free-floating globular domain[1241,1242] attached to the carboxy terminus of the acyl-carrier domain by a long flexible strand of polypeptide 25 amino acids long.

The portion of the fatty-acid synthase system resolved in the crystallographic molecular model of the porcine enzyme is formed from the two sets of five amino-terminal enzymatic domains from the two identical folded polypeptides of the α_2 homodimer. In this resolved portion of the complete homodimer, there are two identical, symmetrically arrayed **open bays** on either side of the complete protein that are each formed by and surrounded by two peninsulas (Figure 3–67).[1240] The upper peninsula in the drawing is formed of three globular enzymatic domains from the carboxy-terminal 1699 amino acids of the resolved portion of one folded polypeptide in the homodimer. The lower peninsula is formed of two globular enzymatic domains from the amino-terminal 414 amino acids of the resolved portion of the other folded polypeptide in the homodimer.

The acyl-carrier domain is carboxy-terminal to the fifth enzymatic domain, which is the domain responsible for oxoacyl reductase (OR). It is in the same folded polypeptide chain as this enzymatic domain, and it is **attached to this fifth domain by a leash** (LSH in Figure 3–67) The leash contains no hydrophobic amino acids that would be necessary for it to have any stable structure. Consequently, it is a flexible, protean, random coil. The leash in the porcine fatty-acid synthase system, –KKAAAPRDGSS–, if fully extended, would be around 4 nm long. The carboxy-terminal serine of the leash is attached to the acyl-carrier domain on the side opposite the phosphopantotheinyl group, and the point of connection is 1.7 nm from that sulfanyl group. These dimensions give the sulfanyl group a range of 5.7 nm from its point of attachment.

The flexibility of the leash permits the acyl-carrier domain to wander randomly around the open bay, in a manner similar to the biotinylated carboxyl-carrier domain wandering back and forth between the two domains in acetyl-CoA carboxylase (Figure 3–65). It picks up an acetyl group at the active site on acyl transferase (AT) that catalyzes both acetyltransferase and malonyltransferase; swings over to the active site of oxoacyl synthase (OS) and drops off that acetyl group on a sulfanyl group in its active site; swings back to the active site of the former enzymatic domain to pick up a malonyl group; swings back over to the active site of oxoacyl synthase, which condenses that malonyl group with the acetyl group, or in later cycles an elongating fatty acid, on the sulfanyl group in its the active site. The 3-oxoacyl group from the condensation ends up on the sulfanyl group of the acyl-carrier domain, which then swings from there to the active sites for oxoacyl reductase (OR), hydroxyacyl dehydratase (DH), and enoyl reductase (ER) before swinging back to the active site for oxoacyl synthase to deposit the longer fatty acyl group on the same sulfanyl group in its active site. When the fatty acyl group becomes the proper length, its transfer to the sulfanyl group in the active site of oxoacyl synthase slows down so dramatically[1243] that the freely floating, carboxy-terminal oleoyl hydrolase (Equation 3–499)

*It is possible that these unrelated domains are the same size because natural selection has pared them both down to the minimum size for the folding of a polypeptide.

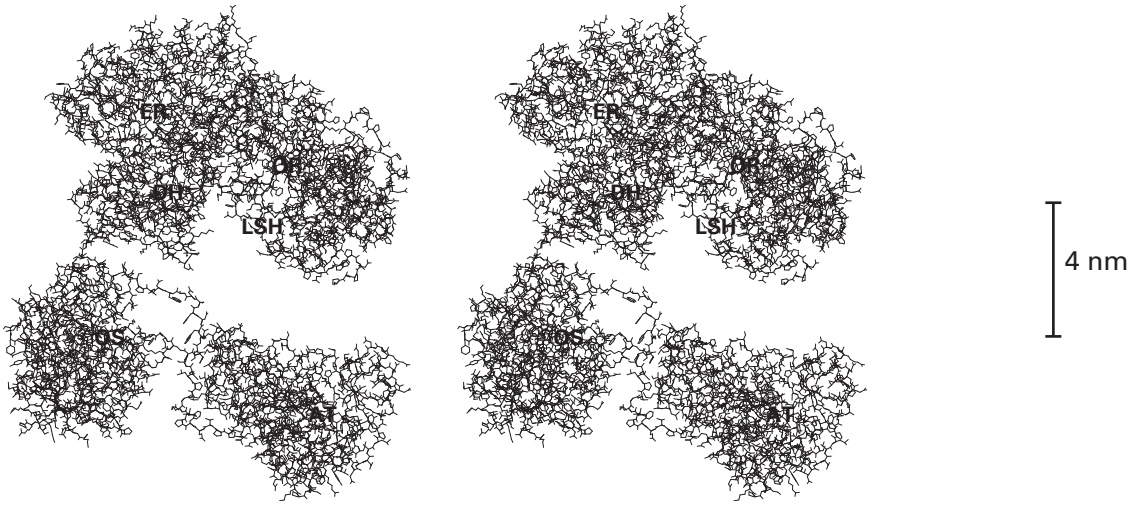


Figure 3–67: Stereodrawing[576] of the crystallographic molecular model of enzymatic domains of the porcine fatty-acid synthase system that form two peninsulas surrounding and creating the open bay around the shoreline of which the acyl-carrier domain ferries the elongating fatty acyl group from active site to active site.[1240] The enzyme is a dimer of two folded polypeptides, each 2512 amino acids long. Because, however, the acyl-carrier domain and the enzymatic domain catalyzing oleoyl hydrolase, which are attached to the carboxy terminus of the fifth enzymatic domain from the amino terminus, are on intentionally flexible leashes, their locations fluctuate dramatically within the crystal and no electron density is observed for either. Consequently, the folded polypeptide in the crystallographic molecular model ends at Glutamate 2113 even though the remaining 399 amino acids are present. The flexible leash, on the end of which is the acyl-carrier domain, is attached at this location in the model, designated as LSH. The leash is about 4 nm long, and the scale provided to the right is that length. The two folded polypeptides that comprise the dimer in the crystallographic molecular model are arrayed around a twofold rotational axis of pseudosymmetry. The relation of the two folded polypeptides is pseudosymmetric because there is a flexible neck connecting the upper peninsula in the drawing to the lower peninpeninsula. This neck is composed of a single strand from each of the two folded polypeptides. There is also a flexible link between the two enzymatic domains on the lower peninsula. Consequently, when the entire molecule crystallizes, the rotational axis is bent at the neck by crystal packing. The axis of pseudosymmetry is vertical and on the left-hand edge of the drawing. Only one half of the entire crystallographic molecular model is drawn. The active sites for acyltransferase (AT), oxoacyl synthase (OS), oxoacyl reductase (OR), hydroxyacyl dehydratase (DH), and enoyl reductase (ER) are labeled. The upper peninsula of the bay is formed from three compact enzymatic domains (ER, OR, and DH), and the lower penninsula is formed from two compact enzymatic domains (OS and AT).

on the longer leash has the time to find it and hydrolyze it from the acyl-carrier domain to give the fatty acid that is the product of the sequence of condensations and reductions.

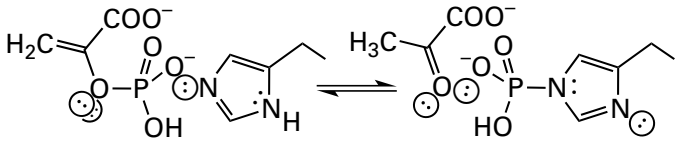
Unlike the biotinylated carboxyl-carrier domain, which is clearly resolved in the crystallographic molecular model of acetyl-CoA carboxylase from *S. cerevisiae* (Figure 3–65) because its biotinyl group is firmly associated with the active site of the acetyl-CoA carboxytransferase, neither the acyl-carrier protein domain nor the enzymatic domain that catalyzes oleoyl hydrolase is resolved in the crystallographic molecular model of the porcine fatty-acid synthase system. The panthotheinyl groups on the acyl-carrier domains in the crystal, in the absence of the active production of fatty acids, must not associate with any active site, and they are wandering aimlessly around in their respective bays in the molecules of enzyme in the crystal.

In one molecular model produced from reconstructive summation of electron microscopic images of the fatty-acid synthase system from *S. cerevisiae*, separate features of scattering density of the proper size for its acyl-carrier domain are observed in the immediate vicinity of the active sites for acyl transferase, oxoacyl synthase, oxoacyl reductase, and enoyl reductase. The scattering densities observed are consistent with the unacylated acyl-carrier domain in this enzyme, in the absence of reactants, spending 30%, 30%, 10%, and 30% of its time associated with the respective active site.[1244] In another molecular model, however, also produced from reconstructive summation of electron microscopic images of the fatty-acid synthase system from *S. cerevisiae*, the acyl-carrier domain can be resolved, and it is associated with the active site of acyl transferase.[1245] In a crystallographic molecular model of the same enzyme, the acyl-carrier domain is also resolved but not associated with any of the active sites.[1246] The fatty-acid synthase system from *S. cerevisiae* is an $\alpha_6\beta_6$ heterododecamer in which six $\alpha\beta$ heterodimers are arranged with 322(D_3) symmetry, and the order in which the different active sites are arranged around each of the six bays in the molecule differs from their order in the mammalian fatty-acid synthase system.

Unlike a biotinylated carboxyl-carrier domain, a lipoyl acyl-carrier domain, or an acyl-carrier domain, the small, globular phosphoryl-carrier domain (99 aa) in pyruvate, phosphate dikinase (Problem 3–13)

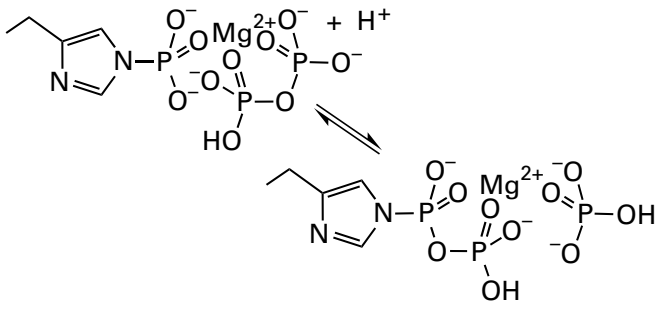
$$\text{phospho}\textit{enol}\text{pyruvate} + MgOPO_3PO_3^{2-} + 2\,H^+ + AMP^{2-} \rightleftharpoons MgATP^{2-} + HOPO_3^{2-} + \text{pyruvate} \quad (3\text{–}500)$$

from *C. symbiosum*, which transfers a phospho group between the two active sites on its two respective enzymatic domains, is not on a leash of flexible polypeptide or on a flexible, jointed arm. It performs the transfer by rotating 100° back and forth around a fixed axis that lies between two adjacent strands of extended, flexible polypeptide connecting the phosphoryl-carrier domain to two enzymatic domains (340 aa), one amino-terminal and one carboxy-terminal to it.[1247-1249] These two strands act as a **stationary spindle on which the phosphoryl-carrier domain revolves**. The imidazolyl group of the histidine that is to carry the phospho group between the two enzymatic domains is phosphorylated by phospho*enol*pyruvate at the active site in the carboxy-terminal enzymatic domain



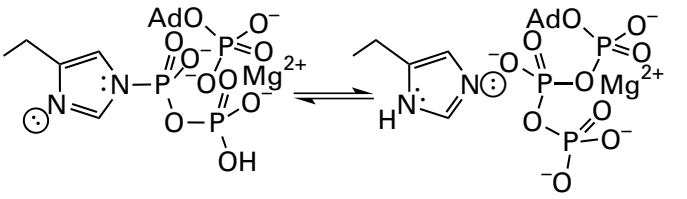
(3–501)

and the phospho group on the imidazolyl group rides on the surface of the rotor to the active site in the amino-terminal enzymatic domain where it is phosphorylated by magnesium diphosphate



(3–502)

and then transfers the resulting magnesium diphospho group[1250] from the imidazolyl group of the histidine to AMP^{2-} to form $MgATP^{2-}$



(3–503)

where Ad is an adenosyl group.

Methionine synthase from *E. coli* is an α_2 homodimer composed of two polypeptides 1226 amino acids long. The two globular **cob(I)alamin methyl-carrier domains** (235 aa) in each folded polypeptide contain the cob(I)alamin that in turn transfers a methyl group among three larger, globular enzymatic domains (325, 261, and 324 aa). Each cob(I)alamin methyl-carrier domain is located between the second and third domains in the sequence of amino acids for the complete polypeptide. In this instance, unlike biotinylated carboxyl-carrier domains, lipoyl acyl-carrier domains, or acyl-carrier domains, which are flexibly anchored domains attached to larger globular structures, the two cob(I)alamin methyl-carrier domains in the homodimer of methionine synthase can be considered the core of the structure because the only interface holding the two intact folded polypeptides together to form the homodimer is between these two methyl-carrier domains. As such, these two domains together form a relatively large, compact dimeric globular structure. Within the interface in this globular structure between these two identical cob(I)alamin methyl-carrier domains is a twofold rotational axis of symmetry relating only these two domains.[1251]

The three enzymatic domains of methionine synthase, listed from the amino terminus of each folded polypeptide to its carboxy terminus, catalyze the respective reactions

$$\text{Co(III)CH}_3 + \text{L-homocysteine} \rightleftharpoons \text{L-methionine} + \text{Co(I)} + \text{H}^+ \quad (3\text{–}504)$$

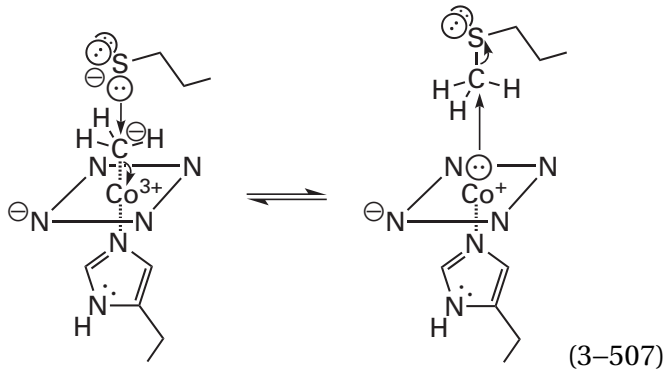
$$\text{Co(I)} + \text{5-methyltetrahydrofolate} + \text{H}^+ \rightleftharpoons \text{tetrahydrofolate} + \text{Co(III)CH}_3 \quad (3\text{–}505)$$

$$\text{Co(II)} + \text{flavodoxin}_{\text{red}} + \textit{S}\text{-adenosylmethionine} \rightleftharpoons \text{flavodoxin}_{\text{ox}} + \textit{S}\text{-adenosylhomocysteine} + \text{Co(III)CH}_3 \quad (3\text{–}506)$$

where Co(III) is methyl cob(III)alamin, Co(I) is cob(I)alamin, and Co(II) is cob(II)alamin. The first two reactions sustain the overall chain reaction synthesizing L-methionine from L-homocysteine and 5-methyltetrahydrofolate, and the third reaction performs the housekeeping that repropagates the chain when it has been terminated adventitiously by the oxidation of the cob(I)alamin.

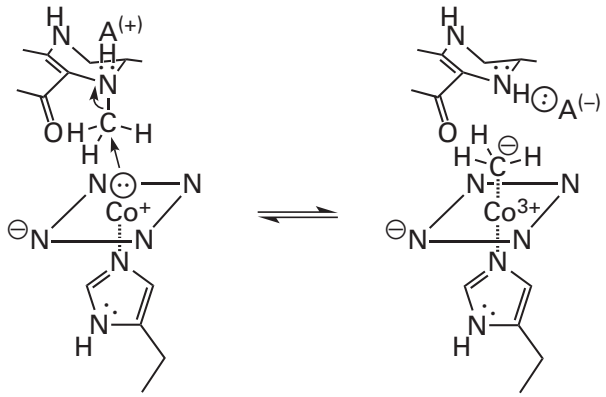
The two enzymatic domains catalyzing transfer of the methyl group from methyl cob(III)alamin to L-homocysteine (Equation 3–504) and transfer of the methyl group from 5-methyltetrahydrofolate to cob(I)alamin (Equation 3–505) are composed of the amino-terminal 616 amino acids of each polypeptide in the multienzymatic complex. They are associated with each other by an asymmetric interdomain interface and together form a compact globular structure.[1252] The globular enzymatic domain catalyzing transfer of the methyl group from *S*-adenosyl-L-methionine to cob(II)alamin (Equation 3–506) is composed of the carboxy-terminal 324 amino acids.[1253] These three domains are not associated with their twins in the other half of the homodimer, and they freely diffuse at random while attached to the dimeric cob(I)alamin methyl-carrier domain.

Each amino-terminal enzymatic domain is connected to one of the domains in the central, symmetric homodimeric cob(I)alamin methyl-carrier domain by a **leash that is a random coil** with the sequence EDVILNRRDDGTERLLELAEKYRGSKTDDTANAQQAEWRSWEVNK. These two leashes emerge from the dimeric central globular domain, composed of two cobalamin-carrier domains with the two cobalamins on opposite sides of its surface. The active sites in the two amino-terminal domains are 5.0 nm apart.[1252] Nevertheless, each leash is long enough to permit the active site in the amino-terminal domain responsible for the nucleophilic substitution in Equation 3–504 to associate with methylcob(III)alamin in a cobalamin methyl-carrier domain and transfer a methyl group between methylcob(III)alamin and L-homocysteine (previously Equation 2–353)



(3–507)

Each leash is also long enough to permit the active site in the amino-terminal domain responsible for the nucleophilic substitution in Equation 3–505 to associate with cob(I)alamin in a cobalamin methyl-carrier domain and transfer a methyl group between 5-methyltetrahydofolate and cob(I)alamin (previously Equation 2–356)



(3–508)

Each carboxy-terminal enzymatic domain that catalyzes the regeneration of cob(I)alamin is attached to the central homodimeric cobalamin methyl-carrier domain by a shorter leash with the sequence KKPRTPP. These two leashes emerge from the central homodimeric domain at locations on its surface that are immediately adjacent to each other. When the leashes are constricted artificially by mutationally inserting a disulfide into them[1253] or by mutating the histidine that provides the axial ligand to the cobalamin,[1255] the carboxy-terminal domain forms a stable complex between its active site and the cobalamin in the cobalamin methyl-carrier domain to which it is attached, a consquence that hinders the overall reaction.

The leash between the globular structure containing the two amino-terminal enzymatic domains and the central cobalamin methyl-carrier domain is so long and so flexible, and the two are so loosely attached to each other, that each cobalamin in the central homodimeric domain probably services at random all four active sites in the two identical amino-terminal globular structures that are unattached to each other and flail independently of each other. The leash is also long enough, however, and contains enough bonds about which free rotation can occur that the amino-terminal globular domain containing the two respective active sites can be considered a free agent that is just as likely to associate with cobalamins on other homodimers of methionine synthase as with cobalamins on the molecule of protein in which it happens to be located, with **little distinction between intramolecular association and intermolecular association**.

The possibility that the transfer of methyl groups among the active sites on the amino-terminal enzymatic domains of methionine synthase is intermolecular rather than intramolecular has been examined by using site-directed mutation to cleave the multienzymatic complex at the Alanines 649 in the middle of the two long leashes between the amino-terminal enzymatic domains and the central homodimeric cobalamin methyl-transfer domain. When the resulting monomeric globular portion containing the two enzymatic domains is mixed in equimolar proportion with the dimeric portion containing the two cob(I)alamin methyl-carrier domains, the observed initial rates of methionine synthesis at 37 °C and saturating concentrations of L-homocysteine and 5-methyltetrahydrofolate are, as might be expected from a bimolecular reaction, directly proportional to the square of the common molar concentration of the two halves from 30 to 300 nM.[1256] Over the same range of concentrations for the intact enzyme, the initial rates are directly proportional to only the concentration of enzyme.* The catalytic constant for the two halves at equimolar concentrations of 270 nM is 11 s^{-1} while that for the intact enzyme[1257,1258] is 30 s^{-1} at all concentrations in the same range. These two observations rule out significant rates of intermolecular transfer of the methyl group by the cobalamin methyl-transfer domain for the intact enzyme at concentrations less than 200 nM. If, however, the concentration of intact enzyme is greater than 1 μM, because the initial rates of the mixture of the dissociated halves increase as the square of their common concentration, most of the methyl transfer by the cobalamin methyl-transfer domain among the enzymatic domains for the intact enzyme must occur intermolecularly.

*Rowena Matthews, personal communication.

It has already been noted that, when a tRNA ligase is aminoacylating the correct tRNA with the correct amino acid, the complex between the tRNA ligase and the transfer RNA, two macromolecules of similar dimensions, is held together by an extensive interface that includes both the anticodon stem at one end of the transfer RNA and the unpaired nucleotides at the 3′ end of the transfer RNA in the acceptor stem at the other end.[1011,1050,1052,1259,1260] These unpaired nucleotides protruding from the acceptor stem must associate with the active site for the aminoacylation catalyzed by the enzyme in such a way that the 3′-hydroxy group at the 3′ end if the transfer RNA can be aminoacylated. In a sense, although the complex is transient, while it is in existence, it is similar to an intact macromolecule composed of two subunits, the transfer RNA and the ligase. It has also been noted that, to ensure that the correct amino acid has been aminoacylated, the active site for aminoacylation is as specific as possible, but the accuracy of the aminoacylation is often double-checked by editing at another active site within the enzyme that hydrolyzes any misacylated 3′-hydroxy group at the 3′ end before the complex dissociates. Consequently, transfer of the aminoacylated 3′-hydroxy group of the transfer RNA between the site for aminoacylation and the site for editing is an example of the transfer of a covalent intermediate between two active sites.

In the crystallographic molecular model of the complex between $tRNA^{Ile}$ and isoleucine—tRNA ligase from *S. aureus*, the unpaired ACCA at the 3′ end of the transfer RNA is located in the site for editing,[1260] the selectivity of which has also already been discussed. The active site for editing and the active site for aminoacylation are 3.4 nm apart, but the space between them is a bay empty of protein and filled with water, similar to the bay in fatty acid synthase (Figure 3–67) but much smaller. In the crystallographic molecular model of the complex between glutamine—tRNA ligase from *E. coli* and $tRNA^{Gln}$, the 3′-hydroxy group of the transfer RNA is inserted into the active site for aminoacylation rather than the site for editing.[1259] By comparing the two structures, it can be seen how the completely flexible, single-stranded tail at the 3′ end of the acceptor stem of a tRNA can swing from the active site for aminoacylation to the active site for hydrolytic editing, easily spanning the 3.4 nm between them,[1260] just as the small carrier domains attached to multienzymatic complexes swing among active sites.

Most multienzymatic complexes do not transfer a substrate or a portion of a substrate between their active sites in the form of a covalent adduct, as do acetyl-CoA carboxylase, pyruvate carboxylase, pyruvate dehydrogenase complex, animal fatty-acid synthase system, pyruvate, phosphate dikinase, and methionine synthase. In these other multienzymatic complexes, the substrate or substrates transferred between the series of active sites responsible for the sequential reactions catalyzed by the multienzymatic complex are freely diffusing, independent molecules. In each multienzymatic complex, the **intermediate substrates** are the products of the reactions catalyzed by each active site in the complex except the last one in the sequence, the **initial reactants** are the reactants that enter the active site for the first reaction in the sequence, and the **final products** are the products that dissociate from the active site for the last reaction in the sequence.

In many of these multienzymatic complexes, if not most of them, even though all the active sites for the complete overall reaction resulting from the sequence of individual reactions are on the same molecule of protein, the intermediate substrates are not transferred preferentially between active sites in the same complex but instead are **transferred by free diffusion through the solution between active sites that are usually on different molecules of the same multienzymatic complex**. When an intermediate substrate dissociates into the solution from the active site catalyzing one of the reactions in the sequence of reactions for which the multienzymatic complex is responsible, it is immediately in free diffusion and has no obligation to associate with the active site catalyzing the next reaction in the sequence on the same molecule of the multienzymatic complex from which it just dissociated. Consequently, there is no catalytic advantage in such circumstances to having the enzymatic domains attached together in the same multienzymatic complex. The active sites in these cases are gathered into the multienzymatic complex to coordinate the biosynthesis of the proteins at the level of expression of the protein, not for the purpose of catalytic cooperation.

Chorismate mutase–prephenate dehydratase from *E. coli* is a multienzymatic complex catalyzing two sequential reactions in the biosynthetic pathway for phenylalanine: the reaction catalyzed by chorismate mutase (previously Equation 3–402)

$$\text{chorismate} \rightleftharpoons \text{prephenate} \qquad (3\text{–}509)$$

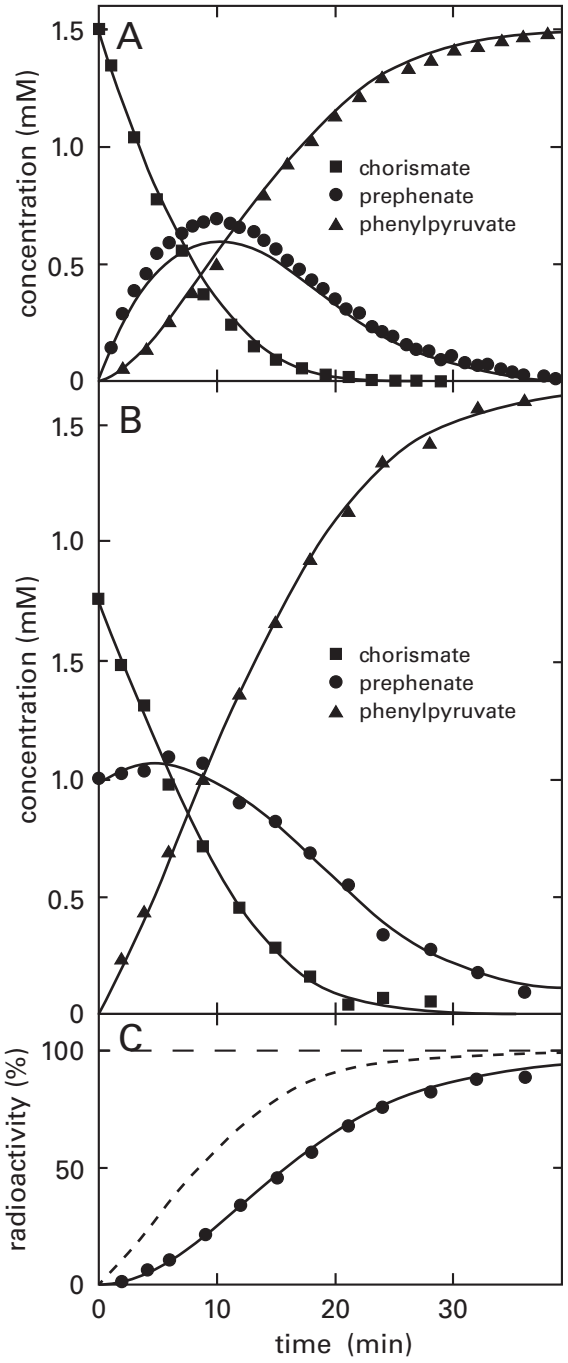


Figure 3–68: Changes in the concentrations of substrates with time in solutions containing *E. coli* chorismate mutase–prephenate dehydratase.[1261] **(A)** Chorismate mutase–prephenate dehydratase was mixed with 1.5 mM chorismate at pH 7.5 and 37 °C. At the noted times (in minutes), samples were removed and assayed for chorismate (■), prephenate (●), and phenylpyruvate (▲). The three smooth curves are for theoretical functions derived from the kinetic constants (K_m and V) for the two active sites and from the assumption that all products and reactants dissociate into the solution and associate from the solution. Any preferential intramolecular channeling between active sites on the same protein would have caused the observed concentrations of prephenate to be less than the theoretical function. **(B)** Chorismate mutase–prephenate dehydratase was mixed under the same conditions with 1.76 mM [U-^{14}C]chorismate (12,000 cpm μmol^{-1}) and 1.0 mM prephenate, and the concentrations of the three substrates, disregarding the radioactivity, were again monitored as a function of time. The curves are calculated with the same assumptions and the same functions as were used for the curves in Panel A. **(C)** In each sample from the experiment in Panel B, the percent of the total carbon-14 radioactivity in phenylpyruvate was determined as a function of time (minutes), disregarding the total molar concentration of phenylpyruvate. The solid line represents the predictions of the functions used in Panels A and B that were derived on the assumption that no channeling occurs. The dashed line is for a function derived on the assumption that prephenate is completely channeled between the active sites.

and the reaction catalyzed by prephenate dehydratase

$$\text{prephenate} + H^+ \rightleftharpoons \text{phenylpyruvate} + CO_2 + H_2O \qquad (3\text{–}510)$$

These two reactions are catalyzed by two distinct active sites[1261] in enzymatic domains that are on the same folded polypeptide.[1262,1263] Prephenate, the intermediate substrate, is the exclusive product of the first reaction and the exclusive reactant in the second reaction. The progress of the overall reaction can be followed by assaying for the concentrations of chorismate, prephenate, and phenylpyruvate as a function of time (Figure 3–68A).[1261] As the reaction progresses, the concentration of prephenate in the solution increases, reaches a maximum, and declines as all the substrates are converted to phenylpyruvate. The important question is whether all the prephenate passes through the solution in going from an active site catalyzing the first reaction to an active site catalyzing the second or if some of it is transferred intramolecularly between the active sites on the same molecule of enzyme without leaving it.

One way to answer the question of whether or not chorismate mutase–prephenate dehydratase transfers prephenate intramolecularly between its two active sites is to evaluate the behavior of the concentrations of the reactant chorismate, the intermediate substrate prephenate, and the final product phenylpyruvate as a function of time after adding enzyme to a solution of chorismate (Figure 3–68A). The fact that **the intermediate substrate appears in solution, builds to a maximum, and then declines** indicates that at least a portion of the prephenate passes through the solution. Both the fact that **the concen-**

tration of the final product shows a distinct lag and the fact that the amount of prephenate observed as a function of time is that predicted from the values of $k_{\text{chorismate}}$ and k_0 for chorismate mutase and the values of $k_{\text{prephenate}}$ and k_0 for prephenate dehydratase (smooth curve in Figure 3–68A) suggest that most if not all the prephenate passes through the solution.

Such **a kinetic argument is often used to rule out intramolecular transfer**.[1264-1267] Another approach is to examine the **effect of adding the intermediate substrate** on the kinetics (Figure 3–68B). Finally, when [^{14}C]chorismate and nonradioactive prephenate were mixed with the enzyme and the production of [^{14}C]phenylpyruvate was monitored (Figure 3–68C), the production of [^{14}C]phenylpyruvate followed the calculated curve (solid line in Figure 3–68C) expected if all the prephenate produced at the active site of chorismate mutase had to pass through the solution to reach the active site of prephenate dehydratase. If all the prephenate produced at the first active site had been transferred to the second active site without leaving the enzyme, the production of [^{14}C]phenylpyruvate would have begun at a steady rate (dashed line in Figure 3–68C). If, however, all the [^{14}C]prephenate enters the solution before it enters the second active site, it should be diluted by the nonradioactive prephenate, and there should be a lag in its production as [^{14}C]prephenate builds up, as was observed.

Suppose that there are **two mutants of a multienzymatic complex**, one in which the active site for the first reaction it catalyzes is inactive and one in which the active site for the second reaction is inactive. If these two mutants are mixed in equimolar concentration and the conversion of reactants of the first reaction into products of the second reaction occurs at the same rate as the rate observed with the same molar concentration of unmutated multienzymatic complex, it can be concluded that intramolecular transfer is not required for the reactions to proceed.

For example, there is a multienzymatic complex in the cytoplasm of *H. influenzae* that has two enzymatic domains: one with an active site catalyzing ribitol-5-phosphate 2-dehydrogenase ($NADP^+$)

$$\text{D-ribulose 5-phosphate} + \text{NADPH} + \text{H}^+ \rightleftharpoons \text{D-ribitol 5-phosphate} + \text{NADP}^+ \quad (3\text{–}511)$$

and the other with an active site catalyzing D-ribitol-5-phosphate cytidylyltransferase

$$\text{D-ribitol 5-phosphate} + \text{MgCTP}^{2-} \rightleftharpoons \text{MgOPO}_3\text{PO}_3^{2-} + \text{CDP-ribitol} \quad (3\text{–}512)$$

A mutant of the multienzymatic complex in which Lysine 386 has been mutated to an alanine in the active site for the former reaction lacks significant activity for the dehydrogenase but has normal activity for the cytidyltransferase, and a mutant in which Arginine 18 has been mutated to an alanine in the active site for the latter reaction lacks significant activity for the cytidylyltransferase but has normal activity for the dehydrogenase. When equimolar amounts of the two mutants are mixed together,[1267] the catalytic constant for the overall reaction, based on the molar concentration of unmutated active sites, is 6 s^{-1} while the catalytic constant for the unmutated intact multienzymatic complex, based on the molar concentration of active sites, is 12 s^{-1}. If the intermediate D-ribitol 5-phosphate were being transferred only intramolecularly between active sites on the same molecule of the multienzymatic complex, the mixture of mutants should have no enzymatic activity because the reactant for the second reaction produced by the former mutant could not be transformed into the product for the second reaction by the latter mutant.

Another way to test whether or not an intermediate is being transferred intramolecularly between active sites is to **add the active site for the second reaction** to a solution of the intact multienzymatic complex while it is catalyzing the overall reaction. Either a mutant that is unable to catalyze the first reaction but can catalyze the second or a fragment of the multienzymatic complex containing only the intact active site for the second reaction can be used. If either protein lacking the first active site is added to the solution and formation of the products of the second reaction increases in rate and the lag in the rate of their formation (see Figure 3–68) decreases, then intramolecular transfer cannot be a necessary step in the reaction.

For example, there is a multienzymatic complex from *E. coli* that contains an enzymatic domain catalyzing glucosamine-1-phosphate *N*-acetyltransferase and an enzymatic domain catalyzing UDP-*N*-acetylglucosamine diphosphorylase. This multienzymatic complex catalyzes the overall reaction that equilibrates $MgUTP^{2-}$, acetyl-SCoA, and D-glucosamine 1-phosphate with $MgUDP^-$, diphosphate, HSCoA, and UDP-*N*-acetyl-α-D-glucosamine. When an amino-terminal fragment of the multienzymatic complex, containing only the active site for UDP-

N-acetylglucosamine diphosphorylase, is added (to a final concentration of 1 μM) to a solution containing 0.013 μM intact multienzymatic complex, the catalytic constant for production of diphosphate from $MgUTP^{2-}$, acetyl-SCoA, and D-glucosamine 1-phosphate increases[1268] from 16 to 44 s^{-1}. In this experiment, the choice of the reactants has made the reaction catalyzed by UDP-*N*-acetylglucosamine diphosphorylase the second reaction in the sequence.

There are **enzymes that catalyze several successive reactions at the same active site** rather than at several different active sites. These enzymes convert a reactant into a product through one or more intermediate substrates. One example of such an enzyme would be aristolochene synthase (Figure 3–48), in which (–)-germacrene A is a tightly held intermediate substrate. The same criteria can be used to decide whether or not the intermediate substrates in such a sequence of reactions dissociate from the lone active site.

For example, human aromatase contains a heme P450 that converts androst-4-ene-3,17-dione into estrone in three successive hydroxylations using successive oxoiron(IV) porphyrins$^{\bullet+}$ formed at the same heme from three successive molecules of oxygen. The two intermediates in the reaction, produced by the first two successive, individual hydroxylations, are 19-hydroxyandrost-4-ene-3,17-dione and 19-oxoandrost-4-ene-3,17-dione, respectively. In this instance, the question is whether the intermediates remain bound on the active site or are released into the solution and then bound again at the same or another active site for the next hydroxylation. Because the concentrations of the two intermediate substrates build up and then decrease at levels predicted for their complete dissociation from and reassociation with the active sites between each successive reaction (see Figure 3–68A) and because the addition of either nonradioactive intermediate dramatically decreases the yield of [1,2,6,7-$^3H_4$]estrone produced from [1,2,6,7-$^3H_4$]androst-4-ene-3,17-dione, it was concluded that the intermediate substrates freely dissociate and reassociate with the active sites in the solution between successive hydroxylations rather than remaining in the same active site for all three hydroxylations,[1269] unlike the situation with (–)-germacrene A in the active site of aristolochene synthase.

There are many multienzymatic complexes, albeit probably the minority, in which intermediate substrates are channeled within the protein between active sites in the complex. A molecule of a multienzymatic complex channels an intermediate substrate between two of its active sites if that substrate passes between them intramolecularly through the molecule of the enzyme without dissociating into the solution and without being covalently attached to the protein. As mentioned previously, intermediate substrates cannot be channeled if they dissociate from any of the active sites in the complex into the solution.

Cavities or tunnels that connect separate active sites are usually observed in crystallographic molecular models of multienzymatic complexes for which evidence of the channeling of an intermediate substrate has been presented. A cavity or a tunnel can connect active sites on two or more separate enzymatic domains in the same folded polypeptide or on two or more separate subunits, each a different folded polypeptide. As in the case of tunnels leading from solution into a single active site, these tunnels connecting active sites can be traced by filling them with atoms of xenon (Figure 3–69).[1270-1272] Usually, however, they are identified as cavities or long tunnels, filled with water or apparently empty, running through the crystallographic molecular model of the protein.

It should be kept in mind, however, that crystallography is always unable to determine whether or not an intermediate substrate actually does pass through a tunnel that is observed. Consequently, kinetic observations, such as the ones described for multienzymatic complexes that do not channel their intermediate substrates, are always essential to conclude that an intermediate substrate is channeled. Several different kinds of observations have been used as **evidence that an intermediate substrate actually is channeled** by a multienzymatic complex between two of its active sites.

A characteristic feature of a multienzymatic complex that is unable to channel intermediate substrates between its active sites is a pronounced lag in the production of the final product in the sequence (Figure 3–68A). This lag results from the requirement that the intermediate substrate—in the case of chorismate mutase–prephenate dehydratase, the prephenate—must accumulate in the solution to a concentration high enough to sustain a steady-state rate for production of the final product—in the case of chorismate mutase–prephenate dehydratase, the phenylpyruvate. The **lack of a lag** in the production of a final product from the initial reactants can be used as evidence that the intermediate substrates do not have to accumulate in the solution

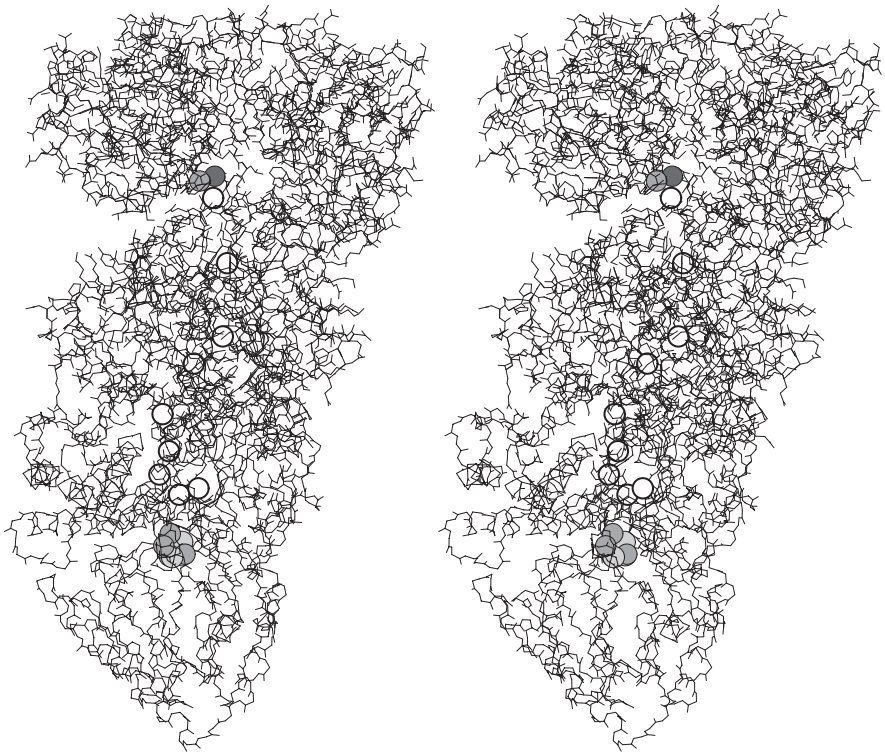

Figure 3–69: Stereodrawing[576] of the tunnel connecting the active sites for anaerobic carbon monoxide dehydrogenase (Equation 3–521) and CO-methylating acetyl-CoA synthase (Equation 3–522) in the multienzymatic complex from *M. thermoacetica*.[1271] The enzyme was purified from a homogenate of bacterial cells under strictly anaerobic conditions.[1270] Crystals were grown from a solution of 200 mM calcium acetate and 20% glycerol at pH 7 with poly(ethylene glycol) as a precipitant, again under anaerobic conditions.[1272] The crystals were exposed to 14 atm of xenon gas for 60 s, and then a data set was collected to Bragg spacing of 0.25 nm. In the resulting map of electron density, nine electron-dense xenon atoms (131 electrons) could be observed in the center of an $\alpha\beta$ heteromonomer of the symmetric $(\alpha\beta)_2$ homodimer, distributed within a tunnel connecting the active site for anaerobic carbon monoxide dehydrogenase, which was identified by its [4Fe–4S–Ni] cluster (**3–133**), and the active site for CO-methylating acetyl-CoA synthase, which was identified by its dinuclear cluster of a nickel ion and a copper ion. The two active sites are located in the two different subunits, α and β, of the $\alpha\beta$ heteromonomer. The nine xenon atoms (represented by open circles) serve to trace the rather tortuous tunnel. The [4Fe–4S–Ni] cluster is drawn in space-filling representation in the lower half of the drawing, and the dinuclear cluster of a nickel ion and a copper ion is also drawn in space-filling representation in the upper half of the drawing. The CO is produced at the active site of the dehydrogenase and then travels up through the tunnel to the active site of the synthase, where it is turned into acetyl-SCoA. Side chains of the amino acids are included in the upper subunit, which contains the active site for CO-methylating acetyl-CoA synthase, to delineate more clearly the wall of the tunnel in this location, but side chains are not included in the lower subunit, which contains the active site for anaerobic carbon monoxide dehydrogenase, because they obscured the tunnel through this subunit.

because they are channeled within the molecule of each multienzymatic complex from one active site to the other intramolecularly.[1273-1278]

For example, a multienzymatic complex from *Bradyrhizobium japonicum* is an α_4 homotetramer, with each subunit composed of a single folded polypeptide that contains two enzymatic domains.[1262,1263] One enzymatic domain has an active site for proline dehydrogenase

$$\text{L-proline} + \text{ubiquinone} + H^+ \rightleftharpoons (S)\text{-1-pyrroline-5-carboxylate} + \text{ubiquinol} \quad (3\text{–}513)$$

and the other has an active site for glutamate-5-semialdehyde dehydrogenase

$$\text{L-glutamate 5-semialdehyde} + NAD^+ + H_2O \rightleftharpoons \text{L-glutamate} + NADH + 2H^+ \quad (3\text{–}514)$$

The intermediate substrate (*S*)-1-pyrroline-5-carboxylate hydrolyzes rapidly and spontaneously to the intermediate substrate L-glutamate 5-semialdehyde during its transfer. The overall reaction catalyzed is a four-electron oxidation of L-proline to L-glutamate using a quinone and NAD^+ as the two respective two-electron oxidants. The production of L-glutamate from L-proline, ubiquinone, and NAD^+ by the multienzymatic complex commences with only a short lag of less than 15 s (upper solid line in Figure 3–70).[1279,1280]

That the short lag observed is not the result of a requirement for L-glutamate 5-semialdehyde to accumulate in the solution could be shown by performing an identical assay to which the same molar amounts of two mutants of the complex were added in place of the unmutated complex. The active site for proline dehydrogenase had been inactivated in one of the mutants and the active site for glutamate-5-semialdehyde dehydrogenase had been inactivated in the other so that the intermediate substrate L-glutamate 5-semialdehyde was required to pass through the solution from an active site for proline dehydrogenase to the active site for glutamate-5-semialdehyde dehydrogenase. In this case, a much longer lag was observed (○ in Figure 3–70), which could be explained quantitatively as a requirement for the accumulation of L-glutamate 5-semialdehyde in the solution (lower solid line in Figure 3–70). Following the lag, the steady-state rate of this reaction (dashed line in Figure 3–70) catalyzed by the two mutants working in concert was the same as that for the unmutated multienzymatic complex. This fact suggests that once adequate concentrations of L-glutamate 5-semialdehyde have accumulated at these concentrations of the active sites, the rate of the overall reaction is determined not by steps that involve L-glutamate 5-semialdehyde in solution associating with the active site for glutamate-5-semialdehyde dehydrogenase but by the rates of steps common to both intramolecular and intermolecular reactions.

In the crystallographic molecular model of this multienzymatic complex in which the site for NAD^+ is occupied,[1279] there is a **large cavity surrounded almost completely by protein** within each of the four subunits. The cavity is filled with disordered molecules of water. The flavin adenine dinucleotide in the active site of proline dehydrogenase is exposed at one end of the cavity, and the NAD^+ in the active site of glutamate-5-semialdehyde dehydrogenase is exposed at the other end of this cavity. It seems reasonable to assume that a molecule of (*S*)-1-pyrroline-5-carboxylate, which is produced by the oxidized flavin from a molecule of L-proline, dissociates from that active site into the cavity and is hydrolyzed to L-glutamate 5-semialdehyde while trapped in the cavity. The resulting L-glutamate 5-semialdehyde is then oxidized by the NAD^+ to L-glutamate at the other end of the cavity before it can escape into the solution. In this way, the intermediate L-glutamate 5-semialdehyde is channeled from one active site to the other within the same molecule of the multienzymatic complex. There are two small openings to the solution in the walls of the cavity through which the reactants L-proline, ubiquinone, and NAD^+ must enter the cavity and through which the products L-glutamate, ubiquinol, and NADH must exit the cavity.* In addition to the absence of a lag, no intermediate substrate in the sequence of reactions catalyzed by a multienzymatic complex accumulates to levels predicted by the steady-state

*When the multienzymatic complex for proline dehydrogenase and glutamate-5-semialdehyde dehydrogenase, in which the flavin is oxidized, is mixed with L-proline and NAD^+, so that only one turnover can occur, the rate at which NADH is produced has no lag (<1 s).[1280] Consequently, the short lag observed in the steady-state assay (Figure 3–70) is a delay required to establish a steady-state rate of flavin oxidation rather than to establish a steady-state rate for the hydrolysis of (*S*)-1-pyrroline-5-carboxylate to L-glutamate 5-semialdehyde or the diffusion of either of these intermediate substrates through the cavity between the active sites.

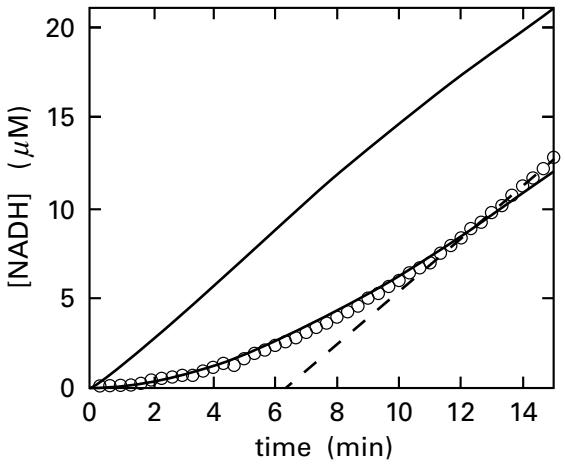

Figure 3–70: Channeling between active sites in the multienzymatic complex from *B. japonicum* that converts L-proline into L-glutamate in the sequential reactions catalyzed by the active sites for proline dehydrogenase and glutamate-5-semialdehyde dehydrogenase, respectively.[1279] The intact multienzymatic complex (0.2 nmol) was assayed at 23 °C in 25 mM NaCl, 10 mM $MgCl_2$, and 50 mM potassium phosphate at pH 7.5, by following continuously at 340 nm the production of NADH as L-proline (40 mM) is oxidized to L-glutamate by the two sequential two-electron oxidations. The first oxidation, at the first active site, is with the oxidant ubiquinone (0.1 mM), and the second oxidation, at the second active site, is with the oxidant NAD^+ (0.2 mM). The concentration of NADH produced during the second reaction as the assay progressed (upper solid line) is plotted as a function of time (minutes). Identical assays were performed with 0.2 nmol of each of two monofunctional mutants of the multienzymatic complex rather than 0.2 nmol of the native multienzymatic complex. The mutant in which Arginine 456 is converted to a methionine has undetectable activity for proline dehydrogenase but has the same specificity constant for L-glutamate 5-semialdehyde and catalytic constant for glutamate-5-semialdehyde dehydrogenase as the intact multienzymatic complex. The mutant in which Cysteine 792 is converted to an alanine has the same specificity constant for proline and catalytic constant for proline dehydrogenase as the intact multienzymatic complex but undetectable activity for glutamate-5-semialdehyde dehydrogenase. The concentration of NADH (○) produced in the same two sequential reactions by this equimolar mixture of mutants is plotted as a function of time (minutes). The solid line through these points is a function calculated from the catalytic constants and the specificity constants for each site under two assumptions: first, that the (*S*)-1-pyrroline-5-carboxylate produced by an active site for proline dehydrogenase dissociates from that active site into the solution and rapidly hydrolyzes to L-glutamate 5-semialdehyde, and second, that the L-glutamate 5-semialdehyde freely diffusing through the solution associates with an active site of glutamate-5-semialdehyde dehydrogenase and is converted into L-glutamate. The reduction of NAD^+ increases in rate as the concentration of L-glutamate 5-semialdehyde builds up in the solution to reach eventually a linear, steady-state rate (dashed asymptote).

rate constants of the individual active sites (as does prephenate in Figure 3–68A). This **lack of accumulation of the intermediate substrates in the solution** is evidence for channeling of the intermediate substrates.[1277,1278,1281] For example, a porcine multienzymatic complex is an α_8 homooctamer,[1282] with each subunit composed of a single folded polypeptide that contains enzymatic domains for glutamate formimidoyltransferase

$$\begin{gathered}\text{tetrahydropteroylpentaglutamate} + \\ \textit{N}\text{-formimidoyl-L-glutamate} \rightleftharpoons \text{L-glutamate} + \\ \text{5-formimidoyltetrahydropteroylpentaglutamate}\end{gathered} \tag{3–515}$$

and formimidoyltetrahydrofolate cyclodeaminase

$$\begin{gathered}\text{5-formimidoyltetrahydropteroylpentaglutamate} \\ + 2\,H^+ \rightleftharpoons NH_4^+ + \\ \text{5,10-methenyltetrahydropteroylpentaglutamate}\end{gathered} \tag{3–516}$$

The fact that no 5-formimidoyltetrahydropteroylpentaglutamate accumulates in the solution when the porcine multienzymatic complex converts tetrahydropteroylpentaglutamate and *N*-formimidoyl-L-glutamate into 5,10-methenyltetrahydropteroylpentaglutamate, L-glutamate, and ammonia has been presented as evidence that the sole intermediate substrate, 5-formimidoyltetrahydropteroylpentaglutamate, is channeled between the two active sites.[1277,1278]

In the two multienzymatic complexes just discussed, the two active sites are on two enzymatic domains of a single folded polypeptide. There are also examples of **intramolecular channeling of an intermediate substrate between two active sites within a noncovalent complex between two separate enzymes**, each composed of its own folded polypeptide with its own active site that catalyzes only one of the two sequential metabolic reactions. In fact, there are a number of organisms in which separate proteins catalyze proline dehydrogenase (Equation 3–513) and glutamate-5-semialdehyde dehydrogenase (Equation 3–514) rather than a single folded polypeptide containing two enzymatic domains responsible for each reaction. For example, in *T. thermophilus* there are two independent enzymes, each homologous (26%, 4.2 gap percent and 33%, 1.9 gap percent) to the respective enzymatic domains in the multienzymatic complex of *B. japonicum*. These two independent enzymes form a noncova-

lent complex with a dissociation constant of 3 μM, and steady-state measurements of the conversion of L-proline to L-glutamate are consistent with intramolecular channeling of the intermediate substrates (*S*)-1-pyrroline-5-carboxylate and L-glutamate 5-semialdehyde within this noncovalent complex,[1283] just as they are channeled in the multienzymatic complex from *B. japonicum*.

There is a multienzymatic complex that has active sites for acetaldehyde dehydrogenase (acetylating)

$$\text{acetyl-SCoA} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{acetaldehyde} + \text{NAD}^+ + \text{HSCoA} \quad (3\text{–}517)$$

and 4-hydroxy-2-oxovalerate aldolase

$$\text{acetaldehyde} + \text{pyruvate} \rightleftharpoons (S)\text{-4-hydroxy-2-oxopentanoate} \quad (3\text{–}518)$$

Together these active sites convert acetyl-SCoA, NADH, and pyruvate to NAD^+, coenzyme A, and (*S*)-4-hydroxy-2-oxopentanoate, as well as converting (*S*)-4-hydroxy-2-oxopentanoate, coenzyme A, and NAD^+ to pyruvate, NADH, and acetyl-SCoA. The multienzymatic complex in bacteria is a $\beta\alpha_2\beta$ heterotetramer. In crystallographic molecular models of the heterotetramers from *Pseudomonas*[1284] and *M. tuberculosis*,[1285] the two active sites for 4-hydroxy-2-oxovalerate aldolase are symmetrically displayed at the two ends of a rotationally symmetric α_2 homodimer that forms the core of the complex, and the two monomeric β subunits, each of which contains an active site for acetaldehyde dehydrogenase (acetylating), are noncovalently and symmetrically associated at the two ends of the central α_2 homodimer. Running between each active site on an α_2 dimer for 4-hydroxy-2-oxovalerate aldolase and an active site for acetaldehyde dehydrogenase (acetylating) on the adjacent β subunit is a tunnel. A number of observations support the conclusion that, in the multienzymatic complex for 4-hydroxy-2-oxovalerate aldolase and acetaldehyde dehydrogenase (acetylating) from *Paraburkholderia xenovorans*, which is homologous (54% identity; 0.6 gap percent) to that from *Pseudomonas*, the sole intermediate substrate for the sequential reactions, acetaldehyde, diffuses back and forth through this tunnel between the active sites at its two ends.[1286] This arrangement makes sense because acetaldehyde is a reactive molecule from which the cytoplasm should be protected.

In the case of two independent enzymes, amidophosphoribosyltransferase and phosphoribosylamine—glycine ligase, from *E. coli*, the intermediate substrate, 5-phospho-β-D-ribosylamine, is the product of the first enzymatic reaction that is used as a reactant in the second. The half life of 5-phospho-β-D-ribosylamine under the conditions in the cytoplasm of the bacterium is only 5 s, a fact that seems to demand channeling. In a solution containing both enzymes, the rate of production of the final product, N^1-(5-phospho-D-ribosyl)glycinamide, from the initial reactants chosen for the experiment, L-glutamine and 5-phospho-α-D-ribose 1-diphosphate, occurs without a lag. The small amount of 5-phospho-β-D-ribosylamine accumulated in the solution was significantly less than the amount necessary to explain the rate of the overall reaction.[1273] Both results are consistent with intramolecular channeling within a complex of the two enzymes, but no complex of the two could be observed under any circumstances. The results suggest that a transient complex forms during the enzymatic reaction to permit what seems to be a required channeling. In this instance, the intermediate substrate, 5-phospho-β-D-ribosylamine, is not harmful, but its hydrolysis is wasteful.

In addition to the lack of a lag in production of the ultimate product of a set of sequential reactions catalyzed by a multienzymatic complex and the lack of significant accumulation of intermediate substrates, **the lack of competition between two different intermediate substrates** is also evidence that channeling is involved in the mechanism. When a multienzymatic complex is able to turn two different reactants into two different products, the opportunity arises of using the two respective intermediate substrates to compete with each other for the second active site in the sequence of reactions.

For example, the multienzymatic complex for 4-hydroxy-2-oxovalerate aldolase and acetaldehyde dehydrogenase (acetylating) from *P. xenovorans*, in addition to being able to turn (*S*)-4-hydroxy-2-oxopentanoate into pyruvate and acetyl-SCoA (sum of Equations 3–518 and 3–517), is also able to turn (*S*)-4-hydroxy-2-oxohexanoate into pyruvate and propionyl-SCoA. With the former reactant, acetaldehyde is the intermediate substrate, and with the latter reactant, propionaldehyde is the intermediate substrate. When the reaction mixture contained the multienzymatic complex and 0.1 mM (*S*)-4-hydroxy-2-oxopentanoate and 1 mM propion-

aldehyde, in addition to coenzyme A and NAD^+, 95% of the product was acetyl-SCoA. When the reaction mixture contained 0.1 mM (*S*)-4-hydroxy-2-oxohexanoate and 1 mM acetaldehyde, 99% of the product was propionyl-SCoA.[1286] Clearly, the particular product of the active site for 4-hydroxy-2-oxovalerate aldolase, acetaldehyde in the former instance or propionaldehyde in the latter instance, is preferentially converted by the active site of acetaldehyde dehydrogenase (acetylating) into the respective acyl-SCoA. The best explanation for this observation is that the respective intermediate substrate is transferred through the tunnel observed crystallographically from one active site to the next while the alternative intermediate substrate in the solution, propionaldehyde or acetaldehyde, respectively, is almost entirely excluded from the tunnel and the active site for acetaldehyde dehydrogenase (acetylating).

It is also possible to conclude that channeling occurs by examining **the effect of a later reaction in the sequence on the first reaction in the sequence**. For example, for the multienzymatic complex for 4-hydroxy-2-oxovalerate aldolase and acetaldehyde dehydrogenase (acetylating) from *P. xenovorans*, the rate for the production of pyruvate, which normally dissociates into the solution from the active site for 4-hydroxy-2-oxovalerate aldolase (Equation 3–518) while the acetaldehyde is channeled, increases by a factor of 15 when NAD^+ and coenzyme A are added to an assay containing only (*S*)-4-hydroxy-2-oxopentanoate.[1286] The explanation for this observed increase in rate is that when NAD^+ and coenzyme A, the substrates for acetaldehyde dehydrogenase (acetylating), are missing, the acetaldehyde produced by the active site of 4-hydroxy-2-oxovalerate aldolase from (*S*)-4-hydroxy-2-oxopentanoate (Equation 3–518) piles up in the tunnel and, as a product, inhibits the turnover of the aldolase, so the rate-limiting step in the enzymatic reaction becomes the rate at which acetaldehyde leaks from the tunnel into the solution. Again, this result is consistent with the tunnel being quite effective at containing the acetaldehyde.

The **channeling efficiency** for an intermediate substrate or substrates being channeled through one of these cavities or tunnels among the active sites is the percentage of the initial reactant that is converted to the final product intramolecularly within the same multienzymatic complex relative to the total amount of initial reactant converted to final product both intramolecularly, by passing from one active site to the next within a molecule of the complex, and intermolecularly, by passing through the solution between active sites on different molecules of the complex.

The channeling efficiency for acetaldehyde through the tunnel in the multienzymatic complex from *P. xenovorans* has been assessed.[1287] In the presence of only acetyl-SCoA, pyruvate, and NADH, the reactants acetyl-SCoA and pyruvate are converted in one direction to (*S*)-4-hydroxy-2-oxopentanoate (sum of Equations 3–517 and 3–518). During this conversion, those molecules of acetaldehyde that are transferred intramolecularly through the tunnel between the two active sites never enter the solution because they are occluded from it by the tunnel. Those molecules of acetaldehyde, however, that leak out of the tunnel in one molecule of the multienzymatic complex enter the solution and, because they are free solutes, can be converted to ethanol by alcohol dehydrogenase

$$\text{acetaldehyde} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{ethanol} + \text{NAD}^+ \quad (3\text{–}519)$$

from *S. cerevisiae* that has been added to the solution.

The initial rates observed in the two assays can be used to estimate the efficiency of channeling. The initial rate at which NADH is oxidized in the presence of the multienzymatic complex, pyruvate, and acetyl-SCoA and in the absence of alcohol dehydrogenase is a measure of the total amount of acetyl-SCoA converted to acetaldehyde at the active site for acetaldehyde dehydrogenase (acetylating) (Equation 3–517), the first step in the overall sequence. The initial rate at which NADH is oxidized in the presence of both the multienzymatic complex and alcohol dehydrogenase is a measure of that same rate of conversion of acetyl-SCoA to acetaldehyde in the active site for acetaldehyde dehydrogenase (acetylating) plus the rate at which acetaldehyde leaks into the solution and is immediately reduced by NADH to ethanol at the active site of alcohol dehydrogenase. The channeling rate is the difference between the initial rate at which acetaldehyde is produced from acetyl-SCoA at the active site of acetaldehyde dehydrogenase (acetylating) and the initial rate at which acetaldehyde leaks out of the multienzymatic complex and is converted to ethanol. The channeling efficiency is the channeling rate divided by the total rate at which acetaldehyde is produced. In this instance, the channeling efficiency was 84%.

The **channeling efficiency in the reverse reaction** has been estimated for the multienzymatic complex from *P. xenovorans* and the homologous (52% identity; 0.6 gap percent) multienzymatic complex from *T. thermophilus*.[1288] The assay contained (*S*)-4-hydroxy-2-oxopentanoate, coenzyme A, and NAD^+ in the presence of aldehyde dehydrogenase (NAD)

$$\text{acetaldehyde} + NAD^+ + H_2O \rightleftharpoons \text{acetate ion} + NADH + 2\,H^+ \quad (3\text{–}520)$$

from *S. cerevisiae* to convert any acetaldehyde leaking into the solution to acetic acid by oxidizing it with the NAD^+ already in the solution. Under these conditions, the initial rate at which acetaldehyde is produced from (*S*)-4-hydroxy-2-oxopentanoate at the active site of 4-hydroxy-2-oxovalerate aldolase (Equation 3–518) is the initial rate at which NAD^+ is oxidized in the presence of both the multienzymatic complex and aldehyde dehydrogenase (NAD) (Equation 3–517) because the acetaldehyde either passes through the tunnel and is converted to acetyl-SCoA at the active site for acetaldehyde dehydrogenase (acetylating) or leaks out of the multienzymatic complex into the solution and is converted to acetate. The initial rate at which the final product, acetyl-SCoA, was produced in the same assay was assessed by measuring acetyl-SCoA in the solution at the completion of the assay. The quotient between the initial rate for production of acetyl-SCoA and the initial rate for reduction of NAD^+ is the channeling efficiency. For the reverse reactions catalyzed by the multienzymatic complexes from *P. xenovorans* and *T. thermophilus*, the channeling efficiencies were 95% and 94%, respectively.

In the measurements of channeling efficiency for the multienzymatic complex of acetaldehyde dehydrogenase (acetylating) and 4-hydroxy-2-oxovalerate aldolase, alcohol dehydrogenase and aldehyde dehydrogenase (NAD) were used as scavengers for acetaldehyde. The **lack of an effect of a scavenger for the intermediate substrate** on the rate of the overall reaction catalyzed by a multienzymatic complex is consistent with channeling of the intermediate substrate out of contact with the solution. For example, a multienzymatic complex from *Moorella thermoacetica* has active sites catalyzing, respectively, anaerobic carbon monoxide dehydrogenase

$$CO_2 + 2\,H^+ + 2\,\text{ferredoxin}_{red} \rightleftharpoons 2\,\text{ferredoxin}_{ox} + H_2O + CO \quad (3\text{–}521)$$

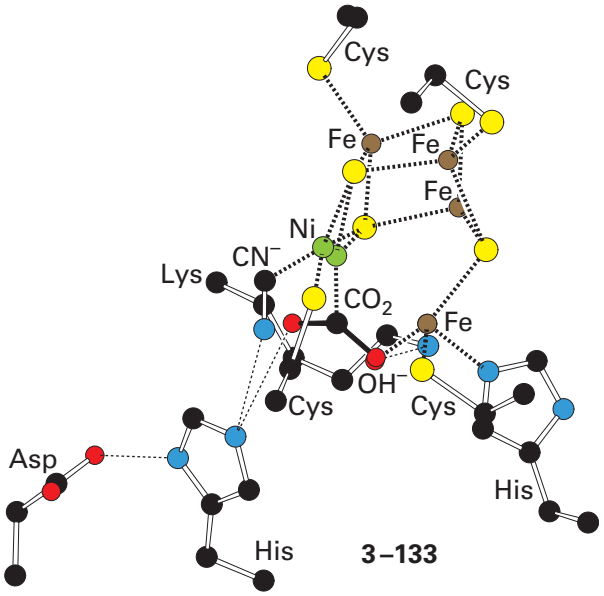
and CO-methylating acetyl-CoA synthase

$$CO + \text{methylcorrinoid protein} + HSCoA \rightleftharpoons \text{corrinoid protein} + \text{acetyl-SCoA} + H^+ \quad (3\text{–}522)$$

Each active site is on a different subunit in the multienzymatic complex,[1289,1290] and they are far apart from each other. Carbon monoxide is the intermediate substrate in this sequence of consecutive reactions. When hemoglobin, which binds CO tightly, is added to the solution, there is no decrease in the rate at which acetyl-SCoA is produced from CO_2.[1274]

Another observation consistent with channeling of an intermediate substrate is the **lack of isotopic dilution**. If the addition of unlabeled intermediate substrate to the solution has little or no effect on the rate of incorporation of radioactive atoms from an initial reactant into a final product, when those radioactive atoms are confined to the portion of the initial reactant that produces the intermediate substrate, this lack of isotopic dilution from the solution is consistent with channeling of the intermediate substrate.[1291-1293] For example, unlabeled CO in solution has no effect on the rate at which carbon-14 from $[^{14}C]CO_2$ is incorporated into acetyl-SCoA by the multienzymatic complex from *M. thermoacetica* (Equations 3–521 and 3–522) or on the specific radioactivity of that acetyl-SCoA.[1292] This observation is consistent with an inability of CO to penetrate the tunnel.

Both the effect of the scavenger and the lack of isotopic dilution are consistent with transfer of CO from one active site to the other within the multienzymatic complex from *M. thermoacetica* rather than through the solution. The active site of anaerobic carbon monoxide dehydrogenase contains a [4Fe–4S–Ni] iron–sulfur–nickel cluster (previously **2–143**)



3–133

and the active site for CO-methylating acetyl-CoA synthase contains a dinuclear cluster of a copper ion and a nickel ion. Consequently, the two active sites are readily identified in a crystallographic molecular model. In the crystallographic molecular model of the multienzymatic complex,[1294] there is a tunnel 7.0 nm long that has been traced with xenon (Figure 3–69),[1271] through which it is believed that CO, produced from CO_2 in the active site of anaerobic carbon monoxide dehydrogenase, passes to the active site of CO-methylating acetyl-CoA synthase. The tunnel can be seen to wind its way through the center of the protein and also passes from one subunit to the other across the interface between them.

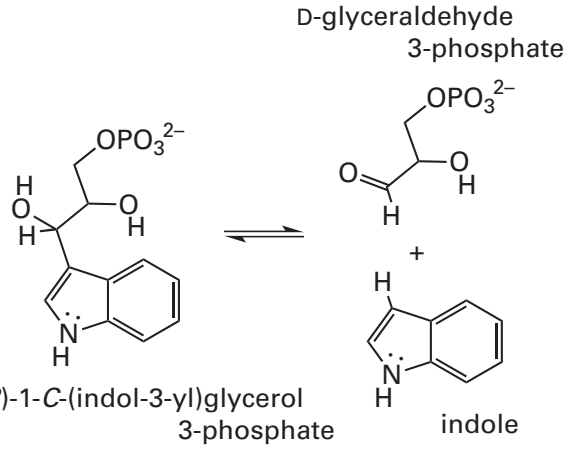
If the rate at which the final products are produced from the initial reactants for the first active site is considerably faster than the rate at which they are produced from the intermediate substrate when it is free in solution, this **preference for the intermediate substrate produced at the first active site** is consistent with channeling of the intermediate substrate.[1274,1284]

Tryptophan synthase is another multienzymatic complex in which the intermediate substrate does not have to enter the solution to be transferred between its two active sites. Tryptophan synthase is an $\alpha\beta_2\alpha$ heterotetramer.[717] The intact heterotetramer catalyzes the reaction

1-*C*-(indol-3-yl)glycerol 3-phosphate + L-serine $\rightleftharpoons$ L-tryptophan + D-glyceraldehyde 3-phosphate + H_2O

(3–523)

The isolated α subunit has an active site that catalyzes indole-3-glycerol-phosphate lyase (previously Equation 1–156)[1295]



(3–524)

and the isolated β_2 homodimer has an active site that catalyzes tryptophan synthase (indole-salvaging) (previously Equation 2–20)[1295]

L-serine + indole $\rightleftharpoons$ H_2O + L-tryptophan

(3–525)

In the crystallographic molecular model of the $\alpha\beta_2\alpha$ heterotetramer from *S. typhimurium*,[717] the two monomeric α subunits are noncovalently and symmetrically associated, one at each end of the central, rotationally symmetric β_2 homodimer, in the same arrangement as the $\beta\alpha_2\beta$ heterotetramer of the multienzymatic complex for acetaldehyde dehydrogenase (acetylating) and 4-hydroxy-2-oxovalerate aldolase. In the crystallographic molecular model of the intact multienzymatic complex, the active site for indole-3-glycerol-phosphate lyase (Equation 3–524) has been located on the α subunit by soaking crystals in a solution of the competitive inhibitor 3-(indol-3-yl)propanol phosphate, and the active site for tryptophan synthase (indole-salvaging) (Equation 3–525) has been located on the β subunits by locating the pyridoxal phosphates present in the enzyme as prosthetic groups. The distance in the crystallographic molecular model between an active site on an α subunit and the closest active site on a β_2 homodimer is 2.5–3.0 nm.

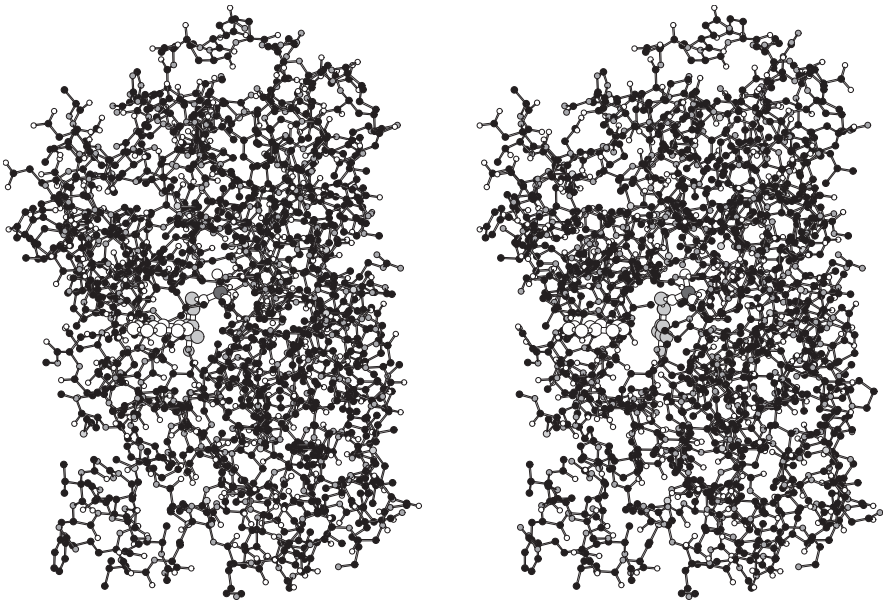


Figure 3–71: Stereodrawing[576] of one of the tunnels connecting the active sites for indole-3-glycerol-phosphate lyase (Equation 3–524) and tryptophan synthase (indole-salvaging) (Equation 3–525) in multimeric tryptophan synthase complex from *S. typhimurium*.[1296] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are sulfurs. The crystallographic molecular model from which the drawing was made is for crystals of the conformation that tryptophan synthase assumes in the presence of K^+, which should be the conformation that exists in the cytoplasm. Indole is released at the active site for indole-3-glycerol-phosphate lyase, and the location at which it is released has been located in the α subunit in the crystallographic molecular model of the complex between tryptophan synthase and the inhibitor 3-(indol-3-yl)propanol phosphate.[717] A molecule of indole (white atoms and white bonds at the top of the tunnel) has been drawn occupying the location of the indolyl group in that model. At the bottom of the tunnel is the pyridoxal phosphate (gray atoms and gray bonds that can be located by its phospho group) occupying the active site for tryptophan synthase (indole-salvaging) in the β subunit of the model of the potassium conformation from which the rest of the drawing is made. The indole has to slide under a proline at the top of the tunnel and also has to push aside the side chain of a leucine near the top. From there on, the tunnel is open, leading straight to the pyridoxal phosphate. The active site for indole-3-glycerol-phosphate lyase is in the α subunit at the interface with the β subunit, and most of the tunnel passes from the interface through the middle of the β subunit.

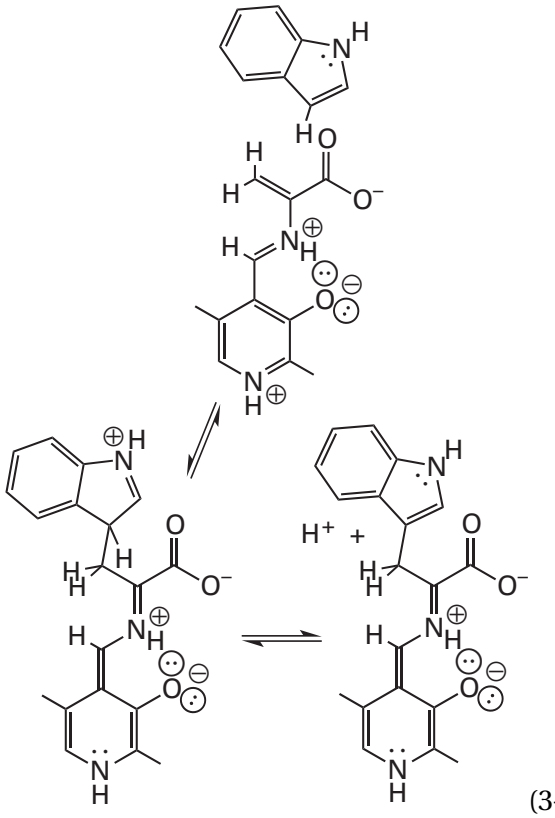
In the crystallographic molecular model, two symmetrically arrayed tunnels pass through the protein. Each tunnel is 2.5 nm long and connects the active site for indole-3-glycerol-phosphate lyase on an α subunit with an active site for tryptophan synthase (indole-salvaging) on a β subunit (Figure 3–71).[717,1296] Each tunnel is enclosed along its length on all sides by protein and is wide enough to permit molecules of the intermediate substrate indole to pass through. These tunnels are much shorter and straighter than the tunnel in the multienzymatic complex for anaerobic carbon monoxide dehydrogenase and CO-methylating acetyl-CoA synthase (Figure 3–69). In the crystallographic molecular model of tryptophan synthase with the inhibitor 3-indolylpropanol phosphate occupying the active sites for indole-3-glycerol-phosphate lyase in the α subunits, the indolyl group is in the bottom of each active site, as far from the solution as possible, and sitting at the opening of the tunnel for that active site. Upon cleavage of the normal initial reactant, 1-*C*-(indol-3-yl)glycerol 3-phosphate, the indole would be released at this location in the active site, and it would be hindered from being released into the solution but not from entering the adjacent tunnel. These details suggest that the indole feeding the active site on a β subunit during the overall reaction (Equation 3–523) is transferred between the two active sites through this tunnel. There are a number of observations verifying the proposal that each of the two tunnels is a **tunnel for indole**.

In the absence of L-serine, intact tryptophan synthase from *Neurospora crassa* produces indole from 1-(indol-3-yl)glycerol 3-phosphate, but the rate at which indole appears in solution is 50 times slower than the rate at which L-tryptophan is produced by the intact multienzymatic complex from 1-(indol-3-yl)glycerol 3-phosphate and L-serine under the same circumstances.[1297,1298] When L-serine is present, indole is no longer produced by the multienzymatic complex from 1-(indol-3-yl)glycerol 3-phosphate. During a reaction in which 100 nmol of L-tryptophan was produced from 1-(indol-3-yl)glycerol 3-phosphate and L-serine, no indole was released into the solution (<2 nmol). An explanation for these kinetic observations is that when L-serine is absent and an active site for tryptophan synthase (indole-salvaging) is not operating, indole piles up in the tunnels and acts as a product inhibitor of indole-3-glycerol-phosphate lyase. Indole can escape from a tunnel into the solution, but only slowly, and this escape is the rate-limiting step in its production in the absence of L-serine. When L-serine is present, all the channeled indole is immediately transformed into L-tryptophan. Indole does not pile up in the tunnels, and it does not have time to leak out of them before it is converted into L-tryptophan.

If indole is transferred between the two active sites through the affiliated tunnel, the **mutation of an amino acid in the wall of the tunnel that sterically blocks it** should prevent the transfer. Under normal circumstances, when 1-*C*-([^{14}C]indol-3-yl)-glycerol 3-phosphate and L-serine are converted in a single turnover to L-[^{14}C]tryptophan by a molar excess of tryptophan synthase, no [^{14}C]indole can be detected (<1%). If Cysteine 170 in the β subunit of tryptophan synthase, which is in the wall of the tunnel, is mutated to a tryptophan, the rate of synthesis of L-[^{14}C]tryptophan from 1-*C*-([^{14}C]indol-3-yl)-glycerol 3-phosphate and L-serine during a single turnover decreases by a factor of 30, and [^{14}C]indole can be detected (10%).[1299] In addition, the rate of synthesis of L-tryptophan from L-serine and indole, rather than 1-*C*-(indol-3-yl)glycerol 3-phosphate, is decreased 20-fold in the mutant, a result that is consistent with indole entering the enzyme from solution only from the end of a tunnel (Figure 3–71) at the active site on an α subunit, which is the location where indole is normally produced (Equation 3–524).

If indole is able to **enter a tunnel only through an active site** on an α subunit and from there pass through the tunnel and enter the active site on the β subunit (Equation 3–525) at the end if the tunnel, this requirement would explain an observation that might seem inconsistent with the channeling of indole between the two active sites. When 1-*C*-([2-^{14}C]indol-3-yl)glycerol 3-phosphate is used as a reactant in the presence of L-serine, L-[2-^{14}C]tryptophan is produced by tryptophan synthase, and no [2-^{14}C]indole is released into the solution.[1300] If, however, a large enough concentration of nonradioactive indole is added to the solution, the rate of production of L-[2-^{14}C]tryptophan decreases remarkably, and significant amounts of [2-^{14}C]indole are released into the solution. As the concentration of nonradioactive indole is increased, the rate of production of L-[2-^{14}C]tryptophan decreases, and the rate of production of [2-^{14}C]indole in solution increases. One explanation for this observation would be that as a tunnel becomes filled with indole that has entered it from solution through the active site on an α subunit while that active site was temporarily empty, the [2-^{14}C]indole produced at that active site by the reaction in Equation 3–524 will dissociate into the solution because it is unable to move

through the overcrowded tunnel. Consistent with this explanation is the fact that, in the intact enzyme, indole from the solution is able to react rapidly with the α-aminoacrylate intermediate (previously Equation 2–14)



(3–526)

formed in the active site on a β subunit (200 s^{-1} at saturation). When, however, glyceraldehyde 3-phosphate is bound at the active sites on the α subunits, blocking the indole from entering the tunnel between the active sites, the rate of this reaction with indole is dramatically inhibited (10 s^{-1}).[1301]

Ammonia is a toxic metabolite, but it is necessary for a large number of biosynthetic reactions. This conflict is resolved by converting ammonia to L-glutamine in the reaction catalyzed in the cytoplasm of all cells by glutamine synthetase

$$NH_4^+ + MgATP^{2-} + \text{L-glutamate} \rightleftharpoons MgADP^- + H_2PO_4^- + \text{L-glutamine} \quad (3\text{–}527)$$

and then releasing the ammonia at the locations where it is needed in a hydrolysis catalyzed by glutaminase

$$\text{L-glutamine} + H_2O \rightleftharpoons \text{L-glutamate} + NH_4^+ \quad (3\text{–}528)$$

Because these two enzymes, when functioning consecutively, would catalyze the hydrolysis of $MgATP^{2-}$, the ammonia produced by glutaminase cannot be released into the cytoplasm, or it would create an ATPase that consumes energy but accomplishes nothing. Consequently, there are a large number of multienzymatic complexes in which an active site for glutaminase is combined with an active site for a particular biosynthetic reaction that has ammonia as one of its reactants. For example, the active site for

$$\text{D-fructose 6-phosphate} + NH_3 \rightleftharpoons H_2O + \text{D-glucosamine 6-phosphate} \quad (3\text{–}529)$$

is combined with an active site for glutaminase in the multienzymatic complex glutamine—fructose-6-phosphate transaminase (isomerizing), which catalyzes the overall reaction

$$\text{D-fructose 6-phosphate} + \text{L-glutamine} \rightleftharpoons \text{L-glutamate} + \text{D-glucosamine 6-phosphate} \quad (3\text{–}530)$$

In the biosynthetic reaction, an acceptor for the ammonia, such as D-fructose 6-phosphate, is the nominal substrate, as in glutamine-fructose-6-phosphate transaminase (isomerizing). In these multienzymatic complexes, the two active sites are connected by a **tunnel through which ammonia is transferred** between them.[954,1302-1308] These tunnels for ammonia vary in length from 1.5 to 4.5 nm.[1302]

Because ammonia rarely, if ever, enters or escapes from the tunnel before it is incorporated into the final product, the two reactions are tightly coupled. For example, glutamine-fructose-6-phosphate transaminase (isomerizing), both from *E. coli* and from *R. norvegicus*, catalyzes, within the error of the measurement,[1309] a **completely stoichiometric reaction** (Equation 3–530). If ammonia were to escape from the tunnel, the reaction would not be stoichiometric. The overall reaction is the sum of Equations 3–528 and 3–529, and these two reactions are catalyzed at two distinct active sites on the multienzymatic complex.[1302] Ammonia cannot substitute for L-glutamine.[1309] If ammonia cannot leak

out of the tunnel, by microscopic reversibility, it cannot leak in.

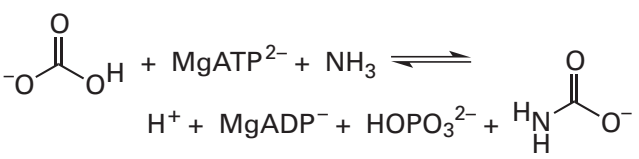
In several amidotransferases, the tunnel for ammonia is formed by a conformational change in the enzyme that is coupled to association of the acceptor for ammonia at its active site or coupled to simultaneous association of glutamine at the active site of glutaminase and association of the acceptor for ammonia at its active site.[953,954,1305,1310-1312] This **induced fit** presumably serves the usual purpose of ensuring that none of the dangerous steps in the reaction, such as the glutaminase reaction (Equation 3–528) or a step activating the acceptor for ammonia, is able to occur until **all the reactants are bound to their respective active sites**.

Such induced fits are common features of multienzymatic complexes that transfer intermediate substrates through tunnels between distant active sites. For example, in tryptophan synthase, the association of 1-*C*-(indol-3-yl)glycerol 3-phosphate with the active site on an α subunit (Equation 3–524) induces a conformational change that **opens the active site** on the affiliated β subunit so that L-serine can associate.[1313] Subsequent formation of the aminoacrylate at the pyridoxal phosphate from L-serine in the active site on a β subunit (Equations 3–525 and 3–526) then induces a conformational change that enhances cleavage of 1-*C*-(indol-3-yl)glycerol 3-phosphate at the active sites on the affiliated α subunit by a factor of 30.[1314,1315]

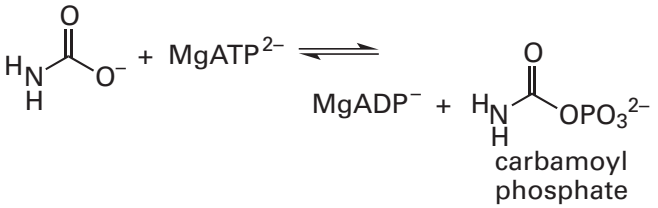
Carbamoyl-phosphate synthase (glutamine-hydrolysing) is a multienzymatic complex composed of two subunits. The smaller of the two (382 aa) is glutaminase, which hydrolyzes L-glutamine to produce the ammonia that is an intermediate substrate

$$H_2O + \text{L-glutamine} \rightleftharpoons \text{L-glutamate} + NH_3 + H^+ \quad (3\text{–}531)$$

The larger subunit (1073 aa) contains the two active sites



(3–532)



(3–533)

on two separate structural domains that are responsible for the synthesis of carbamoyl phosphate from that ammonia.[1316,1317] [^{14}N]Ammonia produced at the glutaminase within the multienzymatic complex from *E. coli*, rather than the [^{15}N]ammonium added to the solution, is the almost exclusive (>95%) reactant for the second reaction,[1291] so it must be channeled. The half life for hydrolysis of carbamate at 25 °C is 28 ms,[1318] so it cannot come into contact with surrounding solution. Because the stoichiometry of the overall reaction

$$HCO_3^- + \text{L-glutamine} + 2\,MgATP^{2-} + H_2O \rightleftharpoons \text{L-glutamate} + 2\,MgADP^- + HOPO_3^{2-} + H_2NCOOPO_3^{2-} + 2\,H^+ \quad (3\text{–}534)$$

catalyzed by the multienzymatic complex is precise, within the error of measurement,[1319] ammonia must be channeled without loss between the first two active sites (Equations 3–531 and 3–532) and carbamate must be channeled, without being hydrolyzed, back and forth between the second and third active sites (Equations 3–532 and 3–533).

In the crystallographic molecular model of the enzyme from *E. coli*, a tunnel runs between the active site for the glutaminase (Equation 3–531) on a smaller subunit and the active site in the adjacent larger subunit at which carbamate is synthesized (Equation 3–532). These two active sites are 4.5 nm apart. The tunnel then continues on to the active site at which carbamoyl phosphate is synthesized (Equation 3–533), which is another 3.5 nm away.[1320] Even though it is longer (9.6 nm) because it has to service three active sites, this tunnel resembles the tunnel (7.0 nm) in the multienzymatic complex containing the active sites for anaerobic carbon monoxide dehydrogenase and CO-methylating acetyl-CoA synthase in its bends and changes of direction (Figure 3–69) and in the fact that it also passes through an interface between two subunits. As a measure of its tortuosity, each tunnel is about 20% longer than the linear distance between the active sites that it services. The tunnel in carbamoyl-

phosphate synthase (glutamine-hydrolysing) is, however, somewhat more deeply buried in the center of the protein.

The results of site-directed mutation confirm that the intermediate substrates for carbamoyl-phosphate synthase (glutamine-hydrolysing) do move through the tunnel in the enzyme. When the tunnel for ammonia is blocked within the smaller subunit of the enzyme by mutating Glycine 359 on its wall to phenylalanine, the catalytic constant for synthesis of carbamoyl phosphate from L-glutamine decreases 70-fold.[1321,1322] When the tunnel for ammonia is blocked within the larger subunit by mutating Cysteine 232, Alanine 251, and Alanine 314 on its wall to valines, the catalytic constant for synthesis of carbamoyl phosphate from L-glutamine decreases more than 500-fold.[1323] When a hole to the solution is made in the tunnel for ammonia by mutating Proline 360 and Histidine 361 in the smaller subunit and Arginine 265 in the larger subunit to alanines, the catalytic constant for synthesis of carbamoyl phosphate from L-glutamine decreases 300-fold.[1324] And when the **tunnel for carbamate** within the larger subunit is blocked at its two narrowest points by mutating Alanine 23 to phenylalanine, Glycine 575 to phenylalanine,[1325] or both Alanine 23 and Glycine 575 in its wall to leucines,[1326] the catalytic constant for synthesis of carbamoyl phosphate decreases by 60-fold, 25-fold, and more than 500-fold, respectively.

The possibility that channeling of an intermediate substrate between two distant active sites across the surface of a multienzymatic complex could occur by **entrapment of the substrate in the ionic double layer*** surrounding the protein, rather than in a tunnel, has been proposed to explain the channeling observed in multienzymatic complexes from *Leishmania tropica* and *T. gondii*, which both contain active sites for thymidylate synthase

$$\text{5,10-methylenetetrahydrofolate} + \text{dUMP} \rightleftharpoons \text{dTMP} + \text{7,8-dihydrofolate} \quad (3\text{–}535)$$

and dihydrofolate reductase

$$\text{NADPH} + \text{7,8-dihydrofolate} + \text{H}^+ \rightleftharpoons \text{5,6,7,8-tetrahydrofolate} + \text{NADP}^+ \quad (3\text{–}536)$$

for which the intermediate substrate is 7,8-dihydrofolate. There is no lag in production of $NADP^+$ in the latter reaction when 7,8-dihydrofolate is produced at the former active site from 5,10-methylenetetrahydrofolate,[1328,1329] and there is no accumulation of tritium-labeled intermediate substrate 7,8-dihydrofolate when tritium-labeled 5,10-methylenetetrahydrofolate is converted to tritium-labeled 5,6,7,8-tetrahydrofolate by the two active sites[1329,1330] operating consecutively. These two facts are consistent with tightly coupled channeling. There is, however, no obvious tunnel between the two active sites, which are 4.0 nm apart in crystallographic molecular models of the multienzymatic complexes.[1329,1331]

The fixed ionic layer of charged side chains of amino acids on the surface of the multienzymatic complex between the active sites for thymidylate synthase and dihydrofolate reductase in the crystallographic molecular model is dramatically enriched in positively charged side chains, which would produce an ionic double layer in which the outer ionic layer is enriched in mobile negative ions. Consequently, dihydrofolate, a dianion, could be confined within the double layer and be transferred through the double layer between the active sites. The experiment in which apparent channeling was observed was performed in a solution of 25 mM $MgCl_2$ (I = 75 mM). Unfortunately, the effect of increasing ionic strength on the channeling efficiency was not assessed. An increase in ionic strength should eliminate channeling within the double layer.[1332] Mutating six of the arginines and lysines between the two active sites, however, to neutral amino acids did not decrease the channeling efficiency,[1333] a result inconsistent with channeling through the double layer. Consequently, the mechanism by which channeling occurs in this multienzymatic complex is unknown.

Many enzymes catalyze reactions that have homopolymers as their reactants, and some of these enzymes have active sites that perform successive reactions on successive segments of the polymer without dissociating from it.[1334] In such an enzyme, the active site is transferred from one monomer of the polymer to the next monomer of that polymer rather than a monomer of the polymer

*The layer of fixed charges on a macromolecule induces counterions of the opposite charge, such as a channeled substrate that is oppositely charged, to become concentrated in the layer of solution surrounding the macromolecule. These two layers, the layer of fixed charges and the layer of mobile charges of the opposite sign, comprise the ionic double layer.[1327]

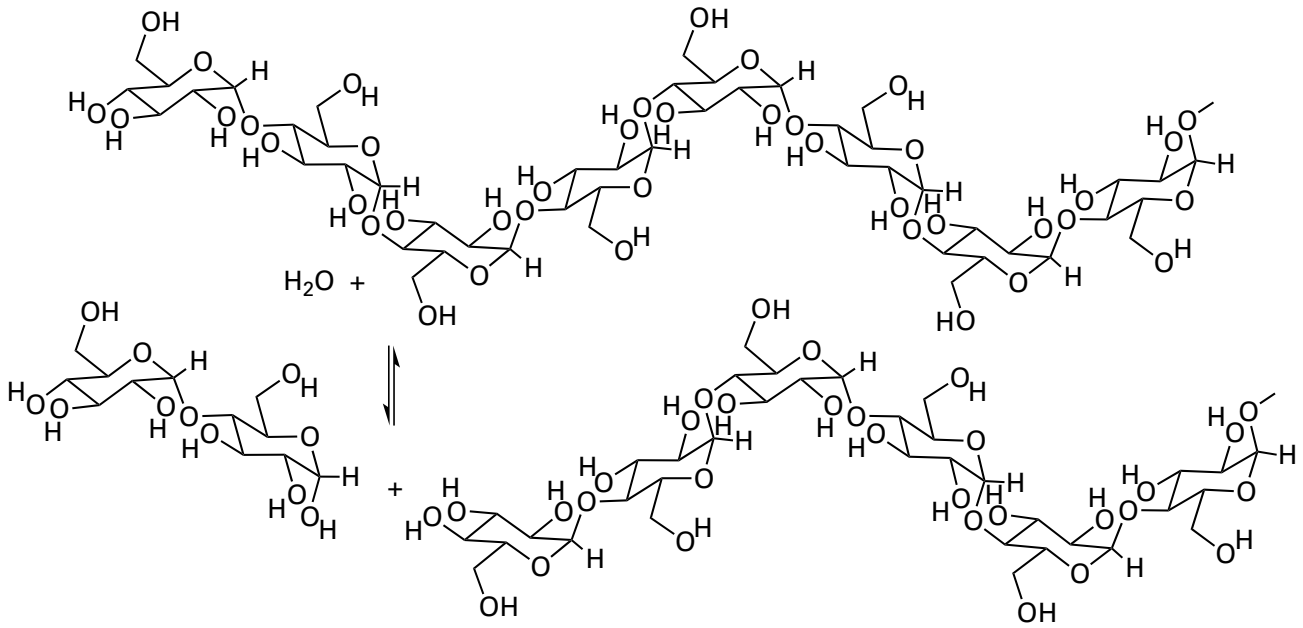


Figure 3–72: Hydrolysis of $(\alpha 1,4)$-glucose$_n$ by β-amylase.

being transferred from one active site to the next active site. For example, β-amylase from *G. max* is an exoglycosidase that hydrolyzes the linear polymer $[(\alpha 1,4)$-D-glucose$]_n$ from the nonreducing end at every other glycosidic linkage to release molecules of maltose (Figure 3–72).[1335] About half the time, the enzyme remains associated with the same molecule of $[(\alpha 1,4)$-D-glucose$]_n$ from which it just released a maltose and releases the next maltose from that same molecule.[1336]

DNA-Directed DNA polymerase catalyzes the alignment with the template of the next 2′-deoxyribonucleoside 5′-triphosphate to be added to an elongating strand of DNA, ensures that the proper base pair is formed between it and the next nucleotide in the template,[1337] and then catalyzes the nucleophilic substitution at phosphorus that attaches the next nucleotide to the elongating strand. The enzyme adds a number of nucleotides to the elongating strand before it dissociates from a particular elongating segment of DNA. The steps in the reaction are association and alignment of the correct 2′-deoxyribonucleoside 5′-triphosphate, nucleophilic substitution at phosphorus, and shifting of the duplex of template and elongating strand by a distance of one base pair to bring the 3′-hydroxy group of the added nucleotide into the position where the 3′-hydroxy group of the initial reactant was located to initiate the next round of elongation. The kinetics of these three steps have been assessed with the DNA-directed DNA polymerase encoded by Escherichia phage T7 at 20 °C. Following association of the 2′-deoxyribonucleoside 5′-triphosphate, there is a slow (0.3 ms^{-1}) conformational change preceding the chemical step, thought to ensure that the correct 2′-deoxyribonucleoside 5′-triphosphate has been properly aligned.[1338] The next step is rapid (>9 ms^{-1}) nucleophilic substitution at phosphorus followed by shifting of the product of elongation in the active site (1.2 ms^{-1}) to position the 3′-hydroxy group that will be the reactant for the next cycle.[1004]

In a **processive reaction**, the active site of an enzyme[1334] catalyzes a reaction within a particular segment of a linear homopolymer and then moves, without dissociating, to the adjacent segment of that homopolymer to catalyze the same reaction within the next segment. If the **processive enzyme** removes segments from one end of the polymer, it moves to the newly created end to remove the next segment and so forth, as in the case of β-amylase (Figure 3–72). If the processive enzyme adds segments to one end of the polymer, it moves to the new end and adds a new segment to the new end and so forth, as in the case of DNA-directed DNA polymerase.

The **processivity** of a reaction catalyzed by a processive enzyme is the ratio between the rate at which the active site moves to the next segment of the polymer and completes its catalysis of the reaction at that location and the rate at which the polymer dissociates from the enzyme. The processivity of the enzyme can be determined by measuring directly the rate at which the enzyme catalyzes the

reaction while bound to the polymer and the rate at which it dissociates from the polymer.[1339] It can also be determined by assessing the distribution of lengths in the final product as a function of the degree to which the reaction has proceeded.[1336] The processivity of β-amylase from *G. max* is 0.55,[1336] that for DNA-directed DNA polymerase β from *R. norvegicus* is 30,[1339] and that for DNA-directed DNA polymerase from Escherichia phage T7 is 1500.[1004] The distribution of products as a function of time can be fit to equations simulating that distribution as a function of the numerical value for the processivity.[1340] The best fit provides an estimate of the processivity.

In the case of the DNA-directed DNA polymerases, the processivity depends on conditions of the assay such as concentration of Mg^{2+}, the temperature, or the presence of polyamines normally present in cytoplasm.[1341] Because DNA and RNA bear significant net negative charge and because associations of proteins with nucleic acids often involve ionic interactions, when either DNA or RNA is the polymer on which the enzyme acts, the processivity of depolymerization or polymerization is often a function of the ionic strength of the solution. Uracil-DNA glycosylase from *E. coli* was perfectly processive at low ionic strength (<30 mM), but when the ionic strength was increased into the cytoplasmic range, the enzyme was significantly less processive.[1342] The processivity of many other processive enzymes probably depends on the conditions of the assay as well. Consequently, the actual processivity of a given enzyme in the cytoplasm of the cell may be considerably different from that measured in an artificial assay.

In addition to measuring the numerical value for the processivity, a test for determining whether or not an enzyme is processive is to add a form of the polymer that can be experimentally distinguished from the polymer on which the enzyme has initiated its reaction and assess whether or not the addition of the competitor changes the rate of the reaction on the original substrate by drawing enzyme away from the polymer on which it is processing.[1343] This approach is analogous to the addition of a scavenger to assess channeling.

A **nonprocessive enzyme** catalyzes a distributive reaction. In a **distributive reaction,** an active site catalyzes a reaction within a particular segment of a linear homopolymer—be it a cleavage of the polymer beyond that segment, the addition of a new segment to that segment, or simply a chemical alteration of that segment— by associating from solution before and dissociating into the solution after the catalytic event within that segment. The dissociated products, either one monomer shorter, one monomer longer, or altered in the one position, become indistinguishable from all the other polymers in solution, and the enzyme then associates at random with another polymer. If the enzyme is nonprocessive, there is no transfer of the active site from one position in the polymer to the next position.

A **perfectly processive enzyme** shortens, elongates or otherwise modifies a polymer without dissociating from it. When, however, a perfectly processive enzyme is operating in a finite environment, as is always the case, the numerical value for its processivity can never be infinity. Because the mean length of a polymer that is being depolymerized is finite, if an enzyme depolymerizing that polymer is perfectly processive, the numerical value for the processivity is equal to the mean length of the polymer. The enzyme can only shorten the polymer until it reaches its end. Because the concentration of the monomer being polymerized is finite, if an enzyme polymerizing a polymer is perfectly processive, the numerical value for the processivity is equal to the concentration of monomeric precursor in solution divided by the concentration of enzyme. The enzyme can only elongate the polymer until the monomers in solution run out.

During a perfectly processive depolymerization, polymers in the solution that are unassociated with a molecule of enzyme remain unaltered until polymers being shortened by the enzyme are completely depolymerized and molecules of the enzyme become available to shorten other polymers. For example, a molecule of exoribonuclease II from *E. coli* rapidly hydrolyzes a molecule of polyadenylic acid exonucleolytically from its 3′ end with complete processivity down to a small oligonucleotide from which the enzyme slowly dissociates, and then it associates with another molecule of polyadenylic acid and processively hydrolyzes it. As the reaction progresses, only intact, undegraded polyadenylic acid, adenosine monophosphate, and these small oligonucleotides are present at significant concentrations in the solution in addition to the enzyme.[1334,1344] The exosome from *S. cerevisiae* is also a perfectly processive exoribonuclease II. When single-stranded RNA labeled with a [^{32}P]phospho group at its 5′ end is mixed with the enzyme, the intact polymer gradually disappears and the only product that can be observed while the polymer is disappearing is the free [^{32}P]mononucleotide that was once on the 5′ end. It can be concluded from this observation that the

rate-limiting step in the processive hydrolysis of single-stranded RNA is its threading through the long tunnel that passes through the center of the protein. Once its 3′ end reaches the active site at the end of the tunnel, the enzyme processively hydrolyzes all the nucleotides in the RNA, one after the other from the 3′ end to the 5′ end, so rapidly that no shorter single-stranded ribonucleic acids can be observed.[1345]

During a perfectly processive polymerization, a molar concentration of polymer equal to the molar concentration of enzyme is continuously elongated until the reactant in the solution providing the monomers runs out while the remainder of the polymer in solution remains unaltered. In the case of nucleic acid polymerases, however, when they are elongating a strand of nucleic acid on a template, as long as there are sufficient nucleoside triphosphates in the solution, a perfectly processive enzyme continues to polymerize until a termination site is reached, at which point the completed polymer dissociates from the active site, leaving the enzyme free to initiate polymerization on another template.

Following a completed depolymerization or polymerization, a perfectly processive enzyme can remain associated for a significant interval with a final product. When DNA helicase I from *E. coli* is mixed with a duplex DNA 343 nucleotides long that is present in molar excess over the concentration of enzyme, the percentage of DNA unwound at the completion of the reaction is directly proportional to the concentration of enzyme.[1346] If the helicase dissociated from the unwound DNA, all the DNA would be unwound by the end of the reaction.

In most enzymes that catalyze processive reactions, at least five monomers in the intact polymer occupy consecutive subsites adjacent to the catalytic site within the active site at which the specific addition or subtraction of a monomer is catalyzed. These successive subsites can be in a groove on the surface of the protein, but usually they are within a tunnel into or out of the active site. For example, cellulose 1,4-β-cellobiosidase (reducing end) Cbh1, a cellulase from *H. jecorina*, hydrolyzes a strand of cellulose, $[(\beta 1,4)$-D-glucose$]_n$, releasing the disaccharide cellobiose from the reducing end of the polymer. Once it associates with the reducing end of a strand of $[(\beta 1,4)$-D-glucose$]_n$ protruding from the surface of solid crystalline cellulose from *Cladophora*, the enzyme proceeds down the polymeric strand[1195] with a processivity of 70 ± 40. In the crystallographic molecular model of the enzyme,[1347,1348] there is a tunnel occupied by the reducing end of the polymer of $[(\beta 1,4)$-D-glucose$]_n$ as it is being hydrolyzed. In this tunnel, there are nine subsites for the association of D-glucosyl monomers in the polymer. Two of these subsites are to the reducing side of the point of hydrolysis. Rapid diffusion of the reducing end of the polymer up the tunnel into these two subsites, after the cellobiose from the previous hydrolysis has dissociated as a product from them and before the next hydrolysis can occur, causes the enzyme to release cellobiose instead of individual molecules of D-glucose. In the case of β-amylase, there are also two subsites beyond the location at which the glycosidic hydrolysis is catalyzed, so two glucosyl groups on the nonreducing end of the $[(\alpha 1,4)$-D-glucose$]_n$ produced in the previous hydrolysis diffuse rapidly into those sites as the disaccharide maltose, the product of the previous hydrolysis (Figure 3–72), dissociates from them, and this movement aligns the next glycosidic linkage in the proper position.[1336]

At the entrance to the tunnel in cellulose 1,4-β-cellobiosidase (reducing end) Cbh1 from *H. jecorin*, distant from the active site, there are two tryptophans in the sequence –ANWRWTHA– that stack upon the hydrophobic faces of the first and fourth D-glucosyl groups in from the opening of the tunnel (see Figure 3–45). When one of these tryptophans is mutated to alanine,[1348] the rate at which the enzyme hydrolyzes 4-methylumbelliferyl-D-lactoside, a monomeric substrate, is unaffected, but the rate at which it hydrolyzes crystalline cellulose when it is associated with the surface of this solid decreases by a factor of 7. This result suggests that the two tryptophans that stack upon the two respective D-glucosyl groups at the entrance of the tunnel are involved in recruiting individual substrate chains into the tunnel to initiate processive hydrolysis, or facilitating movement of the polymer through the tunnel by providing flat surfaces on which $[(\beta 1,4)$-D-glucose$]_n$ can slide, or both of these effects. A completely unrelated enzyme that catalyzes the same processive reaction, cellulose 1,4-β-cellobiosidase (reducing end) CelCCF from *Ruminiclostridium cellulolyticum*,[1349,1350] also has two tryptophans in the unrelated sequence –STWSWII– at the entrance of its tunnel for $[(\beta 1,4)$-D-glucose$]_n$ stacked upon the first and the third D-glucosyl monomers in the polymer occupying the tunnel.[1349,1350]

The **tunnels into or out of an active site are significant factors in ensuring the processivity** of the depolymerization or polymerization catalyzed by an enzyme. For example, consider the long tunnel

(16 nm) of the exosome, a perfectly processive enzyme, that can accommodate 25 nucleotides in the RNA that is its reactant.[1062] If single-stranded RNA is able to thread through the tunnel to the active site, by microscopic reversibility, it must be able to unthread from the tunnel. Suppose that the active site has just hydrolyzed the 5′-phosphodiester of the nucleotide at the 3′ end of a strand of RNA in the tunnel and disconnected it from the rest of the reactant. As the nucleoside 5′-phosphate is dissociating as a product from the active site, the single-stranded RNA in the tunnel is undergoing **linear diffusion in a one-dimensional random walk up and down the tunnel**, but it is highly unlikely that it will unthread all the way out of the tunnel before the nucleotide on the new 3′ end diffuses during its random walk into the now-empty active site and is hydrolyzed, and so forth. In other words, the **tunnel is so long that its length alone traps the polymer** and prevents it from leaving the tunnel before the next monomer can be processed by the active site, even though it is free to diffuse in a random walk up and down the tunnel.

A polymer of cellulose, the product of a polymerization, also threads its way through a long tunnel (6 nm) away from the active site in cellulose synthase.[1064] Suppose that the active site has just transferred the next D-glucopyranose from a molecule of UDP-α-D-glucose to the 4-hydroxy group at the end of the elongating $[(1\rightarrow4)$-β-D-glucosyl$]_n$. The now-elongated cellulose diffuses linearly in a one-dimensional random walk up and down the tunnel. While the D-glucose at the nonreducing end of the elongated strand of cellulose has vacated the active site as a result of this random walk, it is replaced by the D-glucopyranose from another molecule of UDP-α-D-glucose, but it is highly unlikely that the strand of cellulose, which is free to leave, will unthread all the way out of the tunnel before its nonreducing end stumbles in its random walk into the active site now occupied by the UDP-α-D-glucose, and the next D-glucose is added to it, and so forth.

Exodeoxyribonuclease (lambda-induced) from Escherichia phage lambda performs the hydrolysis from the 5′ end of a shorter strand of DNA in a duplex with a much longer strand of DNA that extends beyond the 5′ end of a shorter strand. The enzyme is perfectly processive, completely hydrolyzing the shorter strand to its 3′ end.[1351] The enzyme is a rotationally symmetric trimer with a tunnel that runs along the threefold rotational axis of symmetry and is large enough to accommodate a double-stranded duplex at one end and a single strand of DNA at the other end.[1352] In the crystallographic molecular model of the complex between an inactive mutant of the enzyme and a double-stranded DNA in which the longer strand continues two nucleotides beyond the 5′ end of the shorter strand, nine base pairs in the double-stranded portion of the DNA occupy the larger end of the tunnel, and the two nucleotides at the 3′ end of the longer strand are on their way out of the narrower end of the tunnel.[1353] The tunnel for the double-stranded DNA does not seem long enough to ensure perfect processivity, but in this instance, because the unhydrolyzed single strand of DNA exits the tunnel as the enzyme hydrolyzes the other strand, the enzyme would **remain attached to this single strand** even if the nine base pairs of double-stranded DNA were to diffuse away from the wider portion of the tunnel. The random walk of the single strand would eventually bring the 3′ end of the double strand back to the active site for the next hydrolysis.

In the proteosome from *S. cerevisiae*, there is not a tunnel leading to the active site. In this instance, the ubiquinylated polypeptide being degraded processively feeds into a large central cavity surrounded by the active sites for the peptidases that hydrolyze it.[1354] In this instance, in addition to the random walk of monomers in the polymer in and out of the entrance to the cavity, the length of the polymer that has already entered allows the random walk at the door to continue without dissociation, a situation resembling that of exodeoxyribonuclease (lambda-induced).

Another significant factor, which is often cited, in promoting processivity is **whether or not the reaction is exergonic**. Consider, for example, a DNA-directed DNA polymerase. As each magnesium 2′-deoxyribonucleoside 5′-triphosphate enters the active site and its base pairs with the complementary base on the template, its 2′-deoxyribonucleotide is added to the elongating strand in a simple nucleophilic substitution at phosphorus in which the 3′-hydroxy group on the elongating strand as a nucleophile replaces magnesium diphosphate as the leaving group. In this substitution, a phosphate anhydride is replaced by a phosphate ester, a reaction that is significantly exergonic. It is unlikely that this nucleophilic substitution will be significantly reversible, so the elongation is not complicated by the back reaction. Consequently, the new nucleotide is locked onto the elongating polymer, and the resulting favorable change in free energy could cause the processivity to be unidirectional. The problem with such an exergonic argument, however, is illustrated

by the fact that the processivity of the elongation catalyzed by DNA-directed DNA polymerase β from *R. norvegicus* is only 30 while the processivity for DNA-directed DNA polymerase from Escherichia phage T7 is 1500, even though they catalyze the same nucleophilic substitution at phosphorus, and DNA-directed RNA polymerase, which also catalyzes the same nucleophilic substitution, is perfectly processive. One would suppose, if the change in standard free energy of the reaction were consequential, that the processivity of these three elongations would be more similar.

The problem that a polymerase has to solve is **preventing the dissociation of the elongating strand and the template to which it is attached** from the active site, and it is difficult to see how the change in standard free energy of the reaction that the enzyme catalyzes can contribute to a solution of this problem. There are many nonprocessive enzymes the active sites of which catalyze significantly exergonic reactions and from which all the products of the exergonic reaction rapidly dissociate after each turnover. There are also many processive enzymes that catalyze reactions that are almost isoergonic. For example, the hydrolysis catalyzed by an exosome is the nucleophilic substitution at phosphorus of the hydroxy group on a molecule of water for the 3′-hydroxy group of the RNA. In the active site of an enzyme, this substitution should be isoergonic. In spite of its appeal, whether a reaction catalyzed by the active site is exergonic or isoergonic cannot be so consequential in ensuring processivity, if it is consequential at all, as the long tunnels. The explanation for the differences in processivity among polymerases is the differences in the degree to which they surround their products and prevent their dissociation.

There are **processive enzymes that bias their processivity by hydrolyzing $MgATP^{2-}$** even though the hydrolysis does not participate in the chemical reaction catalyzed by the enzyme. An example of such a processive enzyme is DNA helicase PcrA from *G. stearothermophilus*.[1355] In the cell, the enzyme catalyzes the unwinding of a double-helical DNA. For the enzyme to unwind DNA, it must hydrolyze $MgATP^{2-}$. The unwinding of double-stranded, duplex DNA is endergonic. If it were not endergonic, linear double-stranded DNA would spontaneously unwind from its two ends, which it does not. The hydrolysis of $MgATP^{2-}$ provides the free energy required to unwind the DNA.

It has already been noted that DNA helicase PcrA displays a heavily, if not exclusively, biased diffusion in the 3′ to 5′ direction on single-stranded DNA and that the bias is accomplished by the hydrolysis of one molecule of $MgATP^{2-}$ for each nucleotide traversed.[1209,1210] In a crystallographic molecular model of the enzyme in a complex with magnesium 5′-adenylic imidodiphosphonic anhydride ($MgAMPPNP^{2-}$) and a short double helix of DNA of ten base pairs, one strand of which has a 3′ extension of seven nucleotides beyond the duplex, the double helix is partially unwound by four base pairs.[1356] The resulting four 5′ nucleotide bases of the shorter strand are protruding out into the solution, but the resulting single strand with the 3′ extension can be seen entering a tunnel into the enzyme. The tunnel contains four nucleotides of the 3′ extension, and two nucleotides at the 3′ end have entered the solution and are disordered and not observed in the map of electron density. Presumably, the tunnel is responsible for performing the biased diffusion of the single strand in the 3′ to 5′ direction, and this biased diffusion accomplished by the hydrolysis of $MgATP^{2-}$ simply pulls the single strand away from the unwinding DNA while the other strand enters the solution. It has been shown that the closely related DNA helicase UvrD from *E. coli* (42% identity; 1.1 gap percent) unwinds DNA in discrete steps of four base pairs,[1357] and in the crystallographic molecular model of DNA helicase PcrA, the DNA has been unwound by four base pairs. It seems as though the double-stranded DNA resists unwinding, but when enough pull is exerted, it suddenly unwinds cooperatively in a burst of four base pairs. The cooperativity of this burst may involve the association of the unwound double-stranded DNA with the surface of the helicase.[1358,1359] Once the slack of four nucleotides rapidly moves through the tunnel, it pulls on the DNA again.

In the crystallographic molecular model of DNA helicase PcrA, the closest atom of $MgAMPPNP^{2-}$ in the site for the hydrolysis of $MgATP^{2-}$, which is one of the nonbridging oxygens on the γphosphorus, is 1.5 nm from the closest atom in the single-stranded DNA in the tunnel, so there can be no chemical reaction that involves the two substrates. Rather, there must be a cycle of conformational changes in the enzyme to accomplish the conformational coupling of hydrolysis of the $MgATP^{2-}$ to unidirectional movement of the strand of DNA through the tunnel so that every time a molecule of $MgATP^{2-}$ is hydrolyzed, the single strand moves down the tunnel a distance of one nucleotide.[1356]

One might suppose that the bias of the movement of the polymer through the active site prevents it from dissociating from the enzyme. If, however, the active site were simply a depression or groove in the protein, there would be nothing to prevent the unwinding DNA from dissociating into the solution after one of the steps in movement of the single strand away from the duplex. Again, as with exodeoxyribonuclease (lambda-induced), although the tunnel is short, the unwound single strand extends out from the tunnel into solution, preventing the unwinding DNA from dissociating from the enzyme as the unwinding proceeds.

RecBCD exodeoxyribonuclease V from *E. coli* finds single-stranded breaks in DNA and unwinds as a helicase the double-helical DNA that was to the 3′ side of the break in the 5′ direction. As it unwinds the DNA, it hydrolyzes the broken strand from its 3′ end until it reaches a hot spot for recombination. It then dissociates, leaving the other single strand, which was (and is still) unbroken, intact and the double-stranded DNA, which was originally to the 5' side of the break, also intact.[1360] As it unwinds the double-stranded DNA as a helicase away from the original break and hydrolyzes the unwinding single strand as an exonuclease, the enzyme hydrolyzes two $MgATP^{2-}$ for every base pair unwound.[1361] It unwinds about 350 base pairs $second^{-1}$ at 25 °C.

In a crystallographic molecular model of RecBCD exodeoxyribonuclease V from *E. coli* in a complex with a completely complementary hairpin of double-stranded DNA,[1360] the open end of the hairpin has unwound into two single strands, each four nucleotides long. The strand with a 3′ end is entering a tunnel that leads to a domain in the enzyme that is structurally homologous to the domain in DNA helicase PcrA responsible for the biased diffusion along the single strand of its substrates. From there, another tunnel leads to the active site of exodeoxyribonuclease V. The strand with a 5′ end is entering a tunnel that leads to another domain that is also structurally homologous to the domain in DNA helicase PcrA and that may catalyze a biased diffusion along this strand as well but in the 5′ to 3′ direction.

In DNA helicase PcrA, the DNA seems to unwind in the solution on the surface of the protein.[1358,1359] The surface of the protein itself provides a steric obstruction, as the one single strand is pulled into the protein away from the other that wanders off into the solution. In the crystallographic molecular model of RecBCD exodeoxyribonuclease V,[1360] however, the stack of as yet unwound base pairs sits on top of a pin that sterically splits the double helix as each single strand beyond the split is fed into a separate tunnel in the enzyme. The pin that splits the double helix is formed from a loop of six amino acids. It is at the carboxy-terminal end of one of the long (17 aa) α helices in the enzyme that is well anchored in the protein, and it is at the amino-terminal end of a randomly meandering segment of polypeptide (4 aa) followed by a shorter α helix (6 aa) that is also anchored in the protein. The loop of six amino acids forming the pin has two bulky methionines at its tip. The pin seems to act as a steric obstruction around which the double helix splits in two as it is pulled forward by biased diffusion of one or both unwinding single strands into their tunnels, powered by the hydrolysis of $MgATP^{2-}$.

The transcription of DNA into RNA is accomplished by DNA-directed RNA polymerases. These enzymes perform a sequence of induced fits and processive transfers of reactants within their active sites that represent perhaps the most complicated example of reactants associating with and products dissociating from the active site of an enzyme. In addition, the ultimate description of their mechanism involves the use of an elaborate analogue of the central intermediate in the catalysis performed by one of these enzymes.

DNA-Directed RNA polymerase is required to locate a promoter designating a location within a continuous duplex of DNA at the 3′ end of a sequence of nucleotides, the coding sequence, in one of the strands of deoxyribonucleotides in the duplex, the template, that encodes the sequence of ribonucleotides in the messenger RNA that the enzyme will produce. Once the promoter is located, the enzyme unwinds the DNA to form a bubble of two single strands of DNA, which exposes the 3′ end of the coding sequence on the template encoding the messenger RNA, and the enzyme then places the end of the coding sequence within the catalytic site. The catalytic site initiates the synthesis of a single strand of messenger RNA, starting from its 5′ end, by adding ribonucleotides one at a time in the direction 5′ to 3′. Once initiation is accomplished and a short strand of RNA, forming a heteroduplex with the coding strand of the DNA, has been synthesized, that short strand of RNA is then elongated, again in the direction 5′ to 3′, by incorporating one ribonucleotide at time to produce a messenger RNA complementary to the coding sequence of the DNA. As the strand of messenger RNA is elongated, it must be unwound from the coding strand of the DNA because the messenger RNA that is the final

product is a single strand of nucleic acid. As the bubble of DNA moves through the active site from its upstream end to its downstream end, the downstream end must be unwound to expose the next bases in the template and the upstream end must rewind. Then, when the process is finished and the messenger RNA has dissociated, the bubble can also dissociate and rapidly rewind spontaneously to a complete unaltered duplex of DNA.

DNA-Directed RNA polymerases from different classes of organism differ significantly in their complexity. The simplest is DNA-directed RNA polymerase from Escherichia phage T7,[1362,1363] which is a single folded polypeptide (883 aa). The functional complex for DNA-directed RNA polymerase from bacteria such as *E. coli*, *T. thermophilus*, and *Thermus aquaticus* is an $\alpha_2\beta\beta'\sigma\omega$ heterohexamer (3800 aa).[1364-1367] The core portion of DNA-directed RNA polymerase from eukaryotes such as *S. cerevisiae*, containing the machinery for initiation and elongation, is an even larger protein (4500 aa) of twelve different subunits ranging in length from 1700 to 70 amino acids,[1368,1369] but to accomplish all the necessary functions of messenger RNA production, it requires the cooperation of other proteins. Each enzyme has several independently shifting domains, and the latter two domains have independently shifting subunits. In each case, the various domains and subunits have been given names to indicate similarities among the different enzymes.[1369]

A sequence of nucleotides in double-stranded DNA that identifies a point at which transcription is to occur, a **promoter sequence**, has to be located by DNA-directed RNA polymerase. The A1 promoter from the genomic DNA of Escherichia phage T7 is a strong promoter that is recognized by DNA-directed RNA polymerase from its host, *E. coli*. When the sequence of deoxyribonucleotides downstream from an A1 promoter is extended from 72 to 300 nucleotides, the occupancy of the promoter after 10 min doubles.[1370] The result is reminiscent of the effect of increasing the length of a double-stranded DNA substrate on the rate of its cleavage by type II site-specific deoxyribonuclease EcoRI from *E. coli*. That result was presented as evidence that the deoxyribonuclease associates at random with duplex DNA and then diffuses by a random walk to its restriction site. Consequently, it was concluded that DNA-directed RNA polymerase also **associates at random and diffuses along the DNA** to a promoter. DNA-Directed RNA polymerase from Escherichia phage T7 binds, with dissociation constants in the range of several nanomolar, to DNA from Escherichia phage T7 at many sites along the DNA that are not within promoters. This binding is consistent with this DNA-directed RNA polymerase also associating at random with DNA before it diffuses to a promoter.[1371]

This diffusion can be observed. A large spherical bead, to which a small fluorescent sphere had been affixed, was attached at the end of a molecule of DNA (1300 nucleotides). These labeled molecules of DNA were added to a chamber with a coverslip to which molecules of DNA-directed RNA polymerase from *E. coli* had been firmly attached. Some of these molecules of DNA, each attached to a sphere, were bound by molecules of the polymerase on the coverslip. By following the fluorescence of the smaller sphere asymmetrically bound to the larger bead, it could be seen that the larger bead rotated. It was concluded that the DNA-directed RNA polymerase diffused along the helical DNA in one of its grooves, causing the molecule of DNA, and hence the bead, to rotate. The diffusion was not biased, as would be expected because no source of energy was available, but the properties of the rotation were consistent with **diffusion of the protein along the groove in a random walk**.[1372] By this random walk, the DNA-directed RNA polymerase scans the groove of the DNA searching for a promoter.

In the crystallographic molecular model of a complex between DNA-directed RNA polymerase from Escherichia phage T7 and a short segment of DNA containing a promoter for the polymerase, there are two hairpins of polypeptide: one of β structure in the major groove and one of random meander at the ends of two α helices in the minor groove of the double-helical DNA.[1363] These two hairpins are presumably the structures that **slide along within the grooves of the DNA** and read the sequence of the bases in the grooves. The sliding of these hairpins along the grooves causes the DNA to rotate as the enzyme scans for a promoter sequence during its one-dimensional diffusion. In the molecular model containing the enzyme from Escherichia phage T7, the two hairpins have found a promoter.

In a crystallographic molecular model of the complex between DNA-directed RNA polymerase from *T. aquaticus* and a longer segment (30 nucleotides) of double-stranded DNA containing a promoter, the intact, rigid, linear double-helical DNA runs along the surface of the protein and makes intimate contact with the surface over a length of 25 nucleotides.[1373] The promoter is entirely within the portion of the DNA participating in the intimate contact, and presumably it is within this contact that the reading of the sequence of bases in both the minor

and major grooves takes place as the protein diffuses along the DNA. In this particular complex, the promoter has also been found.

Once the promoter is located, transcription of the coding strand of the DNA into RNA commences. The first step is **unwinding of the double helix of DNA**. The second step is pairing of the correct ribonucleoside triphosphate with the first base on the template strand of DNA at the site at which sequential formation of the phosphodiesters begins. The third step is correct pairing of the second ribonucleoside triphosphate on the second base in the template. The fourth step is formation of the first phosphodiester by nucleophilic substitution at phosphorus. At this point, the successive addition of ribonucleotides commences.

No external source of standard free energy is available to unwind the DNA because the double helix has to be unwound over a significant length before the synthesis of messenger RNA can begin. The synthesis of the messenger RNA, however, once begun, provides significant standard free energy because the addition of each nucleotide is a nucleophilic substitution at phosphorus where a phosphate anhydride is replaced by a phosphate ester. Nevertheless, the initial unwinding must be driven by noncovalent forces between the protein and the single strands of DNA that are formed as the double helix unwinds. In a crystallographic molecular model of DNA-directed RNA polymerase from Escherichia phage T7 and the promoter segment of DNA,[1363] and in a crystallographic molecular model of DNA-directed RNA polymerase from Escherichia phage T7 and the promoter sequence on which the first three ribonucleotides of the messenger RNA have been synthesized,[1374] four or five, respectively, of the nucleotides of the double helix have been unwound, and the two single strands are firmly held by noncovalent forces between their functional groups and side chains from the protein.

In a molecular model produced by reconstructive summation of electron microscopic images of complexes between DNA-directed RNA polymerase from *M. tuberculosis* and a long (90 nucleotides) segment of double-helical DNA containing a promoter in its middle, the DNA has been unwound to form a **"bubble" of two single strands**, each 12–14 nucleotides long, while the duplex DNA has remained doubly helical to each side of the bubble.[1375] The catalytic site responsible for nucleophilic substitution at phosphorus can be identified by the Mg^{2+} within it. The deoxycytidine in the coding strand of DNA at which initiation is to occur is located within the catalytic site in position to identify the complementary guanosine 5′-triphosphate with which the messenger RNA is to commence. In the bubble, this deoxycytidine is 3 nm from the deoxyguanosine in the other, noncoding strand of the bubble with which it was in a base pair in the original double-helical DNA. This much space is more than sufficient both for the guanosine 5′-triphosphate to associate with the cytosine of this deoxycytidine and for the next nucleoside 5′-triphosphate to associate so that the first nucleophilic substitution can occur between the 3′-hydroxy group of the guanosine 5′-triphosphate and the α-phospho group on the 5′-hydroxy group of the second ribonucleoside triphosphate.

A candidate for an intermediate state in the formation of the bubble has been trapped by adding an inhibitor that associates with the active site between the DNA and the catalytic site. In this complex, the bubble has only opened halfway, and the deoxycytidine that is to initiate the synthesis of messenger RNA is still paired with its complementary deoxyguanosine in the unwound portion of the DNA.[1375] One can imagine, by paraphrasing Pauling,[311] that as molecular motions cause the bubble to open at the site where it first opens and the single strands of DNA fit into their subsites, the standard free energy of dissociation for the DNA from the enzyme increases. As the subsequent base pairs unpair as a result of molecular motion and each of them fits into its subsite, the standard free energy of dissociation again increases until the whole segment is unwound.

It has been possible to follow the various **induced fits** that occur between the situation in which the promoter in the rigid, linear double-helical DNA has been recognized and is still bound only on the surface of bacterial DNA-directed RNA polymerase and the situation in which the DNA has entered the active site of the enzyme and the bubble has formed. The initial point is the crystallographic molecular model of the complex of the promoter with DNA-directed RNA polymerase from *T. aquaticus*,[1373] and the final point is the molecular model produced by reconstructive summation of electron microscopic images of complexes between DNA-directed RNA polymerase from *M. tuberculosis* (44% identity; 1.1 gap percent) and the two forms of bubbled DNA.[1375] The process of conversion between these two states was followed by the changes with time of emissions in spectra of fluorescent reporters covalently attached to strategic locations in either DNA-directed RNA polymerase from *M. tuberculosis*

or the long segment of DNA containing the promoter in its middle, and various inhibitors were used to block the process at several of its steps.[1376] In the case of DNA-directed RNA polymerase from *S. cerevisiae*, the induced fits involved in forming the complex with DNA in which the first six bases of the messenger RNA have been synthesized have been defined by comparing crystallographic molecular models of that complex[1377] and the unoccupied enzyme.[1368] In this case, another protein, transcription initiation factor IIB, in addition to the heterododecamer of the eukaryotic DNA-directed RNA polymerase, is required to form the complex accomplishing initiation, and it is present in the crystallographic molecular model of the former complex.

During the initiation phase, in most instances, the active site and the unwound DNA are still open to the solution to allow addition of the first few ribonucleotides, but at a certain point **initiation changes to elongation**. For DNA-directed RNA polymerase from Escherichia phage T7, this transition seems to occur after about seven ribonucleotides have been added to the elongating strand of messenger RNA. At this point, the number of transcripts that dissociate from the active site rather than being elongated decreases significantly.[1378]

In crystallographic molecular models of DNA-directed RNA polymerase from Escherichia phage T7 in complexes with unwound DNA on which seven and eight ribonucleotides have been polymerized, gradual induced fits of the enzyme relative to the complex early in initiation can be observed, which indicates that the enzyme is adjusting to the elongating strand of messenger RNA.[1379] In a comparison of another crystallographic molecular model of the enzyme in which a complex with unwound DNA on which seventeen ribonucleotides have been polymerized[1380] with crystallographic molecular models of complexes with unwound DNA on which only three[1374] or eight[1381] ribonucleotides have been polymerized, the full **induced fit resulting from the transition between initiation and elongation** can be observed. A major rearrangement of the amino-terminal domain in the enzyme has caused it to close over the catalytic site, burying it in an internal cavity, and the conformational change has also created a tunnel through which the elongating RNA emerges. In the active site, the messenger RNA peels away from the template strand of the DNA into the tunnel so that as the elongation proceeds, there is always a heteroduplex of eight base pairs between the elongating messenger RNA and the template strand of the DNA.[1380] All these induced fits explain the decrease in dissociation of the transcript.

In the crystallographic molecular model of the complex of DNA-directed RNA polymerase from Escherichia phage T7 with unwound DNA on which seventeen ribonucleotides have been polymerized, the bubble of DNA can be observed. At the downstream end of the bubble where the DNA is being unwound as elongation proceeds, an α helix "is wedged in the fork where the template and nontemplate strands separate from the downstream duplex" and "serves to divert the direction of the nontemplate strand, promoting its separation from the template" as transcription proceeds.[1380] This diversion by the α helix is a steric effect. Another α helix in the active site performs the same steric role in **splitting the RNA from the template strand** of the DNA after eight base pairs have formed in the heteroduplex. In the case of bacterial DNA-directed RNA polymerase, deletion mutants of the enzyme from *T. aquaticus* indicate that a loop of 14 amino acids protruding into the tunnel of the active site is responsible for splitting the RNA from the template strand of DNA.[1382] In the active site of eukaryotic DNA-directed RNA polymerase, there are also **steric hindrances** at strategic positions in the active site that seem to be involved in unwinding the homoduplex of the DNA and the heteroduplex of the template and the elongating messenger RNA.[1383]

During elongation, **DNA-directed RNA polymerase is required to be perfectly processive**. If the elongating complex of RNA and DNA within the bubble were to dissociate from the enzyme, its structure would be so peculiar that it would be unlikely to survive long enough to associate with another molecule of RNA polymerase. The incompletely elongated messenger RNA associated in a short heteroduplex with the template would dissociate and become a free, incomplete strand of RNA in the cytoplasm, and the DNA would rewind to a complete double helix. The best that could happen to the strand of RNA is that it would be quickly digested rather than translated. Even in this best case, the standard free energy expended at each step in its elongation, which on a total molar basis is considerable, would be wasted. In the crystallographic molecular model of the complex between DNA-directed RNA polymerase from Escherichia phage T7 and the elongating messenger RNA and the bubble of DNA, the burial of the active site, the strand of RNA passing through the tunnel and emerging from the other side into the solution, and the heteroduplex of eight base pairs connecting the

RNA with the template strand of DNA,[1380] acting together, firmly hold both the messenger RNA and the DNA, precluding the dissociation of either of these substrates and ensuring perfect processivity.

The **enclosure of the bubble of DNA and the heteroduplex** between the elongating messenger RNA and the template strand of DNA is even more complete during elongation catalyzed by eukaryotic DNA-directed RNA polymerase. An artificial substrate was constructed for which two single strands of DNA, each 48 deoxyribonucleotides long, were synthesized. A duplex could be formed between the two strands with the 11 mispaired bases creating an artificial bubble of 11 deoxyribonucleotides in the middle, on either side of which all the bases were paired so that the bubble would be firmly anchored in the otherwise double-helical DNA. An RNA that was 30 nucleotides long was also synthesized, in which the first nine ribonucleotides from the 3′ end were complementary to nine of the deoxyribonucleotides in one strand of DNA in the bubble, but the remaining 21 ribonucleotides were not complementary to any sequence of nucleotides in the DNA. A heterotriplex was then formed with the two strands of DNA containing the bubble and the strand of RNA that mimicked an elongating RNA in a bubble of DNA (Figure 3–73A).[1384,1385] This elaborate **analogue of the usual intermediate** in the elongation of messenger RNA was then bound to the heterododecameric DNA-directed RNA polymerase from *Komagataella phaffii* in the absence of the full complement of ribonucleoside 5′-triphosphates that would promote elongation. Three of the ancillary proteins normally required for elongation were added to ensure that the complete complex was formed.

In the molecular model produced by reconstructive summation of electron microscopic images of the final complex of fifteen proteins and the artificial heterotriplex (Figure 3–73B),[1384] the enzyme has closed around the analogue of the intermediate with the heteroduplex between eight of the nine complementary bases of RNA in the bubble of the otherwise double-helical DNA and its 3′ end in the catalytic site. The double-helical DNA on either side of the artificial bubble, upstream and downstream, and the emerging single strand of RNA mimicking the elongating messenger RNA are each now **enclosed in their respective tunnels of protein**. There is little doubt that such an extensive enclosure ensures that the transcription is perfectly processive.

The elongation of messenger RNA by DNA-directed RNA polymerase from *E. coli* is a **remarkably constant process**. A poly(styrene) bead 0.5 μm in diameter was attached to the downstream end of a strand of double-helical DNA containing a promoter and a long coding sequence for the synthesis of messenger RNA. This DNA was introduced into a chamber, one wall of which was a coverslip coated with DNA-directed RNA polymerase from *E. coli* and within which there was a solution with all the ingredients needed for the synthesis of messenger RNA. Once in the chamber, the DNA was bound by the enzyme, transcription was initiated, and elongation proceeded, pulling the bead toward the enzyme as the DNA was transcribed. The bead was then locked in an optical trap in such a way that the DNA was stretched taut by a constant force of 4 pN applied by the optical trap. The chamber was mechanically translated so that while the DNA shortened as the downstream end entered the enzyme, the bead remained in the trap. Under the applied force, the rate at which elongation proceeded (12 ± 2 nucleotides s^{-1}) was remarkably constant over stretches of 1000 nucleotides.[1386]

The diffusion of a molecule of DNA-directed RNA polymerase along double-helical DNA while it is searching for a promoter must be an unbiased random walk[1372] because no standard free energy is provided at this stage. As the messenger RNA is elongated, however, a phosphate anhydride becomes a phosphate ester at each addition of a ribonucleotide. The resulting negative difference in standard free energy creates mechanical work pulling the transcript through the active site. Force can be applied to a poly(styrene) bead, 0.5 μm in diameter, in an optical trap attached to the downstream end of a strand of double-helical DNA that contains a promoter and is bound to DNA-directed RNA polymerase from *E. coli*.[1387] As the force on the bead is increased, rather than being caused to remain constant by moving the chamber, the rate of elongation remains constant until a force equal to around 10 pN is applied, after which it declines to 0 over a range of applied forces from 10 to 20 pN.[1388,1389] This result demonstrates that as the RNA is elongated, mechanical work is being applied by the enzyme to move the bubble and the elongating messenger RNA in the downstream direction.

downstream DNA

Figure 3–73: Stereodrawing[576] of a portion of the molecular model produced by reconstructive summation of electron microscopic images of DNA-directed RNA polymerase II from *K. phaffii* the active site of which has enclosed a heterotriplex of two strands of DNA and one strand of RNA.[1384] The complete heterododecameric complex that forms the core of DNA-directed RNA polymerase II from *K. phaffii*, which had been genetically tagged by altering the DNA of the fungus encoding the protein to facilitate purification, was purified in high yield from cells of *K. phaffii*. All twelve subunits were present in the final complex in equimolar amounts.[1385] Transcription elongation factors Elf1, TFIIS, and Spt5 from *K. phaffii* were expressed in and purified from cells of *E. coli*. Two segments of single-stranded DNA and a single segment of RNA were prepared synthetically. The three segments of nucleic acid were hybridized to form a heterotriplex (Panel **A**) by mixing them in equimolar amounts in 4 mM magnesium acetate, 20 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol, and 150 mM potassium acetate at pH 7.5, heating to 60 °C for 2 min, and gradually cooling the mixture. The purified heterododecameric core of DNA-directed RNA polymerase, the elongation factors Spt5 and Elf1, and the annealed heterotriplex of DNA and RNA were mixed together at pH 7.5 and then passed over a molecular exclusion column to remove any uncomplexed heterotriplex, Spt5, and Elf1. The resulting complex was then mixed with elongation factor TFIIS and subjected to chemical crosslinking to stabilize the then-complete complex and purified a second time by molecular exclusion. A solution of the final purified complex in 0.1 mM tris(2-carboxyethyl)-phosphine, 1 μM zinc acetate, 20 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol, and 150 mM potassium acetate, pH 7.5, was spread on a grid for electron microscopy, the film of solution was vitrified to form a solid of amorphous ice, and the vitrified sample was viewed by electron microscopy. A large collection of images of individual molecules of the complex (682,749) were each assigned orientations, and the images of the particles and their assigned orientation were the data set used to reconstruct a three-dimensional map of scattering density for the complex. This map was of high enough resolution to insert the polypeptides of the various subunits and elongation factors as well as the heterotriplex of DNA and RNA into the map and obtain a molecular model of the complete complex. A portion of that molecular model has been drawn and is presented in Panel **B**. Several of the subunits and elongation factors in the complete molecular model that were not near the heterotriplex of DNA and RNA are omitted from the drawing to increase its clarity, but all the portions of polypeptide adjacent to the DNA and RNA are included. The heterotriplex of DNA and RNA (thick lines) is presented in a line drawing of all its atoms. The dashed line connects two nucleotides in the noncoding strand of DNA in the bubble between which there was no scattering density. This missing sequence of five nucleotides is underlined in Panel **A**. The polypeptide (thin lines) is represented by line segments connecting the α carbons in the sequences of amino acids. An animation of this complex can be downloaded at https://www.science.org/doi/full/10.1126/science.aan8552

The free energy required to create this **mechanical work** must come from the successive nucleophilic substitutions at phosphorus. Unlike in the case of DNA helicase PcrA, however, the creation of the mechanical work that permits the biased translation is not the result of a sequence of conformational changes tightly coupled to the hydrolysis of $MgATP^{2-}$ elsewhere in the protein; rather, it is occurring in the catalytic site each time a phosphate anhydride is replaced by a phosphate ester. Consider the situation just after a phosphodiester has formed in a kinetically irreversible nucleophilic substitution at phosphorus. The heterotriplex can now move in either direction, downstream or upstream. If it moves downstream (the undesired direction), a base pair between the messenger RNA and the template several base pairs upstream from the catalytic site, which had been broken during the process of splitting the messenger RNA from the template, re-forms; a base pair between the two strands of the upstream DNA, which had been re-formed during the process of re-forming the upstream duplex, is broken; and a base pair between the two strands of the downstream DNA, which were broken during the propagation of the bubble, re-forms. The sum of these three changes should be a negative change in standard free energy. If, however, the heterotriplex moves upstream (the desired direction), a base pair between the messenger RNA and the template is broken; a base pair between the two strands of the upstream DNA re-forms; and a base pair between the two strands of the downstream DNA breaks, but the next nucleotide can then be added to the elongating messenger RNA in a nucleophilic substitution at phosphorus that liberates considerable standard free energy. The sum of these four changes should be a even greater negative change in standard free energy than occurs in a movement downstream and should create a ratchet that generates the observed mechanical work.

It should be noted, however, that this ratchet in no way guarantees processivity, which, as has been discussed, results from only prevention of the product of each nucleophilic substitution from dissociating from the active site. From the behavior of the bead when the force has stopped transcription, it was concluded that the excess applied force pulls the DNA out of the entry tunnel on the DNA-directed RNA polymerase by about five to ten base pairs,[1389] but even this rather remarkable distortion has not caused the DNA to dissociate from the enzyme.

Chapter 4
Transfer of Hydrons

Hydron transfers are involved in almost all biochemical reactions, and reactions homologous to those that occur in particular active sites can often be studied in free, aqueous solution. Hydron transfers are also involved in these homologous reactions when they proceed in solution. Water is chosen for the solvent because it is the solvent in which enzymes are usually dissolved and the solvent in which life has evolved. When a reaction that is the same as one that occurs in a particular class of active sites is studied in free solution, homologues of the metabolites normally participating in the enzymatic reaction are chosen because the actual metabolites usually have too many reactive functional groups elsewhere in their structure. In an active site, the chemical reaction catalyzed by the enzyme is confined by the structure of the active site to only those functional groups directly involved in the mechanism. In free solution, however, functional groups that are not involved in the mechanism when the metabolite is in the active site would be involved in the reaction that is being observed as well as in undesired side reactions. The requirements for hydron transfers in such a homologous reaction are established and quantified systematically.

General Acid Catalysis and General Base Catalysis

The chemical mechanism for a reaction in free solution homologous to one catalyzed in an active site usually requires that one or more hydrons be provided for one or more existing or incipient lone pairs of electrons and that one or more hydrons be removed from one or more pairs of electrons. Although mechanistic shorthand permits hydrons to be written as H^+, there is no such thing in aqueous solution as a bare hydron. A hydron in aqueous solution either occupies one pair of electrons or is in the process of being transferred intimately and essentially instantaneously between two pairs of electrons. If a hydron is provided to a reactant, it is provided residing upon a pair of electrons in an acid. Most of the time, the acid, immediately before the transfer occurs, is the donor in a hydrogen bond to a lone pair of electrons that is the base receiving the hydron in that reactant. If a hydron is removed from a reactant, it is removed by being transferred to the lone pair of electrons of a base. Most of the time, the lone pair of electrons on the base, immediately before the transfer occurs, is the acceptor for a hydrogen bond from the acid giving up the hydron in that reactant. The requirements for these acids and bases that participate in one of these reactions are demonstrated by studying systematically changes in rate of the reaction as a function of the pH of the solution and as a function of the concentrations of added acids and bases.

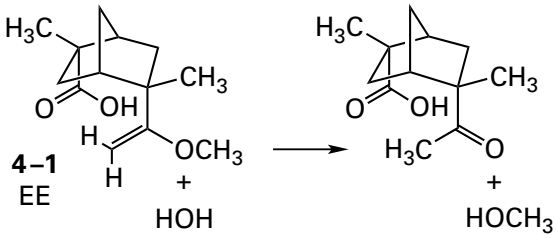
As the pH of a solution is decreased, the concentration of hydronium, an acid, increases. If the observed rate constant for a reaction proceeding in solution increases as the pH of the solution is decreased, in the absence of significant concentrations of other added acids or bases, it is usually assumed that only the increase in the concentration of hydronium is responsible for the increase in rate because the only changes occurring in solution are the increase in the concentration of hydronium and a corresponding decrease in the concentration of hydroxide. **Specific acid catalysis** is the increase in the rate of a reaction due only to an increase in the concentration of hydronium. If the increase in rate is a linear function of the concentration of hydronium, the equation describing the behavior of the observed rate constant as a function of pH will contain the term $k_{H^+}[H^+]$ to account for this catalysis.

The existence of specific acid catalysis is established by measuring the rate constant for the reaction at a series of different values of pH. Although one can use a device known as a pH stat to maintain a fixed pH as the reaction proceeds, the pH of the solution is usually held constant for each individual rate measurement by adding a buffer of sufficient strength to prevent any change in pH due to the reaction itself. If, however, the pH of the solution is maintained with a buffer, one must be aware that the buffer itself, because it is necessarily composed of an acid and its conjugate base, often affects the rate of the reaction (Figure 4–1).[1] To **correct for the effect of the buffer on the observed rate**, the concentration of buffer is varied at constant pH, which

is established only by the ratio of the acid to the conjugate base in the buffer, and the value for the observed rate constant in the absence of buffer is obtained by extrapolation to zero concentration. For example, the observed pseudo-first-order rate constant k_{EE}

$$-\frac{d[\mathrm{EE}]}{dt} = k_{\mathrm{EE}}[\mathrm{EE}] \qquad (4\text{–}1)$$

for hydrolysis of methyl enol ether **4–1** (EE)



(4–2)

was measured at several values of pH and varying concentrations of the buffer potassium phosphate to estimate, by extrapolation, the behavior of the observed rate constant as a function of pH in the absence of any phosphate (Figure 4–1). Because the pseudo-first-order rate constants in the absence of buffer (intersections of the lines with the ordinate) increase as the pH decreases, specific acid catalysis is occurring.

As the pH of a solution is increased, the concentration of hydroxide, a base, increases. If the observed rate constant for a reaction proceeding in solution increases as the pH of the solution is increased, in the absence of significant concentrations of other added acids or bases, it is usually assumed that only the increase in the concentration of hydroxide is responsible for the increase in rate because the only changes occurring in the solution are the increase in the concentration of hydroxide and the corresponding decrease in the concentration of hydronium. **Specific base catalysis** is the increase in the rate of a reaction due only to an increase in the concentration of hydroxide ions. If the increase in rate is a linear function of the concentration of hydroxide, the equation describing the behavior of the observed rate constant as a function of pH will contain the term $k_{OH^-}[OH^-]$ to account for this catalysis. Although this term in an equation for an observed rate constant is mathematically symmetrical to the term $k_{H^+}[H^+]$, hydronium and hydroxide are chemically distinct. While a hydronium can only donate a hydron to a lone pair of electrons or an incipient lone pair of electrons, a hydroxide can either remove a hydron from a pair of electrons or participate in the reaction directly as a nucleophile.

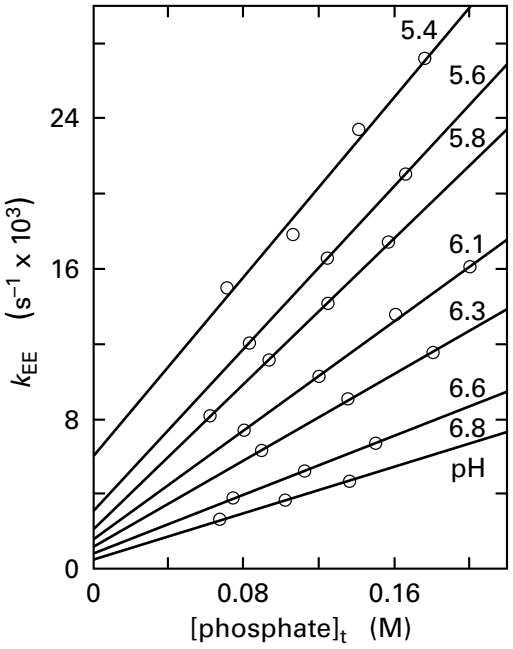


Figure 4-1: Catalysis of the hydrolysis of methyl enol ether 4-1 by phosphate anion at various values of pH.1 Solutions (0.4 mM) of the methyl enol ether 4-1 (EE) were prepared in 5% ethanol and 1 M KCl, with the noted concentrations of total phosphate as the potassium salts at the noted pH and 25 °C. Hydrolysis of the methyl enol ether (Equation 4-1) was followed spectrophotometrically by the decrease in absorbance at 230 nm from the vinyl ether and the increase in absorbance at 280 nm from the ketone. In all instances, the hydrolysis was first-order with respect to the total concentration of methyl enol ether. The pseudo-first-order rate constant was obtained from each kinetic run by nonlinear least-squares analysis of the curves. These pseudo-first-order rate constants, k_{EE} (second$^{-1} \times 10^3$), are plotted as a function of the total concentration of phosphate (molar) at a series of values for pH (noted to the right and above each respective line).

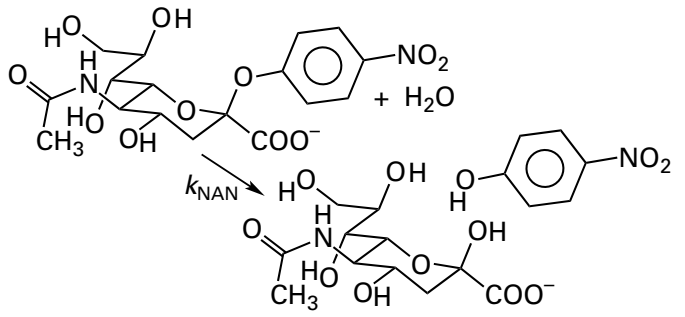
A **pH–rate profile** is a plot of the observed rate constants for a reaction, each of which has been estimated by extrapolation to zero concentration of buffer, as a function of pH at constant temperature and ionic strength in the absence of significant concentrations of other added acids and bases besides the species of the buffer. A pH–rate profile is usually presented as the common logarithms of the observed rate constant for the reaction as a function of pH, which is the negative common logarithm of the concentration of hydronium. The pH–rate profile for hydrolysis of 4-nitrophenyl β-D-*N*-acetyl-neuraminide



(4–3)

shows specific acid catalysis at low pH, specific base catalysis at high pH, and a region between these extremes in which the rate of the reaction is catalyzed by neither hydronium nor hydroxide (Figure 4–2).[2] The rate equation that describes this observed behavior is

$$-\frac{d[\mathrm{NAN}]}{dt} = k_{\mathrm{NAN}}[\mathrm{NAN}] \tag{4–4}$$

where [NAN] is the concentration of 4-nitrophenyl β-D-*N*-acetylneuraminide, and the equation for the observed rate constant is

$$k_{\mathrm{NAN}} = k_{\mathrm{H^+}}[\mathrm{H^+}] + k_{\mathrm{non}} + k_{\mathrm{OH^-}}[\mathrm{OH^-}] \tag{4–5}$$

where k_{non} is the rate constant for the rate of the uncatalyzed reaction, the reaction catalyzed by neither hydronium nor hydroxide. At low pH, $k_{\mathrm{NAN}} = k_{\mathrm{H^+}}[\mathrm{H^+}]$ and the common logarithm of the observed rate constant as a function of pH has a slope of –1. At high pH, $k_{\mathrm{NAN}} = k_{\mathrm{OH^-}}[\mathrm{OH^-}] = k_{\mathrm{OH^-}}K_{\mathrm{w}}[\mathrm{H^+}]^{-1}$, and the common logarithm of the observed rate constant as a function of pH has a slope of +1. At intermediate pH, $k_{\mathrm{NAN}} = k_{\mathrm{non}}$, and the common logarithm of the observed rate constant as a function of pH has a slope of 0. The meaning of the uncatalyzed rate is usually unknown. One possibility, which is usually in the back of the investigator's mind, is that the rate is the result of catalysis by molecules of water, the concentration of which remains constant throughout the measurements, but this does not need to be the case.

Often, a pH–rate profile is **complicated by an acid dissociation of one of the reactants**. For example, unlike the rates of hydrolysis for acetals formed from aldehydes that have no acid–bases within themselves, which are directly proportional to the concentration of hydronium and a function of only the concentration of hydronium at all values of pH,[3]

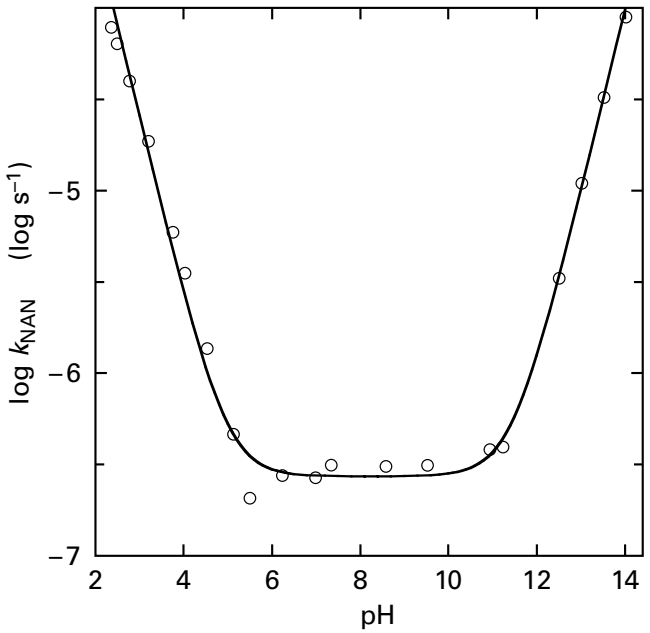


Figure 4–2: pH–Rate profile for the hydrolysis of 4-nitrophenyl β-D-*N*-acetylneuraminide (Equation 4–3) at an ionic strength of 0.3 M and 50 °C.[2] Hydrolysis of 4-nitrophenyl β-D-*N*-acetylneuraminide (NAN) was monitored by following the appearance of 4-nitrophenol at a wavelength of 340 or 408 nm, depending on the pH of the solution. The buffers used, in the noted ranges of pH, were malonic acid, 2.10–3.19; succinic acid, 3.76–4.02; acetic acid, 4.46–5.36; 2-(*N*-morpholino)ethanesulfonate, 5.50–6.30; 3-{[1,3-dihydroxy-2-(hydroxymethyl)propan-2-yl]amino}propane-1-sulfonate, 7.00–8.20; and 3-(cyclohexylamino)propane-1-sulfonate, 10.00–11.13. The pseudo-first-order increases in absorbance were fit by a nonlinear least-squares program to obtain values for the pseudo-first-order rate constants. The common logarithms of these rate constants, k_{NAN} (second^{-1}), are plotted as a function of pH. The solid curve is the common logarithm of Equation 4–5 with $k_{\mathrm{H^+}} = 0.025\ \mathrm{M^{-1}\,s^{-1}}$, $k_{\mathrm{non}} = 2.7\times10^{-7}\ \mathrm{s^{-1}}$, and $k_{\mathrm{OH^-}} = 9.7\times10^{-5}\ \mathrm{M^{-1}\,s^{-1}}$.

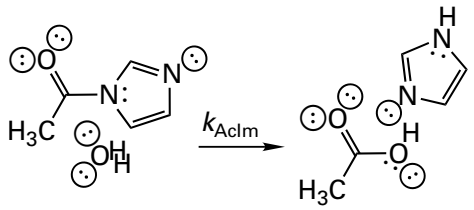
hydrolysis of the acetal of *cis*-cyclohexane-1,2-dioland 4-(dimethylamino)benzaldehyde is independent of the concentration of hydronium as long as the 4-dimethylamino group on the 4-(dimethylamino)benzaldehyde participating in the acetal is hydronated and positively charged. As the pH is increased, however, and the 4-dimethylamino group becomes dehydronated, hydrolysis of the neutral acetal becomes directly proportional to the concentration of hydronium and a function of only the concentration of hydronium[4] at all values of pH greater than its pK_{a}. As long as the 4-dimethylamino group is hydronated, its positive elementary charge, relayed to the aldehyde carbon through the π molecular orbital system of the 4-(dimethylamino)-phenyl group, prevents hydronation of one oxygen on that carbon in the acetal, a hydronation that is indispensable to the hydrolysis.

The pH–rate profile of observed pseudo-first-order rate constants for hydrolysis of *N*-acetylimidazole (AcIm)



(4–6)

estimated by extrapolations to zero buffer concentration, has regions in which the observed rate constant increases with decreases in pH, regions in which it increases with increases in pH, and regions in which it is invariant with pH (Figure 4–3).[5] The reactant itself is not catalyzing the reaction, because at all values of pH the rate of the reaction is first-order in concentration

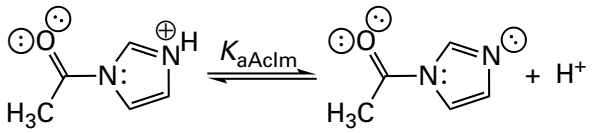
$$-\frac{d[\mathrm{AcIm}]_t}{dt} = k_{\mathrm{AcIm}}[\mathrm{AcIm}]_t \tag{4–7}$$

where $[\mathrm{AcIm}]_t$ is the total concentration of *N*-acetylimidazole in all its forms at any time during the reaction.

The behavior of observed pseudo-first-order rate constants, k_{AcIm}, for hydrolysis of *N*-acetylimidazole as a function of pH can be fully explained by the equation[5]

$$k_{\mathrm{AcIm}} = \left(k_{\mathrm{H^+}}[\mathrm{H^+}] + k_{\mathrm{non}} + k_{\mathrm{OH^-}}[\mathrm{OH^-}]\right)\left(\frac{K_{\mathrm{aAcIm}}}{K_{\mathrm{aAcIm}} + [\mathrm{H^+}]}\right) \tag{4–8}$$

where K_{aAcIm} is the acid dissociation constant of *N*-acetylimidazole ($pK_{\mathrm{aAcIm}} = 3.6$)



(4–9)

Because

$$[\mathrm{AcIm}] = \left(\frac{K_{\mathrm{aAcIm}}}{K_{\mathrm{aAcIm}} + [\mathrm{H^+}]}\right)[\mathrm{AcIm}]_t \tag{4–10}$$

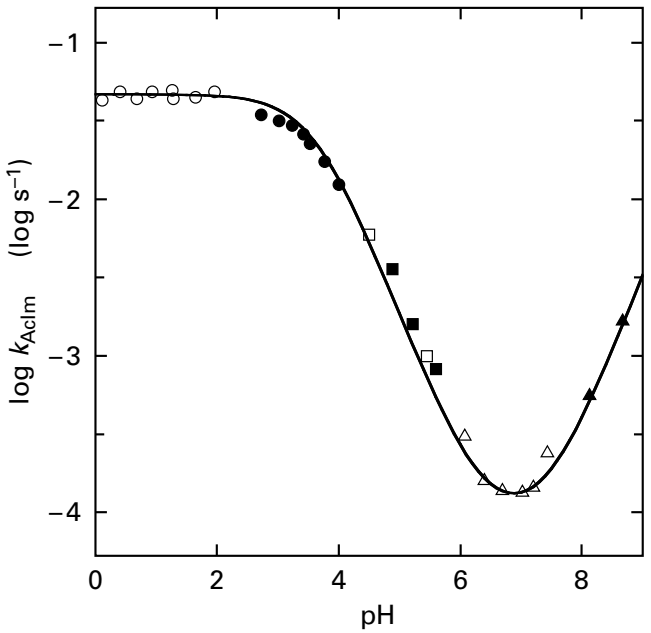


Figure 4–3: pH–Rate profile for the hydrolysis of *N*-acetylimidazole[5] at an ionic strength of 0.2 M and 25 °C. *N*-Acetylimidazole was added to a series of solutions adjusted to the noted values of pH with HCl (○) or buffered at the noted values of pH with sodium formate (●), sodium acetate (□), sodium succinate (■), imidazolium chloride (△), or 2-ammonio-2-(hydroxymethyl)propane-1,3-diol chloride (▲). The ionic strength was maintained by adding the appropriate concentration of sodium chloride. The progress of each reaction was followed by the decrease in absorbance at 245 nm resulting from the loss of *N*-acetylimidazole. All reactions were first-order in *N*-acetylimidazole, and pseudo-first-order rate constants were obtained by plotting the common logarithm of the extent of the reaction as a function of time. The values for the pseudo-first-order rate constants at each pH were extrapolated to zero buffer concentration. The common logarithms of the estimated pseudo-first-order rate constants in the absence of buffer, k_{AcIm} (second^{-1}), are plotted as a function of the pH. The solid curve is the common logarithm of Equation 4–8 with $k_{\mathrm{H^+}} = 186\ \mathrm{M^{-1}\ s^{-1}}$, $k_{\mathrm{non}} = 0.000083\ \mathrm{s^{-1}}$, $k_{\mathrm{OH^-}} = 317\ \mathrm{M^{-1}\ s^{-1}}$, and $K_{\mathrm{aAcIm}} = 10^{-3.6}$ M.

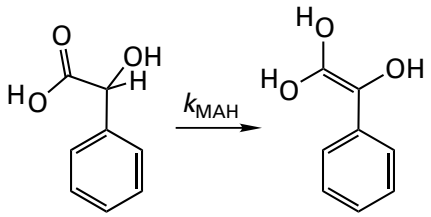
$$-\frac{d[\mathrm{AcIm}]_t}{dt} = \left(k_{\mathrm{H^+}}[\mathrm{H^+}] + k_{\mathrm{non}} + k_{\mathrm{OH^-}}[\mathrm{OH^-}]\right)[\mathrm{AcIm}] \tag{4–11}$$

where [AcIm] is the concentration of the conjugate base of *N*-acetylimidazole (Equation 4–9).

In the case of enolization of mandelic acid (MAH)



(4–12)

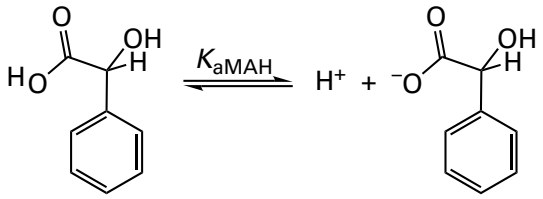
the rate of the reaction is also first-order in the concentration of reactant

$$-\frac{d[\mathrm{MAH}]_t}{dt} = k_{\mathrm{MAH}}[\mathrm{MAH}]_t \tag{4–13}$$

The equation that describes the behavior of the rate constant for enolization as a function of pH is[6]

$$k_{\mathrm{MAH}} = \left(k_{\mathrm{H^+}}[\mathrm{H^+}] + k_{\mathrm{OH^-}}[\mathrm{OH^-}] + k_{\mathrm{2OH^-}}[\mathrm{OH^-}]^2\right)\left(\frac{[\mathrm{H^+}]}{[\mathrm{H^+}] + K_{\mathrm{aMAH}}}\right) \tag{4–14}$$

where K_{aMAH} is the acid dissociation constant for the carboxy group of mandelic acid



(4–15)

Because the concentration of the neutral conjugate acid of mandelic acid

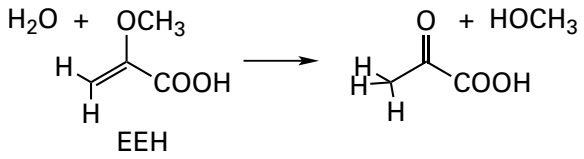
$$[\mathrm{MAH}] = \left(\frac{[\mathrm{H^+}]}{K_{\mathrm{aMAH}} + [\mathrm{H^+}]}\right)[\mathrm{MAH}]_t \tag{4–16}$$

where $[\mathrm{MAH}]_t$ is the total concentration of unenolized mandelic acid, which is the sum of the concentrations of neutral conjugate acid, [MAH], and carboxylate anion, $[\mathrm{MA^-}]$

$$-\frac{d[\mathrm{MAH}]_t}{dt} = \left(k_{\mathrm{H^+}}[\mathrm{H^+}] + k_{\mathrm{OH^-}}[\mathrm{OH^-}] + k_{\mathrm{2OH^-}}[\mathrm{OH^-}]^2\right)[\mathrm{MAH}] \tag{4–17}$$

In this instance, only the concentration of the conjugate acid of the reactant appears in the rate equation, rather than only the concentration of the conjugate base of the reactant, as in the case of *N*-acetylimidazole (Equation 4–11).

The equation that describes the behavior of the rate for hydrolysis of the enol ether 2-methoxyacrylic acid



(4–18)

as a function of pH is

$$-\frac{d[\mathrm{EE}]_t}{dt} = k_{\mathrm{EE}}[\mathrm{EE}]_t = \left(k_{\mathrm{H^+}}[\mathrm{H^+}] + k_{\mathrm{non}}\right)\left(\frac{[\mathrm{H^+}]}{[\mathrm{H^+}] + K_{\mathrm{aEEH}}}\right)[\mathrm{EE}]_t = \left(k_{\mathrm{H^+}}[\mathrm{H^+}] + k_{\mathrm{non}}\right)[\mathrm{EEH}] \tag{4–19}$$

where $[\mathrm{EE}]_t$ is the total concentration of 2-methoxyacrylic acid, both its conjugate acid and its conjugate base, and K_{aEEH} is the acid dissociation constant for 2-methoxyacrylic acid ($pK_a = 3.39$).[7] Again, only the concentration of the conjugate acid appears in the rate equation.

It is often observed that addition of an acid–base to the solution, such as dihydrogen phosphate monoanion and its conjugate base, hydrogen phosphate dianion (Figure 4–1), increases the rate constant of a reaction. **General acid–base catalysis** is the increase in the rate of a reaction due only to an increase in the concentration of an added acid–base to the solution.

Because it is impossible to add an acid to water without simultaneously producing its conjugate base or to add a base without simultaneously producing its conjugate acid, it must be established which of the two forms is responsible for the acceleration observed. This decision is reached by using **the conjugate acid and conjugate base in constant ratio as the buffer**. As the total concentration of the acid–base is increased at constant ratio of conjugate acid to conjugate base and consequently at constant pH, the pseudo-first-order rate constant for the reaction increases (Figures 4–1 and 4–4)[1,8,9] if general acid–base catalysis is occurring.

If the rate constant for the reaction increases linearly with the concentration of buffer at constant pH, the behavior can be described by the equation for the observed rate constant at a particular pH and concentration of buffer

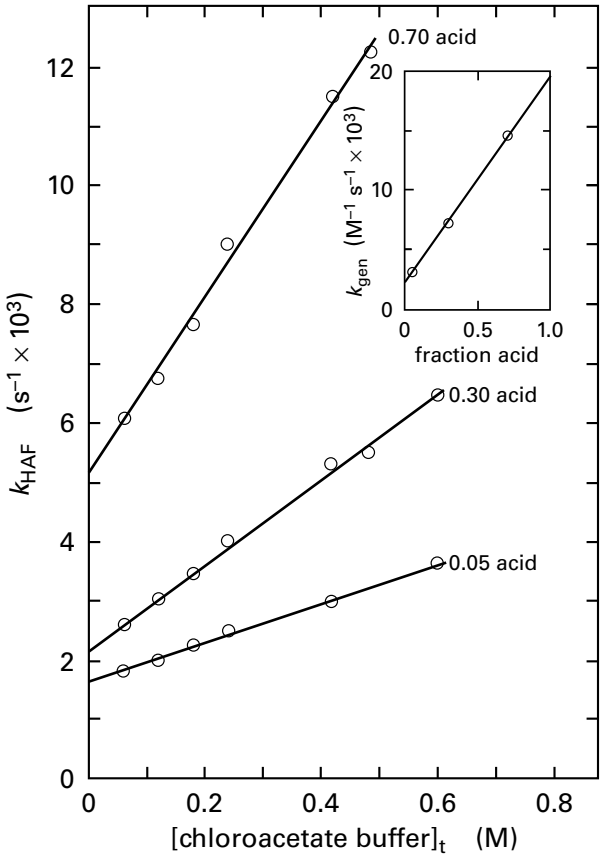


Figure 4–4: Determination of the rate constants for general acid and general base catalysis of the hydrolysis of formaldehyde ethyl hemiacetal (Equation 4–23) by chloroacetate buffers at an ionic strength of 1.0 M and 25 °C.[8] The ethyl hemiacetal of formaldehyde (HAF) was formed by mixing formaldehyde with anhydrous ethyl alcohol and allowing the mixture to stand for 3 h before use. Formaldehyde ethyl hemiacetal was added to a final concentration of 0.1 mM to solutions of 1.00 M KCl containing the noted total concentration of chloroacetic acid and potassium chloroacetate mixed in the ratios 70:30, 30:70, and 5:95 to give the fractions of acid in the buffer noted to the right of each line. Hydrolysis of the ethyl hemiacetal of formaldehyde was followed by trapping the formaldehyde produced with thiosemicarbazide (0.01 M). The increase in absorbance at 275 nm due to formation of the thiosemicarbazone was followed with time. For each individual run, pseudo-first-order rate constants were obtained from the slopes of plots of ln ($A_{275} - A_{\infty 275}$) against time. The pseudo-first-order rate constants, k_{HAF} (second$^{-1} \times 10^3$), are plotted as a function of the total molar concentration of chloroacetate anion plus chloroacetic acid (molar). The slopes of these lines, k_{gen} (molar^{-1} second$^{-1} \times 10^3$; Equation 4–20), are plotted (Equation 4–21) in the inset as a function of the fraction of total chloroacetate that was chloroacetic acid (fraction acid).

$$k_{obs} = k_{pH} + k_{gen}[\text{buffer}]_t \qquad (4\text{–}20)$$

where k_{pH} is a macroscopic rate constant containing the terms for specific acid catalysis, no catalysis, and specific base catalysis (Equation 4–5) and k_{gen} is the **macroscopic rate constant for general acid–base catalysis** reflecting the effects of the added acid and its conjugate base. Its kinetic order is one greater than that of the observed rate constant. This linear behavior states that the term $k_{gen}[\text{buffer}]_t$ producing an increase in the rate constant results from a reaction the transition state of which is composed of the reactant and the conjugate acid of the buffer or from a reaction the transition state of which is composed of the reactant and the conjugate base of the buffer or from both of these reactions proceeding simultaneously. In other words, the acid or the base or both of them, when they participate directly in the reaction, cause it to proceed more rapidly.

If the ratio between the acid and the base in the buffer is changed, and inescapably the pH as well, and the experiment is repeated, the **slope of the line** will usually change (Figures 4–1 and 4–4). If the slope of the line, and hence the rate constant k_{gen}, increases as the ratio between acid and base is increased, the conjugate acid of the buffer is a more important participant in catalysis (Figures 4–1 and 4–4) than its conjugate base. If the slope of the line decreases, the conjugate base of the buffer is a more important participant than its conjugate acid.

The term $k_{gen}[\text{buffer}]_t$ is itself often a sum of two separate terms

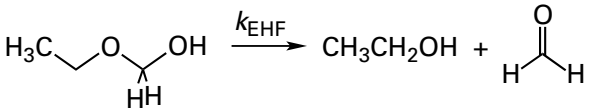
$$k_{gen}[\text{buffer}]_t = k_{ga}[HN^{(+)}] + k_{gb}[\odot N^{(-)}] \qquad (4\text{–}21)$$

where $HN^{(+)}$ is the conjugate acid and $\odot N^{(-)}$ is the conjugate base of the buffer. Numerical values for the two rate constants in this equation are obtained by extrapolation. If k_{gen} is plotted as a function of the fraction of the total buffer that is the conjugate acid, the extrapolated value of the rate constant for the point at which all the buffer is the conjugate acid, $[\text{buffer}]_t = [HN^{(+)}]$ and $[\odot N^{(-)}] = 0$, is the rate constant k_{ga} and the extrapolated value of the rate constant for the point at which all the buffer is the conjugate base, $[\text{buffer}]_t = [\odot N^{(-)}]$ and $[HN^{(+)}] = 0$, is the rate constant k_{gb} (inset to Figure 4–4). If reactants, other than the general acid–base of the buffer, contain no acid–bases themselves with values of pK_a within the range of pH studied (see Equations 4–8 and 4–14), then Equations 4–5, 4–20, and 4–21

can be combined to obtain a **general expression for acid–base catalysis**

$$k_{obs} = k_{H^+}[H^+] + k_{non} + k_{OH^-}[OH^-] + k_{ga}[HN^{(+)}] + k_{gb}[\odot N^{(-)}] \quad (4\text{–}22)$$

In each particular reaction, the two terms in Equation 4–22 governing the particular general acid–base catalyst have **relative degrees of importance reflected in numerical values for the respective rate constants**. Decomposition of the ethyl hemiacetal of formaldehyde (EHF)



(4–23)

in a solution buffered with potassium chloroacetate at 25 °C (Figure 4–4)[8] has an observed pseudo-first-order rate constant k_{EHF}, the equation for which

$$k_{EHF} = k_{pH} + k_{ga}[ClCH_2COOH] + k_{gb}[ClCH_2COO^-] \quad (4\text{–}24)$$

contains two terms of similar magnitude, one directly proportional to the concentration of chloroacetic acid, $[ClCH_2COOH]$ ($k_{ga} = 20 \times 10^{-3}\ M^{-1}\ s^{-1}$), and the other directly proportional to the concentration of chloroacetate anion, $[ClCH_2COO^-]$ ($k_{gb} = 2 \times 10^{-3}\ M^{-1}\ s^{-1}$). Similar results were observed for catalysis of the dehydration of acetaldehyde hydrate by potassium acetate buffers at 25 °C ($k_{ga} = 290 \times 10^{-3}\ M^{-1}\ s^{-1}$, $k_{gb} = 50 \times 10^{-3}\ M^{-1}\ s^{-1}$).[9] Hydrolysis of methyl enol ether **4–1** (Equation 4–2), however, has a pseudo-first-order rate constant the equation for which, within experimental error, contains no term that is directly proportional to the concentration of the conjugate base of the phosphate buffer, $[HOPO_3^{2-}]$, even though it contains a term that is directly proportional to the concentration of the conjugate acid of the phosphate buffer, $[HOPO_3H^-]$ (Figure 4–1). Hydrolysis of *N*-acetylimidazole (Equation 4–6), in a solution buffered with imidazole, has a pseudo-first-order rate constant the equation for which, within experimental error, has no term directly proportional to the concentration of the cationic conjugate acid of imidazole, $[H_2Im^+]$, even though it contains a significant term directly proportional to the concentration of the neutral free base of imidazole, [HIm].[10]

The term $k_{gen}[buffer]_t$ can also be the sum of three terms[11]

$$k_{gen}[buffer]_t = k_{ga}[HN^{(+)}] + k_{gb}[\odot N^{(-)}] + k_{gab}[HN^{(+)}][\odot N^{(-)}] \quad (4\text{–}25)$$

instead of two (Equation 4–21), so that the general expression becomes

$$k_{obs} = k_{H^+}[H^+] + k_{non} + k_{OH^-}[OH^-] + k_{ga}[HN^{(+)}] + k_{gb}[\odot N^{(-)}] + k_{gab}[HN^{(+)}][\odot N^{(-)}] \quad (4\text{–}26)$$

In this case, the observed rate constant is a nonlinear function of the total concentration of buffer. Because the term $k_{gab}[HN^{(+)}][\odot N^{(-)}]$ is directly proportional to the square of the total concentration of buffer, Equation 4–26 is **quadratic in the total concentration of buffer** and the curves are parabolic. The three individual general acid–base rate constants are obtained by fitting the data for several different buffer ratios with Equation 4–26 by nonlinear least squares analysis.

Each term in the equation for the observed rate constant (Equation 4–22 or 4–26), because it appears as the participant in a sum, refers to an **independent route between reactants and products through a different transition state**. If it has been observed that a term in the observed rate constant proportional to the concentration of the conjugate acid of the buffer, or the conjugate acid of any other added acid–base, $k_{ga}[HN^{(+)}]$, is significant, then the path represented by this term is referred to as **general acid catalysis.** If it has been observed that the term in the observed rate constant proportional to the concentration of the conjugate base of the buffer, or the conjugate base any other added acid–base, $k_{gb}[\odot N^{(-)}]$, is significant, then the path represented by this term is referred to as **general base catalysis.**

So far, only unimolecular reactions have been discussed. If the reaction is a **bimolecular reaction**

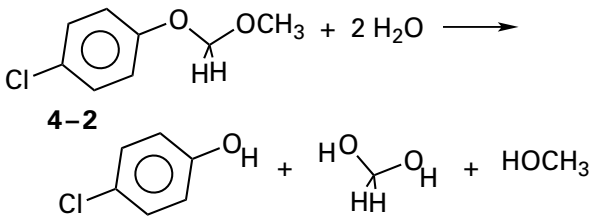
$$A + B \longrightarrow Y + Z \quad (4\text{–}27)$$

for which the rate is directly proportional to concentrations of reactant A and reactant B and if the reaction is susceptible to specific acid, specific base, general acid, and general base catalysis, then the equation for the rate of the reaction is defined by the relation

$$-\frac{d[\mathrm{A}]}{dt} = -\frac{d[\mathrm{B}]}{dt} = k_{\mathrm{H^+}}[\mathrm{H^+}][\mathrm{A}][\mathrm{B}] + k_{\mathrm{non}}[\mathrm{A}][\mathrm{B}] + k_{\mathrm{OH^-}}[\mathrm{OH^-}][\mathrm{A}][\mathrm{B}] + k_{\mathrm{ga}}[\mathrm{HN^{(+)}}][\mathrm{A}][\mathrm{B}] + k_{\mathrm{gb}}[\odot\mathrm{N^{(-)}}][\mathrm{A}][\mathrm{B}] \quad (4\text{–}28)$$

This equation contains a termolecular term involving the concentration of the general acid and a termolecular term involving the concentration of the general base. **A termolecular collision is almost never involved in the mechanism of a chemical reaction.** Consequently, in a bimolecular reaction, in which two molecules must collide to form product, it is probably never the case that those two molecules and a general acid or a general base that is catalyzing the reaction collide simultaneously. A bimolecular reaction is catalyzed by a general acid or a general base because the conjugate base of one of the two reactants participating in the reaction is already pre-associated with the acceptor for a hydrogen bond from that general acid or the conjugate acid of one of the two reactants participating in the reaction is already pre-associated with the donor of a hydrogen bond to that general base, respectively, before two molecules of reactant collide. The rate of the reaction is directly proportional to the molar concentration of a general acid or general base that is catalyzing it because the concentration of the hydrogen bond in the **pre-association** between the one molecule and the general acid or base is directly proportional to the molar concentration of the acid or base. It is these complexes that participate in a productive collision and the resulting transition state that is responsible for that rate constant.

There are many reactions that seem to display neither general acid catalysis nor general base catalysis even though their rates are functions of the pH of the solution. For example, the pseudo-first-order rate constant, k_{FA}, for hydrolysis of formaldehyde acetal **4–2** (FA)



(4–29)

was unaffected by the concentration of buffer (sodium formate), but the pseudo-first-order rate constant was directly proportional to the concentration of hydronium.[12] The relation at 56 °C at an ionic strength of 1.0 M in H_2O is

$$k_{\mathrm{FA}} = 0.018\ \mathrm{M^{-1}\ s^{-1}}[\mathrm{H^+}] \quad (4\text{–}30)$$

In this case, as in the hydrolysis of most acetals and ketals, the rate constant for the reaction is a function only of the concentration of hydronium, it remains proportional to the concentration of hydronium even at relatively high values of pH, and it is unaffected by addition of any other acids or bases to the solution.[3]

As such, hydrolysis of an acetal serves as an example of a reaction that displays specific acid catalysis. **Specific acid catalysis** is the increase in the rate of a reaction produced by decreasing the pH when no general acid catalysis can be observed. **Specific base catalysis** is the increase in the rate of a reaction produced by increasing the pH when no general base catalysis can be observed. The fact that these terms have negative definitions makes them always equivocal. It is always possible that general acid–base catalysis, although it exists, has simply not yet been observed.

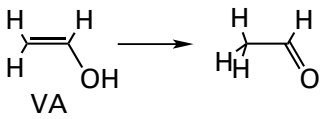
The observed behavior of the rate of a particular reaction as a function of pH and the concentration of general acids and bases is the basis for descriptions of the participation of hydron transfers in the mechanism of that reaction. Although the point was not made at the outset, it should be emphasized now that, as with any set of kinetic measurements, **observations must be clearly distinguished from interpretation of those observations**. All the dissection discussed so far is concerned with fitting the data to phenomenological equations that simply organize what has been measured without any attempt to explain what is observed. Rate equations that have been presented are formal descriptions of the observed behavior of the rate of a reaction as a function of pH and concentrations of general acids

and general bases, and they have intentionally avoided any implication of mechanisms that can explain these observations. Even though no mechanisms were proposed, nevertheless one's intuition intrudes. For example, one might think that general acid catalysis must involve the conjugate acid of the buffer pair and general base catalysis the conjugate base. Such intuitions can often be misleading and should be suppressed.

Kinetics are able to rule out mechanisms that are inconsistent with the observations, but kinetics can never prove a mechanism. As was the case with steady-state kinetics, all that can be concluded is that a mechanism proposed by the investigator is consistent with the observations. What follows describes how **mechanistic proposals are shown to be consistent with the observations**.

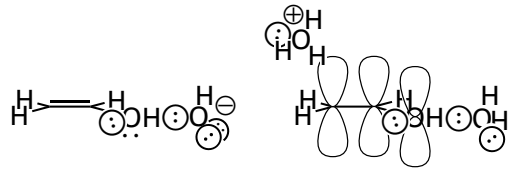
In the case of **pH–rate behavior in the absence of general acids and general bases**, mechanistic inferences are made by **rearranging each term that appears in the rate equation describing the observed behavior.** In the rearrangements, each term in the observed rate equation is converted into a form in which appear explicitly the concentrations of each species proposed by the investigator to be participating in an encounter complex. The investigator, on the basis of her intuition as to what is responsible for the catalysis observed or other observations that do not rely on kinetics, formulates a molecular description of the mechanism of the reaction that involves a certain collection and orientation of particular participants in the transition state for the rate-limiting step in the reaction. An **encounter complex** is a complex of all the necessary molecular participants in the transition state for the production of an intermediate or product, which have been assembled together at an encounter-controlled rate. Most of the time, the participants dissociate before a transition state forms, except in the case of an encounter-controlled reaction. The fact that a rearrangement of one term in the observed rate equation can be made so that it involves all these participants and only those participants in the encounter complex demonstrates that the proposed transition state for the reaction governed by that term is consistent with the observations.

For example, in the case of ketonization of vinyl alcohol (VA)



(4–31)

for which the pH–rate profile is defined by Equation 4–5,[13] the term $k_{OH^-}[OH^-][VA]$ in the observed rate equation is consistent with the existence of hydrogen-bonded encounter complex **4–3**

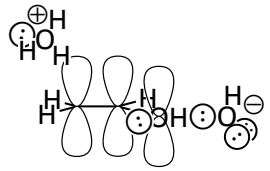


4–3 **4–4**

on the trajectory to a transition state in which a hydron is being removed from the hydroxy group of the vinyl alcohol ($pK_a = 10.5$; Figure 1–23) by a hydroxide to form the enolate. The term $k_{H^+}[H^+]$ in Equation 4–5 is equal to the term $k'_{H^+}[H^+][H_2O]$ because **the concentration of water was constant** during the measurements. This latter term is consistent with the encounter complex **4–4** on the trajectory to a transition state in which a hydron is being added to the π molecular orbital system of the vinyl alcohol while a molecule of water forming a hydrogen bond to the hydroxy group is accepting its hydron. The term $k_{non}[VA]$ can be rearranged to

$$k_{non}[VA] = \left(\frac{k_{non}}{K_w}\right)[H^+][OH^-][VA] \tag{4–32}$$

where K_w is the water constant. This rearrangement of this term in the rate equation is consistent with an encounter complex on the trajectory to a transition state in which a hydron from a hydronium is being added while a hydron is being removed from the vinyl alcohol



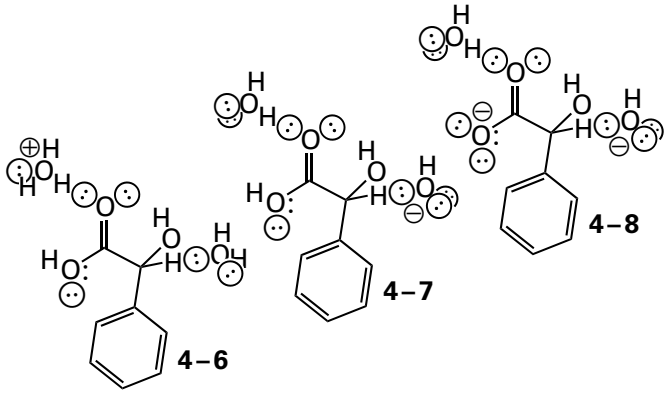
4–5

by a hydroxide. Each rearrangement of the terms demonstrates only that the respective proposed encounter complex is consistent with the observed behavior.

For the mechanism of enolization of mandelic acid (Equation 4–12), the rate equation (Equation 4–17) can be rearranged to

$$-\frac{d[\mathrm{MAH}]_t}{dt} = k'_{H^+}[H^+][H_2O][MAH] + k'_{OH^-}[H_2O][OH^-][MAH] + \left(\frac{k'_{2OH^-}K_w}{K_{aMAH}}\right)[H_2O][OH^-][MA^-] \quad (4\text{–}33)$$

where $k'_{H^+} = k_{H^+}[H_2O]^{-1}$, $k'_{OH^-} = k_{OH^-}[H_2O]^{-1}$, and $k'_{2OH^-} = k_{2OH^-}[H_2O]^{-1}$, which are constants as long as the concentration of water is unchanged. These rearrangements are consistent with the existence of three encounter complexes

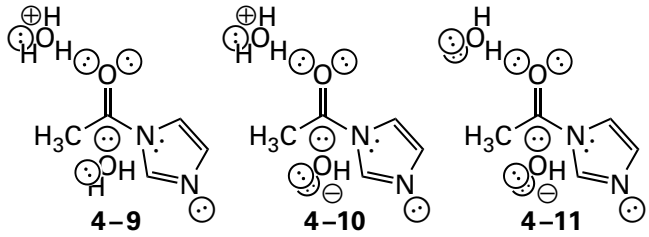


in three respective mechanisms, each on a trajectory to a unique transition state for the enolization. Each trajectory would dominate in a different region of pH.

Another aspect of the importance of distinguishing clearly between observation and explanation is the fact that **there are almost always several explanations** for the observation of specific acid catalysis, specific base catalysis, general acid catalysis, or general base catalysis. For example, the terms in the rate equation for the kinetic mechanism for hydrolysis of *N*-acetylimidazole (Equation 4–11) can be rearranged as the analogous terms were in Equation 4–33, and the rearranged rate equation

$$-\frac{d[\mathrm{AcIm}]_t}{dt} = k'_{H^+}[H^+][H_2O][AcIm] + \left(\frac{k_{non}}{K_w}\right)[H^+][OH^-][AcIm] + k'_{OH^-}[H_2O][OH^-][AcIm] \quad (4\text{–}34)$$

is consistent with the existence of three encounter complexes

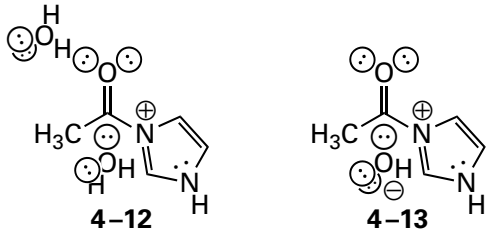


on the trajectories to three respective transition states. The first two encounter complexes themselves, however, can also be rearranged so that, in each case, the hydronium is hydronating nitrogen 3 of the imidazolyl group rather than the acyl oxygen. These two additional encounter complexes are also consistent with the observations.

The rate equation (Equation 4–11), however, can also be rearranged to

$$-\frac{d[\mathrm{AcIm}]_t}{dt} = k''_{H^+}K_{aAcIm}[H_2O]^2[AcImH^+] + \left(\frac{k_{non}K_{aAcIm}}{K_w}\right)[OH^-][AcImH^+] + k'_{OH^-}[H_2O][OH^-][AcIm] \quad (4\text{–}35)$$

where $k''_{H^+} = k_{H^+}[H_2O]^{-2}$. The first two terms in this latter rearrangement are consistent with the existence of the encounter complexes



on the respective trajectories to different transition states. The fact that all these encounter complexes are consistent with the observations illustrates that a mechanism cannot be proven by a rate equation alone. In addition, as all the foregoing examples illustrate, any number of molecules of water can be added to the encounter complexes.

The terms in rate **equations for general acid–base catalysis can also be rearranged** to show that a proposed encounter complex is consistent with the observations. For example, the hydrolysis of ethyl

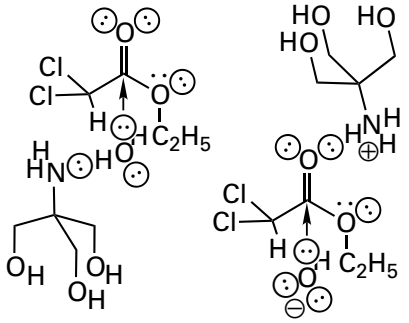
dichloroacetate, $C_2H_5OCOCHCl_2$, in a solution buffered by 2-amino-2-(hydroxymethyl)propane-1,3-diol (Tris) has a pseudo-first-order rate constant that, within experimental error, has no term proportional to the concentration of the conjugate acid of 2-amino-2-(hydroxymethyl)propane-1,3-diol ($TrisH^+$) even though it has a term proportional to the concentration of free base[14] In the rate equation for the reaction, however, this term containing the concentration of free base can be rearranged in two equivalent ways

$$k_{gb}[\text{Tris}][C_2H_5OCOCHCl_2] =$$

$$k'_{gb}[H_2O][\text{Tris}][C_2H_5OCOCHCl_2] =$$

$$\left(\frac{k'_{gb}K_{a\text{TrisH}^+}}{K_{aH_2O}}\right)[OH^-][\text{TrisH}^+][C_2H_5OCOCHCl_2] \qquad (4\text{–}36)$$

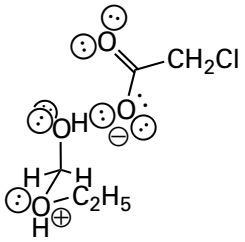
where k'_{gb} is $k_{gb}[H_2O]^{-1}$, $K_{a\text{TrisH}^+}$ is the acid dissociation constant of the conjugate acid $TrisH^+$ ($K_{a\text{TrisH}^+} = 8.1$), and K_{aH_2O} is the acid dissociation constant of water ($pK_{aH_2O} = 15.74$). The first rearrangement in Equation 4–36 implies that the free base of the catalyst, a molecule of the ester, and a molecule of water form the encounter complex on the trajectory to the transition state. The second rearrangement in Equation 4–36 implies that a molecule of the cationic conjugate acid of the catalyst, a molecule of the ester, and a hydroxide form an encounter complex on the trajectory to the transition state. At least three different arrangements of constituents



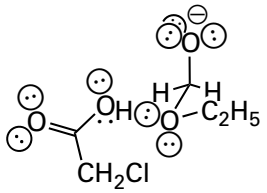
4–14 **4–15** **4–16**

within the encounter complex are consistent with the two rearrangements in Equation 4–36.[14] In each case, the encounter complex is formed in a bimolecular reaction because two reactants participate in a preexisting hydrogen bond.

To decide among the various alternatives for both the observed pH–rate behavior in the absence of general acid–base catalysis and any general acid–base catalysis, **other independent experiments** must be performed. For example, from the results of more extensive studies, it was concluded[8] that the term directly proportional to the concentration of the general acid catalyst chloroacetic acid, $[ClCH_2COOH]$, in the pseudo-first-order rate constant (Equation 4–24) for decomposition of the ethyl hemiacetal of formaldehyde (Equation 4–23) arose from the encounter complex **4–17**



4–17 $k_{ga}[ClCH_2COOH]$



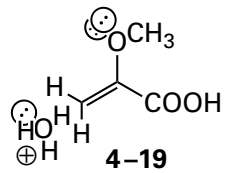
4–18 $k_{gb}[ClCH_2COO^-]$

while the term directly proportional to the concentration of the general base catalyst chloroacetate anion, $[ClCH_2COO^-]$, arose from the encounter complex **4–18**. Ironically, in this instance, contrary to one's immediate intuition, it was concluded that neither term referred to the most straightforward possibility.

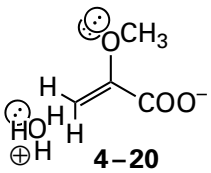
The rate equation for hydrolysis of 2-methoxyacrylic acid (Equation 4–19) can be rearranged to

$$-\frac{d[\text{EE}]_t}{dt} = k_{H^+}[H^+][\text{EEH}] + k_{non}\left(\frac{[H^+]}{K_{a\text{EEH}}}\right)[\text{EE}^-] \qquad (4\text{–}37)$$

where, as before, EEH is the conjugate acid 2-methoxyacrylic acid and EE^- is the conjugate base. The two terms in this rearrangement are consistent with the existence of the respective encounter complexes



4–19

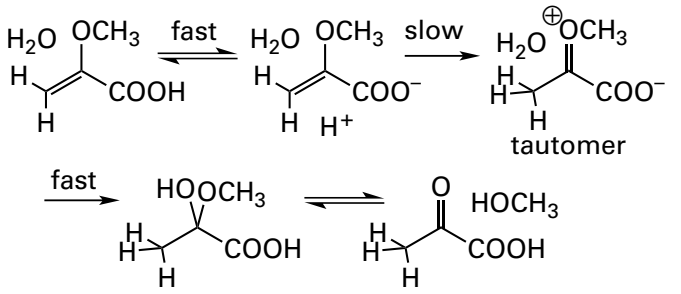


4–20

That these two encounter complexes account for all the hydrolysis is consistent with other observations. Encounter complex **4–19** is that of a hydron with the

neutral enol ether, and encounter complex **4–20** is that of a hydron with the anionic conjugate base of the enol ether.

The pH–rate profile for hydrolysis of 2-methoxyacrylic acid[7] decreases rapidly as the pH of the solution decreases until it levels out to a plateau above pH 0. The rate of hydrolysis is then independent of pH until the pH is increased above the pK_a for the carboxy group (pK_a = 3.39), when it then decreases by a factor of 10 for every increase of one unit of pH. Encounter complex **4–20** is essentially a tautomer of the neutral conjugate acid of the enol ether, EEH, and a molecule of water. The equilibrium between any two tautomers is always independent of pH, so in the range of pH from 0 to 3, where the rate of hydrolysis is independent of pH, this tautomer accomplishes it, and above a pH of 3.39, the decrease in rate is the direct result of the decrease in the concentration of this encounter complex. It follows that at all values of pH greater than 0, encounter complex **4–20** accounts for all the hydrolysis. In this range of pH, it was concluded that the mechanism of hydrolysis is



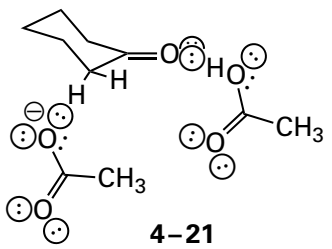
(4–38)

Hydronation of the conjugate base of 2-methoxyacrylic acid (the second step), because it is a hydronation of carbon, is the slow, rate-limiting step in the reaction and forms an actual, zwitterionic tautomer of the neutral conjugate acid. This mechanism is the relevant version of the established mechanism for hydrolysis of enol ethers,[15] in which distal hydronation of the carbon–carbon bond initiates hydrolysis.

The two encounter complexes **4–19** and **4–20** differ from each other only in the state of hydronation of their carboxy groups. Because the rate of the reaction remains the same from pH 0 to pH 3, it must be the case that the rate constant for hydronation of the anionic conjugate base of 2-methoxyacrylic acid at carbon 3 is much greater than the rate constant for hydronation of the neutral conjugate acid. From the pH–rate profile, it could be calculated that these two rate constants differ by a factor of 1300. This difference is reasonable. The carbon of a neutral carboxy group bears significant positive charge because of electron withdrawal by the two oxygens, and this positive charge would destabilize the oxocarbenium ion that is the intermediate in both hydronations, while the carbon of a carboxylato group bears far less positive charge because it is anionic.

All hydrons present in the species the concentrations of which participate in one of the original or rearranged terms in the rate equation are present in the actual encounter complex that gives rise to that term. As was the case with the encounter complex for hydrolysis of 2-methoxyacrylic acid, however, all other tautomers of each encounter complex in which **all these hydrons are present but are in different locations** is also consistent with the same term in the observed rate equation. This ambiguity arises from the simple fact that tautomeric equilibria are independent of pH. Consequently, the observed rate equation can make no distinction among the tautomers of a particular encounter complex, so every tautomer of every encounter complex consistent with a term in the rate equation is a valid candidate for the actual encounter complex.

The term for **concerted general acid–base catalysis**, $k_{gab}[HN^{(+)}][\odot N^{(-)}]$, that appears in some rate equations (see Equations 4–25 and 4–26) for the observed rate constant as a function of the concentration of buffer can also be used to support a particular mechanism. For example, the observed rate equation for the enolization of cyclohexanone, CyH, in buffers of sodium acetate at 25 °C and an ionic strength of 2.0 M has a term 4.8×10^{-7} M^{-2} s^{-1} [HOAc][OAc^-][CyH],[11] where HOAC is acetic acid and OAc^- is acetate. This term is believed to represent the encounter complex

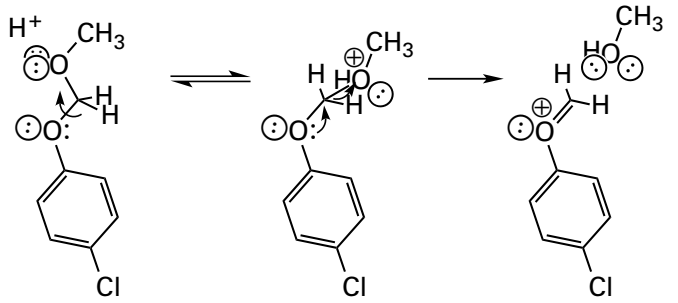


4–21

on the trajectory to a transition state in which a hydron is being added to the carbonyl oxygen of cyclohexanone while a hydron is being removed from its α carbon. In this instance, because a hydrogen bond probably cannot form between a carbon–hydrogen bond and a base, the hydrogen bond that preexists the encounter complex is that between the acetic acid and the carbonyl oxygen.

The distinction between observation and explanation is also critical when considering **specific acid or specific base catalysis** because there are always two different kinetic mechanisms that can explain these observations. A **pre-equilibrium** may occur that involves association of a hydron with or dissociation of a hydron from one of the reactants in a normal acid dissociation followed by a rate-limiting step involving bond-breaking or bond-making. Alternatively, **hydronium may participate as a general acid or hydroxide may participate as a general base** within the encounter complex. In many reactions, only the conjugate base or only the conjugate acid of one of the reactants participates significantly. Because acid–base reactions are so rapid, the equilibrium between the actual reactive species and its unreactive conjugate acid or its unreactive conjugate base can be established rapidly prior to a rate-limiting step that does not involve any hydron transfers in the transition state.

For example, one explanation for the observation of specific acid catalysis in the hydrolysis of formaldehyde acetal **4–2** would be that hydronation of one acetal oxygen in a rapid, normal acid–base equilibrium necessarily precedes the rate-limiting breaking of the bond between the carbonyl carbon and that oxygen, resulting in the departure of the consequently improved leaving group



(4–39)

Because the concentration of the hydronated acetal should be directly proportional to the concentration of hydronium at values of pH significantly greater than the pK_a for the oxygen, which should be less than –3, this mechanism involving a pre-equilibrium rather than specific acid catalysis is nevertheless consistent with the observation of specific acid catalysis (Equation 4–30).

Originally, it was hoped that the distinction between general acid–base catalysis and specific acid–base catalysis could be used to **distinguish a mechanism with a pre-equilibrium from a mechanism in which a hydron must be transferred to or from a reactant in the transition state** of the rate-limiting step. It was supposed that if general acid–base catalysis could not be observed but the reaction displayed specific acid catalysis or specific base catalysis, then the mechanism must involve a pre-equilibrium. Unfortunately, an alternative explanation that is also consistent with the observation of specific acid catalysis or specific base catalysis is that the encounter complex for the rate-limiting step does contain either a hydronium or a hydroxide, respectively, that donate or remove a hydron in the transition state of the rate-limiting step in the role of a general acid or a general base, but that general acid catalysis performed by hydronium inescapably present in the solution or general base catalysis performed by the hydroxide inescapably present in the solution is simply so much more effective that catalysis by other acids and bases cannot be observed. In this alternative explanation, the reaction is in fact susceptible to general acid–base catalysis, but it simply cannot be detected at the concentrations of general acids and bases usually examined. An understanding of this imbalance between hydronium and other general acids or between hydroxide and other general bases requires an understanding of the relevant Brønsted relations.

Another issue related to the decision between a acid–base pre-equilibrium and general acid catalysis by hydronium or general base catalysis by hydroxide is that of the relative magnitudes of the observed rates of general acid or general base catalysis and the rate of the same reaction in the absence of any added acid or base. Even when general acid–base catalysis is observed, it rarely results in increases in rate of more than about a factor of 10 at concentrations of buffer less than 1.0 M (Figures 4–1 and 4–4). Specific acid–base catalysis can simply be viewed as the extreme where the magnitude of general acid–base catalysis is so small that it cannot be detected experimentally above the rate of the reaction in the absence of added acid–bases. Because **general acid–base catalysis is usually unremarkable**, and may often be undetectable, the impression might be left that such catalysis may be expendable in enzymatically catalyzed reactions. To understand the fallacy of this impression as well as the conundrum of the alternative kinetic explanations for the observation of specific acid–base catalysis, the reasons that general acid–base catalysis is so unremarkable when reactions are performed in aqueous solution must be appreciated. Again, the basis of this appreciation is a Brønsted relation.

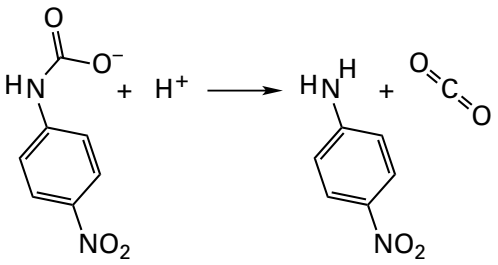
The Brønsted relation for general acid–base catalysis is a function that relates the rate constants or common logarithms of the rate constants for general acid catalysis to the acid dissociation constants or values of pK_a for the catalysts or that relates the rate constants or common logarithms of the rate constants for general base catalysis to the acid dissociation constants or values of pK_a for the conjugate acids of the catalysts.

Suppose that a term in the rate equation for a particular reaction has been designated as the result of **general acid catalysis** because that term is directly proportional to the concentration of the conjugate acid of the buffer in the expression for the observed rate constant, and a series of acids, all with the same type of atom with the same formal elementary charge on which the acidic hydron or hydrons are situated, is chosen for buffering. The Brønsted relation usually observed is

$$\log\left(\frac{k_{ga}}{p}\right) = \log G_A + \alpha\log\left(\frac{qK_a}{p}\right) \qquad (4\text{–}40)$$

where k_{ga} is the observed rate constant for that term, p and q are integers, and $\log G_A$ is a parameter. The other parameter, α, is the **Brønsted coefficient** for general acid catalysis. The term k_{ga}/p is the observed general acid rate constant divided by the number of equivalent hydrons, p, on the general acid. This division yields the rate constant in terms of the molar concentration of acidic hydrons rather than the molar concentration of the general acid itself. The term qK_a/p is the acid dissociation constant of the respective general acid, K_a, **corrected statistically**[16] for the number of equivalent hydrons on the general acid, p, and the number of equivalent lone pairs on its conjugate base, q. After this correction, the dissociation constant of the respective buffer is expressed in terms of the molar concentrations of individual hydrons on the conjugate acid and on the conjugate base.

If $\log(k_{ga}/p)$ is plotted as a function of pK_a + $\log(p/q)$, a linear relation is usually observed with a slope of $-\alpha$. For example, when a series of acids were chosen as general acid catalysts for the cleavage of *N*-(4-nitrophenyl)carbamate



(4–41)

rate constants of the respective terms for general acid catalysis observed for the several catalysts were related to values of pK_a for the acids by a Brønsted relation (Equation 4–40) with $\alpha = 0.84$ (Figure 4–5A).[17] The points for oxygen acids, in which the formal charge number on the oxygen bearing the hydron was 0, and the points for nitrogen acids, in which the formal charge number on the nitrogen bearing the hydron was +1, defined two distinguishable lines of the same slope, a fact demonstrating that **acids with the same atom to which the hydron is attached and which bears the same formal elementary charge usually should be chosen** as the buffers.

Likewise, suppose that a term in the rate equation for a particular reaction has been designated as the result of **general base catalysis** because that term is directly proportional to the concentration of the conjugate base of the buffer in the expression for the observed rate constant, and a series of bases all with the same type of atom with the same formal elementary charge on which the basic lone pair or the basic lone pairs of electrons are situated is chosen for buffering. The Brønsted relation usually observed is

$$\log\left(\frac{k_{gb}}{q}\right) = \log G_B - \beta\log\left(\frac{qK_a}{p}\right) \qquad (4\text{–}42)$$

where k_{gb} is the observed rate constant for that term, $\log G_B$ is a parameter, and K_a is the acid dissociation constant of the conjugate acid of the catalytic general base comprising the buffer. The other parameter, β, is also referred to as a Brønsted coefficient. The integers p and q serve the same purpose as before. The rate constant for general base catalysis is divided by the numbers of equivalent lone pairs q to yield the rate constant in terms of the molar concentration of those lone pairs rather than the molar concentration of the general base. General base catalysis by a series of oxygen bases of the dissociation of 4-methoxyacetophenone bisulfite

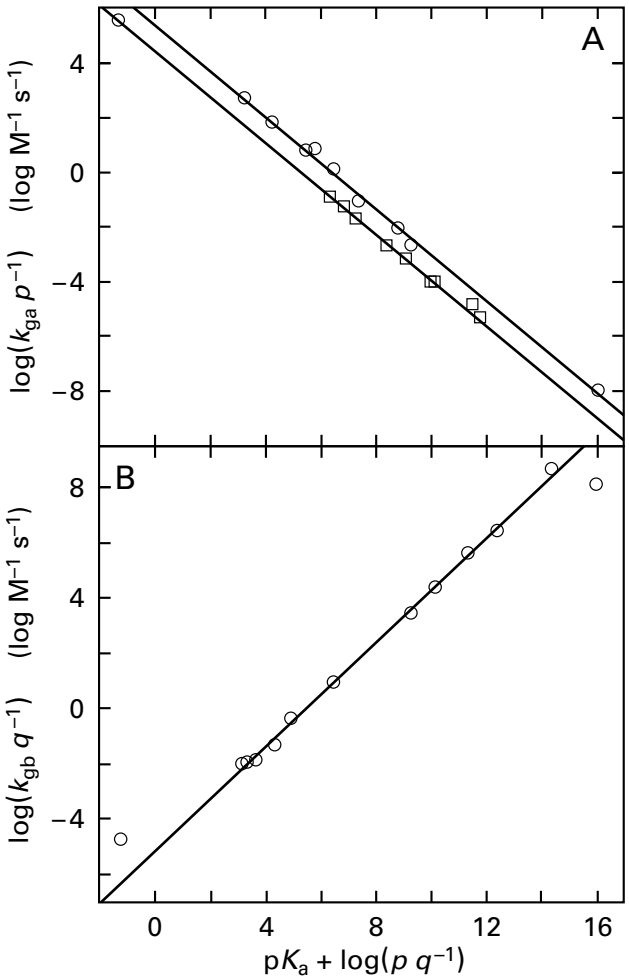


Figure 4–5: Brønsted plots for general acid catalysis and general base catalysis. (**A**) General acid catalysis for the decarboxylation of *N*-(4-nitrophenyl)carbamate (Equation 4–41).[17] Solutions of *N*-(4-nitrophenyl)carbamate were prepared at 1.0 M ionic strength (maintained with KCl) and 25 °C. The solutions were buffered with the respective general acid catalyst and its conjugate base. The decarboxylation was followed spectrophotometrically at 405 nm, the absorption maximum of the product 4-nitrophenylaniline. Rate constants for general acid catalysis, k_{ga}, were determined from the slopes of the lines relating the observed rate constants and the concentration of the respective buffer. The common logarithms of their statistically corrected values, $k_{ga}\ p^{-1}$ (molar^{-1} second^{-1}), are plotted as a function of the negative common logarithms of the statistically corrected values of the acid dissociation constant for each catalyst, $K_a\ q\ p^{-1}$ (molar). Oxygen acids (○), in order of increasing corrected pK_a, were hydronium, glycinium cation, acetic acid, β-glycerophosphate monoanion, cacodylic acid, phosphate monoanion, ethylphosphonate monoanion, boric acid, bicarbonate, and water. Nitrogen acids (□) are plotted separately; they were, in order of increasing corrected pK_a, trifluorethylammonium, imidazolium, 3-quinuclidonium, cyanoethylammonium, morpholinium, 3-hydroxyquinuclidinium, ammonium, quinuclidinium, and pyrrolidinium. (**B**) General base catalysis for the dissociation of 4-methoxyacetophenone bisulfite (Equation 4–43).[18] Solutions of 4-methoxyacetophenone bisulfite were prepared at 1.0 M ionic strength and 25 °C. The solutions were buffered with the general base catalyst and its conjugate acid. The dissociation was followed spectrophotometrically at 285 nm, the absorption maximum of the product 4-methoxyacetophenone. Rate constants for general base catalysis, k_{gb}, were determined from the slopes of the lines relating the observed rate constants and the concentration of the respective buffer. The common logarithms of their statistically corrected values, $k_{gb}\ q^{-1}$ (molar^{-1} second^{-1}), are plotted as a function of the negative common logarithms for the statistically corrected values of the acid dissociation constant for the conjugate acid of each catalyst, $K_a\ q\ p^{-1}$ (molar). The general bases, in order of increasing corrected pK_a for their conjugate acid, were water, formate, glycolate, chloroacetate, acetate, the anion of hexafluoroacetone hydrate, hexafluoro-2-propanolate, ammonia, ethylamine, trifluoroethanolate, guanidine, and hydroxide.

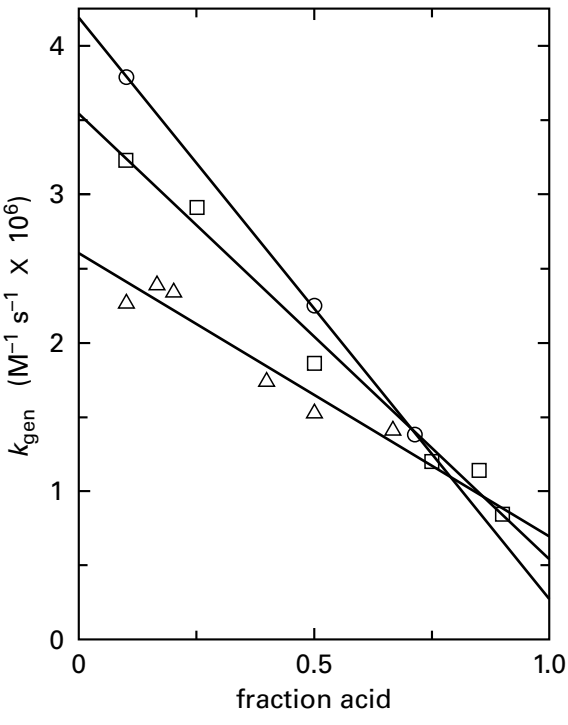

Figure 4–6: Behavior of rate constants for the hydrolysis of α-D-glucopyranosyl fluoride (Equation 4–44) at an ionic strength of 2.0 M and 30 °C as a function of the fraction of the buffer present as the conjugate acid.[19] The progress of the hydrolysis was monitored by polarimetry or nuclear magnetic resonance. The pseudo-first-order rate constants were obtained from linear semilogarithmic plots of the data. The respective rate constants, k_{gen} (molar^{-1} second^{-1} × 10^6; Equation 4–20), for hydrolysis under catalysis by a buffer of ethylphosphonate (○), a buffer of phosphate (□), and a buffer of (trichloro-methyl)phosphonate (△) are plotted as a function of the fraction of the buffer present as the monoanionic conjugate acid. The lines are linear fits of the data.

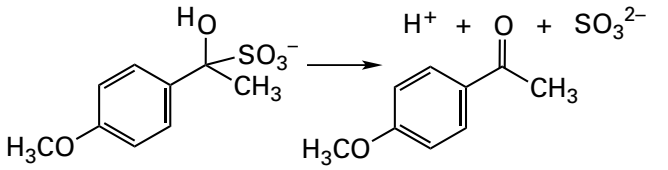
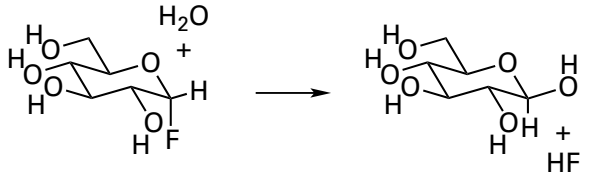


(4–43)



(4–44)

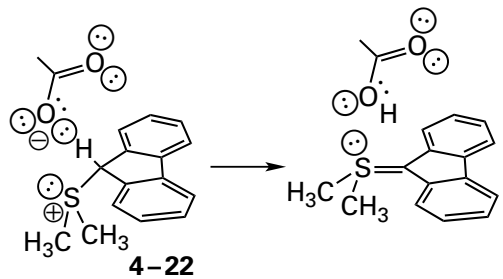
follows a Brønsted relation with $\beta = 0.94$ (Figure 4–5B).[18] As is the case for general acid catalysis, bases with the same atom on which the lone pairs are located and bearing the same formal elementary charge usually should be chosen as the buffers to be examined as general acid–base catalysts.

In **a reaction that is catalyzed by both general acids and general bases**, the lines that describe the behavior of the rate constant k_{gen} as a function of the fraction of acid and base in the buffer for a series of general acid–base catalysts always cross each other (Figure 4–6).[19] This crossing occurs because, as a result of the Brønsted relation, rate constants for general acid catalysis increase with decreases in pK_a for the conjugate acid of the buffer while rate constants for general base catalysis increase with increases in the pK_a for the conjugate acid of the conjugate base of the buffer.

The Brønsted relations demonstrate that **the acidity of the general acid or the basicity of the general base determines the effect of the catalyst** on the rate of the reaction. As might be expected, the more acidic the general acid, the greater will be the rate constant for general acid catalysis. The more basic the general base, the greater will be the rate constant for general base catalysis. The magnitude of values for α and β, however, will determine the strength of these effects. If the value for α or β is small, the acidity or basicity of the catalyst has only a small effect on the respective rate constant, but if α or β is near 1, the acidity or basicity of the catalyst will have a large effect.

If the mechanism of a reaction involves a general acid as the donor of a hydron in the transition state, it is generally assumed that a **small value for the Brønsted coefficient α indicates that the bond between the general acid and its hydron is only marginally broken at the transition state**. Likewise, if the mechanism involves the general base as the acceptor for a hydron in the transition state, a small value for β indicates that the bond between the general base and the hydron is only marginally formed at the transition state. For example, the hydrolysis of α-D-glucopyranosyl fluoride is catalyzed by several phosphates and phosphonates with different values of pK_a. Catalysis by the conjugate acids has a Brønsted coefficient $\alpha = 0.15$, and catalysis by the conjugate bases has a Brønsted coefficient $\beta = 0.06$.[19] Consequently, the hydron from the general acid is only marginally transferred to one of the reactants in the transition state for general acid catalysis, and the hydron from one of the reactants is only marginally transferred to the general base in the transition state for general base catalysis. It was concluded from other observations that the general acid forms a hydrogen bond to the fluoride ion (p$K_{aHF} = 3.2$), leaving the glucoside in the one transition state, and the general base forms a hydrogen bond with a hydron on the nucleophilic molecule of water in the other transition state. Each hydrogen bond, which involves only a small amount of hydron transfer, stabilizes the respective transition state, and the respective reaction is accelerated. When a Brønsted coefficient has a value near 0, any source of a hydron or any lone pair, respectively, will be as effective as any other.

If a general acid acts as a donor of a hydron in the transition state, it is generally assumed that a **value for α near 1.0 indicates that the bond between the general acid and its hydron is largely broken at the transition state**. Likewise, if a general base acts as a hydron acceptor in the transition state, a value for β near 1.0 indicates that the bond between the general base and the hydron is largely formed in the transition state. For example, for removal of the α-hydron from sulfonium cation **4–22**

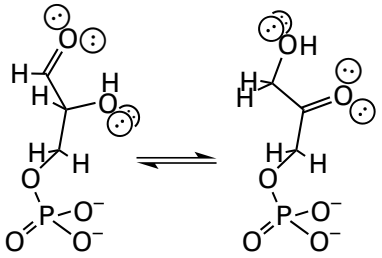


4 – 22

(4–45)

the Brønsted coefficient β for a series of carboxylates, the conjugate acids of which vary in pK_a, was 1.0. Sufficient evidence was provided that this Brønsted

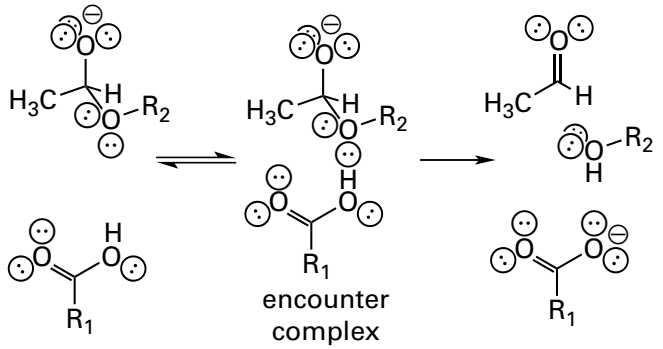
coefficient should be corrected for the effects of solvation to a value of $\beta_{corr} = 0.8$; nevertheless, its magnitude was believed to indicate that the bond between the carbon and the hydron was mostly broken in the transition state.[20] This nonenzymatic reaction is an example of the ability of a carboxylate to remove a hydron from carbon, as Glutamate 164 does in the active site of triose-phosphate isomerase (previously Equation 3–384)



(4–46)

from *Saccharomyces cerevisiae* (Figure 3–37). When a Brønsted coefficient has a value near 1.0, the strength of the acid or the base, respectively, should be fully manifested in the transition state, and the identity of the acid or the base, respectively, is of significant consequence.

In many instances, the value for a **Brønsted coefficient changes as one of the substituents on a reactant is changed**. For example, in a series of acetaldehyde hemiacetals undergoing decomposition



(4–47)

under apparent general base catalysis by a series of carboxylate anions (R_1COO^-), the Brønsted coefficient β increased as the pK_a for the alcohol (R_2OH) that is the product decreased. From other observations, it was concluded that the conjugate acid of the carboxylate actually catalyzed the breakdown of the oxyanionic conjugate base of the hemiacetal (Equation 4–47) so that the Brønsted coefficient for these catalysts, the carboxylic acids, decreased as the alcohol became a better leaving group. As the leaving group improves, the transition state is reached earlier along the reaction coordinate, where the bond between the oxygen of the carboxy group and the hydron in the carboxylic acid is less dissociated.[21] When the Brønsted coefficients (themselves the slopes of lines produced by the values of pK_a for other participants in the reaction) was plotted as a function of the values of pK_a for the leaving groups, a linear relation was observed, the slope of which is the **interaction coefficient**. In this instance, the interaction coefficient quantifies the coupling between dissociation of the carbon–oxygen bond and transfer of the hydron to the oxygen of the leaving group.

As already noted, if a reaction has a mechanism requiring that the transfer of a hydron occur in a step before the rate-limiting step, and if that transfer of a hydron is so rapid as to be at equilibrium, and if no further acid–base catalysis is occurring, then specific acid–base catalysis should be observed. It is also possible, however, that a reaction displays specific acid–base catalysis because the magnitude of the general acid–base catalysis, which in this particular instance does exist, is nevertheless too small to be observed. **The Brønsted relations explain why general acid or general base catalysis is usually weak or sometimes immeasurable**.

Consider a reaction susceptible to general acid catalysis. Assume for the moment that the hydronium, H_3O^+, behaves as a typical general acid in the set of catalytic acids. From the Brønsted relation for the reaction of interest (Equation 4–40)

$$k_{ga,HN^{(+)}} = k_{ga,H_3O^+}\left(\frac{q_{\odot N^{(-)}}}{2}\right)^{\alpha}\left(\frac{p_{HN^{(+)}}}{3}\right)^{1-\alpha}\left(\frac{K_{aNH}}{K_{aH_3O^+}}\right)^{\alpha} \tag{4–48}$$

where NH is any general acid in the series tested as catalysts and the integers 3 and 2 are, respectively, the number of acidic hydrons on a hydronium and the number of basic lone pairs on a molecule of water, its conjugate base. If it is also assumed that terms involving $q_{N^{(-)}}$, 2, $p_{NH^{(+)}}$, and 3 are together nearly equal to 1, then

$$k_{ga,HN^{(+)}} \cong \left(\frac{K_{aNH}}{K_{aH_3O^+}}\right)^{\alpha} k_{ga,H_3O^+} \tag{4–49}$$

If only acid catalysis is kinetically significant, then

$$k_{obs} = k_{non} + k_{H^+}[H^+] + k_{ga,NH}[HN^{(+)}] \quad (4–50)$$

If

$$k_{H^+}[H^+] = k_{ga,H_3O^+}[H_3O^+] \quad (4–51)$$

then

$$k_{obs} \cong k_{non} + k_{H^+}[H^+] + k_{H^+}[HN^{(+)}]\left(\frac{K_{aNH}}{K_{aH_3O^+}}\right)^{\alpha} \quad (4–52)$$

$$k_{obs} \cong k_{non} + k_{H^+}[H^+] + k_{H^+}[HN^{(+)}]\left(\frac{[\odot N^{(-)}][H^+]}{[H_2O][HN^{(+)}]}\right)^{\alpha} \quad (4–53)$$

$$k_{obs} \cong k_{non} + k_{H^+}[H^+] + k_{H^+}[HN^{(+)}]\left(\frac{[\odot N^{(-)}]}{[H_2O]}\right)^{\alpha}\left(\frac{[HN^{(+)}]}{[H^+]}\right)^{1-\alpha} \quad (4–54)$$

Because $[\odot N^{(-)}] << [H_2O]$ under all usual circumstances, the term $([HN^{(+)}]/[H^+])^{1-\alpha}$ must be sufficiently large to counteract the resulting, inescapable effect of the term $([\odot N^{(-)}]/[H_2O])^{\alpha}$ on the rate equation for general acid catalysis to be significant.

In particular, if α is near a value of 1.0, the disparity between the concentration of water, which is the conjugate base of the hydronium, and the concentration of the conjugate base of any general acid other than hydronium will dominate in the third term of Equation 4–54. In this instance, because hydronium is present inescapably in the solution, general acid catalysis by the added acid will not be observed even though general acid catalysis is occurring robustly with hydronium as the general acid and also occurring with the added acid but at an insignificant rate. If, however, α is sufficiently small and the added acid is sufficiently weak so that the chosen concentrations of its conjugate acid are much greater than the concentration of hydronium that can be achieved, then general acid catalysis will be significant.

A similar explanation can be formulated for the competition between specific base catalysis and general base catalysis. In this instance, when β is near a value of 1.0, general base catalysis by added bases will not be observed because general base catalysis by the hydroxide present inescapably in the solution will again dominate.

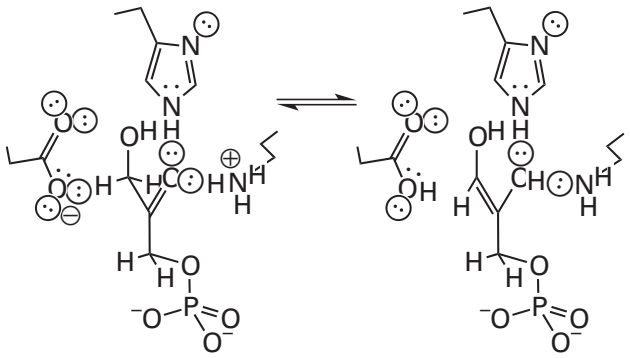
From all these considerations, it is clear that **the reason both general acid catalysis and general base catalysis are so unremarkable in any aqueous solution is that water is always the acid–base present at the highest concentration**. Because the concentration of water is so high relative to the concentration of any added acid or base, the concentrations of its conjugate acid, hydronium, or its conjugate base, hydroxide, are anomalously high relative to the concentration of any added acid or base, respectively. Because of these biases in concentration, hydronium or hydroxide acts preferentially when a general acid or a general base is required in the reaction. Another way of looking at the situation is that H_3O^+ is such a strong acid and OH^- is such a strong base that, even when their concentrations are small relative to an added general acid or general base, respectively, they can compete successfully, as long as the relevant Brønsted coefficient is large enough.

Nevertheless, most reactions homologous to those that occur in particular active sites have an absolute, inescapable requirement for catalytic acids or bases or both. The observation of specific acid–base catalysis and general acid–base catalysis demonstrates this requirement. The fact that the inescapable presence of hydroniums, hydroxides, and molecules of water in solution causes general acid–base catalysis to be so unimpressive leads to the misconception that acid–base catalysis in general is unimpressive. Nothing could be farther from the truth. In fact, **in almost all the reactions catalyzed by enzymes, acid–base catalysis is an essential requirement.**

There is a big difference, however, between a reaction requiring transfers of hydrons when it occurs in aqueous solution and that same reaction when it occurs in the active site of an enzyme. The two situations differ dramatically because a reactant in an active site can no longer diffuse through the solution encountering hydroniums, hydroxides, and molecules of water. Consequently, **the reaction must rely on the acids and bases within the active site**, and usually it must rely on them alone. As a result, whenever a hydron must be added to or removed from an atom in a substrate or an inter-

mediate, there will be a catalytic acid–base in the active site immediately adjacent to that atom. These catalytic acid–bases are usually side chains of the amino acids that comprise the active site. Nor is this requirement exclusive to the active sites of enzymes. Ribosomes use the bases of nucleotides in the nucleic acid that forms their active sites, all of which have hydrons and lone pairs of electrons with reasonable values of pK_a, as catalytic acid–bases for all the same reasons.[22]

A common feature of enzymatic active sites is that donors and acceptors for hydrogen bonds to a reactant often become catalytic acids and catalytic bases, respectively, as the reaction progresses. The active site of an enzyme binds substrates specifically and in the proper orientation in part because aligned hydrogen bonds form between donors and acceptors on the amino acids lining the active site and acceptors and donors on substrates. These donors and acceptors for hydrogen bonds involved in the recognition of substrates (Figures 3–33, 3–34, 3–40, and 3–42) can automatically become catalytic acid–bases when required by the reaction. For example, in the active site of triose-phosphate isomerase (Equation 4–46) from *S. cerevisiae*, the carbonyl oxygen of glycerone phosphate is recognized by participating in a hydrogen bond with the imidazolyl group on Histidine 94 and the ammonio group on Lysine 11 (Figure 3–37), and the hydroxy group on carbon 3 of glycerone phosphate is recognized by participating in a hydrogen bond (0.32 nm) with the amido group in the side chain of Asparagine 9.[23,24] Because the imidazolyl group of Histidine 94 is in its neutral form in the complex,[25] which is a poor acid (pK_a = 14), the ammonio group of Lysine 11 (pK_a = 10.5) is the catalytic acid–base that adds the hydron to and removes the hydron from the oxygen on carbon 2 to catalyze the enolization of glycerone phosphate.[26] Consistent with this conclusion, it is the amino group on Lysine 11 that is responsible for removing a hydron from the hydroxy oxygen on the *cis*-enediol intermediate.[27] While the ammonio group of Lysine 11 hydronates the carbonyl oxygen of glycerone phosphate, the carboxylato group of Glutamate 164 removes the hydron from carbon 3 to form the *cis*-enediol intermediate



(4–55)

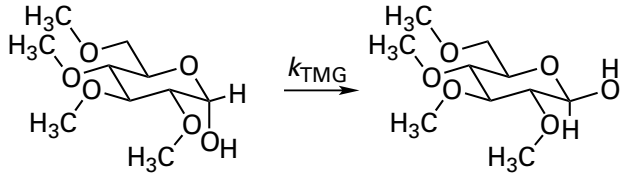
In the reverse direction, while the amino group of Lysine 11 dehydronates the hydroxy group of the *cis*-enediol, the carboxy group of Glutamate 164 adds the hydron to carbon 3 to form glycerone phosphate. In the next step, the imidazolyl group of Histidine 94 hydronates oxygen 2 of the *cis*-enediol simultaneously with the transfer of the hydron already on oxygen 2 back to the amino group of Lysine 11, and then the resulting anionic imidazo group of Histidine 94 swings over to remove the hydron from oxygen 1 of the *cis*-enediol[28] as the carboxy group on Glutamate 164 adds its hydron to carbon 2 to produce D-glyceraldehyde 3-phosphate. In reverse, the imidazolyl group of Histidine 94 adds the hydron to oxygen 1 D-glyceraldehyde 3-phosphate as the carboxylato group on Glutamate 164 removes the hydron from carbon 2 and then the imidazo group swings over to the oxygen on carbon 1 to dehydronate it as the ammonio group on Lysine 11 hydronates it to form the *cis*-enediol.*

The case of triose-phosphate isomerase (Equations 4–46 and 4–55 and Figure 3–37) illustrates the fact that catalytic acid–bases must be provided by an active site, or the reaction will not proceed. If an acid–base were not provided to add or remove a hydron from carbon, the enzymatic reaction would not occur. If an acid–base were not provided to hydronate and dehydronate the carbonyl oxygen of

*The imidazolyl group of Histidine 94 does not seem to move detectably during catalysis because the *B* factors of its atoms are the smallest of the atoms involved in catalysis (Figure 3-37).[23] This apparent immobility is probably due to two facts. First, as soon as it removes the hydron from oxygen 1 of the *cis*-enediol in the forward direction, oxygen 1 becomes a carbonyl oxygen (pK_a = –5) and the imidazolyl returns immediately to the stronger base, the hydroxyl (pK_a = –2) on oxygen 2. Second, in the reverse direction, as soon as the neutral imidazolyl group adds a hydron to oxygen 1 of D-glyceraldehyde 3-phosphate and becomes the anionic imidazolio group, it must immediately return to oxygen 2 to pick up a hydron relayed by oxygen 2 from the ammonio group of Lysine 11. Consequently, it seldom participates in a hydrogen bond to oxygen 1 and almost always participates in a hydrogen bond to oxygen 2.

glycerone phosphate, the rate of the enzymatic reaction would decrease dramatically.[26]

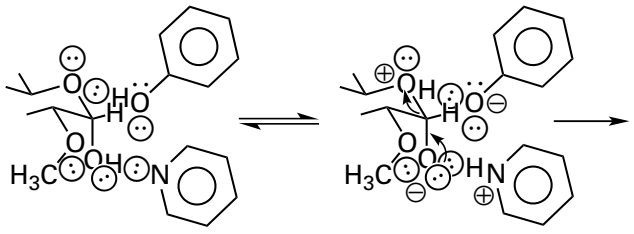
After reactants have bound and, in the process, have displaced waters of hydration within the empty site, the active site has become, by and large, anhydrous. In anhydrous benzene, the anomerization of 2,3,4,6-tetramethyl-D-glucose (TMG)



(4–56)

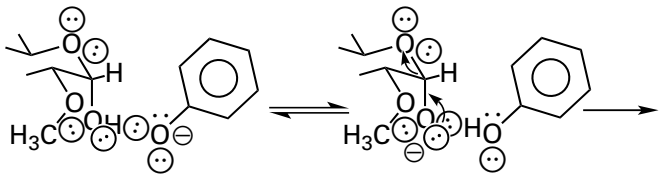
is very slow and variable in rate, suggesting that what little reaction is observed has an absolute requirement for traces of general acids or general bases contaminating the solvent even though it was rigorously purified.[29] When pyridine (Pyr) is added as a catalyst, the rate law contains, in addition to the negligible term for the uncatalyzed reaction, a term of the form $k_{Pyr,TMG}[Pyr][TMG]^2$. When both pyridine and phenol (PhOH) are added, the rate law contains an additional term of the form $k_{Pyr,PhOH,TMG}[Pyr][PhOH][TMG]$.

In these two instances of general acid–base catalysis, the individual terms are termolecular, and it was originally concluded[29] that, in benzene, the anomerization of tetramethyl-D-glucose has an absolute requirement for a general acid and a general base simultaneously



(4–57)

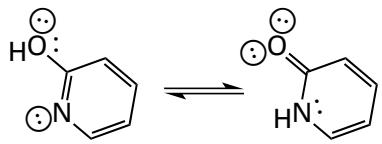
whereas for anomerization in the absence of phenol, the hydroxy group of another 2,3,4,6-tetramethyl-D-glucose would act as the general acid catalyst. It has since been shown that some of the catalysis observed, if not all of it, is due to general base catalysis by either glucosate anion or phenoxide anion acting alone at the hydroxy group on carbon 1 of 2,3,4,6-tetramethyl-D-glucose[30]



(4–58)

Values of pK_a of 9.9 for phenol and 14.4 for one of the hydroxy groups on 2,3,4,6-tetramethyl-D-glucose in aqueous solution should be significantly higher in benzene. Consequently, the molar concentrations of these strongly basic anions responsible for the catalysis are directly proportional either to [Pyr][TMG] or to [Pyr][PhOH], respectively, because pyridine is the strongest base in the solution and hence will be responsible for removing a hydron from either phenol or a hydroxy group in the absence of water. General base catalysis by other strong bases, acting alone, also is sufficient[30] for mutarotation. Nevertheless, all the results agree on the absolute necessity for at least one added catalyst when the anomerization is performed in anhydrous benzene.

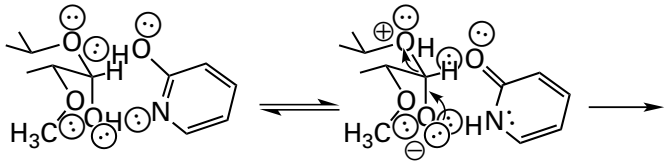
One of the most effective catalysts of the mutarotation of 2,3,4,6-tetramethyl-D-glucose in benzene is 2-hydroxypyridine[31]



4–23

(4–59)

a compound chosen on the assumption that it would be a bifunctional catalyst



(4–60)

At a concentration of 0.05 M in benzene, 2-hydroxypyridine catalyzes the anomerization of tetramethyl-D-glucose 200 times more rapidly than 0.05 M phenol and 0.05 M pyridine.

In aqueous solution, however, the mutarotation of D-glucose is not significantly catalyzed by addition of 0.1 M 2-hydroxypyridine because the unavoidably present hydronium and hydroxide are even more efficient catalysts than 2-hydroxypyridine. Again, the implication of these observations is that

in an active site, in which bound reactants are no longer diffusing through the aqueous solution, the catalytic acids and catalytic bases provided by the active site become essential to catalysis even if, in the guise of general acid–bases, these same catalytic acid–bases are unnecessary when the reactants are dissolved in water.

Another feature of an anhydrous or mostly anhydrous active site in the Michaelis complex with a reactant immediately preceding a transition state is that the **relative permittivity of the active site is much less than the relative permittivity of water**. Acid dissociation constants tabulated for the side chains of the amino acids (aspartic acid, 4.0; glutamic acid, 4.3; histidinium, 6.6; cysteine, 8.7; tyrosine, 9.8; and lysinium, 10.5)[32] are for these acids in a randomly coiled polypeptide when they are fully exposed to the aqueous phase. As reactants and the protein close around a catalytic acid or catalytic base in the side chain of an amino acid in the active site during formation of the catalytically competent Michaelis complex between reactants and enzyme, the contact of the catalytic acid or catalytic base with the aqueous phase diminishes significantly or is completely lost, coincident with a significant decrease in the relative permittivity in its vicinity.

The relative permittivity surrounding an acid **affects its dissociation constant.** According to the Born approximation,[33,34] the standard free energy of solvation for an ion is

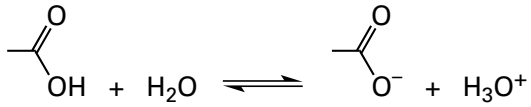
$$-\Delta G^{\circ}_{\text{ion}} = -\frac{Q^2}{2r}\left(1 - \frac{1}{\varepsilon_{\text{r}}}\right) \tag{4–61}$$

where Q is the electric charge (in coulombs) of the ion, ε_{r} is the relative permittivity of the surroundings, and r is the radius of the cavity produced by the ion.[35] In the simplest situation, when an acid or a base in an active site is dehydronated or hydronated, respectively, and the hydron dissociating enters the solution or the hydron associating enters the active site from the solution, then the shift in the pK_{a} for acid dissociation of the acid or the conjugate acid of the base will be determined only by the change in the electric charge of the acid–base during that dissociation or association[36]

$$\Delta \text{p}K_{\text{a}} = -\frac{(2z-1)e^2 N_{\text{A}}}{4.606\,RTr}\left(\frac{1}{\varepsilon_{\text{r,as}}} - \frac{1}{\varepsilon_{\text{r,H}_2\text{O}}}\right) \tag{4–62}$$

where z is the charge number on the acid or on the conjugate acid, $\varepsilon_{\text{r,as}}$ is the relative permittivity of the active site, and $\varepsilon_{\text{r,H}_2\text{O}}$ is the relative permittivity of water. For example, the α-imino group on the amino-terminal proline of 2-hydroxymuconate tautomerase from *Pseudomonas putida* has a pK_{a} of 6.4. This pK_{a} is 3 units lower than the pK_{a} for a fully solvated amino-terminal proline in aqueous solution. The shift in pK_{a} experienced by this imino group could be explained if the relative permittivity of the active site in which it is located is 15.[36] This value would be for the active site unoccupied by any substrate for the enzyme, so when it becomes occupied, the relative permittivity and the pK_{a} for the imino nitrogen should decrease even further.

When a carboxy group dissociates in solution



(4–63)

a positive ion and a negative ion are created. Consequently, as the relative permittivity of the solution decreases, and hence the ability of the surroundings to solvate charge, the acid dissociation constant of a carboxy group decreases, the pK_{a} for the carboxy group increases, and the basicity of the carboxylato group increases. In measurements in mixed solvents of alcohols and water or dioxane and water, values of pK_{a} for the carboxylic acids increase by one unit for every decrease of about 15–20 units in relative permittivity.[37-39] Since the relative permittivity of water is 79 at 25 °C, the limit to a shift in pK_{a} due to a decrease in relative permittivity should be around 4 or 5 units. The increase in pK_{a} with decreasing relative permittivity, however, seems to be magnified in aprotic solvents.[38,40] For example, the pK_{a} for acetic acid, which is 4.76 in water, is 11.1 in dimethylformamide ($\varepsilon_{\text{r}} = 38$) and 11.4 in dimethyl sulfoxide ($\varepsilon_{\text{r}} = 47$).[41] These observations may explain why a carboxylato group is among the most common catalytic bases in active sites. In the unoccupied active site, the pK_{a} of its conjugate acid would be fairly low, causing it to be present mostly as the carboxylato group. Upon occupation of the active site by a reactant, however, in particular a reactant that placed an acidic hydrogen on carbon immediately adjacent to it, the pK_{a} for its conjugate acid, and hence its basicity, should increase significantly.

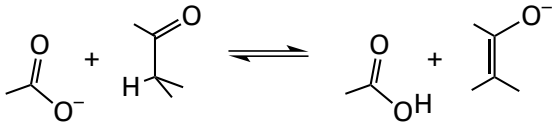
The magnitude of the effect of decreasing the relative permittivity on the pK_{a} for an acid will also **depend on the degree of delocalization of charge** in

the charged species involved. The relative permittivity of the surroundings affects the dissociation constants for acids in which the negative elementary charge created upon dissociation is localized more than when that charge is delocalized. For example, the localized elementary charge on a sulfido group should be destabilized more by a decrease in relative permittivity than the delocalized elementary charge on a phenolate. When the location of the hydron in hydrogen bonds between various phenolates and various carboxylic acids was determined by nuclear magnetic resonance spectroscopy, it was observed that the hydron was on the phenolate oxygen in solvents of high relative permittivity but on the carboxylate oxygen in solvents of low relative permittivity.[42] The conclusion from these observations was that the increase in acid dissociation constant caused by the decrease in the relative permittivity was greater for the carboxy group than the 4-hydroxyphenyl group because the negative elementary charge of the conjugate base is more delocalized in a 4-oxidophenyl group than in a carboxylato group, and consequently a carboxylato group can become more basic than a 4-oxidophenyl group at low relative permittivity.

In more complicated situations, the magnitude of the effect of relative permittivity of an active site on the change in standard free energy of an acid dissociation depends on **the molecular details of the acid dissociation that is occurring**. In free solution, both a carboxylate and the hydronium produced by dissociation of a carboxy group experience low relative permittivity. Under ideal circumstances within a closed active site, in which the hydron is transferred to a neutral acceptor so that its positive elementary charge remains in the active site, the pK_a for a glutamyl or aspartyl side chain could shift from around 4 to around 10, so that the carboxylate anion would become a strong base. If, however, the hydron upon dissociation enters the solution where it will experience high relative permittivity, only the carboxylato group will experience low permittivity and the pK_a will shift by a smaller amount.

Nevertheless, burying an acid–base inside a protein, both by removing it from water, a protic solvent, and transferring it into an aprotic region of lower relative permittivity, causes significant shifts in its pK_a. For example, when 22 interior positions in the folded polypeptide of micrococcal nuclease from *Staphylococcus aureus*, chosen at random, were each in turn mutated to lysine, the pK_a for those buried lysines varied from an unperturbed value of 10.4 (5 substitutions) to values below 7.5 (6 substitutions).[43]

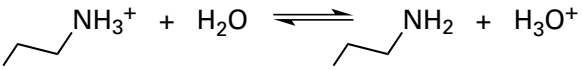
The actual shift that occurs in a pK_a, however, depends strongly on the type of hydron transfer in which the acid–base in an active site participates. If the transfer results in no net change in elementary charge, such as the transfer of a hydron from a carbon α to a carbonyl to a carboxylate



(4–64)

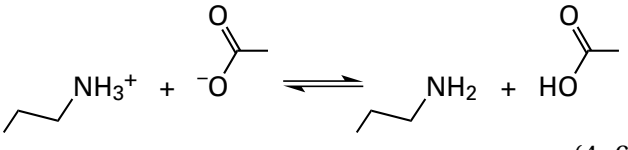
the relative permittivity of the surroundings, as long as they are reasonably uniform, will have much less effect. If, however, the alkylammonium cation of a lysine simultaneously hydronates the enolate oxygen (Equation 4–55), a positive elementary charge and a negative elementary charge disappear during the reaction, and low relative permittivity would decrease the standard free energy of hydron transfer significantly and improve catalysis dramatically.

When a cationic acid dissociates in solution



(4–65)

there is no change in the number of elementary charges in that solution. Consequently, the relative permittivity of the solution has only a small effect on the pK_a for the acid. For example, the changes in the apparent pK_a for *n*-butylammonium cation in the solvents methanol, acetone, and acetonitrile seem to be due almost completely to differences in values of the pK_a for the conjugate acids of the solvents themselves, the respective oxygens of which must act as the acceptor of the hydron, as does the water in Equation 4–65, rather than to any differences caused by relative permittivity.[44,45] Again, however, the effect of the relative permittivity of the surroundings will depend on the type of hydron transfer. For example, in the reaction

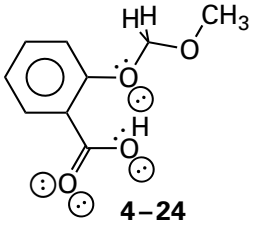


(4–66)

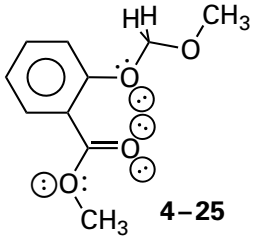
in which a positive elementary charge and a negative elementary charge are disappearing, the relative permittivity of the surroundings will have a significant effect.[46,47]

Another feature of the transfer of a hydron between a substrate and a catalytic acid–base in an active site is its intramolecularity. In the active site of an enzyme, the reaction between the bound substrate and a catalytic acid or catalytic base is an intramolecular reaction, and the **entropy of approximation** gained by converting what would be an intermolecular reaction in solution into an intramolecular reaction in the active site dramatically increases the efficiency of the catalytic acid–base. For example, it is estimated, from the results of site-directed mutation and from rate constants for intermolecular general acid catalysis in aqueous solution, that the general base catalysis in the enolization of mandelate anion (see Equation 4–12) achieved by the imidazolyl group in the active site of mandelate racemase from *P. putida* is 3×10^3 times more effective than that achieved in solution by 1 M imidazole.[6] Again, as before with other similar increases, the use of effective molarity to describe this increase is patently unrealistic.

There are many **examples of nonenzymatic, intramolecular general acid catalysis**. For example, the hydrolysis of acetals (Equation 4–29) is normally an example of pure specific acid catalysis with no evidence of general acid–base catalysis.[3] It is possible, however, to provide an intramolecular general acid catalyst in the form of the 2-carboxy group on phenyl methyl acetal **4–24**



4–24



4–25

The methyl ester **4–25** of acetal **4–24** serves as a control that incorporates the electronic structure without the ability to provide a hydron. The pH–rate profiles for hydrolysis of acetal **4–24** and acetal **4–25** differ remarkably (Figure 4–7).[12] Hydrolysis of acetal **4–25,** as with other acetals, displays only specific acid catalysis. Hydrolysis of acetal **4–24,** however, displays a plateau in its pH–rate profile between pH 1 and 4 such that at values of pH greater than 5, in the neutral range of pH, the rate

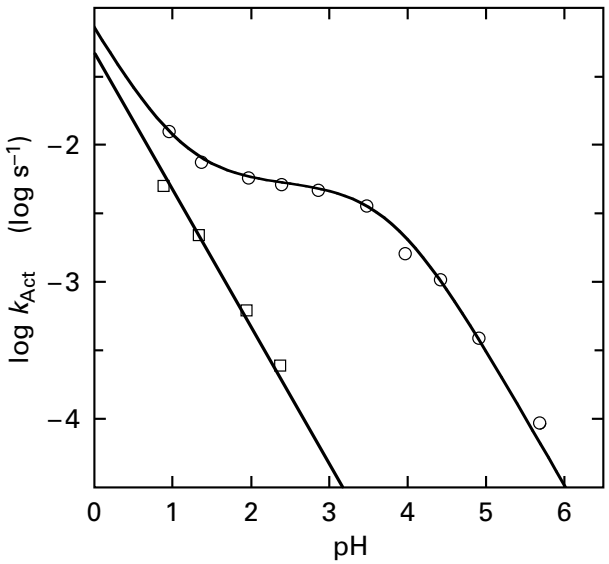


Figure 4–7: Intramolecular general acid catalysis of the hydrolysis of the 2-carboxyphenyl methyl acetal of formaldehyde.[12] Solutions of either 2-carboxyphenyl methyl formaldehyde acetal **4–24** (○) or 2-(methoxycarbonyl)phenyl methyl formaldehyde acetal **4–25** (□) were prepared at an ionic strength of 1.0 M (maintained with KCl) and 56 °C. Solutions were either unbuffered or buffered with sodium formate or potassium acetate. All values for observed rate constants were those obtained by extrapolation to eliminate any effect of buffer on the rate. In most instances, the buffer had no significant effect on the rate of the reaction. The release of the respective phenol as a product of hydrolysis was followed by the increase in absorbance at 302 nm, and pseudo-first-order rate constants, k_{Act}, for each acetal (Act) were obtained from the slopes of plots of the common logarithms of the absorbances as a function of time at the different values of pH. The pH–rate profiles presented are the common logarithms of tabulated pseudo-first-order rate constants for the hydrolysis of the respective acetals, k_{Act} (second^{-1}), plotted as functions of pH.

of its hydrolysis is 270-fold greater than the rate of hydrolysis of the methyl ester. The 2-carboxy group, because it able to hydronate the leaving oxygen intramolecularly in a cyclic transition state in which the hydron is on an oxygen four atoms away, increases the rate of hydrolysis by a factor large enough that general acid catalysis of a reaction in which it was not observed with intermolecular catalysts can now be observed.

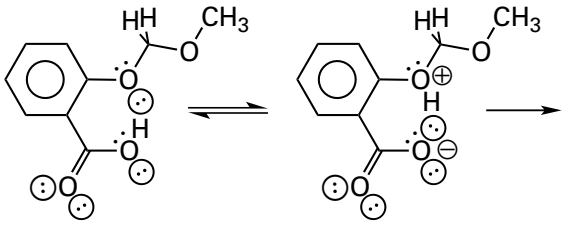
Another instance of intramolecular general acid catalysis is hydrolysis of a methyl acetal of formaldehyde within a significantly more complicated scaffold.[48] In this other nucleophilic substitution, the acidic oxygen–hydrogen of the catalytic carboxy group is five atoms from the oxygen of the acetal rather than four as it is in **4–24**, the oxygen of the

acetal is not conjugated to the carboxy group as it is in **4–24**, and the scaffold holding the groups adjacent to each other is tricyclic, rather than monocyclic as it is in **4–24**. The pH–rate profile for this hydrolysis is almost identical to that in Figure 4–7, and the acceleration at higher values of pH is 100-fold greater than the rate of catalysis by hydronium.

The behavior of hydrolysis of acetal **4–24** (Act) as a function of pH (Figure 4–7) can be explained satisfactorily in the following way.[12] Below pH 1, the concentration of hydronium is so high that specific acid catalysis dominates, and

$$k_{\text{Act}} = k_{\text{H}^+}[\text{H}^+] \tag{4–67}$$

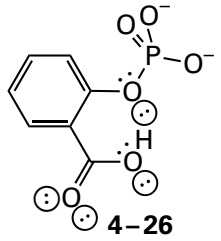
Above pH 1, the concentration of hydronium becomes small enough that intramolecular general acid catalysis dominates



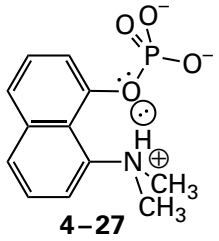
(4–68)

Until the pK_a for the 2-carboxylic acid is reached, the rate of the reaction is invariant with pH. At values of pH in excess of the pK_a for the 2-carboxy group (pK_a = 3.7), the concentration of the carboxylic acid—the species in which intramolecular catalysis can occur—and, consequently, the rate constants decrease by a factor of 10 for every increase of 1 unit in the pH.

The dianionic phosphomonoester **4–26**



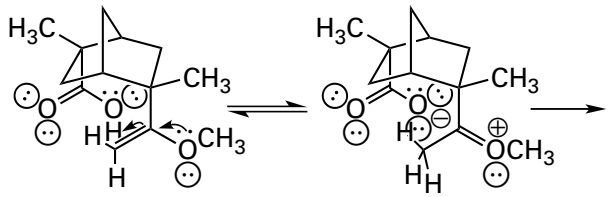
4–26



4–27

which is a phosphoric analogue of acetal **4–24**, also displays intramolecular general acid catalysis of its hydrolysis. This catalysis also results from hydronation of the leaving group by the carboxy group.[49] The intramolecular general acid catalysis observed for the zwitterionic dimethylaminonaphthyl phosphomonoester **4–27** results from hydronation of the leaving group by the ammonium.[50]

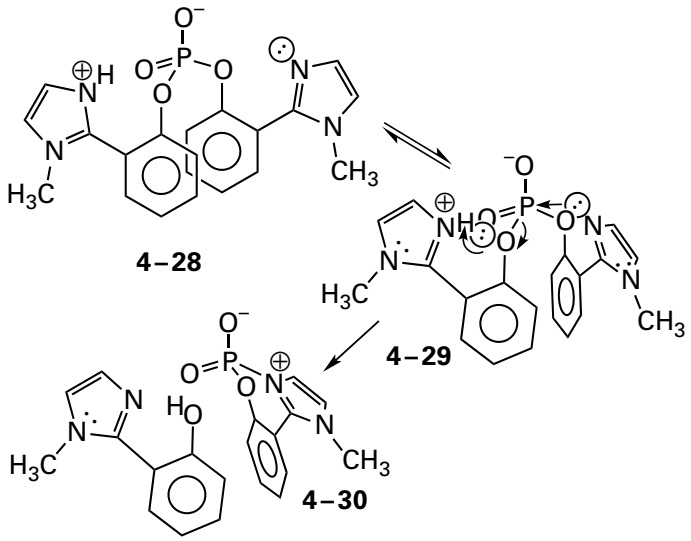
The observed pH–rate profile for hydrolysis of methyl enol ether **4–1** (Equation 4–2) also displays a plateau similar to that observed in Figure 4–7. The existence of this plateau is consistent with the *endo*-carboxylic acid acting as a general acid that intramolecularly hydronates the peripheral carbon of the enol to form the oxocarbenium ion[1]



(4–69)

homologous to the oxocarbenium ion that is the intermediate in hydrolysis of 2-methoxyacrylic acid (Equation 4–38). This oxocarbenium ion then reacts with water at its now dramatically electrophilic carbon. This nonenzymatic reaction is an example of a carboxylic acid that hydronates carbon as Glutamatic Acid 164 does in the active site of triosephosphate isomerase from *S. cerevisiae* (Equations 4–46 and 4–55 and Figure 3–37).

The pH–rate profile (Figure 4–8)[51,52] for the intramolecular nucleophilic substitution of one phenoxy group by the *N*-methylimidazolyl group on the other phenoxy group within the symmetric phosphodiester **4–28**



4–28

4–29

4–30

(4–70)

to give the cyclic *O*-aryl phosphoramidate **4–30**, displays a narrow maximum approached on the two sides by lines of slope +1 and slope –1, respectively.

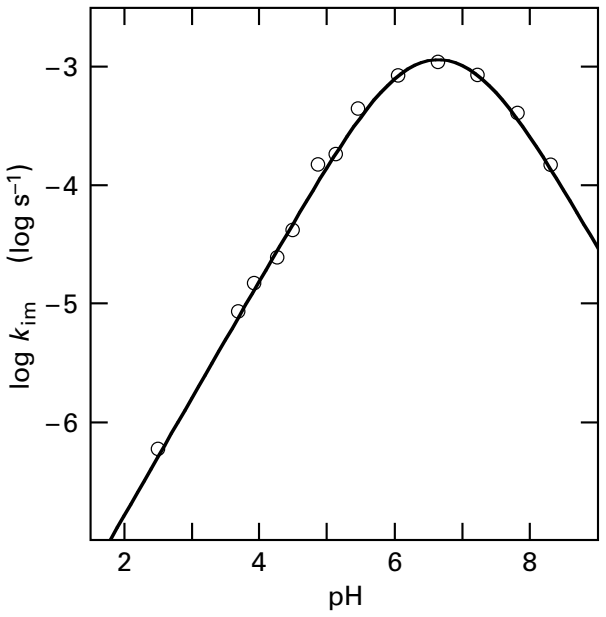


Figure 4–8: Simultaneous intramolecular general acid catalysis and general base catalysis of the hydrolysis of a phosphodiester by two imidazolyl groups.[51,52] The appearance of 2-(1-methyl-1*H*-imidazolyl)phenol resulting from the hydrolysis (Equation 4–70) of bis[2-(1-methyl-1*H*-imidazolyl)phenyl] phosphate (**4–28**) was followed by its absorbance at 290 nm at 60 °C. The rates of appearance of the phenol were first-order. From these rates, rate constants for the hydrolysis were determined at different values of pH. The common logarithms of the rate constants (second^{-1}) for the hydrolysis, k_{im}, are plotted as a function of pH. The solid line is the common logarithm of Equation 4–71 with $k_{im} = 2 \times 10^{-3}$ s^{-1}, pK_{a1} = 6.1, and pK_{a2} = 7.2.

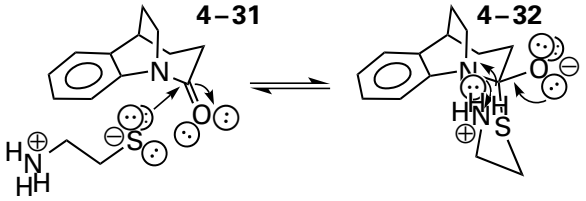
The pH–rate profile is consistent with a rate law of the form

$$-\frac{d[\mathrm{PDE}]_t}{dt} = k_{im}\alpha_{zw}[\mathrm{PDE}]_t = k_{im}\left(\frac{[H^+]}{K_{a1}} + 1 + \frac{K_{a2}}{[H^+]}\right)[\mathrm{PDE}]_t \qquad (4\text{–}71)$$

where $[\mathrm{PDE}]_t$ is the total concentration of phosphodiester **4–28**, k_{im} is a first-order rate constant, and α_{zw} is the fraction of the total phosphodiester that is the zwitterion in which one *N*-methylimidazolyl group is hydronated on nitrogen and the other is unhydronated. Acid dissociation constant K_{a1} is the macroscopic acid dissociation constant for the first hydron from the cation in which both imidazolyl groups are dihydronated and the phospho group is monoanionic, and K_{a2} is the macroscopic acid dissociation constant for the hydron from the cationic imidazolyl group in the zwitterion. The fact that all rates measured in the pH–rate profile (Figure 4–8) are 10^6 times greater than the rate constant for uncatalyzed hydrolysis of diphenylphosphates[53] with leaving groups of the same pK_a is consistent with the absence of any indication of uncatalyzed hydrolysis in the measurements. The fit to the data in the figure is for Equation 4–71 with $k_{im} = 2 \times 10^{-3}$ s^{-1}, pK_{a1} = 6.1, and pK_{a2} = 7.2 at 60 °C. Directly measured values of pK_{a1} and pK_{a2} are 6.2 and 7.8 at 25 °C. This behavior is consistent with encounter complex **4–29** preceding the transition state. In the transition state, the imidazolyl group on the leaving phenoxy group is an intramolecular general acid catalyst of the intramolecular nucleophilic substitution. The concentration of this encounter complex should reach a maximum at the maximum concentration of the zwitterionic species.

It is also possible to **design molecules so that an intramolecular general acid catalyst is brought into an encounter complex as a result of formation of a covalent complex from two separate reactants**. For example, the distorted bicyclic anilide **4–31**



(4–72)

participates in a nucleophilic substitution with thiols to produce the respective monocyclic thioester. When the thiol has been constructed so that it contains a general acid, such as an ammonium, properly positioned in its structure, it brings that general acid into the tetrahedral intermediate (Equation 4–72). If the acidic hydron is four atoms from the sulfur, a cyclic encounter complex can be formed (**4–32**), and the nucleophilic substitution at the acyl group is accelerated by intramolecular general acid catalysis resulting from hydronation of the leaving anilino nitrogen, which is incapable of leaving without being hydronated one way or another. A pendant ammonium (as shown in the equation), acting as the general acid, increases the rate of nucleophilic substitution by a factor of more than 5000; a pendent imidazolium, by a factor of more than 5000; and a pendant carboxylic acid, by a factor of more than 200,000.[54,55]

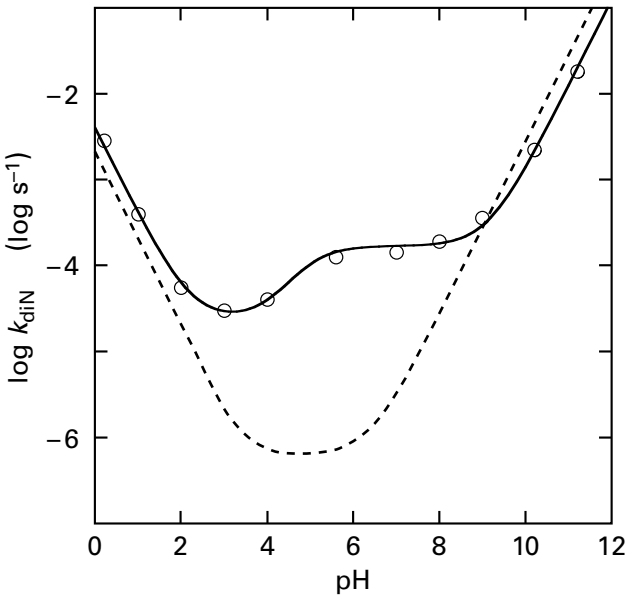


Figure 4–9: Intramolecular general acid catalysis by an ammonio group in the hydrolysis of a phosphodiester.[56] Solutions of either dinucleotide **4–33** (○; solid line) or its homologue in which the 2′-amino group is replaced with a methoxy group (dashed line) were prepared at an ionic strength of 0.1 M (maintained with NaCl) and 90 °C. The pH of the solutions was adjusted with hydrogen chloride or sodium hydroxide or buffered with formate, acetate, 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate, or glycine. Low concentrations of buffers were used, and no buffer catalysis was observed. The progress of the reaction was followed by separating the reactants and products chromatographically. The common logarithms of the pseudo-first-order rate constants, k_{diN} (second^{-1}), for the hydrolysis of each dinucleotide (diN) to produce either 2′-aminouridine or 2′-methoxyuridine, respectively, and 2′,3′-cyclic guanidylic acid (Equation 4–73) are plotted as a function of pH.

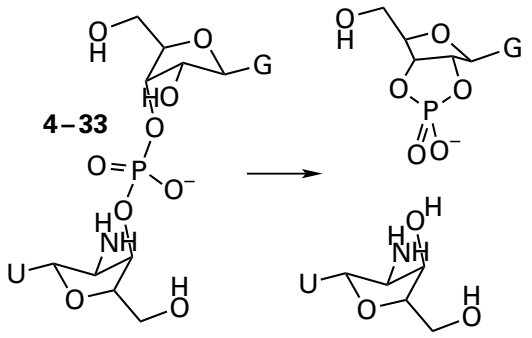
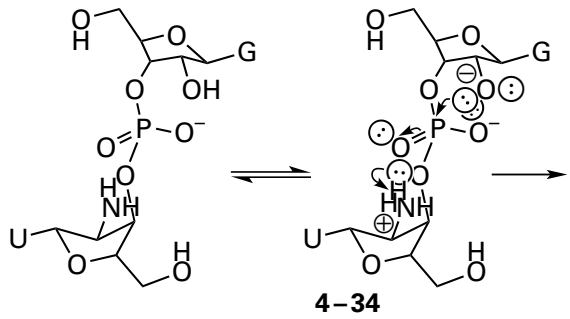
There are also many **examples of nonenzymatic intramolecular general base catalysis**. For example, the amino group in the pseudosymmetric dinucleotide **4–33,** where G is guanine and U is uracil, acts as a formal intramolecular general base catalyst for the intramolecular nucleophilic substitution that results in its cleavage



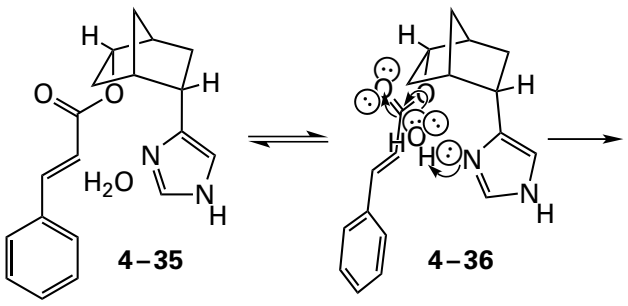
(4–73)

This conclusion follows from the fact that there is a plateau in the pH–rate profile that is not seen when the 2′-amino group is replaced with a methoxy group (Figure 4–9).[56] At values of pH greater than 9, the reaction displays specific base catalysis. Between pH 5 and 9, in the plateau, the reaction is invariant with pH because the amino group, which is unhydronated in this range of pH, is formally acting as an intramolecular general base catalyst. Below the pK_a for the amino group (pK_a = 5), the rate of the reaction decreases as the amino group becomes hydronated until specific acid catalysis takes over below pH 3. Formal intramolecular general base catalysis in this instance, however, actually results from intramolecular general acid catalysis of the reaction by the ammonio group in the tautomeric encounter complex **4–34**



(4–74)

The *endo*-imidazolyl group in norbornyl ester **4–35**, however, acts as an actual rather than a formal intramolecular general base catalyzing the hydrolysis of the ester[57]

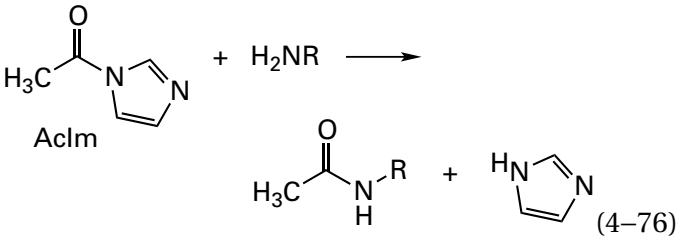


(4–75)

As the pH of the solution is decreased, the pH–rate profile for hydrolysis of norbornyl ester **4–35** displays a plateau consistent with a change in mechanism from specific base catalysis to intramolecular general base catalysis,[57] analogous to the behavior observed in Figure 4–9. Consistent with this conclusion that the imidazolyl group is acting as an internal general base is the observation that the exo isomer of norbornyl ester **4–35** displays no plateau. Encounter

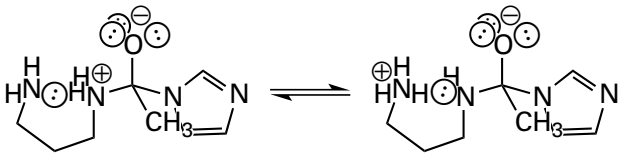
complex **4–36**, which is unavailable to the exo isomer, would be consistent with these observations. At values of pH less than the pK_a for the imidazolyl group, however, the reaction involving intramolecular general base catalysis is only 6 times faster than the reaction involving only specific base catalysis, so the plateau observed for the intramolecular nucleophilic substitution in dinucleotide **4–33** (Figure 4–9) has become simply an inflection in the pH rate profile for this hydrolysis.

An intramolecular general base catalyst can also be brought into an encounter complex as a result of formation **of a covalent complex** from two separate reactants. For example, the observed rate equation for the aminolysis of *N*-acetylimidazole, AcIm, by aliphatic amines, RNH_2



(4–76)

has a term, $k_B[RNH_2][AcIm]$, that is assumed to describe the attack of the unhydronated amine on the acyl carbon of unhydronated *N*-acetylimidazole.[58] The rate constant, k_B, for neutral unhydronated 1,3-diaminopropane is 75 times greater than the respective rate constant for neutral 1-aminopropane even though the conjugate monoacids of each compound have similar values (pK_a = 10.6 and 10.5, respectively) for their acid dissociation constants. This acceleration is believed to be due to the ability of the second amino group of 1,3-diaminopropane to remove intramolecularly a hydron from the tetrahedral intermediate



(4–77)

and thereby lock the distal nitrogen onto the acyl carbon. Intermolecular general base catalysis of the reaction between monoamines and *N*-acetylimidazole is also readily observed, and 1,3-diaminopropane participating as an intramolecular general base (Equation 4–77) is only as efficient as a 1 M concentration of a second molecule of 1-aminopropane acting as an unattached general base catalyst of its own aminolysis of *N*-acetylimidazole. Therefore, the entropy of approximation exerted in this reaction is not dramatic.

Another aspect of the entropy of approximation achieved by an enzymatic active site is that it should **enhance acid and base catalysis synergistically.** It has been observed that nonenzymatic intramolecular general acid–base reactions are more susceptible to intermolecular general acid–base catalysis in the same encounter complex than their entirely intermolecular counterparts. This observation and theoretical considerations suggest that the fewer degrees of freedom that are available to a transition state, the more susceptible it will be to catalysis by external general acids and general bases.[59]

Problem 4–1: The observed rate constants

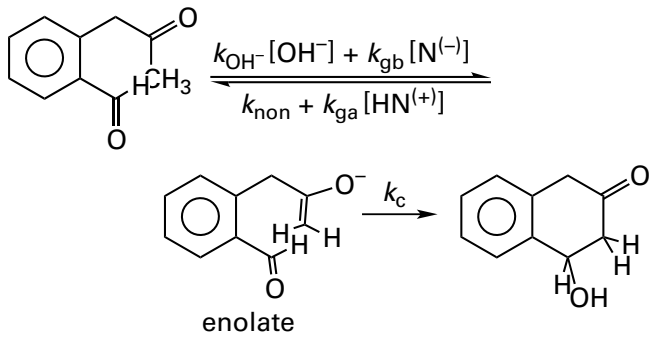
$$-\frac{d[\mathrm{GV}]}{dt} = k_{\mathrm{GV}}[\mathrm{GV}]$$

for hydrolysis of the amide between glycine and D-valine in *N*-(phenylacetyl)glycyl-D-valine (GV) at 37 °C as a function of pH, in the absence of added acid or base, are as follows.[60]

pH	k_{GV} (s^{-1})
0	1.0×10^{-6}
1	3.3×10^{-7}
3	1.3×10^{-9}
5	1.5×10^{-10}
7	2.7×10^{-11}
9	2.3×10^{-10}
11	9.9×10^{-10}
13	6.2×10^{-8}
14	2.4×10^{-6}

(A) Plot the common logarithms of the rate constants as a function of pH.
(B) Draw lines with slopes –1, 0, and +1 through the data.
(C) From these lines, estimate values for the rate constants k_{H^+}, k_{non}, and k_{OH^-}.
(D) Draw the most likely hydrogen-bonded encounter complexes immediately preceding the transition states for the three reactions governed by each rate constant in the form of **4–6**, **4–7**, and **4–8**.

Problem 4–2: Suppose that the kinetic mechanism for the following aldol condensation is[61]



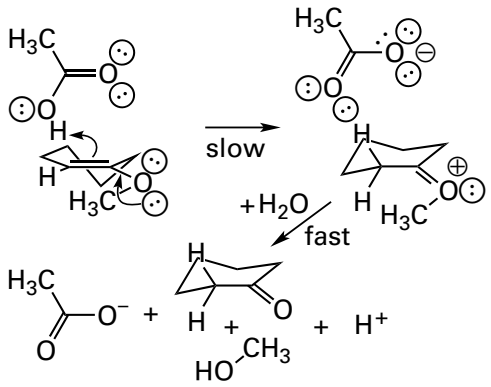
(A) Using the steady-state assumption that, during the course of measurement of the rate

$$\frac{d[\text{enolate}]}{dt} = 0$$

derive a rate equation for the reaction.

(B) What kinetic mechanism in Chapter 3 does this mechanism resemble closely?
(C) What type of behavior should the observed rate constant display as a function of the total concentration of buffer?

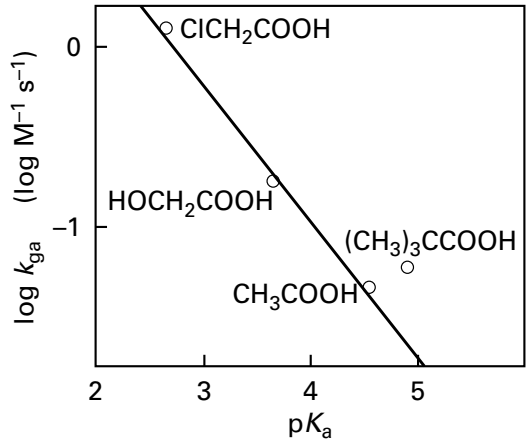
Problem 4–3: Hydrolysis of the methyl enol ether of cyclohexanone in water is catalyzed by general acids; the rate-limiting step is hydronation at the α position of the enol ether



The Brønsted plot of rate constants, k_{ga}, for general acid catalysis by carboxylic acids, where

$$-\frac{d[\text{enol ether}]}{dt} = \left(k_{pH} + k_{ga}[\text{RCOOH}] + k_{gb}[\text{RCOO}^-]\right)[\text{enol ether}]$$

is strictly linear, except for the deviation of pivalic acid, $(CH_3)_3CCOOH$[62]



Suggest a hypothesis to explain this deviation of pivalic acid. How could you test your hypothesis?*

*G. E. Lienhard, Department of Biochemistry, Dartmouth School of Medicine, formulated these problems.

Problem 4–4: The tautomerization of certain imines related to pyridoximines

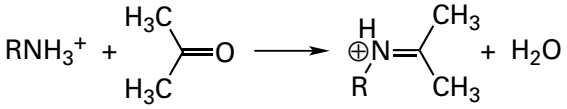
$$R_1R_2C{=}NCHR_3R_4 \longrightarrow R_1R_2CHN{=}CR_3R_4$$

is catalyzed by imidazole buffers.[63] This tautomerization (see Equation 2–22) is homologous with the tautomerization of a pyridoximine to an *N*-pyridoxylimine. There is a term, k_{gab}[Im][ImH$^+$][imine], in the rate equation where Im is the free base of imidazole and ImH$^+$ is the conjugate acid. Draw an encounter complex consistent with this term.*

Problem 4–5: The hydration of 1,3-dichloroacetone is catalyzed by imidazole buffers. The rate equation for the reaction contains a term, k_{gb}[Im]^2[H_2O][$ClCH_2COCH_2Cl$], where Im is the free base of imidazole. Write a mechanism consistent with this term that does not involve addition of imidazole to the carbonyl group of 1,3-dichloroacetone.*

Problem 4–6:

(A) Write a step-by-step mechanism for the following reaction.



Hydroxylamine reacts with the iminium cation to yield the hydroxamate very rapidly, but it reacts only very slowly with acetone. Therefore, it is possible to follow the rate at which the iminium cation is formed when acetone is mixed with various amines by discharging the iminium cation with hydroxylamine as it is formed. It has been shown that the reaction in the direction written, that of formation of the iminium cation, is catalyzed by general acids.

(B) Choose the step in your overall mechanism where a general acid would participate directly and draw a picture of the general acid, NH$^{(+)}$, donating its hydron to the lone pair on the intermediate compound present at that step. Remember, you are considering only the reaction proceeding from left to right. The reverse reaction, hydrolysis of the iminium cation, has been prevented by trapping the iminium cation as it is formed.

Rates at which each of several primary amines, RCH_2NH_2, react with acetone to form the iminium cation were determined at a series of pH values. In addition, values of pK_a for each amino nitrogen in each reactant were determined. With the respective pK_a, the amount of every form of a particular primary amine present at a given pH could be calculated, as well as the pK_a for a primary amino group in a diamine when the other amino group is either neutral or hydronated. From the behavior of the rate constants as a function of pH and a knowledge of the concentrations of the various hydronated species at each pH, the pH-independent rate constants (k_{imn}) for the reaction of each form of a given amine with acetone could be calculated.[64]

amine	pK_a	10^3 k_{imn} (M^{-1} s^{-1})
n-$C_4H_9NH_2$	10.33	94.7
$CH_3O(CH_2)_2NH_2$	9.09	15.8
$CH_3O(CH_2)_3NH_2$	9.82	47.8
$(CH_3)_3N^+(CH_2)_2NH_2$	6.7	0.9
$(CH_3)_2HN^+(CH_2)_2NH_2$	6.71	797
$(CH_3)_2N(CH_2)_2NH_2$	9.27	21
$(CH_3)_2HN^+(CH_2)_3NH_2$	8.50	108
$(CH_3)_2N(CH_2)_3NH_2$	9.75	51.5
$(CH_3)_2HN^+(CH_2)_4NH_2$	9.23	69.4
$(CH_3)_2N(CH_2)_4NH_2$	10.00	66.7
$(CH_3)_2HN^+(CH_2)_5NH_2$	10.06	159
$(CH3)_2N(CH_2)_5NH_2$	10.34	84.4
$(CH_3)_2HN^+CH_2C_5H_8NH_2$[a]	8.33	388
$(CH_3)_2NCH_2C_5H_8NH_2$[a]	9.61	19

[a]These are the tertiary hydronated and unhydronated forms of *trans*-2-[(dimethylamino)methyl]cyclopentylamine.

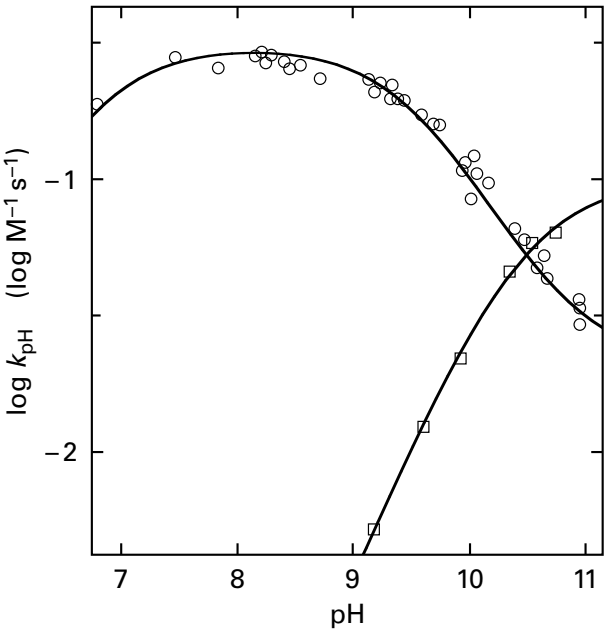
The second-order rate constant for the reaction between acetone and the particular primary amine is noted in the right-hand column. The pK_a listed in the table is for the conjugate acid of the amino group in each primary amine. The primary amine must be unhydronated to add to the ketone, but a diamine can be hydronated or unhydronated at the other nitrogen.

(C) Make a Brønsted plot of all the experimental results. Draw a line through values for all the neutral compounds and the only quaternary ammonium cation, and determine the slope of the line.

All the cationic compounds, except the quaternary ammonium, deviate in their behavior from that expected from the values of pK_a for their primary amino groups.

(D) Explain this deviation in terms of intramolecular general acid catalysis in formation of the iminium cation by drawing several structures, one for each cationic primary amine, that explicitly incorporate this catalytic step and that show the hydron transfer unambiguously.

(E) Explain the two pH–rate profiles displayed in the following figure.[64] First explain the behavior of *n*-butylamine, and then provide a detailed explanation of the increase in rate, followed by the plateau, followed by the decrease in the curve for 2-(dimethylamino)ethylamine as the pH is decreased.



Plot of log (k_{pH}) against pH for formation of the iminium from acetone and either 2-(dimethylamino)ethylamine (○) or *n*-butylamine (□). The rate constant k_{pH} is the observed second-order rate constant at a given pH for formation of the iminium based on the total concentration of primary amine in all forms.

The difference in standard free energy of activation between two reactions is related to the rate constants by

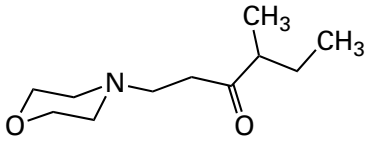
$$\Delta\Delta G^{\circ\ddagger} = -RT\ln(k_1/k_2)$$

(F) Use k_{imn}, the rate of reaction of 5-(*N*,*N*-dimethylammonium)pentylamine, $Me_2N^+H(CH_2)_5NH_2$, as the example of the reaction showing the least intramolecular general acid catalysis. With the Brønsted relation, correct the rate constants of all the other reactions showing intramolecular general acid catalysis for the differences in values of pK_a for their primary amino groups from that of $(CH_3)_2N^+H(CH_2)_5NH_2$ so that they can be compared directly to the rate constant for $(CH_3)_2N^+H(CH_2)_5NH_2$. Calculate $\Delta\Delta^{\ddagger}G^{\circ}_{corr}$ for each corrected value relative to $(CH_3)_2N^+H(CH_2)_5NH_2$. Assume that entropy of approximation is responsible for all this corrected difference in free energy of activation, $\Delta\Delta^{\ddagger}G^{\circ}_{corr} = -T\Delta\Delta^{\ddagger}S^{\circ}_{approx}$, and determine $\Delta\Delta^{\ddagger}S^{\circ}_{approx}$ for $(CH_3)_2N^+H(CH_2)_5NH_2$, $(CH_3)_2N^+H(CH_2)_4NH_2$, $(CH_3)_2N^+H(CH_2)_3NH_2$, *trans*-$(CH_3)_2HN^+CH_2C_5H_8NH_2$, and $(CH_3)_2N^+H(CH_2)_2NH_2$.

(G) Comment on the trend in $\Delta\Delta^{\ddagger}S^{\circ}_{approx}$.

Problem 4–7: Write a mechanism for the enolization of 2-oxo-3-methylpentane to 2-hydroxy-3-methyl-2-pentene.

The rate equation for enolization of the amino-ketone



contains the term $k_{OH^-}[OH^-][^+HNKet]$.[65] Explain this term as the result of intramolecular general acid catalysis.

Enzymatic pH–Rate Profiles

Rates of most enzymatic reactions are functions of pH. The effects of pH on the activity of an enzyme, measured in the standard assay used to purify the enzyme, are theoretically meaningless, and the pH–activity relations that are often encountered have only practical value.[66] If, however, the **effects of pH on underlying parameters that govern the initial rate** for an enzymatic reaction—namely, the catalytic constant and the specificity constants—are assessed, the observed behavior is often informative.

In such experiments, the pH is usually established and maintained by using a buffer. There are two problems that can lead to **artifacts caused by buffers**.[67] First, as the pH is altered, the ionic strength contributed by the buffer changes. To avoid effects of **variation in ionic strength**, a neutral electrolyte, such as potassium chloride, is usually added to maintain a constant ionic strength. It is also possible to use a mix of ionic buffers that both buffer the pH over a large range and maintain ionic strength at the same time.[68] Second, either the conjugate acid or the conjugate base of the buffer chosen to maintain the pH or the neutral electrolyte chosen to maintain the ionic strength can be **inhibitors or activators** of the enzyme. Consequently, the concentrations of the buffer and of the electrolyte are varied independently at constant pH to make sure that they have no effect on enzymatic activity.[69] Often different buffers overlapping each other in the pH ranges examined are used to check whether or not the enzymatic activities are the same at the same pH when it is maintained with different buffers.

A simple example of the effect of pH on one of the steady-state rate constants is a situation in which the **catalytic constant** for the enzymatic reaction **decreases as the pH is decreased** (Figure 4–10A).[70] In such a situation, the decrease in the catalytic constant usually fits the equation for titration of a catalytic base.[71-73] The fraction of any monoprotic acid–base OH that is in the form of its conjugate base, $\alpha(\odot O^{(-)})$, is defined by the relation

$$\alpha\left(\odot O^{(-)}\right) = \frac{\left[\odot O^{(-)}\right]}{\left[OH\right]_t} = \frac{K_{aOH}}{[H^+] + K_{aOH}} \tag{4–78}$$

where $[\odot O^{(-)}]$ is the concentration of the conjugate base, $[OH]_t$ is the total concentration of the acid–base in both forms, and K_{aOH} is its acid dissociation constant. The behavior of the observed catalytic constant, $k_{0,app}$, of triose-phosphate isomerase (Equation 4–46) from *Gallus gallus* as a function of pH (Figure 4–10A) when glycerone phosphate is the reactant can be described by the function

$$k_{0,app} = k_0\left(\frac{K_a}{[H^+] + K_a}\right) \tag{4–79}$$

where k_0 is the value for the observed catalytic constant where it is invariant with pH and it is at its maximum value, and K_a is an acid dissociation constant. From the fit of the equation to the data (curve in Figure 4–10A), $pK_a = 6.0$ and $k_0 = 480\ s^{-1}$.

It is usually more informative, however, to present the **common logarithm of a rate constant as a function of pH** (Figure 4–10B).[74] This convention allows the behavior of the rate constant to be examined over a larger range of pH and reveals whether or not titration of additional acid–bases might be governing the rate constant. Taking the common logarithms of the terms in Equation 4–79

$$\log k_{0,app} = \log k_0 + \log\left(\frac{K_a}{[H^+] + K_a}\right) \tag{4–80}$$

When $pH < pK_a$ so that $[H^+] > K_a$

$$\log k_{0,app} \cong \log k_0 - pK_a + pH \tag{4–81}$$

(dashed line in Figure 4–10B with slope +1), and when $pH > pK_a$ so that $[H^+] < K_a$

$$\log k_{0,app} \cong \log k_0 \tag{4–82}$$

(dashed line in Figure 4–10B with slope 0). The **two asymptotes intersect when pH = pK_a.** Within the range in which observations were made, the behavior of the observed catalytic constant of choline oxidase from *Arthrobacter globiformis* can be fit with Equation 4–80 (curve in Figure 4–10B) and the parameters $pK_a = 6.5$ and $k_0 = 18\ s^{-1}$.

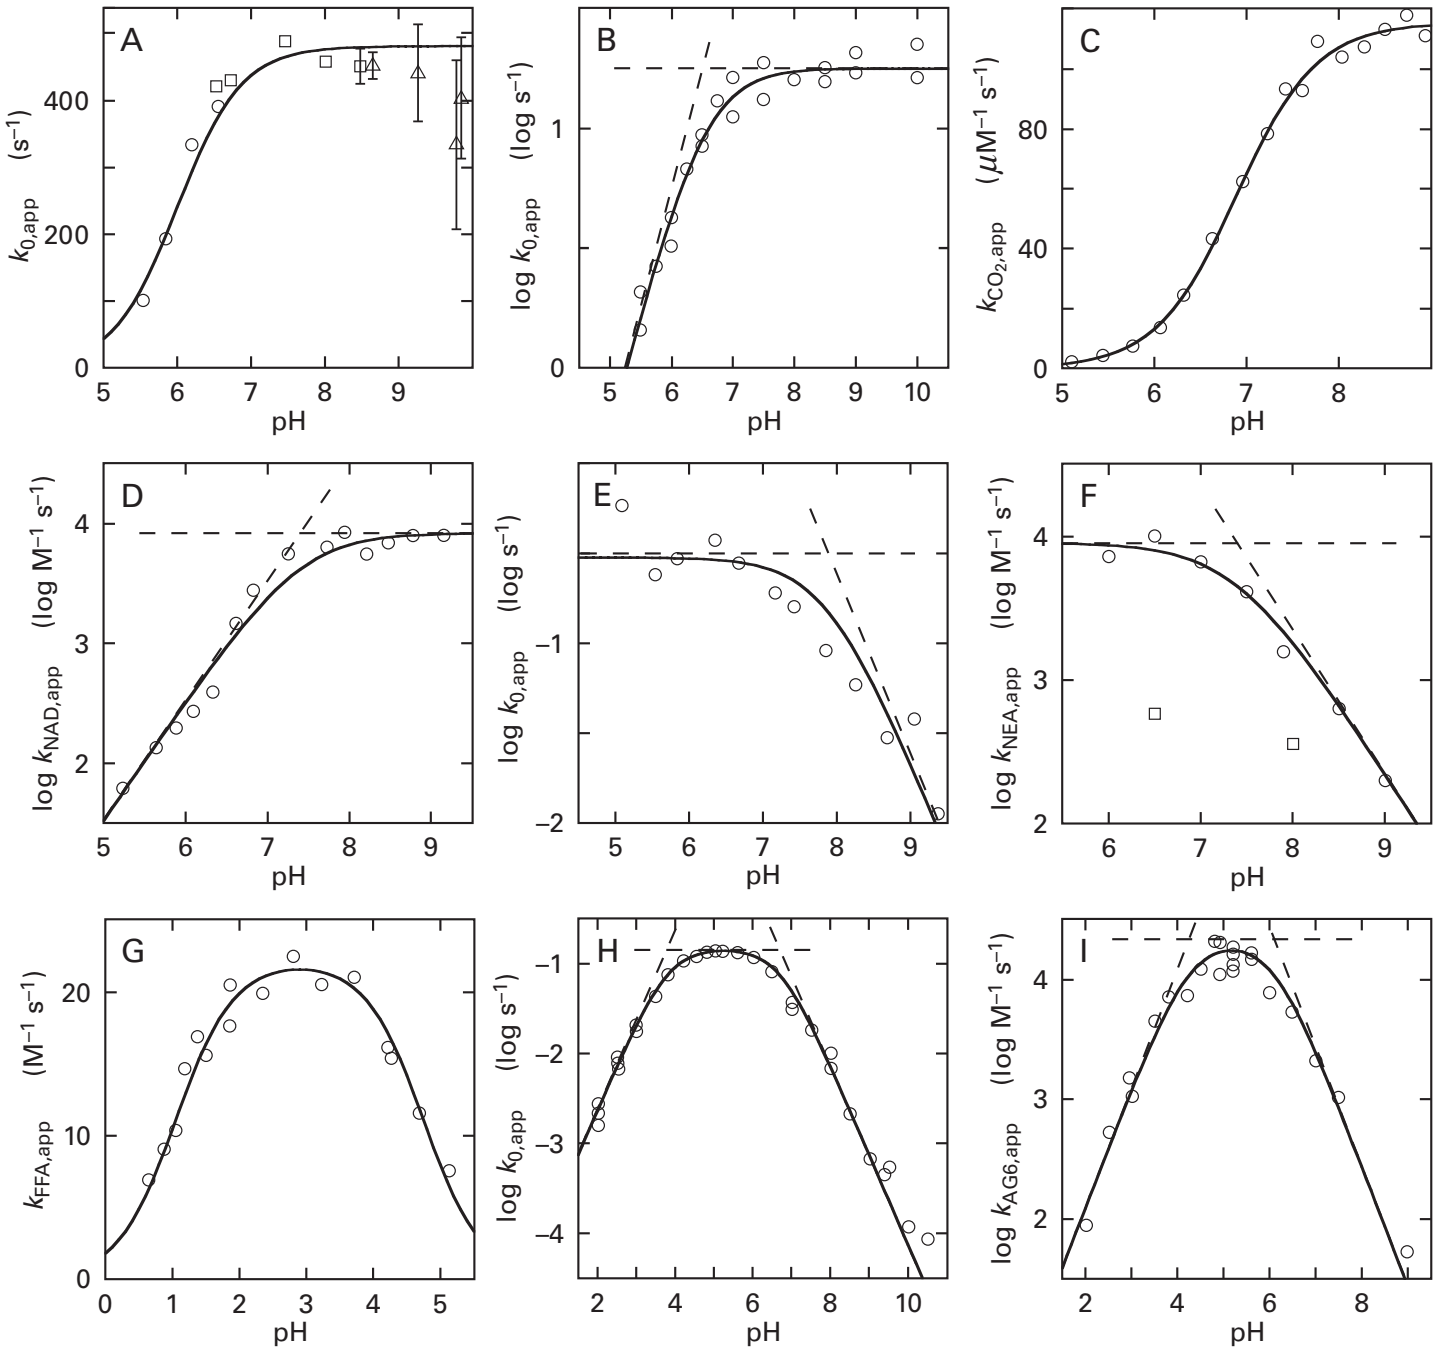


Figure 4–10: pH–Rate profiles for catalytic constants and specificity constants. (**A**) pH–Rate profile for the catalytic constant of triose-phosphate isomerase from *G. gallus* for glycerone phosphate at an ionic strength of 0.1 M and 30 °C.[70] The pH was buffered with 3,3-dimethylglutarate (○), triethanolamine (□), or carbonate (△). The observed catalytic constants, $k_{0,app}$ (second^{-1}), are plotted as a function of pH. (**B**) pH–Rate profile for the catalytic constant of choline oxidase from *A. globiformis* for choline at 25 °C.[74] The pH was buffered with 50 mM potassium phosphate between pH 6 and 8 and with 50 mM sodium phosphate between pH 5 and 6 and between pH 8 and 10. The common logarithms of the observed catalytic constants, $k_{0,app}$ (second^{-1}), are plotted as a function of pH. (**C**) pH–Rate profile for the steady-state specificity constant, k_{CO_2}, of human carbonic anhydrase 2 for CO_2 at an ionic strength of 0.2 M and 25 °C.[75] The pH was buffered only by the enzyme and the substrates. The observed steady-state rate constants, $k_{CO_2,app}$ (micromolar^{-1} oxidase from *F. oxysporum*, in which Aspartate 402 has been changed to a glutamate, for nitroethane anion (NEA) at 30 °C.[78] The pH was maintained by 0.5 M 2-(*N*-morpholino)-ethanesulfonate from pH 6 to 6.5, 0.5 M 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate from pH 7 to 8.1, and 0.5 M 2-amino-2-(hydroxymethyl)propane-1,3-diol from pH 7.9 to 9. The common logarithms of the observed steady-state specificity constants, $k_{NEA,app}$ (molar^{-1} second^{-1}), are plotted as a function of pH. The unassociated data points (□) are for a mutant of the enzyme in which Aspartate 402 has been mutated to alanine. (**G**) pH–Rate profile for the steady-state specificity constant, k_{FFA}, of porcine pepsin for *N*-acetyl-L-phenylalanyl-L-phenylalanine amide (FFA) at 37 °C.[79] The pH and the ionic strength were established by buffers of 0.1 M sodium citrate. The observed steady-state specificity constants, $k_{FFA,app}$ (molar^{-1} second^{-1}), are plotted as a function of pH. (**H**) pH–Rate profile for the catalytic constant of lysozyme from *G. gallus* for (β1,4)-hexa-*N*-acetyl-

second^{-1}), are plotted as a function of pH. (**D**) pH–Rate profile for the steady-state specificity constant, k_{NAD}, of saccharopine dehydrogenase (NAD$^+$, L-lysine-forming) from *S. cerevisiae* for NAD$^+$ at 25 °C.[76] The pH was maintained by using the following buffers at ≥100 mM concentration: 2-(*N*-morpholino)ethanesulfonate from pH 5.5 to 6.8, 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate from pH 6.8 to 8.2 and 2-(cyclohexylamino)ethanesulfonate from pH 8.2 to 10.0. The common logarithms of the observed steady-state specificity constants, $k_{NAD,app}$ (molar^{-1} second^{-1}), are plotted as a function of pH. (**E**) pH–Rate profile for the catalytic constant of human hypoxanthine phosphoribosyltransferase for inosine monophosphate and diphosphate at 23 °C.[77] A mixed buffer consisting of 30 mM 2-(*N*-morpholino)ethanesulfonate, 30 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol, and 30 mM glycine was adjusted to the noted pH with either HCl or NaOH. The common logarithms of the observed catalytic constants, $k_{0,app}$ (second^{-1}), are plotted as a function of pH. (**F**) pH–Rate profile for the steady-state specificity constant, k_{NEA}, of a mutant of nitroethane glucosaminopyranose at an ionic strength of 0.1 M and 40 °C.[80] The pH was controlled in the range 3–9 with 0.01 M sodium acetate, phosphate, or carbonate. No buffer was used below pH 3. The common logarithms of the observed catalytic constants, $k_{0,app}$ (second^{-1}), are plotted as a function of pH. (**I**) pH–Rate profile for the steady-state specificity constants, k_{AG6}, of lysozyme from *G. gallus* for (β1,4)-hexa-*N*-acetylglucosaminopyranose (AG6) from the same kinetic measurements used to obtain the catalytic constants of Panel H.[80] The common logarithms of the steady-state specificity constants, $k_{AG6,app}$ (molar^{-1} second^{-1}), are plotted as a function of pH. In each panel in which common logarithms are plotted, dashed lines of slope +1 or −1 or both are included as asymptotes to the curves that are fit to the data below or above, respectively, or both below and above the values of pK_a indicated by the results. Dashed lines of slope 0 are placed in the same panels at values for the pH-independent catalytic constants, k_0, or steady-state specificity constants.

The **specificity constant** k_A for reactant A* can also **decrease as the pH decreases**. For example, the observed behavior (Figure 4–10C)[75] of the specificity constant for CO_2, $k_{CO_2,app}$, for human carbonic anhydrase 2 (previously Equation 3–445)

$$CO_2 + H_2O \rightleftharpoons HCO_3^- + H^+ \tag{4–83}$$

can be fit (curve in Figure 4–10C) with the equation

$$k_{CO_2,app} = k_{CO_2}\left(\frac{K_a}{[H^+] + K_a}\right) \tag{4–84}$$

and the parameters pK_a = 6.9 and k_{CO_2} = 116 μM^{-1} s^{-1}. The observed behavior (Figure 4–10D)[76] of the common logarithm of the specificity constant for NAD$^+$, $k_{NAD,app}$, in the reaction catalyzed by saccharopine dehydrogenase (NAD$^+$, L-lysine-forming)

$$\begin{aligned}&NAD^+ + N^6\text{-(L-1,3-dicarboxypropyl)-L-lysine} + H_2O\\ &\rightleftharpoons H^+ + \text{2-oxoglutarate} + \text{L-lysine} + NADH\end{aligned} \tag{4–85}$$

from *S. cerevisiae* can be fit (curve in Figure 4–10D) with the equation

$$\log k_{NAD,app} = \log k_{NAD} + \log\left(\frac{K_a}{[H^+] + K_a}\right) \tag{4–86}$$

and the parameters pK_a = 7.4 and k_{NAD} = 8.4 mM^{-1} s^{-1}.

The **catalytic constant** for an enzymatic reaction can **decrease as the pH is increased**. In this situation, the decrease in the catalytic constant as a function of pH usually fits the equation for titration of an acid.[71-73] The fraction of a monoprotic acid–base NH that is in the form of its conjugate acid, $\alpha(NH^{(+)})$, is defined by the relation

$$\alpha(NH^{(+)}) = \frac{[NH^{(+)}]}{[NH]_t} = \frac{[H^+]}{[H^+] + K_{aNH}} \tag{4–87}$$

where $[NH^{(+)}]$ is the concentration of the conjugate acid, $[NH]_t$ is the total concentration of the acid–base in both forms, and K_{aNH} is its acid dissociation constant. The behavior (Figure 4–10E)[77] of the observed catalytic constant, $k_{0,app}$, of human hypoxanthine phosphoribosyltransferase (previously Equation 3–251)

$$\begin{aligned}&\text{magnesium 5-phospho-}\alpha\text{-D-ribose 1-diphosphate}\\ &+ \text{hypoxanthine} \rightleftharpoons \text{magnesium diphosphate}\\ &+ \text{inosine 5′-phosphate}\end{aligned} \tag{4–88}$$

with hypoxanthine as a reactant can be fit (curve in Figure 4–10E) with the function

*In most publications, alternatives for the specificity constant, the limiting rate divided by the Michaelis constant ($V K_m^{-1}$) or the catalytic constant divided by the Michaelis constant ($k_0 K_m^{-1}$), are commonly used. The latter is the specificity constant.

$$\log k_{0,app} = \log k_0 + \log\left(\frac{[H^+]}{[H^+] + K_a}\right) \quad (4–89)$$

and the parameters $pK_a = 7.9$ and $k_0 = 0.32\ s^{-1}$. When $pH < pK_a$ so that $[H^+] > K_a$

$$\log k_{0,app} \cong \log k_0 + pK_a - pH \quad (4–90)$$

(dashed line in Figure 4–10E with slope of 0) and when $pH > pK_a$ so that $[H^+] < K_a$

$$\log k_{0,app} \cong \log k_0 + pK_a - pH \quad (4–91)$$

(dashed line in Figure 4–10E with slope of –1). The two asymptotes intersect when $pH = pK_a$.

The **specificity constant** k_A for reactant A can also **decrease as the pH is increased**. For example, the observed behavior (Figure 4–10F)[78] of the specificity constant $k_{NEA,app}$ for nitroethane anion (NEA) in the reaction catalyzed by a mutant of nitroalkane oxidase

$$\text{nitroethane} + H_2O + O_2 \rightleftharpoons H^+ + \text{nitrite} + \text{acetaldehyde} + H_2O_2 \quad (4–92)$$

from *Fusarium oxysporum*, in which Aspartate 402 has been changed to glutamate, can be fit (curve in Figure 4–10F) with the function

$$\log k_{NEA,app} = \log k_{NEA} + \log\left(\frac{[H^+]}{[H^+] + K_a}\right) \quad (4–93)$$

and the parameters $pK_a = 7.4$ and $k_{NEA} = 9\ mM^{-1}\ s^{-1}$.

In many instances, either the catalytic constant or one or more of the specificity constants **decrease from a maximum both as the pH is decreased and as the pH is increased** (Figure 4–10G).[79] In the simplest case, the behavior is that expected for a reaction that requires an acid–base HN to be in the form of its conjugate acid $HN^{(+)}$ and an acid–base OH to be in the form of its conjugate base $⊙O^{(–)}$.

Define a species $X(HN^{(+)},⊙O^{(–)})$ in which acid–base NH is present only as its conjugate acid, $HN^{(+)}$, and acid–base OH is present only as its conjugate base, $⊙O^{(–)}$. If acid–bases HN and OH titrate independently of each other, it follows from Equations 4–78 and 4–87 that the fraction, $\alpha(HN^{(+)},⊙O^{(–)})$, of the total concentration of X, $[X]_t$, in all four tautomers and states of ionization, that is the tautomer $X(HN^{(+)},⊙O^{(–)})$

$$\alpha\left(HN^{(+)},⊙O^{(–)}\right) = \frac{\left[X\left(HN^{(+)},⊙O^{(–)}\right)\right]}{[X]_t} = \alpha\left(HN^{(+)}\right)\alpha\left(⊙O^{(–)}\right) = \left(\frac{[H^+]}{[H^+] + K_{aNH}}\right)\left(\frac{K_{aOH}}{[H^+] + K_{aOH}}\right) \quad (4–94)$$

where pK_{aNH} is the pK_a of acid–base NH and pK_{aOH} is the pK_a of acid–base OH.

The behavior of the observed specificity constant $k_{FFA,app}$ as a function of pH for the peptide *N*-acetyl-L-phenylalanyl-L-phenylalanine amide (FFA) when it is hydrolyzed by porcine pepsin A, an endopeptidase active at low pH, can be fit (curve in Figure 4–10G) with the function

$$k_{FFA,app} = k_{FFA}\left(\frac{K_{a1}}{[H^+] + K_{a1}}\right)\left(\frac{[H^+]}{[H^+] + K_{a2}}\right) \quad (4–95)$$

and the parameters $pK_{a1} = 1.05$, $pK_{a2} = 4.75$, and $k_{FFA} = 22\ M^{-1}\ s^{-1}$.* The observed behavior (Figure 4–10H)[80] of the catalytic constant $k_{0,app}$ for hydrolysis of (β1,4)-hexa-*N*-acetylglucosaminopyranose (Figure 3–27) by lysozyme from *G. gallus* displays behavior as a function of pH that can be fit (curve in Figure 4–10H) with the function

$$\log k_{0,app} = \log k_0 + \log\left\{\left(\frac{K_{a1}}{[H^+] + K_{a1}}\right)\left(\frac{[H^+]}{[H^+] + K_{a2}}\right)\right\} \quad (4–96)$$

and the parameters $pK_{a1} = 3.8$, $pK_{a2} = 6.7$, and $k_0 = 0.15\ s^{-1}$. Its observed specificity constant $k_{AG6,app}$ for the reactant (β1,4)-hexa-*N*-acetylglucosaminopyranose (AG6) displays behavior (Figure 4–10I)[80] as a function of pH that can be fit (curve in Figure 4–10I) with the function

*It is the accepted convention to distinguish observed values of pK_a by numerical subscripts that increase in number as the observed values of pK_a increase in magnitude.

$$\log k_{AG6,app} = \log k_{AG6} + \log\left\{\left(\frac{K_{a3}}{[H^+] + K_{a3}}\right)\left(\frac{[H^+]}{[H^+] + K_{a4}}\right)\right\} \quad (4–97)$$

and the parameters $pK_{a3} = 4.25$, $pK_{a4} = 6.1$, and $k_{AG6} = 22\ mM^{-1}\ s^{-1}$.

When an **enzyme has two or more reactants**, the pH–rate profile for each specificity constant is usually measured by varying the reactant for the specificity constant at a particular pH to discover the specificity constant for that pH and then repeating the observations at the next pH. All these measurements are made at saturating concentrations of the other reactants. When there are two or more reactants, **each specificity constant will often have its own particular** pH–rate **profile** with its own particular values of pK_a below or above which it decreases. For example, the specificity constant $k_{ch,app}$ for choline (ch) in the reaction of choline oxidase

$$\text{choline} + 2\,O_2 + H_2O \rightleftharpoons \text{betaine} + 2\,H_2O_2 \quad (4–98)$$

from *A. globiformis*[74] decreases below a pK_a of 7.3 when the pH is lowered, but the specificity constant k_{O_2} for molecular oxygen (O_2) is invariant with pH from pH 6 to 10.

For equations of the form

$$\log k_{i,app} = \log k_i + \log\left(\frac{K_{a1}[H^+]}{[H^+]^2 + (K_{a1} + K_{a2})[H^+] + K_{a1}K_{a2}}\right) \quad (4–99)$$

as are Equations 4–96 and 4–97, when $[H^+]^2 > (K_{a1} + K_{a2})^2 > K_{a1}K_{a2}$

$$\log k_{i,app} \cong \log k_i - pK_{a1} + pH \quad (4–100)$$

(dashed line in Figure 4–10H with slope of +1), and when $[H^+] < K_{a1}K_{a2}\,(K_{a1} + K_{a2})^{-1}$

$$\log k_{i,app} \cong \log k_i + pK_{a2} - pH \quad (4–101)$$

(dashed line in Figure 4–10H with slope of –1). If $K_{a1} > K_{a2}$ and the inequalities $K_{a1} + K_{a2} > [H^+] > K_{a1}K_{a2}\,(K_{a1} + K_{a2})^{-1}$ hold over a range of pH, then there is a plateau at the maximum of the curve, as in Figures 4–10G and 4–10H, and

$$\log k_{i,app} \cong \log k_i \quad (4–102)$$

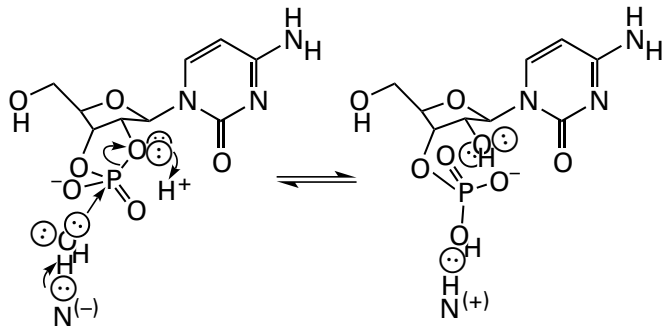
(dashed line in Figure 4–10H with slope of 0). For all values of K_{a1} and K_{a2}, however, the intersection of the lines defined by Equations 4–100 (the line of slope +1) and 4–101 (the line of slope –1) occurs at

$$pH = \frac{pK_{a1} + pK_{a2}}{2} \quad (4–103)$$

which is the **mean of the two values of pK_a.** The maximum value for $\log k_{i,app}$ also occurs when the pH is the mean of the two values of pK_a, a fact that can be verified by setting the derivative of the function in Equation 4–99 at 0.

When values of pK_a are within less than one unit of each other, the two values of pK_a are less well-defined by fitting the data to the appropriate equation. Regardless of how well these values are defined, however, their mean (Equation 4–103) is always well-defined by the intersection of the lines of slope +1 (Equation 4–100) and slope –1 (Equation 4–101).

It can also be observed that when the common logarithm of a steady-state rate constant is plotted as a function of pH, one or both of the lines describing a decrease in the common logarithm of the rate constant as a function of pH, either as the pH is lowered or as it is raised, can have a **slope of +2 or –2** rather than +1 or –1, respectively. For example, when the common logarithm of the specificity constant $k_{cCP,app}$ for hydrolysis of cytidine 2′,3′-cyclic phosphate (cCP) catalyzed by bovine pancreatic ribonuclease



(4–104)

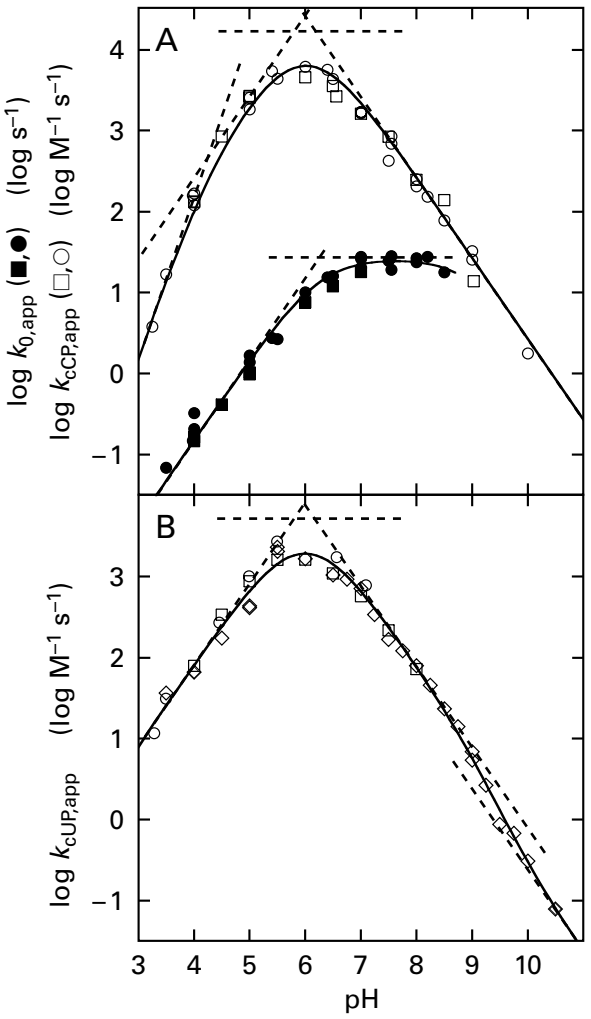


Figure 4–11: pH–Rate profiles for the hydrolyses of 2′,3′-cyclic nucleotide phosphates catalyzed by bovine pancreatic ribonuclease.[84] (**A**) pH–Rate profiles for the steady-state rate constants k_{cCP} (○, □) and the catalytic constant k_0 (●, ■) of bovine pancreatic ribonuclease for cytidine 2′,3′-cyclic phosphate at an ionic strength of 0.2 M and 25 °C. Rate constants were obtained by Eftink and Biltonen[81] (○, ●) with a spectrophotometric assay, a manual calorimetric assay, and a continuous gradient calorimetric assay in solutions buffered with sodium acetate, sodium cacodylate, imidazolium chloride, 2-ammonio-2-(hydroxymethyl)propane-1,3-diol chloride, or sodium glycinate. Rate constants were obtained by Herries, Mathias, and Rabin[84] (□, ■) with both a pH-stat and a spectrophotometric assay in solutions buffered with sodium formate, sodium acetate, sodium malonate, disodium 3,3-dicarboxypentane, imidazolium chloride, *N*-ethylmorpholinium chloride, or sodium borate. In both cases, the steady-state rate constants k_{cCP} and the catalytic constants were derived for each value of pH from the initial rates at several concentrations of cytidine 2′,3′-cyclic phosphate. The common logarithms of the observed steady-state rate constants, $k_{cCP,app}$ (molar^{-1} second^{-1}), and the common logarithms of the observed catalytic constants, $k_{0,app}$ (second^{-1}), respectively, are plotted as a function of pH. Dashed lines of slope +2 and +1 or of slope +1 and −1 are included as asymptotes to the curves that are fit to the data below and above the values of pK_a indicated by the results. Dashed lines of slope 0 are placed at values for the pH-independent steady-state rate constant k_{cCP} (17 mM^{-1} s^{-1}) and catalytic constant k_0 (27 s^{-1}). (**B**) pH–Rate profile for the steady-state rate constants k_{cUP} of pancreatic ribonuclease for uridine 2′,3′-cyclic phosphate at an ionic strength of 0.2 M and 25 °C. Rate constants were obtained by Eftink and Biltonen[81] (○) as described in Panel A. Rate constants were obtained by del Rosario and Hammes[82] (□) with a spectrophotometric assay in solutions buffered with 2-ammonio-2-(hydroxymethyl)propane-1,3-diol acetate. Rate constants were obtained by Machuga and Klapper[83] (◊) with a spectrophotometric assay in solutions buffered with sodium citrate (3.5–4.0), sodium acetate (4.0–6.0), 2-ammonio-2-(hydroxymethyl)propane-1,3-diol cacodylate (5.0–9.0), or sodium glycinate (8.75–10.0). In all cases, the steady-state rate constants k_{cUP} and the catalytic constants were derived for each value of pH from the initial rates at several concentrations of cytidine 2′,3′-cyclic phosphate. The common logarithms of the observed steady-state rate constants, $k_{cUP,app}$ (molar^{-1} second^{-1}), are plotted as a function of pH. A dashed line of slope +1 and two dashed lines of slope −1 are included as asymptotes to the curves that are fit to the data below and above the values of pK_a indicated by the results. A dashed line of slope 0 is placed at the value for the pH-independent steady-state rate constant k_{cUP} (4.5 mM^{-1} s^{-1}).

is plotted as a function of pH, its decrease at high pH defines a line of slope −1, but its decrease at low pH defines a line of slope +1 that becomes a line of slope +2 below pH 4 (Figure 4–11A).[81-84]

This behavior is that expected of a system in which there are three acid–bases involved in the reaction, NH, OH, and SH, and **the tautomer of the system** X(HN$^{(+)}$,⊙O$^{(-)}$,⊙S$^{(-)}$) is the only active species. This tautomer is the one with monoprotic acid–base HN as its conjugate acid, HN$^{(+)}$; monoprotic acid–base HO as its conjugate base, ⊙O$^{(-)}$; and monoprotic acid–base HS as its conjugate base, ⊙S$^{(-)}$. By extension, in such a situation, if each acid–base titrates independently of the other

$$\alpha\left(HN^{(+)},\odot O^{(-)},\odot S^{(-)}\right) = \left(\frac{[H^+]}{[H^+]+K_{aNH}}\right)\left(\frac{K_{aOH}}{[H^+]+K_{aOH}}\right)\left(\frac{K_{aSH}}{[H^+]+K_{aSH}}\right) \quad (4\text{–}105)$$

where pK_{aSH} is the pK_a for acid–base SH. For bovine pancreatic ribonuclease hydrolyzing cytidine 2′,3′-cyclic phosphate

$$\log k_{cCP,app} = \log k_{cCP} + \log\left\{\left(\frac{K_{a1}}{[H^+]+K_{a1}}\right)\left(\frac{K_{a2}}{[H^+]+K_{a2}}\right)\left(\frac{[H^+]}{[H^+]+K_{a3}}\right)\right\} \quad (4\text{–}106)$$

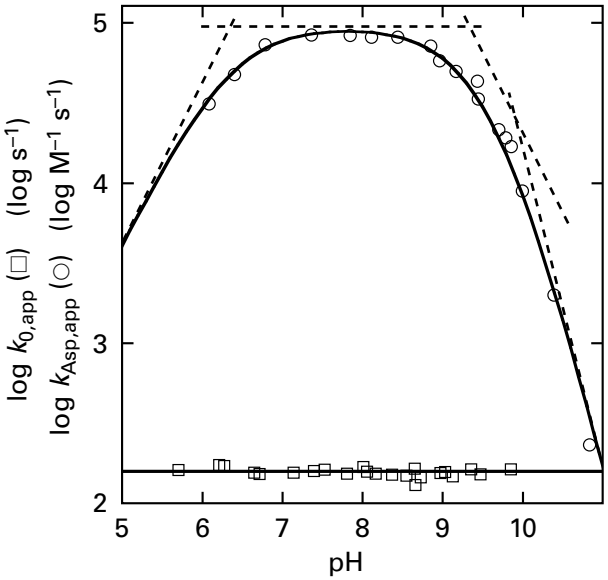

Figure 4–12: pH–Rate profiles for the transamination of aspartate catalyzed by aspartate transaminase.[85] Solutions of L-aspartate and 2-oxoglutarate at various concentrations were prepared at values of pH buffered with 1,4-bis(2-hydroxyethyl)piperazine, 2-(*N*-morpholino)ethanesulfonate, 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate, 3-[[tris(hydroxymethyl)methylamino]-propane-1-sulfonate, 2-(cyclohexylamino)ethanesulfonate, or 3-(cyclohexylamino)propane-1-sulfonate and 25 °C. The reaction was initiated by adding enzyme, and the initial rates were monitored by coupling the production of oxaloacetate to the oxidation of NADH (decrease in A_{340}) with malate dehydrogenase. From the set of initial rates at a given pH as a function of the concentrations of both L-aspartate and 2-oxoglutarate and from a knowledge of the molar concentration of the enzyme, values of the catalytic constant and the specificity constant, k_{Asp}, for L-aspartate could be ascertained. The common logarithms for the observed values of the apparent specificity constant for aspartate, $k_{Asp,app}$ (○, molar^{-1} second^{-1}), are plotted as a function of pH, and the common logarithms of the observed values for the apparent catalytic constant, $k_{0,app}$ (□, second^{-1}), are plotted as a function of pH. The dashed lines are the asymptotes of the curve fit to the data (Equation 4–109) for common logarithms of the observed values for the apparent specificity constants for aspartate, $k_{Asp,app}$, below pK_{a1} (slope +1), between pK_{a1} and pK_{a2} (slope 0), between pK_{a2} and pK_{a3} (slope –1), and above pK_{a3} (slope –2).

When pH < pK_{a1} < pK_{a2} < pK_{a3}

$$\log k_{cCP,app} \cong \log k_{cCP} - pK_{a1} - pK_{a2} + 2\,pH \tag{4–107}$$

which defines a line of slope +2. The line of slope +1 intersects the line of slope +2 when pH = pK_{a1}. The curve fit to the data for $k_{cCP,app}$ (Figure 4–11A) has pK_{a1} = 4.2, pK_{a2} = 5.8, pK_{a3} = 6.2, and k_{cCP} = 17 mM^{-1} s^{-1}.

In the case of porcine aspartate transaminase (previously Equation 2–29)

L-aspartate + 2-oxoglutarate
$\rightleftharpoons$ oxaloacetate + L-glutamate (4–108)

when the common logarithm of the specificity constant $k_{Asp,app}$ for L-aspartate is plotted as a function of pH, its decrease at high pH defines a line of slope –1 that becomes a line of slope –2 above pH 10 (Figure 4–12).[85] This behavior is that expected for a situation in which the tautomer of the system X(HN$^{(+)}$,HO$^{(+)}$,⊙S$^{(-)}$) is the only active species. This tautomer is the one with monoprotic acid–base HN as its conjugate acid, HN$^{(+)}$; monoprotic acid–base HO as its conjugate acid, HO$^{(+)}$; and monoprotic acid–base HS as its conjugate base, ⊙S$^{(-)}$. For aspartate transaminase, the behavior of the common logarithm of $k_{Asp,app}$ as a function of pH can be fit (curve in Figure 4–12) with the function

$$\log k_{Asp,app} = \log k_{Asp} + \log\left\{\left(\frac{K_{a1}}{[H^+] + K_{a1}}\right)\left(\frac{[H^+]}{[H^+] + K_{a2}}\right)\left(\frac{[H^+]}{[H^+] + K_{a3}}\right)\right\} \tag{4–109}$$

and the parameters pK_{a1} = 6.35, pK_{a2} = 9.4, pK_{a3} = 9.9, and k_{Asp} = 95 mM^{-1} s^{-1}. When pH > pK_{a3} > pK_{a2} > pK_{a1}

$$\log k_{Asp,app} \cong \log k_{Asp} + pK_{a2} + pK_{a3} - 2\,pH \tag{4–110}$$

which defines a line of slope –2.*

Other examples in which a common logarithmic line of slope +1 is followed by one of slope +2 as the pH is decreased, so that the two values of pK_a on the one side of the maximum are clearly distinguished, are the behavior of the common logarithm of the catalytic constant $k_{0,app}$ below pH 7 for the retroaldol cleavage of (2*R*)-ethyl-(3*S*)-methylmalate by isocitrate lyase from *Dianthus caryophyllus*[86] and the behavior of the specificity constant $k_{Tyr,app}$ for L-tyrosine below pH 7 in the electrophilic aromatic substitution catalyzed by tyrosine phenol-lyase from *Pantoea agglomerans*.[87] In other instances, the two values of pK_a are too close together to obtain individual estimates for each of them when fitting the data

*Although not pertinent to the present discussion, which is concerned only with fitting curves to observations, the pK_a of 9.4 observed in the fit has been shown to be due to pH-dependent inhibition of the enzymatic reaction by the buffer used in the measurements.[67]

because the transition to a line with a slope of +2 on the acidic side of the maximum or a slope of –2 on the basic side of the maximum is too abrupt to observe the transition from a line of slope +1 or –1, respectively. In these instances, only an average of the two values of pK_a can be ascertained on either the acidic side[88-90] or the basic side[88,89,91,92] of the maximum, respectively. It is also possible to have a line of slope +3 or –3, identifying three different acid–bases on one side of the maximum.[90]

Another observation identifying the involvement of an additional acid–base is that of an inflection in the curve describing the behavior of a kinetic constant as a function of pH. Such an inflection is observed at around pH 9 in the behavior of the specificity constant $k_{cUP,app}$ for hydrolysis of uridine 2′,3′-cyclic phosphate (cUP) by bovine pancreatic ribonuclease (Figure 4–11B). This inflection can be fit (solid curve in the figure) with the equation

$$k_{cUP,app} = k_{cUP}\left\{\left(\frac{K_{a1}}{[H^+] + K_{a1}}\right)\left(\frac{[H^+]}{[H^+] + K_{a2}}\right)\left(\frac{[H^+]}{[H^+] + K_{a3}}\right)\right\} + k'_{cUP}\left\{\left(\frac{K_{a1}}{[H^+] + K_{a1}}\right)\left(\frac{[H^+]}{[H^+] + K_{a2}}\right)\left(\frac{K_{a3}}{[H^+] + K_{a3}}\right)\right\} \quad (4–111)$$

and the parameters pK_{a1} = 5.8, pK_{a2} = 6.2, pK_{a3} = 9.2, k_{cUP} = 4.5 mM^{-1} s^{-1}, and k'_{cUP} = 1.4 mM^{-1} s^{-1}. This behavior is that expected if the tautomer of the system X(⊙$S^{(-)}$,$NH^{(+)}$,$OH^{(+)}$) is enzymatically active and has a steady-state rate constant k_{cUP}, the tautomer of the system X(⊙$S^{(-)}$,$NH^{(+)}$,⊙$O^{(-)}$) is enzymatically active and has a steady-state rate constant k'_{cUP} less than k_{cUP}, and the other six tautomers and states of ionization of the system have negligible activity.

As with all kinetic measurements, the observations, the mathematical equations used to describe those observations, and the curves fit to the data with these equations must be clearly distinguished from chemical explanations of the behavior and the kinetic mechanisms derived from those explanations. Again, kinetics can only disprove a proposed mechanism; kinetics cannot prove a mechanism. A mechanism can be shown only to be consistent with the observations. From here on, examples of chemical explanations and kinetic mechanisms derived from those explanations and their consistency with the observations will be discussed.

If it is assumed that the enzyme remains in its native conformations and has not unfolded at either high or low values of pH in the range selected for the measurements, several **general conclusions** can be reached from an examination of observations of the behavior of the steady-state kinetic constants as a function of pH.

If the value for the observed catalytic constant or an observed specificity constant decreases as the pH is decreased, there **must be a catalytic base** that participates directly in the enzymatic reaction or the titration of which causes the polypeptide forming the active site to shift into an inactive conformation. In either case, when the conjugate acid of that base is formed by addition of a hydron, the enzymatic reaction cannot proceed effectively. The region of the pH–rate profile where the value for the observed rate constant decreases by a factor of 10 for every increase in the hydron concentration of a factor of 10 must occur at **values of pH less than the pK_a for the conjugate acid of this catalytic base**. This is the region in which the common logarithm of the rate constant as a function of pH has a slope of +1. The catalytic base is responsible for this decrease in the catalytic constant as the pH is decreased.

If the value for the observed catalytic constant or an observed specificity constant decreases as the pH is increased, there **must be a catalytic acid** that participates directly in the enzymatic reaction or the titration of which causes the polypeptide forming the active site to shift into an inactive conformation. In either case, when the conjugate base of that acid is formed by removal of a hydron, the enzymatic reaction cannot proceed effectively. The region in which the value for the parameter decreases by a factor of 10 for every decrease in the hydron concentration of a factor of 10 must occur at **values of pH greater than the value of pK_a for this catalytic acid**. This is the region in which the common logarithm of the rate constant as a function of pH has a slope of –1. The catalytic acid is responsible for this decrease in the catalytic constant as the pH is decreased.

As was discussed in detail earlier, other than the numerical values for rate constants, which are often informative, the conclusions drawn from steady-state kinetics measured at a constant pH rely entirely on the behavior of the rate of the enzymatic reaction as the concentrations of reactants are varied. Therefore, the kinetic mechanisms shown to be consistent with the observations describe only the entry and the exit of substrates from the active site, not what occurs after reactants are assembled in the active site or what occurs before products dissociate from

the active site. When variation of the steady-state rate constants of the enzymatic reaction with pH is observed, **the concentration of a catalytic acid is decreased** as the pH is raised or **the concentration of a catalytic base is decreased as the pH is lowered**, just as the concentrations of reactants and products are varied in normal steady-state measurements. Consequently, the kinetic mechanisms shown to be consistent with the observations describe the role of the catalytic acid or the catalytic base, respectively, in the reaction within the active site and the step or steps in the kinetic mechanism at which it is acts as an acid or as a base.

There are several possible explanations for a situation in which changes in the slope of the curve for the common logarithm of the catalytic constant occur at different values of pH than changes in the slope of the curve for the common logarithm of a specificity constant (Figures 4–10H, 4–10I, 4–11, and 4–12). Either the acids and bases involved in controlling these rate constants are different, or values of pK_a for the same acids and bases have changed as the reaction has progressed through its several steps, or the effects of these acids and bases on these parameters differ in their magnitude, or these changes in slope result from changes in the rate-limiting step of the enzymatic reaction that manifest themselves at different values of pH.

With these general facts in mind, specific kinetic mechanisms can be examined. Assume that the kinetic mechanism of a particular enzyme is **the simplest kinetic mechanism** for an active site catalyzing a conversion of reactant A

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A \xrightarrow{k_2} E + Z \qquad (4\text{–}112)$$

to which many enzymatic mechanisms can be reduced by using saturating concentrations of all the reactants other than reactant A. In this instance, system X consists of both reactant A in all its tautomers and states of ionization and the collection of all the consequential catalytic acids and bases in the active site in all possible tautomers and states of ionization. Suppose, however, that titration of only four monoprotic acid–bases (NH, OH, PH, and SH) in system X affect the enzymatic activity, that titration of each is independent of titration of the others, and that hydronations and dehydronations of these four acid–bases are so rapid that they are always at equilibrium with the pH of the solution.

Suppose also that acid–bases NH and OH are both in the active site or both on reactant A, or one is in the active site and one is on the reactant. Suppose also that acid–base NH, wherever it is located, must be present as its conjugate acid, $NH^{(+)}$, and acid–base OH, wherever it is located, must be present as its conjugate base, $\odot O^{(-)}$, **before the active site can associate productively with reactant A** to form the Michaelis complex E·A. In this case, there is a set of active tautomers of the active site uncomplexed with reactant A, E_{act}, and a set of active tautomers of reactant A, A_{act}, in which together the two relevant acid–bases, again regardless of where they are located, are in their required states of ionization, and

$$[E_{act}][A_{act}] = \alpha_{E,A}(NH^{(+)})\,\alpha_{E,A}(\odot O^{(-)})[E][A] \qquad (4\text{–}113)$$

where [E] is the concentration of all tautomers and states of ionization of all forms of the active site uncomplexed with reactant A, [A] is the concentration of all tautomers and states of ionization of free reactant A, $\alpha_{E,A}(NH^{(+)})$ is the fraction of uncomplexed active site or free reactant in which acid–base NH is present as its conjugate acid, and $\alpha_{E,A}(\odot O^{(-)})$ is the fraction of uncomplexed active site or free reactant A in which acid–base OH is present as its conjugate base.

Suppose that acid–bases PH and SH, situated either on the active site or on the reactants, are both within the Michaelis complex E·A between the active site and reactant A. Suppose also that acid–base PH must be present as its conjugate acid, $PH^{(+)}$, and acid–base SH must be present as its conjugate base, $\odot S^{(-)}$, **before the Michaelis complex between the active site and reactant A can be converted to products** free in solution. In other words, "there is only one state of ionization of the active site that is capable of catalyzing the interconversion of [reactant] and product."[66] Assume also for the moment that k_2, the rate constant for the rate-limiting step in the reaction converting the Michaelis complex to products free in solution, is a microscopic rate constant produced by a single transition state in which both the conjugate acid of acid–base PH and the conjugate base of acid–base SH accomplish their catalysis. In this case, there is only one active tautomer of the Michaelis complex, $(E{\cdot}A)_{act}$, between active site and reactant A that can precede that transition state, much as an encounter complex precedes its transition state, and in which

the two relevant acid–bases are in their required states of hydronation so that

$$\left[(\mathrm{E{\cdot}A})_{\mathrm{act}}\right] = \alpha_{\mathrm{E{\cdot}A}}(\mathrm{PH}^{(+)})\,\alpha_{\mathrm{E{\cdot}A}}(\odot\mathrm{S}^{(-)})\left[\mathrm{E{\cdot}A}\right] \tag{4–114}$$

where [E·A] is the concentration of all tautomers and states of ionization of the Michaelis complex between active site and reactant A, $\alpha_{\mathrm{E{\cdot}A}}(\mathrm{PH}^{(+)})$ is the fraction of these complexes in which acid–base PH is present as its conjugate acid, and $\alpha_{\mathrm{E{\cdot}A}}(\odot\mathrm{S}^{(-)})$ is the fraction of these complexes in which acid–base SH is present as its conjugate base.

If

$$[\mathrm{E}]_{\mathrm{t}} = [\mathrm{E}] + [\mathrm{E{\cdot}A}] \tag{4–115}$$

where $[\mathrm{E}]_{\mathrm{t}}$ is the total concentration of all tautomers and states of ionization of all forms of the active site, and the relevant steady-state assumption is

$$k_1\left[\mathrm{E}_{\mathrm{act}}\right]\left[\mathrm{A}_{\mathrm{act}}\right] = (k_{-1} + k_2)\left[(\mathrm{E{\cdot}A})_{\mathrm{act}}\right] \tag{4–116}$$

it follows that

$$v_0 = \frac{k_{0,\mathrm{app}}k_{\mathrm{A,app}}[\mathrm{E}]_{\mathrm{t}}[\mathrm{A}]_0}{k_{0,\mathrm{app}} + k_{\mathrm{A,app}}[\mathrm{A}]_0} \tag{4–117}$$

where

$$k_{\mathrm{A,app}} = \left(\frac{k_1k_2}{k_{-1} + k_2}\right)\alpha_{\mathrm{E,A}}(\odot\mathrm{O}^{(-)})\,\alpha_{\mathrm{E,A}}(\mathrm{NH}^{(+)})$$

$$= \left(\frac{k_1k_2}{k_{-1} + k_2}\right)\left(\frac{K_{\mathrm{aOH}}}{[\mathrm{H}^+] + K_{\mathrm{aOH}}}\right)\left(\frac{[\mathrm{H}^+]}{[\mathrm{H}^+] + K_{\mathrm{aNH}}}\right) \tag{4–118}$$

and

$$k_{0,\mathrm{app}} = k_2\alpha_{\mathrm{E{\cdot}A}}(\odot\mathrm{S}^{(-)})\,\alpha_{\mathrm{E{\cdot}A}}(\mathrm{PH}^{(+)})$$

$$= k_2\left(\frac{K_{\mathrm{aSH}}}{[\mathrm{H}^+] + K_{\mathrm{aSH}}}\right)\left(\frac{[\mathrm{H}^+]}{[\mathrm{H}^+] + K_{\mathrm{aPH}}}\right) \tag{4–119}$$

If all the foregoing assumptions, which are many, are met, then values of the acid dissociation constants for acid–base NH and acid–base OH, each present in either the active site unassociated with reactant A or free reactant A, can be obtained from the behavior of the specificity constant k_{A} as a function of pH. Values of acid dissociation constants for the acid–bases SH and PH, present in the Michaelis complex between active site and reactant A, can be obtained from the behavior of the catalytic constant k_0 as a function of pH.

This derivation is the basis for **the usual, often unsupported, assumption** that values of $\mathrm{p}K_{\mathrm{a}}$ affecting the catalytic constant k_0 are those for Michaelis complexes between the active site and reactant A and that values of $\mathrm{p}K_{\mathrm{a}}$ affecting the specificity constant k_{A} for reactant A are those for the form of the active site with which reactant A associates or those for the form of reactant A itself that associates. The likelihood, however, that all the assumptions will apply to a particular enzymatic reaction is probably low.

There are **two special cases** of this general behavior that should be considered.

For many enzymes, the value of the **catalytic constant is invariant with pH** while the value of the specificity constant for reactant A is a function of pH. Suppose that rate constant k_2 in Equation 4–112 is invariant with pH because there is no essential catalytic acid in the Michaelis complex that can be dehydronated and there is no essential catalytic base in the Michaelis complex that can be hydronated in the range of pH over which the enzyme remains folded. If these are the circumstances, then $k_{0,\mathrm{app}} = k_2$ and the catalytic constant will be invariant with pH while the specificity constant k_{A} can be any function of pH. The Michaelis constant

$$K_{\mathrm{mA}} = \frac{k_{0,\mathrm{app}}}{k_{\mathrm{A,app}}} = \frac{k_2}{k_{\mathrm{A,app}}} \tag{4–120}$$

will be a function of pH reciprocal to that of the specificity constant. This situation, however, would also be consistent with an active site that closes over reactants so tightly that hydrons cannot enter the active site from the solution or leave the active site into the solution, regardless of the values for $\mathrm{p}K_{\mathrm{a}}$ of the catalytic acid–bases.

For many enzymes, the value for **the Michaelis constant, K_{m}, is invariant with pH** while the catalytic constant decreases below a $\mathrm{p}K_{\mathrm{a}}$ or decreases above a $\mathrm{p}K_{\mathrm{a}}$ or both. For example, the Michaelis constant for nitrile hydratase from *Comamonas testosteroni* is invariant with pH from pH 4 to 10 while both

the catalytic constant and the specificity constant, $k_{AC,app}$, for acrylonitrile (AC), the only reactant for the enzyme other than water, the concentration of which cannot be varied, decrease as the pH is lowered below a pK_a of 6.1 and decrease as the pH is raised above a pK_a of 9.2.[93] This behavior can be understood, if the simplest kinetic mechanism (Equation 4–112) applies, by making several assumptions. First, catalytic acid $NH^{(+)}$ is identical to catalytic acid $PH^{(+)}$ and catalytic base $\odot O^{(-)}$ is identical to catalytic base $\odot S^{(-)}$. Second, association of the reactant with the active site is unaffected by the state of ionization of either of these acid–bases or any others so that the dissociation constant for a reactant from the enzyme is invariant with pH. Third, rate constant k_{-1} is greater than rate constant k_2 at all values of pH. By factoring the equation for the apparent specificity constant

$$k_{A,app} = \left(\frac{k_1}{k_{-1}}\right)\left[k_2\left(\frac{K_{aSH}}{[H^+] + K_{aSH}}\right)\left(\frac{[H^+]}{[H^+] + K_{aPH}}\right)\right]$$

$$= \left(\frac{k_1}{k_{-1}}\right) k_{2,app} = \left(\frac{k_1}{k_{-1}}\right) k_{0,app} \qquad (4–121)$$

This equation explains why the same values of pK_a apply to both the catalytic constant and the specificity constant k_A for reactant A. From Equations 4–119 and 4–121, the Michaelis constant

$$K_{mA} = \frac{k_{0,app}[E]_t}{k_{A,app}[E]_t} = \frac{k_{-1}}{k_1} \qquad (4–122)$$

and is invariant with pH.

The fact that the individual rate constants appear in different factors in Equation 4–121 implies that **catalytic acids and catalytic bases can affect the underlying kinetic constants**, in this instance rate constant k_2, rather than just the forms of the enzyme present and the observed steady-state kinetic constants. For example, for a series of peptides (pep) that are reactants for bovine α-chymotrypsin, it was possible to determine independently the pH–rate profiles of rate constant k_2 and rate constant k_3 in the kinetic mechanism (previously Equation 3–91)

$$EOH + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EOH{\cdot}A \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} E{-}O\underset{\underset{O}{\|}}{\overset{}{\diagdown}}R{\cdot}Z \xrightarrow{k_3} EOH + Z + Y \qquad (4–123)$$

for the enzymatic reaction.[94] As might be expected, because the chemistries of the two steps are quite different, the two rate constants had significantly different pH–rate profiles.

As noted above, when an enzyme has more than one reactant, the form of the enzyme with which reactant A, B, or C associates in a kinetic experiment is usually the **enzyme present at saturating concentrations of the other reactants**. This form of the enzyme, therefore, is usually one in which the active site is already occupied by one or more of the other reactants. For example, when the specificity constant k_{NAD} for NAD^+ was measured for saccharopine dehydrogenase (NAD^+, L-lysine forming) from *S. cerevisiae* (Equation 4–85), the other reactant, N^6-(L-1,3-dicarboxypropyl)-L-lysine (saccharopine, sac), was at saturation; and when the specificity constant k_{sac} for N^6-(L-1,3-dicarboxypropyl)-L-lysine was measured, NAD^+ was at saturation. Because this particular enzyme has been shown to associate with each reactant in the absence of the other, when the specificity constant k_{NAD} was measured, the form of the enzyme with which NAD^+ was associating was the complex between enzyme and saccharopine, E·sac, and when the specificity constant k_{sac} was measured, the form of the enzyme with which saccharopine was associating was the complex between enzyme and NAD^+, E·NAD^+. Consequently, it is not surprising that the specificity constants k_{NAD} and k_{sac} are governed by different values of pK_a. It has already been noted that the specificity constant k_{NAD} decreases when the pH is lowered below a pK_a of 7.4 (Figure 4–10D). The specificity constant k_{sac} decreases when the pH is lowered below a pK_{a1} of 6.2 and decreases when the pH is raised above a pK_{a2} of 7.2.[76] Neither reactant has a pK_a in this range, so it must be acid–bases with different values of pK_a in the complexes E·sac and E·NAD^+, respectively, that are responsible for these differences.

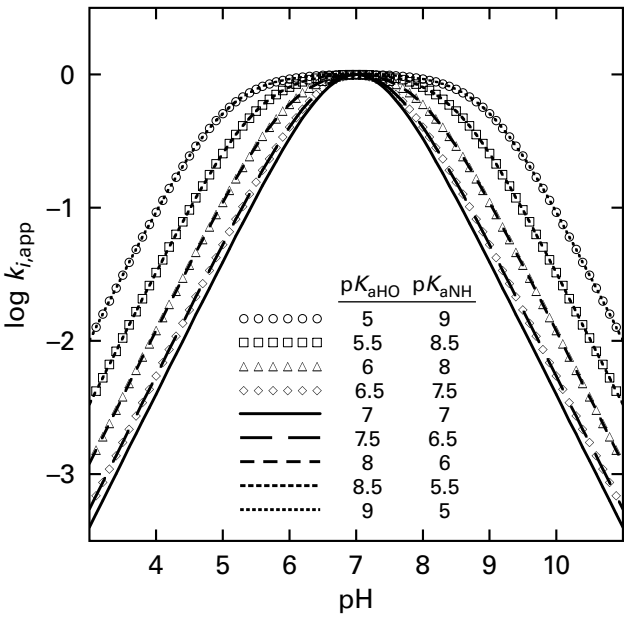

Figure 4–13: Shapes of the pH–rate profiles for an active site in which a general acid–base, HO, must be the conjugate base ⊙O$^{(-)}$ and a general acid–base, NH, must be the conjugate acid $^{(+)}$NH for the enzyme to be active. pH–Rate profiles defined by Equation 4–124 for different values of pK_{aHO} and pK_{aNH} are plotted. The values of pK_{aHO} and pK_{aNH} for each curve are given in the central table. The pH-independent rate constant k_i in Equation 4–124 was adjusted in each case to the respective value that gave a maximum value for log $k_{i,app}$ of 0 for each curve so that only the shapes of each curve could be compared. In the descending order of the table, these values for k_i are 1.02, 1.06, 1.21, 1.73, 4.00, 17.3, 121, 1060, and 10,200. The common logarithms of $k_{i,app}$ are plotted as a function of pH.

The ambiguity of reverse hydronation must be taken into account before the assignment of particular acid–bases to the observed values of pK_a and the assignment of their roles in the enzymatic reaction can be designated. For equations of the form

$$\log k_{i,app} = \log(k_i K_{a1}) + \log\left\{\frac{[H^+]}{[H^+]^2 + (K_{a1} + K_{a2})[H^+] + K_{a1}K_{a2}}\right\} \quad (4\text{–}124)$$

as are Equations 4–118 and 4–119, the argument of the first common logarithm to the right of the equal sign is a constant, and the argument of the second common logarithm is **symmetric in K_{a1} and K_{a2}.** At the moment, values of pK_{a1} and pK_{a2} are observed values of pK_a of unknown origin in the absence of independent assignment. Consider Equation 4–118, the equation for the specificity constant $k_{A,app}$, while realizing that the same argument can be made for Equation 4–119, the equation for the catalytic constant. The curve for the specificity constant can be defined by a situation in which pK_{aOH} = pK_{a1} (the lower of two observed values of pK_a) and pK_{aNH} = pK_{a2} (the higher of two observed values of pK_a). The curve can also be defined by the reverse situation, in which pK_{aOH} = pK_{a2} and pK_{aNH} = pK_{a1}. Because of the symmetry of Equation 4–124, the shapes of these two curves are identical (Figure 4–13). The only observed values are those for the pH at which two changes in slope occur on the curve and a rate constant that cannot be assigned to any function of the underlying fundamental rate constants, so there is no way to decide which observed pK_a goes with the catalytic acid and which goes with the catalytic base. Usually, in the absence of any observations to the contrary, it is simply assumed that pK_{aOH}, the pK_a for the catalytic base, is actually pK_{a1} and that pK_{aNH}, the pK_a for the catalytic acid, is actually pK_{a2}. This assumption seems reasonable because it gives the smaller value for k_i (Equation 4–124), which one might believe to be the easier value of this rate constant for natural selection to achieve.

There is, however, also the possibility that pK_{aOH}, the pK_a for the catalytic base, is actually pK_{a2} and that pK_{aNH}, the pK_a for the catalytic acid, is actually pK_{a1}. In this case, a minor tautomer of either the unoccupied active site or the reactant or both is enzymatically active. The tautomer with the stronger conjugate base (⊙O$^{(-)}$) and the stronger conjugate acid (NH$^{(+)}$) is the active species because, if by convention pK_{a1} < pK_{a2}, then pK_{aNH} < pK_{aOH}. In the case of the equation for the catalytic constant (Equation 4–119), if pK_{aSH}, the pK_a for the catalytic base, is actually pK_{a2} and pK_{aPH}, the pK_a for the catalytic acid, is actually pK_{a1}, then pK_{aPH} < pK_{aSH}, and a minor tautomer of the Michaelis complex is the actual active tautomer.

Reverse hydronation is the situation in which a minor tautomer of either unassociated reactant or unassociated active site, rather than the respective major tautomer, or a minor tautomer of the Michaelis complex of the two, rather than the major tautomer, is the active form of the active site.[95,96] In each case, the observations cannot distinguish which of the two tautomers, the major one or the minor one, is the one that is active and which is inactive. Nor can they distinguish which observed value of pK_a, pK_{a1} or pK_{a2}, belongs to the catalytic base and which to the catalytic acid for the simple reason that the ratio between any two tautomers of the system

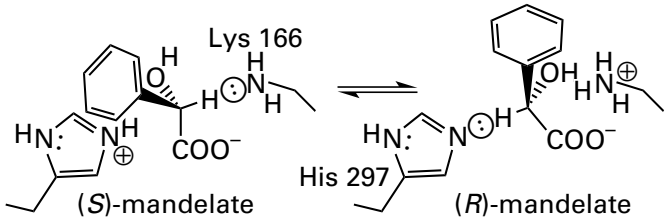
$$\frac{\alpha(\odot O^{(-)}, NH^{(+)})}{\alpha(HO^{(+)}, \odot N^{(-)})} = \frac{K_{aOH}}{K_{aNH}} \qquad (4\text{–}125)$$

is invariant with pH. For example, if the simplest kinetic mechanism (Equation 4–112) applies to the catalytic constant of lysozyme and $pK_{a1} = pK_{aOH} = 3.8$, where $\odot O^{(-)}$ is the catalytic base, and $pK_{a2} = pK_{aNH} = 6.7$, where $NH^{(+)}$ is the catalytic acid (Figure 4–10H), then $k_2 = 0.15\ s^{-1}$ (Equation 4–119). If, however, $pK_{a1} = pK_{aNH} = 3.8$ and $pK_{a2} = pK_{aOH} = 6.7$, which gives an identical fit to the data because of the symmetry of Equation 4–124, then $k_2 = 120\ s^{-1}$.

On the one hand, the fact that, for example, rate constant k_2 is greater in a case of reverse hydronation means that natural selection has had the burden of making the enzyme more efficient. On the other hand, **a stronger base and a stronger acid are made available**, which might make it easier for natural selection to make the enzyme more efficient, if the Brønsted coefficients for the reaction catalyzed by the enzyme are large enough.

Consider, for the sake of argument, a catalytic base being used in the active site of an enzyme. If the pH of the cytoplasm is less than the pK_a for the conjugate acid of that base, only a fraction of the enzyme will be in the active ionization state at that pH. The higher the pK_a for the acid–base being used as a catalytic base, the stronger will be that catalytic base, but the smaller will be the fraction of enzyme that is active at the pH of the cytoplasm. If the Brønsted coefficient for the base in its catalysis of the reaction catalyzed by the enzyme were 1, then the increased rate of the reaction catalyzed by the proper tautomer of the system that would be brought about by increasing the basicity of the catalyst would cancel the decreased rate of the enzymatic reaction at the pH of the cytoplasm resulting from the decreased concentration of the proper tautomer of the system. For example, the hydroxide bound to a zinc ion in human carbonic anhydrase 3 (see Equation 4–83) acts as a catalytic base in the enzymatic reaction, and the pK_a for its conjugate acid is the pK_a that governs the behavior of the specificity constant $k_{CO_2,app}$ for CO_2 in the hydration catalyzed by the enzyme. When the pK_a for the water bound to the zinc is increased experimentally, the value for k_{CO_2}, which is the value for $k_{CO_2,app}$ at high pH (Equation 4–84), increases with a Brønsted coefficient of 0.9 in response to the increase in its basicity.[97] In this case, the increase in the maximum specificity constant k_{CO_2} almost compensates for the decrease in the apparent specificity constant $k_{CO_2,app}$ at low pH caused by the increased pK_a for the water bound to the Zn^{2+}. The Brønsted coefficients for most reactions, however, are usually significantly less than 1.

The reverse hydronation that occurs with mandelate racemase



(4–126)

from *P. putida,* although its explanation jumps ahead in the overall argument, summarizes the various aspects of reverse hydronation in explicit terms. The standard free energy of (*S*)-mandelate (*S*-man) in free solution must be the same as the standard free energy of (*R*)-mandelate (*R*-man) in free solution because water is not a chiral molecule. Consequently, the equilibrium constant for the reaction must be 1, and the active site must catalyze the reaction in one direction as readily as in the other. The steady-state kinetic constants[98] in the two directions, *S* to *R* (*SR*) and *R* to *S* (*RS*) at pH 7.4, $k_{0SR} = 490 \pm 10\ s^{-1}$, $k_{0RS} = 650 \pm 60\ s^{-1}$, $k_{S\text{-man}} = 6.1 \pm 0.6\ M^{-1}\ s^{-1}$, and $k_{R\text{-man}} = 6.4 \pm 0.6\ M^{-1}\ s^{-1}$, confirm that requirement and satisfy the **Haldane equation**

$$K_{eq} = 1 = \frac{k_{S\text{-man}}}{k_{R\text{-man}}} \qquad (4\text{–}127)$$

which relates the steady-state kinetic constants to the equilibrium constant of the reaction in the solution.[99]

In the active site of a crystallographic molecular model for the complex between the enzyme from *P. putida* and 2-hydroxy-2-(4-iodophenyl)acetic acid, carbon 2 of this analogue of mandelate, 2-hydroxy-2-phenylacetic acid, sits between the side chain of Lysine 166 and the side chain of Histidine 297.[100] Lysine 166 is positioned to remove the hydron from (*S*)-mandelate, and Histidine 297 is positioned to remove the hydron from (*R*)-mandelate (Equation 4–126). When Histidine 297 is mutated to asparagine, the enzyme no longer racemizes mandelate, but it is able to exchange the hydron on (*S*)-mandelate for a deuteron in the solution but not the hydron on (*R*)-mandelate.[101] This result is that expected from the crystallographic molecular model of the complex.

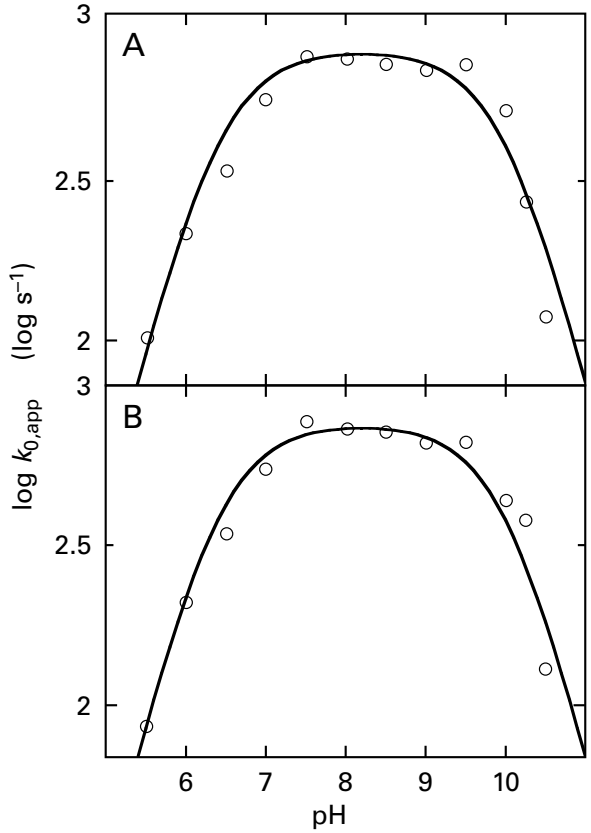


Figure 4–14: pH–Rate profiles for the catalytic constant of mandelate racemase from *P. putida* for (*R*)-mandelate (**A**) and (*S*)-mandelate (**B**) at 25 °C.[101] The buffers, all at 0.1 M, were 2-(*N*-morpholino)ethanesulfonate, pH 5.5, 6.0, and 6.5; 1,4-piperazinediethanesulfonate, pH 6.5, 7.0, and 7.5; 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonate, pH 7.5, 8.0, and 8.5; 3-[[tris(hydroxymethyl)methyl]amino]propane-1-sulfonate, pH 8.5 and 9.0; 2-(cyclohexylamino)ethanesulfonate, pH 9.0, 9.5, 9.75, and 10.0; 3-(cyclohexylamino)propane-1-sulfonate, pH 10.0, 10.25, and 10.5. The common logarithms of the observed catalytic constants $k_{0,app}$ (second^{-1}) are plotted as a function of pH. The data in each panel are fit with Equation 4–96, in both cases with values of pK_{a1} = 6.4 and pK_{a2} = 10.0.

Suppose that, in the encounter complex preceding the transition state for one step in an enzymatic reaction, one side chain in the active site acts as a catalytic acid and another acts as a catalytic base. Also suppose that, in the transition state, the hydron is being transferred from that catalytic acid to the substrate and a hydron is being transferred from the substrate to that catalytic base. If these conditions are met, it necessarily follows inescapably from the principle of microscopic reversibility that **in the encounter complex preceding that same transition state when the reaction is proceeding in the reverse direction, the conjugate base of the catalytic acid in the forward direction must be acting as a catalytic base, and the conjugate acid of the catalytic base in the forward direction must be acting as a catalytic acid.** For example, in the reaction catalyzed by mandelate racemase, for a single transition state in which the hydrons are being transferred simultaneously, in the encounter complex for the racemization of (*S*)-mandelate, the amino group of Lysine 166 acts as a catalytic base and the imidazolio group of Histidine 297 acts as a catalytic acid. In the encounter complex for the racemization of (*R*)-mandelate, the imidazolyl group of Histidine 166 acts as a catalytic base and the ammonio group of Lysine 166 acts as a catalytic acid. In a reaction such as that catalyzed by mandelate racemase, where there is probably only one rate-limiting transition state, in this case the transition state for removal of a hydron from carbon, accompanied by hydronation of that same carbon at its opposite face, the pH–rate profile for the catalytic constant should be governed by the pK_a for the side chain acting as a catalytic base (Lysine 166 in one direction and Histidine 297 in the other) as well as the pK_a for the side chain acting as a catalytic acid (Histidine 297 in one direction and Lysine 166 in the other). It follows that if values for pK_a for the two conjugate acids in any such enzymatic reaction are far enough apart that they cannot possibly shift enough to change their order, **reverse hydronation must occur in one, but only one, of the directions**.

The observed acid dissociation constants (pK_{a1} = 6.4 and pK_{a2} = 10.0) governing the pH–rate profile for the catalytic constant when (*R*)-mandelate is the reactant (Figure 4–14A) are identical within experimental error to those governing the pH–rate profile for the catalytic constant when (*S*)-mandelate is the reactant (Figure 4–14B).[101] Because these two values of pK_a are so different from each other, each acid–base governing these pH–rate profiles, if these are actually values of pK_a for acid–bases, must be titrating independently of the other. Because the two enantiomers of mandelate are indistinguishable in an achiral solution, the equilibrium constant for the reaction must be 1 not only at one pH but at all values of pH. Therefore, it follows from the Haldane equation that $k_{S\text{-man}}$ must equal $k_{R\text{-man}}$ at all values of pH. Because the apparent values of pK_a for the catalytic constant in each direction are identical, either the Michaelis constants in the two directions are invariant with pK_a or their variation with pH must have the same apparent values of pK_a as each other and as those for the catalytic constants.

From all the arguments just presented, it can be concluded that if the tautomer of the Michaelis

complex $^{+}$HHEK⊙·(*S*)-mandelate is responsible for racemization of (*S*)-mandelate, then the tautomer of the Michaelis complex ⊙HEKH^{+}·(*R*)-mandelate is responsible for the racemization of (*R*)-mandelate (Equation 4–126). In these two complexes, $^{+}$HH is the conjugate acid of Histidine 297, ⊙H is the conjugate base of Histidine 297, KH^{+} is the conjugate acid of Lysine 166, and K⊙ is the conjugate base of Lysine 166. Because of the symmetry of Equation 4–99, if association of (*S*)-mandelate with the enzyme has the same effect on the acid dissociations of acid–bases $^{+}$HHE and KH^{+} as does that of (*R*)-mandelate, which seems reasonable, the pH–rate profile for the catalytic constant of tautomer $^{+}$HHEK⊙·(*S*)-mandelate must be governed by the same two values of pK_a as the pH–rate profile for the catalytic constant of tautomer ⊙HEKH^{+}·(*R*)-mandelate (Figure 4–13), as is observed (Figure 4–14). This conclusion would follow from the fact that the ratio for concentrations of the two tautomers, [$^{+}$HHEK⊙·(*S*)-mandelate] and [⊙HEKH^{+}·(*R*)-mandelate], must be invariant with pH.

The pK_a of 6.4 has been assigned to the conjugate acid of Lysine 166 because the catalytic constant of the exchange of the hydron in (*S*)-mandelate for a deuteron in the solution catalyzed by Lysine 166 (Equation 4–126), in the mutant in which Histidine 297 has been changed to asparagine, has a pH–rate profile governed by a pK_a of 6.4 for a catalytic base.[101] The pK_a of 6.4 is significantly less than the pK_a for a fully solvated lysine on the surface of a protein exposed to the aqueous phase (10.5), but this decrease in pK_a can be explained by the fact that, in the complex between enzyme and substrate,[100] the cationic conjugate acid of the side chain of Lysine 166 is unsolvated by water and immediately adjacent (0.37 nm) to a Mg^{2+}. The pK_a of 10.0 can then be assigned to Histidine 297, which is significantly greater than the pK_a for a fully exposed histidine on the surface of a protein (6.6), but this increase in pK_a can be explained by the facts that the π nitrogen of its imidazolyl group, opposite from the catalytic τ nitrogen, forms a hydrogen bond with the carboxylato group of Aspartate 270 and that the negatively charged carboxylato group of Glutamate 317 is nearby.

Consequently, when (*S*)-mandelate is racemized by the major tautomer, $^{+}$HHEK⊙, the conjugate acid of the catalytic base, the amino group of Lysine 166, has a lower pK_a than the catalytic acid, the imidazolium of Histidine 297. In this instance, although the concentration of the active tautomer $^{+}$HHEK⊙ is far greater than that of the minor tautomer ⊙HEKH^{+}, it contains a weaker acid, the imidazolio group, and a weaker base, the amino group. When (*R*)-mandelate is racemized by the minor tautomer ⊙HEKH^{+}, the catalytic base, the imidazolyl group of Histidine 297, has a conjugate acid with a higher pK_a than the catalytic acid, the ammonio group of Lysine 166. In this instance, although the concentration of this active tautomer is far less than that of the major tautomer $^{+}$HHEK⊙, it contains a stronger acid and a stronger base, and reverse hydronation is operating. It should, however, be noted that the designation of which hydronation is reverse hydronation is based only on the convention that it is due to hydronation performed by the minor tautomer. Either hydronation could have been called "reverse hydronation".

In a twist on this usual **trade-off between basicity and the concentration of a base** at a pH less than the pK_a for its conjugate acid, a neighboring imidazolium cation in the active site of papain from *Carica papaya* lowers the pK_a for the sulfanyl group of a cysteine, increasing the concentration of the tautomers and states of ionization in which it is the conjugate base at neutral pH without decreasing its nucleophilicity in the reaction catalyzed by the enzyme.[102]

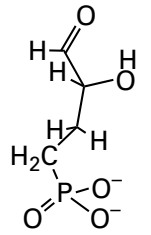
The most straightforward acid dissociation constants in a pH−rate profile to assign are acid dissociation constants of the free reactants. In such a case, one acid dissociation constant affecting the **specificity constant** k_A is an acid dissociation constant of reactant A. For example, when bovine pancreatic ribonuclease hydrolyzes cytidine 2′,3′-cyclic phosphate, there is a pK_a of 4.2 (change in slope in Figure 4–11A) that affects the specificity constant $k_{cCP,app}$ for cytidine 2′,3′-cyclic phosphate. When the same enzyme, however, hydrolyzes uridine 2′,3′-cyclic phosphate, there is a pK_a of 9.2 (inflection in Figure 4–11B) that affects its specificity constant $k_{cUP,app}$. These are the respective values of pK_a for the conjugate acids of the cytosine in cytidine 2′,3′-cyclic phosphate and the uracil in uridine 2′,3′-cyclic phosphate. The pK_a of 4.2 is not observed when the enzyme hydrolyzes uridine 2′,3′-cyclic phosphate, and the pK_a of 9.2 is not observed when the enzyme hydrolyzes cytidine 2′,3′-cyclic phosphate (Figure 4–11). The respective absences of these values of pK_a, in addition to the coincidence of the values of pK_a, are consistent with the conclusion that the acid–bases with these values of pK_a are on the two respective reactants and not on the enzyme. It follows that cytidine 2′,3′-cyclic phosphate must have a

neutral cytosine, not its cationic conjugate acid, to associate productively with pancreatic ribonuclease, but uridine 2′,3′-cyclic phosphate can have either a neutral or a monoanionic uracil and still associate productively with pancreatic ribonuclease. The latter form, however, has a specificity constant k_{cUP} that is 3.2 times smaller than that of the former.

The pH–rate profile for the specificity constant k_{Cth} for the reactant L-cystathionine (Cth) for cystathionine β-synthase from *S. cerevisiae* decreases as the pH is raised above a pK_a of 8.6. This pK_a has been assigned to the acid dissociation constant of one of the ammonio groups in the zwitterion of L-cystathionine (pK_a = 8.5). The pH–rate profile for the Michaelis constant $K_{m,pep}$ for the reactant *N*-(*N*-furylacryloyl-L-phenylalanyl)glycine for carboxypeptidase C from *S. cerevisiae* decreases as the pH is lowered below a pK_a of 3.58 ± 0.14. This pK_a has been assigned to the acid dissociation constant of the carboxy-terminal carboxy group of the reactant (pK_a = 3.44 ± 0.01). This assignment leads to the conclusion that *N*-(*N*-furylacryloyl-L-phenylalanyl)-glycine must be anionic to associate with the active site.[103]

In the case of porcine aspartate transaminase (Equation 4–108), the pK_a of 9.9 governing the behavior of the specificity constant $k_{Asp,app}$ for L-aspartate (Figure 4–12) is indistinguishable from that of the microscopic pK_a for the α-amino group of L-aspartate (9.85).[104] When L-cysteine sulfinate (CS) is used as a reactant for aspartate transaminase from *Escherichia coli*, the pK_a governing the decrease in its specificity constant $k_{CS,app}$ at high pH is 9.0, which is the pK_a for the α-amino group of L-cysteine sulfinate, but when L-aspartate is used as a reactant with the enzyme from *E. coli*, the pK_a governing the decrease in the specificity constant $k_{Asp,app}$ is 9.6,[67] which is the same, within experimental error, as that for the porcine enzyme. This shift in observed values of pK_a for the enzyme from *E. coli* clearly identifies each observed value of pK_a as that for the α-amino group of the respective reactant.

A pK_a of 6.0 governs the behavior of the specificity constant $k_{GAP,app}$ for glyceraldehyde 3-phosphate (GAP) in the reaction catalyzed by triose-phosphate isomerase (Equation 4–46) from *G. gallus*. Acid dissociation of the phospho group of glyceraldehyde 3-phosphate has a pK_a of 6.3. 2-Hydroxy-4-phosphonobutyraldehyde

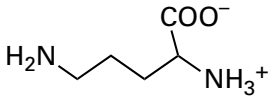


4–37

is also a substrate for triose-phosphate isomerase, but the pK_a for the phosphonate is 7.6 rather than 6.3 for the phosphate. The pK_a governing the specificity constant $k_{HPB,app}$ for 2-hydroxy-4-phosphonobutyraldehyde (HPB) is 7.5 rather than 6.0.[105] Because the apparent pK_a governing the kinetics shifts as expected when one reactant is substituted with the other, it must be the case in each instance that the pK_a in the pH–rate profile is that for the reactant.

In the cases of the human nonspecific tyrosine kinase Csk,[106] alkaline phosphatase from *E. coli*,[107] and chalcone isomerase from *Medicago sativa*,[108] sets of four or five different reactants were used for each enzyme. In each case, reactants in each set differed in pK_a over ranges of 1–2 units of pH. Each pK_a governing the variation of the specificity constants for the respective reactants as a function of pH agreed with the pK_a for that particular reactant. The fact that in each instance **the pK_a observed in the behavior of the specificity constant matched the pK_a for the reactant itself** clearly indicated that each pK_a observed kinetically was that of the respective reactant free in solution before it associated with the enzyme and that only one particular state of ionization of the reactant could associate efficiently and productively with the enzyme.

One way to treat these acid dissociations of a reactant is to **eliminate them from consideration**. If acid dissociation constants for the reactant are known and the form of the reactant that binds to the enzyme can be determined independently, the concentration of reactant in the appropriate form, α_A, can be calculated for each pH and total concentration of reactant, and a corrected specificity constant, $k'_{A,app}$, for just the concentration of the active tautomer and state of ionization of that reactant can be determined for each pH. This correction eliminates acid dissociation constants of the reactant from the data and leaves only acid dissociation constants of the enzyme. Because the effect of its acid dissociation constants is only on the free concentration of the competent form of the reactant, this correction is not mechanism-dependent. For example, from the kinetic behavior of the reaction, it was concluded that only zwitterionic L-ornithine

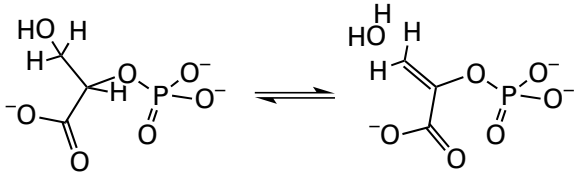


4–38

was a substrate for ornithine carbamoyltransferase from *E. coli*. Total concentrations of L-ornithine were corrected with an equation for α_{orn} so that a corrected value for the specificity constant, $k'_{orn,app}$, could be tabulated at each pH.[109]

The assignment of a pK_a in the pH–rate profile for a specificity constant to the pK_a for that reactant is straightforward because the pK_a for the reactant in the solution is the relevant value, but the pH–rate profile for the **catalytic constant** is governed by values of pK_a for the participants in the Michaelis complex. Usually, the pK_a for an acid–base on a reactant changes, often significantly, when it associates with the active site. For example, by following the nuclear magnetic resonance spectra as a function of pH for the fluorine-19 in 4-fluoro-3-hydroxybenzoate, both in solution and when it was bound to 3-hydroxybenzoate 6-monooxygenase from *Rhodococcus jostii*, it could be shown that the pK_a for its 3-hydroxy group decreased from 8.7 to 7.1 upon association with the active site.[110]

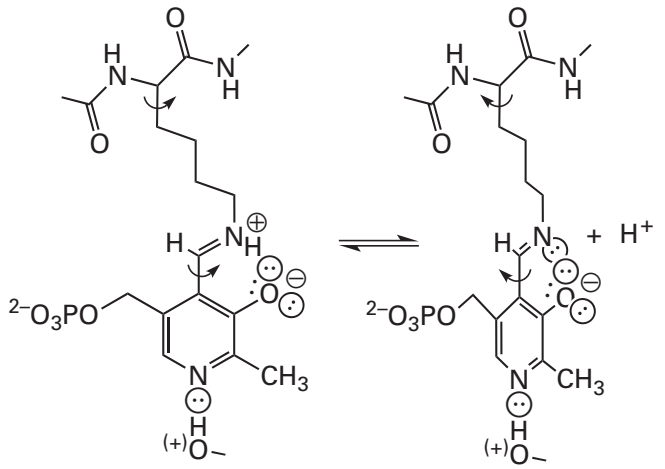
Consequently, if a **reactant within its complex with the active site** participates in an acid dissociation that affects the enzymatic reaction a measurement, such as the one for 4-fluoro-3-hydroxybenzoate, a measurement must be made of reactant within the active site to assign its pK_a to the pK_a in the pH–rate profile for the catalytic constant. For example, the catalytic constant for dehydration of 2-phospho-D-glycerate catalyzed by phosphopyruvate hydratase (previously Equation 3–393)



(4–128)

from *S. cerevisiae* decreases as the pH is decreased. The observed pK_a governing this decrease is 5.9 ± 0.1. This pK_a is within experimental error of the pK_a for the phospho group of 2-phospho-D-glycerate (5.82 ± 0.05) when it is bound to the active site of the enzyme.[111] This independent measurement of the pK_a was made from phosphorus-31 nuclear magnetic resonance spectra of the complex between enzyme and 2-phospho-D-glycerate at different values of pH.

When the reactant does not have an acid dissociation constant equal to an apparent acid dissociation constant governing the behavior of its specificity constant, it is usually assumed that the observed acid dissociation constant in a pH–rate profile is that for an acid–base in the active site of the enzyme. The assignment of a particular acid–base to a particular pK_a in the observed pH–rate profile is least ambiguous when there is an **independent measurement of the pK_a for a particular acid–base in the active site** that gives a value indistinguishable from that observed in the kinetic experiments. For example, dissociation of the hydron from the aldimine nitrogen on the internal lysylpyridoximine (previously Equation 2–2)

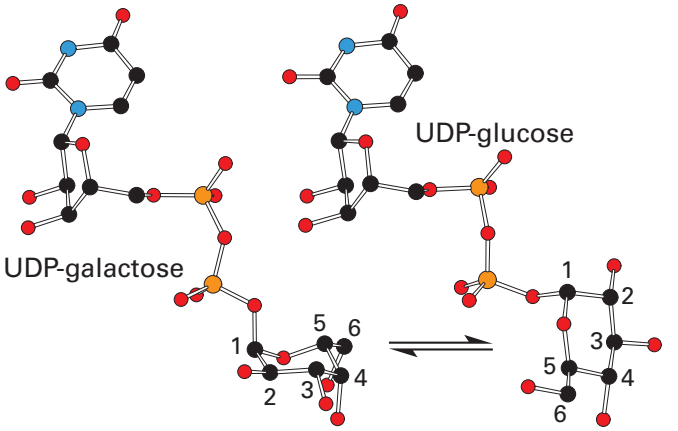


(4–129)

in the active site of porcine aspartate transaminase (Equation 4–108) can be assessed by following the absorbance of the enzyme, which shifts to shorter wavelengths as the dipolar π system is shortened upon dissociation of the hydron.[112] The pK_a for this acid dissociation at 25 °C is 6.3. In the steady-state kinetics of the enzyme,[85] the specificity constant $k_{Asp,app}$ for L-aspartate decreases as the pH decreases below a pK_a of 6.35 (Figure 4–12). This pK_a has been assigned to acid dissociation of the lysylpyridoximine on the basis of indistinguishable numerical values of pK_a. If this assignment is correct, then it is consistent with the conclusion that when the conjugate acid of the lysylpyridoximine is present, the active site cannot bind reactant productively, but when the conjugate base is present, it can. A chemical explanation for this conclusion[85] would be that because L-aspartate enters the active site with its α-amino group hydronated, the first step in the reaction would be for the phenolate oxyanion of the lysyl-

pyridoximine (Equation 4–129) to remove that hydron (Figure 2–2). This explanation would require that the oxygen of the phenolate be free of the hydrogen bond to the iminium nitrogen and available to act as a base. It is also possible, however, that the active tautomer of the system is that in which the α-amino group of the aspartate is unhydrated in solution, and thus a base, and the lysylpyridoximine is hydronated already, which would produce the same result by reverse hydronation and may make more chemical sense.

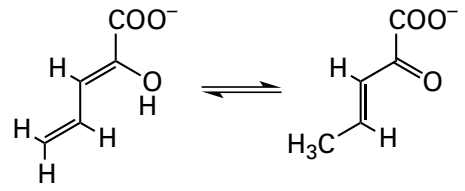
The visible spectrum of the prosthetic nicotinamide-adenine dinucleotide in UDP-glucose 4-epimerase



(4–130)

from *E. coli* has an absorption in a visible spectrum arising from charge transfer between the nicotinamide and the 4-oxidophenyl group of Tyrosine 149.[113] This charge-transfer band decreases in intensity below a pK_a of 6.1 as the 4-oxidophenyl group becomes hydronated in a mutant of the enzyme in which Serine 124 has been replaced with alanine. The pH–rate profile of the specificity constant $k_{Uga,app}$ for the reactant UDP-D-galactose (Uga) for this mutant also decreases as the pH is decreased below a pK_a of 6.1, which, consequently, has been assigned to Tyrosine 149.[114] It is assumed that Tyrosine 149 must be the unhydronated anion for the UDP-D-galactose to associate with the active site.

In the cases of aspartate transaminase and UDP-glucose 4-epimerase, the facts that the prosthetic groups, lysylpyridoximine (Equation 4–129) and NAD^+, are in the respective active sites is obvious. In most other instances, however, the amino acid side chains that are candidates for acid–bases with acid dissociation constants governing the behavior of the steady-state rate constants are usually identified by **examining the locations of the various acid–bases in a crystallographic molecular model of the active site of the enzyme.** For example, in the model of 2-hydroxymuconate tautomerase from *Pseudomonas*,[115] the amino-terminal proline of the enzyme is located in a pocket that was assumed to be the active site. The pK_a for the imino group of this proline was determined to be 6.4 ± 0.2 by following the nuclear magnetic resonance spectrum of its nitrogen, which had been enriched in nitrogen-15.[116] This acid dissociation constant agreed with the pK_a (6.2 ± 0.3) that governs a decrease in the specificity constant $k_{HPD,app}$ for tautomerization of the reactant 2-hydroxy-2*Z*,4-pentadienoate (HDP)



(4–131)

as the pH of the solution is decreased. It was concluded that the amino-terminal proline must be in the unhydronated neutral state of ionization for 2-hydroxy-2*Z*,4-pentadienoate to associate with the active site and that the imino nitrogen of the proline acts as a catalytic base in the reaction. This conclusion was also consistent with later crystallographic observations.[117]

In the crystallographic molecular model of a complex of D-glucose 6-phosphate and an inactive mutant of glucose-6-phosphate dehydrogenase [$NAD(P)^+$] from *Leuconostoc mesenteroides*,[118] Histidine 240 forms a hydrogen bond to the hydroxy group on carbon 1 of the β-pyranose of D-glucose 6-phosphate from which a hydron is removed during the reaction. The pK_a for the imidazolyl group of this histidine was determined to be 6.4 by following the chemical shift of the hydron on carbon 2 in nuclear magnetic resonance spectra as a function of pH.[119] This **independently determined acid dissociation constant agreed with the pK_a (6.3) that was observed in the behavior as a function of pH** of the catalytic constant k_0 for dehydrogenation of D-glucose 6-phosphate.

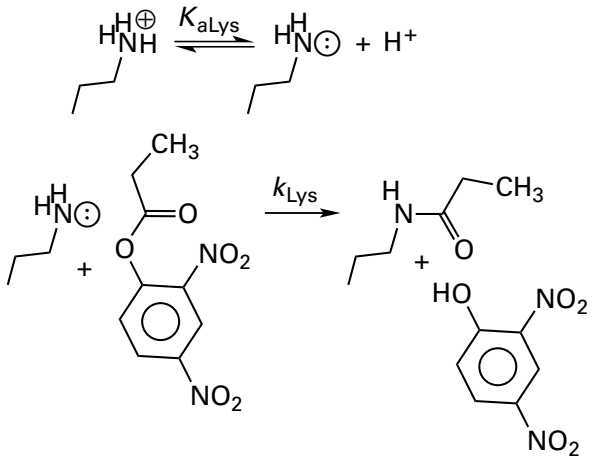
In the crystallographic molecular models of complexes between peptide deformylase from *E. coli*, the enzyme responsible for hydrolytically removing the formyl group from *N*-formylmethionyl proteins, and two inhibitors that mimic an *N*-formylated peptide[120] and a tripeptide with methionine at its amino terminus that mimics the product of hydrolysis,[121] Glutamate 133 is positioned properly to be a catalytic acid. A mutant in which Glutamate 133

has been replaced by aspartate is still enzymatically active, and the pK_a of Aspartate 133 in the mutant has been determined to be 10.1 by following the decrease in the infrared absorption of the C=O stretch (1740 cm^{-1}) of its carboxy group as a function of pH.[122] The observed value of this pK_a and the behavior of several mutants have been used to assign to Aspartate 133 the pK_a (10.1) above which the catalytic constant for the enzymatic reaction of the mutant decreases as the pH is raised and to assign it a role as a catalytic acid in the enzymatic reaction. If this assignment is correct, it is a rather dramatic example of a shift in pK_a for a carboxy group brought about by an active site.

In the crystallographic molecular model of a complex between (β1,4)-xylotetraose and an inactive mutant of endo-1,4-β-xylanase from *Bacillus circulans*, the position at which a xylan is normally hydrolyzed by the enzyme is immediately adjacent to both Glutamate 172 and Glutamate 78 within the active site of the enzyme,[123] in keeping with the usual arrangement of catalytic acid–bases in the active sites of glycosidases. The pK_a of Glutamate 78 (4.6 ± 0.1) and the pK_a of Glutamate 172 (6.7 ± 0.2) were determined from carbon-13 nuclear magnetic resonance spectra of the enzyme from bacteria grown on [δ-^{13}C]glutamate.[124] These values of pK_a agreed with those governing the behavior of the specificity constant $k_{NPX,app}$ for hydrolysis of 9-nitrophenyl β-xylobioside (NPX) catalyzed by the enzyme. The value of the specificity constant decreases below the pK_a of 4.6 as the pH is decreased, and it decreases below the pK_a of 6.7 as the pH is increased.

At first glance, it seems that assigning Glutamate 78 as the catalytic base and Glutamate 172 as the catalytic acid would be reasonable. Because, however, reverse hydronation cannot be ruled out by a pH–rate profile alone, the situation in which Glutamate 78 is the catalytic base and Glutamate 172 is the catalytic acid cannot be distinguished from the situation in which Glutamate 78 is the catalytic acid and Glutamate 172 is the catalytic base from these results alone. On the basis of crystallographic molecular models and identification of a covalent intermediate in the enzymatic reaction, it has been determined that Glutamate 78 is actually the catalytic base in the direction of hydrolysis and Glutamate 172 is the catalytic acid.[125]

Although there is some disagreement on this point, one way to determine the pK_a for a particular amino acid in a protein is to **monitor, as a function of pH, the rate of its modification by a reagent that can react with only one of its states of ionization**.[126] Normally, an electrophilic reagent is used to modify the amino acid so that only the conjugate base of the amino acid, a nucleophile, will react. For example, the lysine in the active site of acetoacetate decarboxylase from *Clostridium acetobutylicum* can be propionylated with 2,4-dinitrophenyl propionate



(4–132)

The rate of propionylation as a function of pH provides a pK_a for this lysine of 5.9 (Figure 4–15).[127]

The pK_a observed in such a chemical modification of the active site of an enzyme can often be correlated with the value of a pK_a observed in a kinetic measurement. For example, the active site of phospho*enol*pyruvate carboxykinase (GTP) from *G. gallus* contains a cysteine and a histidine. The enzyme is inactivated by iodoacetamide, a reagent that modifies cysteines preferentially, in a reaction governed by a pK_a of 8.2 ± 0.1.[92] The enzyme is also inactivated by diethyl dicarbonate, a reagent that modifies histidines almost exclusively, in a reaction governed by a pK_a of 6.7.[128] These inactivations were assumed to result from the modification of the cysteine and the histidine in the active site of the enzyme. On the basis of these two measured values of pK_a, the pK_a (8.15 ± 0.09) governing the specificity constant $k_{IDP,app}$ for $MgIDP^-$ and the pK_a (6.7 ± 0.3) governing the catalytic constant k_0 of the enzyme were assigned, respectively, to the cysteine and the histidine modified in these reactions.[92]

One drawback of determining the pK_a for a particular functional group on an amino acid in an active site by the rate of its alkylation with a nonspecific electrophile is the possibility that the **electrophile associates with the active site before modifying** it. Cysteine 645 is the nucleophilic catalyst in human arginine deiminase

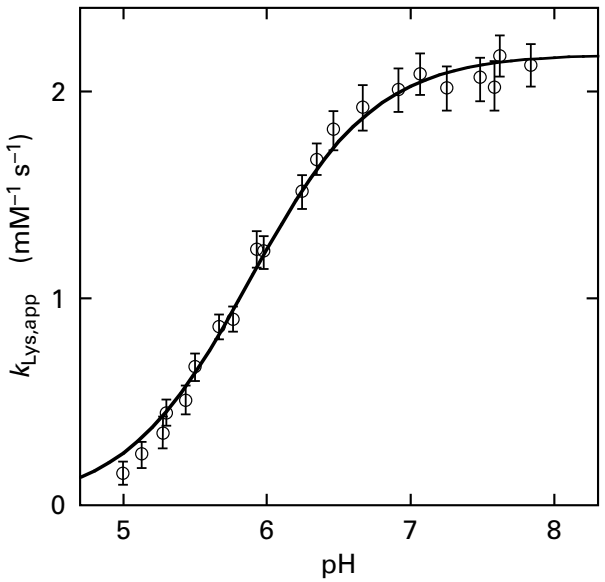


Figure 4–15: pH–Rate profile for the reaction of 2,4-dinitrophenyl propionate with acetoacetate decarboxylase.[127] Solutions of 2,4-dinitrophenyl propionate were prepared at various values of pH buffered with lutidine sulfate, *N,N,N′,N′*-tetramethyl-1,2-ethanediammonium sulfate, or 4-[(2-dimethylamino)ethyl]-morpholinium sulfate at 30 °C. The spontaneous rate of hydrolysis was recorded, and then a sample of acetoacetate decarboxylase was added. This addition caused a burst of 2,4-dinitrophenol production. The small rate of spontaneous hydrolysis of 2,4-dinitrophenol in the absence of enzyme was subtracted from the rate of this burst, and a pseudo-first-order rate constant was calculated from the rate at which the enzyme reacted with 2,4-dinitrophenyl propionate for each sample. These pseudo-first-order rate constants were divided by the respective concentrations of 2,4-dinitrophenyl propionate to obtain the observed second-order rate constant, $k_{Lys,app}$ (millimolar^{-1} second^{-1}), for the reaction of acetoacetate decarboxylase with 2,4-dinitrophenyl propionate, and these rate constants are plotted as a function of pH. In separate experiments, it was shown that the amplitude, in molarity, of the entire corrected burst of 2,4-dinitrophenol was equal to the molar concentration of active sites; that after the burst was complete, the enzyme had lost greater than 98% of its activity; that the loss of activity was coincident with the burst; that enzyme acetylated at the lysine within its active site showed no burst; and that occupation of the active site with acetopyruvate also eliminated the burst. The curve drawn through the points is that for an acid–base titration (Equation 4–79) with a pK_a of 5.88 and a value for the pH-independent rate constant at high pH of 2.18 mM^{-1} s^{-1}.

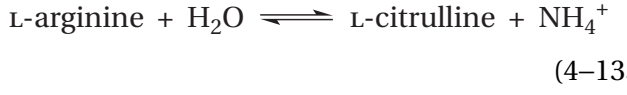


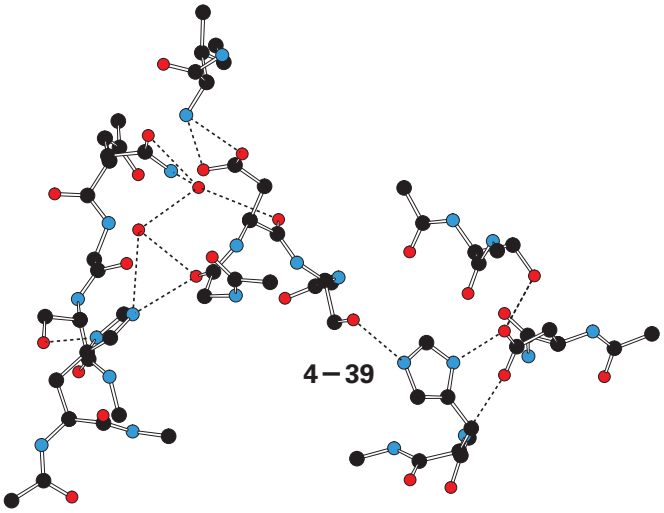
(4–133)

that adds to the guanidinio group of the reactant L-arginine in a nucleophilic substitution in which ammonia is the leaving group to form an (*N,S*-dialkyl)-thiourea as an intermediate in the enzymatic reaction. The pK_a of the sulfanyl group of Cysteine 645 (8.3 ± 0.07) was determined by its rate of reaction with iodoacetamide. The fact that the pK_a determined by its reaction with 2-chloroacetamidine (7.9 ± 0.16), which is more likely to form a complex with the active site because of its resemblance to the portion of the L-arginine at which the nucleophilic substitution occurs, was almost the same as that determined by iodoacetamide was presented as evidence that the former reaction was a simple bimolecular nucleophilic substitution providing an accurate measure of the pK_a and did not involve binding of the reagent to the active site. The pH–rate profile of the specificity constant for L-arginine in the enzymatic reaction decreases above a pK_a of 8.2 as the pH is increased, and it decreases below a pK_a of 7.3 as the pH is decreased. The pK_a of 8.2 was assigned to the sulfanyl group of Cysteine 645. Because its sulfanyl group must be unhydronated for it to act as a nucleophile, it was concluded that the pH–rate profile is recording a reverse hydronation in which the acid–base with the pK_a of 7.3 is acting as an acid while the unhydronated sulfanyl group of Cysteine 645 is acting as a nucleophile.[129]

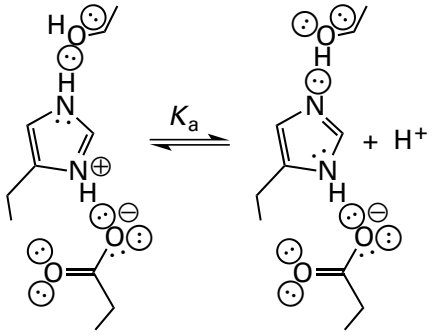
In the crystallographic molecular model of bovine chymotrypsin,[130] Histidine 57 is located in the active site adjacent to Serine 195, which bears the hydroxy group at which the acyl intermediate in the enzymatic reaction is formed (Figure 3–6, Equation 4–123).[131] The pK_a of Histidine 57 in the unoccupied enzyme has been assigned as 6.8 on the basis of the rate of its arylation with 1-fluoro-2,4-dinitrobenzene, which decreases below this value of pK_a.[132] This measured value of the pK_a could be in error if the reaction of Histidine 57 with 1-fluoro-2,4-dinitrobenzene involves a step in which 1-fluoro-2,4-dinitrobenzene binds to the active site before the arylation. The imidazolio group in an equivalent complex formed from a histidine, a serine, and an aspartate in the active site of phospholipase C from *Bacillus cereus* has a pK_a, determined by nuclear magnetic resonance spectroscopy,[133] of 6.0, which gives an estimate for the pK_a for an imidazolyl group in such a situation.

It is known from crystallographic molecular models that the lone pair on the τ nitrogen of the

conjugate base of the imidazolyl group in the histidine in chymotrypsin accepts a hydrogen bond from the hydroxy group of Serine 195 (see the stereodrawing[134] for chymotrypsin in Problem 3–30)[130]



It is also known from neutron diffraction that the nitrogen–hydrogen bond on the π nitrogen in the cationic conjugate acid of the imidazolyl group is the donor in a hydrogen bond with the anionic carboxylato group of Aspartate 102 acting as an acceptor.[135] Therefore, the microscopic pK_a of 6.8 for dissociation of a hydron from Histidine 57, measured by the arylation, should be for



(4–134)

It has been determined by nuclear magnetic resonance spectroscopy[136] that the pK_a of Aspartate 102 is less than 1.5, presumably because it is engaged in this hydrogen bond with the imidazolio group of Histidine 57 at low pH, as well as additional hydrogen bonds. The pK_a for the hydroxy group of the serine should be considerably greater than 6.8, so in the acidic tautomer of the complex, the imidazolyl group should be the dihydronated conjugate acid as drawn.

In this instance, the pK_a for the carboxylato group is so low that no tautomer of the complex in which it is hydronated exists in the normal ranges of pH. Consequently, the carboxylato group mainly serves to orient the imidazolyl group by providing an acceptor for the hydrogen bond. In the active site of histone deacetylase from *Danio rerio*, the imidazolyl group of Histidine 137, which hydronates the amino group that leaves from the tetrahedral intermediate, is oriented by a hydrogen bond from the carbamoyl group of Glutamine 179, which is neither a reasonable acid nor reasonable base.[137]

The rate constant at saturating concentration of reactant for the acylation of Serine 195 in the active site of bovine chymotrypsin by nitrophenyl esters, the first chemical step in the kinetic mechanism (Equation 4–123) for hydrolysis of these esters catalyzed by the enzyme (Figure 3–6), is a function of pH and decreases as the pH is decreased below a pK_a of 6.7.[138] The coincidence of this pK_a with that observed directly for Histidine 57 by following the rate of its arylation suggests that the pK_a governing the pH–rate profile of the catalytic constant of the acylation reaction is that of Histidine 57. If this is the case, then the pK_a for this histidine in the Michaelis complex between enzyme and nitrophenyl ester must be same as in free enzyme, and it must be the conjugate base (Equation 4–134) for the active site to be capable of catalyzing the acylation. Because a hydron must be removed from Serine 195 either before or while the tetrahedral intermediate is formed in the acylation, the role of the imidazolyl group of Histidine 57 in the conjugate base of the hydrogen-bonded complex must be to act as the necessary catalytic base (Figure 3–6). The role of Aspartate 102, however, seems to be simply to provide the acceptor for a hydrogen bond from the imidazolyl group. Consistent with this conclusion is the fact that when the homologous aspartate in subtilisin from *Bacillus amyloliquefaciens* was mutated to cysteine,[139] the value of $k_0\,K_{m,pep}^{-1}$ for hydrolysis of a peptide (pep) that is a reactant for the enzyme decreased by only a factor of 10.

A similar hydrogen-bonded complex responsible for removing a hydron from a nucleophilic serine in the active site of β-lactamase from *Mycobacterium tuberculosis* is formed by the ammonio group of Lysine 73 and the carboxylato group of Glutamate 166.[140] In this instance, unlike the imidazolyl group in the active site of chymotrypsin, the pK_a for the ammonio group of Lysine 73 should be significantly closer to that of the hydroxy group of the serine, so the conjugate base should be more able to remove the hydron from the hydroxy group. Nevertheless, the hydron probably remains on the hydroxy group when the ammonio group dissociates and becomes

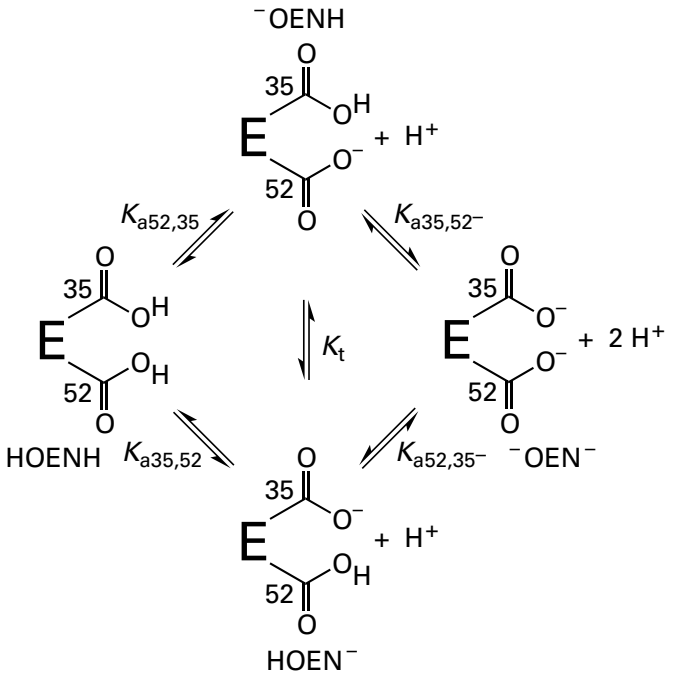
an amino group because, if it were to transfer to the imidazolyl group, the complex would be the zwitterion.

There is a similar hydrogen-bonded complex between the ammonio group of Lysine 165 and the carboxylato group of Aspartate 169 in the active site of phosphoribulokinase from *R. sphaeroides*, which uses $MgATP^{2-}$ to phosphorylate D-ribulose 5-phosphate (pr). When Aspartate 169 is mutated to alanine,[141] $k_0\,(K_{m,pr}K_{mATP})^{-1}$ decreases by a factor of 1.2×10^5, and when Lysine 166 is mutated to alanine,[142] $k_0\,(K_{m,pr}K_{mATP})^{-1}$ decreases by a factor of 2.3×10^6. These values are consistent with the two participants in the hydrogen-bonded complex acting in concert rather than the situation in chymotrypsin in which the carboxylato group only provides an acceptor for a hydrogen bond, the elimination of which is not so dramatic.

Independent determination of the pK_a for the side chain of an amino acid in the active site of an enzyme can also **rule out its assignment to a particular pK_a**. For example, the pK_a of Lysine 73 in the active site of β-lactamase from plasmid TEM-1 has been estimated to be 10.0 from the rate of its modification by 2,4,6-trinitrobenzenesulfonate.[143] This pK_a, if it is an accurate estimate, does not agree with either of the two values of pK_a (5. 6 and 7.8) that govern the behavior of the specificity constant $k_{BPC,app}$ for hydrolysis of benzylpenicillin (BPC) catalyzed by the enzyme.[144]

Contrary to the assumption that was made earlier to simplify the discussion of pH–rate profiles, the acid–bases in an active site often do not titrate independently of each other. If two or more of the acid–bases are close enough together within the active site, titration of one of them can shift the value or values of pK_a for the others. In such a case, **a tautomeric linkage governs microscopic values of pK_a**. The participants in a tautomeric linkage involving only two acid–bases are a linked pair.

The situation in the active site of lysozyme is an illustration of a **linked pair** participating in a tautomeric linkage.[145] In the crystallographic molecular model of lysozyme from *G. gallus*,[146] Glutamate 35 and Aspartate 52 are immediately adjacent to the site at which hydrolysis of a poly-(β1,4)-*N*-acetylglucosaminopyranose (Figure 3–27) occurs in the nucleophilic substitution catalyzed by the enzyme. Microscopic acid dissociation constants for these two carboxy groups have been estimated from the difference between the direct acid–base titrations of the enzyme and a derivative of the enzyme in which Aspartate 52 had been ethyl-esterified.[147] From fits of this difference titration curve and the direct titration curve of the unesterified enzyme to the appropriate equations, microscopic acid dissociation constants for these two carboxy groups



(4–135)

at 25 °C in 0.15 M KCl were estimated to be $pK_{a52,35} = 4.4$, $pK_{a52,35^-} = 5.2$, $pK_{a35,52} = 5.2$, and $pK_{a35,52^-} = 6.0$. As required by the linkage of the four equilibria among the tautomers and states of ionization

$$pK_{a52,35} + pK_{a35,52^-} = pK_{a35,52} + pK_{a52,35^-} \qquad (4\text{–}136)$$

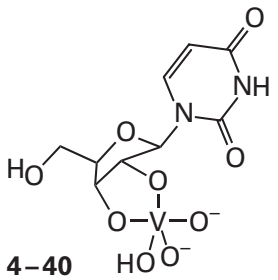
Because these two carboxy groups are adjacent to each other in the active site, the anionization of either one raises the microscopic pK_a of the other one by 0.8 unit. It is also possible to estimate, in a similar fashion, the **four values of microscopic pK_a for two catalytic acid–bases** in the unoccupied active site of an enzyme from differences between the pH–rate profiles for the specificity constant $k_{A,app}$ of the unmutated enzyme and that of a mutant in which one of the two acid–bases has been eliminated.[148]

In Equation 4–135, there are two tautomers of the state of ionization of the dicarboxylic acid that contain only one hydron: one in which the hydron is on Glutamate 35 and one in which the hydron is

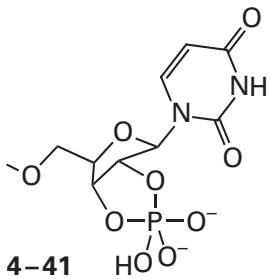
on Aspartate 52.* It is always the case that only one of the **two tautomers** in such a situation is enzymatically active in a particular direction of the reaction, and the fraction of the active sites that exist in this tautomer will determine the ultimate apparent catalytic constants in that direction at a given pH. Reverse hydronation is a corollary of this rule.

No pH–rate profile can distinguish between these two tautomers because the equilibrium constant, K_T, relating the two tautomers cannot be a function of pH (Equation 4–125), so the ratio between the two tautomers does not vary with pH. To decide on the role of each catalytic group in such a situation requires **information other than a pH–rate profile**. For example, it was proposed by the crystallographers that, from their locations in the active site, Aspartate 52 would act as the anionic conjugate base and Glutamic Acid 35 would act as a catalytic acid in hydrolysis of poly-(β1,4)-*N*-acetylglucosaminopyranose catalyzed by lysozyme.[146] It was, however, only serendipitous that these roles assigned by the crystallographer from an examination of the molecular model agree with one's intuition because the concentration of the other tautomer, in which Aspartate 52 is the catalytic acid and Glutamate 35 is the catalytic base, must increase and decrease in parallel with the concentration of the tautomer in which Aspartate 52 is the catalytic base and Glutamate 35 is the catalytic acid, and its increase and decrease must be governed by the same apparent values of pK_a. Consequently, if this situation were an example of reverse hydronation, the same pH–rate profile would have been observed.

Histidine 12 and Histidine 119 are located immediately adjacent to each other in the active site of bovine pancreatic ribonuclease,[149-151] and each is adjacent to the phosphodiester at which the nucleophilic substitution catalyzed by the enzyme occurs after it has associated with the active site. From an examination of a crystallographic molecular model of a complex between enzyme and uridyl vanadate (**4–40**)



4–40



4–41

an analogue of phosphorane **4–41** that is an intermediate in the enzymatic reaction, it was concluded that Histidine 119 acts as a catalytic base and Histidine 12 acts as a catalytic acid in the enzymatic reaction.[152]

pH–Titration curves for these two adjacent imidazolyl groups have been followed by nuclear magnetic resonance spectroscopy.[153-155] Each titration curve has been fit with the equation[156]

$$\delta_{\mathrm{CHobs},i} = \delta_{\mathrm{CH^+},i} + \Delta\delta_{\mathrm{CH},i}\left\{\frac{K_{\mathrm{a}i,j^+}[\mathrm{H^+}] + K_{\mathrm{a}i,j}K_{\mathrm{a}j,i^+}}{[\mathrm{H^+}]^2 + (K_{\mathrm{a}i,j^+} + K_{\mathrm{a}j,i^+})[\mathrm{H^+}] + K_{\mathrm{a}i,j}K_{\mathrm{a}j,i^+}}\right\} \quad (4\text{–}137)$$

where $\delta_{\mathrm{CHobs},i}$ is the observed chemical shift for a proton on carbon 2 of the neutral imidazolyl group *i* at a given pH, δ_{CH,i^+} is the observed chemical shift for the proton on carbon 2 of imidazolyl group *i* when it is hydronated and cationic, $\Delta\delta_{\mathrm{CH},i}$ is the change in chemical shift for the proton on carbon 2 of imidazolyl group *i* upon its dehydronation, $K_{\mathrm{a}i,j^+}$ is the acid dissociation constant for imidazolyl group *i* when imidazolyl group *j* is hydronated and cationic, $K_{\mathrm{a}i,j}$ is the acid dissociation constant for imidazolyl group *i* when imidazolyl group *j* is unhydronated and neutral, and $K_{\mathrm{a}j,i^+}$ is the acid dissociation constant for imidazolyl group *j* when imidazolyl group *i* is hydronated and cationic. This equation defines the observed titration of a proton on carbon 2 of imidazolyl group *i*, and the same equation with the subscripts *i* and *j* switched defines titration of the proton on carbon 2 of imidazolyl group *j*. Parenthetically, Equation 4–137 is valid for any physical property that detects state of hydronation and any types of acid–bases, and it can be used to estimate relevant microscopic acid dissociation constants in such situations. From the fits of this equation to titration curves at 0.3 M NaCl and 30 °C, p$K_{\mathrm{a}119,12^+}$ = 6.01 ± 0.02, p$K_{\mathrm{a}119,12}$ = 6.29 ± 0.02, p$K_{\mathrm{a}12,119^+}$ = 5.80 ± 0.03, and p$K_{\mathrm{a}12,119}$ = 6.08 ± 0.04. Because these imidazolyl groups are adjacent to each other in the active site,

*It should be noted that, as is the case with most tautomers, the hydron is not transferred between the two carboxy groups because they are too far apart, but a hydron associates with each one from the solution and dissociates from each one into the solution.

the cationization of one lowers the pK_a for the other by 0.28 ± 0.05 unit.

In a crystallographic molecular model of the unoccupied active site of endo-1,4-β-xylanase from *B. circulans*, each of the two carboxy groups that are the catalytic acid–bases, those on Glutamate 78 and Glutamate 172, participates in a hydrogen bond with the same molecule of fixed water.[157] From observations of their nuclear magnetic resonance spectra, it was concluded that their ionizations are linked. The values obtained were p$K_{a78,172}$ = 4.6, p$K_{a78,172^-}$ = 5.8, p$K_{a172,78}$ = 5.5, and p$K_{a172,78^-}$ = 6.7. Consequently, the ionization of either one increases the pK_a for the other by 1.2. When the pK_a of Glutamate 78 is lowered by synthetically replacing it in turn with 4-fluoroglutamate and 4,4-difluoroglutamate, the pK_a below which the specificity constant decreases shifts from 4.7 to 3.4 and 3.0, as expected because this pK_a has been assigned to Glutamate 78. The pK_a above which the specificity constant decreases, however, which was assigned to Glutamate 172, also shifts from 7.1 to 6.0 and 6.0 upon the respective modification.[158] Because the specificity constant should reflect values of pK_a for the unoccupied enzyme, even though Glutamate 172 is unmodified, its apparent values for pK_a in the unoccupied active site nevertheless seem to be affected by modification of Glutamate 78, which is not a requirement of the linkage (Equation 4–136).

The carboxy groups in the active sites of lysozyme and endo-1,4-β-xylanase and the imidazolyl groups in the active site of bovine pancreatic ribonuclease are examples of acid–bases that are close enough to affect each other's acid dissociations. As a result of such an interaction, **a single pK_a cannot be assigned to either of these carboxy groups or either of these imidazolyl groups**.

These examples can be used to illustrate **what it means in practice for two acid–bases in an active site to titrate independently of each other**. Glutamatic Acid 78 (p$K_{a78,172}$ = 4.6) in endo-1,4-β-xylanase is more acidic than Glutamic Acid 172 (p$K_{a172,78}$ = 5.5). If Glutamic Acid 78 were even more acidic, then, as the pH of the solution was raised, it would be almost completely unhydronated and anionic before Glutamic Acid 172 began to ionize significantly. In this case, the anionization of Glutamatic Acid 78, because it would almost completely precede the anionization of Glutamic Acid 172, would not affect the titration of Glutamic Acid 172, and the anionization of Glutamic Acid 172, because it would almost completely follow the anionization of Glutamic Acid 78 would not affect the titration of Glutamic Acid 78. As a result, these two carboxy groups would titrate independently of each other, even though the interaction between them would remain just as strong. In other words, in the situation in which their ionizations were independent of each other, the only consequential acid dissociations during the titration would be p$K_{a78,172}$ for Glutamic Acid 78 when Glutamic Acid 172 was un-ionized and p$K_{a172,78^-}$ for Glutamic Acid 172 when Glutamic Acid 78 was anionized.

It has already been noted that the value for the specificity constant decreases below the pK_a of 4.6 as the pH is decreased and decreases below the pK_a of 6.7 as the pH is increased. These values agree with p$K_{a78,172}$ (4.6) and p$K_{a172,\,78^-}$ (6.7) and are consistent with the conclusion that only these two values of pK_a are consequential. So in practice, Glutamic Acid 78 and Glutamic Acid 172 titrate independently of each other because their acidities are different enough.

The acidities of Histidine 119 (p$K_{a119,12^+}$ = 6 .01) and Histidine 12 (p$K_{a12,119^+}$ = 5.80), however, are much closer together, but the interaction energy between them (ΔpK_a = 0.28) is much smaller than the interaction energy between the two carboxy groups (ΔpK_a = 1.2) in the active site of endo-1,4-β-xylanase. If there were insignificant interaction between them, for example, because they were more distant from each other, they would, by definition, titrate independently of each other, each with its own single unambiguous microscopic pK_a, unaffected by the state of ionization of the other, even though their values of pK_a are almost the same.

Consequently, **either large differences in pK_a or insignificant energies of interaction lead to independent titration of two acid–bases in an active site.**

In the case of lysozyme, the difference in pK_a between the carboxy groups is also large enough, and hence the equilibrium constant between the tautomers is small enough, that the pH–rate profile (Figure 4–10I) for specificity constant $k_{AG6,app}$ at an ionic strength of 0.1 M and 40 °C can be fit with Equation 4–97 to give pK_{a1} = 4.25 and pK_{a2} = 6.1, which are indistinguishable, within the error of measurement, from p$K_{a52,35}$ (4.4) and p$K_{a35,52^-}$ (6.0).

By **incorporating tautomeric linkage into the kinetic mechanism** chosen to explain an observed pH–rate profile, it can be seen that the resulting rate equation automatically incorporates reverse hydronation. Consider the interacting acid dissociation constants

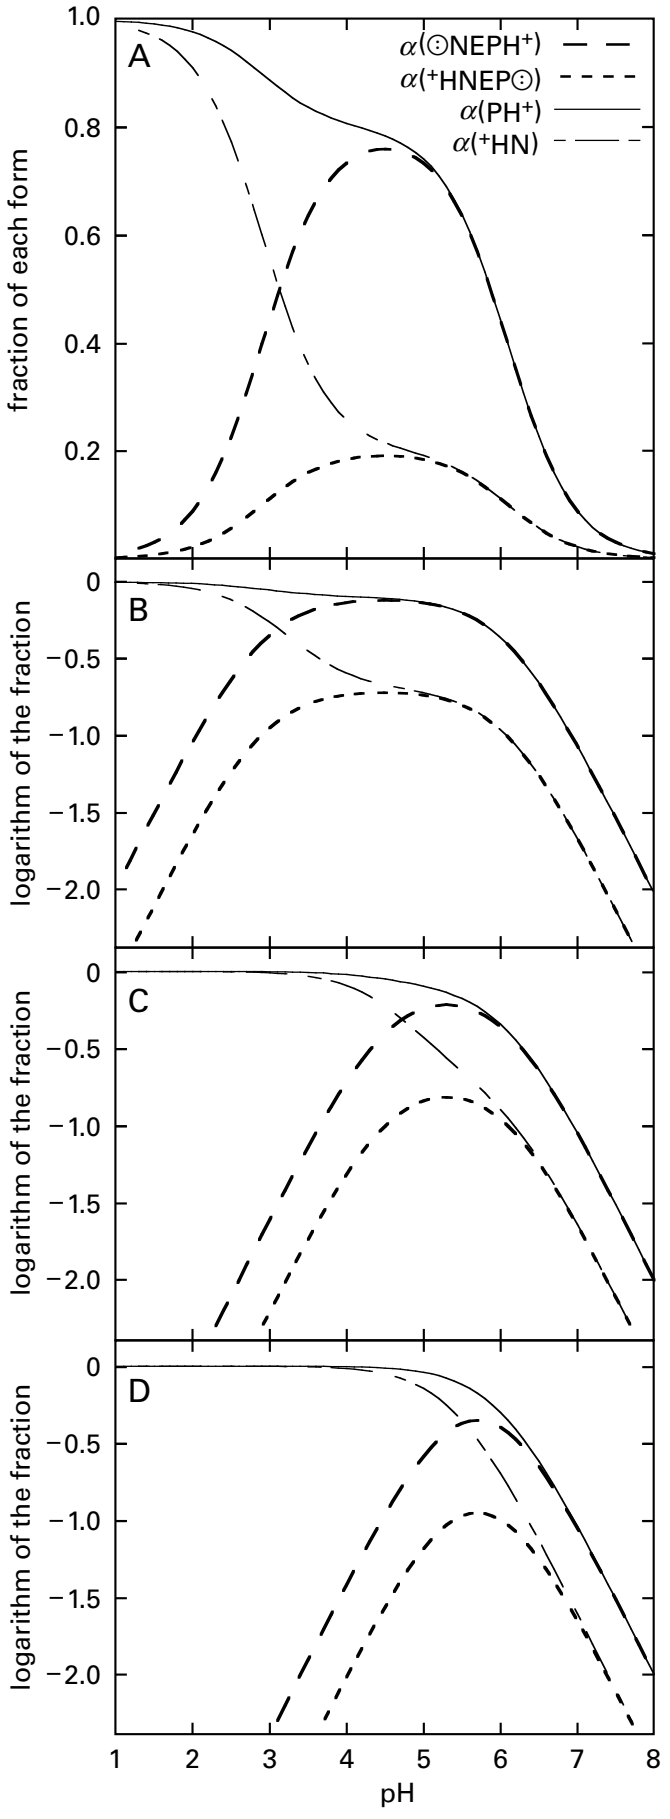


Figure 4–16: Fractions of either a particular tautomer of two acid–bases or the hydronated ionization states of two tautomerically linked acids as a function of the pH of the solution. The plots are for α(⊙NEPH$^+$) (Equation 4–140), α($^+$HNEP⊙) (Equation 4–141), α(PH$^+$) (Equation 4–146), or α($^+$HN) (see Equation 4–146 and switch NH$^+$ and PH$^+$) or for the common logarithms of these fractions. (**A**) Direct plots for pK_{aNH^+,PH^+} = 3.0, pK_{aPH^+,NH^+} = 3.6, p$K_{aNH^+,P\odot}$ = 5.4, and p$K_{aPH^+,N\odot}$ = 6.0. (**B**) Plots of the common logarithms for pK_{aNH^+,PH^+} = 3.0, pK_{aPH^+,NH^+} = 3.6, p$K_{aNH^+,P\odot}$ = 5.4, and p$K_{aPH^+,N\odot}$ = 6.0. (**C**) Plots of the common logarithms for pK_{aNH^+,PH^+} = 4.6, pK_{aPH^+,NH^+} = 5.2, p$K_{aNH^+,P\odot}$ = 5.4, and p$K_{aPH^+,N\odot}$ = 6.0. (**D**) Plots of the common logarithms for pK_{aNH^+,PH^+} = 5.4, pK_{aPH^+,NH^+} = 6.0, p$K_{aNH^+,P\odot}$ = 5.4, and p$K_{aPH^+,N\odot}$ = 6.0. In this last situation, the dissociations of the two acids are unlinked.

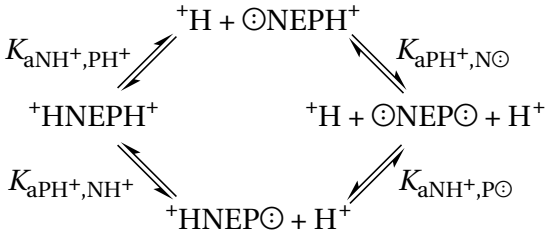

(4–138)

where NH$^+$ and PH$^+$ are cationic catalytic acids in the active site, K_{aNH^+,PH^+} is the dissociation constant of acid NH$^+$ when acid PH$^+$ is hydronated and cationic, $K_{aNH^+,P\odot}$ is the dissociation constant of acid NH$^+$ when acid PH$^+$ is the unhydronated conjugate base and uncharged, K_{aPH^+,NH^+} is the dissociation constant of acid PH$^+$ when acid NH$^+$ is hydronated and cationic, and $K_{aPH^+,N\odot}$ is the dissociation constant of acid PH$^+$ when acid NH$^+$ is the unhydronated conjugate base and uncharged. Mathematically, this linkage is identical to that of Equation 4–135 because the only difference is the identity of the four species and the names for the acid dissociation constants; the hydrons dissociating in each step are identical. Consequently, the result of the following derivation would be the same for Equation 4–135 or any other pair of linked acid dissociations.

If

$$\alpha(\odot\mathrm{NEPH}^+) = \frac{[\odot\mathrm{NEPH}^+]}{[^+\mathrm{HNEPH}^+] + [^+\mathrm{HNEP}\odot] + [\odot\mathrm{NEPH}^+] + [\odot\mathrm{NEP}\odot]} \tag{4–139}$$

it follows that

$$\alpha(\odot\mathrm{NEPH}^+) = \frac{K_{\mathrm{aNH}^+,\mathrm{PH}^+}[\mathrm{H}^+]}{[\mathrm{H}^+]^2 + (K_{\mathrm{aNH}^+,\mathrm{PH}^+} + K_{\mathrm{aPH}^+,\mathrm{NH}^+})[\mathrm{H}^+] + K_{\mathrm{aNH}^+,\mathrm{PH}^+}K_{\mathrm{aPH}^+,\mathrm{N}\odot}} \quad (4\text{–}140)$$

and by the equivalent derivation that

$$\alpha({}^+\mathrm{HNEP}\odot) = \frac{K_{\mathrm{aPH}^+,\mathrm{NH}^+}[\mathrm{H}^+]}{[\mathrm{H}^+]^2 + (K_{\mathrm{aNH}^+,\mathrm{PH}^+} + K_{\mathrm{aPH}^+,\mathrm{NH}^+})[\mathrm{H}^+] + K_{\mathrm{aNH}^+,\mathrm{P}\odot}K_{\mathrm{aPH}^+,\mathrm{NH}^+}} \quad (4\text{–}141)$$

Because $K_{\mathrm{aNH}^+,\mathrm{PH}^+}K_{\mathrm{aPH}^+,\mathrm{N}\odot} = K_{\mathrm{aNH}^+,\mathrm{P}\odot}K_{\mathrm{aPH}^+,\mathrm{NH}^+}$, the denominator is identical for both $\alpha(\odot\mathrm{NEPH}^+)$ and $\alpha({}^+\mathrm{HNEP}\odot)$.* Plots of Equations 4–140 and 4–141 (Figure 4–16) are indistinguishable from plots of kinetic equations for an enzymatic reaction catalyzed by an acid and a base that titrate independently of each other (Figures 4–10G, 4–10H, 4–12, and 4–14) rather than being tautomerically linked. The only term that differs between Equations 4–140 and 4–141 is the acid dissociation constant in the respective numerators, so as equations describing the observed behavior, they are indistinguishable. When there is no interaction between acid NH^+ and acid PH^+, $K_{\mathrm{aNH}^+,\mathrm{PH}^+} = K_{\mathrm{aNH}^+,\mathrm{P}\odot}$ and $K_{\mathrm{aPH}^+,\mathrm{NH}^+} = K_{\mathrm{aPH}^+,\mathrm{N}\odot}$ and Equation 4–140 becomes Equation 4–94.

If one steady-state rate constant is directly proportional to the fraction of the enzyme in the tautomer $\odot\mathrm{NEPH}^+$, then

$$k_{i,\mathrm{app}} = \frac{k_i K_{\mathrm{aNH}^+,\mathrm{PH}^+}[\mathrm{H}^+]}{[\mathrm{H}^+]^2 + (K_{\mathrm{aNH}^+,\mathrm{PH}^+} + K_{\mathrm{aPH}^+,\mathrm{NH}^+})[\mathrm{H}^+] + K_{\mathrm{aNH}^+,\mathrm{PH}^+}K_{\mathrm{aPH}^+,\mathrm{N}\odot}} \quad (4\text{–}142)$$

If one steady-state rate constant is directly proportional to the fraction of the enzyme in the form ${}^+\mathrm{HNEP}\odot$, then

$$k_{i,\mathrm{app}} = \frac{k_i K_{\mathrm{aPH,NH}^+}[\mathrm{H}^+]}{[\mathrm{H}^+]^2 + (K_{\mathrm{aNH}^+,\mathrm{PH}^+} + K_{\mathrm{aPH}^+,\mathrm{NH}^+})[\mathrm{H}^+] + K_{\mathrm{aNH}^+,\mathrm{P}\odot}K_{\mathrm{aPH}^+,\mathrm{NH}^+}} \quad (4\text{–}143)$$

Equations 4–142 and 4–143 have the same form as Equation 4–99. The observed acid dissociation constants, K_{a1} and K_{a2} in Equation 4–99, are simply the two roots of the quadratic term in the denominator of Equations 4–142 and 4–143.

Consequently, the data can be fit as successfully with either Equation 4–99, Equation 4–142, or Equation 4–143, and the pH–rate profiles alone can never distinguish whether the situation described by Equation 4–99, Equation 4–142, or Equation 4–143 applies. Nor is there any reason to expect consequential interaction between the acid–bases governing the behavior, regardless of observed values of $\mathrm{p}K_{\mathrm{a}}$, from the pH–rate profile alone. It follows that **any pH–rate profile is always consistent with either the catalytic acid–bases titrating independently of each other or one of the tautomers of a tautomeric linkage being the active tautomer**.

If, for bovine pancreatic ribonuclease, Histidine 119 is the catalytic base $\mathrm{N}\odot$ and Histidine 12 is the catalytic acid PH^+, as concluded from the crystallographic molecular model, then from nuclear magnetic resonance spectroscopy, $\mathrm{p}K_{\mathrm{aNH}^+,\mathrm{PH}^+} = \mathrm{p}K_{\mathrm{a119,12}^+} = 6.01$, $K_{\mathrm{aPH}^+,\mathrm{NH}^+} = \mathrm{p}K_{\mathrm{a12,119}^+} = 5.80$, and $K_{\mathrm{aPH}^+,\mathrm{N}\odot} = \mathrm{p}K_{\mathrm{a12,119}} = 6.08$. These values can be corrected for the difference in temperature between the measurements by nuclear magnetic resonance spectroscopy (30 °C) and those for the pH–rate profile (25 °C) with the relation

$$\frac{d\ln K_{\mathrm{a}}}{d(T^{-1})} = -\frac{\Delta H^\circ}{R} \quad (4\text{–}144)$$

where ΔH° is the heat of ionization of an imidazolyl group (37 kJ mol^{-1}).[159] When the corrected values are used as parameters in Equation 4–142, the resulting curves that are generated fit the measurements of $k_{\mathrm{cCP,app}}$ (Figure 4–11A) and $k_{\mathrm{cUP,app}}$ (Figure 4–11B). The data can also be fit with Equation 4–95 and the parameters $\mathrm{p}K_{\mathrm{a1}} = 5.8$ and $\mathrm{p}K_{\mathrm{a2}} = 6.2$, which are the respective roots of the quadratic equation in the denominator of Equation 4–142. In this interpretation, in which Histidine 119 is the catalytic base and Histidine 12 is the catalytic acid governing the pH–rate profile, based solely on the assignments of

*Note the similarity of Equations 4–140 and 4–141 to the factor in the second term on the right in Equation 4–137.

the crystallographic molecular model, catalysis performed by these catalytic acid–bases in the direction of hydrolysis would be an example of reverse hydronation because the pK_a of the conjugate acid of the imidazolyl group of Histidine 119 is greater than the pK_a for the imidazolium group of Histidine 12.

Consistent with the assignment of the observed pK_a of 5.8 to Histidine 12 and the observed pK_a of 6.2 to Histidine 119 is the fact that, when the imidazolyl group of Histidine 12 is replaced synthetically by a 4-fluoroimidazolyl group, the observed pK_a of 5.8 shifts to an observed pK_a of 3.4, and when the imidazolyl groups of both Histidine 12 and Histidine 119 are replaced by 4-fluoroimidazolyl groups, the observed pK_a of 6.2 shifts to an observed pK_a of 4.6.[160]

To this point it has been assumed that only one tautomer of a singly hydronated, linked pair of acid–bases is the catalytically active form of the active site because one linked pair of acid–bases would be acting as a catalytic base and the other as a catalytic acid in one direction and switching roles in the opposite direction, as was extensively described for mandelate racemase. It is also possible, however, that two acid–bases in the active site participate in a tautomeric linkage but that **only one of the two acts as a catalytic base or a catalytic acid and the other, the spectator acid–base, merely perturbs the acid dissociation constant of that catalytic acid or base**. For example, suppose that acid PH^+ in the previous tautomeric equilibrium (Equation 4–138) acts as a catalytic acid but the other acid, NH^+, although it is tautomerically linked to acid PH^+, is a spectator that has no role in catalysis. Suppose also that the spectator acid NH^+ is positively charged when it is hydronated and decreases the pK_a of the catalytic acid, PH^+, when it, the catalytic acid, is hydronated. In that case, catalysis should depend only on the fraction, $\alpha(PH^+)$, of the acid–base PH that is in the hydronated ionization state. Because

$$\alpha(PH^+) = \frac{[^+HNEPH^+] + [\odot NEPH^+]}{[^+HNEPH^+] + [^+HNEP\odot] + [\odot NEPH^+] + [\odot NEP\odot]} \quad (4\text{–}145)$$

it follows that

$$\alpha(PH^+) = \frac{K_{aNH,PH^+}[H^+] + [H^+]^2}{[H^+]^2 + (K_{aNH^+,PH^+} + K_{aPH^+,NH^+})[H^+] + K_{aNH^+,PH^+}K_{aPH^+,N\odot}} \quad (4\text{–}146)$$

Titration curves (Figure 4–16) of the catalytic acid, $\alpha(PH^+)$, and the spectator acid, $\alpha(NH^+)$, are quite different from titration curves of the two tautomers, $\alpha(\odot NEPH^+)$ and $\alpha(^+HNEP\odot)$. Suppose the value of pK_a for each of the two acids is shifted significantly enough by dehydronation of the other—for example, in Figure 4–16A,B, where the values are $pK_{aPH^+,NH^+} = 3.6$ and $pK_{aPH^+,N\odot} = 6.0$ and $pK_{aNH^+,PH^+} = 3.0$ and $pK_{aNH^+,P\odot} = 5.4$. Suppose also that the values of pK_a for the two acids when the other is unhydronated are close enough together that the concentrations of the two tautomers are of equal magnitude, again as they are in Figure 4–16A,B. Under these conditions, the titration curve for the catalytic acid has an unmistakable inflection, as does that of the spectator acid, and the pH–rate profile for catalysis should also display such an inflection. In fact, titration curves for Aspartate 10 and Aspartate 70 in the active site of ribonuclease H from *E. coli*,[161] determined by nuclear magnetic resonance spectroscopy, show inflections that are quite similar to those seen in Figure 4–16. As the shift of the one pK_a caused by dehydronation of the one acid decreases in magnitude, however, the inflections become less obvious (Figure 4–16C) before they disappear completely when there is no linkage between the two acid–bases (Figure 4–16D).

Values of pK_a for the plots in Figure 4–16A,B were intentionally chosen to exaggerate the inflections. In most cases, values of pK_a in a situation where a spectator acid–base shifts the pK_a for a catalytic acid–base, which is probably quite common, are usually not so extreme, either because the shifts produced by the one upon the other are not so large, as in the case of ribonuclease, or because values of pK_a for the acid–bases when the other is neutral are much larger so the equilibrium constant relating the concentrations of the tautomers is far from 1, as in the case of mandelate racemase. In either situation, the inflections are not noticed because the data are almost never extensive enough to define them. The inflection in Figure 4–11B is obvious only because the data are of exceptional quality.

It seems that most active sites perturb values of pK_a for their catalytic acid–bases. Therefore, the shifts in pK_a for the catalytic acid–bases caused by the surroundings that occur in the active sites of ribonuclease T_1 from *Aspergillus oryzae*, enoyl-CoA hydratase from *R. norvegicus*, lysozyme from *G. gallus*, bovine pancreatic ribonuclease, and mandelate racemase from *Pseudomonas putida*, which have already been described, are not unusual. These shifts in pK_a can be dramatic. For example, the pK_a of 7.0 below which the catalytic constant for IMP dehydrogenase from *Tritrichomonas foetus* decreases as the pH is lowered has been assigned to Arginine 418,[162,163] which would represent a shift in pK_a of around 6 units caused by the active site. In the active site of human medium-chain acyl-CoA dehydrogenase occupied by an acyl-SCoA eight carbons long,[164] the pK_a of Glutamate 376 is 9.2, which would represent a shift in pK_a of around 5 units.

Even though the reasons for these shifts in pK_a are usually obscure, and they have occurred over time for reasons usually understood only by natural selection, the temptation to rationalize them has not been resisted by observers as well as this author. For example, the pK_a for the ammonio group in Lysine 115 in acetoacetate decarboxylase from *C. acetobutylicum* is 5.9 (Figure 4–15),[127] even lower than the pK_a for Lysine 166 in mandelate racemase. In the crystallographic molecular model of the active site of this enzyme, Lysine 115 is found in a nonpolar funnel,[165] and it has been proposed that this nonpolar environment prevents solvation of the ammonio group and lowers its pK_a by lowering the relative permittivity of its surroundings (Equation 4–62).

It has been pointed out, however, that ad hoc explanations such as the one just given for the shift in pK_a for the ammonio group of the Lysine 115 may well be too simplistic. When 30 mutations—either single mutations, double mutations, or triple mutations—were made in amino acids surrounding Tyrosine 57 in the active site of steroid Δ-isomerase from *P. putida* and the pK_a of Tyrosine 57 was assessed for each mutant, many of the shifts caused by the mutations seemed counterintuitive. The conclusion reached[166] was that the "perturbations are more complex than suggested by visual inspection."

In cases where the value of a pK_a governing the catalytic constant is for the acid dissociation constant of the same group responsible for the value of pK_a governing the specificity constants, those **values of pK_a usually shift when reactant binds**, and the structure, identity of the various hydrogen bonds, and relative permittivity of the active site all change, **causing observed values of pK_a for specificity constants and the catalytic constant to differ**.[167] For example, in human acyl-CoA dehydrogenase (previously Equation 2–114)

$$\begin{aligned}&\text{octanoyl-SCoA} + \\ &\quad \text{oxidized electron-transfer flavoprotein} \\ &\qquad \rightleftharpoons \textit{trans}\text{-oct-2-enoyl-SCoA} + \\ &\qquad\quad \text{reduced electron-transfer flavoprotein}\end{aligned} \tag{4–147}$$

the pK_a of Glutamate 376, which is the catalytic base that removes a hydron from carbon 2 of acyl-SCoA during the reaction to form the enolate, shifts from 4.3 in the free enzyme to 9.3 when 4-thiaoctenoyl-SCoA, an analogue of the reactant octanoyl-SCoA, associates with the active site. This shift may explain the pK_a of 8.3 observed in the pH–rate profile for the catalytic constant of the enzyme with the actual reactant, octanoyl-SCoA.[164,168]

If Aspartate 52 and Glutamate 35 are responsible for the two observed values of pK_a governing the catalytic constant k_0 of lysozyme (3.8 and 6.7; Figure 4–10H), then the microscopic values of pK_a for Aspartate 52 in the free enzyme (4.4 and 5.2) have shifted to a lower value, and they have coalesced because they are no longer linked to the ionization of Glutamate 35. Likewise, the microscopic values of pK_a for Glutamate 35 in the free enzyme (5.2 and 6.0) have shifted to a higher value, and they have coalesced because they are no longer linked to the ionization of Aspartate 52. The linkage is probably eliminated because the substrate now sits between the two and their values of pK_a shift in opposite directions. The latter can be explained as a shift caused by the hydrogen bond Glutamic Acid 35 forms with the oxygen of the leaving group in the hydrolysis (Figure 3–27), which should raise its pK_a. If the lower pK_a, however, is still that of Aspartate 52, then the decrease in the pK_a for its side chain, which does not form a hydrogen bond with a reactant in the Michaelis complex and which finds itself in less polar surroundings in the complex, has no obvious explanation.

An active site can also **shift the pK_a for a substrate** upon its association. For example, the pK_a of nitrogen 1 of uracil in the complex between uracil-DNA glycosylase from *E. coli* and its substrates (uracil and a double-helical DNA fragment of 11 base pairs from which the enzyme has removed the uracil) has been determined by nuclear magnetic

resonance spectroscopy[169] to be 6.3 while the pK_a of uracil is free solution is 9.5. This shift in pK_a is caused by a hydrogen bond between the imidazolium of Histidine 187 and the acyl oxygen on carbon 2 of uracil,[170] and the shift may increase the ability of the uracil to leave during the nucleophilic substitution catalyzed by the active site.

Reasons other than a shift in pK_a, however, can explain the difference in the effects of pH on a specificity constant and a catalytic constant. In the case of porcine aspartate transaminase (Equation 4–108), where two values of pK_a govern the behavior of the specificity constant $k_{Asp,app}$ for L-aspartate, the catalytic constant of the enzyme is unaffected by pH (Figure 4–12). The pK_a of 6.35, assigned to the lysylpyridoximine (Equation 4–129) in the unoccupied active site, and the pK_a of 9.9, assigned to the α-amino group of the reactant L-aspartate, should become irrelevant once the first of the many hydron transfers in the mechanism have occurred (Figure 2–2), well before the rate-limiting step of the reaction, which is independent of pH.

An appealing explanation for the observation that **a catalytic constant is unaffected by pH** would be that once reactant has bound and the active site has closed around it, the acid–bases in the active site are no longer accessible to the solution and as a result cannot participate in acid dissociations. In the case of hexokinase from *S. cerevisiae*, however, which closes rather completely around its reactants (Figure 3–55), the catalytic constant nevertheless decreases as the pH is lowered below an apparent pK_a of 5.0.[171,172]

Because the pH–rate profiles for mandelate racemase (Figure 4–14) are for its catalytic constants in the two respective directions, the values of pK_a observed, 6.4 and 10.0, should be those for Lysine 166 and Histidine 297 in the complex between enzyme and the respective reactant (Equation 4–119). If this assignment is correct, which seems reasonable for an enzyme with such a simple mechanism, in which the rate-limiting step is the difficult removal of the hydron from the carbon,[101] then Lysine 166 and Histidine 297 in the Michaelis complex between enzyme and substrate are accessible enough to the solution to participate readily in acid dissociations.

The **shift caused by a hydrogen bond**, for example, when reactant binds to lysozyme, is an example of a common reason for the shift in pK_a of a catalytic acid–base upon formation of a Michaelis complex. If the catalytic lone pair of electrons on a catalytic base in the active site participates as an acceptor in a hydrogen bond with reactant, the pK_a for the conjugate acid of that catalytic base will decrease upon formation of the hydrogen bond in the complex between enzyme and reactant; and if the catalytic hydron on a catalytic acid in the active site participates as a donor in a hydrogen bond to the reactant, the pK_a for that catalytic acid will increase upon formation of the hydrogen bond. For example, in the crystallographic molecular model of the complex between androstenedione and the active site of human aromatase, the carboxy group of Aspartic Acid 309 is the donor in a hydrogen bond with the carbonyl group at carbon 3 of androstenedione. The pK_a for the carboxy group of this aspartic acid in the complex between the active site and androstenedione, measured by ultraviolet difference spectroscopy of the complex,[173] is 8.2, considerably greater than the pK_a (4.0) for aspartic acid on the surface of a protein. The pK_a of Glutamatic Acid 167 in the active site of triose-phosphate isomerase from *Trypanosoma brucei* shifts from around 4 in the unoccupied active site to a pK_a of around 10 when the active site associates with phosphoglycolate,[174] an analogue of the *cis*-1,2-enediolate intermediate in the enzymatic reaction. In the crystallographic molecular model of the complex between phosphoglycolate and the active site of triose-phosphate isomerase from *S. cerevisiae*, the carboxy group of Glutamic Acid 165 (the homologue of Glutamic Acid 167 in the enzyme from *T. brucei*) is a donor in a hydrogen bond to one carboxylato oxygen in phosphoglycolate.

In the case of bovine pancreatic ribonuclease, if the observed pK_a of 9.0 governing the behavior of the catalytic constant of the enzyme for the hydrolysis of cytidine 2′,3′-cyclic phosphate (Figure 4–11A) is that of Histidine 12, then its pK_a has increased from 5.8 in part because it acts as a donor in a hydrogen bond with the anionic phospho oxygen of the reactant. If the observed pK_a of 6.25 governing the behavior of the catalytic constant of the enzyme (Figure 4–11A), however, were that of Histidine 119, then its pK_a would not have shifted from an observed pK_{a2} of 6.2 for the unoccupied enzyme, even though one anionic oxygen of the phosphate in the reactant has slid in between Histidine 119 and the hydronated cationic Histidine 12.[152] This consideration seems to require that the pK_a of 6.25 governing the behavior of the catalytic constant is not that of Histidine 119 and that its pK_a has shifted out of the range of measurement.

Formation of a hydrogen bond can also affect the pK_a for an amino acid in the unoccupied active

site of an enzyme. For example, in the examination of the large array of mutants of steroid Δ-isomerase from *P. putida*, the authors[166] concluded that in the unmutated native enzyme, three donors of hydrogen bonds to the hydroxy group on Tyrosine 57, acting together within a cluster of hydrogen bonds that dictates what is a donor and what is an acceptor, are responsible for lowering the pK_a of Tyrosine 57 to 6.3.

Apparent values of pK_a observed in a pH–rate profile of a steady-state rate constant are often not registering the pK_a of any acid–base in the active site. To this point, it has been assumed that values of pK_a observed in the pH–rate profiles of steady-state rate constants are actual values of pK_a for specific acid–bases in the active site of the enzyme. When, however, a pK_a that appears to govern a steady-state rate constant cannot be confidently assigned by another observation to a reactant or a particular amino acid known crystallographically to be in the active site of the enzyme, **the likelihood that the kinetically observed pK_a is not an actual pK_a** must be considered.

Whether or not it is explicitly stated by the investigator, treating values of pK_a observed in a pH–rate profile of a catalytic constant or the specificity constant for reactant A as actual values of pK_a assumes that the kinetic mechanism for the reaction is as simple as that of Equation 4–112 or its equivalent for reactant A. It has been pointed out, however, that **the kinetic mechanism of Equation 4–112 is too simple to describe the kinetic mechanisms of most if not all enzymes**.[66] Any increase in the complexity of the mechanism can cause the catalytic constant or the specificity constant for reactant A, or both of them, no longer to be simple products of the fractions of free enzyme, free reactant, and their various complexes that are the proper tautomers for catalysis (Equations 4–118 and 4–119).[127] Therefore, in many if not most cases, the intersections of the asymptotes (Figures 4–10, 4–11, 4–12, and 4–14) are not values of pK_a for particular side chains in the active site. Any statement that they are must be accompanied by independent evidence of this claim, as has been done so far in this discussion in describing the identity of the acid–base responsible for particular situations.

The situation, however, is nothing more serious than an instance of what is true of all kinetic mechanisms: they may be consistent with the observations but cannot be proven by the observations. If, however, the kinetic mechanism of a particular enzymatic reaction with a particular reactant has been established independently and it differs from the kinetic mechanism in Equation 4–112, then **the meaning of the intersections of asymptotes** can be stated explicitly because an equation for the initial rate of the enzymatic reaction can be derived by the usual formalism, and it becomes clearer whether or not any of these intersections define acid dissociation constants of amino acids in the active site.[127]

To illustrate the fact that there is **no requirement for apparent values of pK_a to be actual values of pK_a** for amino acids in the active site or on the reactants, a simple example of a situation in which an apparent pK_a is not an actual pK_a can be formulated.[175] Suppose that an enzymatic reaction has two steps following association of all its reactants: a slow step independent of pH, followed by a step that requires a particular hydronated acid–base in the active site acting as a catalytic acid. Suppose also that reactants are all present at saturation so that the catalytic constant of the enzymatic reaction is being followed as a function of pH. Finally, suppose that at low pH, well below the pK_a of the catalytic acid in the complex, the second step, the one requiring the catalytic acid, is much faster than the first and that the first step is the rate-limiting step of the overall reaction. As the pH is raised, steady-state flux through the two steps, and hence the catalytic constant, will remain constant even as the pH rises above the actual pK_a for the acid–base in the complex because the second step would still remain faster than the first. Above a certain value of pH, however, there would be a **change in the rate-limiting step** as the concentration of hydronated catalytic acid–base in the complex becomes so small that the rate of the second step necessarily has become slower than the first. Above this value of pH, the catalytic constant of the enzyme, now limited by the second step rather than the first, would decrease by a factor of 10 for every increase of 1 unit in pH. Therefore, the pH at which the change in the rate-limiting step occurs only appears to define an acid dissociation constant of the occupied active site; the actual value of the pK_a for the catalytic conjugate acid of the acid–base controlling the rate of the second step is smaller than the pH at which the asymptotes in the common logarithmic pH–rate profile of the catalytic constant intersect.

A similar argument can be made for a situation in which the second step requires a particular unhydronated catalytic acid–base in the active site. In this instance, the change in rate-limiting step defined by the intersection of the asymptotes in the

common logarithmic pH–rate profile of the catalytic constant at the apparent pK_a, which seems to define the pK_a of the conjugate acid of the catalytic base, would actually occur at a pH less than the pK_a of the conjugate acid of the catalytic base, at the point at which the concentration of the required, unhydronated catalytic acid–base becomes small enough that the second step becomes slow enough to be rate-limiting.

The decrease in the common logarithm of the catalytic constant k_0 as a function of pH with a slope of –1 above the pH of the intersection in the first case (as in Figure 4–10E) and the decrease in the common logarithm of the catalytic constant k_0 as a function of pH with a slope of +1 below the pH of the intersection in the second case (as in Figure 4–10B) still result from the decrease in the concentration of the catalytic acid or the catalytic base, respectively, of a factor of 10 for every unit of pH. The intersections of the asymptotes, however, are no longer values of pK_a for the respective catalytic acid–base governing the behavior. In the former case, the actual pK_a for the catalytic acid is less than the pH at the intersection of the asymptotes; in the latter case, the actual pK_a for the conjugate acid of the catalytic base is greater than the pH at intersection; and in each case, the **intersection of the asymptotes defines only the pH at which the rate-limiting step changes**. Consequently, if the pK_a for a candidate for a catalytic acid in the enzymatic reaction is measured independently and found to be less than the apparent pK_a governing a pH–rate profile, or if the pK_a for the conjugate acid of a candidate for a catalytic base in the enzymatic reaction is measured independently and found to be greater than the apparent pK_a governing a pH–rate profile,[176] this discordance cannot be used as an argument ruling out the involvement of either acid–base as a catalyst in the mechanism of the enzyme. Nevertheless, the decrease in rate constant above or below a particular pH does indicate that there is an acid–base that must be hydronated or an acid–base that must be unhydronated for the enzymatic reaction to proceed.

A change in rate-limiting step can involve **dissociation of a product** as one step. For example, the catalytic constant k_0 of the reaction catalyzed by dihydrofolate reductase from *E. coli* (previously Equation 3–428)

$$\text{NADPH} + \text{7,8-dihydrofolate} + \text{H}^+ \rightleftharpoons \text{5,6,7,8-tetrahydrofolate} + \text{NADP}^+ \quad (4\text{–}148)$$

is determined both by the rate for hydride transfer from NADPH to 7,8-dihydrofolate and by the rate for dissociation of the product $NADP^+$ from the active site.[177] The rate constant for hydride transfer, k_{HT}, measured directly, is dependent on pH, decreasing above a pK_a of 6.5 from a maximum at 25 °C of 950 s^{-1} as a catalytic acid is titrated. The rate constant, k_{diss}, for dissociation of $NADP^+$ is independent of pH and has a value of 15 s^{-1}. At low pH, dissociation of the product $NADP^+$ is the rate-limiting step for turnover because the catalytic acid is stoichiometrically hydronated. As the pH is increased, however, there is a change in rate-limiting step at pH 8.3, which is identified by an intersection of asymptotes for the catalytic constant (Figure 4–17).[177,178] At high pH, hydride transfer is the rate-limiting step for turnover. If the rate of dissociation of $NADP^+$ is accelerated by using a different folate[179] or the rate of hydride transfer is decreased by mutating the enzyme,[180] the pH–rate profile of the catalytic constant k_0 is governed by the intrinsic pK_{aNH} of 6.5 of the catalytic acid required for hydride transfer. This situation is an example in which the actual pK_a for the catalytic acid is less than the pH at which the asymptotes intersect.

In the case of micrococcal nuclease from *S. aureus*, however, the dependence on pH of the catalytic constant of the enzyme for hydrolysis of single-stranded DNA decreases below an apparent pK_a of 7.3 as the pH is lowered. At this pH, the rate-limiting step changes from dissociation of the product at high pH to hydrolysis of the phosphodiester at low pH. This change in rate-limiting step was demonstrated by examining the effect of viscosity of the solution on the catalytic constant as a function of pH.[181] In this instance, the intrinsic pK_a for the acid–base below which the rate constant for hydrolysis decreases, leading eventually to the change in rate-limiting step at pH 7.3, is 8.7. This situation is an example in which the actual pK_a for the catalytic base is greater than the pH at which the asymptotes intersect.

Stickiness of a reactant can cause a change in rate-limiting step. A reactant is sticky if its rate of dissociation from the active site is slower than its conversion to product free in solution. In the simplest kinetic mechanism (previously Equations 3–55 and 3–62)

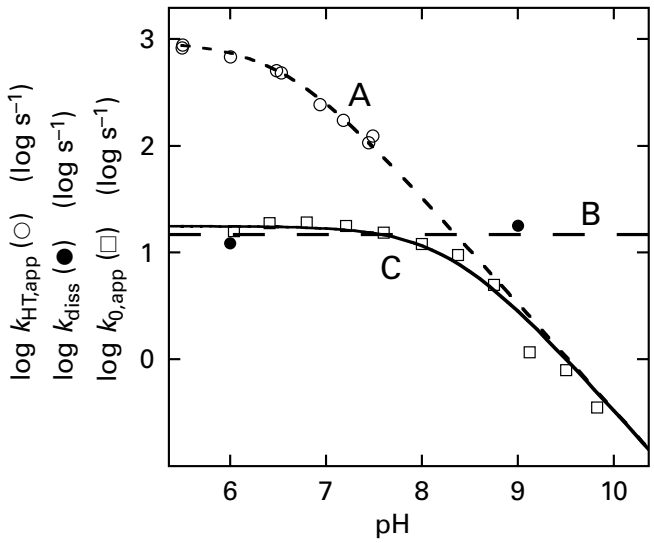

Figure 4–17: Change in rate-limiting step as a function of pH for the catalytic constant of dihydrofolate reductase from *E. coli* for NADPH and 7,8-dihydrofolate.[177] (**A**) The rate for transfer of the hydride from NADPH to 7,8-dihydrofolate on the active site was monitored at 25 °C as a decrease in fluorescence of NADPH following rapid mixing of the two reactants at saturating concentrations with the enzyme (as in Figure 4–18). The buffer contained 50 mM 2-(*N*-morpholino)ethanesulfonate, 25 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol, 25 mM ethanolamine, and 100 mM sodium chloride. Over the pH range used, the ionic strength of this buffer remains constant. The common logarithms of the observed rate constants for transfer of the hydride, $k_{HT,app}$ (○, second^{-1}), are plotted as a function of pH. The dashed curve is for Equation 4–89 with $k_{HT} = 950$ s^{-1} and p$K_a = 6.55$. (**B**) The rate for the dissociation of the product 5,6,7,8-tetrahydrofolate from the active site was monitored at 25 °C as a decrease in fluorescence at 340 nm after rapid mixing of the preformed complex between the enzyme, 5,6,7,8-tetrahydrofolate, and NADPH with a solution of methotrexate, which immediately associates with the active site following dissociation of 5,6,7,8-tetrahydrofolate to prevent its rebinding. The common logarithms of the observed rate constants for the dissociation, k_{diss} (●, second^{-1}), are plotted. The dissociation was measured at pH 6 and 9 and found to be the same within the error of measurement. The horizontal dashed line is placed at the mean of these two measurements. (**C**) The initial rates for conversion of NADPH and 7,8-dihydrofolate to 5,6,7,8-tetrahydrofolate and NADP$^+$ catalyzed by the enzyme were measured at 30 °C by following the decrease in absorbance of NADPH at 340 nm.[178] The same buffer described above was used to establish the pH. The common logarithms of the observed catalytic constants of the enzyme, $k_{0,app}$ (□, second^{-1}), are plotted as a function of pH. Even though the behavior observed is due to a change in rate-limiting step, Equation 4–89 with $k_0 = 18$ s^{-1} and p$K_a = 8.3$ (solid curve) fits the data satisfactorily.

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A \xrightarrow{k_2} E + Z \tag{4–149}$$

$$v_0 = \frac{k_2[E]_t\left(\frac{k_2k_1}{k_{-1}+k_2}\right)[E]_t[A]_0}{k_2[E]_t + \left(\frac{k_2k_1}{k_{-1}+k_2}\right)[E]_t[A]_0} \tag{4–150}$$

the specificity constant k_A is $k_1k_2(k_2 + k_{-1})$, and if the reactant in this simple mechanism is sticky, $k_{-1} < k_2$. In the case of murine cyclic AMP-dependent non-specific serine/threonine protein kinase, the specificity constant $k_{pep,app}$ for phosphorylation of the peptide LRRASLG (pep) decreases with pH above an apparent pK_a of 9.3. This behavior was shown, by studies of the effects of viscosity, to result from a change in rate-limiting step from association of the reactant at low pH, where the reactant was sticky ($k_{-1} < k_2$), to turnover of reactant at high pH.[182] In this instance, as the pH is increased, the rate constant for association of the reactant, k_{-1}, remains constant, but the microscopic rate constant for a step following association of the reactant depends on a catalytic acid. The concentration of this catalytic acid, and hence k_2, decreases as the pH is raised above its pK_a, until the rate-limiting step is no longer association of the reactant but some step following association. This decrease in the rate constant k_2 eventually causes the reactant no longer to be sticky because k_2 eventually becomes less than k_{-1}.

It is also possible for a change in rate-limiting step to occur in a situation in which **each of two acid–bases in the active site accomplishes its catalysis in a different step** of the mechanism. Consider the kinetic mechanism

$$E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} E{\cdot}A' \xrightarrow{k_7} E + Z \tag{4–151}$$

where A′ is an intermediate in the transformation of A to Z. If the step governed by rate constant k_6 is catalyzed by a catalytic base, $\odot O^{(-)}$, in the active site and the step governed by rate constant k_7 is catalyzed by a catalytic acid, $NH^{(+)}$, and

$$k_{6,app} = k_6\left(\frac{K_{aOH}}{[H^+] + K_{aOH}}\right) \quad (4–152)$$

and

$$k_{7,app} = k_7\left(\frac{[H^+]}{[H^+] + K_{aNH}}\right) \quad (4–153)$$

then by microscopic reversibility

$$k_{-6,app} = k_{-6}\left(\frac{[H^+]}{[H^+] + K'_{aOH}}\right) \quad (4–154)$$

where K_{aOH} is the acid dissociation constant of acid–base OH when A occupies the active site and K'_{aOH} is its acid dissociation constant when A′ occupies the active site. Solving the steady-state rate equation with the pH-dependent forms of the rate constants gives the catalytic constant

$$k_0 = \frac{k_{6,app}k_{7,app}}{k_{-6,app} + k_{7,app}} = \frac{K_{aOH}([H^+] + K'_{aOH})k_6k_7}{\{k_{-6}([H^+] + K_{aNH}) + k_7([H^+] + K'_{aOH})\}([H^+] + K_{aOH})} \quad (4–155)$$

At low pH (below pK_{aOH}, pK'_{aOH}, and pK_{aNH}) the rate of the step governed by k_6 (Equation 4–152) is so slow that it is rate-limiting. As the pH is raised within this low range, the catalytic constant increases by a factor of 10 for each increase in pH of 1 unit. At high pH (above pK_{aOH}, pK'_{aOH}, and pK_{aNH}) the catalytic constant does not decrease with pH but remains constant because $k_{-6,app}$ is decreasing as the pH is increasing in parallel with $k_{7,app}$, so the partition of E·A′ forward through the step governed by k_7 and backward through the step governed by k_{-6} remains constant.

In the intermediate range of pH, outcomes involving inflections as well as changes in slope in the pH–rate profiles are possible, depending on the values of rate constants and acid dissociation constants. If, however, pK_{aOH} = pK'_{aOH}, there are no intermediate inflections, and the curves all have only a single change in slope from +1 to 0 at a p$K_{a,app}$. This outcome can be explained by making $K_{aOH} = K'_{aOH}$ in Equation 4–155. In this case it reduces to a form

$$k_{0,app} = k_0\left(\frac{K_{a,app}}{[H^+] + K_{a,app}}\right) \quad (4–156)$$

for which

$$K_{a,app} = \frac{k_{-6}K_{aNH} + k_7K_{aOH}}{k_{-6} + k_7} \quad (4–157)$$

Consequently, the value of the observed p$K_{a,app}$ can take on any value between pK_{aHA} and pK_{aNH} depending on the values of k_{-6} and k_7, which determine the pH at which a change in rate-limiting step from the step governed by k_6 to the step governed by k_7 occurs. Again, a simple change in slope with an apparent pK_a is not the result of an actual pK_a but instead the result of a change in rate-limiting step.

Up to this point, with the exception of this most recent instance, one constraint that has been placed on explanations of pH–rate profiles of the catalytic constant when two acid–bases are acting catalytically is that they both accomplish their catalysis in the same transition state. The reason for this requirement is clear after considering the behavior defined by this most recent derivation (Equation 4–155), in which each of the two acid–bases accomplishes its catalysis in a different transition state. Because of microscopic reversibility, the step governed by k_{-6} must be catalyzed by the conjugate acid of the catalytic base or the conjugate base of the catalytic acid that catalyzes the step governed by k_6. Consequently, at infinite pH, the catalytic constant has become invariant with increasing pH rather than decreasing with a slope of –1 when a base catalyzes the step governed by k_6 and an acid catalyes the step governed by k_7. When an acid catalyzes the step governed by k_6 and a base catalyzes the step governed by k_7, the catalytic constant becomes invariant with pH at infinitely low pH rather than decreasing with a slope of +1. Whether or not a change in slope is observed in the range of pH chosen for the observations, either from +1 to 0 or from 0 to –1, will depend on the values of rate constants k_6, k_{-6}, and k_7. Peculiar inflections can occur at intermediate ranges of pH in each instance if the pK_a for the acid–base involved in the step governed

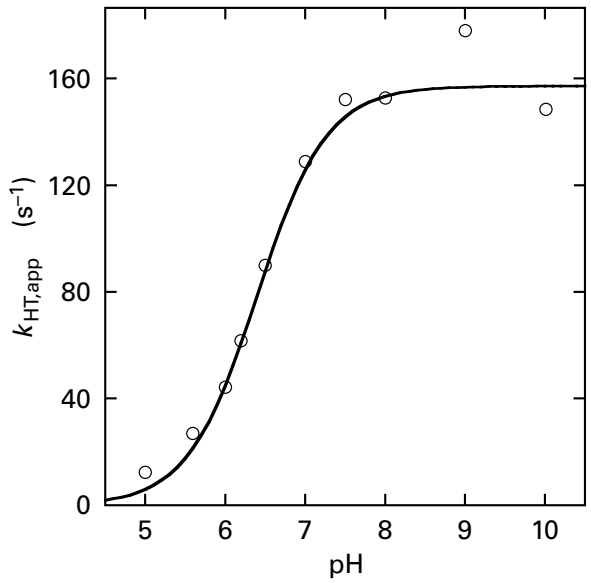

Figure 4–18: pH–Rate profile for transfer of a hydride from ethanol to NAD^+ (Equation 4–158) at the active site of liver alcohol dehydrogenase.[185] Solutions of 200 mM ethanol and 4 mM NAD^+ were prepared at various values of pH buffered with sodium phosphate or sodium glycinium phosphate at an ionic strength of 0.1 M and 25 °C. Each solution was mixed in turn with an equal volume of alcohol dehydrogenase at a 30 mM concentration of active sites. The mixing was performed in a stopped-flow apparatus, and the change in absorbance at 340 nm was monitored by an oscilloscope. A rapid increase of absorbance at 340 nm was observed, corresponding in magnitude to a single hydride transfer for each active site. The pseudo-first-order rate constant for this burst of absorbance was measured from each kinetic trace. The values of this rate constant, $k_{HT,app}$ (second^{-1}), for transfer of the hydride (HT) are plotted as a function of pH. The line drawn is for an acid–base titration with a pK_a of 6.4 and a pH-independent rate constant, k_{HT}, of 155 s^{-1}.

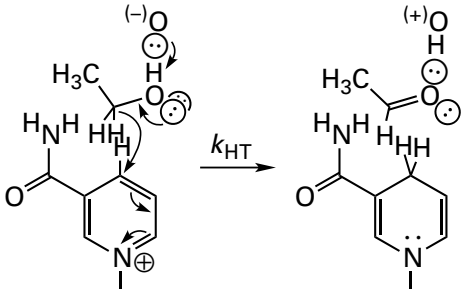
by k_6 and k_{-6} changes its pK_a during the step. It follows that when each of the two acid–bases accomplishes its catalysis in a different transition state, a significantly more complex pH–rate profile results that often if not usually defies explanation.

A change in rate-limiting step combined with hydronation of a catalytic base or dehydronation of a catalytic acid can also cause an inflection in the pH–rate profile of the catalytic constant as the pH is lowered below the pK_a for the catalytic base or raised above the pK_a for the catalytic acid.[183]

When a pH–rate profile for a steady-state rate constant is governed by observed, apparent values of pK_a to which no catalytic acid–bases can be assigned unambiguously—for example, in a situation when an observed pK_a is actually the pH at which a change in rate-limiting step occurs in a reaction—**a kinetic procedure that measures the pH–rate profile for the rate of only one step** in the kinetic mechanism can provide the pK_a for a catalytic acid or catalytic base in the active site. For example, the rate-limiting step in the reaction catalyzed by equine alcohol dehydrogenase

$$NAD^+ + \text{ethanol} \rightleftharpoons \text{acetaldehyde} + NADH + H^+ \qquad (4\text{–}158)$$

is release of NADH,[184] so the behavior of the steady-state rate constants as a function of pH when ethanol and NAD^+ are reactants does not reveal any values of pK_a for catalytic acids and bases in the active site. Because the absorbance of NAD^+ at 340 nm increases significantly at the instant it accepts a hydride while it is within the active site, monitoring an enzymatic reaction involving this coenzyme at this wavelength follows only this one explicit chemical step. Ethanol and NAD^+ can be added rapidly to a solution containing equine alcohol dehydrogenase, and the change in absorbance at 340 nm for only the transfer of a hydride can be monitored. If the concentrations of these two reactants are high enough, all the active sites in the solution will be filled much faster than the rate for hydride transfer[184]



(4–159)

and only this one step should contribute to the observed rate constant. Under these circumstances, the observed rate constant k_{HT} for transfer of hydride decreases below a pK_a of 6.4 when the pH is lowered (Figure 4–18).[185] Because only a single pK_a appears to be controlling the behavior, it was assumed to be the microscopic pK_a for a single catalytic base in the active site. This assumption is valid only if all acid–base reactions and the two respective associations of reactants are so much faster than hydride transfer that they all reach equilibrium before any hydride transfer can occur and if all the other steps in the enzymatic mechanism preceding hydride transfer, if there are any, are rapid. Presumably this pK_a is for the catalytic base that removes the hydron from the hydroxy group of the ethanol. In the crystallographic molecular model of the complex of the

enzyme with trifluoroethanol,[186] this catalytic base is the hydroxy group of Serine 48, which relays the basicity of the sulfido group of Cysteine 46.

The state of hydronation of acid–bases in a site on a protein with which a ligand associates will usually affect the observed dissociation constant for that ligand. If this is the case, then when the protein binds an inhibitor, activator, drug, reactant, product, or any other ligand at a particular site, the apparent dissociation constant that is measured will usually be a function of pH. Consider the simplest situation in which only a form of the site containing an acid, $STH^{(+)}$, and a form of the site containing its conjugate base, $\odot ST^{(-)}$, exist in significant concentration within the range of pH covered. The ligand, L, can bind to either form of the site, and hydrons can enter or leave the occupied site

$$\begin{array}{ccc} L + STH^{(+)} & \underset{K_{dL1}}{\rightleftharpoons} & L{\cdot}STH^{(+)} \\ \Big\Updownarrow K_{aST} & & \Big\Updownarrow K_{aST\cdot L} \\ L + ST\odot^{(-)} + H^+ & \underset{K_{dL2}}{\rightleftharpoons} & L{\cdot}ST\odot^{(-)} + H^+ \end{array} \qquad (4\text{–}160)$$

In this mechanism, the equilibrium constants K_{aST} and $K_{aST\cdot L}$ are acid dissociation constants and the equilibrium constants K_{dL1} and K_{dL2} are dissociation constants for the ligand from the two states of hydronation for the site. It can be shown by inspection that

$$K_{aST}K_{dL1} = K_{aST\cdot L}K_{dL2} \qquad (4\text{–}161)$$

If the apparent dissociation constant for ligand L is defined as

$$K_{dL,app} = \frac{([STH^{(+)}] + [\odot ST^{(-)}])[L]}{[L{\cdot}STH^{(+)}] + [L{\cdot}\odot ST^{(-)}]} \qquad (4\text{–}162)$$

then it follows that

$$K_{dL,app} = \frac{\left(\dfrac{K_{aST\cdot L}}{[H^+] + K_{aST\cdot L}}\right)}{\left(\dfrac{K_{aST}}{[H^+] + K_{aST}}\right)} K_{dL2} \qquad (4\text{–}163)$$

and

$$\log K_{dL,app} = \log K_{dL2} + \log\left(\frac{K_{aST\cdot L}}{[H^+] + K_{aST\cdot L}}\right) - \log\left(\frac{K_{aST}}{[H^+] + K_{aST}}\right) \qquad (4\text{–}164)$$

For the moment, assume that the ligand binds more tightly to the site containing the acid than the site containing its conjugate base ($K_{dL1} < K_{dL2}$). Then, because of Equation 4–161, $K_{aST} > K_{aST\cdot L}$. When $[H^+] > K_{aST} > K_{aST\cdot L}$

$$\log K_{dL,app} \cong \log K_{dL2} - pK_{aST\cdot L} + pK_{aST} = \log K_{dL1} \qquad (4\text{–}165)$$

which is invariant with pH. When $K_{aST} > [H^+] > K_{aST\cdot L}$

$$\log K_{dL,app} \cong \log K_{dL2} - pK_{aST\cdot L} + pH \qquad (4\text{–}166)$$

which increases as pH is increased. When $K_{aST} > K_{aST\cdot L} > [H^+]$

$$\log K_{dL,app} \cong \log K_{dL2} \qquad (4\text{–}167)$$

which is invariant with pH. When the common logarithm of the apparent dissociation constant is plotted as a function of pH, the horizontal asymptote defined by Equation 4–165 is at the value for $-\log K_{dL1}$; the horizontal asymptote defined by Equation 4–167 is at the value for $-K_{dL2}$; the intersection of the horizontal asymptote defined by Equation 4–165 and the asymptote of slope +1 defined by Equation 4–166 occurs when $pH = pK_{aST}$; and the intersection of the horizontal asymptote defined by Equations 4–167 and the asymptote of slope +1 defined by Equation 4–166 occurs when $pH = pK_{aST\cdot L}$.

Examination of the mechanism of Equation 4–160 reveals that, as with any pH–rate profile for an enzymatic reaction, no distinction can be made between an ionization of the site and an ionization of the ligand from only the pH–dissociation behavior. Were the ligand and the site in the equation switched so that the mechanism was actually

$$\begin{array}{ccc} ST + LH^{(+)} & \underset{K_{dL1}}{\rightleftharpoons} & ST{\cdot}LH^{(+)} \\ \Big\Updownarrow K_{aL} & & \Big\Updownarrow K_{aST\cdot L} \\ ST + L\odot^{(-)} + H^+ & \underset{K_{dL2}}{\rightleftharpoons} & ST{\cdot}L\odot^{(-)} + H^+ \end{array} \qquad (4\text{–}168)$$

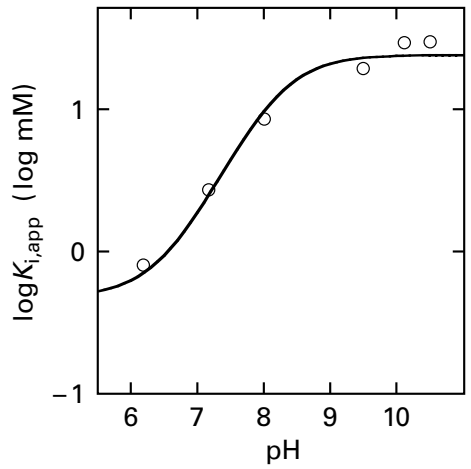


Figure 4–19: Dependence on pH of competitive substrate inhibition by 2-oxoglutarate of the transamination catalyzed by aspartate transaminase from L-aspartate and 2-oxoglutarate.[85] Solutions containing various concentrations of L-aspartate and 2-oxoglutarate at various values of pH (see Figure 4–10) were prepared at 25 °C. The reaction was initiated by adding aspartate transaminase, and the production of oxaloacetate was followed by coupling it to the oxidation of NADH with malate dehydrogenase. The decrease in A_{340} with time was used to measure initial rates. Both 2-oxoglutarate and L-aspartate are reactants in the reaction catalyzed by aspartate transaminase under these circumstances. Each of them, however, at high concentration, higher than that necessary to obtain their respective maximum rates, becomes an inhibitor of the enzyme. Each is a competitive inhibitor with respect to the other. From the competitive inhibition observed at high concentrations of 2-oxoglutarate (OG) at each pH, a value for the inhibition constant, K_{iOG}, was calculated. The common logarithms of these observed dissociation constants (millimolar) are plotted as a function of pH. The curves drawn are fits of Equation 4–164 to the data.

and the ligand was the acid–base rather than the site, the same equations would be derived for the behavior of the observed dissociation constant as a function of pH, except that the meaning of the values of pK_a observed would also be switched. This consideration illustrates the fact that the behavior of a dissociation constant as a function of pH indicates only whether a hydron is taken up from the solution as the complex is formed or a hydron is released to the solution as it forms.

The reaction catalyzed by porcine aspartate transaminase (Equation 4–108) can be divided into two steps

$$\begin{aligned}\text{(Lysyl 258)pyridoxamine 5′-phosphate} &+ H_2O \\ + \text{ L-aspartate} &\rightleftharpoons \text{oxaloacetate} + \\ \text{pyridoxamine 5′-phosphate} &+ \text{Lysine 258}\end{aligned} \qquad (4\text{–}169)$$

and

$$\begin{aligned}\text{Lysine 258} &+ \text{pyridoxamine 5′-phosphate} + \\ \text{2-oxoglutarate} &\rightleftharpoons \text{L-glutamate} + H_2O + \\ &\text{(Lysyl 258)pyridoximine 5′-phosphate}\end{aligned} \qquad (4\text{–}170)$$

where Lysine 258 is the lysyl side chain from the enzyme that forms the internal pyridoximine 5′-phosphate (Equation 4–129).[187] If 2-oxoglutarate (OG) enters the active site when the prosthetic group is lysylpyridoximine 5′-phosphate, no further reaction can occur. Therefore, 2-oxoglutarate is a competitive inhibitor with respect to L-aspartate. The observed inhibition constant for 2-oxoglutarate is a function of pH and obeys Equation 4–164 (Figure 4–19).[85] By fitting Equation 4–164 to the data, it was found that $K_{dOG,1} = 0.5$ mM, $K_{dOG,2} = 24$ mM, p$K_{aST} = 6.5$, and p$K_{aST\cdot OG} = 8.2$. Because, however, the site and the ligand are indistinguishable, these values are the same as values of $K_{dOG,1} = 0.5$ mM, $K_{dOG,2} = 24$ mM, p$K_{aL} = 6.5$, and p$K_{aL\cdot OG} = 8.2$.

These values state either that 2-oxoglutarate binds more tightly to the more hydronated, more cationic form of the active site or that the conjugate acid of 2-oxoglutarate binds more tightly to the active site than its conjugate base. These values also state that, after 2-oxoglutarate has associated with the active site, it either raises the pK_a of the acid in the active site, the acid dissociation of which is linked to its binding, or the pK_a of 2-oxoglutarate itself increases. In either case, in the midrange, a hydron is taken up as the ligand associates. Again, a decision between these two possibilities must be made from observations other than the behavior of a dissociation constant as a function of pH. The two values of pK_a for 3-oxoglutarate are 2.5 and 4.7. These values do not agree with pK_{aL}, but the pK_{aST} of 6.5 does agree with the pK_a for the iminium nitrogen of the internal lysylpyridoximine (Equation 4–129). If 2-oxoglutarate, a dianion, binds adjacent to this imine, it should bind more tightly when the imine is positive rather than zwitterionic, and the presence of the 2-oxoglutarate should cause the iminium nitrogen to be a weaker acid than it is in the absence of 2-oxoglutarate.

In this example of the association of 2-oxoglutarate with aspartate transaminase, the pK_a of the site increases because the ligand is anionic, and the same behavior would have been observed were the ligand the acid–base and the site anionic. Had the ligand been a cation or had the site been cationic, the pK_a of the site or the ligand, respectively, would have decreased upon association. In situations in

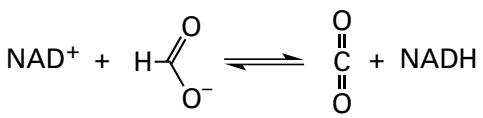
which the pK_a of the site or the ligand decreases upon association, the common logarithm of the dissociation constant begins with a plateau but then decreases in the midrange before reaching a second lower plateau.

The behavior of the inhibition constant for 2-oxoglutarate as a function of pH is unusual in that the full course of the effect of linkage between association of a hydron and association of the inhibitor with enzyme is observed. In most instances, only a portion of the entire linkage is observed within the range of pH chosen for the measurements. For example, the common logarithm of the inhibition constant of the inhibitor phosphoglycolate from the active site of triose-phosphate isomerase from *S. cerevisiae* increases with pH, with a slope of +1 over the range from pH 4 to 10. This observation is consistent with the two conclusions that, at all values of pH, a hydron is taken up by the complex when it forms and the titration is in the midrange between the plateaus. When Tyrosine 208 is mutated to phenylalanine, however, the common logarithm of the inhibition constant decreases with a slope of –1 only below a pK_a of 6.3; above the pK_a of 6.3, it is invariant with pH in a plateau.[188] Consequently, because the ligand is the same and the enzyme has changed, the mutation has shifted the pK_a of the site from above 10 to 6.3.

To explain the observed behavior of the dissociation constant for an inhibitor, K_i, as a function of pH, it is often assumed, by analogy with the explanation of pH behavior in steady-state rate constants, that, unlike 2-oxoglutarate, the inhibitor can bind to only one form of the enzyme. For example, this explanation would be equivalent to making the assumption in Equation 4–160 not only that K_{dL2} was greater than K_{dL1} but also that K_{dL2} was infinitely large. For Equation 4–161 to hold in the limit, as it must, this explanation would require that K_{aLST} be 0 if K_{dL1} and K_{aST} are to remain finite. Therefore, if the ligand can bind only to the hydronated state, $STH^{(+)}$, of the site, it necessarily follows that in the occupied site the hydronated acid can no longer dissociate. This example could lead to the conclusion that if the ligand can bind only to one state of ionization of the site, then the acid–bases within the site cannot participate in hydron exchanges with the solution once the site is occupied. This latter statement seems unlikely in most instances, but when the active site of HIV-1 retropepsin from human immunodeficiency virus is occupied by the inhibitor pepstatin, the carboxy group on one of the two catalytic aspartates in the active site remains hydronated and the carboxylato group on the other remains unhydronated[189] in nuclear magnetic resonance spectra collected in the range of pH from 2.7 to 6.2. Nevertheless, this range is not from minus infinity to infinity.

It is usually assumed that the dissociation constant, K_i, observed for an inhibitor of an enzymatic reaction from steady-state kinetic measurements is a simple equilibrium constant between the active site and the inhibitor. If the inhibitor is a close enough analogue of the reactant, the effect of pH on its constant should be an accurate reflection of the effect of pH on only the step in the kinetic mechanism of the enzyme in which the normal reactant associates with the active site. In particular, values of pK_a measured for the dissociation constant of an inhibitor can **support the conclusion that a pK_a observed in a steady-state pH–rate profile is actually for acid dissociation of a catalytic acid–base** rather than, for example, due to a change in rate-limiting step. The apparent dissociation constant for 2,4-diamino-6,7-dimethylpteridine, acting as a competitive inhibitor of dihydrofolate reductase (Equation 4–148) from *E. coli*, varies with pH.[178] It increases below an apparent pK_a of 5.9 and increases above an apparent pK_a of 7.9.* The specificity constant k_{DHF} for 7,8-dihydrofolate (DHF) for the reaction catalyzed by dihydrofolate reductase decreases above a pK_a of 8.1. Because 2,4-diamino-6,7-dimethylpteridine resembles 7,8-dihydrofolate and is a competitive inhibitor with respect to 7,8-dihydrofolate, the coincidence of these two apparent values for pK_a (pK_a = 7.9 and pK_a = 8.1), each of which should be for free enzyme, suggests that they reflect the same acid dissociation. The pK_a for the apparent dissociation constant of the inhibitor, because it governs an equilibrium between a protein and a ligand rather than a steady state, should be associated with a simple acid dissociation constant for free enzyme rather than a complex kinetic parameter. Therefore, the apparent pK_a observed in the behavior of k_{DHF} should also be a simple pK_a for a side chain in the free enzyme.

Azide anion ($N{=}N{=}N^-$), although a linear triatomic monoanion, is a competitive inhibitor of formate dehydrogenase



(4–171)

*Recall that as a dissociation constant increases, the affinity of the site for the ligand decreases.

from *S. cerevisiae* with respect to formate, a bent tetraatomic monoanion. The inhibition constant for azide[190] increases as the pH is lowered below a pK_a of 6.4, and it increases as the pH is increased above a pK_a of 8.3. If the inhibition constant for azide is detecting only acid dissociation constants for side chains in the free enzyme and if the specificity constant k_{FRM} for formate (FRM) is also governed only by the same acid dissociation constants for free enzyme, then the respective values of pK_a should coincide. For the reaction catalyzed by formate dehydrogenase, the specificity constant k_{FRM} decreases below a pK_a of 6.1 and decreases above a pK_a of 8.5. The pK_a of 8.5 could be that of Histidine 325, which is immediately adjacent to the azide and should be cationic for the azide to bind.[191]

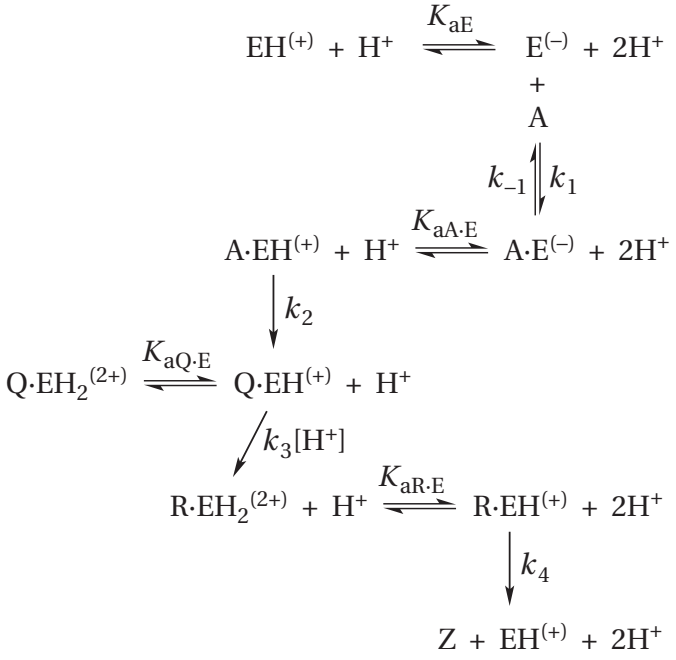
Problem 4–8:

(A) Show that the kinetic mechanism



gives a rate equation of the form

$$v_0 = \frac{k_{0,app}\, k_{A,app}\, [E]_t\, [A]_0}{k_{0,app} + k_{A,app}\, [A]_0}$$

where

$$k_{0,app} = k_0 \left(\frac{K_{a1}}{[H^+] + K_{a1}} \right) \left(\frac{[H^+]}{[H^+] + K_{a2}} \right)$$

and

$$k_{A,app} = k_A \left(\frac{K_{a3}}{[H^+] + K_{a3}} \right) \left(\frac{[H^+]}{[H^+] + K_{a4}} \right)$$

(B) Write the expressions defining the four observed apparent acid dissociation constants, K_{a1}, K_{a2}, K_{a3}, and K_{a4}. Are any of them actually acid dissociation constants?

Problem 4–9: Acid dissociations of most substrates are equilibria established so rapidly that they are always fully at equilibrium at times longer than a millisecond. The equilibration of nitroethane and nitroethane anion, however, is so slow that one or the other can be used as a reactant for nitroalkane oxidase from *F. oxysporum*.

(A) Write the acid dissociation of nitroethane, drawing the conjugate acid and conjugate base with all lone pairs of electrons in proper hybridization and each in its most stable resonance hybrid.

When nitroethane anion is used as a reactant with the enzyme, the behavior of log $k_{NEA,app}$ as a function of pH displays behavior consistent with the existence of an acid–base with a pK_a of 7.4 ± 0.1 (Figure 4–10F).

(B) Is this behavior consistent with the participation of a catalytic acid or a catalytic base in the enzymatic reaction?

When neutral nitroethane (NE) is used as a reactant, the following measurements were made for the steady-state rate constant k_{NE}.[78]

pH	$k_{NE,app}$ (M^{-1} s^{-1})
6.0	230
6.5	1360
7.0	2930
7.5	4320
7.9	5350
8.1	6140
8.3	4490
8.5	7880
8.7	7590
8.8	7130
9.0	8930

(C) What is the pK_a for the acid–base that could be responsible for this behavior?
(D) Would it participate as a catalytic acid or a catalytic base in the reaction?
(E) What suggests that the acid–base in both reactions might be the same one?

When Aspartate 402 in the enzyme is mutated to alanine, the acid–base responsible for the decrease in $k_{NEA,app}$ at high pH seems to be lost (□, Figure 4–10F).

(F) What might the side chain of Aspartate 402 be responsible for in the enzymatic reaction?

Problem 4–10: Show that Equation 4–163 follows from Equation 4–162.

Site-Directed Mutation

Site-directed mutation is another method that can be used to assign a particular amino acid to a pK_a governing a pH–rate profile. When a catalytic acid or catalytic base in the side chain of an amino acid in the active site of an enzyme that has been definitively assigned crystallographically[192-197] to the role of adding a hydron to, or removing a hydron from, a reactant during the reaction catalyzed by an enzyme is mutated to a side chain incapable of performing that role, the common logarithm of the steady-state rate constant traditionally used for the catalytic proficiency of a particular enzyme, $\log[k_0\,(K_{mA}K_{mB}\ldots)^{-1}]$, at the optimum pH for catalysis, decreases by 4.2 ± 1.2 units.[113,197-239] The range of this **decrease in the common logarithm of rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$** for the set of enzymes* chosen is 2.5–8.7.

The **upper limit to the range of decreases in rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$ due to mutation** of a catalytic acid–base, observed in studies where that decrease for the mutant could be accurately measured,[240] is a factor of 10^9. There are also many instances in which no enzymatic activity could be measured for a mutant, but in most of these instances, lower limits for the levels of detection[231,241-244] unfortunately were not reported. From the results presented in these studies, however, it can be inferred that the actual lower limits of detection, which determine the upper limits on rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$ of the mutants, are usually much greater than a decrease of 10^9 would have produced. Consequently, these observations, in which no enzymatic activities were observed, are all consistent with decreases of less than a factor of 10^9 in the value of rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$. When decreases of 10^5 or greater in rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$ are observed, the possibility that the residual activity results from misincorporation of the wild-type amino acid at the point of mutation should be considered.[209] If misincorporation is occurring, the decrease in catalytic proficiency upon mutation is actually greater than that observed.

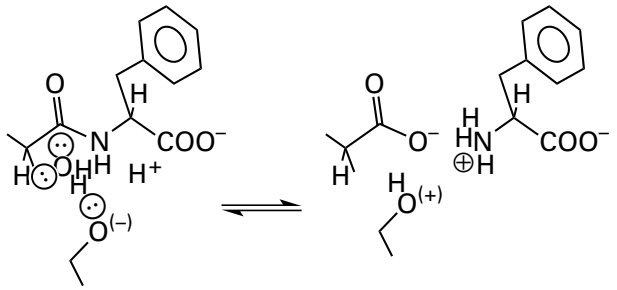
*This mean and standard deviation are for 50 side chains known to participate as general acids and bases in the reactions catalyzed by 37 enzymes (9 of which had two reactants) chosen at random.

It is also possible that the rate-limiting step in the normal enzymatic reaction is not the chemical step requiring acid–base catalysis in which the mutated amino acid participates. If the step in which a particular amino acid participates as a catalytic acid–base is not the rate-limiting step, the decrease in steady-state rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$ observed when that amino acid is mutated will be **less than the actual decrease in the rate constant for that step** in the enzymatic mechanism, and the decrease in the rate constant for that step could be much greater than the kinetic observations suggest. For example, when Tyrosine 146 in thymidylate synthase from *Lactobacillus casei* was replaced by aspartate, the value of $k_0\,(K_{mTHF}K_{m,dU})^{-1}$ for the reactants 5,10-methylenetetrahydrofolate (THF) and deoxyuridine monophosphate (dU) decreased by a factor of 1×10^5. The rate-limiting step of the enzymatic reaction, however, shifts from formation of a covalent intermediate between the active site and deoxyuridine monophosphate to the conversion of that covalent intermediate into the product deoxythymidine monophosphate,[245] so the effect of the mutant on the value of the rate constant for the step in which that covalent intermediate is converted into product must be greater than 1×10^5. Nevertheless, in those instances in which there is clear crystallographic evidence for the involvement of the amino acid as an acid–base in the reaction, several of which may well be involved in steps that are not rate-limiting, mutation of that amino acid almost always results in a decrease in the steady-state rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$ of greater than a factor of 1000.

Consequently, it can be concluded that **if the mutation of a particular amino acid in an enzyme causes a decrease of less than a factor of 1000 in the value for rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$, its side chain is probably not participating in the enzymatic reaction as a catalytic base or a catalytic acid.** In particular, when a crystallographic molecular model of a complex between the enzyme and one or more of its substrates or an analogue of its substrate is not available, any claim that a particular side chain the mutation of which results in a decrease of less then 1000 in rate constant $k_0\,(K_{mA}K_{mB}\ldots)^{-1}$ is a catalytic acid or catalytic base involved in the reaction catalyzed by that enzyme should be considered with suspicion. In fact, one of the most convincing ways to rule out the participation of an amino acid as a catalytic acid or catalytic base in the mechanism is to show that its mutation has little effect on catalysis.[193,210,246-256] Occasionally, an increase in rate of catalysis is observed upon mutation of a particular amino acid.[257,258] Amusingly, it has also been observed that a catalytically inactive mutant of the enzyme, by binding reactant tightly and occluding it from the solvent, can decrease the rate of the nonenzymatic reaction that would otherwise occur when reactant is free in solution.[208]

All these observations emphasize **the importance of the active site providing acid–bases that were not required in solution,** where reactants have access to hydroniums, molecules of water, and hydroxides.

The conclusion that a decrease of less than 1000 should be treated with suspicion does not mean that a role for the side chain as a catalytic acid–base has been ruled out completely. For example, from crystallographic molecular models of complexes of bovine carboxypeptidase A



(4–172)

with several analogues of the tetrahedral intermediate in the enzymatic reaction,[259] it is clear that the hydroxy of Tyrosine 248 can swing into the active site[260] to hydronate the nitrogen (0.32 nm) that leaves from the intermediate during hydrolysis of the peptide bond catalyzed by this enzyme. When this tyrosine is mutated to phenylalanine,[261] the value of $k_0\,K_{mA}^{-1}$ decreases by only a factor of about 10. In this instance, the missing tyrosine is no longer able to swing over to cover the substrate, and the nitrogen that must be hydronated, which is a relatively strong base, remains exposed to the solution, which readily provides the hydron. Nevertheless, the tyrosine does improve catalysis relative to that performed by the solution. There is little question that the amino-terminal proline in the active site of 2-hydroxymuconate tautomerase from *P. putida* is responsible for removing one of the hydrons from carbon 5 of (2*Z*,4*E*)-2-hydroxyhexa-2,4-dienedioate (muc),[262] yet when it is mutated to either alanine or glycine,[263] the value of $k_0\,K_{m,muc}^{-1}$ decreases by only a factor of 20. In this case, however, each mutation simply replaces one amino group with another amino group in the same location, so the effects are minimal.

Even when large decreases in activity are observed upon mutation of an amino acid, that observation provides no information about the role of that amino acid in catalysis or even whether or not it has a role. There are many instances in which the mutation of an amino acid outside the active site nevertheless causes significant decreases in the catalytic proficiency of the enzyme. Consequently, **a crystallographic molecular model of the active site occupied by some ligand that can identify candidates for catalytic roles is still required**, not only to decide which amino acids to mutate but also to have any understanding of the observed effects of the mutations on catalysis. There is no reason to mutate an amino acid in a protein unless the question that the mutation will be able to answer is clearly stated and will provide useful information.

If a hydron must be removed from or added to a reactant during a reaction, that **reaction cannot occur on the active site of an enzyme unless the active site provides a basic lone pair of electrons or an acidic hydron**, respectively, immediately adjacent to the immobilized reactant, or unless the position from which the hydron must be removed or added remains accessible to the solution, as in the mutant of carboxypeptidase A. When a side chain providing the required lone pair of electrons or acidic hydron is removed from the active site by mutation, another lone pair of electrons or acidic hydron must have steped in if the enzyme retains any activity. In some instances, that lone pair of electrons or that hydron may be provided fortuitously by another side chain in the active site. An example is triose-phosphate isomerase from *S. cerevisiae*, in which the histidine acting as a catalytic acid–base (Equations 4–46 and 4–55 and Figure 3–37) has been mutated and its role is filled, albeit considerably less ably, by Glutamate 164.[28]

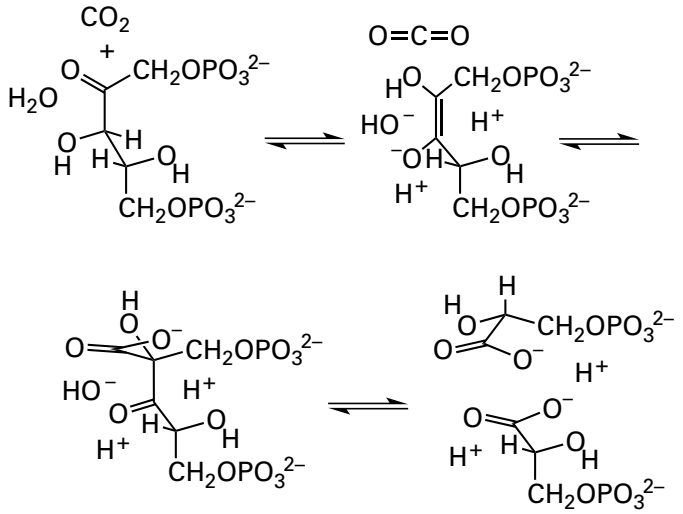
In most instances, however, it is probably a **molecule of water**, occupying the location in the active site of the mutant usually occupied by the now-missing heteroatom of the acid–base[118,264,265] that steps in as the catalytic acid or catalytic base. For example, when Aspartate 222, the catalytic acid–base in porcine aspartate transaminase, is mutated to threonine, a molecule of water that occupies the identical location to the catalytic oxygen in the carboxy group of the aspartate steps in to cause the mutant to retain 5% of the value of $k_0\ K_{m,Asp}^{-1}$ for the substrate L-aspartate;[266] and when the catalytic acid–base Histidine 143 is mutated to leucine, a molecule of water that occupies the identical location to the catalytic nitrogen in the imidazolyl group of the histidine steps in to cause the mutant to retain 50% of the value of $k_0\ K_{m,Asp}^{-1}$. The aspartate and the histidine participate in a hydrogen bond and together form the acid responsible for hydronation of nitrogen 1 of the prosthetic pyridoxal 5′-phosphate, a hydronation that is required by the enzymatic reaction.

The molecule of water that steps in to take the place of the catalytic acid–base is probably a molecule of water occupying the empty active site before reactant associates (Figure 3–32), and it remains in place rather than being displaced as in the wild-type enzyme by the normal juxtaposition of reactant and unmutated catalytic side chain. There are four problems with this subtitution that cause the rate constant for its removal or addition of the hydron to be slow. First, this molecule of water is usually either a **weaker base or a weaker acid** than the normal catalytic side chain. Second, this molecule of water **cannot be precisely aligned** by the active site, which would normally align the now-missing side chain that was mutated. An exception to this problem is the mutation of carboxypeptidase, where the base that must be hydronated, the amino group of the tetrahedral intermediate, is a strong one and is exposed to the molecules of water in the solution as a result of the mutation. Third, the effectiveness of the molecule of water that has stepped in **depends on the Brønsted coefficient** for the transfer of the hydron. Fourth, there is the problem of whether or not the rate of the step catalyzed by the unmutated acid–base was the rate-limiting step of the reaction. The wide variation in decreases in rate observed upon mutation reflects the wide variation in the severity of these four problems.

In some instances, it is possible to **supply a more satisfactory acid–base to the mutant** than a molecule of water and **rescue the enzymatic activity**. For example, the conjugate base of any one of several primary amines can replace the catalytic primary amine lost when Lysine 258 in aspartate transaminase from *E. coli* (Equation 4–108) is replaced by alanine.[267] The exogenous primary amine can rescue some of the enzymatic activity. In this instance, the **exogenous amines** participate in a simple bimolecular reaction with the active site and do not display saturation in their ability to rescue the catalytic activity. Consequently, they act from the solution in a bimolecular collision with the Michaelis complex, and the rate constant of the rescued reaction is a linear function of the concentration of amine. A concentration of 1 M methylamine allows the mutant to display 12% of the enzymatic activity of the wild

type. This result demonstrates that, in this instance, a primary amine entering the active site from solution, and presumably occupying transiently the location that is occupied by the amino group of the lysine in the unmutated enzyme, is a more effective acid–base than the molecule of water that most certainly catalyzes the enzymatic reaction in the active site of the mutant in the absence of the amino group of the lysine. The fact that a small portion of the enzymatic activity can be rescued in many instances provides a paradigm for the rescue that molecules of water perform in the absence of general acid–bases added to the solution.

In the case of rescue of a mutant of ribulose-bisphosphate carboxylase (previously Equation 3–424)



(4–173)

from *Rhodospirillum rubrum* in which Lysine 329 (corresponding to K332A in Figure 3–53) was converted to alanine, ethylamine displayed saturation with an apparent dissociation constant of 0.13 M in its ability to rescue the enzymatic activity. At saturation, ethylamine was able to achieve an increase in the limiting rate for the enzymatic reaction of a factor of 80 relative to that of the mutant and accomplished a limiting rate that was 2% of the activity of the wild type.[268]

Imidazole, when present at saturation, can rescue 0.1% of the enzymatic activity of a mutant of nucleoside-diphosphate kinase from *Dictyostelium* in which Histidine 122 has been replaced by glycine,[269] and it can rescue 0.1% of the enzymatic activity of a mutant of (*S*)-mandelate dehydrogenase from *P. putida* in which Histidine 274 has been replaced by glycine.[270]

Guanidinium, when present at saturation, can rescue 10% of the enzymatic activity in a mutant of ornithine carbamoyltransferase from *E. coli* in which Arginine 57 has been replaced by alanine,[271] and it can rescue 7% of the enzymatic activity in a mutant of IMP dehydrogenase from *T. foetus* in which Arginine 418 has been replaced by alanine.[162]

Formate can rescue the enzymatic activity of cytidine deaminase from *E. coli*. When Glutamate 104 is mutated to alanine, $k_0\,K_{mCyt}^{-1}$ for the reactant cytidine (Cyt) decreases by a factor of 4×10^6 and the catalytic constant decreases by a factor of 1×10^8 to a value of 2.6×10^{-6} s^{-1}. Formate occupies the vacancy in the active site caused by eliminating the carboxymethyl group of the glutamate by converting it to an alanine, and the enzymatic activity at saturation with cytidine becomes a linear function of the concentration of formate[199] with a rate constant of 3.6×10^{-5} M^{-1} s^{-1}. Consequently, at 2 M formate, the catalytic constant of the mutant increases by a factor of 30, but it is still less than the catalytic constant of the wild type by a factor of 4×10^6. A mutant of steroid Δ-isomerase from *P. putida* in which Aspartate 38 has been mutated to glycine has a catalytic constant 2.4×10^4 times smaller than that of the wild type (36 s^{-1}), and the enzymatic activity has become a linear function of the concentration of formate with a rate constant of 0.12 M^{-1} s^{-1}. At 2 M formate, the rate constant for the enzymatic reaction (0.24 s^{-1}) is only a factor of 150 smaller than that of the wild-type enzyme.[272]

An exogenous substitute can also rescue a mutant defective in **a site used to recognize a reactant**. Acetate can rescue 100% of the hydrolytic activity toward tosylglycyl-L-prolyl-L-arginine amide of a mutant of anionic trypsin from *R. norvegicus* in which Aspartate 171, which sits in the subsite recognizing the side chain of L-arginine in the substrate (Figure 3–46), has been mutated to serine.[273]

α-L-Fucosidase from *Saccharolobus solfataricus* hydrolyzes an α-glycosidic bond between an L-fucosyl group and the rest of an oligosaccharide. The reaction proceeds with retention of configuration at the glycosidic carbon of L-fucose. It is believed that the first step in the reaction is a nucleophilic substitution between one oxygen on the carboxylato group of Aspartate 242, followed by hydrolysis of this covalent intermediate. When this aspartate is mutated to glycine, the enzymatic activity toward 4-nitrophenyl-α-L-fucoside is lost. If, however, azide is added to the assay[274] at a concentration of 2 M, a small amount (0.5%) of the cleavage of glycoside catalyzed by the enzyme is rescued, the product is the β-L-fucosyl azide instead of α-L-fucose.[244] The

azide has replaced the carboxylato group of Aspartate 242, rescuing the enzymatic activity, and its nucleophilic substitution for the 4-nitrophenoxy group in the reactant produces a stable product, which, because it is no longer covalently attached to the enzyme, dissociates from the active site.[274]

There seems to be at least one **naturally occurring example** of the rescue of enzymatic activity. In 1,4-dihydroxy-2-naphthoyl-CoA synthases from mycobacteria, there is an aspartate that is a catalytic acid–base responsible for removing an acidic hydron from a carbon α to the thioester in the reactant 4-(2-carboxyphenyl)-4-oxobutanoyl-SCoA to form the enolate. This enolate initiates an intramolecular Claisen condensation and aromatization that yields 1,4-dihydroxy-2-naphthoyl-SCoA. In the homologous 1,4-dihydroxy-2-naphthoyl-CoA synthase from *E. coli* (44% identity; 0.17 gap percent) and other bacteria, that catalytic aspartate is replaced by glycine. These latter enzymes, unlike those from mycobacteria, require bicarbonate for enzymatic activity. In a crystallographic molecular model of the enzyme from *E. coli*, it can be seen that the bicarbonate occupies the same location as the carboxylato group of the aspartate in the crystallographic molecular model of the enzyme from *M. tuberculosis* and rescues the enzymatic activity by providing its carboxylato group.[275]

The ability to rescue the enzymatic activity of a mutant missing a side chain by adding an appropriate acid–base to the solution can be exploited for **Brønsted analysis**. Acid–bases with a series of different values of pK_a are used to rescue the mutant, and a plot of the common logarithms of the second-order rate constants for their ability to restore activity against their values of pK_a gives an estimate for the Brønsted coefficient for the catalysis performed by the side chain that was mutated.[267] For example, eight amines with different values of pK_a were used to rescue a mutant of human peptidyl-glutamate 4-carboxylase in which Lysine 217 had been replaced by alanine. The Brønsted coefficient for their ability to rescue the mutant was 0.7. This result suggests that the hydron removed from the hydroxy group of the *gem*-diol of the epoxide of vitamin K (**2–103** in Figure 2–49) is mostly transferred to the amino group of the lysine in the transition state for that step in the reaction.[276]

It is also possible to attach the acid–base that is rescuing the mutant covalently to the position that has been mutated, precluding the need to add it to the solution.[277] For example, when Lysine 166 (corresponding to K175A in Figure 3–53) in the active site of ribulose-bisphosphate carboxylase from *R. rubrum* was mutated to cysteine, no enzymatic activity could be detected, but when the sulfanyl group of that cysteine was alkylated with aziridine to covalently restore the amino group in the same location in the active site, 45% of the enzymatic activity was restored.[278] This example is not so much a rescue as mutation of lysine to 3-thialysine.[279]

Although the following description is certainly simplistic, the **effects of site-directed mutations on the pH–rate profiles** for the catalytic constant and the specificity constants of an enzyme are most readily understood graphically (Figure 4–20). Consider the situation in which one side chain, HO, in the active site acts as a catalytic base, $O\odot^{(-)}$, and another side chain, NH, in the active site acts as a catalytic acid, $NH^{(+)}$, in the catalysis accomplished by the enzyme. The acid and the base titrate independently of each other; both accomplish their catalysis in the same transition state; and in the absence of both the catalytic base and the catalytic acid when both have been removed by site-directed mutation, the enzyme would catalyze the reaction with a basal catalytic constant, k_0, or specificity constant, k_A, for reactant A of a certain value independent of the pH (indicated by the horizontal line labeled E in Figure 4–20).

If only catalytic base $O\odot^{(-)}$ is present in the active site, when only the amino acid NH providing the catalytic acid has been mutated, the increase in the catalytic constant, $k_{0,app}$, or the specificity constant for reactant A, $k_{A,app}$, caused by the presence of HO at a particular pH is equal to the increase it provides when acid–base HO is fully unhydronated times the fraction that is unhydronated, $\alpha(\odot O^{(-)})$ (Equation 4–78). The pH–rate profile for this situation is the curve labeled HOE in Figure 4–20.

If only catalytic acid–base NH is present in the active site, when only the amino acid providing HO has been mutated, the increase in the catalytic constant, $k_{0,app}$, or the specificity constant for reactant A, $k_{A,app}$, caused by the presence of NH at a particular pH is equal to the increase it provides when acid–base NH is fully hydronated times the fraction that is hydronated, $\alpha(NH^{(+)})$ (Equation 4–87) The pH–rate profile for this situation is the curve labeled ENH in Figure 4–20.

When both HO and NH are present in the active site, which is the case in the native enzyme, the increase in the catalytic constant, $k_{0,app}$, or the specificity constant for reactant A, $k_{A,app}$, caused by their presence at a particular pH would be equal to the product of the increases that they each provide when

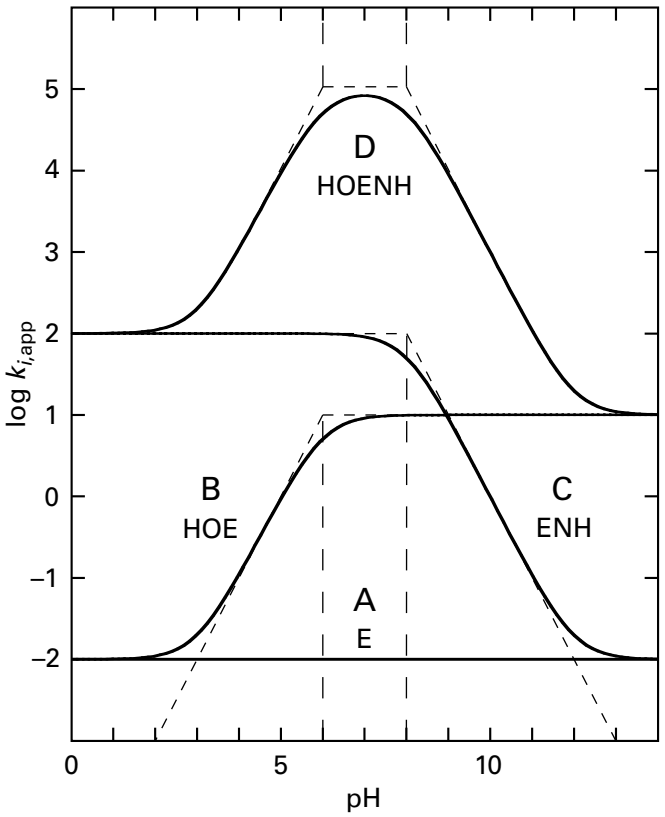


Figure 4–20: Theoretical pH–rate profiles for enzymatic reactions catalyzed by a catalytic base alone, a catalytic acid alone, and a catalytic base and a catalytic acid together in the active site of an enzyme. The explanation is the same for the pH–rate profiles of the steady-state rate constants k_A, k_B, and k_C and the catalytic constant k_0, so a generic steady-state rate constant k_i will be considered. The only differences among the behaviors of the rate constants are the complexes between enzyme and reactants to which the respective values of the pK_a refer. (**A**) In the absence of both the catalytic base and the catalytic acid, when the enzyme E is in the appropriate complex with reactants, the rate constants $k_{i,app}$ have low but finite basal values (horizontal line labeled E) that will be invariant with pH within the normal range because there is neither a catalytic acid nor a catalytic base in the active site. (**B**) If the enzyme has only a catalytic base, $^{(-)}\odot$O–, in its active site, the conjugate acid of which has a pK_a in the normal range for the appropriate complex with reactants, then the rate constants $k_{i,app}$ (curve labeled HOE) will be at the basal value at low pH when the unhydronated catalytic base is present at too low a level to catalyze the reaction. As the pH increases, however, the rate constants will begin to increase as the concentration of the unhydronated catalytic base increases, and they will finally reach a higher level (chosen to be 1000-fold the basal rate) when the catalytic base is fully unhydronated above its pK_a (chosen to be 6) and fully committed to the enzymatic reaction. When the curve over the range of pH in which the rate constants are increasing most rapidly is fit to an asymptote of slope +1 (dashed line) and the curve at high pH is fit to a horizontal asymptote (dashed line), the intersection of these two asymptotes is an estimate of the pK_a for the conjugate acid of the catalytic base in the appropriate complex with reactants. (**C**) If the enzyme has only a catalytic acid, –NH$^{(+)}$, in its active site, with a pK_a in the normal range for the appropriate complex with reactants, the rate constants $k_{i,app}$ (curve labeled ENH) will be at the basal value at high pH when the hydronated catalytic acid is present at too low a level to catalyze the reaction. As the pH decreases, however, the rate constants will begin to increase as the concentration of the hydronated catalytic acid increases, and they will finally reach a higher level (chosen to be 10,000-fold the basal rate) when the catalytic acid is fully hydronated below its pK_a (chosen to be 8) and fully committed to the enzymatic reaction. When the curve over the range of pH in which the rate constants are increasing most rapidly is fit to an asymptote of slope –1 (dashed line) and the curve at low pH is fit to a horizontal asymptote (dashed line), the intersection of these two asymptotes is an estimate of the pK_a for the catalytic acid in the appropriate complex with reactants. (**D**) If the enzyme has only one catalytic base, $^{(-)}\odot$O–, and only one catalytic acid, –NH$^{(+)}$, in its active site, with values of pK_a in the normal range for the appropriate complex with reactants, the rate constants $k_{i,app}$ (curve labeled HOENH) will be at the values for the reaction catalyzed only by the catalytic base at high pH when the hydronated catalytic acid is present at low levels, and they will be at the values for the reaction catalyzed only by the catalytic acid at low pH when the unhydronated catalytic base is present at low levels. As the pH, however, respectively increases or decreases, the rate constant will begin to increase and almost reach the highest possible level (10^7-fold the basal rate), which would be reached if the catalytic base could be fully unhydronated while the catalytic acid is fully hydronated at a pH between the two values of pK_a. When the curve over the range of pH in which the rate constant is increasing most rapidly at low pH is fit to an asymptote of slope +1 (dashed line), the curve over the range of pH in which it is increasing most rapidly at high pH is fit to an asymptote of slope –1 (dashed line), and a horizontal line is drawn at the rate constant that would be reached if the catalytic base could be fully unhydronated while the catalytic acid is fully hydronated, the intersection of these three asymptotes is an estimate for the two values of pK_a.

fully unhydronated and hydronated, respectively, times $\alpha(NH^{(+)},\odot O^{(-)})$ (Equation 4–94). The pH–rate profile for this situation is the curve labeled HOENH in Figure 4–20.

Each of these three types of pH–rate profiles has been observed in various native enzymes (Figure 4–10), but **an experimental paradigm of the theoretical effects of mutation** has been reported for protein-tyrosine-phosphatase from *Yersinia entereocolitica*. The effects of mutation of Glutamate 290 to glutamine, mutation of Aspartate 356 to asparagine, and mutation of both amino acids at the same time on the catalytic constant of this enzyme (Figure 4–21)[280] mimic the expected behavior. The pK_a of 4.7 governing the decrease in the pH–rate profile of the catalytic constant for the wild type (○) as the pH is decreased is lost in the mutant of Glutamate 290 (●), but the pK_a of 5.2 governing the decrease in the pH–rate profile as the pH is increased remains. The pK_a of 5.2 observed in the pH–rate profile of the catalytic constant for the wild type is lost in the mutant of Aspartate 356 (□), but the pK_a of 4.7 remains. When both amino acids are mutated, the remaining enzymatic activity has a catalytic constant that is independent of pH (■). Consequently, the pK_a of 4.7 governing the pH–rate

behavior of the unmutated enzyme must be that of Glutamate 290, and the pK_a of 5.2 must be that of Aspartate 356. In this instance, the fact that the acid–base catalysis provided by Glutamate 290 and the acid–base catalysis provided by Aspartate 356 are each relatively small (factors of around 100 and 10, respctively) has allowed the entire consequence of their catalysis to be observed.

There are many paradigmatic examples of a decrease in a steady-state rate constant above an apparent pK_a or a decrease in a steady-state rate constant below an apparent pK_a being lost upon mutation of a catalytic acid or a catalytic base, respectively, in the active site of an enzyme. In each case, the loss of the apparent pK_a is accompanied by a large overall decrease in that rate constant as expected (Figure 4–20). In most of the following examples, the respective rate constants for the unmutated enzymes decrease either above (ENH in Figure 4–20) or below a particular pK_a (HOE in Figure 4–20), while the same rate constants for the mutated enzymes do not (E in Figure 4–20). The greatest decrease observed in each rate constant upon mutation occurs at the optimum pH for the unmutated enzyme, either below (difference between ENH and E below pH 8 in Figure 4–20) or above (difference between EOH and E above pH 6 in Figure 4–20) the pK_a at which the rate constant for the unmutated enzyme begins to decrease while the rate constant for the mutated enzyme does not. When Histidine 40 is mutated to glutamine, the catalytic constant of glucose-6-phosphate dehydrogenase (coenzyme F_{420}) from *M. tuberculosis* at the respective optima of pH decreases by a factor of 1000, and the pK_a of 8.0, above which the catalytic constant decreases as the pH is increased, is lost. These facts are consistent with the conjugate acid of Histidine 40 playing the role of a catalytic acid in the enzymatic reaction.[281] When Glutamate 73 is mutated to alanine, the catalytic constant for the deacetylase LpxC from *Aquifex aeolicus* at the respective optima of pH decreases by a factor of 700, and the pK_a of 6.1, below which the catalytic constant decreases as the pH is decreased, is lost. These facts are consistent with Glutamate 73 playing the role of a catalytic base in the enzymatic reaction.[282] When Histidine 104 is mutated to glutamine, the specificity constant $k_{\alpha Gal}$ for the mutarotation of α-D-galactose (αGal) by aldose 1-epimerase from *E. coli* at the respective optima of pH decreases by a factor of 5000, and the pK_a of 7.6, above which the specificity constant decreases as the pH is increased, is lost.

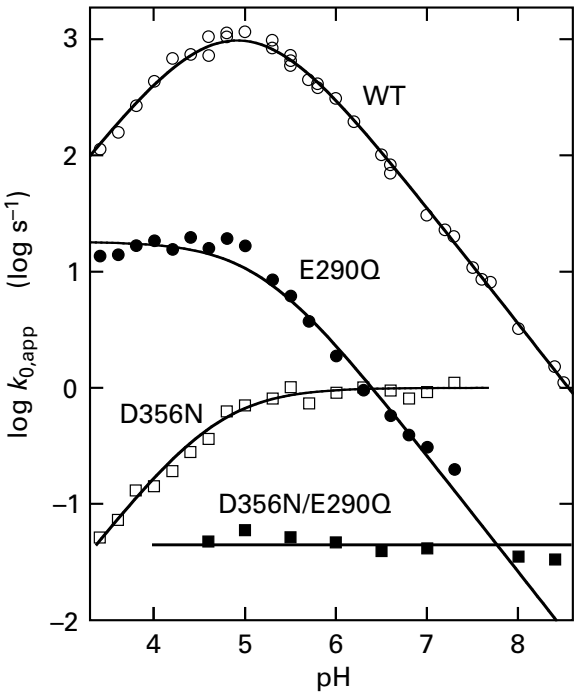

Figure 4–21: pH–Rate profiles for the hydrolysis of 4-nitrophenyl phosphate catalyzed by mutants of protein-tyrosine-phosphatase from *Y. entereocolitica*.[280] Initial rates for the hydrolysis were measured with a spectrophotometric assay at an ionic strength of 0.15 M and 30 °C for several concentrations of 4-nitrophenyl phosphate at each of the chosen values of pH, and catalytic constants were obtained from these initial rates. The pH was maintained with the following buffers: pH 3.4–3.8, 100 mM sodium formate; pH 4.0–5.7, 100 mM sodium acetate; pH 5.8–6.5, 50 mM sodium succinate; pH 6.6–7.3, 50 mM sodium 3,3-dimethylglutarate; pH 7.5–8.7, 100 mM sodium glycinamide. The common logarithms of the values of the catalytic constant $k_{0,app}$ for a portion (amino acids 219–462) of the wild-type protein-tyrosine-phosphatase containing the complete active site (WT, ○), a mutant of that same portion in which Glutamate 290 had been mutated to glutamine (E290Q, ●), a mutant of that same portion in which Aspartate 356 had been mutated to asparagine (D356N, □), and a double mutant of that same portion in which both mutations had been made (D356N/E290Q, ■) are plotted as a function of pH. The curve for the unmutated enzyme was fit to the data with pK_{a1} = 4.63 ± 0.07 and pK_{a2} = 5.20 ± 0.06. The curve for the mutant D356N was fit to the data with pK_a = 4.70 ± 0.04. The curve for the mutant E290Q was fit to the data with pK_a = 5.16 ± 0.06.

These facts are consistent with Histidine 104 playing the role of a catalytic acid in the enzymatic reaction.[283] When Histidine 52 is mutated to leucine, the bimolecular rate constant for association of hydrogen peroxide with the active site of cytochrome-*c* peroxidase from *S. cerevisiae* at the respective optima of pH decreases by a factor of 10^5, and the pK_a of 5.4, below which the rate constant decreases as the pH is lowered, is lost. These facts are consistent with Histidine 52 playing the role of a catalytic base in the enzymatic reaction.[284] When Histidine 464 is mutated to glutamine, the catalytic constant of

thioredoxin-disulfide reductase from *Drosophila melanogaster* at the respective optima of pH decreases by a factor of 50, and the pK_a of 9.3, above which the catalytic constant decreases as the pH is increased, is lost. These facts are consistent with the conjugate acid of Histidine 464 playing the role of a catalytic acid in the enzymatic reaction.[255]

The curves labeled HOE, ENH, and HOENH in Figure 4–20 are drawn so that the observed rate constant, $k_{i,app}$, which can be either a catalytic constant or a specificity constant, decreases at values of pH below the value of the respective pK_a, decreases at values of pH above the value of the respective pK_a, or decreases at values of pH below and above the respective values of the pK_a only to the level that the rate constant would be in the absence of the catalytic base or catalytic acid that is titrating. The assumption is that **when the fraction of the catalytic base or catalytic acid in the required state of ionization becomes so small** that the rate constant for the reaction catalyzed by that catalytic base or catalytic acid becomes smaller than the rate constant that the enzyme would display in its absence, the rate constant of the enzymatic reaction becomes the rate constant that it has in the absence of that acid or base.

The changes in slope at these points in the theoretical curves producing rate constants that become invariant with pH result from a change in mechanism. The mechanism catalyzed by the catalytic base or catalytic acid is replaced by a mechanism not involving that catalytic base or catalytic acid. In theory, this mechanism would be the one that the enzyme uses when that catalytic acid or catalytic base has been eliminated by mutation.

Data for the effects of pH on rate constants for an enzymatic reaction catalyzed by an unmutated enzyme have rarely if ever been gathered over the range necessary to observe these changes in slope at low pH and at high pH, if they indeed exist. There is a hint of such a change in slope in Figure 4–10H at high values of pH. It is also possible that the inactive, hydronated catalytic base or the inactive, unhydronated catalytic acid, respectively, interferes with the mechanism with the lower rate constant that is observed when that base or acid is removed by site-directed mutation, which probably represents catalysis by water. If the inactive hydronated base or the inactive unhydronated acid sterically blocks access of a molecule of water that could provide the necessary catalysis, the curve for the common logarithm of the rate constant would not level out at this lower level. It would continue to drop with a slope of +1 or −1 indefinitely because the mechanism observed with the respective mutant is precluded in the wild type by this interference with the access of water into a proper location and orientation, and a hydron cannot disappear or appear magically. Consequently, the lack of any indication of a plateau at low pH or high pH in the pH–rate profiles of native enzymes could be yet another indication of the absolute necessity for a catalytic acid or catalytic base, which in the complete absence of the usual catalytic acid–base would be supplied by a molecule of water. Most pH–rate profiles, however, unlike that for ribonuclease (Figure 4–11), are not determined over sufficiently wide ranges to conclude that such plateaus do not exist.

If the pH–rate profile for the common logarithm of one of the steady-state rate constants of an enzyme is a straightforward sum of the contributions of the catalytic acid–bases catalyzing a reaction within the active site of the native enzyme (Figure 4–20), then the contribution of a particular catalytic acid–base to that pH–rate profile should be represented by the difference between the pH–rate profiles for the wild type and for a mutant in which that catalytic acid–base has been removed (Figure 4–22). The simplest possible example is represented by the pH–rate profile for the catalytic constant, k_0, of β-glucosidase from *Agrobacterium faecalis*, which for the native enzyme is governed by a single pK_a of 7.8 (○; Figure 4–22A).[285] When Glutamate 470 is mutated to glycine, the catalytic constant of the mutant, which is 1800 times less than that of the wild type at its maximum, is invariant with pH. The **difference pH–rate profile**, which represents the contribution of Glutamate 470 to the catalysis of the unmutated wild-type enzyme relative to that of the mutant, demonstrates that Glutamate 470 is the catalytic acid responsible for the decrease in the catalytic constant above an apparent pK_a of 7.8.

In contradistinction to the change just described, the pH–rate profile for the catalytic constant of mRNA interferase toxin RelE from *E. coli* for hydrolysis of messenger RNA after its translation on the ribosome has been initiated is invariant with pH. When, however, Arginine 81 in the enzyme is mutated to alanine, the catalytic constant decreases by a factor of 80,000, and the pH–rate profile for the catalytic constant of the mutant is pH-dependent, decreasing below a pH of greater than 9. In the difference pH–rate profile, which defines the contribution of Arginine 81 to catalysis, the catalytic constant decreases by a factor of 10 for every increase

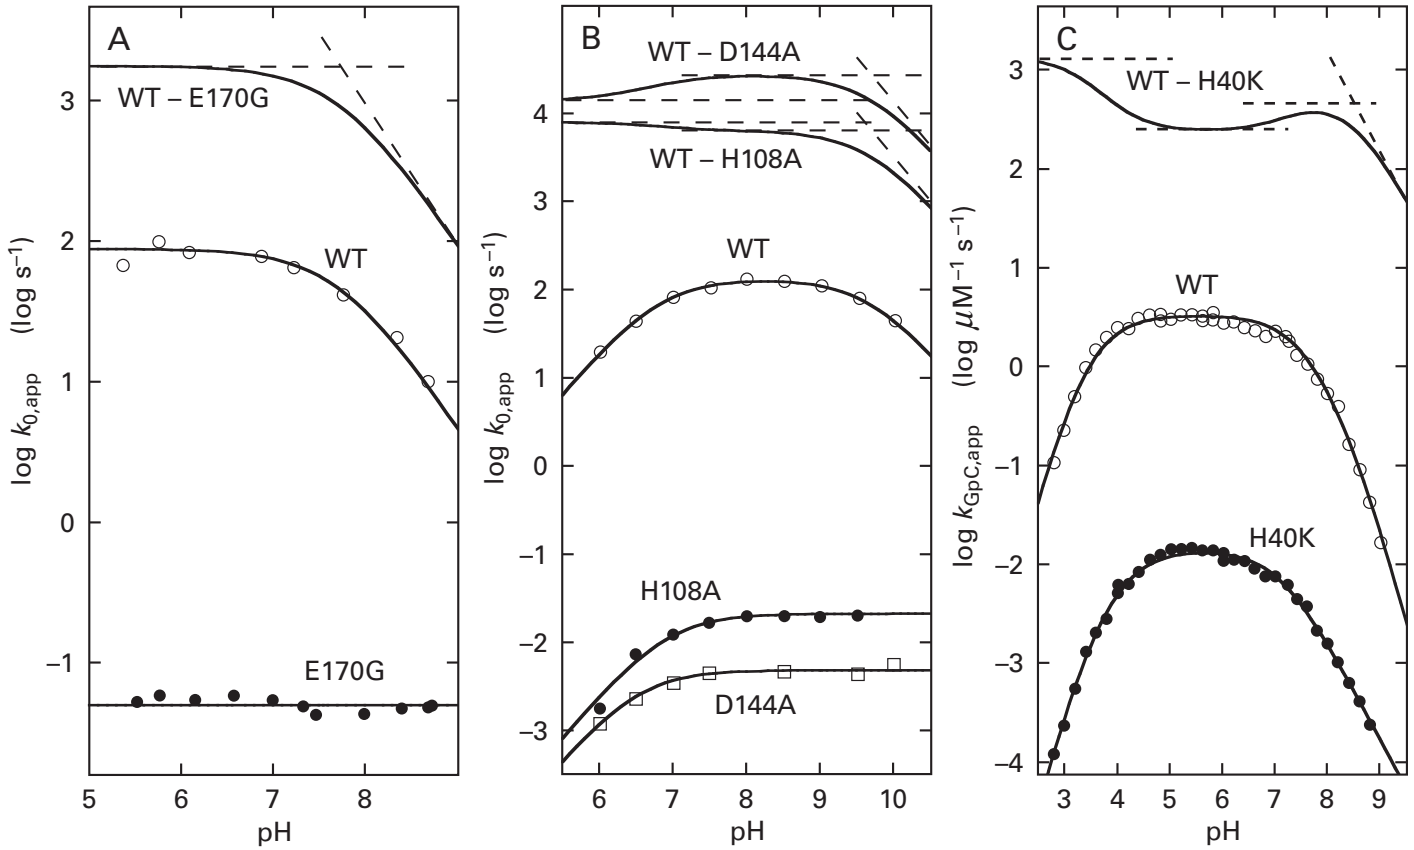

Figure 4–22: Difference pH–rate profiles for site-directed mutants. (**A**) pH–Rate profiles for the catalytic constant of β-glucosidase from *A. faecalis* for 2′,4′-dinitrophenyl β-D-glucopyranoside at an ionic strength of 0.2 M and 37 °C.[285] The common logarithms of the observed catalytic constants $k_{0,app}$ (second^{-1}) are plotted as a function of pH for the wild-type enzyme (WT, ○) and for a site-directed mutant in which Glutamate 170 had been converted to glycine (E170G, ●). The two sets of data were fit with Equation 4–89 or a horizontal line, respectively. The top curve, the difference pH–rate profile, is the difference between the pH–rate profiles fit to data for the wild type and data for the mutant. (**B**) pH–Rate profiles for the catalytic constant of phosphoribosylglycinamide formyltransferase from *E. coli* for 10-formyl-5,8-dideazafolate and N^1-(5-phospho-D-ribosyl)glycinamide at an ionic strength of 0.15 M and 25 °C.[218] The common logarithms of the observed catalytic constants $k_{0,app}$ (second^{-1}) are plotted as a function of pH for the wild-type enzyme (WT, ○), for a site-directed mutant in which Histidine 108 had been converted to alanine (H108A, ●), and for a site-directed mutant in which Aspartate 144 had been converted to alanine (D144A, □). The three sets of data were fit with Equations 4–96, 4–80, and 4–80, respectively. The top two curves are the respective differences between the pH–rate profile fit to the data for the wild type and the pH–rate profiles fit to the data for each mutant. (**C**) pH–Rate profiles for the steady-state rate constant k_{GpC} of ribonuclease T_1 from *A. oryzae* for the dinucleotide guanylyl-(3′-5′)cytidine (GpC) at an ionic strength of 0.1 M and 35 °C.[219] The common logarithms of the observed steady-state rate constants k_{GpC} (micromolar^{-1} second^{-1}) are plotted as a function of pH for the wild-type enzyme (WT, ○) and for a site-directed mutant in which Histidine 40 had been converted to lysine (H40K, ●). The two sets of data were fit with Equations 4–109 and 4–97, respectively. The top curve, the difference pH–rate profile, is the difference between the pH–rate profiles fit to data for the wild type and data for the mutant. In each panel (A–C), dashed lines of slope +1, 0, or –1 are included as asymptotes to the functions defining the difference pH–rate profiles.

of a unit of pH over the range of the measurements, with no indication of a pH below which it becomes invariant.[286] Consequently, it was concluded that the pH–rate profile of the wild type is invariant with pH because, in the range of the measurements, catalysis by a base of unknown identity in the mutant was increasing by a factor of 10 for every increase of one unit of pH while catalysis by the cationic conjugate acid of the guanidinio group of Arginine 81 is decreasing by a factor of 10 for every increase of one unit of pH. These two factors, necessarily represented by lines of slope –1 and +1, multiply to create the invariance of the catalytic constant for the wild type with pH. In this instance, the mutation has revealed acid–base catalysis where none seemed to be occurring rather than eliminating acid–base catalysis that is observed with the native enzyme. The reason for the invariance of the catalytic constant for the wild type is that the pK_a for the catalytic acid and the pK_a for the catalytic base in the Michaelis

complex are outside the values of pH chosen for the measurements. The results also suggest that the pK_a of Arginine 81, if it is acting as the catalytic acid in the Michaelis complex, as the authors have concluded, is less than 5, a rather startling proposal since the pK_a for an arginine in a protein, when fully exposed to the solution, is 13.

In more complicated instances, a difference pH–rate profile is a simple way of **isolating the various contributions of the particular acid–base** that has been mutated. For example, the pH–rate profile for the catalytic constant of phosphoribosylglycinamide formyltransferase from *E. coli* decreases above a pK_a of 9.7 (Figure 4–22B).[218] In a crystallographic molecular model of the active site of the enzyme, the carboxy group of Aspartate 144 and the imidazolyl group of Histidine 108 form a hydrogen bond.[287] When either Aspartate 144 or Histidine 108 is mutated, the difference pH–rate profile between either mutant and the wild type shows that both side chains together are responsible for the single pK_a of 9.7, just as the ammonio group of Lysine 165 and the carboxylato group of Aspartate 169 appear to be equally responsible for the acid–base catalysis in the active site of phosphoribulokinase from *Rhodobacter sphaeroides*. Consequently, this pK_a is for dissociation of a hydron from the hydrogen-bonded complex of Aspartate 144 and Histidine 108, and the observation is consistent with the conclusion that, in this instance, this complex is a composite acid–base that acts as a catalytic acid in the enzymatic reaction.

A **composite acid–base** is formed by the combination of more than one simple acid–base. The participating acid–bases are all part of a hydrogen-bonded network from which a hydron can dissociate from a peripheral acidic position or with which a hydron can associate at a peripheral lone pair. These dissociations and associations are often accompanied by shifts in the hydrons in the hydrogen bonds of the network. Within each level of ionization, the hydrogen-bonded network will have more than one tautomer. For example, in the case of a hydrogen-bonded complex between a carboxy group and a imidazolyl group (Equation 4–134), as in the case of the composite acid–base formed from Aspartate 144 and Histidine 108 in the active site of phosphoribosylglycinamide formyltransferase (Figure 4–22B), there are three reasonable tautomers: one in which the two hydrons are on the imidazolyl group (Equation 4–134), one in which the hydron of the hydrogen bond has transferred to the carboxy group and a neutral imidazolyl group is the acceptor for a hydrogen bond from the neutral carboxy group, and one in which the hydron other than the one in the hydrogen bond is on the carboxy group rather than the imidazolyl group and the neutral imidazolyl group is the donor in the hydrogen bond to the other, now acyl, oxygen of the carboxy group. When the hydrogen-bonded complex is the conjugate acid of a cationic imidazolio group and an anionic carboxylato group (Equation 4–134), its conjugate base is the hydrogen-bonded complex of a neutral imidazolyl group and a carboxylato group. At this level of ionization, when a hydron dissociates from the conjugate acid or associates with the conjugate base, the hydrogen bond remains intact and the complex remains an intact composite acid–base. Dissociation of a hydron from or association of a hydron with a composite acid–base, however, can disrupt the hydrogen bonding. For example, dissociation of a hydron from a composite acid between a neutral imidazolyl group and a carboxylato group would eliminate the hydrogen bond between them because there would no longer be a hydron between them with which a hydrogen bond could form.

The difference pH–rate profile in Figure 4–22B also shows that Aspartate 144 shifts the pK_a of yet another catalytic acid–base in the active site from 6.5 in its absence to 6.8 in its presence (inflection in the difference pH–rate profile around pH 6.7) while Histidine 108 shifts the pK_a of the same group from 6.9 to 6.8 (inflection in the difference pH–rate profile around pH 6.9). These effects are those that would be expected from an anion, the carboxylate of Aspartate 144, and a cation, the imidazolium of Histidine 108, which, on the basis of these observations, should be the tautomer of the composite acid–base present in the greatest concentration at this level of ionization (Equation 4–134).

In the case of ribonuclease T_1 from *A. oryzae*, the pH–rate profile for the specificity constant $k_{GpC,app}$ for transesterification of the dinucleotide guanylyl(3′-5′)cytidine (GpC) is governed by values of pK_a of 3.4, 3.4, 7.5, and 8.5 (Figure 4–22C).[219] The difference pH–rate profile for the mutant in which Histidine 40 in the active site[288] has been mutated to lysine demonstrates that Histidine 40 is responsible for the pK_a of 8.5. This observation is consistent with the cationic imidazolio group acting as a catalytic acid in the enzymatic reaction. In addition, Histidine 40 shifts the pK_a of another catalytic acid–base, probably the carboxy group of Glutamate 58, from 4.1 to 3.4 (inflection in the difference pH–rate profile around pH 3.8), as expected for a cationic imidazolium. It also seems, however, to shift the

pK_a of yet another catalytic acid–base from 7.1 to 7.5 (inflection in the difference pH–rate profile around pH 7.3), which cannot be explained as the effect of a cationic side chain. This shift can be explained, however, as the result of the new lysine that takes the place of Histidine 40 in the mutant. The ammonio group of this lysine could very well end up adjacent to Histidine 92 in the active site and shift its pK_a from 7.5 in the wild type to 7.1 in the mutant. The pK_a of Histidine 92 in the wild-type enzyme has been estimated by nuclear magnetic resonance spectroscopy to be 7.2.[219]

The difference pH–rate profile for the specificity constant k_{dpc} for 3′-dephosphocrotonyl-SCoA (dpc) for enoyl-CoA hydratase from *Rattus norvegicus*, in which Glutamate 144 has been mutated to glutamine, has an inflection below pH 7 resembling the inflection below pH 5 in the difference pH–rate profile for the mutant of ribonuclease T_1 (upper curve in Figure 4–22C), but this inflection does not begin to plateau as the pH is decreased as does the curve for the mutant of ribonuclease T_1.[289] It was concluded that the pK_a for a catalytic base, which was assigned as the pK_a for the carboxylato group of Glutamate 164 by examination of crystallographic molecular models, has a pK_a of less than 5 in the native enzyme and that its pK_a has shifted to a value of 6.8 in the mutant in which the carboxylato group of Glutamate 144 is missing. In other words, the carboxylato group of Glutamate 144 in the native enzyme causes the pK_a of that carboxy group of Glutamate 164 to shift from 6.8 to less than 5.

The proposal that the lysine inserted in place of Histidine 40 in the active site of ribonuclease T_1 shifts the pK_a of the carboxy group of Glutamate 58 is an example of the fact that the **identity of the amino acid that replaces the catalytic amino acid in the active site often has a significant effect** on the outcome of the site-directed mutation. For example, Tyrosine 146 in thymidylate synthase from *L. casei* was replaced in turn by 15 other amino acids,[245] and values of $k_0\,(K_{mTHF}K_{m,dU})^{-1}$ for the reactants 5,10-methylenetetrahydrofolate (THF) and deoxyuridine monophosphate (dU) decreased by various factors between 500 and 1.5×10^5, and the differences have no obvious explanation. When Histidine 238 in the active site of murine adenosine deaminase is replaced by glutamate, rate constant $k_0\,K_{m,Ad}^{-1}$, where $K_{m,Ad}$ is the Michaelis constant for adenosine (Ad), decreases 275,000-fold. When, however, Histidine 238 is replaced by arginine, the decrease in the steady-state rate constant $k_0\,K_{m,Ad}^{-1}$ is only a factor of 50.[290] Aspartate 326 in human creatine kinase is more than 0.7 nm away from any atom in the creatine or $MgATP^{2-}$ participating in the transfer of the phospho group between them.[291] When Aspartate 326 is replaced by glutamate, the steady-state rate constant $k_0\,K_{m,cycr}^{-1}$, where $K_{m,cycr}$ is the Michaelis constant for cyclocreatine (cycr), decreases by a factor of only 3, and when it is replaced by asparagine, $k_0\,K_{m,cycr}^{-1}$ decreases by a factor of only 7. When, however, Aspartate 326 is replaced by alanine, $k_0\,K_{m,cycr}^{-1}$ decreases by a factor of 200.[193] From the first two factors, the correct conclusion, that Aspartate 326 is not a catalytic acid–base, would be drawn, but the last factor of 200 is ambiguous. Consequently, a conclusion that an amino acid in the active site is a catalytic acid–base, based solely on the order of magnitude of the decrease in a kinetic constant upon its mutation, can be seen to be even more tenuous.

Tyrosine 16 forms a hydrogen bond with the carbonyl group at carbon 3 in the reactant estr-5(10)-ene-3,17-dione (ed), which is the carbonyl group α to the hydron removed during catalysis to form the enolate while estr-5(10)-ene-3,17-dione is in the active site of steroid Δ-isomerase from *P. putida*. When Tyrosine 16 is replaced by phenylalanine, the steady-state rate constant $k_0\,K_{m,ed}^{-1}$ decreases by a factor of 70,000. When, however, Tyrosine 16 is replaced by alanine, glycine, serine, or threonine, the decrease in the steady-state rate constant $k_0\,K_m^{-1}$ is only a factor of 280 ± 70.[290] In this case it seems that the phenylalanine precludes formation of a hydrogen bond to the carbonyl group by a molecule of water, while smaller replacements do not.

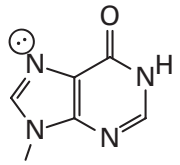
When Histidine 281 in the active site of benzoylformate decarboxylase from *P. putida* is replaced by alanine, the steady-state rate constant $k_0\,K_{m,bf}^{-1}$, where bf is the reactant benzoylformate, decreases 700-fold, which is on the borderline of suggesting that it is a catalytic acid–base in the enzymatic reaction. When, however, Histidine 281 is replaced by threonine, asparagine, tyrosine, glutamine, or tryptophan, the decrease in rate constant $k_0\,K_m^{-1}$ is less and less, and when it is replaced by phenylalanine, the decrease is only a factor of 10, which is insignificant.[292] One can conclude that Histidine 281 is not a catalytic acid–base in the enzymatic reaction, while the opposite conclusion might have been reached if only the substitution of alanine had been made.

The different mutants of benzoylformate decarboxylase just described were almost all cases in which an acid–base was replaced with a side chain that is not an acid base in the normal range of pH.

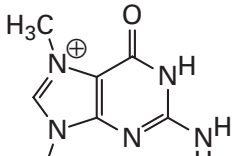
It is also possible, however, to **replace a catalytic acid–base with other side chains that are acid–bases** of different size and strength to assess their ability to assume the role of the normal catalytic side chain,[293] but conclusions drawn from these results, in the absence of crystallographic molecular models of the mutant active sites occupied by substrates or analogues of substrates, are ambiguous because of steric differences that accompany the differences in pK_a among the limited set of amino acids that are available to take the place of the one mutated.

In an enzyme in which a metallic hydroxide acts as a catalytic base, the **metallic cation can be mutated** by replacing it with another one, and the effect of that mutation on the pH–rate profile can identify the hydroxide on the metal as a catalytic acid–base responsible for one of the observed acid dissociation constants. For example, when the prosthetic metallic cation in the active site of human histone deacetylase is changed from the natural Zn^{2+} to Co^{2+}, a pK_a in the pH–rate profile, above which the specificity constant for a fluorescent unnatural reactant for the enzyme decreases, shifts from 9.1 to 10. This is the shift expected if zinc hydroxide (pK_a in water = 9.0) has been replaced by cobalt hydroxide (pK_a in water = 9.6).

A **reactant for the enzyme can also be mutated** to identify the role of a catalytic acid–base in the catalytic mechanism of an enzyme. For example, when hypoxanthine (**4–42**)



4–42



4–43

in a trinucleotide that is a reactant for human DNA-3-methyladenine glycosylase II was replaced with 7-methylguanine (**4–43**), the decrease in the pH–rate profile for the catalytic constant of the enzyme above a pK_a of 6.4 was no longer observed.[294] This result identified the side chain with this pK_a as a catalytic acid responsible for hydronating nitrogen 7 of the hypoxanthine to make it cationic and a better leaving group during hydrolysis of the N-glycosidic linkage. This hydronation is not necessary for nitrogen 7 in 7-methylguanine because it is methylated and already cationic.

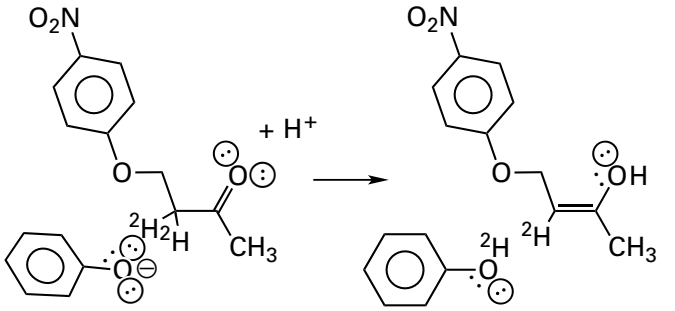
Kinetic Isotope Effects

Reactions in which a **hydron, hydrogen atom, or hydride is transferred in a rate-affecting step** proceed more slowly when the protium on the reactant is replaced by deuterium. For example, removal of deuterium (^{2}H) as a deuteron from 4-(4-nitrophenoxy)-[3,3-$^2H_2$]butan-2-one by phenoxide anion acting as a general base in aqueous solution



(4–174)

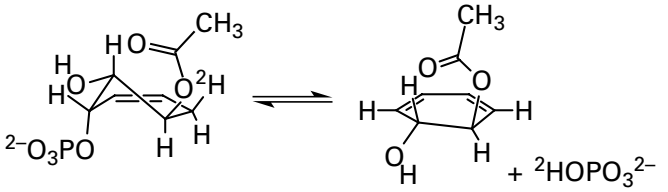
occurs 6.1 times more slowly than removal of that hydrogen as a proton from the same position by the same base.[296] This decrease in rate produced by replacing protium with deuterium is an example of a kinetic isotope effect.

A kinetic isotope effect is a change in a rate constant produced by substitution of the isotope of one or more atoms in a reactant for another isotope. A **primary kinetic isotope effect** is a kinetic isotope effect for a reaction in which the bond between the one atom that has been isotopically substituted and an atom to which it is covalently attached is broken or in which such a bond is formed. A **primary deuterium kinetic isotope effect** is a primary kinetic isotope effect produced by substitution of a deuterium for a protium in a reactant. Undeuterated reactant has a hydrogen at the substituted position, but since the relative natural abundance of deuterium is 0.0156%, the vast majority of hydrogen is protium, so substitution of a hydrogen at natural abundance by a deuterium is essentially substitution of protium with deuterium.

If a step in the mechanism of a reaction is **rate-affecting**, an increase or decrease in its forward rate constant, its rate constant in reverse, or both of them will cause a change in an observed rate constant of the overall reaction, but this change will not necessarily be of the same magnitude as the increase or decrease in the microscopic rates of that rate-affecting step. Because of the definition of a rate-limiting step,[297] a rate-affecting step must be or must precede the rate-limiting step in a reaction.

The appearance of a **primary deuterium kinetic isotope effect for a rate constant of an enzymatic reaction** provides experimental evidence that removal of the hydrogen that has been substituted, as either a hydron, hydrogen atom, or hydride, from the reactant is a step in the enzymatic reaction and that the step is a rate-affecting step.

The **hydron** at carbon 6 in 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate is removed by nitrogen 5 of the prosthetic flavin[298] in the active site of chorismate synthase from *Neurospora crassa* during the elimination catalyzed by the enzyme. When the protium at the *pro-R* position on carbon 6 is replaced synthetically by deuterium, the catalytic constant of the enzyme for deuterated reactant



(4–175)

is 2.7 ± 0.2 times smaller than it is for undeuterated reactant, and the specificity constant k_{CPS} for the synthetic (6*R*)-[6-^{2}H]-5-*O*-(1-carboxyvinyl)-3-phosphoshikimate (CPS) is 1.6 ± 0.1 times smaller.[299]

A **hydrogen atom** is removed from the methyl group of toluene by a glycyl radical in the active site of benzylsuccinate synthase from *Thauera aromatica* before addition of the resulting benzyl radical to the double bond of fumarate to produce benzylsuccinate. When perdeuterated toluene is used as a reactant, the catalytic constant of the enzyme is 1.7 ± 0.2 times smaller than when undeuterated toluene (tol) is used as a reactant, and the specificity constant k_{tol} is 2.9 ± 0.1 times smaller.[300]

A **hydride** is transferred from the 4*S* position of reduced thionicotinamide-adenine dinucleotide phosphate to an oxidized flavin adenine dinucleotide in the active site of trypanothione-disulfide reductase from *Trypanosoma congolense*. When reduced (4*S*)-[4-^{2}H]thionicotinamide-adenine dinucleotide phosphate is used as a reactant, the catalytic constant of the enzyme is 4.7 ± 1.0 times smaller than when reduced, undeuterated 3-thionicotinamide-adenine dinucleotide phosphate (tNADPH) is used as a reactant, and the specificity constant k_{tNADPH} is 6.9 ± 0.9 times smaller.[301]

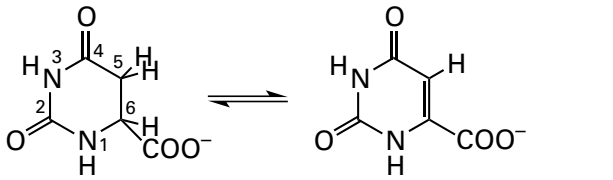
The **deuterium kinetic isotope effect**, ${}^{D}k_i$, on a particular rate constant, k_i, is the ratio between the rate constant for undeuterated reactant, $k_{i\mathrm{H}}$, and the rate constant for the deuterated reactant, $k_{i\mathrm{D}}$

$$ {}^{\mathrm{D}}k_i \equiv \frac{k_{i\mathrm{H}}}{k_{i\mathrm{D}}} \qquad (4\text{–}176) $$

For example, the primary deuterium kinetic isotope effect[299] on the catalytic constant, ${}^{D}k_0$, of chorismate synthase (Equation 4–175) from *N, crassa* for replacement of the *pro-R* hydrogen at carbon 6 in 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate with deuterium is 2.7 ± 0.2.

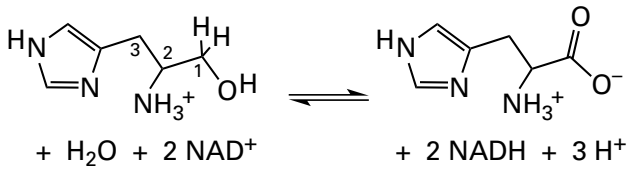
In the case of the reaction catalyzed by trypanothione-disulfide reductase, the existence of the significant primary deuterium kinetic isotope effects is evidence that the transfer of an actual hydride between the nicotinamide and the flavin is occurring in this enzymatic reaction rather than consecutive transfers of an electron, a hydron, and an electron. In many of the **reactions catalyzed by flavoenzymes** that have NADH or NADPH as substrates, there are significant, often quite large, primary deuterium kinetic isotope effects more consistent with the transfer of a hydride between NADH or NADPH and oxidized flavin than two successive single electron transfers.

If **two hydrogens are removed from the reactant** by the active site, the primary deuterium kinetic isotope effect is usually greater for the reactant in which these two hydrogens are replaced by deuterium than for the two respective reactants in which only one is replaced.[302] For example, in the reduction catalyzed by human dihydroorotate dehydrogenase (quinone)



(4–177)

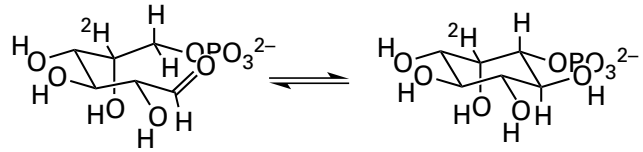
where flavin is a prosthetic flavin mononucleotide in the active site, the primary deuterium kinetic isotope effect on the rate constant for reduction of flavin at saturating dihydroorotate is 4.2 ± 0.1 for [5,5-$^2H_2$]-(*S*)-dihydroorotate, 3.8 ± 0.1 for [6-^{2}H]-(*S*)-dihydroorotate, and 8.0 ± 0.2 for [5,5,6-$^2H_3$]-(*S*)-dihydroorotate.[303] In the reaction catalyzed by histidinol dehydrogenase from *Salmonella typhimurium*



(4–178)

the two hydrides are removed from carbon 1 of the histidinol in two distinct steps that are separated from each other by dissociation of the NADH formed in the first oxidation and association of NAD^+ for the second oxidation. It has been observed that, at pH 6.7, the primary deuterium kinetic isotope effect on the catalytic constant for (1*S*)-[1-^{2}H]histidinol is 1.6 ± 0.1, that for (1*R*)-[1-^{2}H]histidinol is 1.5 ± 0.1, and that for [1,1,-$^2H_2$]histidinol is 2.0 ± 0.2. These observations demonstrate that each of these two steps, in which one of the two hydrides is transferred, is a rate-affecting step in the overall enzymatic reaction.[304]

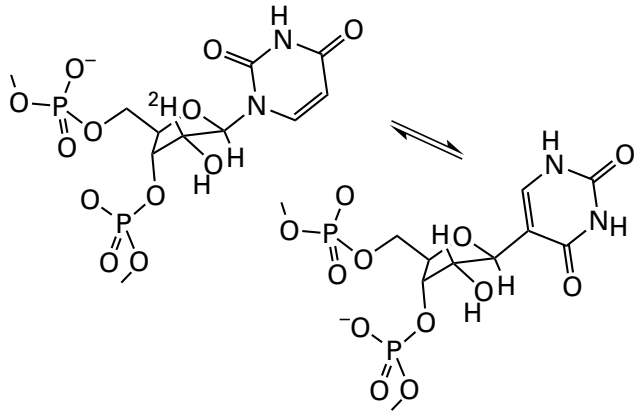
Kinetic isotope effects can also be used to provide **evidence for removal of a hydrogen** in an enzymatic mechanism even though that hydrogen ends up occupying the same position in the respective product. For example, substitution of a hydrogen with deuterium at carbon 5 on D-glucose 6-phosphate produced a deuterium kinetic isotope effect of 1.5 on the rate of the reaction catalyzed by inositol-3-phosphate synthase



(4–179)

from *R. norvegicus*. This isotope effect was used as evidence that this hydrogen is removed in one rate-affecting step of the enzymatic reaction even though it remains at the same location in the product of the overall reaction.[305]

In the isomerization catalyzed by tRNA pseudouridine[55] synthase

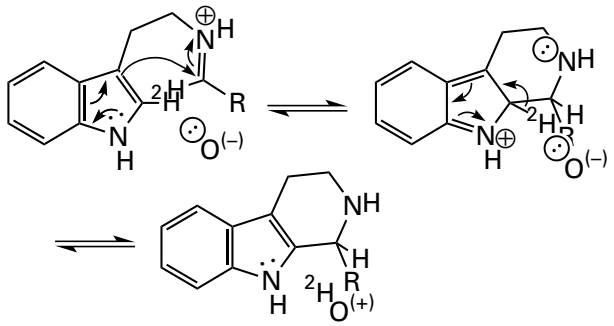


(4–180)

from *E. coli*, the hydrogen on carbon 2′ of uridine seems to be uninvolved. Nevertheless, when it is replaced with a deuterium, the deuterium kinetic isotope effect on the specificity constant, k_U, for a uridine (U) in the proper position in a polyribonucleotide that is a reactant for the enzyme is 3.6. This value is so large that it must be a primary deuterium kinetic isotope effect, and the hydrogen at carbon 2′ must be removed by a base in the active site during the isomerization.[306] The conclusion drawn from this observation is that, following dissociation of the anionic eneimide that is the leaving group and that is the conjugate base at nitrogen 1 of the uracil ($pK_a = 9.5$), the resulting oxocarbenium ion of the ribose, which is quite unstable, is stabilized as the neutral enol ether by removal of the now-acidic hydron from carbon 2′ until the eneimide of the uracil can rotate to the proper orientation so that carbon 5 of the eneimide, which is also nucleophilic, rather than nitrogen 1 can add to carbon 1′ of the ribose. Consequently, addition of carbon 5 as a nucleophile should be a simple addition to the double bond between carbons 1′ and 2′ of the enol ether either before, after, or coincident with readdition of the hydron to carbon 2′.

α-Galactosidase MelA from *Citrobacter freundii* catalyzes the hydrolysis of α-galactosides, which appears to be simply a dissociative nucleophilic substitution with an oxocarbenium ion as an intermediate. When either phenyl α-D-[2-^{2}H]galactopyranoside or phenyl α-D-[3-^{2}H]galactopyranoside is used as a reactant, however, the deuterium kinetic isotope effects on the respective specificity constants for these galactosides were both 1.74.[307,308] These isotope effects are again too large to be secondary or tertiary kinetic isotope effects and must be primary deuterium kinetic isotope effects. These deuterium kinetic isotope effects, and the fact that there is a prosthetic NAD^+ in the active site of the enzyme, led to two conclusions: first, that the NAD^+ removes the hydride from carbon 3 of D-galactose, and second, that the enol formed by removal of a hydron from carbon 2 by a catalytic base permits β-elimination of the phenolate rather than a nucleophilic substitution like the one in the active site of lysozyme.

Another conclusion that can be drawn from a primary deuterium kinetic isotope effect is that **the chemical mechanism of an enzymatic mechanism is the same as the chemical mechanism of the reaction in solution.** For example, strictosidine synthase from *Rauvolfia serpentina* catalyzes intramolecular addition to carbon 2 of the indolyl group of an electrophilic iminium in the adduct between tryptamine and an aldehyde, followed by rearomatization of the indolyl group



(4–181)

When the protium on carbon 2 of the indolyl group of the tryptamine is replaced by deuterium, the primary deuterium kinetic isotope effect (2.7 ± 0.1) on the catalytic constant of the enzymatic reaction is indistinguishable from the primary deuterium kinetic isotope effect (2.0–2.6) for the same substitution in the nonenzymatic electrophilic aromatic substitution.[309] It was concluded that the chemical mechanism on the active site was the same as that in solution, a Pictet–Spengler electrophilic aromatic substitution, the mechanism for which has been extensively studied.[310] The fact that the deuterium isotope effect results from substitution of the hydrogen on carbon 2 requires that, in both the enzymatic reaction and the reaction in solution, the rearomatization of the adduct between iminium and the indolyl group be at least rate-affecting if not rate-limiting. Consequently, this specific substitution has focused attention on this particular step in the mechanism. In solution, the intramolecular electrophilic aromatic substitution is catalyzed by acetate as a general base, so it was also concluded that there should be a catalytic base in the active site

responsible for accepting the hydron during the rearomatization in the active site.

Tritium kinetic isotope effects are also observed in enzymatic reactions. A **tritium kinetic isotope effect** is a kinetic isotope effect produced by substitution of a tritium (T) for a protium in a reactant. For example, the tritium kinetic isotope effect, ${}^{T}k_{DA}$, for the specificity constant, k_{DA}, for [2-^{3}H]-D-alanine (DA) when it is oxidized to pyruvate by porcine D-amino-acid oxidase is 12.6 ± 0.1.[311]

Deuterium or tritium can be substituted synthetically for a hydrogen on carbon, on hydrogen, or on phosphorus,[312] and it can be expected to remain on that carbon, hydrogen, or phosphorus long enough to perform an experiment. Deuterons or tritons on sulfur, oxygen, or nitrogen, however, exchange rapidly with the hydrons of the water. If deuterium oxide is used in place of water to ensure that deuterium is present on a particular oxygen, nitrogen, or sulfur, then all the oxygens, nitrogens, and sulfurs accessible to the solution will have their hydrogens replaced with deuterium. Because it is not possible to confine deuterium to just one oxygen, nitrogen, or sulfur in either a reactant or the enzyme itself, and because enzymes having molecular hydrogen or phosphites[312,313] as their substrates are rare, almost all hydrogen kinetic isotope effects reported in studies of enzymes are primary deuterium or tritium kinetic isotope effects produced by **synthetic or enzymatic replacement of a hydrogen on a carbon in a reactant by deuterium or tritium**, respectively.

Again, as always, a distinction should be made between observation and explanation. The explanation for an observed primary deuterium isotope effect on one of the steady-state rate constants follows from **the kinetic mechanism chosen for the reaction by the investigator**. If the kinetic mechanism, which is the product of his intuition, is wrong, even though it is consistent with all the observations, the conclusions drawn from the explanation of the observed primary deuterium isotope effect may be mistaken.

An enzymatic reaction always consists of three or more microscopic steps, each, by definition, with its own distinct transition state. To obtain information beyond the fact that dissociation of the bond between a particular carbon and its hydrogen does or does not occur in a rate-affecting step in an enzymatic reaction, the deuterium or tritium kinetic isotope effect on the microscopic rate constant for the step in which that carbon–hydrogen bond dissociates must be measured directly or extracted from the steady-state rate constants. A primary kinetic isotope effect is the kinetic isotope effect on a steady-state rate constant for an enzymatic reaction during which the bond between the atom that has been isotopically substituted and an atom to which it is covalently attached is broken. An **intrinsic kinetic isotope effect** is the kinetic isotope effect on the microscopic rate constant for a specific step in an enzymatically catalyzed reaction, not necessarily a step in which the bond at which the substitution has taken place is broken. An **intrinsic, primary deuterium kinetic isotope effect** is the deuterium kinetic isotope effect on a microscopic rate constant for the specific step in an enzymatic reaction in which the bond is broken between another atom and a hydrogen that has been isotopically substituted with deuterium.

Usually, rate constants for several rate-affecting microscopic steps in the kinetic mechanism of an enzymatic reaction contribute to the observed steady-state rate constants, such as the catalytic constant and the specificity constants. Usually, however, **only one of these microscopic steps can display intrinsic, primary deuterium kinetic isotope effects** on its forward reaction and its reaction in reverse. This microscopic step is the one in which the bond between the carbon and the hydrogen that is isotopically substituted is broken or re-formed, respectively. It necessarily follows that the observed primary deuterium kinetic isotope effect on any one of the steady-state rate constants for the enzymatic reaction is less than the intrinsic, primary deuterium kinetic isotope effects for the step in which hydrogen is actually transferred.

For a particular kinetic mechanism, the observed primary deuterium kinetic isotope effect on one steady-state rate constant is the consequence of the intrinsic, primary deuterium kinetic isotope effect on the microscopic rate constants for the step in the kinetic mechanism in which a bond between the hydrogen that is isotopically substituted and another atom is broken. Because, for hydrogen, such a bond is always broken during the transfer of hydrogen from one atom to another atom and because this transfer is usually reversible in the kinetic mechanism of an enzyme, a bond between the isotopically substituted hydrogen and another atom is **broken in both directions of a particular microscopic step** in which the transfer of that hydrogen occurs. Consequently, each of the two rate constants, forward and reverse, for the step in which hydrogen is transferred exhibits an intrinsic, primary deuterium kinetic isotope effect. These two

intrinsic, primary deuterium kinetic isotope effects, however, do not have to be equal. If they differ, then there must also be a deuterium isotope effect on the equilibrium constant for that microscopic step, which is the ratio of the two rate constants, forward and reverse.

The first step in attempting to formulate an **explanation of the observed primary deuterium kinetic isotope effect** on one steady-state rate constant by dissecting the kinetics of the enzymatic reaction into its components is to examine the ratio between the definition of that steady-state rate constant when the microscopic rate constants, forward and reverse, for the step in which hydrogen is transferred are those for the carbon–hydrogen bond and the definition of that steady-state rate constant when the microscopic rate constants for that same step are for the carbon–deuterium bond. For example, for the kinetic mechanism (previously Equation 3–109)

$$\begin{aligned} E + A + B &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}A + B \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} E{\cdot}A{\cdot}B \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \\ E{\cdot}Z{\cdot}Y &\xrightarrow{k_4} E{\cdot}Z + Y \xrightarrow{k_5} E + Y + Z \end{aligned} \tag{4–182}$$

the steady-state rate constants are (previously Equations 3–117 through 3–120)

$$k_0 = \frac{k_3k_4k_5}{k_3k_4 + k_3k_5 + k_{-3}k_5 + k_4k_5} \tag{4–183}$$

$$k_B = \frac{k_2k_3k_4}{k_{-2}k_{-3} + k_{-2}k_4 + k_3k_4} \tag{4–184}$$

$$k_A = k_1 \tag{4–185}$$

and

$$k_{AB} = \frac{k_1k_2k_3k_4}{k_{-1}(k_{-2}k_{-3} + k_{-2}k_4 + k_3k_4)} \tag{4–186}$$

If the microscopic step governed by k_3 and k_{-3} is the step in which hydrogen that is isotopically substituted is transferred, then

$$^{D}k_0 \equiv \frac{k_{0,H}}{k_{0,D}} = \frac{(k_{3D}k_4 + k_{3D}k_5 + k_{-3D}k_5 + k_4k_5)k_{3H}}{(k_{3H}k_4 + k_{3H}k_5 + k_{-3H}k_5 + k_4k_5)k_{3D}} \tag{4–187}$$

$$^{D}k_B \equiv \frac{k_{B,H}}{k_{B,D}} = \frac{(k_{-2}k_{-3D} + k_{-2}k_4 + k_{3D}k_4)k_{3H}}{(k_{-2}k_{-3H} + k_{-2}k_4 + k_{3H}k_4)k_{3D}} \tag{4–188}$$

and

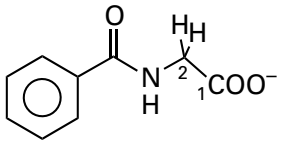
$$^{D}k_{AB} \equiv \frac{k_{AB,H}}{k_{AB,D}} = {}^{D}k_B \tag{4–189}$$

where k_{3H} and k_{-3H} and k_{3D} and k_{-3D} are the microscopic rate constants for undeuterated substrate and deuterated substrate, respectively.

These **ratios defining the primary deuterium kinetic isotope effect on the steady-state rate constants based on the chosen kinetic mechanism** can be useful in dissecting the relative magnitudes of the microscopic rate constants in a kinetic mechanism. For example, a kinetic mechanism consistent with all the steady-state kinetic observations for peptidylglycine monooxygenase from *R. norvegicus* is

$$\begin{aligned} E + HA + O_2 &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E{\cdot}HA + O_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \\ E{\cdot}HA{\cdot}O_2 &\xrightarrow{k_3} E{\cdot}HAOH \xrightarrow{k_4} E + HAOH \end{aligned} \tag{4–190}$$

where HA is hippurate (benzoylglycine)



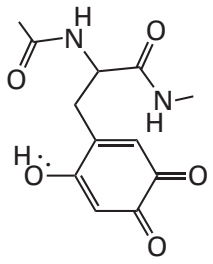
4–44

an analogue of a peptide with a carboxy-terminal glycine, and HAOH is the product of the hydroxylation, (*S*)-2-hydroxyhippurate. For this kinetic mechanism, the primary deuterium kinetic isotope effect on the specificity constant k_{HA} for [2,2-$^2H_2$]hippurate, at any concentration of oxygen, should be

$$^{D}k_{HA} = \frac{^{D}k_3k_{-1}k_{-2} + k_{3H}(k_{-1} + k_2[O_2])}{k_{-1}k_{-2} + k_{3H}(k_{-1} + k_2[O_2])} \tag{4–191}$$

where ${}^{D}k_3$ is the intrinsic, primary deuterium kinetic isotope effect for removal of hydrogen from the glycyl group of hippurate. The fact that the concentration of O_2 had no effect within experimental error on the observed primary deuterium kinetic isotope effect for the specificity constant ${}^{D}k_{HA}$ (4.8) led to the conclusions that $k_{-1} > k_2[O_2]$ and that the first step in the enzymatic reaction, the binding of hippurate, is at equilibrium in the range of concentrations of O_2 examined.[314] If this conclusion is correct, if the kinetic mechanism chosen is correct, and if $k_{-2} > k_{3H}$, which seems likely considering how small a molecule of O_2 is, then ${}^{D}k_3 = 4.8$. Even if all these assumptions are correct, this assignment could still be incorrect if the kinetic mechanism that has been chosen by the investigators is incorrect.

Taking the ratios of the definitions of the observed steady-state rate constants derived from the chosen kinetic mechanism is a simple and unambiguous way to interpret the degree to which an intrinsic, primary isotope effect could manifest itself in the primary deuterium kinetic isotope effect on these rate constants. As with the effects of pH on the kinetics of an enzymatic reaction, however, the interpretation of a primary deuterium kinetic isotope effect is most straightforward if the step in the mechanism in which hydrogen is transferred can be studied directly. For example, when a high molar concentration of bovine primary-amine oxidase, in the oxidized form, was mixed with a high concentration of the reactant dopamine, the transfer of hydride from the dopamine to the prosthetic 2,4,5-trihydroxyphenylalanylquinone (previously **2–156**)



4–45

on the protein[315] could be followed directly by the change in absorbance that occurs during the transfer.[316] The rate of the reaction was extrapolated to saturation with dopamine to eliminate the contributions of the rate of association of dopamine with the active site. The deuterium kinetic isotope effect upon the rate of reduction of 2,4,5-trihydroxyphenylalanylquinone observed when [1,1-$^2H_2$]dopamine was used as reactant was 13. In the mechanism usually written for this reaction, the hydrogen in question is removed as a hydron by a catalytic base within the active site,[315] and the observed kinetic isotope effect is assumed to be the intrinsic, primary deuterium kinetic isotope effect for this step. When the specificity constant k_{DAm} for [1,1-$^2H_2$]dopamine (DAm) was assessed, the primary deuterium kinetic isotope effect was only 6. When the same experiments, however, were performed with another reactant, [1,1-$^2H_2$]benzylamine,[317] the intrinsic, primary deuterium kinetic isotope effect observed directly (13) was the same as the primary deuterium kinetic isotope effect (12) on the specificity constant k_{BAm} for benzylamine (BAm).

The effect of an intrinsic kinetic isotope effect on the steady-state rate constants can also be defined in terms of the commitment forward and the commitment in reverse. Consider an enzymatic reaction that proceeds through a series of steps that occur in a linear, unbranched order, for example

$$\begin{array}{l} E_1 \underset{k_{-1}}{\overset{k_1[A]_0}{\rightleftharpoons}} E_2 \underset{k_{-2}}{\overset{k_2[B]_0}{\rightleftharpoons}} E_3 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E_4 \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \\ \qquad\qquad E_5 \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} E_6 \underset{k_{-6}[Y]_0}{\overset{k_6}{\rightleftharpoons}} E_7 \underset{k_{-7}[Z]_0}{\overset{k_7}{\rightleftharpoons}} E_1 \end{array} \qquad (4\text{–}192)$$

If neither product Y nor product Z is present and the initial rates are being measured, the conversion of E_6 to E_7 is irreversible. If the reactant that is isotopically substituted is reactant B, if the step at which the carbon–hydrogen bond is broken is the step governed by rate constants k_4 and k_{-4}, if reactant A is present at saturation, and if all forms of the enzyme are in steady state, then Equation 4–192 can be rewritten as

$$E_2 \underset{k_{-23}}{\overset{k_{23}[B]_0}{\rightleftharpoons}} E_4 \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} E_5 \xrightarrow{k_{56}} E_7 \xrightarrow{k_7} E_2 \qquad (4\text{–}193)$$

where the composite rate constants are defined as

$$k_{23} = \frac{k_2 k_3}{k_{-2} + k_3} \qquad (4\text{–}194)$$

$$k_{-23} = \frac{k_{-2} k_{-3}}{k_{-2} + k_3} \qquad (4\text{–}195)$$

and

$$k_{56} = \frac{k_5 k_6}{k_{-5} + k_6} \tag{4–196}$$

Suppose that the step in a linear unbranched kinetic mechanism in which an isotopically substituted hydrogen is transferred is step i, the step governed by rate constants k_i and k_{-i}. The **commitment forward**, c_f, is the ratio[318] between the forward elementary rate constant ($k_{i\mathrm{H}}$) for step i when the reactant is not deuterated and the composite rate constant k_{ri} for reversal of the reaction from the form of the enzyme immediately preceding this step, E_i, to the point at which the reactant that is isotopically substituted has been released back into the solution. For example, for the mechanism of Equation 4–192

$$c_f \equiv \frac{k_{i\mathrm{H}}}{k_{ri}} = \frac{k_{4\mathrm{H}}}{k_{-23}} = \frac{k_{4\mathrm{H}}(k_{-2} + k_3)}{k_{-2}k_{-3}} \tag{4–197}$$

The **commitment in reverse**, c_r, is defined as the ratio between the reverse elementary rate constant ($k_{-i\mathrm{H}}$) for step i and the composite rate constant k_{fi} for forward flux from the form of the enzyme immediately following this step, E_{i+1}, through the first kinetically irreversible step in the mechanism. For example, for the mechanism of Equation 4–192

$$c_r \equiv \frac{k_{-i\mathrm{H}}}{k_{fi}} = \frac{k_{-4\mathrm{H}}}{k_{56}} = \frac{k_{-4\mathrm{H}}(k_{-5} + k_6)}{k_5 k_6} \tag{4–198}$$

Many kinetic mechanisms for enzymatic reactions, no matter how complex, can be rewritten in the form of the kinetic mechanism in Equation 4–109 by using composite rate constants. Once this conversion has been done, all the mechanisms become formally equivalent, and the definitions of the two commitments become the same as Equations 4–197 and 4–198.

It can be shown[318,319] that, for any linear, unbranched kinetic mechanism, if the reactant that is deuterated is reactant B and if substitution of a hydrogen by a deuterium affects rates of only step i, then the **primary deuterium kinetic isotope effect on the specificity constant** k_B for reactant B

$${}^{D}k_B \equiv \frac{k_{BH}}{k_{BD}} = \frac{{}^{D}k_i + c_f + c_r({}^{D}K_{eqi})}{1 + c_f + c_r} \tag{4–199}$$

where ${}^{D}k_i$ is the intrinsic, primary deuterium kinetic isotope effect ($k_{i\mathrm{H}}\ k_{i\mathrm{D}}^{-1}$) for the forward reaction of step i and ${}^{D}K_{eqi}$ is the primary equilibrium isotope effect for that same step

$${}^{D}K_{eqi} \equiv \frac{K_{eqi\mathrm{H}}}{K_{eqi\mathrm{D}}} = \frac{[E_{i+1,\mathrm{H}}]_{eq}\,[E_{i,\mathrm{D}}]_{eq}}{[E_{i,\mathrm{H}}]_{eq}\,[E_{i+1,\mathrm{D}}]_{eq}} = \frac{k_{i\mathrm{H}}k_{-i\mathrm{D}}}{k_{-i\mathrm{H}}k_{i\mathrm{D}}} \tag{4–200}$$

where $E_{i,\mathrm{H}}$ and $E_{i+1,\mathrm{H}}$ are the respective forms of the enzyme with protiated reactant and protiated catalytic acid, respectively, and $E_{i,\mathrm{D}}$ and $E_{i+1,\mathrm{D}}$ are forms of the enzyme with deuterated reactant and deuterated catalytic acid, respectively. The same equation should hold for any isotopic substitution, either in the reactant or in the enzyme itself, that affects the rate constants, forward and reverse, for only one step in the kinetic mechanism. This equation applies because the derivation deals only with the elementary rate constants for the mechanism, not with the identity of the isotopic substitution that causes the change in the two elementary rate constants and not with whether or not a bond to the substituted element is broken and re-formed, respectively, in the step governed by those rate constants.

A **primary equilibrium isotope effect** is the effect substitution of one isotope for another isotope at a particular atom that is transferred during a reaction has on the equilibrium constant for that reaction. The **primary deuterium equilibrium isotope effect** that results when a protium is substituted by deuterium depends upon the stability of the σ bond between product and deuterium relative to the stability of the σ bond between product and protium and the stability of the σ bond between reactant and deuterium relative to the stability of the σ bond between reactant and protium.

The difference in the stabilities of a carbon–protium bond and a carbon–deuterium bond, or in the stabilities of a bond between another atom and a protium and a bond between that atom and a deuterium, can be estimated from vibrational frequencies in infrared spectra. These estimates are tabulated as fractionation factors.[320,321] **Fractionation factors** are theoretically calculated primary equilibrium isotope effects for transfer of a hydrogen from a particular position in a particular molecule to a reference molecule such as acetylene (carbon to carbon) or water (carbon to oxygen).

An estimate of a particular equilibrium primary isotope effect is made by dividing the fractionation factor for the hydrogen in the reactant by the frac-

tionation factor for the hydrogen in the product. For example, the estimated equilibrium primary isotope effect for transfer of a hydrogen from acetone to hydroxide to form the enolate and water should be 0.93, given the tabulated fractionation factors (relative to acetylene) of 1.432 and 1.539 for acetone and water, respectively. Primary deuterium equilibrium isotope effects vary from 0.8 to 1.2 for transfer of a deuterium from carbon to a carboxylic acid or an amine, from 2.0 to 2.5 for transfer from carbon to a sulfanyl group, and from 0.7 to 1.5 for transfer between two carbons.

For a linear, unbranched mechanism such as that in Equation 4–192, the **primary deuterium kinetic isotope effect on the catalytic constant**, k_0, of the enzyme can be expressed in a form similar to that in Equation 4–199

$$^{D}k_0 \equiv \frac{k_{0,H}}{k_{0,D}} = \frac{^{D}k_i + \alpha_0 + c_r(^{D}K_{eqi})}{1 + \alpha_0 + c_r} \qquad (4–201)$$

where $^{D}k_i$, K_{eqi}, and c_r are the same as they are in Equation 4–199. The ratio α_0, however, is not a commitment but a ratio of rate constants

$$\alpha_0 = \frac{k_{iH}}{\{k_{(i-1)} + k_{-(i-1)}\}\alpha_{i-1}} \qquad (4–202)$$

where k_{iH} is the forward rate constant for step i when the reactant is protiated and the term $\{k_{i-1} + k_{-(i-1)}\}$ is the rate constant for the approach to equilibrium of the step preceding the step in which the intrinsic, primary isotope effect is exerted. The term α_{i-1} is a fraction determined by the mechanism chosen for the reaction. It is the quotient of the steady-state concentration of E_{i-1}, the form of the enzyme preceding E_i, divided by the sum of the concentrations of all forms of the enzyme other than E_i. This quotient is for the situation in which all reactants are at saturation. In estimating the value for α_{i-1}, the step preceding the step in which the isotopically substituted hydrogen is transferred, step $i-1$, is considered to be irreversible with a rate constant of $k_{(i-1)}$. Taken together, the denominator in Equation 4–202 is a measure of the rate at which E_i is regenerated from E_{i+1} in the forward direction.

The accepted kinetic mechanism of D-xylose reductase

$$NADH + H^+ + \text{D-xylose} \rightleftharpoons \text{xylitol} + NAD^+ \qquad (4–203)$$

from *S. cerevisiae* has seven consecutive, unbranched steps. Values for all 14 of the individual rate constants in this kinetic mechanism, forward and reverse, have been determined,[322] and the intrinsic, primary deuterium kinetic isotope effect (6.5) on the step in which hydrogen is transferred from [5-^{2}H]NADH to D-xylose has been determined independently of the steady-state kinetics.[323] The appropriate microscopic rate constants were used to calculate the commitment forward (3.1) and the ratio α_0 (10.6). The value calculated for the commitment in reverse (0.00004), even though it must have a value other than 0, is not significantly different from 0 and, in any case, is too small to affect the observed kinetic isotope effect (see Equation 4–201). All these numerical values and an estimate from fractionation factors of $^{D}K_{eq}$ for the transfer of hydrogen were used to calculate the expected observed primary deuterium kinetic isotope effect (Equation 4–201) on the catalytic constant $^{D}k_0$ (1.5) and the observed primary kinetic isotope effect (Equation 4–199) on the specificity constant $^{D}k_{xyl}$ (2.3) for xylose (xyl). These estimates agreed with observed values (1.55 ± 0.1 and 2.1 ± 0.3, respectively) for these kinetic isotope effects. This agreement between calculated and observed primary deuterium kinetic isotope effects was presented as one piece of evidence that the individual rate constants determined for the kinetic mechanism, the calculated intrinsic, primary deuterium kinetic isotope effect, and the kinetic mechanism itself were correct. In this instance, rather than gaining insight into the step in the mechanism in which hydrogen is transferred, the primary deuterium kinetic isotopic effects were used to validate a particular kinetic mechanism.

Another reason for expressing a kinetic isotope effect in terms of the commitment forward c_f and the commitment in reverse c_r and the ratio α_0, rather than a simple ratio of definitions of the steady-state rate constants, is to understand **what causes the kinetic isotope effect on a steady-state rate constant to be less than the intrinsic kinetic isotope effect** for the microscopic step in which the isotopically substituted bond is broken. The fraction of the intrinsic, primary deuterium isotope effect on step i, $^{D}k_i$, that is seen in the observed kinetic isotope effect on the specificity constant, $^{D}k_B$, for reactant B will depend on the magnitudes of c_f and c_r, respectively (Equation 4–199).

If c_f is large so that E_i is almost always converted to E_{i+1} without significant reversal from E_i to reactant free in solution, then almost every molecule of reactant that associates with the enzyme is converted to product, regardless of whether it is proteated or deuterated. Because those isotope effects on association of substrates with an active site that have been measured are small,[324,325] it is usually assumed that they are negligible. If this assumption is correct, there is no discrimination between substituted and unsubstituted reactant at the step of association, and there are no kinetic isotope effects on the steady-state rate constants for the overall reaction.

If c_r is large so that E_{i+1} often reverses to E_i before the first product is released, and c_f is small so that E_i often reverses to release reactant B, then both reactant and product come to equilibrium on the active site and association of the reactant also comes to equilibrium. Under these conditions, the kinetic isotope effect observed for the specificity constant for isotopically substituted reactant will be the equilibrium isotope effect of only the affected step, and this isotope effect can be less than 1 or greater than 1.

The full intrinsic kinetic isotope effect will be seen on the kinetic isotope effect for the specificity constant only if two conditions apply. First, the commitment forward c_f is small because the form of the enzyme immediately preceding the step in which the intrinsic kinetic isotope effect occurs is in equilibrium with free reactant. Second, the commitment in reverse c_r is small either because the chemical step is kinetically irreversible or because once the product of that step is formed, it immediately dissociates as free product. Under these conditions, the rate-limiting step in the reaction, which is the only significant rate-affecting step, is the step in which the full instrinsic kinetic isotope effect occurs, and the observed isotope effect on the specificity constant, $^{D}k_B$, for reactant B is the intrinsic isotope effect on step i, $^{D}k_i$. This equivalence does happen, as in the case of peptidylglycine monooxygenase, but not so often as one might expect.

Because the equation for the kinetic isotope effect on the catalytic constant k_0 (Equation 4–201) is of the same form as the equation for the specificity constant for isotopically substituted reactant (Equation 4–199), arguments similar to those that were just made can be made again. In this case, however, the ratio α_0 takes the place of c_f, and the reason for a large or a small value for α_0 are quite different from the reasons for a large or small value for c_f.

If, when all the reactants are at saturation, the rate at which E_i is replenished from E_{i+1} in the forward direction, through all the consecutive steps in the reaction other than that governed by k_i and k_{-i}, is slow relative to the forward rate constant k_{iH} for the step in which the intrinsic kinetic isotope effect occurs so that α_0 is large, then there will be little or no kinetic isotope effect on the catalytic constant k_0 because the step with rate constant k_i is not a significant rate-affecting step.

If, however, the rate of the step in which the intrinsic kinetic isotope effect occurs is slow relative to the rate at which E_i is regenerated in the forward direction from E_{i+1} so that as soon as E_{i+1} is formed, it is converted to E_i, and if c_r is small, then step i becomes the only significant rate-affecting step, as well as the rate-limiting step in the enzymatic reaction. Under these conditions, the intrinsic kinetic isotope effect is fully expressed on the catalytic constant. This situation again does not occur so often as one might expect.

It should be noted that formally equivalent circumstances cause values for the observed acid dissociation constants in the pH–rate profiles for the steady-state rate constants of an enzymatic reaction to differ from the intrinsic acid dissociation constants for the active site. The only difference is that a kinetic isotope effect changes an intrinsic rate constant discontinuously while variation of the pH changes it continuously.

An example of the **masking of an intrinsic, primary deuterium kinetic isotope effect** by another step in the reaction occurs with equine alcohol dehydrogenase (Equation 4–158).[326] With the native enzyme, the primary deuterium kinetic isotope effect on the catalytic constant, $^{D}k_0$, is only 1.3 for deuterioethanol as a reactant because dissociation of NADH as a product, which is a step subsequent to hydride transfer, is the rate-limiting step in the reaction. Slow dissociation of NADH causes the commitment in reverse to be large. When the enzyme is modified at several lysines within its active site by amidination with the methyl imidate of 2-pyridinecarboxylic acid, the rate constant for dissociation of NADH is increased more than 30-fold. With the modified enzyme, the primary deuterium kinetic isotope effect on the catalytic constant is 5. The increase observed in the primary deuterium kinetic isotope effect upon amidination arises because c_r has decreased to insignificance and the step in which hydride is transferred has become rate-limiting rather than the subsequent dissociation of NADH.

In the case of L-lactate dehydrogenase (previously Equations 1–90 and 3–27)

$$\text{NADH} + \text{H}^+ + \text{pyruvate} \rightleftharpoons \text{NAD}^+ + \text{L-lactate} \quad (4\text{–}204)$$

from *Oryctolagus cuniculus*, L-lactate usually must dissociate as a product before NAD^+ can dissociate. As the concentration of the product L-lactate in the solution increases, inhibiting dissociation of NAD^+ and causing c_r to increase rather than decrease, the primary deuterium kinetic isotope effects for isotopic substitution at carbon 4 of NADH on the specificity constant k_{pyr} for pyruvate (pyr) and the catalytic constant k_0 decrease from 1.93 ± 0.02 and 1.75 ± 0.03 to 1.16 ± 0.02 and 0.93 ± 0.05, respectively.[327] The fact that the primary deuterium kinetic isotope effect on the catalytic constant is now less than 1 suggests that it is actually registering the equilibrium isotope effect for the step in which the deuterium is transferred from NADH to pyruvate and that, at steady state, the transfer of the hydride is at equilibrium.

A smaller-than-expected kinetic isotope effect on a steady-state rate constant is often cited as evidence that the intrinsic kinetic isotope effect has been masked by other rate-affecting steps. For example, from the fact that the primary tritium kinetic isotope effect on the catalytic constant of methylmalonyl-CoA mutase from *Propionibacterium freudenreichii* was only 4.9, it was concluded that removal of the protium by a catalytic base in the active site was not the only rate-affecting step in the enzymatic reaction.[328]

Because c_f and the ratio α_0 are not determined by the same intrinsic rate constants, it is usually the case that if an intrinsic, primary deuterium kinetic isotope effect is masked by steps other than the step in which hydrogen is transferred, the primary deuterium kinetic isotope effect on the catalytic constant k_0 and the primary deuterium kinetic isotope effect on the specificity constant, ^Dk_B, for isotopically substituted reactant B, will be different. In fact, it is usually the case that they differ, and the difference is assumed to mean that isotopically insensitive steps are rate-affecting at least in the case of the smaller value of the two.[329]

When c_f, c_r, and the ratio α_0, however, are all insignificant (Equations 4–199 and 4–201), then the observed primary deuterium kinetic isotope effect for the specificity constant, ^Dk_B, for reactant B equals the observed primary deuterium kinetic isotope effect, $^Dk_0$, for the catalytic constant k_0 because both are equal to the intrinsic isotope effect on step i, ^Dk_i. The **equivalence of the observed primary deuterium kinetic isotope effects for the catalytic constant and the specificity constant** for isotopically substituted reactant is usually assumed to mean that the intrinsic, primary deuterium kinetic isotope effect is fully manifest in both rate constants. For example, at pH 5, the primary deuterium kinetic isotope effects for both the specificity constant $^Dk_{NE}$ for nitroethane (NE) and the catalytic constant $^Dk_0$ for nitroalkane oxidase from *F. oxysporum* are 7.5 and 7.4, respectively.[330] These values are within the range for the observed primary deuterium kinetic isotope effects for removal of a hydron from a nitroalkane by a general base in solution,[331] which is an intrinsic deuterium kinetic isotope effect. This latter coincidence and the equivalence of the two primary deuterium kinetic isotope effects on the steady-state rate constants led to the conclusion that both rate constants were registering the intrinsic, primary deuterium kinetic isotope effect in the active site of the enzyme.

The Swain–Schaad relation provides another equation that can be used to dissect contributions of the various steps in a kinetic mechanism to the observed kinetic isotope effects on the steady-state rate constants and to obtain values for the intrinsic kinetic isotope effects on the step in which the bond that is isotopically substituted is broken and re-formed. From a semiclassical explanation of primary kinetic isotope effects, which is based on differences in ground-state vibrational energies, it has been proposed that, on the basis of the differences in mass among hydrogen, deuterium, and tritium, the following relation, the Swain–Schaad relation, should hold[332] for intrinsic, primary kinetic isotope effects on the rate constant k_i

$$^Tk_i \equiv \frac{k_{iH}}{k_{iT}} = \left(\frac{k_{iH}}{k_{iD}}\right)^{1.44} = {}^Dk_i{}^{1.44} \quad (4\text{–}205)$$

As an example, if an intrinsic, primary deuterium kinetic isotope effect for a step in a given reaction is 7, then the intrinsic, primary tritium kinetic isotope effect for the same step should be 16. This relation is consistent with observed values for the primary deuterium and tritium kinetic isotope effects for various reactions, and it is used widely as an established fact.[333] It has been pointed out, however, that the exponent on the relation is not precise: it

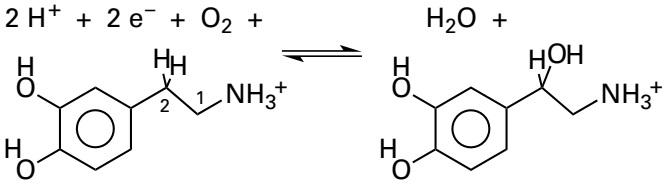
should fall in a range between 1.33 and 1.58 for a reaction in which an intrinsic, primary deuterium kinetic isotope effect is greater than 3, but it will have a much wider range when an intrinsic, primary deuterium kinetic isotope effect is less than 3.[334,335] Consequently, deviations from the equality of Equation 4–205 within these ranges are not unexpected and cannot be used to make the argument that the values observed require a special explanation. In spite of this uncertainty, the value of 1.44 for the exponent is usually considered to be precise when the relation is used in calculations.[336]

One use of the Swain–Schaad relation is to **validate a conclusion** that the observed primary deuterium kinetic isotope effect on a steady-state rate constant is actually the intrinsic, primary deuterium kinetic isotope effect for the step in which the bond is broken. For example, the observed primary deuterium kinetic isotope effect (4.4) on the specificity constant k_{DS} for [2-^{2}H]-D-serine (DS) in the reaction catalyzed by porcine D-amino-acid oxidase and the observed primary tritium isotope effect (8.6) on the same rate constant satisfy Equation 4–205. Consequently, it was concluded that the observed primary deuterium kinetic isotope effect must be the intrinsic, primary deuterium kinetic isotope effect on the step in the enzymatic reaction in which hydrogen is transferred, and the commitments forward and in reverse, which by definition cannot be affected by isotopic substitution, must be negligible (Equation 4–199).[311]

Another use of this correlation is **to estimate the intrinsic, primary deuterium kinetic isotope effect** when the commitments are not negligible.[333,337] Numerical values for these commitments, c_f and c_r, and the ratio α_0 are almost never available as they were for D-xylose reductase. If the equilibrium constant for the step in the enzymatically catalyzed reaction in which the bond is broken is not affected significantly by substitution of deuterium or tritium for hydrogen, then by combining Equations 4–199 and 4–205

$$\frac{^{D}k_B - 1}{^{T}k_B - 1} = \frac{^{D}k_i - 1}{^{D}k_i^{1.44} - 1} \qquad (4\text{–}206)$$

Very accurate values for the deuterium and tritium kinetic isotope effects on the specificity constants, $^{D}k_B$ and $^{T}k_B$, for reactant B are required for the proper use of this equation.[338] For example, it has been used to estimate the intrinsic, primary deuterium kinetic isotope effect in the reaction catalyzed by bovine dopamine β-monooxygenase[339]



(4–207)

The observed primary deuterium kinetic isotope effect on the specificity constant k_{DAm} for [2,2-^{2}H$_2$]dopamine (DAm) was 2.756 ± 0.054, and the observed primary tritium kinetic isotope effect on k_{DAm} when [2-^{3}H]dopamine was used as a reactant was 6.079 ± 0.220, so the intrinsic, primary deuterium kinetic isotope effect calculated with Equation 4–206 is 9.4 ± 1.3. The magnitude of this value was presented as evidence that the transition state in the step at which hydrogen is removed is symmetric and the equilibrium constant for this step is close to 1.

Malate dehydrogenase (oxaloacetate-decarboxylating) (NADP$^+$) from *Columba livia* catalyzes the reaction

$$NADP^+ + (S)\text{-malate} \rightleftharpoons CO_2 + \text{pyruvate} + NADPH \qquad (4\text{–}208)$$

in which a hydride is removed from malate and carbon dioxide dissociates from the intermediate oxaloacetate, a β-oxo carboxylic acid that would normally be prone to decarboxylation. By measuring deuterium, tritium, and carbon-13 kinetic isotope effects and applying both Equations 4–199 and 4–206 as well as other kinetic measurements, it was possible to calculate[340] an intrinsic, primary deuterium kinetic isotope effect (5.7 ± 0.3) for hydride transfer from malate to NADP$^+$ during formation of the intermediate oxaloacetate. This value is in the range expected for an isoergonic hydride transfer with a symmetric transition state if bending vibrational modes do not contribute significantly to the free energy of activation. The directly observed primary deuterium kinetic isotope effect on the specificity constant k_{mal} for malate (mal), however, is only 1.5 at all values of pH,[318] because hydride transfer is not the only rate-affecting step in the overall reaction.

If a kinetic mechanism is chosen by the investigator for a particular enzymatic reaction, the cata-

lytic constant and the specificity constant for an isotopically substituted reactant can also be expressed in steady-state rate equations that contain only rate constants for the chemical steps in which the isotope participates and c_f, c_r, and the ratio α_0. Observed values for the catalytic constant and the specificity constant for unsubstituted, deuterated, and tritiated reactant each provide two simultaneous equations for these two kinetic parameters, for a total of six simultaneous equations. The Swain–Schaad relations for the forward and reverse rate constants of the step in which the carbon–protium bond, the carbon–deuterium bond, and the carbon–tritium bond are broken provide **four more simultaneous equations**. Although the Swain–Schaad relations are transcendental, these ten simultaneous equations containing ten or fewer unknowns can be solved by successive approximation for values of the intrinsic deuterium kinetic isotope effect, c_f, c_r, and the ratio α_0. For example, values for these four parameters—4.91 ± 0.01, 4.6, 0.1, and 0.2—for the reaction catalyzed by phosphogluconate dehydrogenase (NADP$^+$-dependent, decarboxylating)

$$\text{NADPH} + \text{D-ribulose 5-phosphate} + \text{CO}_2 \rightleftharpoons \text{6-phospho-D-gluconate} + \text{NADP}^+ \quad (4\text{–}209)$$

from *Cyberlindnera jadinii* were estimated from the six equations for the observed catalytic constants and the observed specificity constants for D-[1-^{1}H]ribulose 5-phosphate, D-[1-^{2}H]ribulose 5-phosphate, and D-[1-^{3}H]ribulose 5-phosphate and the four Swain–Schaad relations.[341]

Consequently, in advantageous circumstances, values of the deuterium and tritium kinetic isotope effects on the catalytic constant and the specificity constant for the reactant permit extraction of the primary kinetic isotope effects on the microscopic rate constant for the step in the kinetic mechanism in which a bond involving the atom substituted is broken and, with luck, the numerical value for that rate constant.

Any alteration in the active site that decreases the rate constants for the microscopic step in which hydrogen is transferred will increase the magnitude of the effects of the intrinsic, primary deuterium kinetic isotope effect on the primary deuterium or tritium kinetic isotope effects on the catalytic constant (Equation 4–201) and the specificity constant for isotopically substituted reactant (Equation 4–199). One way to decrease these rate constants is to **mutate an amino acid**, the side chain of which is a catalyst in the step in which hydrogen is transferred. For example, when Glutamate 182 in fructose-bisphosphate aldolase

$$\text{glycerone phosphate} + \text{D-glyceraldehyde 3-phosphate} \rightleftharpoons \text{D-fructose 1,6-bisphosphate} \quad (4\text{–}210)$$

from *E. coli* is mutated to alanine, the primary deuterium kinetic isotope effect on the catalytic constant for the condensation of [3(*S*)-^{2}H]glycerone phosphate increases from 1.04 to 6.0, while the catalytic constant itself decreases 60-fold.[342] The problem with this approach is that the catalytic acid–base has been changed from the one in the native enzyme to probably a molecule of water, and this change should have a significant effect on the intrinsic, primary kinetic isotope effect. One way to get around this problem is to decrease the rate constant for the microscopic step in which hydrogen is transferred by mutating an amino acid peripheral to the site at which the transfer occurs[343,344] rather than one participating directly in the transfer. All that is required is that mutation decreases the microscopic rate constants.

Another way to decrease the microscopic rate constants for the step in which hydrogen is transferred is to **increase or decrease the pH**. As the concentration of the enzymatically active tautomers catalyzing the step in which hydrogen is transferred decreases with the change in pH, rate constants for that step decrease, the commitments and the ratio α_0 decrease, and the primary deuterium kinetic isotope effects on the specificity constant and the catalytic constant increase.[345,346] For example, the specificity constant k_{Met} for L-methionine as an alternative reactant for tryptophan 2-monooxygenase from *Pseudomonas savastanoi* decreases below a pK_a of 5.0 and above a pK_a of 9.8. The primary deuterium kinetic isotope effect on the specificity constant, $^D k_{Met}$, for [β,β,β,α-^{2}H$_4$]-L-methionine increases below a pK_a of 5.1 and above a pK_a of 10.0 from 1.8 ± 0.2 in the midrange. At both low and high pH, these primary deuterium kinetic isotope effects approach a limiting value of 5.2 ± 0.8,[347] which is probably the intrinsic, primary deuterium kinetic isotope effect for the step in which hydrogen is transferred. In each case, as the microscopic rate constants for the step in which hydrogen is trans-

ferred decrease as the pH is decreased or as the pH is increased, this decrease causes that step to become more and more rate-affecting, if not rate-limiting, and the intrinsic, primary deuterium kinetic isotope effect to become more and more manifest.

When the value for a steady-state rate constant decreases as the pH is lowered below an apparent pK_a, the increase in the primary deuterium isotope effect often sets in at a lower pH than that pK_a. Likewise, when the value for a steady-state constant decreases as the pH is raised above an apparent pK_a, the increase in the primary deuterium isotope effect often sets in at a higher pH than that pK_a. In both cases, the rate of the step in which hydrogen is transferred usually has to **decrease a certain amount before the step becomes significantly rate-affecting** or rate-limiting. For example, the specificity constant k_{glyc} for glycerol (glyc) for the reaction catalyzed by glycerol dehydrogenase from *Cellulomonas* decreases as the pH is lowered below a pK_a of 7.8, but the primary deuterium kinetic isotope effect for [2-^{2}H]glycerol[348] increases below an apparent pK_a of 7.3 from a constant value of 1.15 to a limiting value of 2.44. The catalytic constant for the reaction catalyzed by dihydrofolate reductase from *M. tuberculosis* decreases as the pH is raised above a pK_a of 6.8, but the primary deuterium kinetic isotope effect for (4*R*)-[4-^{2}H]NADH[349] increases above an apparent pK_a of 7.4 from a constant value of 1.1 to a limiting value of 2.6.

Decreasing the rate constants of the step in which hydrogen is transferred, however, **does not always completely reveal an intrinsic, primary deuterium kinetic isotope effect**. For example, when the pH is decreased below an apparent pK_a of 6.5 that governs the behavior of both the specificity constant k_{DHO} for dihydroorotate (DHO) and the catalytic constant of orotate reductase (NADH) from *Clostridium oroticum*, the primary deuterium kinetic isotope effect for L-[5*R*,5*S*-$^2H_2$]dihydroorotate on k_{DHO} increases from 1.0 to a limiting value of 1.9, and that on k_0 increases from 1.0 to a limiting value of 1.3.[350] Neither limit, however, is probably the intrinsic, primary deuterium kinetic isotope effect.

Each mutation and each decrease or increase in pH just discussed must have decreased a rate constant for the step in which hydrogen is transferred, rather than other steps governing the commitments, to be able to increase the primary deuterium kinetic isotope effect on a steady-state rate constant (Equations 4–199 and 4–201). Consequently, the fact that each mutation and each decrease or increase in pH increases the respective primary deuterium kinetic isotope effect proves that the amino acid mutated or the side chain titrating participates catalytically in this step but not that it necessarily is the catalytic base that removes the hydron. Contrariwise, if the mutation of an amino acid does not increase a small primary deuterium kinetic isotope effect on one steady-state rate constant, even though it decreases that steady-state rate constant dramatically, then that side chain is probably not a catalytic acid–base in the step in which the hydrogen is transferred.[351]

In the preceding discussion, the difficulties of extracting an intrinsic, primary kinetic isotope effect from steady-state kinetic observations have been presented, as well as ways to extract those kinetic isotope effects. The following discussion will **assume that an intrinsic, primary kinetic isotope effect has been extracted** one way or another and that its value is reliable.

The semiclassical explanation for an intrinsic, primary deuterium kinetic isotope effect is based on an examination of vibrational energy levels.[352] An intrinsic, primary deuterium kinetic isotope effect on the microscopic step in which hydrogen is transferred is for a transition state in which the bond between carbon and hydrogen is breaking and a new bond between the hydrogen and another atom is forming. In the reactant, the carbon–hydrogen bond in the ground state participates in a stretching vibration. In the transition state a portion or all of this stretching vibration is lost. Consider a linear, symmetric transition state in which hydrogen is being transferred as a hydron, hydrogen atom, or hydride from carbon to a lone pair of electrons on a general base, radical, or electrophile such as NAD^+ or $flavin_{ox}$, respectively. Suppose that the carbon–hydrogen bond has been broken completely but the bond to that general base, radical, or electrophile has not yet begun to form. In such a transition state, all the stretching vibration present in the reactant has been converted into translational motion along the reaction coordinate. The vibrational energy that has been converted into translational energy is part of the free energy of activation. The conversion of vibrational energy into translational energy causes the kinetic isotope effect.

In either a molecule or a transition state, the arrangement of nuclei and the accompanying electrons in space creates a surface of potential energy. If one nucleus is moved with respect to the other nuclei, the potential energy varies. If, for example, only the hydrogen in a carbon–hydrogen bond in

the ground state of a molecule is moved along the axis of the bond, the function for the potential energy for stretching that bond is generated (Figure 4–23). Because the nucleus of a deuterium atom has the same charge number as the nucleus of a protium atom, the function for the potential energy of a carbon–deuterium bond is identical to that for a carbon–protium bond.

Stretching vibration along a particular carbon–hydrogen bond in a molecule is controlled by the function for the potential energy of this vibrational mode, but it is quantized. This stretching vibration of a particular carbon–hydrogen bond is only one of many vibrational modes in the molecule. In the semiclassical treatment, the energy for each vibrational energy level in vibrational mode j in a particular molecule

$$E_{n,j} = \frac{h}{2\pi}\left(n + \tfrac{1}{2}\right)\sqrt{\frac{f_j}{\mu_j}} \qquad (4\text{–}211)$$

where h is the Planck constant, f_j is the force constant for vibrational mode j, n is the quantum number for energy level n, and μ_j is the reduced mass

$$\frac{1}{\mu_j} = \sum_{k=1}^{o} \frac{1}{m_k} \qquad (4\text{–}212)$$

of the o atoms participating in vibrational mode j. The force constant, f_j, for vibrational mode j is determined only by the function for the potential energy of vibrational mode j.

For the stretching vibrational mode of a carbon–hydrogen bond, the **force constant** is determined by the function for the potential energy for stretching along that bond. Because potential energy is not a function of mass but only of electric charge, the function is the same for both a carbon–protium bond and a carbon–deuterium bond. If the function for the potential energy, and hence the force constant f_j for vibrational mode j, remains the same when one of the o atoms participating in vibrational mode j is replaced by an isotope of greater mass so that the lighter atom (l) becomes a heavier atom (h), the **change in zero-point energy** ($n = 0$) caused by the isotope effect

$$\Delta E_{0,\mathrm{ie},j} = \frac{h\sqrt{f_j}}{4\pi}\left(\sqrt{\frac{1}{\mu_{j,\mathrm{h}}}} - \sqrt{\frac{1}{\mu_{j,\mathrm{l}}}}\right) < 0 \qquad (4\text{–}213)$$

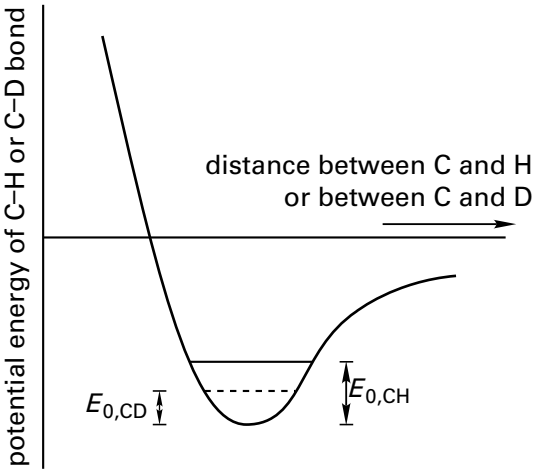


Figure 4–23: Schematic drawing of the potential energy for the stretching of a carbon–hydrogen bond. The potential energy is plotted as a function of the distance between the nuclei of the carbon atom and the respective isotope of the hydrogen atom. When that distance is short, the nuclei repel and the potential energy rises dramatically. When the distance is long, the atoms do not interact and the potential energy is near zero. At intermediate distances, electron overlap creates a covalent bond, which is a favorable interaction with a negative potential energy. The potential energy for a carbon–deuterium bond is the same as that for a carbon–protium bond. Because the stretching vibrations within the bottom of the potential well are quantized, they can only take on certain energies. The zero-point energy for a carbon–protium bond, $E_{0,\mathrm{CH}}$, is higher than that for a carbon–deuterium bond, $E_{0,\mathrm{CD}}$, because of the difference in mass between a hydron (1.67×10^{-24} g) and a deuteron (2.34×10^{-24} g). The drawing is not even close to scale. The ground-state energy of the carbon–hydrogen bond should be about –340 kJ mol^{-1} below the origin, while $E_{0,\mathrm{CH}}$ should be only +17.4 kJ mol^{-1}.

Because, as the equation demonstrates, $\Delta E_{0,\mathrm{ie},j}$ is less than 0, the zero-point energy always decreases when a heavier isotope replaces a lighter isotope.

The frequency, ν_j, of a quantum of light that, during its absorption, excites vibrational mode j from its zero point ($n = 0$) to its first excited state ($n = 1$) is directly proportional to the difference in energy between these two energy levels

$$h\nu_j = \frac{h}{2\pi}\sqrt{\frac{f_j}{\mu_j}} \qquad (4\text{–}214)$$

the constant of proportionality being the Planck constant. It follows from Equations 4–213 and 4–214 that

$$\Delta E_{0,\mathrm{ie},j} = \frac{h\nu_{j,\mathrm{l}}}{2}\left(\sqrt{\frac{\mu_{j,\mathrm{l}}}{\mu_{j,\mathrm{h}}}} - 1\right) \qquad (4\text{–}215)$$

where $\nu_{j,l}$ is the **frequency of the infrared light absorbed by vibrational mode *j*** in the molecule with the lighter element, $\mu_{j,l}$ is the reduced mass of the atoms participating in vibrational mode j for the molecule with the lighter element, and $\mu_{j,h}$ is the reduced mass of the atoms participating in vibrational mode j for the molecule with the heavier element.

The infrared absorptions for the stretching vibrations of carbon–protium bonds in alkanes, alcohols, and ketones fall at frequencies between 2900 and 3000 cm^{-1}. Consequently, the difference in zero-point energies between a carbon–deuterium bond and a carbon–protium bond from Equation 4–215 should be 4.7 ± 0.1 kJ mol^{-1}. If all the zero-point free energy were lost in the transition state, a carbon–protium bond would require **4.7 kJ mol^{-1} less free energy of activation** to reach the transition state than a carbon–deuterium bond because it would start out at a level of energy 4.7 kJ mol^{-1} higher. This situation should lead to an enhancement in rate of the reaction when protium is present rather than deuterium, and

$$\frac{k_{CH}}{k_{CD}} = e^{-\Delta\Delta G^{\circ\ddagger}/RT} = 7 \qquad (4\text{–}216)$$

It should be kept in mind that, in the derivation of this equation, several assumptions have been made along the way.

Extensive tabulations are available of the observed primary deuterium kinetic isotope effects for nonenzymatic removal of hydrogen as a hydron from various carbons by various general bases in solution.[296] If a large number of these values for the simple intrinsic, primary deuterium kinetic isotope effects for nonenzymatic removals of hydrons from carbon by general bases are plotted as a function of the difference in pK_a between the carbon acid and the conjugate acid of the general base, there seems to be a **maximum when the two values of the pK_a are the same**,[296] but it is not a dramatic one. As the pK_a for the conjugate acid of the general base becomes larger or smaller than the pK_a for the carbon acid, the primary deuterium kinetic isotope effect decreases monotonically. When the difference in pK_a is 10, about half of the primary deuterium kinetic isotope effect has been lost. For example, the primary deuterium kinetic isotope effect for removal of a hydron from sulfonatoacetone[353] by hydroxide anion ($\Delta pK_a = -2.0$) is 7.4, but the primary deuterium kinetic isotope effect for removal of the same hydron by acetate anion ($\Delta pK_a = 9.6$) is 3.8. These decreases in the kinetic isotope effect on either side of the maximum are thought to result from increasing asymmetry of the transition state due to changes in the relative attractive forces of the two lone pairs for the hydron that sits between them in that transition state.[352]

When the pK_a for the conjugate acid of the general base is equal to the pK_a for the carbon acid, values of the observed primary deuterium kinetic isotope effects for nonenzymatic removal of hydrogen as a hydron from various carbons by various general bases in solution lie between 6 and 12. Because such **isoergonic transfers of a hydron** should proceed through symmetric transition states, they should represent maximum values that can be obtained.[352] Values in excess of 7 are usually explained by physical organic chemists by assuming that zero-point energy from the bending vibrations of the carbon–hydrogen bond, which also disappear in the transition state, as well as zero-point energy from the stretching vibrations is incorporated into the translational energy along the reaction coordinate.

The stretching frequency of the bond between hydrogen and the carbon of the acid is completely converted into translational motion along the reaction coordinate, and as a result, this vibrational mode disappears. The transition state, however, sits at a col on the potential energy surface. Because the potential energy surface in the vicinity of the transition state has literally the shape of a col, perpendicular to the reaction coordinate at the col is a another potential well with the col at its bottom. This potential well has a symmetrical vibrational mode associated with it. If the carbon and the base that removes the hydron have equal affinity for the hydron, then the hydron remains stationary as vibration occurs in this perpendicular symmetrical vibrational mode of the transition state, and there is no difference in energy between the transition state with protium and the one with deuterium. In this situation, the maximum change in standard free energy of vibration between the transition state and the zero point of the vibration is realized. If, however, the affinities of the carbon and the base differ from each other, then the hydron moves in concert with the atom that has the higher affinity, and the transition state containing deuterium will have a lower energy than that containing protium. This deuterium kinetic isotope effect on standard free energy of the transition state decreases the difference in the primary deuterium kinetic isotope effect on the reaction. As a result, the greater the difference in pK_a, regardless of its sign, between the

carbon and the conjugate acid of the base, the smaller will be the primary deuterium kinetic isotope effect on the rate of the hydron transfer.

Similar arguments have been applied to intrinsic, primary deuterium kinetic isotope effects for **transfer of a hydrogen atom**[354] and **transfer of a hydride**. For example, the reduction potential of the hydride acceptor in the oxidation–reductions of benzyl alcohol catalyzed by alcohol dehydrogenase from *S. cerevisiae* and equine alcohol dehydrogenase (Equation 4–158) was changed monotonically from –0.32 to –0.26 V by using four different analogues of NAD^+, and the intrinsic, primary deuterium kinetic isotope effect observed with [1,1-$^2H_2$]benzyl alcohol increased from 4 to 6.5. This increase was presented as evidence that as the reduction potential became more positive, the transition state for hydride transfer became more symmetric.[355] Because an increase in reduction potential should cause the transition state to occur earlier, the change is proposed to be between a late transition state and a more symmetric transition state.

The maximum magnitudes expected from a semiclassical explanation for intrinsic, primary deuterium kinetic isotope effects and intrinsic, primary tritium kinetic isotope effects for bonds other than carbon–deuterium and carbon–tritium bonds depend on the reduced mass of the two atoms participating in the bond (Equation 4–215). The differences in zero-point energies between protium and deuterium for **nitrogen–hydrogen** (3300 cm^{-1}) and **oxygen–hydrogen** (3300 cm^{-1}) bonds[296] are between 5 and 6 kJ mol^{-1}, so the maximum primary deuterium kinetic isotope effects seen with these bonds are in the same range as those for carbon–hydrogen bonds. Again, however, it should be mentioned that although these estimates are of interest, it is not possible to measure a primary kinetic isotope effect for a specific nitrogen–hydrogen bond or a specific oxygen–hydrogen bond in an enzymatic reaction, which of necessity must occur in aqueous solution.

One purpose for measuring an intrinsic, primary deuterium isotope effect is to use its value to make arguments, such as those made for removal of a hydron from sulfonatoacetone or oxidation–reduction of benzyl alcohol catalyzed by alcohol dehydrogenase, about **the structure of the transition state** using the ratio between the observed intrinsic, primary deuterium isotope effect and a theoretical primary deuterium kinetic isotope effect calculated from semiclassical theory. It is common practice to equate this ratio to the fraction of the bond in question that has been broken in the transition state. Any such argument, however, must make the **assumption that there are no other contributions beyond the differences in zero-point energies** producing that kinetic isotope effect. Even with this assumption, the argument would not be valid if, in addition to differences in zero-point energy, quantum mechanical tunneling of the protium also contributes to the differences between the intrinsic rate constants for protium and deuterium for the transfer of hydrogen. If quantum mechanical tunneling contributes to a significant degree, arguments about the structure of the transition state would be equivocal because the magnitude of the kinetic isotope effect would no longer be related only to vibrational parameters. Consequently, it would not be possible to calculate an upper limit to the intrinsic, primary deuterium kinetic isotope effect with which to compare the observed kinetic isotope effect.

Quantum mechanical tunneling is a result of the uncertainty principle. If the uncertainty principle is valid, it follows that the actual position of a protium is only a distribution of probabilities that it will occupy a precise location. This distribution of probabilities is unaffected by the distribution of the potential energy of that protium as a function of its position relative to the other atoms. A barrier of potential energy along a reaction coordinate (Figure 3–25) lies between the position of a hydrogen atom in the reactant and its position in the product. In the semiclassical treatment, the height of this impenetrable barrier determines the rate constant for transfer of the protium. If, however, the width of this barrier of potential energy at some point below its summit is of the same order of magnitude as the width of the distribution of probabilities for the position of the protium, then there will be a large enough probability that the protium is located on the other side of the barrier and that it will be there in a shorter period of time than would be required for it to pass over the barrier through a semiclassical transition state.* Its existence on the other side of the barrier in this shorter period of time is its ability to **tunnel through the barrier of potential energy**. Because uncertainty in position is inversely proportional to the mass of a particle, protium tunnels more effectively than deuterium because it can tunnel at a lower point below the summit.

*This view of the uncertainty principle assumes that it applies to the actual position of the protium and not just to the uncertainty in ascertaining its position.

There are behaviors that are supposed to be **signatures of quantum mechanical tunneling** and that have been observed for intrinsic, primary deuterium kinetic isotope effects for the transfer of hydrogen in enzymatic reactions.

Intrinsic, primary deuterium kinetic isotope effects greater than around 10 are thought to be an indication that quantum mechanical tunneling is occurring.[356,357] For example, the intrinsic, primary deuterium kinetic isotope effect for removal of a hydron from the carbon between the 9Z double bond and the 12,13-radical cation of (9*Z*,12*Z*)-9,12-octadecadienoate[358-360] at 30 °C by a catalytic base in the active site of lipoxygenase from *Glycine max* is 60. The primary deuterium kinetic isotope effect for removal of a hydrogen atom from (*R*)-methylmalonyl-SCoA by the prosthetic adenosylcobalamin[361] in the active site of methylmalonyl-CoA mutase from *P. freudenreichii* is 30. The primary deuterium kinetic isotope effect for inner-sphere transfer of a hydrogen atom from D-galactose to a tyrosyl radical[362] within the coordination sphere of the copper ion in the active site of galactose oxidase from *Hypomyces rosellus* is 16, and the primary deuterium kinetic isotope effect on the catalytic constant for production of perdeutero-13-hydroperoxy-(9*Z*,11*E*)-9,11-octadecadienoate from perdeutero-(9*Z*,12*Z*)-9,12-octadecadienoate by human prostaglandin-endoperoxide synthase,[363] which also involves the transfer of a hydrogen atom from carbon 11 of (9*Z*,12*Z*)-9,12-octadecadienoate to a tyrosyl radical in the active site, is 22 at 50 °C.*

Primary deuterium kinetic isotope effects that are larger than the maximum expected from a semiclassical description, however, could have **other explanations** than quantum mechanical tunneling. In addition to the loss of bending vibrations of the carbon–hydrogen bond, it could also be the case that the zero-point vibrational energies of other covalent bonds in the vicinity that are coupled to the stretching vibration of the carbon–hydrogen bond change as the carbon–hydrogen bond disappears in the transition state. These changes in zero-point energies of other vibrational levels should contribute to the magnitude of the observed primary deuterium isotope effect. This coupling could be significant in a situation such as the active site of a protein in which there are a significant number of covalent bonds in the vicinity of the carbon–hydrogen bond being broken, the vibrations of which could be coupled to it. When the atoms of carbon-12, nitrogen-14, and nonexchangeable protium in the protein of pentaerythritol tetranitrate reductase from *Enterobacter cloacae* were substituted with carbon-13, nitrogen-15, and deuterium, the intrinsic, primary deuterium kinetic isotope for transfer of the hydride on the reactant NADH to the prosthetic flavin in the active site decreased from 8.2 to 5.4.[365] When the nonexchangeable atoms of protium in the protein of alanine racemase from *Geobacillus stearothermophilus* were substituted with deuterium, the primary deuterium kinetic isotope on the specificity constant for L-alanine increased from 1.6 to 3.8.[366]

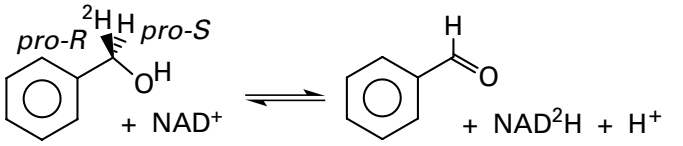
The **lack of an effect of temperature** on the value for an enzymatic intrinsic, primary deuterium kinetic isotope effect is inconsistent with the semiclassical explanation and is thought to indicate a significant contribution from tunneling.[367-370] Intrinsic deuterium kinetic isotope effects that are considerably larger than the semiclassical maxima are usually invariant with temperature. For example, the intrinsic deuterium kinetic isotope effect of 60 for lipoxygenase from *G. max* is temperature-independent,[359] as well as the deuterium kinetic isotope effect of 45 for the specificity constant, k_{LA}, for perdeuterated (9Z,12Z)-octadeca-9,12-dienoic acid (linoleic acid; LA) in the reaction catalyzed by human arachidonate 15-lipoxygenase[371] and the deuterium kinetic isotope effect of 22 for the catalytic constant of the reaction catalyzed by human prostaglandin-endoperoxide synthase with perdeuterated linoleic acid.[363] Most investigators who study enzymatic primary deuterium kinetic isotope effects attribute large primary deuterium kinetic isotope effects that are invariant with temperature to quantum mechanical tunneling.

Even in situations in which the observed intrinsic kinetic isotope effect is not outside the semiclassical range, however, invariance of the kinetic isotope effect with changes in temperature is considered to be strong evidence for tunneling. For example, one step in the reaction catalyzed by sarcosine oxidase from *Arthrobacter* is transfer of a hydride from the methyl group of *N*-methylglycine (sarcosine) to the oxidized, prosthetic flavin in the active site. The intrinsic, primary deuterium kinetic isotope effect for this step is 7.3, which is not significantly larger than the semiclassical maximum, but the slope of the plot of the natural logarithm of the intrinsic kinetic isotope effect as a function of inverse temperature (0.07 ± 0.25) is indistinguishable from 0 between

*Although not necessarily the case in these instances, there are kinetic anomalies that can inflate estimates of intrinsic, primary deuterium kinetic isotope effects artifactually, and that should be avoided.[364]

277 and 307 K. This invariance of the intrinsic kinetic isotope effect with temperature was presented as evidence for quantum mechanical tunneling. The lack of a statistically significant effect of temperature on the intrinsic kinetic tritium kinetic isotope effect of 6.1 for hydride transfer from (*R*)-[4-^{3}H]NADPH to 7,8-dihydrofolate[372] in the active site of dihydrofolate reductase (Equation 4–148) from *E. coli* between 278 and 317 K and the lack of a statistically significant effect of temperature on the intrinsic kinetic isotope effect of 2.3 for hydride transfer from phosphite to NAD^+ in the active site of phosphonate dehydrogenase[313] from *Pseudomonas stutzeri* between 278 and 317 K were presented as evidence for the involvement of quantum mechanical tunneling in these enzymatic reactions even though the observed primary kinetic isotope effects are significantly less than the semiclassical maxima.

Secondary deuterium and tritium kinetic isotope effects are also thought to reveal quantum mechanical tunneling. A **secondary kinetic isotope effect** is a kinetic isotope effect in which the isotopic substitution occurs at another atom that is attached to an atom participating in the breaking of a bond, other than the two atoms between which the bond is broken.* Alcohol dehydrogenase from *S. cerevisiae* removes the *pro-R* hydride from benzyl alcohol



(4–217)

The secondary tritium kinetic isotope effect resulting from substitution of the *pro-S* protium with a tritium when the *pro-R* hydrogen is a protium is 1.30 ± 0.02, but the secondary tritium kinetic isotope effect resulting from substitution of the *pro-S* protium with a tritium when the *pro-R* hydrogen is a deuterium is 1.18 ± 0.03. These results are consistent with the distance between the carbon of benzyl alcohol and carbon 4 of the nicotinamide being greater in the transition state for protide transfer than in the transition state for deuteride transfer.[373] Quantum mechanical tunneling of a protide should occur at longer distances than the distance required by quantum mechanical tunneling of deuteride.

*Because the primary use of secondary kinetic isotope effects is to identify intermediates in enzymatic reactions, they will be discussed in detail in Chapter 5.

Because vibrational frequencies, and hence zero-point energies, are unaffected by increases in hydrostatic pressure,[374] there should be no **effect of hydrostatic pressure** on an enzymatic primary deuterium kinetic isotope effect. There are, however, enzymatic primary deuterium kinetic isotope effects that decrease in magnitude as hydrostatic pressure is applied.[375-377] These results, however, suggest only that something other than the semiclassical explanation is operating, not necessarily tunneling.

Nonenzymatic transfers of hydrogen homologous to those that occur in active sites can also display these signatures of quantum mechanical tunneling. These observations have led to the conclusion that tunneling also occurs in many of these reactions in free solution.[378-380] These observations raise the question of **whether the active site of an enzyme can enhance the amount of tunneling that occurs in the same reaction nonenzymatically** or the amount of tunneling that occurs in the active site is the same as the amount of tunneling that occurs in the same reaction in solution, and hence not indicative of some extraordinary property of an active site. For example, the abstraction of hydrogen atoms from methylmalonyl-SCoA and ethylene glycol by the 5′-deoxyadenosyl radicals formed from the prosthetic adenosylcobalamins in the active sites of methylmalonyl-CoA mutase from *P. freudenreichii*[361] and propanediol dehydratase from *Klebsiella pneumoniae*,[381] respectively, have very similar, elevated primary deuterium kinetic isotope effects that have the signature of quantum mechanical tunneling. Measurements that quantify the contribution of tunneling during the abstraction of a hydrogen from ethylene glycol by adenosylcobalamin in free solution, an analogous nonenzymatic reaction, gave identical results within experimental error to the primary deuterium kinetic isotope effects in the enzymatic reactions. It was concluded that, in this case, these active sites do not enhance the tunneling inherent in the nonenzymatic reaction.[382] The same conclusion was reached for the tunneling that has been proposed to occur in the hydron transfers catalyzed by a lipoxygenase from *G. max*[383] and nitroalkane oxidase from *F. oxysporum*.[384] Observations of secondary kinetic isotope effects, however, suggest that the active site of steroid Δ-isomerase from *C. testosteroni* produces tunneling that does not occur when the hydron transfer proceeds nonenzymatically in solution.[385] Nevertheless, any claim that an active site enhances tunneling requires that the tunneling involved in the nonenzymatic reaction be assessed. In most instance where this claim is made about

enzymatic active sites, this requirement has not been satisfied.

One simple way an active site could increase the contribution of quantum mechanical tunneling, once reactants are properly aligned for in-line transfer of a hydron, hydrogen atom, or hydride, is by **narrowing the distance between the hydrogen in the reactant and the location of its destination in the product** to increase the overlap between the probability densities of the hydrogen in the donor and the hydrogen at the destination.[386] When the distance between an amino nitrogen and a phenolate oxygen was increased from what should be a compressed distance of 0.26 nm to a longer distance of 0.27 nm, the kinetic isotope effect for the intramolecular transfer of a hydron from oxygen to nitrogen, coupled to an oxidative electron transfer, decreased from 2.1 to 1.3, consistent with a decreased contribution of tunneling to the transfer.[387] Steric forces in a protein can compress and shorten a hydrogen bond,[388] and compressed hydrogen bonds between catalytic acids and catalytic bases in active sites and their acceptors and donors on analogues for intermediates of high energy are often observed. It is possible that the distance between a hydrogen on carbon and either a catalytic base, an atom supporting an unpaired electron, or an electrophilic atom such as carbon 4 on NAD^+ could be shortened in a complex between an active site and a reactant by **steric compression** to enhance tunneling and catalyze the transfer of hydrogen. For example, in triose-phosphate isomerase from *S. cerevisiae* (Equations 4–46 and 4–55 and Figure 3–37), an enzyme that has anomalies in kinetic isotope effects considered to be indicative of quantum mechanical tunneling,[389] the oxygen of the carboxylate responsible for removing the hydron from carbon is only 0.30 and 0.308 nm from the two carbons between which it transfers the hydron.[23] Both distances are less than 0.38 nm, which is the sum of the van der Waals radii of oxygen (0.15 nm) and hydrogen (0.115 nm) and the length of a carbon–hydrogen bond (0.11 nm).[390]

From the crystallographic molecular model of a complex between aralkylamine dehydrogenase (azurin) from *Alcaligenes faecalis* and phenylhydrazine, it was concluded that the basic oxygen of the carboxylate of Aspartate 128β would be compressed below the van der Waals limit against the carbon–hydrogen bond of a reactant from which it is required to remove a hydron.[391] The intrinsic, primary deuterium kinetic isotope effect for the dehydrogenation of [1,1-$^2H_2$]tryptamine catalyzed by this enzyme is 55 at 20 °C, well in excess of the semiclassical limit, a fact that suggests tunneling could be occurring in this enzymatic reaction.

In crystallographic molecular models of complexes of NAD^+, trifluoroethanol, an inactive analogue of the reactant ethanol, and two mutants of equine alcohol dehydrogenase (Equation 4–158), changes in the distance between carbon 4 of NAD^+ and carbon 1 of trifluoroethanol, the carbon from which a hydride is removed from the normal reactant ethanol, were observed.[392] In the mutant in which Phenylalanine 93 was mutated to tryptophan, the distance was 0.32 nm—less than the sum (0.4 nm) of the van der Waals radii of carbon (0.175 nm) and hydrogen (0.115 nm) and the length of a carbon–hydrogen bond (0.11 nm)—but in the mutant in which Valine 23 was mutated to alanine, the distance was 0.40 nm. This increase in distance, and presumably an accompanying decrease in compression, led to a decrease in anomalous primary deuterium kinetic isotope effects for hydride transfer, a change that may indicate a decrease in quantum mechanical tunneling as compression is decreased.

In the crystallographic molecular model[393] of the complex between dihydrofolate reductase (Equation 4–148) from *E. coli* and $NADP^+$ and folate, the two oxidized substrates between which there is no hydride to transfer, the distance between carbon 4 of nicotinamide and carbon 6 of folate, between which a hydride is transferred in the normal enzymatic reaction, is 0.33 nm. This distance is already less than van der Waals contact (0.35 nm) between two carbon atoms even without the hydride being there and not counting the radii of hydrogens that are on these carbons in the two substrates. This compression exerted by the active site between the donor and the acceptor of the hydride is a steric effect caused by the shoving of the nicotinamide up against the folate by the side chain of Isoleucine 14. The intrinsic, primary tritium kinetic isotope effect for transfer of the hydride from (*R*)-[4-^{3}H]NADPH to 7,8-dihydrofolate, although only 6 at 25 °C, is invariant with temperature, a fact that is consistent with quantum mechanical tunneling. When Isoleucine 14 is mutated to valine, alanine, or glycine so that the size of the side chain decreases mutant to mutant and the nicotinamide is held more and more loosely until the compression is eliminated, the intrinsic, primary tritium kinetic isotope effect for hydride transfer becomes more and more dependent on temperature until it has become consistent with the semiclassical description in the absence of quantum mechanical tunneling.[372]

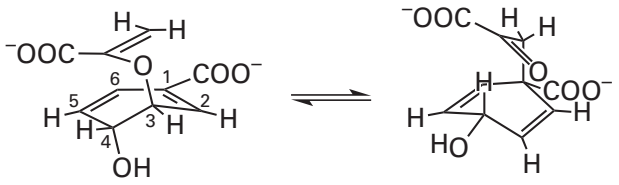
If steric compression that enhances tunneling is actually **yet another strategy that can be used by enzymes** to catalyze reactions, it is not surprising that natural selection has discovered it.

Primary kinetic isotope effects also result from isotopic substitutions of the heavier atoms that are within the second row. The fractional difference in mass is much smaller between carbon-13 and carbon-12, between carbon-14 and carbon-12, between nitrogen-15 and nitrogen-14, between oxygen-17 and oxygen-16, and between oxygen-18 and oxygen-16 than between hydrogen-2 and hydrogen-1 and between hydrogen-3 and hydrogen-1. Consequently, primary kinetic isotope effects for carbon-13, carbon-14, nitrogen-15, oxygen-17, and oxygen-18 are much smaller than primary kinetic isotope effects for deuterium or tritium (Equation 4–215). Using the semiclassical treatment, assuming that the bond being broken is between carbon-12 and the respective element from the second row that is being substituted, and assuming that only the respective stretching vibrational modes of the bond between carbon-12 and the respective element in the second row being substituted contribute to the primary kinetic isotope effects, maximum values expected for primary kinetic isotope effects of carbon-13, carbon-14, nitrogen-15, oxygen-17, and oxygen-18 (Equation 4–215) should be 1.05, 1.09, 1.04, 1.03, and 1.07, respectively.

Primary kinetic isotope effects for substitutions of carbons and oxygens have been often measured. When a carbon–carbon bond is broken during a rate-limiting step, if one carbon-12 is replaced with carbon-13, the largest primary kinetic isotope effects, ^{13}k, that have been observed[394,395] are about 1.07. When a carbon–carbon bond is broken during a rate-limiting step, if one carbon-12 is replaced instead with carbon-14, the largest primary kinetic isotope effects, ^{14}k, that have been observed[396] are between 1.09 and 1.15. When a carbon–nitrogen bond is broken during a rate-limiting step, if nitrogen-14 is replaced with nitrogen-15, the largest primary kinetic isotope effects, ^{15}k, that have been observed[397] are about 1.025. When a carbon–oxygen bond is broken during a rate-limiting step, if oxygen-16 is replaced with oxygen-18, the largest primary kinetic isotope effects, ^{18}k, that have been observed[398] are about 1.08. The fact that the largest primary carbon kinetic isotope effects observed are greater than those expected is probably due to changes in the transition state of other vibrational modes in which the carbon that is isotopically substituted participates, because, unlike a hydrogen atom, carbon is usually bonded to two or three other atoms.

Primary kinetic isotope effects produced by these isotopic substitutions of larger atoms are used in similar arguments to those used for primary deuterium kinetic isotope effects. The observation of such a primary kinetic isotope effect is presented as evidence that the bond containing the substituted atom is broken in a rate-limiting[399,400] or rate-affecting[401] step in the kinetic mechanism of the enzymatic reaction. Increases in a primary kinetic isotope effect when a mutation is made in the active site[402] can demonstrate that a change in the rate-limiting step is caused by the mutation. Both a change[403,404] and the lack of a change[405] in the primary kinetic isotope effect when the concentration of a reactant is varied during measurements of initial rates have been cited as evidence for a particular kinetic mechanism.

Because tunneling cannot occur in such reactions, the magnitude of an intrinsic, primary kinetic isotope effect[406] for the isotopic substitution of one of these heavier elements is often **used to define the structure of the transition state** for the step in which the bond containing the substituted atom is broken. For example, the primary carbon-13 kinetic isotope effect for the reactant [1-^{13}C]chorismate is 5-fold smaller than the primary oxygen-18 kinetic isotope effect for the reactant [3-^{18}O]chorismate for the concerted rearrangement catalyzed by chorismate mutases (previously Equation 1–161)

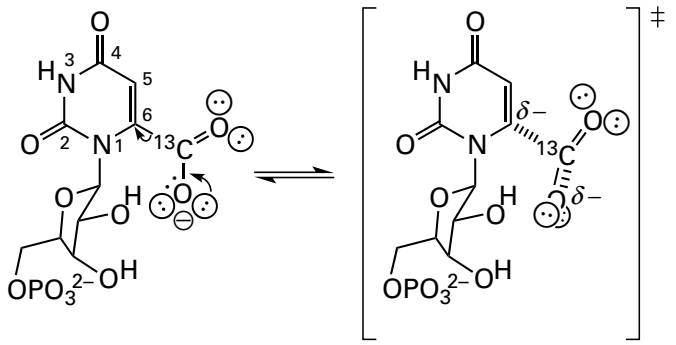


(4–218)

from *Bacillus subtilis* and *E. coli*. This fact was one of the observations used to conclude that, in the transition state, the bond between the oxygen of the migrating *enol*pyruvyl group and carbon 3 of the chorismate is almost completely broken while the bond between the vinyl carbon of the migrating *enol*pyruvyl group and carbon 1 is just beginning to form.[407,408]

The intrinsic, primary carbon-13 kinetic isotope effect for the step in the enzymatic mechanism of orotidine-5′-phosphate decarboxylase from *E. coli*

in which [*carboxy*-^{13}C]orotidine 5′-monophosphate is decarboxylated



(4–219)

is 1.05–1.07. This fact suggests that the carbon–carbon bond is almost completely broken in the transition state for this step in the enzymatic reaction.[409] The primary carbon-13 kinetic isotope effect on the specificity constant, k_{OMP}, for [*carboxy*-^{13}C]orotidine 5′-monophosphate (OMP) is 1.0255 ± 0.0005 while that on the specificity constant, k_{FOMP}, for [*carboxy*-^{13}C]-5-fluoroorotidine 5′-monophosphate (FOMP) is smaller, 1.0106 ± 0.0001. This fact suggests that the transition state occurs earlier in the latter reaction than in the former,[410] a conclusion consistent with heterolytic dissociation of the carbon–carbon bond that produces a carbanion at carbon 6 of orotidine 5′-monophosphate. Because this carbanion would be destabilized by the 5-fluoro group and significantly more difficult to form, the transition state should occur earlier for the fluoro reactant.

The intrinsic, primary nitrogen-15 kinetic isotope effect on the rate-liming step in hydrolysis of *N*-benzoyl-L-arginine amide by papain from *C. papaya* is 1.024. Because this value is at the upper limit for observed primary nitrogen-15 kinetic isotope effects on nonenzymatic reactions, this result was presented as evidence that the rate-limiting step in the enzymatic reaction is dissociation of the α-amino group of the L-arginine amide from the tetrahedral intermediate formed when the sulfido group of Cysteine 25 in the active site adds nucleophilically to the amide in the reactant.[397]

Secondary isotope effects, although they are quite small, are also observed for isotopic substitutions of carbon, nitrogen, and oxygen at atoms adjacent to an atom at which a bond is broken. For example, the intrinsic secondary nitrogen-15 kinetic isotope effect is 1.0025 ± 0.0002 for the step in the mechanism of aspartate carbamoyltransferase from *E. coli* in which the carbamoyl group in carbamoyl phosphate is transferred in a nucleophilic substitution from the oxygen of phosphate to the α-amino group of L-aspartate. The secondary nitrogen-15 kinetic isotope effect on dissociation of monomeric metaphosphate from the monoanion of carbamoyl phosphate during its decomposition is 1.0028 ± 0.0002. This fact suggests that, in the active site of the enzyme, the nucleophilic substitution is dissociative, with monomeric metaphosphate leaving before the α-amino group adds to the carbonic carbon of the resulting carbamate.[411]

Solvent kinetic isotope effects are the effects on the rate of a reaction that result when another isotopic form of the solvent is substituted for the naturally occurring isotopic form. The only solvent kinetic isotope effects that can be measured for enzymatic reactions, **solvent deuterium kinetic isotope effects**, are those observed when ^2H_2O is used as solvent instead of ^1H_2O.* It is possible to use the existence of a solvent deuterium kinetic isotope effect on the catalytic constant or a specificity constant as evidence for a contribution of hydron transfer to a rate-affecting step in the enzymatic mechanism.[412] The quantitative interpretation of the observed effects is similar to that for a primary deuterium kinetic isotope effect (Equations 4–199 and 4–201). Major drawbacks of these measurements, however, are that the hydron being transferred cannot be identified and that it is possible for the rates of several steps in the mechanism to be affected rather than just one. These drawbacks make the interpretation considerably less informative.

When ^2H_2O is substituted for ^1H_2O, **only hydrons on heteroatoms**—in the case of enzymes and substrates, oxygen, nitrogen, and sulfur—can exchange rapidly enough with the deuterons in solution and subsequently produce the resulting kinetic isotope effects that are observed. Hydrogens that are transferred during the enzymatic reaction as hydrogen atoms or hydrides are almost always uninvolved in such exchanges. Consequently, unlike experiments in which a hydrogen on a carbon in a substrate is synthetically changed to a deuterium, the deuterons that are participating in the enzymatic reaction and producing the solvent deuterium kinetic isotope effect can be on either heteroatoms in the substrate or, more likely, heteroatoms of the catalytic acid–bases in the active site. These catalytic acid–bases often are the same ones responsible for the decreases in steady-state kinetic constants above or below

*It should be obvious that, for practical reasons, solvent tritium kinetic isotopic effects cannot be measured.

particular values of pK_a observed in pH–rate profiles. By examining the solvent deuterium kinetic isotope effects on pH–rate profiles, the solvent deuterium kinetic isotope effects observed at a particular pH can be understood.

When ^2H_2O is substituted for ^1H_2O, apparent values of pK_a governing the pH–rate profiles for enzymatic reactions almost always shift to higher values of pH. These **upward shifts in pK_a** are revealed in pH–rate profiles of the common logarithms of steady-state rate constants (Figure 4–24).[413,414] The shift in pK_a can be only for the acid dissociation of the conjugate acid of the catalytic acid–base, and an acid dissociation constant is an equilibrium constant. Consequently, an acid dissociation constant always decreases when ^2H_2O is substituted for ^1H_2O. Therefore, each shift in pK_a is an upward shift, both when an apparent steady-state rate constant decreases below a particular pK_a, because the catalytic acid–base is acting as a base, and when an apparent steady-state rate constant decreases above a particular pK_a, because the catalytic acid–base is acting as an acid. The increases in pK_a observed for catalytic acid–bases in enzymatic reactions that result from substitution of ^2H_2O for ^1H_2O are usually in the range of 0.4–1.0 unit of pH.[413-416]

These upward shifts of pK_a have a significant effect on the value for a solvent deuterium kinetic isotope effect when it is measured at only one particular pH. In such an instance, the observed value could either be a result of an intrinsic, primary deuterium kinetic isotope effect on the actual transfer of the hydron between the heteroatom on the reactant and the catalytic acid–base that accepts or donates the hydron, an informative value, or simply due to the usual uninformative shift in pK_a. Consequently, a solvent deuterium isotope effect measured in the absence of a pH–rate profile can be misleading.

When an apparent steady-state rate constant decreases below an apparent pK_a but does not decrease above an apparent pK_a (Figure 4–24B), the solvent deuterium kinetic isotope effect at all values of pH will usually be normal. A **normal kinetic isotope effect** is a decrease in a rate constant that results from substitution of a lighter isotope with a heavier isotope. Measurements of a solvent deuterium kinetic isotope effect at values of pH below a pK_a at which the rate constant is decreasing is normal because both the decrease in the solvent deuterium kinetic isotope effect resulting from the shift in pK_a and the intrinsic solvent deuterium kinetic isotope effect on the pH-independent microscopic rate constant for transfer of the hydron are in the same direction.

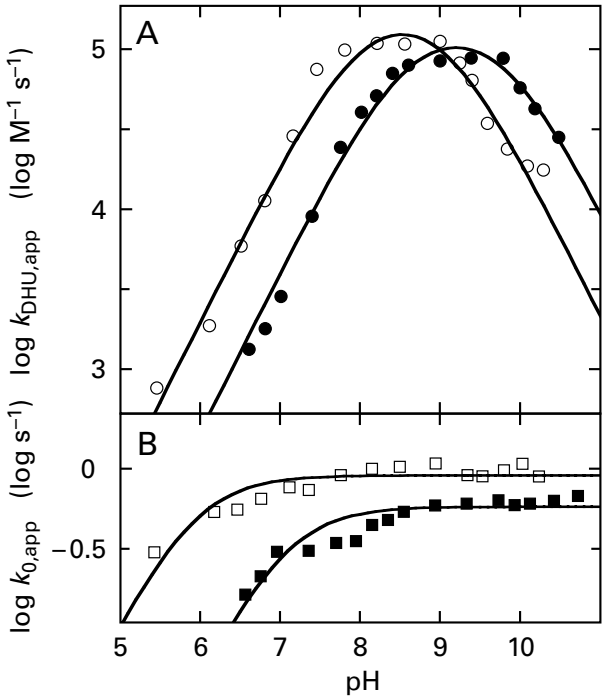


Figure 4–24: Effect of pH on the solvent deuterium kinetic isotope effect for the reaction catalyzed by porcine dihydropyrimidinase.[413] Initial rates for the conversion of 5,6-dihydrouracil into 3-ureidopropanoate that is catalyzed by the enzyme were measured spectrophotometrically at 225 nm in solutions prepared in H_2O and in D_2O with various concentrations of 5,6-dihydrouracil at various values of pH. Values for the specificity constant $k_{DHU,app}$ (○, ●, molar^{-1} second^{-1}) for 5,6-dihydrouracil (DHU) and the catalytic constant $k_{0,app}$ (□, ■, second^{-1}) were determined at each pH in H_2O (○, □) and at each pD in D_2O (●, ■), and their common logarithms are plotted as a function of the pH. The curves fit to the data for the steady-state rate constant $k_{DHU,app}$ are those for Equation 4–97 (replacing AG6 with DHU) with pK_{a3} = 8.05, pK_{a4} = 9.0, and k_{DHU} = 220 mM^{-1} s^{-1} in H_2O and pK_{a3} = 8.6, pK_{a4} = 9.8, and k_{DHU} = 160 mM^{-1} s^{-1} in D_2O. The curves fit to the data for the catalytic constant $k_{0,app}$ are those for Equation 4–80 with pK_a = 5.9 and k_0 = 0.91 s^{-1} in H_2O and pK_{a3} = 7.05 and k_0 = 0.58 s^{-1} in D_2O.

When a apparent steady-state rate constant decreases above an apparent pK_a, however, the solvent deuterium kinetic isotope effect at values of pH greater than the apparent pK_a will usually be inverse (Figure 4–24A). An **inverse kinetic isotope effect** is a counterintuitive increase in an apparent rate constant resulting from substitution of a lighter isotope for a heavier isotope. This inverse solvent deuterium kinetic isotope effect at a particular pH results from the fact that the upward shift in pK_a

produced by substitution of a hydron with a deuteron raises the profile at values of pH greater than the pK_a of the deuterated acid–base. This increase resulting from the shift in pK_a usually has a greater effect on the rate constant at a given pH than the normal kinetic isotope effect on the underlying pH-independent microscopic rate constant for transfer of the hydron from the catalytic acid that is observed at low pH.

Usually, the **pH-independent solvent deuterium kinetic isotope effects on the underlying apparent rate constants are normal**, as they are in Figure 4–24 (notice that, at the respective maxima in Figure 4–24A and at the pH-independent plateaus in Figure 4–24B, the apparent rate constants have normal solvent deuterium kinetic isotope effects). When a hydron is substituted with a deuteron, the transfer of the hydron usually becomes slower. In some instances, however, the solvent deuterium kinetic isotope effects on the pH-independent rate constants are inverse.[416,417] As with inverse primary deuterium kinetic isotope effects, one reason for inverse solvent deuterium kinetic isotope effects is that c_r is large and the equilibrium isotope effect, $^{D}K_{eq}$, is inverse. Another possibility is that the tautomeric equilibrium between an active and an inactive tautomer of the active site is shifted by substitution of deuterons for hydrons in favor of the active tautomer, again by an equilibrium isotope effect.

If the only effect of changing solvent from ^1H_2O to ^2H_2O is on hydron transfer in a single microscopic step in the kinetic mechanism and if c_f, c_r, and the ratio α_0 are small, the solvent deuterium kinetic isotope effects on the steady-state rate constants should be the same and equal to the intrinsic solvent deuterium kinetic isotope effect. If they are not the same, it is, as usual, taken as evidence that other steps in the reaction are rate-affecting and suppress the intrinsic solvent deuterium kinetic isotope effect.[418] As with primary deuterium kinetic isotope effects, if mutation of an amino acid[419,420] or changes in the reactant[421] decrease a steady-state rate constant but increase the solvent deuterium kinetic isotope effect on that rate constant, one can conclude that the amino acid or the reactant is a direct participant in a step in which a hydron that is in rapid exchange with hydrons in the solution is transferred.

In simple situations in which all hydron transfers occur in only one step, it is also possible to use solvent deuterium kinetic isotope effects at a fixed pH, if they exist, to **estimate how many hydrons are being transferred in the transition state** of that step.[422] The equation[423,424] that is used to describe the value of a particular rate constant as a function of the mole fraction of D_2O in a solvent of H_2O, x_{D_2O}, is

$$\frac{k_x}{k_{ref}} = \prod_{i=1}^{n} \left(1 - x_{D_2O} + \phi_i^{\ddagger} x_{D_2O}\right) \qquad (4\text{–}220)$$

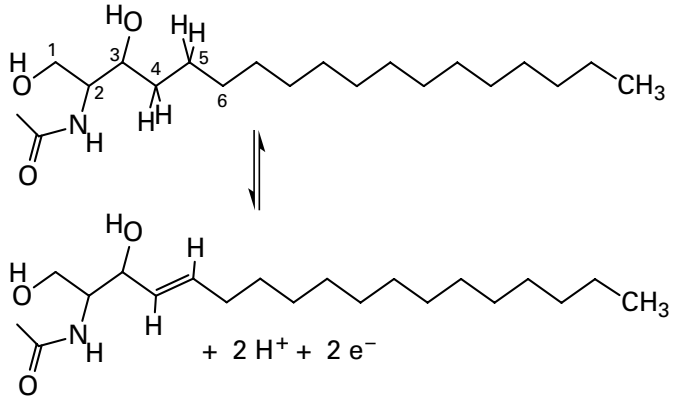
where k_x is the rate constant in a solvent of mole fraction x_{D_2O}, k_{ref} is the rate constant in ^1H_2O, $^{\ddagger}\phi_i$ is a fractionation factor for the ith hydron that is transferred in the transition state (‡), and n is the number of hydrons being transferred. In theory, there is a unique fractionation factor for each hydron; in practice, values for the fractionation factors obtained from the fit of the equation to the data are usually the same within the error of measurement.[424-426] This equation applies for both normal and inverse[414] solvent deuterium kinetic isotope effects. It must be the case, however, that the kinetic isotope effect being plotted is an intrinsic solvent deuterium kinetic isotope effect that is not masked by commitments.[427] It is also necessary to distinguish solvent deuterium kinetic isotope effects on the transfer of hydrons in a transition state from the effect of ^2H_2O on the viscosity of the solution[428] or on conformational changes in the enzyme.[429]

If only one hydron is being transferred in the transition state of the step that displays the intrinsic solvent deuterium kinetic isotope effect, there should be a linear relation between the fraction of protium in the solvent that has been replaced by deuterium and the numerical value for that kinetic isotope effect.[415,430] As hydrogen is replaced by deuterium, the microscopic rate constant should change linearly in concert. Such a linear solvent deuterium kinetic isotope effect on the catalytic constant of L-aspartate oxidase from *E. coli* was the basis of the conclusion that only one hydron was being transferred in the transition state of the reaction, a conclusion consistent with the mechanism of the enzyme being the same as other amino acid oxidases even though it is unrelated to them.[431]

If, however, two hydrons are being transferred in the transition state of the step in the reaction producing the deuterium solvent kinetic isotope effect, then the numerical value for the intrinsic deuterium solvent kinetic isotope effect should be a quadratic function (Equation 4–220) of the fraction of hydrogen that has been replaced with deuterium, as was seen with the solvent deuterium kinetic isotope effect on the catalytic constant of nitrile hydratase from *Pseudonocardia thermophila* (Figure 4–25).[424-426]

The result in this instance cannot distinguish between a quadratic fit and a cubic fit, but it definitely indicates that more than one hydron is being transferred in the transition state. This conclusion was used to argue that, in the transition state for the reaction, a hydron is removed from the water that adds nucleophilically to the nitrile by the hydroxy group of Serine 112 in the active site simultaneously with the transfer of the hydron that was on the hydroxy group of the serine to the 4-oxidophenyl group of Tyrosine 68.[432] In this way, the basicity of the oxido group of Tyrosine 68 is relayed through Serine 112 by two coincident hydron transfers.

In addition to identifying steps in a kinetic mechanism in which a hydrogen is transferred, primary deuterium kinetic isotope effects can also be used to determine the regiochemistry or stereochemistry of a transfer of a hydrogen catalyzed by an enzyme.[433,434] For example, the primary deuterium kinetic isotope effect for the desaturation of a [4,4-$^2H_2$]ceramide by sphingolipid 4-desaturase



(4–221)

from *R. norvegicus* was 8.3 while that for the [5,5-$^2H_2$]ceramide was 1.02, even though a hydrogen is removed from both carbon 4 and carbon 5 during the enzymatic reaction. These observations demonstrate that the rate-limiting step in the reaction is removal of the hydrogen atom from carbon 4 by the prosthetic oxodiiron(IV) in the active site[435]

The primary deuterium kinetic isotope effect for the specificity constant k_{Ppc} for the oxidation of (2*S*,6*R*)-[6-^{2}H]pipecolate (Ppc) by L-pipecolate oxidase from *Macaca mulatta* is 3.7 while that for (2*S*,6*S*)-[6-^{2}H]pipecolate is 1.0. This fact indicates that the enzyme removes the *pro-R* hydrogen rather than the *pro-S* hydrogen from carbon 6 during the

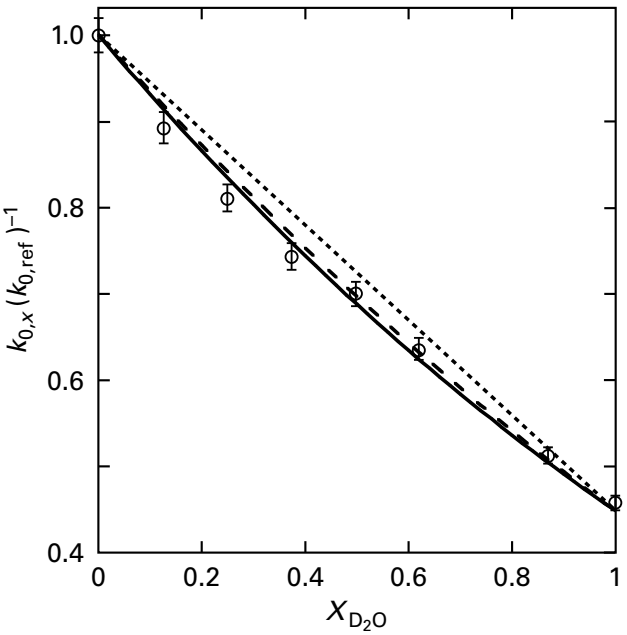


Figure 4–25: Variation in the numerical value of the catalytic constant k_0 for nitrile hydratase from *P. thermophila* with changes in the mole fraction (x_{D_2O}) of D_2O in the solvent.[425] Solutions containing various concentrations of benzonitrile were prepared at pH 7.6 and 25 °C. The solutions were prepared with various mole fractions of D_2O in H_2O. The hydration of benzonitrile was followed by the change in absorbance at 242 nm. For each mole fraction of D_2O, the initial rates at several concentrations of benzonitrile were used to obtain the catalytic constant k_0. The ratio of the catalytic constant, $k_{0,x}$, at each mole fraction (x_{D_2O}) of D_2O to the catalytic constant, $k_{0,ref}$, in pure H_2O is presented as a function of the mole fraction (x_{D_2O}) of D_2O. The solid curve is for the cubic version of Equation 4–220 ($n = 3$) with a common fractionation factor $^{\ddagger}\phi = 0.765$. The curve of long dashes is for the quadratic version of Equation 4–220 ($n = 2$) with fractionation factors of $^{\ddagger}\phi_1 = 0.66$ and $^{\ddagger}\phi_2 = 0.68$. The line of short dashes simply connects the values of the two curves at 0 and 1.

oxidation.[433,436] The **stereochemistry for removal of hydrogen** from a reactant, such as the one in this last example, provides information about the orientation of the acceptor for the hydrogen in an active site.

Problem 4–12: Phosphopyruvate hydratase catalyzes the reaction

$$\text{2-phospho-D-glycerate} \rightleftharpoons \text{phospho}\textit{enol}\text{pyruvate} + H_2O$$

(A) Write a mechanism for this reaction that has at least two steps, in each of which a hydron transfer occurs. Indicate all removals and additions of hydrons. Incorporate catalytic acids, –$NH^{(+)}$, and catalytic bases, –$B\odot^{(-)}$, on the enzyme into your mechanism.

2-Phospho[2-^{2}H]glycerate was synthesized as a reactant for phosphopyruvate hydratase from *S. cerevisiae*. There are 46,700 g for every mole of active sites. The following data were obtained under the same set of conditions (0.9 μg of phosphopyruvate hydratase mL^{-1} at pH 7.81 and 30 °C) for the two reactants.[437]

2-phospho-[2-^{1}H]glycerate		2-phospho-[2-^{2}H]glycerate	
$[PGA]_0$[a] (mM)	v_0 (ΔA_{230} min^{-1})	$[PGA]_0$[a] (mM)	v_0 (ΔA_{230} min^{-1})
0.25	0.480	0.25	0.228
0.10	0.369	0.10	0.169
0.05	0.274	0.05	0.123
0.025	0.180	0.025	0.086

[a]Concentration of phosphoglycerate (PGA) of noted isotopic composition.

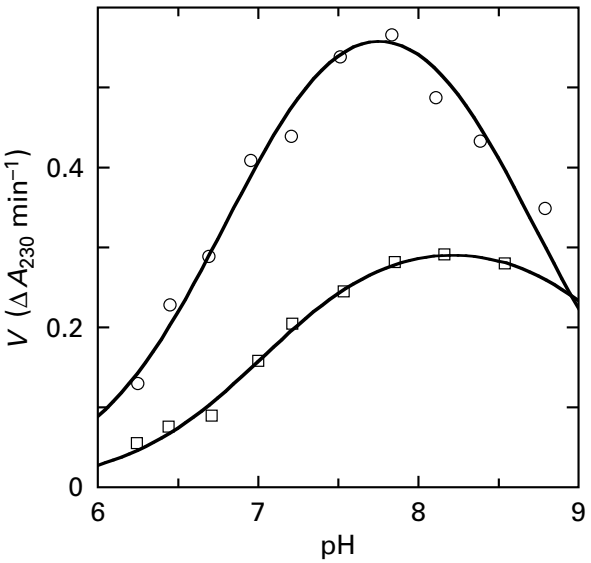
where v_0 is the initial rate of the dehydration.

(B) Determine the limiting rate V (Equation 3–45) and the Michaelis constant K_m (Equation 3–44) for each substrate under these conditions.

(C) How are they related to the catalytic constant and the steady-state rate constant k_{PGA} for phosphogylycerate (PGA)?

(D) What piece of information is missing to prevent the calculation of k_0 and k_{PGA}?

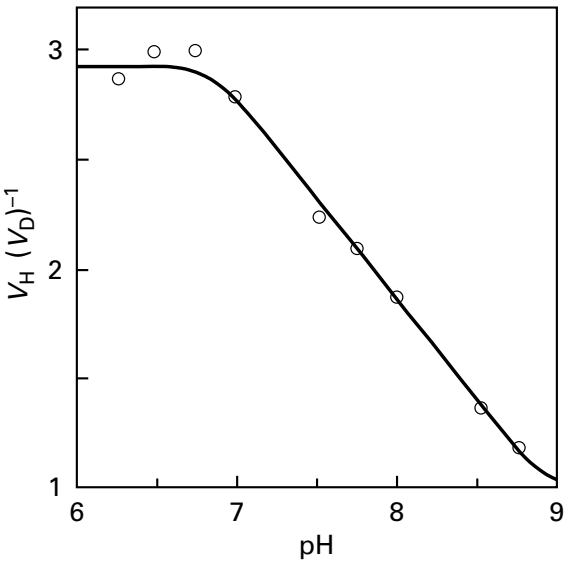
The limiting rate V for the enzymatic reaction was measured in the direction of dehydration, as a function of pH for the reactants containing protium and deuterium, respectively.[437]



Maximum rates V (ΔA_{230} min^{-1}) for (○) protiated and (□) deuterated reactants as a function of pH.

(E) Why would a plot of the catalytic constant (Equation 3–46) for protiated reactant show a maximum?

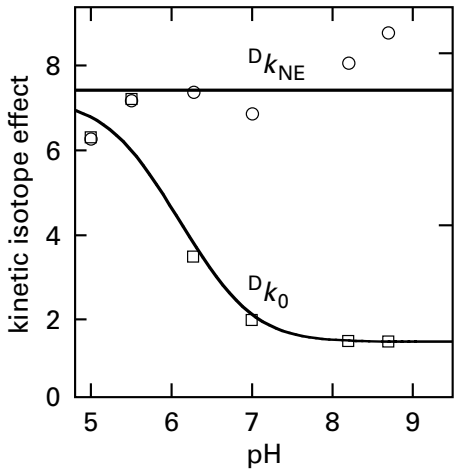
When the ratios between the maximum rates for protiated reactant and deuterated reactant, $V_H (V_D)^{-1}$, are plotted as a function of pH, the following results were obtained.[437]



(F) Explain, in terms of the considerations you made in parts A–C, why the magnitude of the

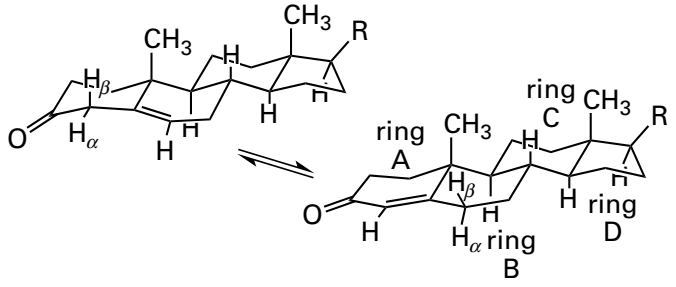
primary deuterium kinetic isotope effect diminishes as the pH is raised.

Problem 4–13: The primary deuterium kinetic isotope effects on the specificity constant k_{NE} (○) for [1,1-$^2H_2$]nitroethane (NE) and the catalytic constant k_0 (□) for the reaction catalyzed by nitroalkane oxidase from *F. oxysporum* are plotted as a function of pH.[330]



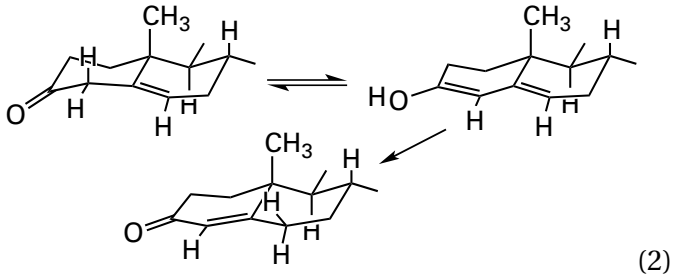
(A) Why does the primary deuterium kinetic isotope effect for k_0 increase as the pH is decreased?
(B) What is probably the intrinsic, primary deuterium kinetic isotope effect for the step in which the hydrogen on nitroethane is transferred?
(C) What can be deduced about the magnitudes of the commitment forward, c_f, the commitment in reverse, c_r, and the ratio α_0 at pH 8?
(D) The change in which of these three parameters is responsible for the increase in $^Dk_0$ at low pH?

Problem 4–14: The enzyme steroid Δ-isomerase catalyzes the following reaction.



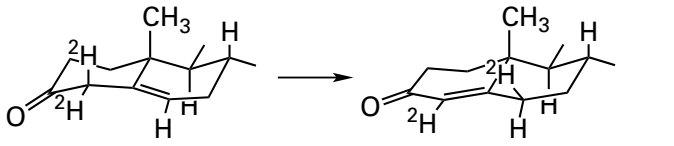
(1)

The enzyme has been purified from *C. testosteroni* and *P. putida*. The enzyme is rather tolerant about R, using many steroids as substrates. Since the chemical transformation occurs in only the A and B rings, the C and D rings will no longer be drawn. The same transformation catalyzed by the enzyme occurs spontaneously, albeit at a much reduced rate, under acidic conditions. The mechanism of this nonenzymatic reaction is

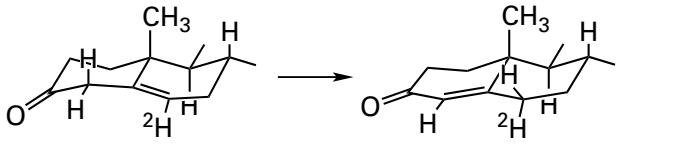


(2)

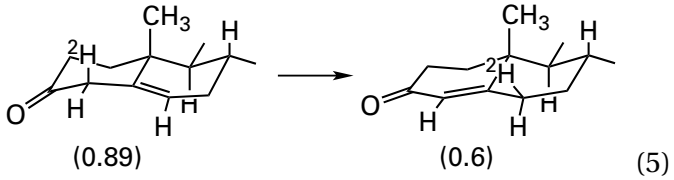
When the following deuterated reactants were synthesized and mixed with the enzyme in buffered H_2O, the noted products were obtained.[438] The numbers in parentheses below each structure are the moles of deuterium for each mole of the respective compound.



(3)



(4)



(5)

In each case, the reaction is written as if it were irreversible because the equilibrium strongly favors the conjugated product. The absolute configuration of each deuterated product was verified by infrared spectroscopy; and its deuterium content, by mass spectrometry.

The kinetics of the reaction in Equation 5, in which the 4β-monodeuterated ketosteroid was used as substrate, were compared with those of the reaction in which the undeuterated ketosteroid of

the same structure was used as substrate. It was determined that the deuterium kinetic isotope effect on the catalytic constant was 5.35.

(A) Write out a detailed enzymatic mechanism that explains the observations. Choose specific amino acid side chains to perform various catalytic functions. At the moment, you do not know which amino acid side chains actually perform these roles, but you should pick appropriate ones. Start with reactant bound to the active site and finish with product bound to the active site. Draw the structure of substrate, intermediates, and product in sawhorse configuration, and indicate clearly all stereochemistry. Your mechanism must explain the absolute configuration of the deuterated products and the retention of deuterium in the product.

(B) When the enzymatic reaction was performed in deuterium oxide (^2H_2O) with an undeuterated reactant, 0.12 mole of deuterium was incorporated at the 6β position for every mole of product produced. As the reactions of Equations 3 and 5 proceed, some deuterium is lost to the solvent. Explain all these observations by referring to your mechanism in part A. At which step is the deuterium gained from or lost to the solvent, and how does this happen? Present your answer in a series of acid–base equilibria.

The magnitude of the primary deuterium kinetic isotope effect observed for the catalytic constant suggests that dissociation of the 4β carbon–hydrogen bond is the rate-limiting step in the reaction. If it is, all subsequent steps are very rapid and can be ignored. Convince yourself that, under these circumstances, the simplest kinetic mechanism, the one in Equation 4–149, is appropriate. The specificity constant, k_{KS}, for β-monodeuterated ketosteroid (KS) for the reaction of Equation 5 is ${}^{D}k_{KS} = 380\ \mu M^{-1}\ s^{-1}$, while that for the same reactant when the ketosteroid is undeuterated is ${}^{H}k_{KS} = 910\ \mu M^{-1}\ s^{-1}$. The catalytic constant ${}^{H}k_0$ for the undeuterated substrate is $2.8 \times 10^5\ s^{-1}$.

(C) Make the reasonable assumption that the presence of a deuterium at the 4β position has no effect on the binding of substrate to the enzyme so that ${}^{D}k_1 = {}^{H}k_1$ and ${}^{D}k_{-1} = {}^{H}k_{-1}$. Explain mathematically why ${}^{H}k_{KS} \neq {}^{D}k_{KS}$, and determine definite values for k_1, k_{-1}, and ${}^{D}k_2$.

(D) Copy the drawing of the structure of the A and B rings of a ketosteroid; and, on your drawing, indicate how the enzyme could strain it and cause it to resemble the intermediate in the enzymatic reaction.

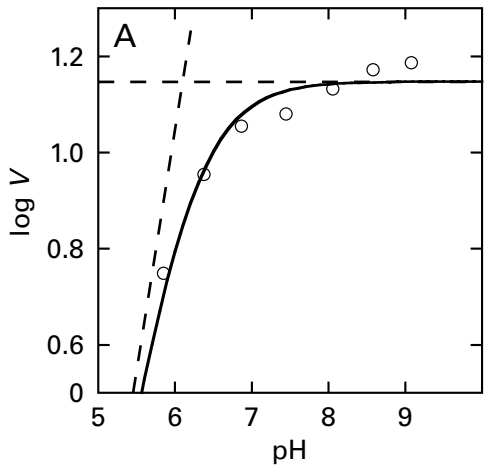
Problem 4–15: Human adenine phosphoribosyltransferase catalyzes the following reaction.

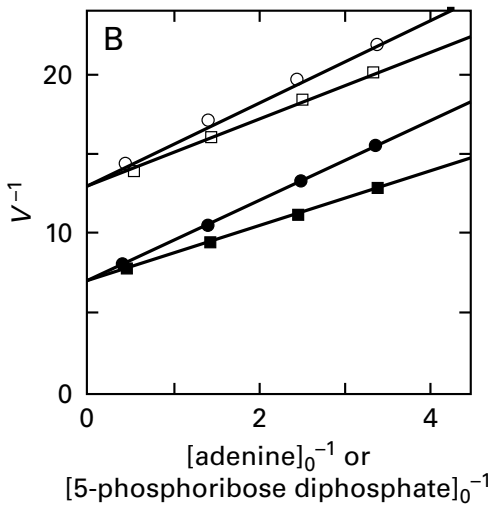
magnesium 5-phospho-α-D-ribose 1-diphosphate
+ adenine $\rightleftharpoons$ adenosine 5′-phosphate
+ magnesium diphosphate

(A) Draw a chemical mechanism for the enzymatic reaction as it would occur within the active site. Use specific amino acid side chains as catalytic acids and bases. Draw the reaction with proper stereochemistry at carbon 1 of the ribose throughout.

The kinetics of the enzymatic reaction have been examined as a function of pH (Figure A),[439] and a solvent deuterium kinetic isotope effect was observed when the enzymatic reaction is carried out in ^2H_2O.[439]

Figure: Effect of pH and solvent deuterium isotope effect for the reaction catalyzed by human adenine phosphoribosyltransferase.[439] (**A**) The limiting rate V of the enzymatic reaction at 10 °C and at saturation with both 5-phospho-α-D-ribose 1-diphosphate and adenine is plotted as a function of pH. (B) Reciprocals of the maximum rates V^{-1} at saturation with adenine and different unsaturating concentrations of 5-phospho-α-D-ribose 1-diphosphate (■) in H_2O, maximum rates at saturation with 5-phospho-α-D-ribose 1-diphosphate and different unsaturating concentrations of adenine (●) in H_2O, maximum rates at saturation with adenine and different unsaturating concentrations of 5-phospho-α-D-ribose 1-diphosphate (□) in D_2O, and maximum rates at saturation with 5-phospho-α-D-ribose 1-diphosphate and different unsaturating concentrations of adenine (■) in H_2O are plotted as a function of the reciprocals of the concentration of reactant present below saturation.

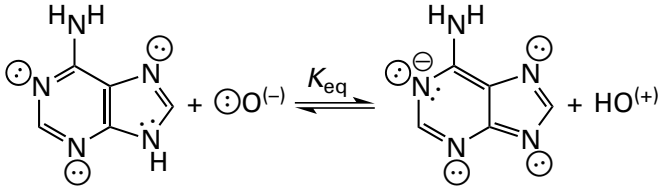




(B) What appears to be the pK_a of the group in the active site the ionization of which causes the behavior observed in Figure A? Is it a catalytic acid or a catalytic base in the mechanism of the enzymatic reaction? What form of the enzyme is titrating? What side chain in your mechanism could be the group that is titrating?

In ^2H_2O, the only form of adenine present is N^6,N^6,N^9-trideuteroadenine. The possibility can now be examined that the deuterium solvent kinetic isotope effect seen in Figure B could arise from removal of a deuterium atom from N^6,N^6,N^9-trideuteroadenine during a rate-limiting step in the enzymatic reaction.

(C) From the value for the equilibrium constant for the following acid–base reaction in solution



where HO has a pK_a = 6.1 and adenine has a pK_a = 9.8 and with the assumption that hydron transfer in the direction of hydronating the adenine anion is encounter-controlled with a value of 10^{10} M^{-1} s^{-1} (Figure 1–1B), calculate the rate constant for transfer of the hydron from adenine to the base.

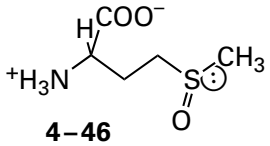
(D) Considering the effect of approximation, what would you expect to be the first-order rate constant for hydron removal from adenine on the active site?

(E) The catalytic constant of human adenine phosphoribosyltransferase is 4 s^{-1} at 37 °C.[440] To what is the solvent deuterium kinetic isotope effect not due, and to what else could it be due?

Stereochemistry

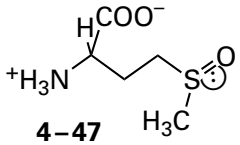
Enzymes usually catalyze reactions in which only one enantiomer or diastereomer of each reactant is converted into only one enantiomer or diastereomer of each product. This behavior is so fundamental to biochemistry that different diastereomers of the same compound are given different names. For example, (3*S*,4*R*,5*R*)-1,3,4,5,6-pentahydroxyhexan-2-one is called D-fructose and (3*S*,4*S*,5*R*)-1,3,4,5,6-pentahydroxyhexan-2-one is called D-tagatose.

The **chiral exclusivity of the usual active site** is illustrated in the extreme by the L-methionine *S*-oxide reductases. Two enantiomers of methionine sulfoxide



4–46

L-methionine (*R*)-sulfoxide



4–47

L-methionine (*S*)-sulfoxide

are produced at random when methionines in proteins are oxidized adventitiously, unavoidably, and nonenzymatically. Even though the structures differ by only the stereochemistry of a lone pair of electrons, the spontaneous inversion of the lone pair of electrons at the sulfur to equilibrate the two diastereomers does not occur at a significant rate at physiological temperatures[441] Consequently, two different, unrelated enzymes, L-methionine (*R*)-*S*-oxide reductase and L-methionine (*S*)-*S*-oxide reductase, are required to reduce the two enantiomers back to L-methionine[442,443] because the catalytic groups

operating on the one enantiomer must be in a different orientation from those operating on the other when the respective substrate is bound within the respective active site.

For enzymes that catalyze bimolecular or trimolecular reactions, the identities of the diastereomers or enantiomers that are substrates for enzymatic reactions **dictate how these substrates must be positioned by the active site** relative to each other to maintain the stereochemistry required of reactants and products. These relative orientations are observed in the crystallographic molecular model of a particular active site for such an enzyme when it is occupied by more than one of its substrates or analogues of its substrates. For example, there are two different enzymes, fructose-bisphosphate aldolase (Equation 4–210) and a class II tagatose-bisphosphate aldolase, in the cytoplasm of *E. coli*. These two enzymes convert the same two substrates, D-glyceraldehyde 3-phosphate and glycerone phosphate, into D-fructose 1,6-bisphosphate and D-tagatose 1,6-bisphosphate, respectively. Two different enzymes are required because the enamine of glycerone phosphate is aligned on the opposite faces of the carbonyl carbon on glyceraldehyde 3-phosphate in the respective active sites to accomplish the proper aldol condensations.[444]

The chiral exclusivity of active sites, however, is not universal. There are a few enzymes that are able to perform the same reaction on several different substrates as long as the differences are not at the positions at which the reaction occurs. The absolute configuration of each of these different substrates at these positions must be the same[445] because each of the different reactants still must be complementary to the one and only configuration of the catalytic groups in the active site.

An even rarer exception to the rule of chiral exclusivity, however, is a class I fructose-bisphosphate aldolase in *S. aureus* that produces D-tagatose 1,6-bisphosphate, D-psicose 1,6-bisphosphate, and D-sorbose 1,6-bisphosphate in addition to D-fructose 1,6-bisphosphate; each product is formed from D-glyceraldehyde 3-phosphate and glycerone phosphate.[446] These four products are the four 2-oxo-D-hexoses that are diastereomeric at carbons 3 and 4, the two carbons that are joined in the aldol condensations catalyzed by the enzyme. This **rare stereochemical promiscuity** results from two departures from the usual requirement that reactants be held in the active site by donors and acceptors for hydrogen bonds and steric effects in only one rigid orientation relative to each other so that only one of the possible diastereomeric products results. In fact, this particular exception to the rule illustrates how the stereochemical requirement is enforced in most cases. First, there are two different sets of donors and acceptors for hydrogen bonds that permit the hydroxy group on the nucleophilic carbon in the enamine that is the intermediate in the reaction catalyzed by the enzyme (Figure 4–26) to assume either the *E* or *Z* configuration,[447] which directs either the *Re* or *Si* face*, respectively, of carbon 3 in the enamine toward the aldehyde and produces the *R* or *S* configuration at carbon 3 in the product. Second, the aldehyde of D-glyceraldehyde 3-phosphate is able to present either its *Si* or *Re* face to the double bond of the enamine (Figure 4–26),† which produces the *R* or *S* configuration, respectively, at carbon 4.

In the case of class II tagatose-bisphosphate aldolase from *E. coli*, the active site provides donors and acceptors for the hydroxy group of the enamine of glycerone phosphate in only one orientation so that only the *Si* face of carbon 3 is directed toward the aldehyde, and the active site holds the carbonyl group of the aldehyde of D-glyceraldehyde 3-phosphate tightly so that only its *Re* face is directed toward the enolate. Consequently, only D-tagatose 1,6-bisphosphate is the product. In the case of fructose-bisphosphate aldolase from *E. coli*, the *Si* face of the enolate is directed to the *Si* face of the aldehyde so that only fructose 1,6-bisphosphate is the product.

Another departure from the almost universal stereochemical rigor of active sites, albeit less dramatic than that of fructose-bisphosphate aldolase from *S. aureus*, occurs in *N*-acetylneuraminate lyase from *E. coli*, in which either the *Si* or the *Re* face of an aldehyde is presented to the enolate of pyruvate.[448] In this instance, however, the face of the aldehyde presented to the enolate depends on the identity of that aldehyde, so for each aldehyde, the reaction is stereospecific.

*If the substituents around a trigonal carbon, when one of its two faces is being viewed, appear in a clockwise sense in order of priority, the face that is being viewed is the *Re* face. The opposite face, in which they appear to the observer in counterclockwise order, is the *Si* face.

†The sawhorse drawings of open-chain molecules used in this book are oriented so that the lower carbon in a carbon–carbon bond that is drawn diagonally is always in front of the upper carbon.

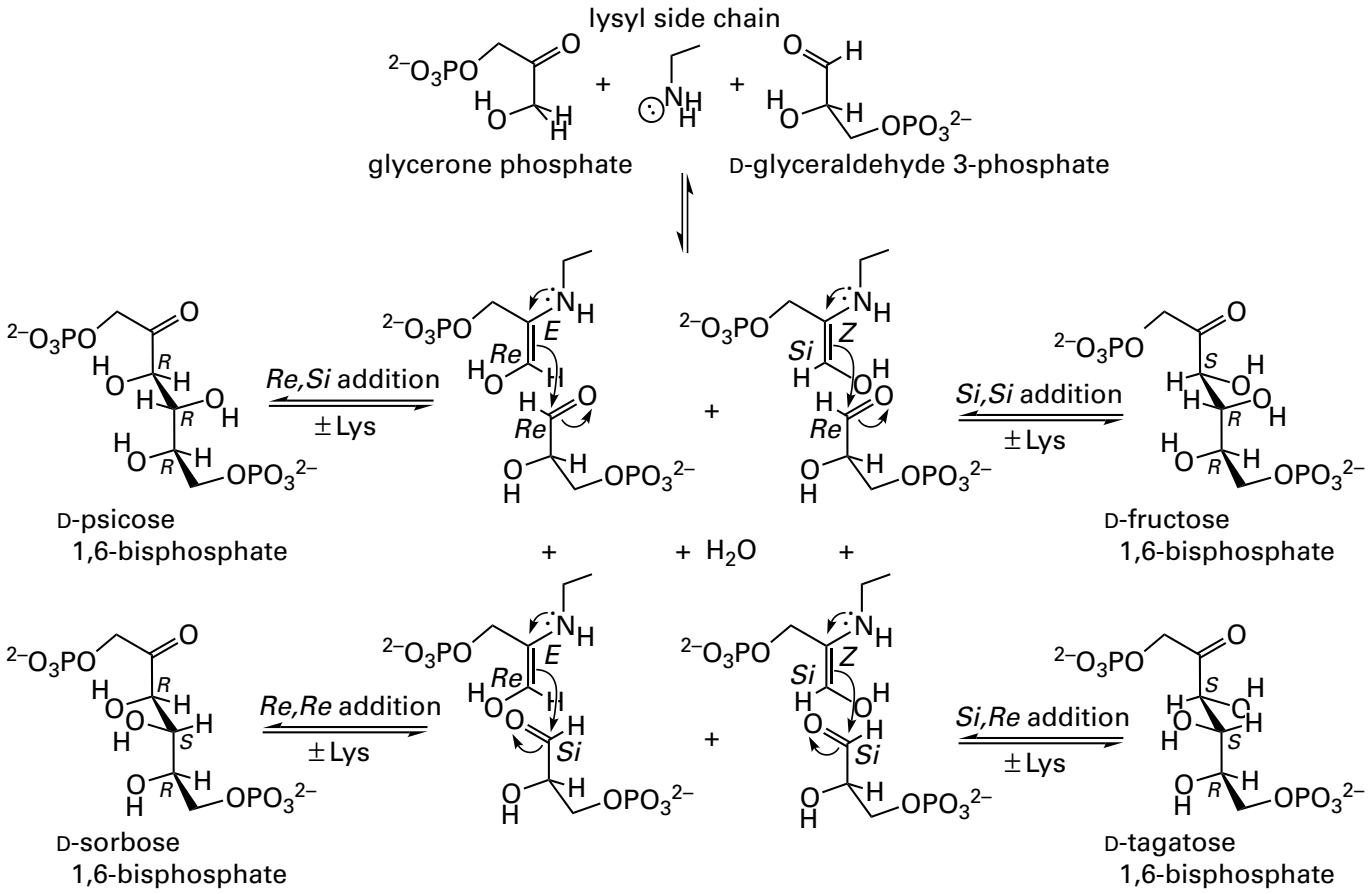


Figure 4–26: Stereochemical explanation for the promiscuity of the products from the reaction catalyzed by class I fructose-bisphosphate aldolase in *S. aureus* that produces D-psicose 1,6-bisphosphate, D-sorbose 1,6-bisphosphate, and D-tagatose 1,6-bisphosphate, in addition to D-fructose 1,6-bisphosphate, from glycerone phosphate and D-glyceraldehyde 3-phosphate. Stereochemical designations are given for the three chiral carbons in each of the four products, the double bond in each of the four enamines, the distal carbon in each of the four enamines, and the front face of each of the four aldehyde carbons. In each of the four additions, the enolate is added to the back face of the aldehyde, so the stereochemical designation for the addition (written above the arrows) is opposite from that for the front face.

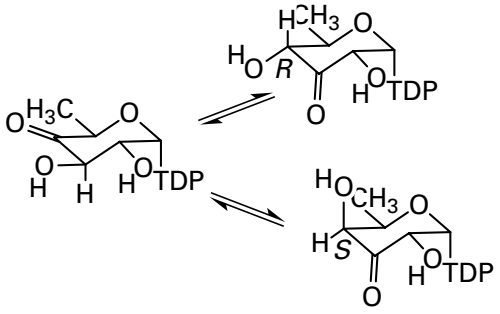
There are also examples where the same enzyme in two different species catalyzes the **same chemical reaction but with different stereochemical outcome**s even though each enzyme operates with chiral exclusivity. For example, the TDP-4-oxo-6-deoxy-α-D-glucose-3,4-oxoisomerases



(4–222)

from *Thermoanaerobacterium thermosaccharolyticum* and *Aneurinibacillus thermoaerophilus*, respectively, are closely related enzymes (48% identity; 0 gap percent), but the former produces exclusively the *R* epimer at carbon 4 of the hexose and the latter produces exclusively the *S* epimer (Equation 4–222). Strangely enough, both active sites contain the histidine responsible for transferring the hydron between the two oxygens, the tyrosine responsible for hydronating carbon 4 to produce the *R* epimer in the former instance, and the histidine responsible for removing the hydron from carbon 3 in both instances and hydronating carbon 4 to produce the *S* epimer in the latter instance, and these catalytic acid–bases are in the same locations in both active sites.[449] Presumably, the structures of the two active sites are different enough that the histidine cannot

reach carbon 4 in the former instance and the tyrosine cannot reach carbon 4 in the latter instance.

In spite of the few exceptions that prove the rule, the degree of **stereochemical preference displayed by an active site for the formation of bonds between elements of the second and third rows is usually quite high** because, in most cases, whenever the incorrect diastereomer is produced by the enzyme in either direction, it cannot participate in the next reaction in the metabolic pathway to which the enzyme contributes. An extreme case is that of enoyl-CoA hydratase

trans-2-enoyl-SCoA + H_2O $\rightleftharpoons$ (3*S*)-3-hydroxyacyl-SCoA (4–223)

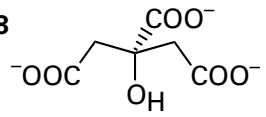
from *R. norvegicus*, which produces 400,000 times more (3*S*)-3-hydroxybutyryl-SCoA than (3*R*)-3-hydroxybutyryl-SCoA.[450] The chiral exclusivity of a particular enzyme can be decreased or the chirality of the product can even be inverted by mutation of amino acids in the active site,[451-455] but these mutant enzymes are not required to participate in metabolism and be subjected to natural selection. Whether or not cells of *S. aureus* do anything with the D-sorbose 1,6-bisphosphate and D-psicose 1,6-bisphosphate produced by their class I tagatose-bisphosphate aldolase is unclear, but they are able to ferment D-sorbitol.[456] Because it is so fundamental to the coordination of metabolism and so easy to understand, the stereochemical exclusivity of enzymatic catalysis when substrates are participants in metabolism is taken for granted.

There are natural instances, however, in which reactants and products of an enzymatic reaction do not participate in metabolism and are not required to have a particular stereochemistry, but the enzymatic reaction still proceeds with high stereochemical preference. For example, haloacetate dehalogenase from *Rhodopseudomonas palustris* dehalogenates a wide variety of haloacetates, including 2-fluoro-2-phenylacetate. When racemic 2-fluoro-2-phenylacetate is used as a reactant, the enzyme defluoronates only (*S*)-2-fluoro-2-phenylacetate (selectivity for *S* over *R* greater than 500) and produces only (*R*)-2-hydroxy-2-phenylacetate.[457] The observed inversion of configuration is consistent with the established mechanism for the reaction in which the carboxylato group of Aspartate 110 displaces the fluorine in a concerted nucleophilic substitution with inversion of configuration, followed by hydrolysis of the resulting aspartyl ester. Whenever (*R*)-2-fluoro-2-phenylacetate associates with the active site, the fluoro group ends up on the same side of the reactant as the carboxylato group of Aspartate 110, and the nucleophilic substitution cannot occur. Consequently, the strict stereochemistry observed for most enzymatic reactions, even in cases where it is unnecessary, is a consequence of the inescapable orientation of the catalytic groups in the active site relative to the orientation in which the reactant is bound within the active site. These facts are common to almost all active sites, regardless of the purpose of the enzymatic reaction.

The **stereochemistry of the diastereomers and enantiomers that are substrates for the enzymes** and that dictate the structure of active sites were, by and large, determined by organic chemists interested only in the stereochemistry of metabolites and natural products but not in their biosynthesis or catabolism. As a result of these determinations, in most cases the stereochemistry of the substrates for a particular enzymatic reaction had been elucidated before the enzymatic reaction itself was discovered. Consequently, the chemical determination of the absolute* stereochemistry of substrates is usually not a subject for a study of enzymatic mechanisms.

There are exceptions to this generalization. Citrate

4–48



is achiral because the two carboxymethyl groups on the tertiary carbon are identical. To an organic chemist, citrate is simply 3-carboxy-3-hydroxypentanedioate, a molecule of little stereochemical interest. Citrate, however, is prochiral.

A prochiral molecule is a molecule that is achiral but that could become chiral by a single substitution or addition. Citrate is a prochiral molecule because if one, and only one, of the carboxymethyl groups is substituted, say by a carboxydideuteromethyl group, the product of the substitution would be chiral. A **prochiral carbon** is any tetrahedral carbon to which are attached two chemically identical functional groups and two other functional groups, each of which is different from the two

*The absolute stereochemistry of enantiomers and diastereomers that had been previously related to each other was established in 1951 from anomalous scattering of X-rays.[458]

identical ones and different from each other, and that is capable of becoming chiral if one of the identical functional groups were replaced by a functional group different from the other two or a trigonal carbon to which are attached three different functional groups and that is capable of becoming chiral if an additional functional group, different from the other three, were attached. Although chemically identical, the two identical functional groups on a prochiral carbon can be distinguished as unique by a diastereomeric observer. For example, you, as a diastereomeric observer, can readily tell the difference between the two carboxymethyl groups on citrate: one is to the left and the other is to the right when the carboxy group is pointed away from you and the hydroxy group is pointed downward. A substitution of one and only one carboxymethyl group is formally equivalent to distinguishing the left carboxymethyl group from the right carboxymethyl group.

Properly, a prochiral, tetrahedral carbon to which the identical functional groups are attached is distinguished from the functional groups themselves, which should not be described as prochiral. The functional groups are classified as enantiotopic or diastereotopic. If replacement of one of the two identical functional groups on a prochiral, tetrahedral carbon with an achiral functional group different from the other two on the same atom would form one of a pair of enantiomers, then the two identical functional groups are **enantiotopic functional groups**. If replacement of one of the two identical functional groups on a prochiral, tetrahedral carbon with a functional group different from the other two on the same atom would form one of a pair of diastereomers, then the two identical functional groups are **diastereotopic functional groups**. If the two identical functional groups are diastereotopic, there must be a chiral center in one of the nonidentical functional groups. **Stereoheterotopic functional groups** are two identical functional groups that are either enantiotopic or diastereotopic.

The two identical but distinguishable stereoheterotopic functional groups on a prochiral center can be unambiguously designated as *pro-R* or *pro-S*.[459] Choose one of the two identical functional groups and assume that its priority is greater than the other. If this choice makes carbon *R*, the functional group chosen for elevation is the ***pro-R* functional group**; if this choice makes carbon *S*, the functional group chosen for elevation is the ***pro-S* functional group**.

A **trigonal carbon**, such as one carbon in a carbon–carbon double bond or a carbonyl carbon, can also be a prochiral carbon. A trigonal carbon is a **prochiral carbon** if addition of a functional group to that carbon, different from the other three functional groups on that carbon, would cause it to be chiral. In practice, this property usually requires that the three functional groups on the prochiral, trigonal carbon are all different from each other. The two faces of a trigonal, prochiral carbon are **enantiotopic faces** if addition to that carbon of an achiral functional group different from the other three would form one of a pair of enantiomers, and the two faces of a trigonal carbon are **diastereotopic faces** if addition to that carbon of a functional group different from the other three would form one of a pair of diastereomers. A **stereoheterotopic face** is a face that is either enantiotopic or diastereotopic. The stereoheterotopic face of a trigonal carbon is the ***Re* face** if the three functional groups, when viewed from that side of the carbon, appear in a clockwise sense in order of priority. The stereoheterotopic face of a trigonal carbon is the ***Si* face** if the three functional groups, when viewed from that side of the carbon, appear in a counterclockwise sense in order of priority.

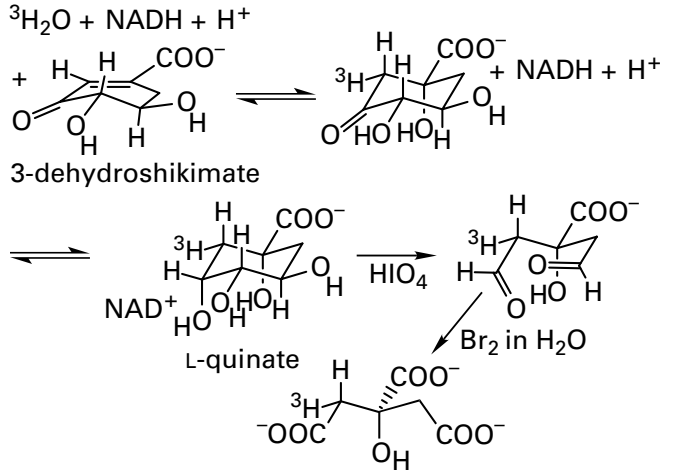
Unlike chirality, **prochirality has been of great interest in enzymology**. For example, citrate (*Si*)-synthase (previously Equation 3–226)

$$H^+ + \text{HSCoA} + \text{citrate} \rightleftharpoons H_2O + \text{oxaloacetate} + \text{acetyl-SCoA} \qquad (4\text{–}224)$$

catalyzes the aldol condensation between the enolate of acetyl-SCoA and the carbonyl group on oxaloacetate (2-oxobutanedioate) to produce citrate. In solution, the enolate would add to the carbonyl carbon in oxaloacetate from one or the other of its two surfaces with equal probability because oxaloacetate is achiral. In the active site of citrate synthase, however, it can approach from only one of the two possible directions because both the enolate and the carbonyl group are held in unique orientations. Because this stereochemical question arises only in the context of the enzymatic reaction, it is relevant to the mechanism of the enzyme but not to the stereochemistry of citrate itself.

In a homogenate from *Klebsiella aerogenes* containing ^3H_2O, NADH, and two enzymes, 3-dehydroquinate dehydratase and quinate dehydrogenase, 3-dehydroshikimate is hydrated by the first enzyme

and then reduced by the second to produce (6*R*)-[6-^{3}H]-L-quinate. L-Quinate is a compound the absolute stereochemistry of which had been determined by organic chemists in the past. The (6*R*)-[6-^{3}H]-L-quinic acid produced by the two enzymes was oxidized with periodic acid and then further oxidized with bromine

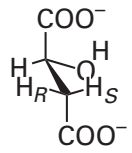


(4–225)

to produce citrate tritiated only in the *pro-R* carboxymethyl group.* This synthetic (2*R*,3*R*)-[2-^{3}H]citrate, when equilibrated with porcine aconitate hydratase, lost all its tritium to water. It had been previously demonstrated that one of the two tritiums in citrate produced from [3,3-$^3H_2$]oxaloacetate is also lost to water on equilibration with aconitate hydratase while neither of the two tritiums on citrate produced from [2,2,2-$^3H_3$]acetyl-SCoA is lost to water on equilibration with aconitate hydratase. Consequently, the *pro-R* carboxymethyl group in citrate produced by animal citrate synthase must come from oxaloacetate, and the *pro-S* carboxymethyl group must come from the enolate of acetyl-SCoA.[460]

It was later found that the citrate synthase from *Clostridium kluyveri* produces citrate in which the *pro-R* carboxymethyl group, rather than the *pro-S* carboxymethyl group, comes from the enolate of acetyl-SCoA.[461] In the two active sites, the enolates of acetyl-SCoA are held on opposite sides of the carbonyl, the *Si* face and the *Re* face, respectively, of oxaloacetate.[462] The animal enzyme is citrate (*Si*)-synthase, and the bacterial enzyme is citrate (*Re*)-synthase. Since it is cryptic, the stereochemistry of citrate synthase is irrelevant to metabolism.

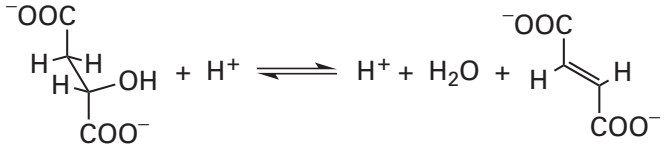
An elucidation of the stereochemistry of an enzymatic reaction that removes a stereoheterotopic hydron from a prochiral methylene carbon or that adds a stereoheterotopic hydron to a trigonal, prochiral carbon to produce a prochiral methylene carbon provides information about the relative positions of catalytic acids and bases within the active site. As with a skeletal model of citrate, when you observe the skeletal model of a substrate such as (*S*)-malate



4–49

you can readily distinguish the two hydrogens on carbon 3 because you are diastereomeric. If carbon 2 is placed behind and carbon 4 is placed in front and down, as in the view of **4–49,** one hydrogen on carbon 3 is to the right and the other is to the left. No matter how the skeletal model is rotated in space or about its bonds, you can always identify the right hydrogen and the left hydrogen. In this instance, the two hydrogens are diastereotopic hydrogens. Replacement of either would produce a diastereomer because of the chiral center at carbon 2.

When (*S*)-malate is bound as a reactant to fumarate hydratase



(4–226)

from *M. tuberculosis*, it is bound with the two carboxylato groups in the trans configuration because the product, fumarate, is the *trans*-acid. The two carboxylato groups and the hydroxy group participate in hydrogen bonds with particular amino acids at the proper locations (Figure 4–27),[463,464] and these hydrogen bonds pin the substrate in the trans configuration with the carboxylate adjacent to the hydron to be removed in the proper rotational orientation

*Although it is not relevant to the stereochemical determination because all that was required was to place a tritium anywhere on only the *pro-R* carboxymethyl group, the stereochemistry of the hydration catalyzed by 3-dehydroquinate dehydratase is a syn addition as shown.

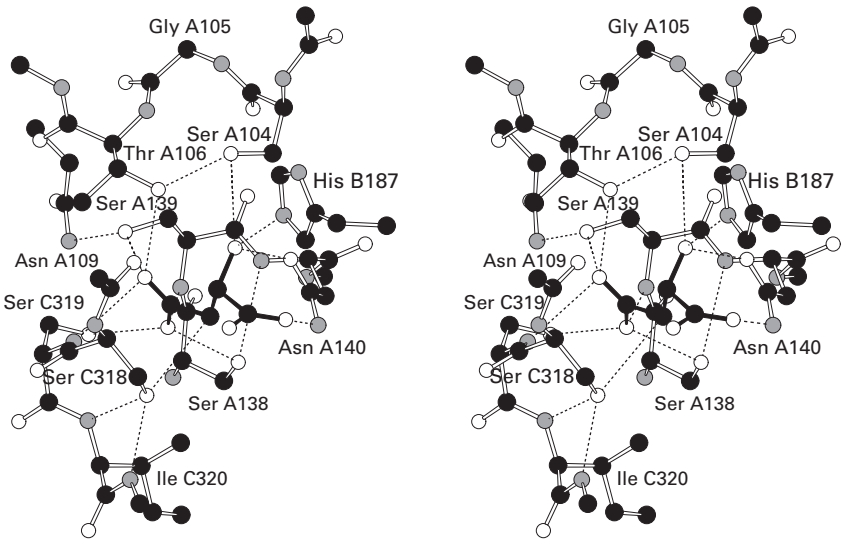


Figure 4–27: Stereodrawing[134] of the crystallographic molecular model of the active site of fumarate hydratase from *M. tuberculosis* occupied by the substrate (*S*)-malate (black bonds).[464] Black atoms are carbons, white atoms are oxygens, and small gray atoms are nitrogens. The enzyme was expressed in *E. coli*, purified, and crystallized in 26.5% (v/v) PEG400, 5% (v/v) glycerol, 200 mM $CaCl_2$, and 100 mM 2-ammonio-2-(hydroxymethyl)-propane-1,3-diol chloride at pH 8.6. Crystals of the enzyme were soaked in the solution from which they were crystallized, supplemented with 20 mM fumarate. A data set to Bragg spacing of 0.22 nm was collected. Electron density consistent only with (*S*)-malate was observed in the active site. Each of the four active sites in the homotetramer is constructed from amino acids from three of the subunits. In the drawing, the amino acids from each subunit are distinguished with the letters A, B, and C. There is only one paradigmatic catalytic acid–base, Histidine B187, which is responsible for hydronating the leaving hydroxy group. The two oxyanions at carbon 1 of the *gem*-enediolate occupy two adjacent oxyanion holes, one formed by the amido nitrogen–hydrogen of Serine A139 and the hydroxy groups of Serine A138 and Serine C319 and the other formed by the amido nitrogen–hydrogen of Serine C319 and the hydroxy groups of Threonine A106 and Serine A139. Notice that the elimination is forced by the active site to be almost precisely anti.

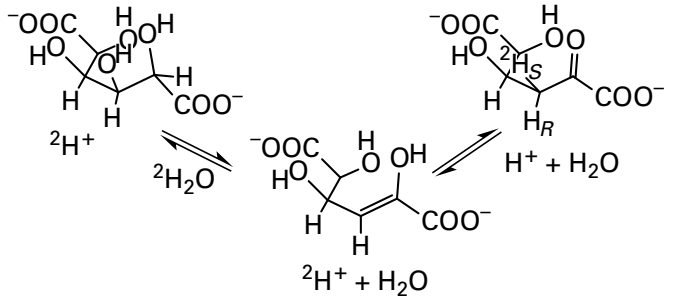
to achieve maximal overlap between its π molecular orbital system and the σ bond between carbon 3 and the hydron that will be removed. There is a catalytic base within the active site responsible for removing the hydron from carbon 3 during the elimination. That **catalytic base is positioned so that it can remove only one of the two stereoheterotopic hydrons on the prochiral carbon**. This positioning results from the fact that the most efficient way to accomplish such a difficult transfer is for the **the hydron to be on the line of centers** between carbon 3 and the heteroatom of the catalytic base. Consequently, during the enzymatic reaction, the hydron removed from almost every molecule of (*S*)-malate will be the same one, either *pro-R* or *pro-S*, in almost every turnover, and the hydron added to carbon 3 of almost every molecule of fumarate will end up being only the *pro-R* or the *pro-S* hydrogen because every active site in the solution is the same diastereomer.

The stereochemistry for the removal of a stereoheterotopic hydron, hydrogen atom, or hydride is usually elucidated by using deuterium or tritium to replace selectively one of the two stereoheterotopic hydrogens, or both of them in turn, in the reactant. Likewise, the stereochemistry for addition of a hydron, hydrogen, or hydride to produce a prochiral carbon is usually elucidated by requiring the enzyme to add deuterium or tritium to produce a chiral carbon in the product rather than a prochiral carbon. For example, when the hydration of fumarate by porcine fumarate hydratase (50% identity and 1.1 gap percent relative to that from *M. tuberculosis*) proceeds in ^2H_2O, the product is (2*S*,3*R*)-[3-^{2}H]malate.[465-467] Consequently, every time a molecule of fumarate is converted by the active site to (*S*)-malate, the hydron almost always is added to the *Re* face of carbon 3 and becomes the *pro-R* hydrogen on carbon 3. Conversely, every time a molecule of (*S*)-malate is converted to fumarate by porcine fumarate hydratase, the *pro-R* hydrogen on carbon 3 is almost always removed, not the *pro-S*, because the *pro-R* side is the side of the reactant on which the catalytic base in the active site just happened to end up as evolution by natural selection proceeded.

If a catalytic base in an active site removes only one of the two stereoheterotopic hydrons from a prochiral carbon, as is the case in fumarate hydratase, it must also be true that the resulting catalytic acid in the active site of an enzyme can create a prochiral carbon by **stereoheterotopic addition of a hydron**, as is also in the case in fumarate hydratase. Any **planar, trigonal, prochiral carbon** has a *Re* face and a *Si* face, which can be distinguished as unique by a diastereomeric observer or active site. If one and only one of the three functional groups around a trigonal, prochiral carbon is a hydrogen, then addition of another hydrogen to that carbon produces a tetrahedral, prochiral carbon. For example, galactarate dehydratase (D-*threo*-forming) from *Agrobacterium tumefaciens* catalyzes the dehydration of *meso*-galactarate* and subsequent tautomerization of the resulting enol



(4–227)

to give (2*S*,3*R*)-2,3-dihydroxy-5-oxohexanedioate. When the reaction is carried out in ^2H_2O, a deuteron ends up in the *pro-S* position on carbon 4 of (2*S*,3*R*)-2,3-dihydroxy-5-oxohexanedioate (Figure 4–28) because the catalytic acid that adds the hydron is on the *Si* face of the carbon–carbon double bond in the enol.[468] The *S*-hydroxy group on the carbon in the reactant is replaced by the *pro-S* deuteron in the product, so the reaction proceeds with **retention of configuration** at carbon 4. Because the deuteron from ^2H_2O ends up on only one of the two diastereotopic positions on carbon 3, it must be the case that a catalytic acid in the active site adds the hydron to carbon 3 rather than the keto–enol tautomerization occurring in solution after the enol is released as a product. This determination is not inconsequential because the keto–enol tautomerization in solution would be facile.

Unlike the active site of fumarate hydratase, however, in which the orientation of the catalytic acid–base was established by happenstance because the two faces of the achiral fumarate are identical to each other in reactivity, it may be the case that, in some instances in which diastereomeric molecules

*A *meso* compound is an achiral member of a set of diastereoisomers which also includes one or more chiral members. A *meso* compound is achiral because it is superposable on its mirror image, but it nevertheless contains two or more chiral centers so that one or more members of the set of diastereomers are chiral.

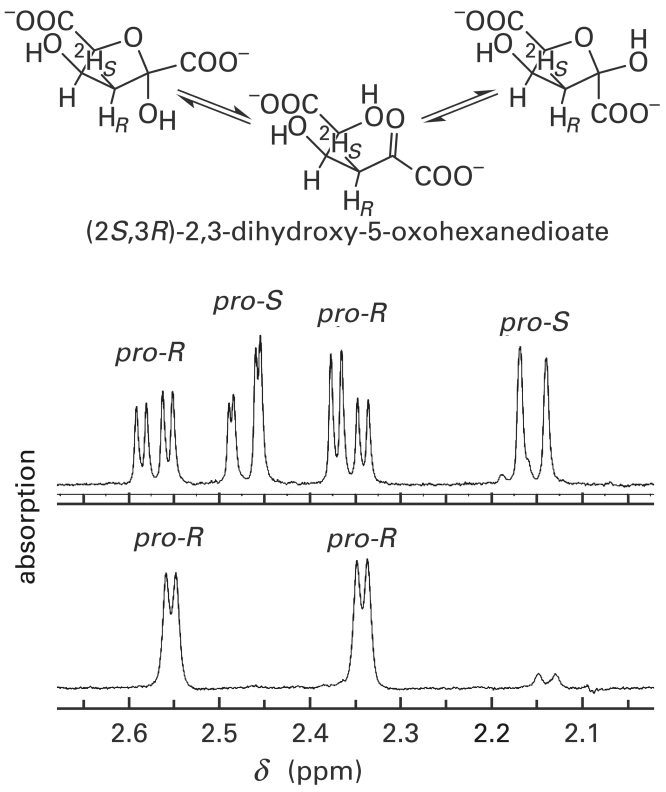


Figure 4–28: Determination of the prochiral stereochemistry of the reaction catalyzed by galactarate dehydratase (D-*threo*-forming) from *A. tumefaciens*.[468] Portions (those between 2.7 and 2.0 ppm) of two proton nuclear magnetic resonance spectra of different samples of (2*S*,3*R*)-2,3-dihydroxy-5-oxohexanedioate, the product of the enzymatic reaction when *meso*-galactarate is the reactant, are shown. These portions of the spectra contain the absorptions from the two protons on carbon 4 in the two furano anomers of (2*S*,3*R*)-2,3-dihydroxy-5-oxohexanedioate present at equilibrium in the solution. The (2*S*,3*R*)-2,3-dihydroxy-5-oxohexanedioate that gave the upper spectrum was obtained when *meso*-galactarate was dehydrated by galactarate dehydratase (D-*threo*-forming) in ^1H_2O. Absorptions from both the 4-*pro*-*S* and the 4-*pro*-*R* hydrons in (2*S*,3*R*)-2,3-dihydroxy-5-oxohexanedioate are observed. These assignments for the spectra of the anomers were made from the respective magnitudes of the vicinal C3–C4 ^1H–^1H coupling constants, ^1H–^{13}C heteronuclear single quantum coherence nuclear Overhauser effects, and ^{13}C nuclear magnetic resonance spectra. The respective absorptions are split by the other hydrogen on carbon 4 and the hydrogen on carbon 3 into doublets of doublets. Dehydration of *meso*-galactarate by the enzyme was then performed in ^2H_2O so that the hydrogen on prochiral carbon 4 that was added by the enzyme in place of the hydroxy group removed during the dehydration (Equation 4–227) would be a deuterium. The absorption from the 4-*pro*-*S* proton was missing from the spectrum (lower two panels) of the deuterated product, and the vicinal splitting of the 4-*pro*-*R* proton by the 4-*pro*-*S* hydrogen was also missing from the absorption of the 3-*pro*-*R* proton. These observations demonstrate that the hydron added by the enzyme to carbon 4 is the 4-*pro*-*S* hydrogen from (2*S*,3*R*)-2,3-dihydroxy-5-oxohexanedioate. are substrates, steric differences or differences in acidity caused by differences in the electronic configurations in the two possible diastereomeric transition states influence which hydron on the substrate is chosen by natural selection for removal. Any **isotropic solution of achiral molecules**—for example, an aqueous solution containing salts and achiral general acids and achiral general bases or achiral oxidants and achiral reductants—can make **no distinction between two enantiotopic hydrogens** on a prochiral carbon and will usually make little distinction between diastereotopic hydrogens.

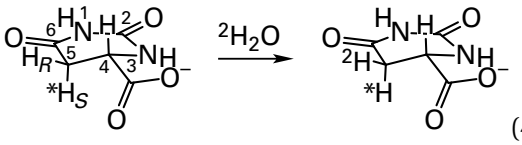
This conclusion, that a particular reaction, if carried out in free solution, would proceed with little or no distinction between *pro*-*R* and *pro*-*S* hydrogens, however, cannot be drawn unconditionally if the reactant itself, as in the case of (*S*)-malate, has a chiral center in the vicinity of the site of reaction so that the two hydrogens are diastereotopic. For example, (*S*)-5,6-dihydroorotate undergoes hydron exchange in a free solution of ^2H_2O, at pH 7.8 and 37 °C, 10-fold more rapidly at the *pro*-*R* position at carbon 5 than at its *pro*-*S* position[469]

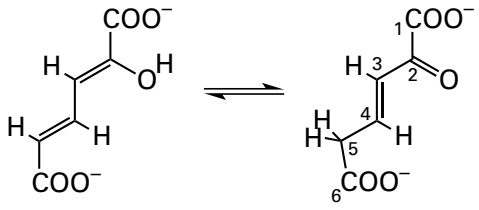


(4–228)

presumably because of the rigidity provided by the ring, the proximity of the chirality at carbon 4, and the steric hindrance produced by the carboxylato group. Regardless, however, of this steric preference in solution, bovine dihydroorotate dehydrogenase (quinone), within the error of measurement, removes only the *pro*-*S* hydrogen from carbon 5. The intermediate enol in the enzymatic reaction is generated by removal of a hydron by a catalytic base in the active site positioned by natural selection, for no apparent reason, to remove the less acidic, more sterically hindered hydron of the reactant.

The example of dihydroorotate dehydrogenase illustrates the point that **the final choice of which stereoheterotopic hydron on a prochiral carbon is removed by a catalytic base or added by a catalytic acid in the reverse reaction proceeding in an active site is arbitrary**. Unless there are overriding chemical advantages, the choice is the random outcome of evolution by natural selection, has no metabolic consequences, and is **inconsequential, cryptic, and not a factor in natural selection**. The choice of which stereoheterotopic hydron is removed or added is a result only of the arbitrary absolute config-

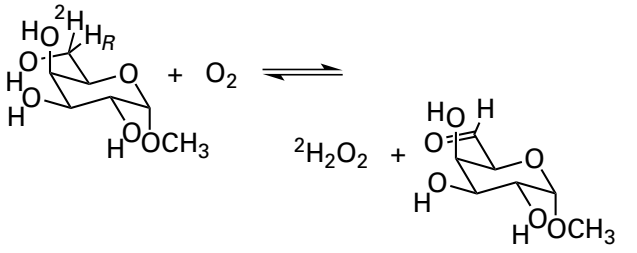
uration of the active site. For the same reason that you are, the active site of an enzyme is also diastereomeric. Just as you are formed from diastereomeric molecules of protein, it is formed from a diastereomeric molecule of protein. A molecule of protein is diastereomeric in large part because it is assembled from only L-amino acids. When 2-hydroxymuconate tautomerase



(4–229)

from *P. putida* was synthesized from D-amino acids, the synthetic D-enzyme catalyzed the same reaction because the two substrates are achiral, but its active site produced [5*R*-^{2}H]-(3*E*)-2-oxohex-3-enedioate from (2*Z*,4*E*)-2-hydroxyhexa-2,4-dienedioate when the reaction was run in ^2H_2O by adding the hydron to the *Re* face of the carbon–carbon double bond. In contrast, the natural L-enzyme in ^2H_2O produces [5*S*-^{2}H]-(3*E*)-2-oxohex-3-enedioate by adding the hydron to the *Si* face of the carbon–carbon double bond.[470]

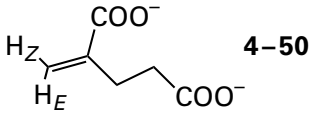
Although most active sites are not nearly so selective as that of enoyl-CoA hydratase (Equation 4–223), the **selectivity of an active site for removal of stereoheterotopic hydrogens is usually quite high**. For example, the diastereotopic hydrogen removed from carbon 6 of methyl α-D-galactopyranoside by galactose oxidase (previously Equation 2–305)



(4–230)

from *Gibberella zeae* is the *pro-S* hydrogen 98% ± 2% of the time,[433] and the enantiotopic hydrogen abstracted from glycine by glycine oxidase from *B. subtilis* is the *pro-S* hydrogen 99% of the time.[471] That **the stereoheterotopic preference at a prochiral carbon is never absolute**, however, is indicated by the fact that when deuterium rather than protium must be removed during the enzymatic reaction, the degree of stereochemical preference is usually measurably less.[433,469,471]

In the cases of hydronation of fumarate in the active site of fumarate hydratase and hydronation of the intermediate enol in the active site of galactarate dehydratase (D-*threo*-forming), the hydron or deuteron is added to one face of a prochiral carbon. If the two other positions around a carbon in a double bond are hydrogens, then the carbon itself is not prochiral. If, however, the carbon at the other end of the double bond has two different functional groups, then the two hydrogens on the first carbon can nevertheless be distinguished as **the *E* and *Z* hydrogens**, respectively, depending on their locations relative to the functional group of higher priority on the adjacent carbon across the double bond. For example, the two protiums on 2-methyleneglutarate can be distinguished as *E* (*entgegen*) or *Z* (*zusammen*) relative to the carboxy group, which has the highest priority



4–50

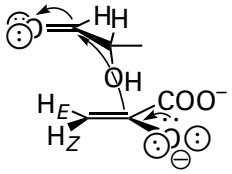
The absorptions of *E* and *Z* hydrogens in a nuclear magnetic resonance spectrum have different chemical shifts. For example, when the *E* protium is replaced synthetically by deuterium, the equilibration of the deuteron between the *E* and *Z* positions positions in the reactant [*E*-^{2}H]-2-methyleneglutarate by 2-methyleneglutarate mutase (Table 2–3) from *Eubacterium barkeri* can be followed by nuclear magnetic resonance spectroscopy.[472] This equilibration is evidence that there is an intermediate in the enzymatic isomerization such as a radical, carbanion, or carbenium ion in which the double bond has been broken; that the radical, carbanion, or carbenium ion is on the carbon with the hydrogen and the deuterium; and that the intermediate has a lifetime long enough to permit free rotation at the methylene carbon. Free rotation of a planar trigonal carbon with two hydrogens around a single bond to the rest of the molecule is difficult if not impossible to prevent.

Phospho*enol*pyruvate with a carbon–carbon double bond in which one carbon has two hydrogens attached to it is involved in many enzymatic reactions. Both **(*E*)- and (*Z*)-[3-^{2}H]phospho*enol*-pyruvate** have been synthesized[473-475] and have been used in stereochemical studies. Addition of carbon, nitrogen, oxygen, or sulfur to carbon 3 of

phospho*enol*pyruvate causes carbon 3 to become prochiral. For example, in the enzymatic reaction catalyzed by 3-deoxy-8-phosphooctulonate synthase

D-arabinose 5-phosphate + phospho*enol*pyruvate + H_2O ⇌ phosphate + 2-dehydro-3-deoxy-D-octonate 8-phosphate (4–231)

the trigonal carbon 3 of phospho*enol*pyruvate becomes the tetrahedral, prochiral carbon 3 of the 2-dehydro-3-deoxy-D-octonate 8-phosphate, which is (4*R*,5*R*,6*R*,7*R*)-4,5,6,7,8-pentahydroxy-2-oxooctanate 8-phosphate. When the active site of the enzyme from *E. coli* adds the enolate of (*Z*)-[3-^{2}H]phospho-*enol*pyruvate to the aldehydic carbonyl of arabinose 5-phosphate, the product is (3*S*)-[3-^{2}H]-2-dehydro-3-deoxy-D-octonate 8-phosphate. When (*E*)-[3-^{2}H]phospho*enol*pyruvate is used as reactant, the product is (3*R*)-[3-^{2}H]-2-dehydro-3-deoxy-D-octonate 8-phosphate.[476] In each product, when unlabeled phospho*enol*pyruvate is used as reactant, carbon 3 is prochiral. Both of these complementary stereochemical observations, as well as the known stereochemistry of the undeuterated product, demonstrate that the *Si* face of the enolate of pyruvate, resulting from hydrolysis of the phospho group of phospho*enol*pyruvate, adds to the *Re* face of the formyl group of D-arabinose 5-phosphate[477]

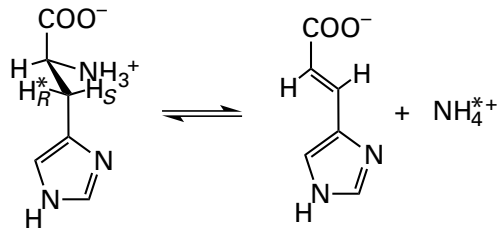


4–51

In this instance, the **stereochemistry of the prochiral product defines the orientation of each reactant relative to the other** rather than the orientation of a catalytic acid–base because neither hydrogen is removed during the enzymatic reaction. Consequently, in this instance, the two hydrogens are reporter groups reporting on the stereochemistry.

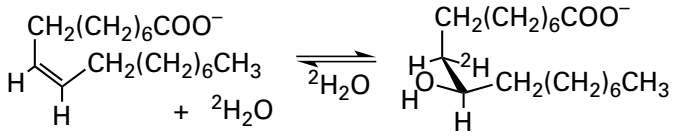
Fumarate hydratase catalyzes an anti **addition–elimination** (Equation 4–226). This conclusion was based on the facts that the (*S*)-hydroxy group is the leaving group in the elimination, addition of the hydroxy group always produces (*S*)-malate, the hydron is added to the *Re* face of carbon 3 in fumarate, the *pro-R* hydrogen on carbon 3 of (*S*)-malate is removed during the elimination, and fumarate is the *trans*-diacid. In aqueous solution, such **addition–eliminations that involve general base catalysis usually proceed in an anti sense**, with the general base that removes the hydron from the side of the reactant opposite the side from which the leaving group departs.[478] This preference may be due entirely or only in part to steric effects that would result if the general base and the leaving group were required to sit on the same side of the reactant in a syn elimination.

As in the case of fumarate hydratase, many **enzymatic reactions also show this anti preference**. For example, histidine ammonia-lyase from *Pseudomonas striata* catalyzes the anti elimination of ammonia from L-histidine



(4–232)

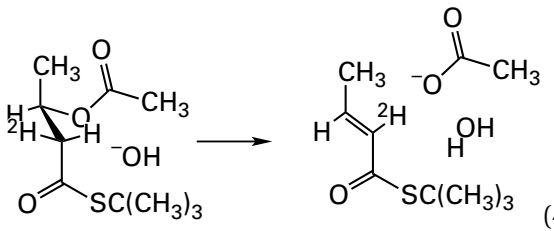
because the *pro-R* hydron is removed[479] and added[480] during the reaction and the product of elimination is the *trans*-acid. Addition of water to the aliphatic double bond in oleic acid, catalyzed by an enzyme from a pseudomonad, also proceeds in an anti sense



(4–233)

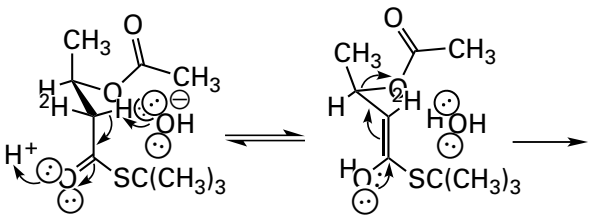
because the reactant acid is cis, carbon 10 in the product is *R*, and deuterium ends up at the *pro-R* position on carbon 9 when the reaction is carried out in ^2H_2O.[481]

It has been found, however, that certain eliminations that occur in solution, in particular, eliminations proceeding through carbanionic intermediates or eliminations involving ion pairing between the leaving group and the general base that removes the hydron, can yield variable percentages of the products of syn elimination.[478] A particularly relevant example for the present purposes is the elimination of acetate from (2*R*,3*R*)-*S*-*tert*-butyl-3-acetoxy-[2-^{2}H]butanethioate with catalysis by hydroxide[482]



(4–234)

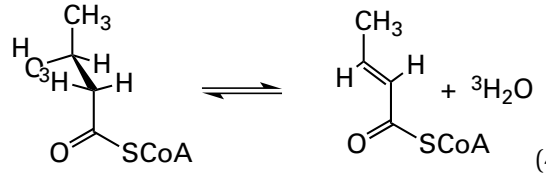
The yield of deuterated product (43% of the total yield of the *E* isomer) was used to calculate that when carbon 2 has two hydrogens and no deuterium kinetic isotope effect is operating, the yield of syn product (Equation 4–234) would be 14%. This elimination probably proceeds through an intermediate enol



(4–235)

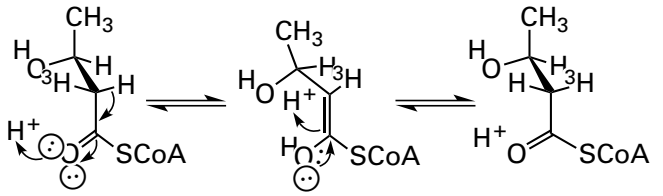
In any event, the product ratios observed suggest that the difference in free energy of activation between syn and anti elimination–addition is probably fairly small and can be influenced considerably by the conditions.

Syn elimination–additions adjacent to a carbonyl group or an acyl group permitting an intermediate enol have also been observed in enzymatically catalyzed reactions. The dehydration of (2*R*,3*S*)-3-hydroxy[2-^{3}H]butyryl-SCoA to produce crotonyl-SCoA, catalyzed by bovine enoyl-CoA hydratase



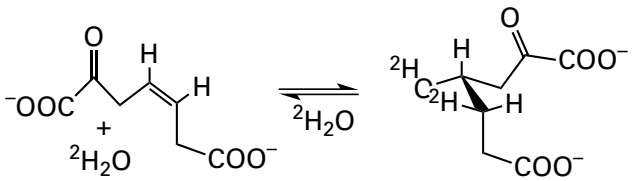
(4–236)

produces trans product that has only 20% the specific radioactivity of the reactant.[483] Therefore, even though the tritium kinetic isotope effect would be against the reaction as it is found to occur, the enzyme nevertheless removes the triton because it is in the *pro-R* position and aligned with a catalytic base in the active site, and the reaction is a syn elimination. Upon correction for the kinetic isotope effect, a hydron in the *pro-S* position is removed by the enzyme from (3*S*)-3-hydroxybutyryl-SCoA at a rate more than 200 times slower than a hydrogen in the *pro-R* position,[289,450] even though the carbon–hydrogen bond should be more sterically accessible, because it is on the opposite side of the reactant from the hydroxy group as it is held in the active site with the methyl and acyl carbons in the necessary trans configuration. The reason that the exclusivity is probably greater than a factor of 200 is that tritium remaining in the product (20%) of elimination from tritiated reactant probably arises in part from nonenzymatic racemization of the reactant during its synthesis or during the incubation



(4–237)

Addition of ^2H_2O to the cis double bond in *Z*-2-oxohept-4-ene-1,7-dioate catalyzed by 2-oxohept-4-ene-1,7-dioate hydratase from *E. coli*



(4–238)

is a syn addition because the reactant is cis and the product has the *S* configuration at both carbon 4 and carbon 5.[484] At first glance, hydration would seem to be an addition to a carbon–carbon double bond unconjugated to a carbonyl, but during the overall addition, a deuteron stereospecifically replaces a hydron on carbon 3 that is α to the carbonyl group at carbon 2, so the mechanism[485] is initiated by removal of this hydrogen as a hydron to produce the conjugated dienolate. Then carbon 5 of the dienolate is hydronated to produce the α,β-unsaturated carbonyl, and the equivalent of a hydroxide adds to carbon 4, the β carbon, in a Michael addition to produce the enolate, which is then rehydronated on carbon 3. The last step places the deuteron from ^2H_2O on carbon 3. Nevertheless, additions of a hydron to carbon 4 and of a hydroxide to carbon 5 are syn, a stereochemical result suggesting that the conjugate base of the catalytic acid that added the hydron

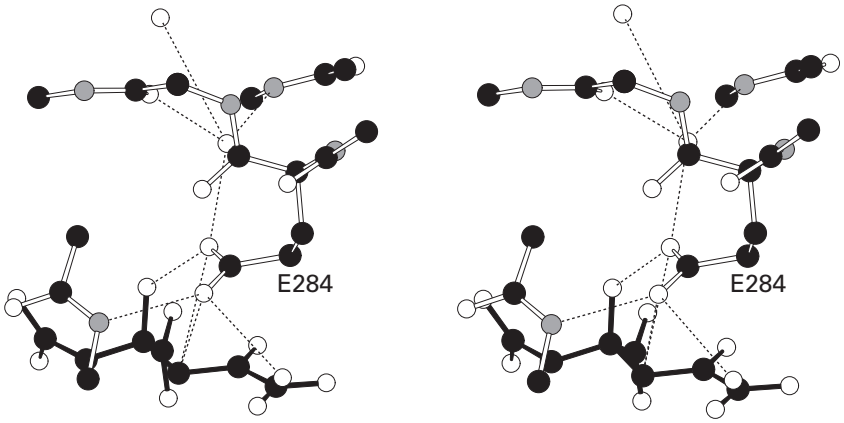


Figure 4–29: Stereodrawing[134] of the active site in the crystallographic molecular model of 2-oxo-4-carboxy-3-hexenedioate hydratase from *Sphingobium* occupied by (4*S*)-2-oxo-4-carboxy-4-hydroxyhexanedioate (black bonds).[487] Black atoms are carbons, white atoms are oxygens, and small gray atoms are nitrogens. Deoxyribonucleic acid encoding the entire gene of the enzyme was chemically synthesized and incorporated into a plasmid that permitted it to be expressed in *E. coli* with six consecutive histidines at its amino terminus. The protein was purified on a solid phase on which nickel ions had been chelated. The purified protein was crystallized from a solution in which (4*S*)-2-oxo-4-carboxy-4-hydroxyhexanedioate and 2-oxo-4-carboxyhex-3-enedioate were first brought to equilibrium by the enzyme in a total concentration of 1.3 mM along with 12% poly(ethylene glycol) and 0.1 M sodium malonate at pH 5. Diffraction data to Bragg spacing of 0.202 nm were collected, and a map of electron density was calculated. Phases were obtained by molecular replacement using the crystallographic molecular model of the enzyme from *R. palustris*. The substrate (4*S*)-2-oxo-4-carboxy-4-hydroxyhexanedioate within the active site is drawn along with the side chain of Glutamate 284. Several molecules of water, which connect the oxygens of the carboxy group of Glutamate 284 with the solution, are also drawn, as well as donors and acceptors for hydrogen bonds to the molecules of water and one of the oxygens of the carboxy group. The two donors and the one acceptor are from amido groups in the polypeptide backbone.

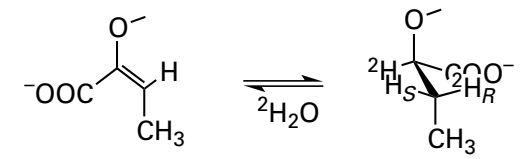
to carbon 5 of the dienolate, possibly the carboxy group of Aspartic Acid 79,[486] then removes a hydron from the molecule of water that adds to carbon 4 from the same side of the resulting α,β-unsaturated carbonyl.

In the active site of 2-oxo-4-carboxy-3-hexenedioate hydratase from *Sphingobium*, which performs a syn addition of water to carbon 3 and carbon 4 of the α,β-unsaturated carbonyl in (3*Z*)-2-oxo-4-carboxyhex-3-enedioate when it is the reactant, one of the oxygens of the carboxylato group of Glutamate 284 removes the hydron from the molecule of water as it adds to the β carbon to produce the enolate. This oxygen also delivers a hydron to the α carbon of the enolate to complete the hydration. Ironically, in this instance, the stereochemistry was assigned as syn from the crystallographic molecular model of the complex between the active site and the substrate (4*S*)-2-oxo-4-carboxy-4-hydroxyhexanedioate (Figure 4–29),[487] which is the product of the hydration and the preferred participant in the equilibrium within the active site. One of the oxygens of the carboxy group of Glutamate 284, which was shown to be the required catalytic acid–base by site-directed mutation, is only 0.28 nm from the *pro-S* hydrogen on carbon 3 that is hydronated in the hydration but distant from the *pro-R* hydrogen. The other oxygen of the carboxy group forms a hydrogen bond (0.22 nm) with the hydroxy group that is added during the hydration, identifying its role as the catalytic base in the hydration. The hydration is a syn addition because the carboxy group can be on only one side of the carbon–carbon double bond.

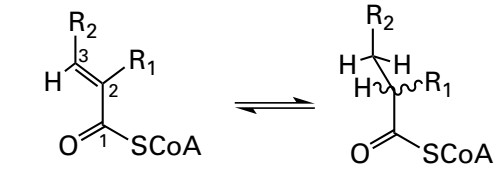
Enzymatically catalyzed **dehydrogenation–hydrogenations** at positions adjacent to a carbonyl or acyl group, because they can also involve rigid intermediate enolates, proceed with either exclusively syn or exclusively anti stereochemistry. For example, UDP-*N*-acetylmuramate dehydrogenase from *E. coli* reduces the (*E*)-1-carboxy-2-methylvinyl group



(4–239)

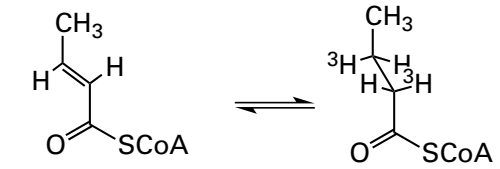
on the reactant, UDP-*N*-acetyl-3-*O*-[(*E*)-1-carboxy-2-methylvinyl]-D-glucosamine, with anti addition of a hydron and a hydride. This conclusion follows from the fact that when hydrogenation is run with NADP^{2}H in ^2H_2O, the (*E*)-1-carboxy-2-methylvinyl group becomes a (1*R*,2*R*)-[1,2-$^2H_2$]-1-carboxypropyl group.[488]

Enoyl thioester reductases reduce the double bond on their substrates with a hydride from NAD or NADPH and a hydron



(4–240)

Enzymes catalyzing this reduction, depending on the reactant reduced and the species from which they are isolated, add the hydride to either the *Re* face or the *Si* face of carbon 3 to produce the enolate. The hydron is then added to either the *Re* face or the *Si* face of carbon 2 of the enolate to proceed with either syn or anti hydrogenation.[489] For example, enoyl-[acyl-carrier-protein] reductase (NADPH) in the fatty-acyl-CoA synthase from *S. cerevisiae* performs the anti addition of a hydride from NADPH to the *Si* face of carbon 3 and of a hydron to the *Si* face of carbon 2 of crotonyl-SCoA[490]



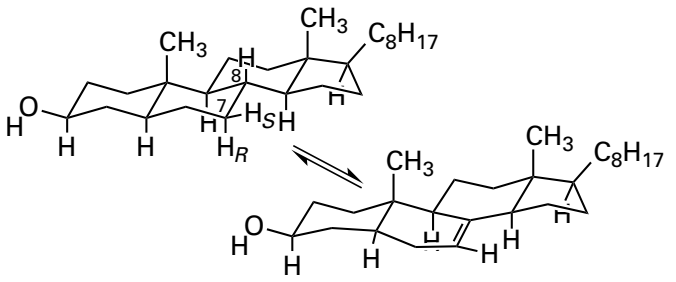
(4–241)

The same enzyme (35% identity; 2.2 gap percent) in the fatty acid synthase from *G. gallus* performs the syn addition of a hydride from NADPH to the *Re* face of carbon 3 and of a hydron to the *Si* face of carbon 2 of crotonyl-SCoA.[491]

Such examples of both stereochemical outcomes in both elimination–additions and dehydrogenation–hydrogenations adjacent to carbonyl and acyl groups again illustrate the fact that the stereochemical outcome of an enzymatic reaction often depends on the adventitious positioning of the catalytic acids and bases and prosthetic groups within the active site relative to the bound reactant or the adventitious positioning of the bound reactant within the active site relative to catalytic acids and bases and prosthetic groups, rather than any innate electronic preference of the reaction.

Enzymatically catalyzed **dehydrogenation–hydrogenations at positions unconjugated to a carbonyl**

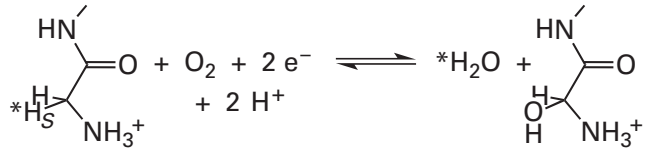
or acyl group usually proceed with syn stereochemistry.[492] The dehydrogenation of 5-α-cholestan-3β-ol to Δ^7-5α-cholestan-3β-ol, catalyzed by an enzyme in *Eurycotis floridana*



(4–242)

proceeds with removal of the methine hydrogen at carbon 8 and the *pro-S* hydrogen at carbon 7. This conclusion follows from the facts that, when (7*S*)-[7-^{3}H]-5α-cholestan-3β-ol was fed to roaches, the tritium was removed (>90%), but when (7*R*)-[7-^{3}H]-5α-cholestan-3β-ol was fed to roaches, the tritium was retained (>85%) in the product.[493] By use of the four (*Z*)-hexadec-11-enoates stereospecifically monodeuterated at the *pro-R* and *pro-S* positions at carbons 13 and 14, it could be shown that a desaturase from *Thaumetopoea pityocampa* removes the *pro-S* hydrogens from each carbon during the syn dehydrogenation of (*Z*)-hexadec-11-enoate to produce (*Z*,*Z*)-hexadeca-11,13-dienoate.[494] The oxidants in these two reactions are unknown.

The stereochemistry of **enzymatic reactions that involve radical intermediates** provides insight into the orientation in the active site relative to the substrate of a prosthetic group containing a radical or the side chain of an amino acid, such as tyrosine or tryptophan, containing a radical that can abstract a hydrogen atom from a carbon or that, in their respective hydrogenated forms, can add a hydrogen atom to a carbon radical. Such reactions involving the **abstraction of hydrogen atoms from carbon** producing intermediate radicals usually proceed in an active site with stereoheterotopic selectivity during the abstraction and during addition of a functional group to the resulting carbon radical, even though the carbon radical produced by the abstraction must be planar and chemically equivalent on both sides of the plane. For example, as noted above in passing, porcine peptidylglycine monooxygenase (previously Equation 2–309)

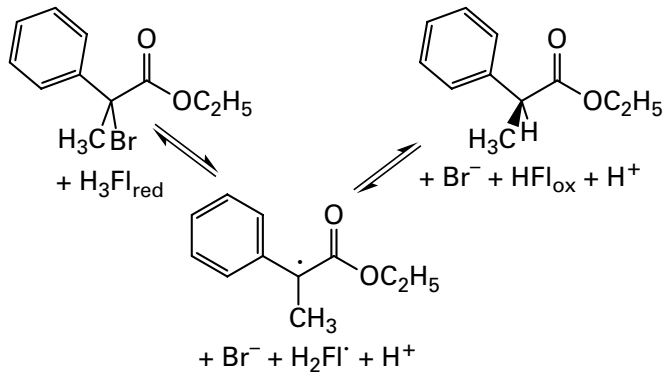


(4–243)

removes the *pro-S* hydrogen from the glycyl group of a reactant[495] and replaces that hydrogen with the equivalent of a hydroxyl radical with retention of configuration.[496] This result is consistent with a mechanism in which the hydroxylating species produced from molecular oxygen bound to one or both of the prosthetic copper ions in the active site (Figure 2–58C) abstracts the hydrogen atom and also hydroxylates the resulting glycyl radical from the same side. Consequently, the stereochemistry is consistent with the favored mechanism for the reaction and adds support to it.

A methyltransferase from *Micromonospora echinospora* uses a 5′-adenosyl radical produced from *S*-adenosyl-L-methionine to remove a hydrogen atom from the methylene of a hydroxymethyl group on a reactant and a methylcobalamin to methylate the resulting radical on the carbon of the former hydroxymethyl group. Sterically, it would make chemical sense to have the 5′-adenosyl radical positioned on one side of the plane of the radical and the methylcobalamin on the other side because both of these participants are quite large and electron density for the radical exists on both sides, but the reaction proceeds with retention of configuration.[497] Several results with alternative reactants for the enzyme and the fact that the *pro-R* hydrogen is abstracted greater than 95% of the time suggest that the hydroxymethyl group is held firmly in one orientation, presumably by hydrogen bonds to its hydroxy group. Therefore, it seems that both the methylcobalamin and the adenosyl radical produced from *S*-adenosyl-L-methionine, which are sizable molecules, somehow have access to the same side of the carbon. There is an unrelated methyltransferase from *Streptomyces fradiae* that also methylates the methylene in a hydroxymethyl group, also using both a 5′-adenosyl radical produced from *S*-adenosyl-L-methionine and methylcobalamin in apparently the same mechanism, but the methylation occurs with inversion of configuration,[498] as one might expect.

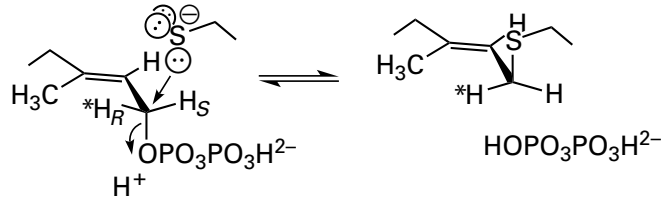
A mutant of 2-enoate reductase, a flavoenzyme from *Gluconobacter oxydans*, is able to replace bromine on ethyl 2-bromo-2-methyl-2-phenyl acetate with hydrogen. The reaction proceeds through the widely delocalized ethyl 2-phenylcarboxymethyl radical



(4–244)

which must be planar and chemically equivalent on each of its faces, *Re* and *Si*. Nevertheless, when racemic 2-bromo-2-methyl-2-phenyl acetate is used as a reactant, the enzyme debrominates both enantiomers at the same rate, but the product is almost exclusively (*S*)-2-methyl-2-phenyl acetate (97%).[499] In this instance, the prosthetic flavin that provides the hydrogen atom that adds to the radical, which is bound in the active site in only one orientation, can only be on one side of its plane, and it just happens to be on the *Re* face.

Racemization is one criterion for a nonenzymatic dissociative nucleophilic substitution at a saturated carbon that proceeds with an intermediate carbenium ion in solution. Human protein farnesyltransferase and human protein geranylgeranyltransferase, which share the same catalytic subunit, catalyze a nucleophilic substitution in which a farnesyl group or a geranylgeranyl group is transferred to the sulfido group of a cysteine in one of a set of particular proteins



(4–245)

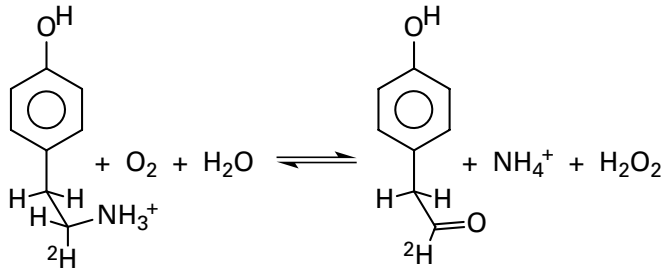
The nucleophilic substitution may[500] proceed through an allyl carbenium ion, which would be a logical intermediate because of its stability.[501] Both the (*S*)-[1-^{2}H] and (*R*)-[1-^{2}H] enantiomers of both farnesyldiphosphate[502] and geranylgeranyldiphosphate[503] were prepared synthetically. The products of their reactions with cysteinyl peptides, when catalyzed by the respective enzyme, had nuclear magnetic resonance spectra demonstrating that inversion of configuration at prochiral carbon 1 of the respective reactant had occurred in each case. This inversion of configuration is consistent with crystallographic molecular models of protein farnesyltransferase from *R. norvegicus* (97% identity relative to human) in complexes with farnesyldiphosphate and a farnesylated peptide, respectively, in which the diphospho group that leaves and the sufido group that adds are found on opposite sides of the active site.[504] They are too far apart, however, for an associative, concerted nucleophilic substitution. This separation is consistent with the evidence suggesting a dissociative nucleophilic substitution and would make perfect sense because, if the diphosphate anion were required to dissociate from the active site to make room for the sulfido group on the same side of the alkyl carbenium ion, water would certainly intervene and react with it to produce the alcohol. Consequently, the sulfido group must be waiting on the other side to react as soon as the dissociation producing the allyl carbenium ion has occurred. In reactions catalyzed by enzymes, inversion of configuration or **the lack of racemization cannot be used as an argument against a dissociative mechanism because the active site necessarily positions reactants in a particular orientation regardless of whether the reaction is dissociative or associative.**

There are instances, however, in which removal or addition of a stereoheterotopic hydrogen from or to a prochiral carbon or stereoheterotopic addition of a functional group to produce a prochiral carbon **does proceed with racemization**. For example, tyrosine 2,3-aminomutase from *Chondromyces crocatus* converts (2*S*)-[3,3-^{2}H$_2$]-L-tyrosine into a mixture of (2*S*,3*R*)- and (2*R*,3*S*)-[2,3-^{2}H$_2$]-3-amino-3-(4-hydroxyphenyl)propanoate even though the catalytic base in the active site always removes the *pro-S* deuteron from carbon 3 of the reactant. From these observations, it was concluded that the resulting deuteronated catalytic base transfers its deuteron to the *S* position on carbon 2 when the product is to be (3*R*)-[2,3-^{2}H$_2$]-3-amino-3-(4-hydroxyphenyl)-propanoate or to the *R* position on carbon 2 when the product is to be (3*S*)-[2,3-^{2}H$_2$]-3-amino-3-(4-hydroxyphenyl)propanoate. The relative proportions of the two products in the mixture vary as the pH of the solution is changed.[505]

If it can be shown that only one of the two stereoheterotopic hydrogens on a prochiral carbon is removed or added as a hydron during an enzymatic reaction, then it is evident that a catalytic base in the active site always removes that hydron or that a catalytic acid in the active site always adds that hydron, respectively. In such instances, the catalytic

base or acid could be a molecule of water, but it must be confined by the active site to act at only one stereoheterotopic position. If, however, the step in the reaction in which the hydron is removed or added had occurred in solution, such an absolute preference would not have been displayed. Consequently, one explanation for the occasional lack of stereoheterotopic discrimination leading to racemization is that the prochiral carbon from which a stereoheterotopic hydron is removed or to which a hydron is stereoheterotopically added is **well exposed to the solution while on the active site**, and molecules of water, hydroniums, or hydroxides free in the solution are relied upon by the enzyme to receive or give that hydron. It is often assumed that this involvement of the solvent is the case,[506] even in the absence of any supporting evidence.

Abstraction of hydrogen from a substrate or abstraction of hydrogen by a radical intermediate in an enzymatic reaction can also proceed with racemization. Isobutyryl-CoA mutase from *Streptomyces cinnamonensis*, which catalyzes its reaction with a prosthetic adenosylcobalamin (Table 2–3), produces [3-^{2}H]butyryl-SCoA from [2-^{2}H]isobutyryl-SCoA that is 60% *pro-R* and 40% *pro-S*.[507] Primary-amine oxidase from *O. cuniculus* produces 74% 1-deuterio-2-(4-hydroxyphenyl)ethanal from (*R*)-[1-^{2}H]tyramine



(4–246)

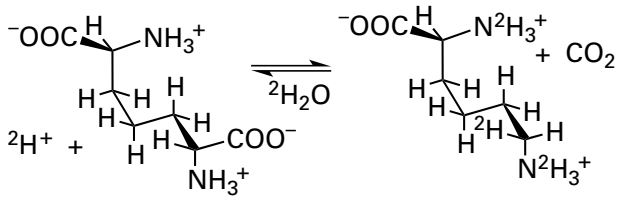
and 81% 1-deuterio-2-(4-hydroxyphenyl)ethanal from (*S*)-[1-^{2}H]tyramine.[508] These results, after correction for the kinetic isotope effect, are consistent with the enzyme removing the *pro-R* hydrogen from tyramine only 1.2 times more often than the *pro-S* hydrogen.

An assessment of the stereochemical outcome of an enzymatic reaction in which stereospecifically deuterated reactants are used or stereospecifically deuterated products are formed is usually made by nuclear magnetic resonance spectroscopy, optical rotation, circular dichroism, or mass spectrometry.

Two enantiotopic protons on a prochiral carbon in an achiral molecule are identical and indistinguishable in a nuclear magnetic resonance spectrum. If, however, there are one or more chiral centers elsewhere in the molecule, then the absorptions of the two diastereotopic protons on the prochiral carbon in the **nuclear magnetic resonance spectrum** have different chemical shifts. If the difference is large enough, then the two protons can be distinguished from each other (Figure 4–28). Because through-bond electron withdrawal is the same for both diastereotopic protons on a prochiral carbon, there is no reliable way to assign the absorptions in the spectrum to the two protons in the absence of other information. It is possible, however, as was done for the spectrum of (2*S*,3*R*)-2,3-dihydroxy-5-oxohexanedioate, to use through-space nuclear Overhauser effects to make the assignments unambiguously.[468] When a deuteron is added stereoheterotopically to a carbon that would be prochiral were a proton added, the absorption for the stereoheterotopic proton at that position in undeuterated product is no longer present in the spectrum of deuterated product (Figure 4–28), and its absence identifies the diastereotopic hydron on the prochiral carbon that is added by the catalytic acid in the active site.

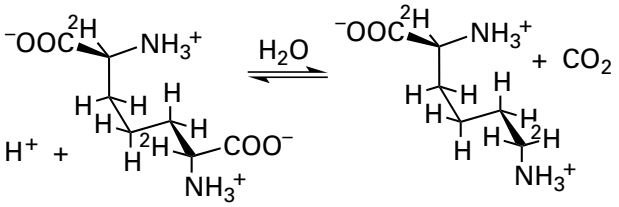
The **optical rotation** of a deuterated product can be measured to determine the outcome of an enzymatic reaction. If a hydrogen is added stereoheterotopically to a reactant to produce a prochiral carbon in the product, the enzymatic reaction is run, on the one hand, with a reactant in which the lone hydrogen on the carbon that will become prochiral has been replaced by deuterium and, on the other hand, with undeuterated reactant but with a deuterated source of the hydrogen that will be added to that carbon, usually the water. The resulting deuterated products from these two reactions will be of opposite stereochemistry at the carbon to which hydrogen or deuterium, respectively, has been added. Because they are enantiomers or diastereomers, their optical rotation can be measured and compared with the optical rotation of synthetic versions of the deuterated product of known stereochemistry.

Diaminopimelate decarboxylase from *Lysinibacillus sphaericus* catalyzes the decarboxylation of *meso*-(2*S*,6*R*)-2,6-diaminopimelate by forming its external pyridoximine in the active site from a prosthetic pyridoxal 5′-diphosphate. Because the biologically relevant (*S*)-lysine is the product, the enzyme must decarboxylate the *R* end of the *meso* reactant. Undeuterated *meso*-(2*S*,6*R*)-2,6-diaminopimelate was converted to (2*S*)-[6-^{2}H]lysine in ^2H_2O



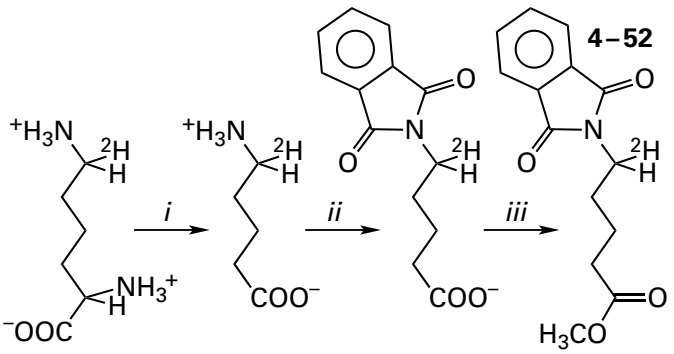
(4–247)

and *meso*-(2*S*,6*R*)-2,6-diamino-[2,6-$^2H_2$]pimelate was converted to (2*S*)-[2,6-$^2H_2$]lysine in H_2O



(4–248)

Each product, which should have the opposite stereochemistry from the other at carbon 6, was separately converted to the respective phthalimido valerate **4–52**



(4–249)

with (*i*) L-lysine oxidase,[509] (*ii*) phthalic anhydride, and (*iii*) diazomethane.[510] The resulting product has only one chiral carbon, the one on which the deuterium is located, so the two products are enantiomers of each other.

The two products had equal but opposite specific rotations at 589 nm. The specific rotation of the product from the decarboxylation of Equation 4–247 was –0.92°, and that of Equation 4–248 was +0.84°. The specific rotation of authentic (*R*)-5-phthalimido-[5-^{2}H]valerate, synthesized from L-glutamate, had a specific rotation of –0.95°. This observation demonstrated that the product from the decarboxylation of Equation 4–247 had *R* stereochemistry and that of Equation 4–248 had *S* stereochemistry. Therefore, in the normal enzymatic reaction carried out in ^1H_2O, the hydron that replaces carbon dioxide becomes the *pro-R* hydrogen at carbon 6 of the product, and the reaction proceeds with inversion of configuration at that carbon.

When a stereoheterotopic hydrogen in a compound is replaced by deuterium, the replacement either creates **circular dichroism,** if the compound was achiral before the replacement, or alters the prexisting circular dichroism, if the compound was chiral before the replacement. For example, (3*E*)-2-oxohex-3-enedioate, the product of the reaction catalyzed by 2-hydroxymuconate tautomerase (Equation 4–229), is an achiral molecule. When the reaction is run in ^2H_2O, a deuterium is added by the active site to carbon 5. The [5-^{2}H]-(3*E*)-2-oxohex-3-enedioate produced by the enzyme was converted, with lead acetate in acetic acid followed by potassium permanganate in sulfuric acid, into [2-^{2}H]glutaric acid, which had a molar ellipticity of +180° at 210 nm. (2*S*)-[2-^{2}H]Glutaric acid and (2*R*)-[2-^{2}H]glutaric acid were synthesized chemically in a route that involved significant racemization at carbon 2. Nevertheless, the synthetic (2*S*)-[2-^{2}H]glutaric acid had a molar ellipticity of +110° at 210 nm, and the synthetic (2*R*)-[2-^{2}H]glutaric acid had a negative molar ellipticity. These results demonstrate that the catalytic acid in the active site of the enzyme adds the hydron that becomes the *pro-S* hydron at carbon 5 in (3*E*)-2-oxohex-3-enedioate.

When a particular stereoheterotopic hydrogen is removed by an active site from a prochiral carbon and the two stereoheterotopic hydrogens on the chiral carbon in the reactant are replaced in turn by deuterium, **mass spectrometry** can determine the outcome of the two reciprocal reactions. The pair of monodeuterated reactants in which the *pro-R* and *pro-S* hydrogens, respectively, have been replaced by deuterium are synthesized, and the mass spectra of products of the enzymatic reaction from each reactant can reveal which hydrogen is removed by the active site. For example, synthetic methyl [6*S*-^{2}H]-*α*-D-galactopyranoside was converted to 1-*O*-methyl-*α*-D-galactose-6-aldehyde by galactose oxidase (Equation 4–230), and the enzymatic product was then converted chemically with *tert*-butyldimethylsilyl trifluoromethanesulfonate to 1-*O*-methyl-2,3,4-tris-(*tert*-butyldimethylsilyl)-*α*-D-*galacto*-pyran-6-aldehyde. The molecular ion of this final silylated product had a mass of 409 unified atomic mass units, but when synthetic methyl [6*R*-^{2}H]-*α*-D-galactopyranoside was used as a reactant and the product of the enzymatic reaction was *tert*-butyldimethylsilylated, the molecular ion of the final product had a mass of 410 unified atomic mass units. Further-

more, the pattern of secondary ions for the final product from the [6*S*-^{2}H] diastereomer was the same as that from undeuterated reactant, and the pattern of secondary ions for the final product from the [6*R*-^{2}H] diastereomer was the same as that from the deuterated [6,6-$^2H_2$] reactant.[433] These results demonstrate that the *pro-S* hydrogen is abstracted from methyl α-D-galactopyranoside by the prosthetic copper–hydroxyphenyl radical in the active site.

To avoid any ambiguity, stereochemical studies of enzymatic reactions should be designed so that **both stereochemical outcomes at a prochiral carbon are examined** by one of these techniques in turn.

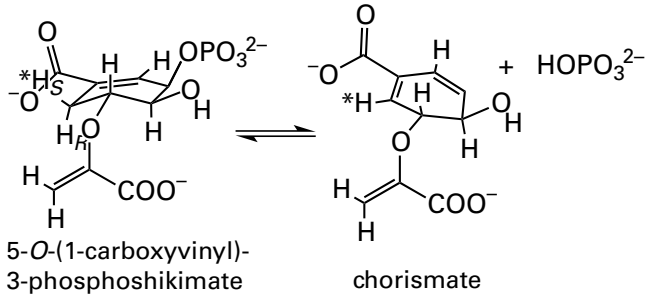
If the question to be answered is which of the two stereoheterotopic hydrogens on a particular **prochiral carbon in the reactant** is removed by a catalytic base or prosthetic group in the active site, then deuterium is positioned synthetically at each of the two stereoheterotopic positions on that chiral carbon in turn. For example, both the synthetic 6*S* and the synthetic 6*R* diastereomers of methyl [6-^{2}H]-α-D-galactopyranoside were converted to 1-*O*-methyl-α-D-galactose-6-aldehyde by galactose oxidase (Equation 4–230), and the catalytic base in the active site removed the 6*S* deuterium from the former but removed the 6*S* hydrogen from the latter.[233] Consequently, the prosthetic copper–hydroxyphenyl radical always abstracts the *pro-S* hydrogen from methyl α-D-galactopyranoside during the normal enzymatic reaction.

If the question to be answered is which of the stereoheterotopic hydrogens on a particular chiral carbon has been added to give a **prochiral product** by a catalytic acid or a prosthetic group in the active site, then the stereochemistry of the product of the enzymatic reaction is inverted to give two opposite stereochemical products at that chiral carbon. For example, in the stereochemical study of the reaction catalyzed by diaminopimelate decarboxylase, (2*S*,6*R*)-2,6-diaminopimelate was converted to (6*R*)-[6-^{2}H]-L-lysine in ^2H_2O (Equation 4–247), and (2*S*,6*R*)-2,6-diamino-[2,6-$^2H_2$]pimelate was converted to (6*S*)-[2,6-$^2H_2$]-L-lysine in H_2O (Equation 4–248). It could be concluded from the results that the hydron that replaces carbon dioxide during the normal enzymatic reaction almost always becomes the *pro-R* hydrogen in the product. The occurrence of the reciprocal outcomes in a stereochemical study provides reassurance that the observations resulted from only the stereochemistry of the active site rather than some anomalous kinetic isotope effect.

The ultimate assignment of the absolute stereochemistry of the pair of reactants presented separately to an enzyme or the pair of products produced separately by an enzyme is usually **based on an unambiguous stereochemical synthesis**, either enzymatic or chemical, of one or both members of the labeled pair of reactants or products. For example, the two deuterated stereoisomers of the reactant methyl α-D-galactopyranoside that were converted 1-*O*-methyl-α-D-galactose-6-aldehyde by galactose oxidase (Equation 4–230) were synthesized stereospecifically, and the two stereoisomers of the product, L-lysine, in the case of diaminopimelate decarboxylase (Equations 4–247 and 4–248) were synthesized stereospecifically.

An example of such a stereochemical synthesis would be that for the two diastereomers of D-[6-^{2}H]shikimate with opposite stereochemistry at carbon 6 (Figure 4–30).[511] The stereochemistry of the final product at carbon 6 is dictated by the fact that the Diels–Alder cycloaddition retains the stereochemistry of the dienophile, so H_Z ends up cis to the methoxycarbonyl group and H_E ends up trans.[512] The two D-[6-^{2}H]shikimates of known stereochemistry were synthesized from the two appropriate methyl deuterioacrylates. In the separate syntheses, methyl (*Z*)-[3-^{2}H]acrylate yields (3*R*,4*S*,5*R*,6*R*)-[6-^{2}H]shikimate, and methyl (*E*)-[2,3-$^2H_2$]acrylate yields (3*R*,4*S*,5*R*,6*S*)-[6-^{2}H]shikimate.[511]

When these two diastereomers, each the product of a separate stereochemical synthesis, were separately incubated with the bacterium *E. coli*, (3*R*,4*S*,5*R*,6*S*)-[6-^{2}H]shikimate was the precursor to deuterio-L-phenylalanine and (3*R*,4*S*,5*R*,6*R*)-[6-^{2}H]shikimate was the precursor to undeuterated L-phenylalanine, as determined by mass spectrometry of the products. Between shikimate and L-phenylalanine, the hydrogen at carbon 6 of the shikimate is removed during the elimination catalyzed by chorismate synthase



(4–250)

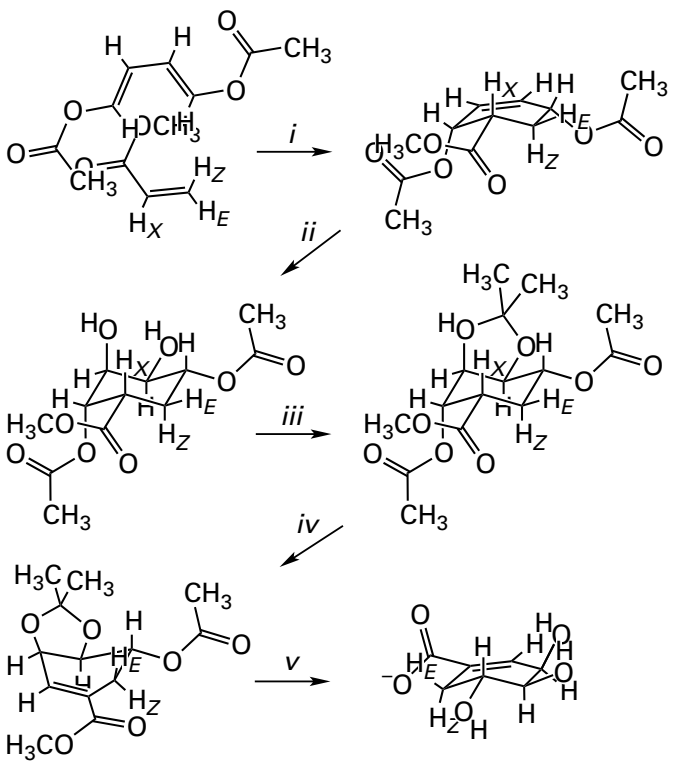


Figure 4–30: Synthesis of D-shikimate from methyl acrylate and *trans,trans*-1,4-diacetoxy-1,3-butadiene.[511,512] (*i*) The diene and dienophile were condensed in anhydrous xylene at reflux in a Diels–Alder cycloaddition that proceeded with the usual stereochemical consequences. In the direction of approach shown, methyl acrylate is below the diene. The two inwardly directed hydrogens on the diene are pushed upward, and the two outwardly directed acetoxy groups respond by rotating downward. The *Z*-hydrogen and the methoxycarbonyl group of the dienophile are pushed downward, and the *E*-hydrogen and the *X*-hydrogen respond by rotating upward to give the enantiomer drawn. The other enantiomer of the endo product is produced when the dienophile approaches from the top of the diene. (*ii*) Osmium tetroxide in tetrahydrofuran/pyridine was used to perform a cis-hydroxylation of the carbon–carbon double bond. The hydroxylation proceeded trans to the two adjacent acetoxy groups because of their bulk and the bulk of the osmium tetroxide. (*iii*) The two vicinal cis-hydroxy groups were incorporated into an acetal with anhydrous acetone under a stream of hydrochloric acid. (*iv*) The elimination of acetic acid by concerted loss of the acidic hydron, H_X^+, and the good leaving group, CH_3COO^-, was accomplished by pyrolysis in a sealed tube at 285 °C. (*v*) The acetal and the two esters were hydrolyzed in 60% acetic acid to yield racemic shikimic acid. The D-enantiomer of shikimate was isolated as the crystalline salt with (–)-1-amino-1-phenylethane.

Therefore, the *pro-R* hydrogen is removed during this anti elimination. Removal of this nonacidic hydrogen at carbon 6 is catalyzed by flavin mononucleotide, which is situated in the active site adjacent to the *pro-R* hydrogen on 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate in the crystallographic molecular model of the complex between chorismate synthase from *Streptococcus pneumoniae* (37% identity; 2.2 gap percent) and oxidized flavin mononucleotide and 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate.[298]

Determination of the stereoheterotopic preference of an active site can be used to identify in a crystallographic molecular model the catalytic acid–base or prosthetic group responsible for removing a stereoheterotopic hydrogen or for adding a hydrogen to a prochiral carbon. For example, every time a molecule of (*S*)-malate is converted to fumarate by the active site of porcine fumarate hydratase, the *pro-R* hydrogen is always removed. This fact identifies Serine C318 in the active site of fumarate hydratase from *M. tuberculosis* (Figure 4–27)[464] as the catalytic base responsible for removal of the hydrogen, even though the hydroxy group of serine ($pK_{a1} = -3$ and $pK_{a2} = 14.2$) seems to be an unlikely catalytic base. The hydroxy group of the serine, however, is located in an oxyanion hole formed by two amido groups of the polypeptide backbone, which should lower its second pK_a significantly by stabilizing the oxido group that is the conjugate base.

In the active site in a crystallographic molecular model of the bimolecular complex between UDP-*N*-acetyl-3-*O*-[(*E*)-1-carboxy-2-methylvinyl]-D-glucosamine and UDP-*N*-acetylmuramate dehydrogenase from *E. coli*, which performs the anti addition of a hydride and a hydron to the carbon–carbon double bond in the (*E*)-1-carboxy-2-methylvinyl group (Equation 4–239), the prosthetic flavin providing the hydride is on one face of the double bond. Consequently, the hydroxy group of Serine 229 on the other face has been assigned as the donor of the hydron during the addition on the basis of the observed anti addition. The more acidic hydron on Tyrosine 125 is relayed to the hydroxy group of this serine through three fixed molecules of water in the active site[513] to increase its acidity.

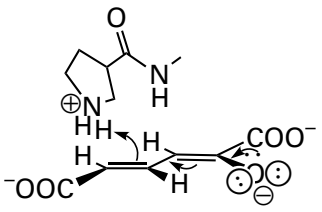
In the reaction catalyzed by (2*E*,6*E*)-farnesyldiphosphate synthase (previously Equation 3–406)

magnesium isopentenyl diphosphate +
magnesium geranyl diphosphate $\rightleftharpoons$
$MgOPO_3PO_3^{2-}$ + H^+ +
magnesium (2*E*,6*E*)-farnesyl diphosphate
(4–251)

from *E. coli*, the *pro-R* hydron is removed from carbon 2 of isopentenyl diphosphate in the final step of the reaction during formation of the new 2*E* double bond in the product (see Figure 1–26).[514] In the crystallographic molecular model of the active site of the enzyme, occupied by isopentenyl diphosphate and dimethylallyl *S*-thiolodiphosphate, the *pro-R* hydrogen on carbon 2 of isopentenyl diphosphate is directed toward one oxyanion of the diphosphate on dimethylallyl *S*-thiolodiphosphate, and the distance between carbon 2 of isopentenyl diphosphate and that oxygen is 0.42 nm.[515] This distance is close to the sum (0.38 nm) of the van der Waals radii of oxygen (0.15 nm) and hydrogen (0.115 nm) and the length of a carbon–hydrogen bond (0.11 nm), and no other catalytic acid–base is in the immediate vicinity. Knowledge of the prochiral stereochemistry of the reaction identifies this oxygen as the catalytic base that removes the hydron during the reaction.

Several other enzymes that catalyze homologous alkylations of polyisoprenoids proceed with prochiral stereochemistry that is always consistent with the diphosphate that leaves ending up immediately adjacent to the enantiotopic hydrogen on carbon 2 of isopentenyl diphosphate that is removed during the reaction.[516] The conformation of dimethylallyl *S*-thiolodiphosphate, an inactive analogue of the substrate dimethylallyl diphosphate, in the active site of isoprene synthase from *Populus canescens* places one oxygen of the diphospho group immediately adjacent to the hydron removed from carbon during the production of isoprene from dimethylallyl diphosphate by the enzyme.[517]

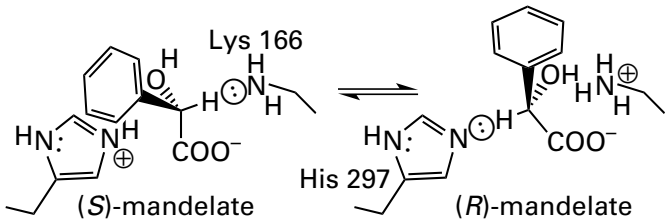
In the tautomerization of 2-hydroxy-*trans,trans*-muconate catalyzed by 2-hydroxymuconate tautomerase from *P. putida* (Equation 4–229), a hydron is added to a trigonal, prochiral carbon that has a hydrogen as a substituent. When the enzymatic reaction is carried out in ^2H_2O, a hydron is added stereospecifically to carbon 5 to produce only one prochiral product, (5*S*)-5-carboxy-2-oxo-3(*E*)-[5-^{2}H]pentenoate.[518] This stereochemical result confirmed the identification of the amino-terminal proline of the protein in the active site of a crystallographic molecular model of the enzyme from *P. putida*[262] as the catalytic acid that adds the hydron to the *Si* face



4–53

of carbon 5 of the conjugate base of 2-hydroxy-*trans,trans*-muconate.

The determination of retention of configuration, as in the case of galactarate dehydratase (Equation 4–227) and peptidylglycine monooxygenase (Equation 4–243), determines the orientation of one catalytic group. In instances such as the decarboxylation catalyzed by diaminopimelate decarboxylase (Equations 4–247 and 4–248), however, **the determination of inversion of configuration defines the relative orientation of more than one catalytic group.** This definition can be used to assign the role of particular catalytic groups in the crystallographic molecular model of an active site. The simplest example of such an assignment is that for the active site of mandelate racemase



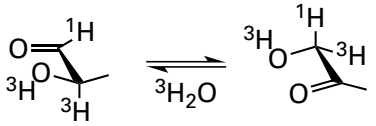
(4–252)

which by definition proceeds with inversion of configuration. As previously noted, in the active site in the crystallographic molecular model of a complex between the enzyme from *P. putida* and 4-iodomandelate, Lysine 166 sits on the same side as the hydrogen on carbon 2 of (*S*)-mandelate, and Histidine 297 sits on the same side as the hydrogen on carbon 2 of (*R*)-mandelate.[100]

Isomerizations catalyzed by a set of related isomerases—glucose-6-phosphate isomerase from *O. cuniculus*, ribose-5-phosphate isomerase from *Spinacia oleracea*, mannose-6-phosphate isomerase from *O. cuniculus*, triose-phosphate isomerase (Equation 4–46) from *O. cuniculus*, xylose isomerase from *Levilactobacillus brevis*, L-arabinose isomerase from *L. brevis*, and L-fucose isomerase from *K. aerogenes*—share a common mechanism, which has been demonstrated by stereochemical studies. In each reaction, an aldose is isomerized to a ketose. The aldose that is the natural substrate in each

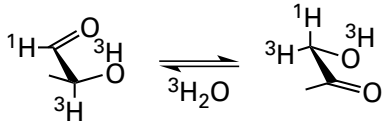
reaction has a chiral center at carbon 2 next to the carbonyl carbon of its aldehyde, but both possible enantiomorphs at carbon 3, *S* and *R*, are represented within the set. The ketose that is a substrate in each reaction is a primary alcohol with a prochiral center at carbon 1 where the aldehyde of the corresponding aldose is located.

The stereochemistry for addition of hydrogen to produce prochiral carbon 1 of the ketose has been determined for each isomerase. When the aldose is *R* at carbon 2 (D-glyceraldehyde 3-phosphate, D-glucose 6-phosphate, D-ribose 5-phosphate, and L-arabinose), the ketose produced in the enzymatic reaction has the hydrogen that was added to it at the *pro-R* position on carbon 1



(4–253)

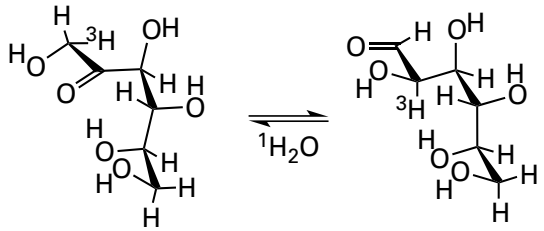
When the aldose is *S* at carbon 2 (D-mannose 6-phosphate and L-fucose), the ketose produced has the hydrogen that was added to it at the *pro-S* position on carbon 1



(4–254)

These conclusions were reached by bringing the reactions to equilibrium in ^3H_2O, isolating products, and determining their absolute stereochemistries.[519-522]

This set of enzymes also displays various degrees of **internal hydron transfer** between carbons 2 and 1 during their isomerizations. For example, when the product of the reaction is trapped by glucose-6-phosphate dehydrogenase, it can be shown that the glucose-6-phosphate isomerases from *Homo sapiens*, *O. cuniculus*, and *S. cerevisiae* will transfer a tritium from carbon 1 of [2*R*-^{3}H]-D-fructose 6-phosphate to carbon 2 of D-glucose 6-phosphate



(4–255)

when the reaction is run in ^1H_2O.[523] The ratio between transfer of the tritium intramolecularly and its loss to solvent while it is briefly located on the catalytic base responsible for removing it and then adding it back varies from 5 to 0.3 depending on the species and the conditions. Within the active site of triose-phosphate isomerase (Equation 4–46) from *O. cuniculus*, it can be calculated that 18% of the protium in an unlabeled molecule of glycerone phosphate is transferred from carbon 3 to carbon 2 of D-glyceraldehyde 3-phosphate at pH 7.9 and 25 °C.[524] Similar results have been observed with D-mannose 6-phosphate and mannose-6-phosphate isomerase.[525]

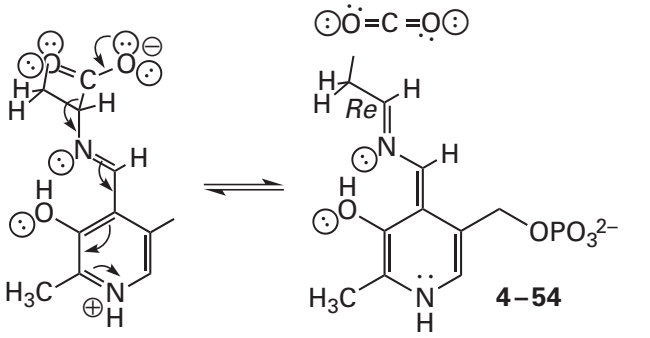
All these facts have led to the conclusion that **a single catalytic base–acid** in the active site of each isomerase removes the hydron from the carbon with the hydroxy group in the substrate to form a *cis*-enediol, moves **across the face of the planar *cis*-enediol**, and adds the hydron back to the intermediate *cis*-enediol from the same face from which it was removed. Later, when crystallographic molecular models of complexes between the active sites of these enzymes and substrates and inhibitors were constructed,[526-531] these stereochemical results identify each catalytic acid–base in the respective active sites that is properly positioned to transfer the hydron between the two carbons, as does Glutamate 164 in the active site of triose-phosphate isomerase (see Equation 4–55 and Figure 3–37).

In this instance, **the stereochemistry was crucial to the identification**. For example, in the active site of triose-phosphate isomerase from *S. cerevisiae*, in the absence of the determination of the stereoheterotopic preference of the active site, Lysine 11 and Glutamate 164 would both be candidates for the role of the catalytic acid–base or catalytic acid–bases that add and remove hydrons from the two carbons. There is no reason that the hydron should be transferred between the two carbons in one of these isomerizations rather than being removed by one base and added by another acid. Furthermore, the prochiral stereochemistries of the primary alcohols in the ketoses are inconsequential to metabolism, so there is no reason for natural selection to pick Glutamic Acid 164 as the sole catalytic acid–base on the basis of this criterion. Consequently, the stereochemical observations of hydron addition and transfer provide the information that allows assignments of the roles of the catalytic acid–bases observed crystallographically.

In contradistinction to the absolute stereochemistry of these isomerases, the catalytic base in human lactoylglutathione lyase can remove the

lone hydron on the chiral carbonyl carbon of either the *S* or the *R* thiohemiacetal formed between glutathione and carbon 1 of a lactaldehyde to produce a *cis*-enediol. Nevertheless, it always delivers the hydron to the *Si* face of the carbon in the *cis*-enediol that was carbon 2 of the lactaldehyde.[532]

A number of stereochemical determinations have been performed for active sites containing **prosthetic pyridoxal 5′-phosphates** that have provided information about the orientations and identities of their catalytic acid–bases. The reaction catalyzed by diaminopimelate decarboxylase (Equations 4–247 and 4–248) introduces the conclusions that can be drawn from stereochemical determinations for active sites with this prosthetic group. The base to which the hydron is added by the catalytic acid within the active site of diaminopimelate decarboxylase is quinonoid intermediate **4–54** formed by the decarboxylation of the external pyridoxamine of the amino group on carbon 6 of *meso*-(2*S*,6*R*)-2,6-diaminopimelate



(4–256)

Because the 6*R* carbon in the reactant is decarboxylated and because the *pro-R* hydrogen in the product is added by the active site of the enzyme from *L. sphaericus*, the decarboxylation occurs with inversion of configuration. The catalytic acid must add a hydron to the *Re* face (the face toward the viewer in Equation 4–256) of the carbon that has just been decarboxylated in the quinonoid intermediate. Therefore, determining the stereochemistry of this reaction has revealed the relative orientation of the catalytic acid–base within the active site relative to the planar π molecular orbital system of the quinonoid intermediate.

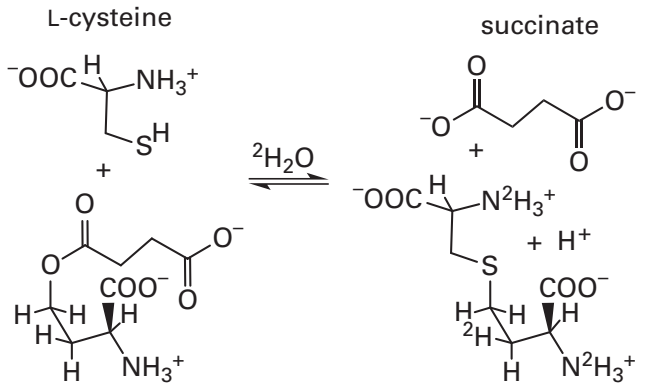
In the crystallographic molecular model of diaminopimelate decarboxylase from *Arabidopsis thaliana* (28% identity; 2.1 gap percent) in which the 6-amino group of L-lysine has formed an external pyridoximine with the prosthetic pyridoxal 5′-phosphate,[533] the *pro-R* hydrogen on carbon 4 of L-lysine in one of the two active sites in the α_2 dimer is in van der Waals contact (0.41 nm) with the sulfido group of Cysteine 366 from the opposite subunit, and the sulfido group and carbon 4 are in the proper orientation for transfer of a hydron between them. The homologous cysteine is in the same position in both aligned sequences of amino acids of the enzymes from *L. sphaericus* and *A. thaliana*. The *pro-S* hydrogen in the external pyridoximine with L-lysine, however, is pointed toward an open space in the active site occupied by one fixed molecule of water but large enough to accommodate a carboxylato group. The imidazolio group of Histidine 218 is adjacent to the open space, and it could form a hydrogen bond with one oxygen on the carboxylato group of *meso*-2,6-diaminoheptanedioate when it is the reactant to ensure that the carboxylato group bears a negative elementary charge as required by the decarboxylation.

Diaminopimelate decarboxylase catalyzes a decarboxylation of an (*R*)-amino acid that occurs with inversion of configuration. D-Ornithine/D-lysine decarboxylase from *Salmonella enterica*, which is a homologue of diaminopimelate decarboxylase from *L. sphaericus* (27% identity; 1.8 gap percent), also catalyzes a decarboxylation of an (*R*)-amino acid that occurs with inversion of configuration, and the homologous cysteine, Cysteine 387, is also in the same location in the active site adjacent to pyridoxal 5′-phosphate.[534]

There are many enzymes using **pyridoxal 5′-phosphate as a prosthetic group to catalyze decarboxylations of amino acids** that are chemically equivalent to those catalyzed by diaminopimelate decarboxylase and D-ornithine/D-lysine decarboxylase. Each of these other enzymes, however, usually has as its reactant the respective naturally occurring (*S*)-amino acid, but the hydron added nevertheless becomes the *pro-R* hydrogen in the product,[510] as does the hydron added by diaminopimelate decarboxylase. Each of these other decarboxylases must have, as has diaminopimelate decarboxylase, a catalytic acid in its active site on the *Re* face of the respective enamine **4–54** (Equation 4–256). In these decarboxylases, carbon dioxide leaves from the *Re* face of the quinonoid intermediate rather than the *Si* face because the amino acid has the *S* configuration. Therefore, these other enzymes proceed with retention of configuration. The catalytic acid–bases that catalyze the decarboxylation step, if any are required, must reside on the same face (the *Re* face) as the catalytic acid that hydronates the resulting enamine in the next step, and there must

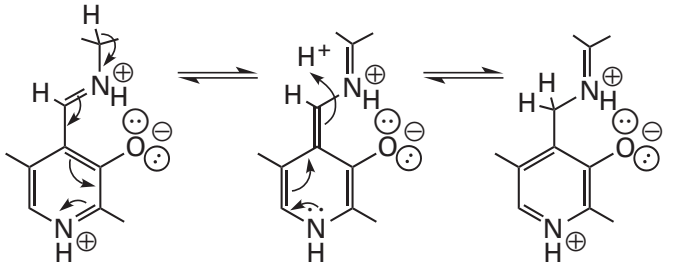
be enough space on the *Re* face to accommodate the carboxylato group of the (*S*)-amino acid.

A **more extensive set of stereochemical conclusions** has been drawn for the nucleophilic substitution catalyzed by the active site of cystathionine γ-synthase (previously Equation 2–31)



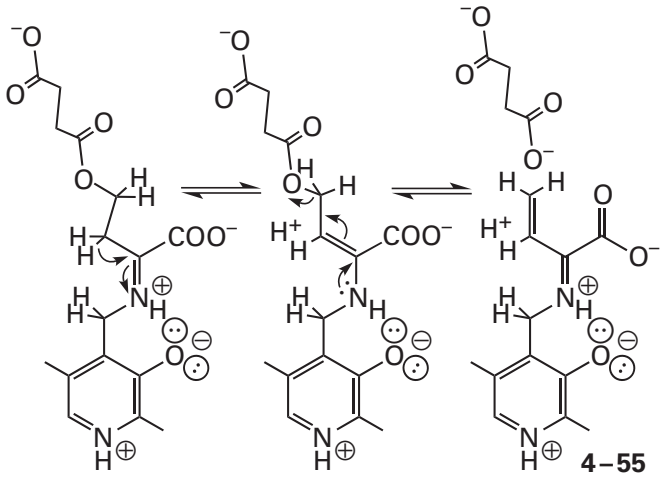
(4–257)

from *S. typhimurium*[535] and its prosthetic pyridoxal 5′-phosphate. In the normal reaction, the stripped intermediate **4–55** is formed from O^4-succinyl-(*S*)-homoserine by tautomerization of its external pyridoximine to form the *N*-pyridoxylimine



(4–258)

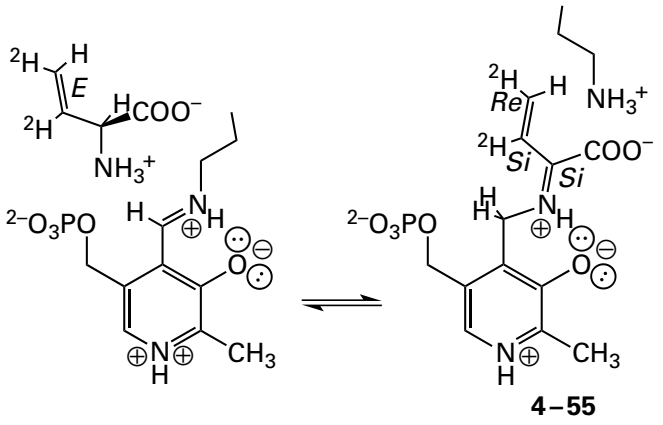
followed by the elimination that proceeds through removal of the β-hydron and expulsion of the leaving group, succinate, from the γ carbon (Equations 2–4, 2–21, 2–32, and 2–34, respectively)



(4–259)

The sulfido group of L-cysteine then replaces the carboxylato group of the succinate, and the sequence of steps proceeds in reverse.

N-Pyridoxylimine **4–55** happens to be the *N*-pyridoxylimine (Equation 4–258) of vinylglycine, and the enzyme will also accept (*S*)-vinylglycine as a reactant



(4–260)

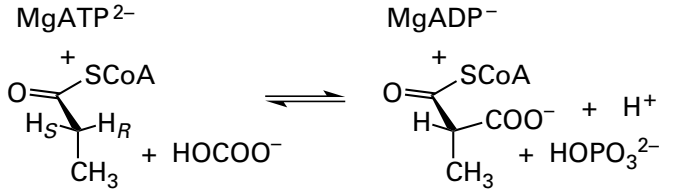
and produce L-cystathionine from it. Both (*E*)-[3,4-$^2H_2$]-(*S*)-vinylglycine and (*Z*)-[4-^{2}H]-(*S*)-vinylglycine were synthesized chemically, and the absolute stereochemistries of the L-cystathionines produced from these two vinylglycines were determined. From these results, it was concluded that the sulfido group of L-cysteine is added to the *Re* face of (*E*)-[3,4-$^2H_2$]vinylglycine (the face toward the viewer in Equation 4–260) and to the stereochemically equivalent *Si* face of (*Z*)-[4-^{2}H]vinylglycine during the respective productions of L-cystathionine. The hydron added to intermediate **4–55** at the β carbon was already known to become the *pro-R* hydrogen of the product (Equation 4–257)[536] so it must be added to the *Si* face of the β carbon in intermediate

4–55.* There are more consequential requirements at the α carbon in proceeding from the reactant and generating the product, both of which must be 2*S*-amino acids. The hydron removed from the α carbon of O^4-succinyl-(*S*)-homoserine to produce the initial quinonoid intermediate (Equation 4–258) must have been removed from what becomes its *Re* face, and the hydron added to the α carbon of the final quinonoid intermediate, which results from addition of the sulfanyl group to intermediate **4–55** and its dehydronation at the 4′ carbon of the pyridoxyl group, must be added to its *Re* face (the face opposite the *Si* face at the α carbon in Equation 4–260).

In the crystallographic molecular model[537] of the complex between cystathionine γ-synthase from *Nicotiana tabacum* (34% identity; 0.8 gap percent relative to *S. typhimurium*) and an inhibitor of the enzyme that forms an intermediate analogous to **4–55**, the 4-hydroxy group of Tyrosine 163 sits on the *Si* face of the β carbon at a distance of 0.30 nm from it and in a location from which its conjugate base could remove a hydron from the incoming sulfido group of L-cysteine and deliver that hydron to the *Si* face of the β carbon (see reverse of Equation 4–259). Because the succinyl group leaves to produce intermediate **4–55** (Equation 4–259) from the same face at which the sulfido group adds to intermediate **4–55**,[535] the hydroxy group of Tyrosine 163 must remove the hydron from the β carbon of the *N*-pyridoxylimine of O^4-succinyl-(*S*)-homoserine and probably hydronates the oxygen of the leaving group in the steps that follow formation of the *N*-pyridoxylimine. All these assignments for the role of Tyrosine 163 based on the crystallographic molecular model **required unambiguous knowledge of the stereochemistry of the enzymatic reaction** because there is also a tyrosine that could act as a catalytic acid–base on the *Si*, *Re*, *Re* face of intermediate **4–55**.

Lysine 261, which forms the internal pyridoximine in the resting enzyme,[538] sits on the *Re* face of the α carbon in the complex with the inhibitor, at a distance of 0.34 nm from it and in a location from which it can remove a hydron from the 4′ carbon of the 5′-phosphopyridoxyl group of the tautomer of the external pyridoximine and deliver it to the *Re* face of the α carbon in the quinonoid intermediate (reverse of the first step in Equation 4–258) to form the external pyridoximine of the product L-cystathionine. Presumably, Lysine 261 removes the hydron from the *Re* face of the α carbon of the initial external pyridoximine of O^4-succinyl-(*S*)-homoserine to form the quinonoid intermediate and then hydronates carbon 4′ of the 5′-phosphopyridoxyl group during the tautomerization (Equation 4–258).

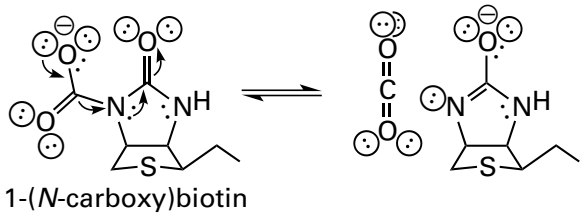
Determination of the stereochemistry of **carboxylases** provides information about the orientations and identities of catalytic acid–bases in the respective active sites. The enzymatic reaction catalyzed by porcine propionyl-CoA carboxylase



(4–261)

proceeds with retention of configuration at carbon 2. This conclusion is based on two observations. When either deuterium[539] or tritium[540] is substituted for the *pro-S* hydrogen, it is retained in the product. When deuterium is substituted for the *pro-R* hydrogen, it is not retained in the product.[540] Therefore, the catalytic base in the active site that removes the hydron to produce the enolate at carbon 2 must be on the same side of the reactant as the 1-(*N*-carboxy)biotin that delivers the activated carbonic acid to that same carbon in the enolate.

In the crystallographic molecular model of the complex between propionyl-CoA carboxylase from *Streptomyces coelicolor* and biotin and propionyl-SCoA, the *pro-R* hydrogen of carbon 2 of propionyl-SCoA is directed toward nitrogen 1 of biotin, and the distance between carbon and nitrogen is 0.42 nm. It has been proposed that, during the enzymatic carboxylation, biotin dissociates from the carboxy group at nitrogen 1 of 1-(*N*-carboxy)biotin (**1–107**) to give CO_2



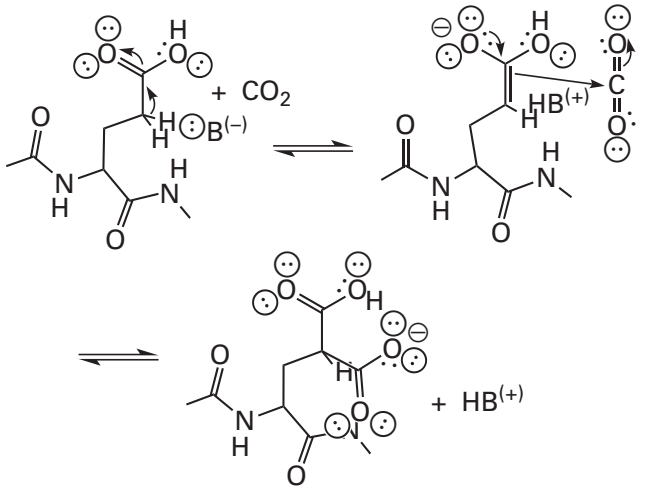
(4–262)

which is held in place by the active site. The resulting conjugate base of the biotin, which, because it is, at the moment of dissociation, the ureido anion, is a

*Note that the priorities for the β carbon and the γ carbon reverse when an oxygen or sulfur is added to the γ carbon.

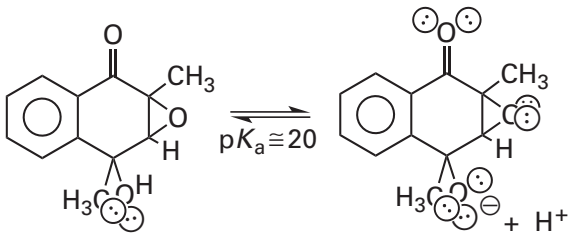
strong base ($pK_a \cong 27$), then removes the *pro-R* hydron from carbon 2 of propionyl-SCoA, and the adjacent, entrapped CO_2 then adds to the resulting enolate at the same face from which the hydron was removed.[541] These assignments of the several roles are based almost entirely on the stereochemical determinations.

In the carboxylation catalyzed by peptidyl–glutamate 4-carboxylase from *R. norvegicus*, however, in which biotin is not involved, the *pro-S* hydron is removed from carbon 4 of L-glutamate also by a strong base (previously Equation 2–222)



(4–263)

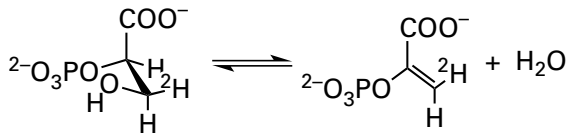
but in this case the strong base is provided by vitamin K (previously in Equation 2–225)



(4–264)

and carbon dioxide adds to the enolate from its other face, so the carboxylation in this case proceeds with inversion of configuration.[542]

Information about the relative orientation of reactants or catalytic functional groups or both of them within the active site can be gained by determining whether an **addition–elimination** catalyzed by an enzyme proceeds in a syn sense or an anti sense. This information is analogous to that gained by determining whether retention or inversion of configuration occurs at a particular chiral or prochiral carbon. For example, in the elimination–addition catalyzed by phosphopyruvate hydratase



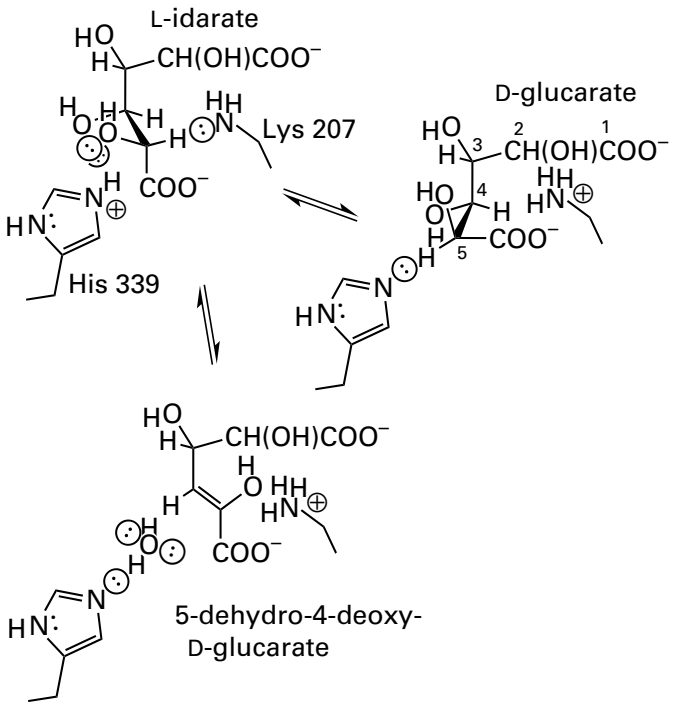
(4–265)

from *O. cuniculus*, the reaction proceeds with anti elimination or addition of water, because the deuterium of (3*R*)-[3-^{2}H]-D-2-phosphoglycerate is found trans to the phosphate in (*E*)-[3-^{2}H]phospho*enol*pyruvate that is the product, with no detectable (*Z*)-[3-^{2}H]phospho*enol*pyruvate.[543] Therefore, in the active site of the enzyme, the catalytic base that removed the hydron from carbon 2 of D-2-phosphoglycerate is on the *Si* face of carbon 2 in the resulting phospho*enol*pyruvate, and the catalytic acid that hydronated the hydroxy group of D-2-phosphoglycerate to convert it to a competent leaving group is on the *Re* face of carbon 3 in the resulting phospho*enol*pyruvate. In the crystallographic molecular model of the complex between phosphopyruvate hydratase from *S. cerevisiae* (62% identity; 0.5 gap percent relative to *O. cuniculus*) and an equilibrium mixture of phospho*enol*pyruvate and 2-phospho-D-glycerate, the 6-ammonio group of Lysine 345 is on the *Si* face of carbon 2 of phospho*enol*pyruvate, its nitrogen atom 0.31 nm from carbon 2. Consequently, this amino group has been assigned as the base that removes the hydron from carbon 2 of 2-phospho-D-glycerate. As expected from the stereochemical observations, the hydroxy group that is added to phospho*enol*pyruvate is found on its *Re* face of carbon 3, accepting hydrogen bonds from the carboxy group of Glutamic Acid 211 and the imidazolyl group of Histidine 373. Consequently, both of these acids have been assigned as catalytic acids that improve the leaving group or, in reverse, the nucleophile.[544]

There are several **related dehydratases that share a common set of acid–bases catalyzing anti eliminations**. Phosphopyruvate hydratase, mandelate racemase, glucarate dehydratase, D(–)-tartrate dehydratase, L-fuconate dehydratase, muconate cycloisomerase, and galactonate dehydratase all share a common ancestor, a conclusion based on alignment of sequences and superposition of crystallographic molecular models.[545-551] Each enzyme uses the 6-amino group of a lysine to remove a hydron α to a carboxy group,[100,101,543,544,549,551-557] as in the active site of phosphopyruvate hydratase (Equation 4–265).

In the active site of mandelate racemase from *P. putida*, Histidine 297, in a homologous position to Histidine 345 in phosphopyruvate hydratase, sits on the opposite side of the substrates from this lysine, Lysine 166, to operate on the other hydron in the racemization catalyzed by the enzyme[558] (Equation 4–252).

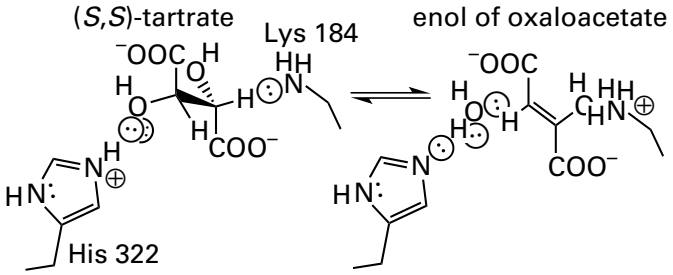
In the active site of glucarate dehydratase from *E. coli*,[554] Histidine 339, in the homologous position to Histidine 297 in mandelate racemase, sits on the opposite side of the substrates from Lysine 207, in the homologous position to Lysine 166 in mandelate racemase. Histidine 339 removes the hydron on carbon 5 of D-glucarate and Lysine 207 adds a hydron to carbon 5 during the epimerization between D-glucarate and L-idarate catalyzed by the enzyme[559] (upper equilibrium in Equation 4–266)



(4–266)

the same roles played by the homologous amino acids in the epimerization of mandelate by mandelate racemase. Histidine 339, however, also hydronates the hydroxy group that leaves from the carbon equivalent to carbon 4 of D-glucarate in the dehydration of L-idarate that is also catalyzed by the active site of glucarate dehydratase,[556] as does the homologous histidine in phosphopyruvate hydratase. In this instance, in contradistinction to the theme of the present discussion, the conclusions that the dehydration of L-idarate must be anti and that the hydron that is removed during the dehydration must be removed by the amino group of Lysine 207 are based so far only on arguments of homology and on the orientation of the product, 4-deoxy-5-dehydro-D-glucarate, when it is bound in the active site in the crystallographic molecular model of its complex with the enzyme,[554] rather than any stereochemical observations.

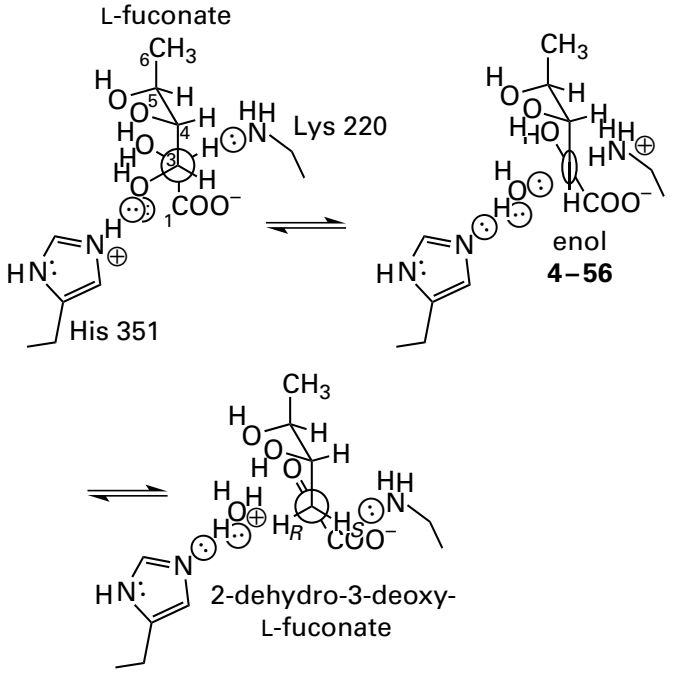
In the active site of D(–)-tartrate dehydratase from *Bradyrhizobium japonicum*, the homologous Histidine 322 sits on opposite side of the substrates from the homologous Lysine 184, which removes the hydron from (*S,S*)-tartrate during its dehydration to the enol of oxaloacetate. The imidazolyl group of Histidine 322 hydronates the hydroxy group that leaves in the elimination catalyzed by the enzyme.[551]



(4–267)

Again, the dehydration is assigned as an anti elimination based only on the conformation assumed by (*S,S*)-tartrate in the crystallographic molecular model of its complex with a mutant of the enzyme in which Lysine 184 has been replaced with alanine.

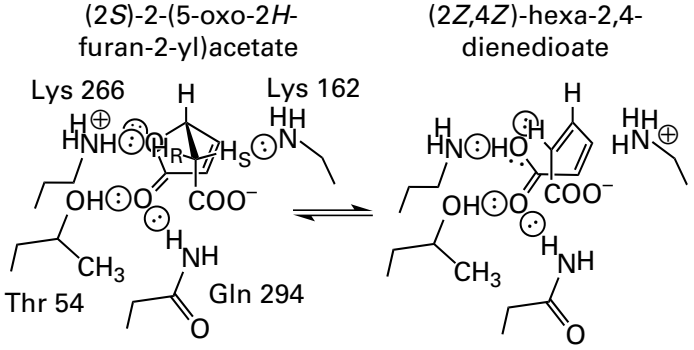
In the active site of L-fuconate dehydratase from *Xanthomonas campestris*, the homologous Histidine 351, which also hydronates the hydroxy group that leaves in the dehydration catalyzed by the enzyme, sits on the opposite side of the substrates from the homologous Lysine 220, which removes the hydron from carbon 2 of L-fuconate during its dehydration.[549] The fact that the hydron ending up on prochiral carbon 3 of 2-dehydro-3-deoxy-L-fuconate (the ultimate product) is the *pro-S* hydrogen suggests that the 6-ammonio group of Lysine 220, operating on the same face of the intermediate enol **4–56** as it did when it removed the hydron from carbon 2, provides the hydron added to carbon 3.



(4–268)

The fact that the *pro-S* hydrogen on carbon 3 of the product is always a deuteron[549] when the reaction is performed in ^2H_2O means that the 6-amino group of Lysine 220, if it does operate on both of these carbons as shown in Equation 4–268, does not transfer the same hydron from carbon 2 to carbon 3 but equilibrates completely with the solution before adding the hydron to carbon 3.

In the active site of muconate cycloisomerase from *Mycolicibacterium smegmatis*, the 6-amino group of the homologous Lysine 162 removes the *pro-S* hydron from the carboxymethyl group of the lactone, (2*S*)-2-(5-oxo-2*H*-furan-2-yl)acetate, in the anti elimination catalyzed by this enzyme.[553,560] In the sequence of amino acids for the protein, however, the homologous histidine is replaced by Glycine 292 and the leaving group in the elimination is instead improved by the 6-ammonio group of Lysine 266, acting as a catalytic acid, and a hydrogen bond from the amido group of Glutamine 294. This glutamine is only two positions in the sequence of amino acids away from that normally occupied by the homologous histidine, and along with the hydroxy group of Threonine 54, it acts as an oxyanion hole



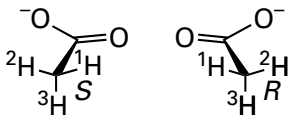
(4–269)

All these observations on homologous enzymes that nevertheless catalyze different reactions **illustrate the versatility of an active site in which there are two catalytic acid–bases**, one on each side of the position in which substrates are bound, to which natural selection can add a third or fourth catalytic acid–base as circumstances require. Such an anti arrangement of catalytic acid–bases can catalyze epimerization or anti elimination. These results also illustrate that a determination that an elimination is anti identifies at least two catalytic acid–bases in the active site of a crystallographic molecular model. This family of enzymes is also an example of the fact that when the reaction catalyzed by an enzyme is changed by evolution through natural selection, the same catalytic groups are often co-opted to play similar roles even though the new reaction may be completely different from the old.[561]

Addition–eliminations discussed so far have all been anti eliminations, but **syn eliminations** also occur in active sites within the same family. In the active site of muconate cycloisomerase from *P. putida*, the *pro-R* hydron is removed by homologous Lysine 171 from the carboxymethyl group of (2*S*)-2-(5-oxo-2*H*-furan-2-yl)acetate, rather than the *pro-S* hydron as in muconate cycloisomerase from *M. smegmatus* (Equation 4–269). In the resulting **syn elimination**, rather than the anti elimination, the leaving group is improved by the imidazolyl group of nonhomologous Histidine 24.[552,553,562] Thus there are muconate cycloisomerases that share a common ancestor (35% identity) and catalyze the same reaction with the same apparent stereochemistry but have a different, albeit cryptic, prochiral stereochemistry enforced by different, nonhomologous catalytic groups in the respective active sites. The related enzyme 3-carboxy-*cis*,*cis*-muconate cycloisomerase also shows both syn[563] and anti[552] stereochemistry in different species. That both syn and anti stereochemistries can occur for the same addition–

elimination reiterates that there are no significant inherent preferences for one over the other.

One of the most sophisticated stereochemical tools to study the orientation of catalytic acid–bases within an active site has been chiral methyl groups. The first compound with a chiral methyl group to be prepared was [^{3}H,^{2}H]acetate in its two enantiomeric forms



4–57 **4–58**

One of the two original **syntheses of enantiomeric [^{2}H,^{3}H]acetate** proceeds from [^{3}H]glyoxylate* (Figure 4–31)[564] by (*i*) reduction with NAD^{1}H and L-lactate dehydrogenase (Equation 4–204) from mammalian muscle, (*ii*) reduction of the carboxylate to the alcohol with lithium aluminum hydride, (*iii*) activation for nucleophilic substitution of one of the two equivalent hydroxy groups of the ethylene glycol at random with 4-bromobenzenesulfonyl chloride, (*iv*) nucleophilic substitution with a deuteride from lithium aluminum deuteride with inversion of configuration, and (*v*) oxidation of the alcohol to the carboxylic acid with oxygen over platinum. The synthesis provides an equimolar mixture of [^{2}H]acetate and (*R*)-[^{2}H,^{3}H]acetate. The stereochemistry of tritiated product is assigned directly as *R* because L-lactate dehydrogenase (Equation 4–204) is known[565] to produce the *S* isomer of glycolate from [^{3}H]glyoxylate and unlabeled NADH and the nucleophilic substitution with deuteride proceeds with inversion of configuration. The (*S*)-[^{2}H,^{3}H]acetate can be obtained by the same sequence of reactions with the exception that glyoxylate reductase from *S. oleracea* is used in the first step to produce stereochemically pure (*R*)-[^{3}H]glycolate rather than (*S*)-[^{3}H]glycolate. The two enantiomeric acetates can be converted readily to the two acetylcoenzymes A, which are the usual substrates for enzymes operating on acetate, with acetate kinase and phosphate acetyltransferase.[566]

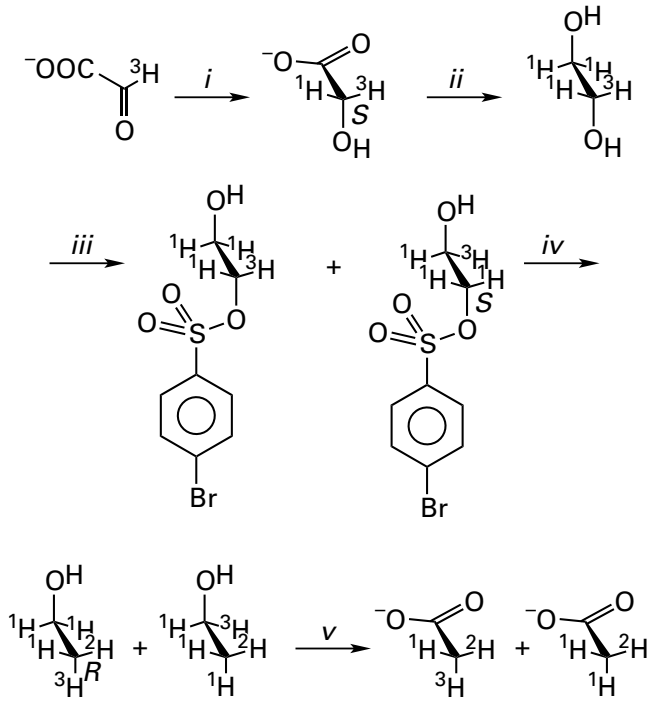


Figure 4–31: Synthesis of chiral acetate from [2-^{3}H]glyoxylate.[564] (*i*) [2-^{3}H]Glyoxylate was reduced with NADH and L-lactate dehydrogenase to produce (2*S*)-[2-^{3}H]glycolate. (*ii*) The methyl ester of (2*S*)-[2-^{3}H]glycolate was reduced chemically with $LiAlH_4$ to produce (1*S*)-[1-^{3}H]ethylene glycol. (*iii*) An equimolar mixture of the two 4-bromobenzenesulfonates (brosylates) of the labeled ethylene glycol was produced by sulfonylation with 4-bromobenzenesulfonyl chloride. (*iv*) The leaving ability of a 4-bromobenzenesulfonyl group was exploited to promote reduction of the two regioisomers with [^{2}H]$LiAlH_4$ by substitution with deuteride with inversion of configuration. (*v*) The resulting equimolar mixture of (2*R*)-[2,2-^{2}H,^{3}H]ethanol and (1*S*)-1-tritio-2-deuterioethanol was oxidized with O_2 over a platinum catalyst, producing a mixture of (*R*)-[^{2}H,^{3}H]acetate and [^{2}H$_1$]acetate. Because only a portion of the original [2-^{3}H]glyoxylate was actually tritiated, the only effect of the equimolar yield of [^{2}H$_1$]acetate was to halve the specific radioactivity of the product relative to that of the initial [2-^{3}H]glyoxylate, not to introduce a species of acetate that was not already unavoidably present.

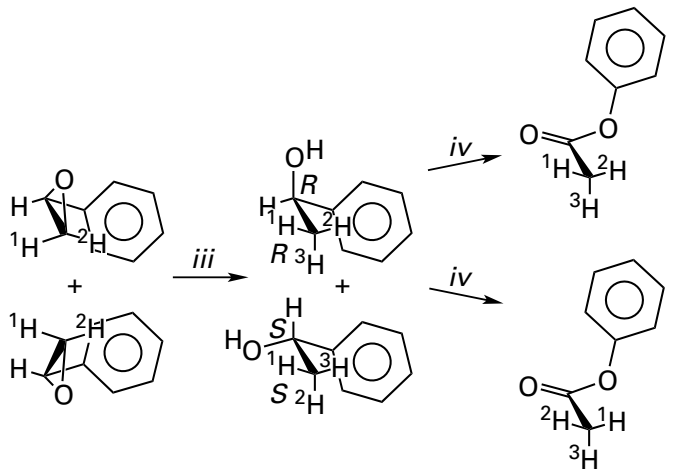
Other syntheses of enantiomeric [^{2}H,^{3}H]acetate avoid the requirement for enzymatic steps by resolving two enantiomers as diastereomeric salts or adducts[566-568] and then converting the two resolved enantiomers separately to the respective enantiomeric acetates. For example, the carbon–carbon triple bond in [2-^{2}H]-1-phenylethyne was (*i*) reduced stereospecifically with diimide to give (*Z*)-[2-^{2}H]-1-phenylethene, which was then (*ii*) epoxidized with peroxybenzoic acid to give an equimolar mixture of the two diastereomers of (*Z*)-[2-^{2}H]-1-phenyloxirane resulting from epoxidation at the two faces of (*Z*)-[2-^{2}H]-1-phenylethene. This diastereomeric mixture of the two (*Z*)-[2-^{2}H]-1-phenyloxiranes

*Although it is prohibitive to synthesize glyoxylate in which all of the hydrogen is tritium—in other words, the tritium is "carrier free"—the fact that most of the [^{3}H]glyoxylate has a hydrogen at carbon 2, and consequently most of the [^{2}H,^{3}H]acetate has a hydrogen rather than a tritium at carbon 2, is inconsequential to the way in which the final analysis of chirality is performed.



(4–270)

was then (*iii*) reduced with $Li^3HB(C_2H_5)_3$ to produce an equimolar mixture of [2*R*-^{2}H,^{3}H]-(*R*)-1-phenylethanol and [2*S*-^{2}H,^{3}H]-(*S*)-1-phenylethanol. The chirality at carbon 1 was exploited to resolve the two diastereomers of 1-phenylethanol by fractional crystallization of their brucine phthalates. The two diastereomers were then (*iv*) oxidized to the respective [2,2-^{2}H,^{3}H]phenyl ketones with CrO_3 followed by oxidation with peroxytrifluoroacetic acid to produce a Baeyer–Villiger rearrangement (Equation 4–270). The two enantiomeric phenyl [^{2}H,^{3}H]acetates were (*v*) saponified, and the acetates were collected as the respective sodium salts.[566] Another synthesis begins with (*S*)-[1,1-^{2}H,^{3}H]ethanol and (*R*)-[1,1-^{2}H,^{3}H]ethanol prepared by reduction of [1-^{2}H]ethanal with two enantiomeric 9-borabicylo[3.3.1]nonanes,[569] and yet another relies on the ability of rhenium to participate in a planar double bond with carbon and yet remain tetrahedral and enantiomeric.[570]

The **use of enantiomeric [^{2}H,^{3}H]acetyl-SCoA to answer a stereochemical question relies upon the kinetic isotope effect** and the planar, rigid structure of an enolate. Consider (*R*)-[^{2}H,^{3}H]acetyl-SCoA bound to an active site (Figure 4–32). The first step in most enzymatic reactions using acetyl-SCoA as a reactant is removal of a hydron from the acetyl group to create its enolate. The acetyl-SCoA will be bound unavoidably to the active site through its coenzyme A and should form a hydrogen bond at its acyl oxygen with at least the catalytic acid, $–NH^{(+)}$, that hydronates the oxo oxygen to catalyze formation of the enol or the oxyanion hole required to stabilize the oxyanion of the enolate. The chiral methyl group, because it cannot participate in a hydrogen bond or be hindered sterically, will be free to rotate. Assume that the catalytic base required to remove the hydron

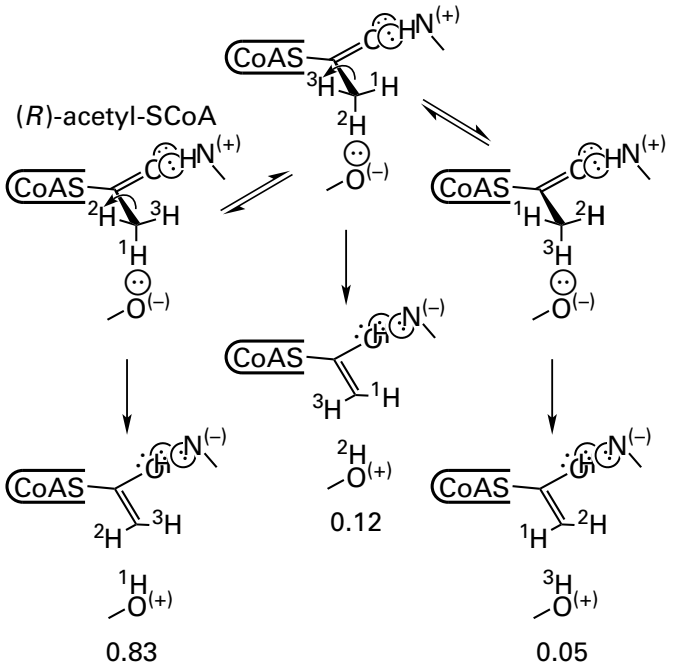


Figure 4–32: Production of three respective enols of (*R*)-[^{2}H,^{3}H]acetyl-SCoA at the active site of an enzyme. In the active site of the enzyme, the coenzyme A thioester of the reactant will be extensively immobilized by noncovalent interactions (symbolized by a cup), and the acyl oxygen will be hydrogen-bonded by at least the catalytic acid, $–NH^{(+)}$ responsible for hydronation of the enolate. As each hydrogen spins by the catalytic base, $–O\odot^{(–)}$, responsible for its removal, the probability that it will be removed should be directly proportional to the appropriate kinetic isotope effect. If the kinetic isotope effects for this hydron removal were ${}^{H}k/{}^{D}k = 7$ and ${}^{H}k/{}^{T}k = 16$, then the probability that the base will remove the protium is 0.83; the deuterium, 0.12; and the tritium, 0.05. The products of each reaction are planar and rigid, and they are pinned to the active site.

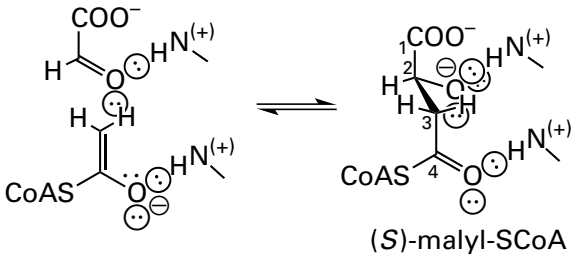
from the carbon of the methyl group, $–O\odot^{(–)}$, to form the enolate is on the *Si* face of the acyl carbon and that normal, semiclassical maximum kinetic isotope effects of ${}^{D}k = 7$ and ${}^{T}k = 16$ govern removal of the hydron by the base. If this kinetic isotope effect applies and the base is on the *Si* face, 83% of the enolate formed would be the (*E*)-[^{2}H,^{3}H]enolate and 12% would be the (*Z*)-[^{3}H]enolate. A fraction (5%) of the enolate would be the (*E*)-[^{2}H]enolate and would have lost its tritium altogether and would no longer be radioactive. Rotation about the carbon–carbon bond of the enolate cannot occur because of its double bond. The electrophile added to the nucleophilic enolate in the second step of the reaction will approach either from the respective upper faces in the drawing, in which case inversion of configuration will occur at the α carbon, or from

the respective lower faces in the drawing, in which case retention of configuration will occur at the α carbon.

In the reaction catalyzed by malate synthase

acetyl-SCoA + glyoxylate + H_2O $\rightleftharpoons$ (*S*)-malate + HSCoA (4–271)

the electrophile is the carbonyl group of glyoxylate



(4–272)

where the numbering is for the malate that is the final product. Because (*S*)-malate is the product of the reaction, the enolate of acetyl-SCoA must add to the *Si* face of the glyoxylate as shown. This stereochemical conclusion follows only from the known stereochemistry of the product. The cryptic stereochemistry at the methylene carbon of the enolate of acetyl-SCoA can be assessed by using the pair of enantiomeric [^{2}H,^{3}H]acetyl-SCoAs.

The strategy for determining the cryptic stereochemistry is most easily understood by making a prediction (Figure 4–33). Consider for the moment only the major product (87%) of acid dissociation, the [^{2}H,^{3}H]enolate of acetyl-SCoA (Figure 4–32). If the reaction proceeds with retention of configuration at carbon 3 of malate, then (*R*)-[^{2}H,^{3}H]acetyl-SCoA should give (2*S*,3*R*)-[3,3-^{2}H,^{3}H]malate as the major product and (*S*)-[^{2}H,^{3}H]acetyl-SCoA should give (2*S*,3*S*)-[3,3-^{2}H,^{3}H]malate as the major product. If the reaction proceeds with inversion of configuration at carbon 3 of malate, then (*R*)-[^{2}H,^{3}H]acetyl-SCoA should give (2*S*,3*S*)-[3,3-^{2}H,^{3}H]malate as the major product and (*S*)-[^{3}H,^{3}H]acetyl-SCoA should give (2*S*,3*R*)-[3,3-^{2}H,^{3}H]malate as the major product. The product of retention from (*R*)-[^{2}H,^{3}H]acetyl-SCoA is identical to the product of inversion from (*S*)-[^{2}H,^{3}H]acetyl-SCoA, and the product of retention from (*S*)-[^{2}H,^{3}H]acetyl-SCoA is identical to the product of inversion from (*R*)-[^{2}H,^{3}H]acetyl-SCoA. The same respective identities are true for the other two products of acid dissociation, the [^{3}H]enolate and the [^{2}H]enolate (Figure 4–32).

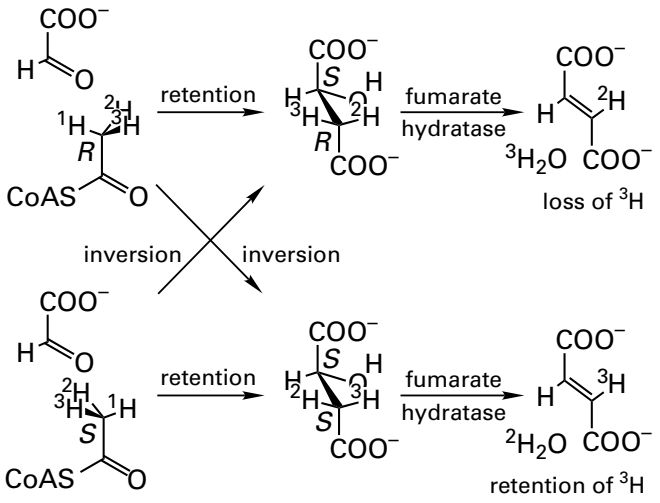


Figure 4–33: Predictions for the stereochemical consequences of the malate synthase reaction if it proceeds either with inversion of configuration or with retention of configuration from either (*R*)-[^{2}H,^{3}H]acetyl-SCoA or (*S*)-[^{2}H,^{3}H]acetyl-SCoA. The actual stereochemistries of the products from each enzymatically catalyzed nucleophilic addition of each enantiomer to glyoxylate are assessed by examining the loss of tritium upon dehydration of the two respective (2*S*)-malates with fumarate hydratase.

Fumarate hydratase is used to distinguish the labeled products from malate synthase. The dehydration catalyzed by fumarate hydratase is always anti regardless of the disposition of isotopes of hydrogen on carbon 3 of the malate (Figure 4–27). Fumarate hydratase removes the tritium from (2*S*,3*R*)-[3,3-^{2}H,^{3}H]malate (as shown in Figure 4–33) but removes the hydrogen from (2*S*,3*S*)-[3-^{3}H]malate and the deuterium from (2*S*,3*R*)-[3-^{2}H]malate. The latter two products always accompany (2*S*,3*R*)-[3,3-^{2}H,^{3}H]malate (Figure 4–32). Fumarate hydratase, however, removes the deuterium from (2*S*,3*S*)-[3,3-^{2}H,^{3}H]malate (as shown in Figure 4–33), but it removes the tritium from (2*S*,3*R*)-[3-^{3}H]malate and the hydrogen from (2*S*,3*S*)-[3-^{2}H]malate. The latter two products, in turn, always accompany (2*S*,3*S*)-[3,3-^{2}H,^{3}H]malate.

If the kinetic isotope effects in the active site of malate synthase had been $^{D}k = 7$ and $^{T}k = 16$ and if the stereochemistry at carbon 3 is disregarded for a short moment, then 83% of the malate produced from either enantiomer of [^{2}H,^{3}H]acetyl-SCoA should have been (2*S*)-[3,3-^{2}H,^{3}H]malate; 12%, (2*S*)-[3-^{3}H]malate; and 5%, (2*S*)-[3-^{2}H]malate (Figure 4–32). Consequently, 95% of the malate produced has a tritium at carbon 3. Now, if the stereochemistry at carbon 3 is considered, then upon incubation with fumarate hydratase, the malate

that is the product of the reaction should lose 87% (83/95) of its tritium if it is a mixture of 83% (2*S*,3*R*)-[3,3-^{2}H,^{3}H]malate, 12% (2*S*,3*S*)-[3-^{3}H]malate, and 5% (2*S*,3*R*)-[3-^{2}H]malate. It should lose 13% (12/95) of its tritium if it is a mixture of 83% (2*S*,3*S*)-[3,3-^{2}H,^{3}H]malate, 12% (2*S*,3*R*)-[3-^{3}H]malate, and 5% (2*S*,3*S*)-[3-^{2}H]malate.

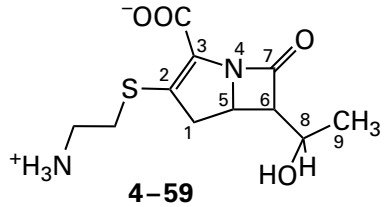
When (*R*)-[^{2}H,^{3}H]acetyl-SCoA was incubated with glyoxylate and malate synthase from *S. cerevisiae*, the [^{3}H]malate produced lost only 31% of its tritium upon conversion to fumarate,[566] so it must have been a mixture of (2*S*,3*S*)-[3,3-^{2}H,^{3}H]malate, (2*S*,3*R*)-[3-^{3}H]malate, and (2*S*,3*S*)-[3-^{2}H]malate. When (*S*)-[^{2}H,^{3}H]acetyl-SCoA was incubated with glyoxylate and malate synthase, the [^{3}H]malate produced lost 69% of its tritium upon conversion to fumarate, so it must have been a mixture of (2*S*,3*R*)-[3,3-^{2}H,^{3}H]malate, (2*S*,3*S*)-[3-^{3}H]malate, and (2*S*,3*R*)-[3-^{2}H]malate. Therefore, malate synthase catalyzes the condensation with inversion of configuration at the methyl carbon of acetyl-SCoA.

The losses of tritium observed (31% and 69%) were closer to 50% than the predicted losses (13% and 87%). In independent experiments,[571] it was determined that the intrinsic kinetic isotope effect ^Dk for malate synthase is 3.7. This observation explains, in part, the percentages of tritium loss that are greater and less than theoretical, respectively. Usually, the actual intrinsic kinetic isotope effects will be less than the theoretical maxima. In addition, exchange of the various isotopes of hydrogen on the acetyl-SCoA, both enzymatic and nonenzymatic, leading to racemization and eventually resulting in a ratio of 50% and 50%, will occur slowly but continuously in the aqueous solutions used for the experimental mixtures. Both the less-than-maximum intrinsic deuterium and tritium kinetic isotope effects and the racemization will tend to cause the two losses of tritium to become closer to 50%.

If the reaction catalyzed by malate synthase proceeds by inversion of configuration, then the catalytic base within the active site that removes the hydron from the methyl group to form the enolate must be on the opposite side of bound acetyl-SCoA from the position at which the carbonyl of glyoxylate is held within the active site, with its *Si* face directed toward the methyl carbon of bound acetyl-SCoA. Because the glyoxylate could be on either side of the enolate, there is no way to learn from the stereochemical result alone whether the catalytic base in the active site is on the *Si* face of the acyl group of bound acetyl-SCoA, as shown in Figure 4–32, or on its *Re* face. **Only the relative stereochemistry of the reaction is assessed**. On the basis of these stereochemical observations, however, it was possible for the crystallographers to assign the role of removing the hydron from the acetyl-SCoA to the carboxy groups of the homologous Aspartate 632 and Aspartate 631, respectively, in the crystallographic molecular models of complexes between the homologous (56% identity; 0.4 gap percent) malate synthases from *E. coli*[572] and *M. tuberculosis*[573] and various substrates and inhibitors. Both homologous aspartates are in locations that would position them on the *Si* face of acyl carbon of the enolate (as in Figure 4–32), the face of the enolate opposite from the glyoxylate when it occupies the active site. Crystallographic determination of the position of the glyoxylate within the active site resolves the ambiguity.

Once it was shown that malate synthase proceeds with inversion of configuration at the methyl carbon of acetyl-SCoA, a criterion for deciding the chirality of any chiral [^{2}H,^{3}H]acetate produced in any enzymatic reaction became available.[574] (*R*)-[^{2}H,^{3}H]Acetate is the enantiomeric [^{2}H,^{3}H]acetate which, when converted to malate by malate synthase, produces [^{3}H]malate that retains most of its tritium upon incubation with fumarate hydratase, and (*S*)-[^{2}H,^{3}H]acetate is the enantiomeric [^{2}H,^{3}H]acetate which, when converted to malate by malate synthase, produces [^{3}H]malate that loses most of its tritium upon incubation with fumarate hydratase. A method for determining by tritium nuclear magnetic resonance spectroscopy the absolute stereochemistry of any [^{3}H,^{3}H]methyl group that can be converted to methylamine has also been devised.[575]

The assay that uses malate synthase and fumarate hydratase can be expanded to assess the absolute stereochemistry of any [^{2}H,^{3}H]methyl group in a molecule if that methyl group can be converted into the methyl group of [^{2}H,^{3}H]acetate without racemization. This conversion is usually done by chemically oxidizing the immediate product of the enzymatic reaction. For example, a culture of *Streptomyces cattleya* incorporates a methyl group derived from L-methionine, through *S*-adenosyl-L-methionine, into thienamycin



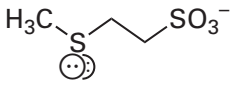
4–59

The methyl group ends up as carbon 9 of the thienamycin. After the 6*S* and 6*R* diastereomers of [6,6-^{2}H,^{3}H]-L-methionine, which were synthesized from (*R*)-[^{2}H,^{3}H]acetate and (*S*)-[^{2}H,^{3}H]acetate, respectively,[576] were fed separately to cultures, the thienamycin produced by the bacteria was oxidized with CrO_3 in H_2SO_4 to give [^{2}H,^{3}H]acetic acid containing the undisturbed methyl group. The [^{2}H,^{3}H]acetates were determined to be *S* and *R*, respectively,[577] by the criterion of tritium loss or tritium retention following treatment with malate synthase and fumarate hydratase. Consequently, the reaction at the methyl groups of the two respective *S*-adenosyl-L-methionines produced from the two diastereomers of L-methionine proceeds with retention of configuration. This conclusion is of interest because almost every other methylation performed by active sites using *S*-adenosyl-L-methionine as the methyl donor proceeds with inversion of configuration in a concerted nucleophilic substitution.

Coenzyme-B sulfoethylthiotransferase (previously Equation 2–358)

$$\text{CoBSH + methyl-SCoM} \rightleftharpoons \text{methane + CoBS–SCoM} \quad (4\text{–}273)$$

where CoBSH is coenzyme B and methyl-SCoM is methylcoenzyme M, in addition to producing methane from methyl-SCoM (previously **2–173**)

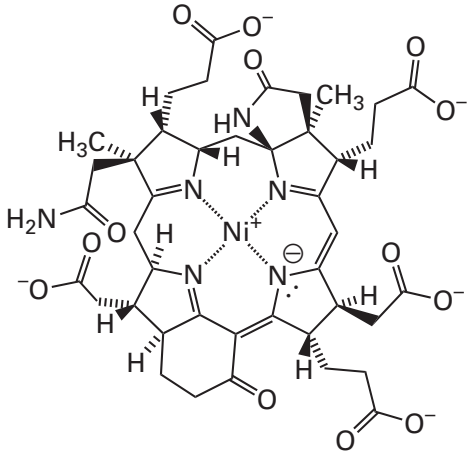


4–60

will produce ethane from ethyl-SCoM. The *R* and *S* enantiomers of [1,1-^{2}H,^{3}H]ethyl-SCoM were produced from [1-^{2}H]acetaldehyde in separate stereospecific syntheses that differed only in the stereoisomer of *B*-(3-pinanyl)-9-borabicyclo[3.3.1]-nonane used as a reductant. These enantiomers were separately incubated with a cell-free extract from the methanogenic bacterium *Methanosarcina barkeri* in ^1H_2O and the resulting ethanes were photochemically chlorinated and oxidized with basic permanganate, the radioactive products were the *R* and *S* enantiomers of [^{2}H,^{3}H]acetate, respectively. Consequently, the overall substitution of the sulfanyl group by a hydride* to produce the ethane proceeds with net inversion of configuration.[569]

*The replacement of a sulfur with a tritium inverts the priority relative to carbon.

Unlike the result for the methylation producing thienamycin (**4–59**), this result is consistent with the expected nucleophilic substitution at that carbon by the nucleophilic nickel(I) in coenzyme F_{430} (previously **2–175**)



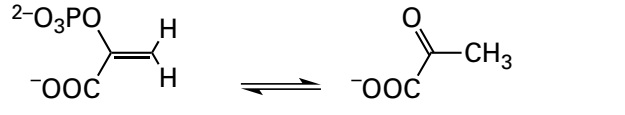
4–61

with $^-$SCoM as the leaving group, which should proceed with inversion of configuration, followed by reduction of the resulting methyl nickel with retention of configuration, presumably the result of the nickel in the methyl coenzyme F_{430} delivering the hydride to its own methyl group from a ligand position immediately adjacent to the carbon–nickel bond. The enantiomers of [1,1-^{2}H,^{3}H]ethane itself have been used to examine the stereochemistry of soluble methane monooxygenase from *Methylococcus capsulatus* (previously Equation 2–295)

$$H^+ + NADH + CH_4 + O_2 \rightleftharpoons CH_3OH + NAD^+ + H_2O \quad (4\text{–}274)$$

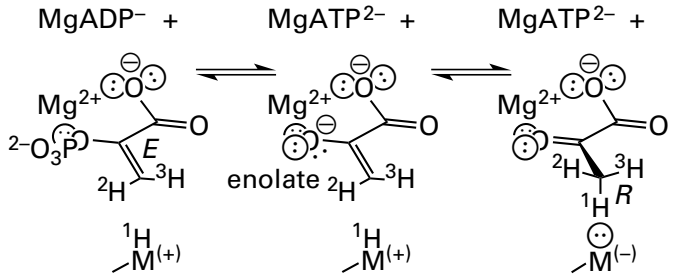
which also will accept ethane as a substrate.[578]

Both the ***Z* and *E* stereoisomers of [3,3-^{2}H,^{3}H]phospho*enol*pyruvate** have been synthesized enzymatically (see Problem 4–26)[579,580] and can be used as complementary reactants for one of the many enzymes using phospho*enol*pyruvate. For example, the active site of pyruvate kinase produces a methyl group from a methylene group of phospho*enol*pyruvate during its enzymatic reaction



+ $MgADP^-$ + H^+ + $MgATP^{2-}$ (4–275)

by adding a hydron to carbon 3 of the enolate of phospho*enol*pyruvate. The *Z* and *E* stereoisomers of [3,3-^{2}H,^{3}H]phospho*enol*pyruvate were separately incubated with pyruvate kinase from *O. cuniculus* in ^1H_2O to generate the two respective enantiomers of [3,3-^{2}H,^{3}H]pyruvate. These enantiomers were oxidized with H_2O_2 to produce the respective enantiomeric [^{2}H,^{3}H]acetates. The [3,3-^{2}H,^{3}H]pyruvate produced by the enzyme from (*E*)-[3,3-^{2}H,^{3}H]phospho*enol*pyruvate gave (*R*)-[^{2}H,^{3}H]acetate (68% retention of ^{3}H)

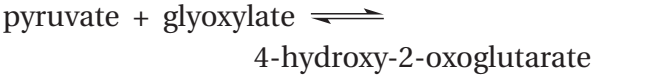


(4–276)

and the [3,3-^{2}H,^{3}H]pyruvate from (*Z*)-[3,3-^{2}H,^{3}H]phospho*enol*pyruvate gave (*S*)-[^{2}H,^{3}H]acetate (84% loss of ^{3}H).[579] Therefore, the catalytic acid that adds the hydron to the enolate of pyruvate during the enzymatic reaction must be on its *Si* face.

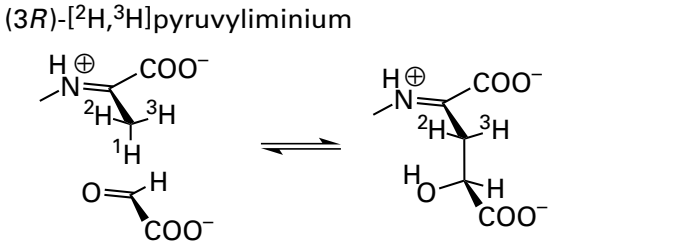
In the crystallographic molecular model of a complex between pyruvate kinase from *O. cuniculus* and $MgATP^{2-}$ and glyoxylate, which is an analogue of the enolate of pyruvate (Equation 4–276), a molecule of water, which is a ligand to the Mg^{2+} in $MgATP^{2-}$, is the only catalytic acid that sits on the face of the glyoxylate that would be the *Si* face of the enolate of pyruvate being mimicked by the glyoxylate and that could provide the hydron to the *Si* face.[581] Although this molecule of water is a decent acid in isolation,* a hydron from Glutamic Acid 363 can be relayed through two other molecules of water and the hydroxy group of Serine 361 through this molecule of water on the *Si* face of the enolate to its carbon 3.

The two **enantiomeric [3,3-^{2}H,^{3}H]pyruvates of known absolute stereochemistry** that were produced by pyruvate kinase (Equation 4–276), the stereochemistry of which were determined from the respective chiral acetates, can be used to follow stereochemistry in the many enzymatic reactions involving pyruvate as a reactant. For example, bovine 4-hydroxy-2-oxoglutarate aldolase



(4–277)

removes an acidic hydron from carbon 3 of pyruvate when it is in the enamine formed by addition of the amino group of Lysine 196 and then condenses this enamine of pyruvate with the carbonyl of glyoxylate. The 4-hydroxy-2-oxoglutarate produced can be converted directly to malate by oxidation with H_2O_2 rather than converting it to acetate and then to malate. The [^{3}H]malate produced from (3*R*)-[3,3-^{2}H,^{3}H]pyruvate lost 81% of its tritium upon incubation with fumarate hydratase, and the [^{3}H]malate produced from (3*S*)-[3,3-^{2}H,^{3}H]pyruvate retained 63% of its tritium upon incubation with fumarate hydratase.[582] Therefore, 4-hydroxy-2-oxoglutarate aldolase proceeds with retention of configuration at carbon 3 of pyruvate



(4–278)

In this case, it seems likely that the same catalytic base that removed the hydron from pyruvate to form its enolate then acts as a catalytic acid to hydronate the carbonyl oxygen of glyoxalate to improve its electrophilicity, or at least transfer the hydron during nucleophilic addition of the enolate, because, as the retention of configuration reveals, the hydron is removed from the same side of the pyruvate to which the aldehyde adds.

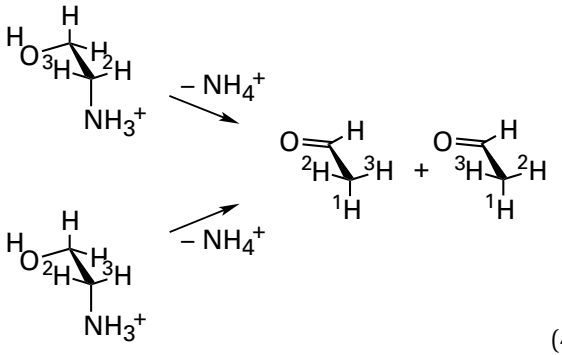
In the crystallographic molecular model of human 4-hydroxy-2-oxoglutarate aldolase (90% identity; 0 gap percent) in which the imine between Lysine 196 and pyruvate has been formed in the active site, a fixed molecule of water is located 0.3 nm from the carbon of the methyl group of the imine and 0.26 nm from the 4-hydroxy group of Tyrosine 168 on the same side that, in the enamine, adds to the aldehyde of the glyoxalate.[583] This molecule of water, through which the basicity of the 4-oxido group of Tyrosine 168 can be relayed, seems to be the base that removes the hydron from the imine to

*The pK_a of a molecule of water in the inner coordination sphere of a magnesium ion free in aqueous solution is 11.4.

form the enamine, and then the enamine adds to the carbonyl at the same face from which the hydron was removed.

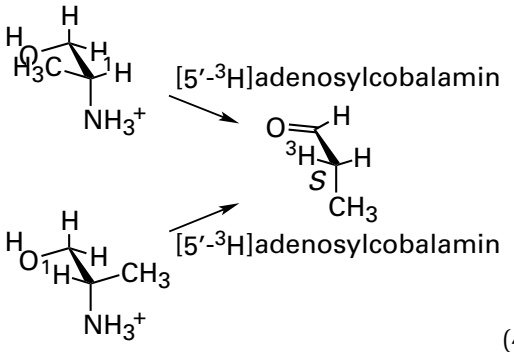
As with reactions involving enantiomeric [^{2}H,^{3}H]acetyl-SCoA, conclusions drawn from reactions involving enantiomeric [^{2}H,^{3}H]pyruvate depend upon an intrinsic kinetic isotope effect and the inability of an enol, enolate, enaminium, or enamine of pyruvate to undergo rotation between carbons 2 and 3 (Equation 4–276) because of the double bond. The fact that chirality, the result of either inversion or retention of configuration, is actually retained in products of these reactions states that the intermediate, in which the formerly chiral carbon has lost the protium, deuterium, or tritium, cannot, as expected, rotate around the bond because such rotation would lead to racemization.

The stereochemistry of an enzymatic reaction involving a chiral methyl group can also **demonstrate that an intermediate in the reaction is able to rotate** around an adjacent carbon–carbon bond during its lifetime. When either the *R* or the *S* enantiomer of [2,2-^{2}H,^{3}H]ethanolamine is converted to [^{2}H,^{3}H]acetaldehyde



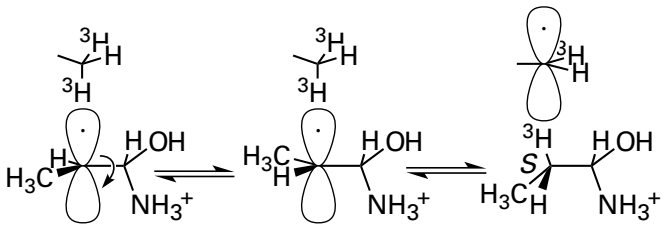
(4–279)

by clostridial ethanolamine ammonia-lyase (Table 2–3), an enzyme with a prosthetic coenzyme B_{12} in its active site, the [^{2}H,^{3}H]methyl group on the resulting [^{2}H,^{3}H]acetaldehyde is racemic.[584] This racemization is not due to the release of an achiral but rigid intermediate that is then rendered racemic by further reaction with the solvent, because when either the *R* or the *S* enantiomer of 2-aminopropanol is used as a reactant with the same enzyme, the products are enantiomeric rather than racemic. When (2*R*)-2-aminopropanol is converted to propionaldehyde with ethanolamine ammonia-lyase containing [5′-^{3}H]adenosylcobalamin, (2*S*)-[2-^{3}H]propionaldehyde is the product, but when (2*S*)-2-aminopropanol is the reactant, (2*S*)-[2-^{3}H]propionaldehyde is again the product[585]



(4–280)

All these results can be explained if an intermediate formed at some step in the reaction catalyzed by ethanolamine ammonia-lyase is free to rotate about its carbon–carbon bond while bound in the active site. For example, if the intermediate is the radical, produced by removal of a hydrogen atom from the *pro-S* position[585] of carbon 1 followed by a 1,2-migration of the amino group across one of its faces, then the resulting radical at carbon 2 produced from (2*S*)-2-aminopropanol



(4–281)

should be able to rotate before it is quenched by the return of the hydrogen atom from [5′-^{3}H]-5′-deoxyadenosine in order to explain the stereochemistry of the product. A similar argument, however, can be made if the intermediate is a carbenium ion or a carbanion rather than the radical. The intermediate produced from (2*R*)-2-aminopropanol would already be the second rotamer in Equation 4–281 rather than the first rotamer. If the second rotamer is the more stable one in the cases of both the 2*S* and 2*R* enantiomers of 2-aminopropanol because of steric interactions in the active site, then both enantiomers would give the same product, (2*S*)-[2-^{3}H]propionaldehyde, as is observed. Rotation of the type described would also explain the racemization observed in the case of [2,2-^{2}H,^{3}H]ethanolamine in which the two substituents on carbon 2 are merely isotopes of hydrogen, which cannot be sterically distinguished,

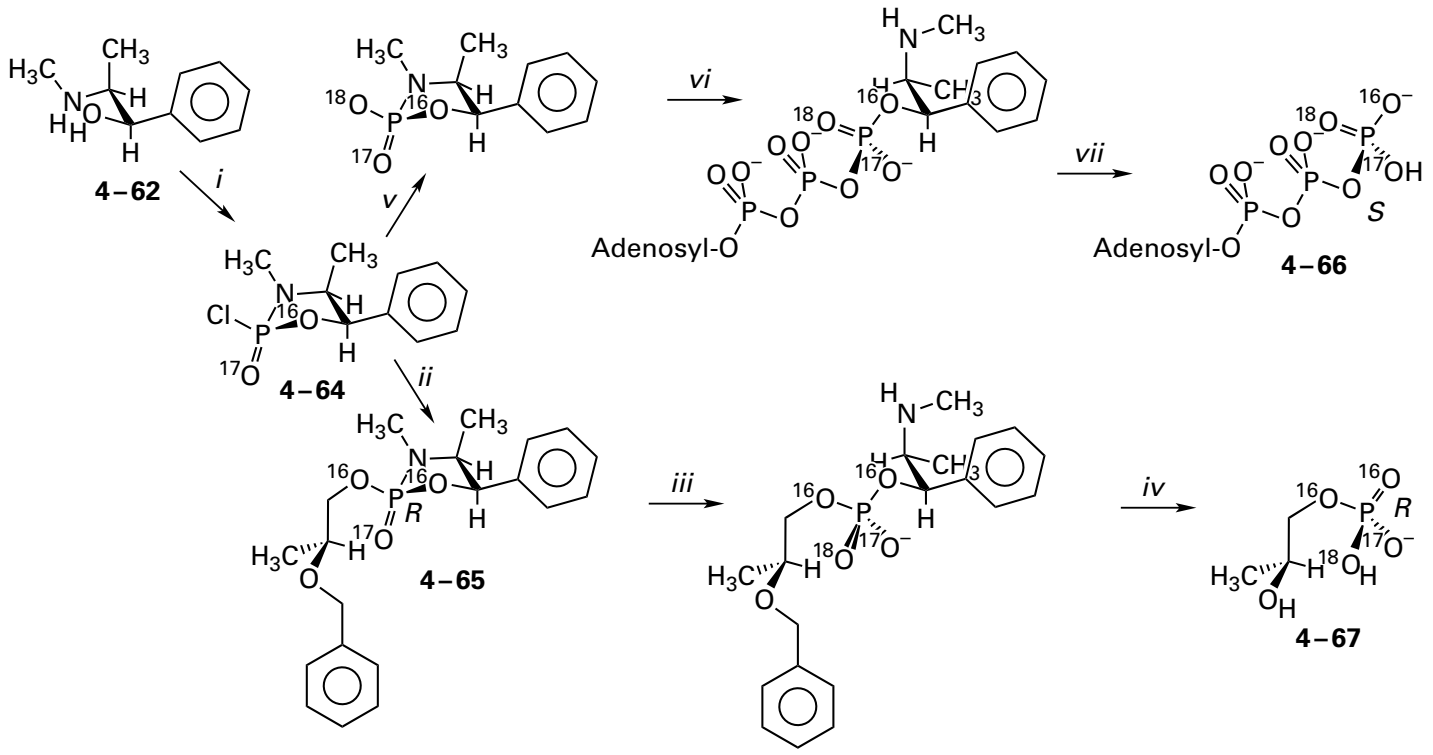


Figure 4–34: Synthesis of either 1-(*R*)-[^{17}O,^{18}O]phospho-(2*S*)-propane-1,2-diol (**4–67**)[586] or adenosine (*S*)-[γ,γ-^{17}O,^{18}O]triphosphate (**4–66**).[588] (1*R*,2*S*)-2-(Methylamino)-1-phenylpropanol (**4–62**) was (*i*) converted to the cyclic phosphoramidochloridic ester **4–64** with [^{17}O]$POCl_3$ in ether with triethylamine as the base. (*ii*) Cyclic phosphoramidochloridic ester **4–64** was submitted to substitution with 2-benzyl-(*S*)-propane-1,2-diol, again with triethylamine as the base, and the two diastereomeric epimers at phosphorus were resolved chromatographically. (*iii*) The major epimer was hydrolyzed in acidic $H_2{}^{18}O$, and (*iv*) the phosphate amido ester was reduced with H_2 over palladium on carbon to produce the monoester **4–67**. The two diastereomeric epimers at phosphorus of cyclic phosphoramidochloridic ester **4–64** were separated chromatographically, and (*v*) the major one was hydrolyzed with Li^{18}OH in $H_2{}^{18}O$ and dioxane. (*vi*) The product of this reaction was submitted to nucleophilic substitution with ADP^{3-} in dimethyl sulfoxide, and (*vii*) adenosine (*S*)-[γ,γ-^{17}O,^{18}O]triphosphate was released by reduction with H_2 over palladium on carbon in ethanol–water.

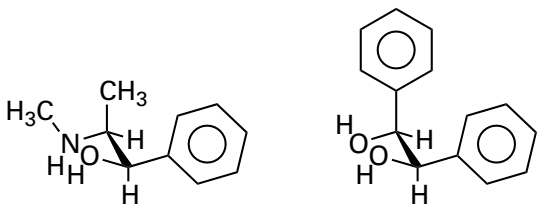
rather than the methyl group in the intermediate from 2-aminopropanol, which can. In this instance, stereochemistry has provided information about two properties of the reaction: namely, that the intermediate is capable of dihedral rotation about its central carbon–carbon bond within its lifetime and that it is sterically confined by its surroundings.

The wide use of enantiomeric [^{2}H,^{3}H]acetate, in which three otherwise identical hydrogen atoms are distinguished by using the three isotopes protium, deuterium, and tritium, inspired the synthesis and use of chiral phospho groups in which three otherwise identical oxygen atoms are distinguished by using the three isotopes oxygen-16, oxygen-17, and oxygen-18. A chiral phospho group can be **prepared synthetically from specific diastereomers of vicinal bisnucleophiles**, such as 2-(methylamino)-1-phenyl-1-propanol (**4–62**)[586] or 1,2-diphenylethylene glycol (**4–63**)[587]



The particular diastereomer chosen to initiate the synthesis determines the stereochemistry of the ultimate phospho group (Figure 4–34).[586,588] For example, 1-[(*R*)-^{17}O,^{18}O]phospho-(2*S*)-propane-1,2-diol (**4–67**) was synthesized from (1*R*,2*S*)-2-(methylamino)-1-phenylpropanol (**4–62**) as follows. (1*R*,2*S*)-2-(Methylamino)-1-phenylpropanol was

(*i*) converted to the cyclic phosphoramidochloridic ester **4–64** with [^{17}O]phosphoryl trichloride. Cyclic phosphoramidochloridic ester **4–64** was then submitted to (*ii*) nucleophilic substitution with 2-benzyl-(*S*)-propane-1,2-diol, and the two epimers at the phosphorus of the resulting diastereomeric cyclic [^{17}O]phosphoramidic diester **4–65** were resolved chromatographically. The major epimer from the chromatography was (*iii*) hydrolyzed in acidic $H_2{}^{18}O$, and the resulting phosphate diester was (*iv*) reduced with H_2 over palladium on carbon to produce a stereochemically pure monoester.

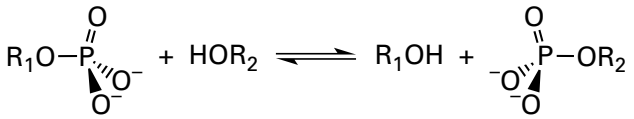
Because the chirality of the major epimer at phosphorus of the phosphoramidate chosen for further reaction after the chromatography was unknown and because the stereochemistry of the nucleophilic substitution at this particular phosphorus had never been determined, the synthesis itself, although stereospecific, did not define the chirality at phosphorus in the final monoester, 1-[^{17}O,^{18}O]phospho-(2*S*)-propane-1,2-diol. Because, however, the final product was a diastereomer, the stereochemistry at phosphorus could be assigned unambiguously as *R* by **metastable ion mass spectrometry** of the cyclic products of intramolecular nucleophilic substitution at phosphorus by the hydroxy group in the (2*S*)-2-hydroxypropyl group.[586] This assignment serves as the basis for stereochemical assignments of the other diastereomeric phosphates in the synthesis. Because reduction with H_2 over palladium on carbon (step *iv*) does not disturb the chirality at phosphorus and hydrolysis in acidic $H_2{}^{18}O$ (step *iii*) proceeds with inversion of configuration, it follows that the major epimer of the cyclic [^{17}O]phosphoramidic diester **4–65** that was purified chromatographically and chosen blindly must have had the *R* configuration at phosphorus as shown.

Once the assignment of the absolute stereochemistry of 1-(*R*)-[^{17}O,^{18}O]phospho-(2*S*)-propane-1,2-diol had been established, a rapid **routine assay for the stereochemistry of a [^{17}O,^{18}O]phospho group** in either the reactant or the product of a chemical synthesis, chemical reaction, or enzymatic reaction by phosphorus nuclear magnetic resonance spectroscopy became available. Usually, the chiral [^{17}O,^{18}O]phospho group in the product of a reaction is transferred enzymatically by reactions of known stereochemistries to a reference diol, either *S*-propane-1,2-diol (dephospho **4–67** in Figure 4–34)[589] or D-glucose.[590] The resulting phosphate monoester is then intramolecularly cyclized to the cyclic diester with inversion of configuration to produce three unique cyclic diesters, which are methylated at random to produce six *O*-methyl diastereomers. Because the presence of oxygen-17 broadens the absorbances of phosphorus in a nuclear magnetic resonance spectrum, signals from only the four cyclic diesters that contain only oxygen-16 and oxygen-18 are observed. The mixture of these four diastereomers from 1-(*R*)-[^{17}O,^{18}O]phospho-(2*S*)-propane-1,2-diol has a phosphorus nuclear magnetic resonance spectrum that can be readily distinguished from the spectrum for the mixture of the four diastereomers from 1-(*S*)-[^{17}O,^{18}O]phospho-(2*S*)-propane-1,2-diol.

Adenosine [γ,γ-^{17}O,^{18}O]triphosphate (**4–66**)[588] can also be synthesized from (1*R*,2*S*)-2-(methylamino)-1-phenylpropanol (Figure 4–34). (*v*) The major epimer of diastereomeric cyclic phosphoramidochloridic ester **4–64** is chromatographically purified and then hydrolyzed with $Li^{18}OH$ in $H_2{}^{18}O$ and dioxane with retention of configuration. (*vi*) The product of this hydrolysis is submitted to nucleophilic substitution at phosphorus with ADP^{3-} with inversion of configuration, and (*vii*) adenosine [γ,γ-^{17}O,^{18}O]triphosphate is released by reduction with H_2 over palladium on carbon. Again, the synthesis does not define the stereochemistry at phosphorus. When, however, the γ-phospho group of adenosine [γ,γ-^{17}O,^{18}O]triphosphate was transferred, with retention of configuration,[591] to 1-phospho-(*S*)-propane-1,2-diol, using alkaline phosphatase from *E. coli*, the nuclear magnetic resonance spectrum identified the product of the synthesis as adenosine (*R*)-[γ,γ-^{17}O,^{18}O]triphosphate.

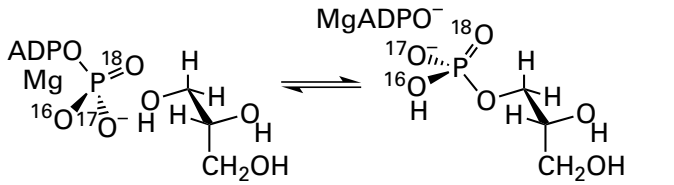
Another approach to enantiomeric phosphate has been to use two isotopes of oxygen, oxygen-16 and oxygen-18, and replace the third oxygen with sulfur.[592] For example, two syntheses of adenosine (*R*)-[γ-^{18}O]-γ-thiotriphosphate have been developed,[593,594] and the absolute stereochemical preferences of acetate kinase and pyruvate kinase have been exploited to determine the absolute stereochemistry of any [^{18}O]thiophosphate that can be transferred to become the β-phosphate on ADP^{3-}.[595] A chiral triester of thiophosphate, in which a cyclohexyl group, a methyl group, and a 4-nitrophenyl group are substituents on the three oxygens of thiophosphate, has been used as a chiral reactant for aryldialkylphosphatase from *Sphingobium fuliginis* to demonstrate that the enzyme proceeds with inversion of configuration at phosphorus. In this case, no isotopes had to be used because the product of the reaction was the chiral ethylcyclohexylthiophosphodiester.[596]

Chiral phospho groups have been used to examine the stereochemistry of nucleophilic substitutions at phosphorus of the type



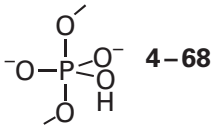
(4–282)

catalyzed by a large collection of enzymes. In all cases, the enzymes catalyze the transfer of a phospho group from an atom of oxygen in one compound to an atom of oxygen in another compound. The significant majority of these enzymatic reactions **proceed with inversion of configuration at phosphorus**. For example, glycerol kinase from *E. coli* proceeds with inversion of configuration at phosphorus[588]



(4–283)

These observations suggest that such enzymatic reactions are simple in-line nucleophilic substitutions at phosphorus. If a **phosphorane** (see **1–56**)



4–68

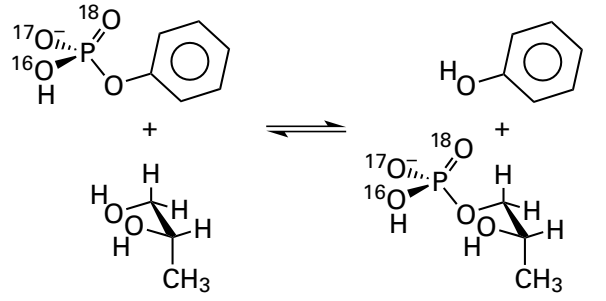
is formed during this nucleophilic substitution, it necessarily has the oxygen of the acceptor at one axial position and the oxygen of the donor at the other axial position, and these inversions of configuration imply that no pseudorotation takes place. A mechanism in which the oxygen that is the donor resides at an equatorial position in the phosphorane and then assumes an axial position by pseudorotation prior to departure would proceed with retention of configuration. In the active sites of those enzymes that catalyze nucleophilic substitutions at phosphorus that proceed with inversion of configuration, the donor and acceptor must be held in such a way that the oxygen of the acceptor lies upon the opposite side of phosphorus on the line of the phosphorus–oxygen bond of the donor, as in Figures 3–38 and 3–40.

Inversion of configuration, however, **cannot rule out monomeric metaphosphate** as an intermediate in an enzymatically catalyzed nucleophilic substitution at phosphorus because, in the active site of an enzyme, the acceptor and the phospho group of the donor are always held rigidly in place by the noncovalent forces and steric forces of the surroundings. Consequently, inversion of configuration is to be expected of a nucleophilic substitution at phosphorus that involves monomeric metaphosphate as an intermediate (Figure 3–41).

There are several enzymatic nucleophilic substitutions at phosphorus, however, that proceed with **retention of configuration at phosphorus**. In these instances, there is independent evidence that a phosphorylated form of the enzyme acts as a **phosphorylated intermediate** in the enzymatic mechanism. For example, alkaline phosphatase catalyzes nucleophilic substitutions at phosphorus in which the donor and acceptor can be any two alcohols, including water, which is the alcohol where R is H. Because water is usually present at high concentration, it is usually the acceptor when any phosphate monoester is the reactant for alkaline phosphatase. For this reason, the enzymatic reaction is usually hydrolysis of a phosphate monoester (previously Equation 3–380)

(4–284)

If, however, an alcohol other than water is present in the solution at high concentration, the phosphate will be transferred from the donor to that alcohol as well. Alkaline phosphatase from *E. coli* transfers phosphate from phenylphosphate to (*S*)-propane-1,2-diol with retention of configuration[591]



(4–285)

It has been established independently that, in the first step of the enzymatic reaction, the donor transfers the phosphate to Serine 102 within the active site of the enzyme.[597] The donor then leaves the active site and is replaced by the acceptor, and the phosphate is transferred from Serine 102 to the acceptor.

The detailed structure of the active site[597] is consistent with both transfers occurring with inversion of configuration, which would produce net retention of configuration.

Nucleoside-diphosphate kinase catalyzes a nucleophilic substitution at phosphorus

$$MgXTP^{2-} + MgYDP^{-} \rightleftharpoons MgXDP^{-} + MgYTP^{2-} \quad (4\text{–}286)$$

where XTP and YTP are any number of nucleoside 5′-triphosphates and XDP and YDP are the corresponding nucleoside 5′-diphosphates. Its usual purpose is to use $MgATP^{2-}$ to phosphorylate a nucleoside 5′-diphosphate other than $MgADP^{-}$ by transferring the γ-phospho group from $MgATP^{2-}$ to one oxygen in the β-phospho group of the nucleoside 5′-diphosphate and, in this way, to maintain the concentrations of all the nucleoside 5′-triphosphates at high levels relative to their 5′-diphosphates. Bovine nucleoside-diphosphate kinase proceeds with **retention of configuration at phosphorus**,[598] and independent results for the enzyme from *S. cerevisiae* (58% identity; 0 gap percent) are consistent with a mechanism in which the nucleoside triphosphate phosphorylates the imidazolyl group of a histidine within the active site, leaves as the nucleoside diphosphate, and is replaced by the other nucleoside diphosphate, which accepts the phosphate from the resulting *N*-phosphoimidazolyl group.[599-601]

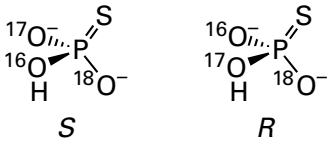
The results with nucleoside diphosphate kinase can be contrasted with those obtained with adenylate kinase

$$MgATP^{2-} + AMP^{2-} \rightleftharpoons ADP^{3-} + MgADP^{-} \quad (4\text{–}287)$$

an enzyme that catalyzes a chemically equivalent reaction. Adenylate kinase from *O. cuniculus* proceeds with **inversion of configuration at phosphorus**.[593] The difference between the reactions catalyzed by nucleoside-diphosphate kinase and adenylate kinase is that the phospho group in the phosphoimidazolyl intermediate in the former reaction (Equation 4–286) always reacts with a nucleoside diphosphate, including the $MgADP^{-}$ that results from phosphorylation of the enzyme by $MgATP^{2-}$. If there were a phosphoimidazolyl intermediate in the active site of adenylate kinase, it would have to transfer its phospho group to both a nucleoside monophosphate, AMP^{2-}, and a nucleoside diphosphate, $MgADP^{-}$. In addition, the active site would have to be able to recognize each as an adenine nucleotide. These two nucleoside phosphates, AMP^{2-} and $MgADP^{-}$, are quite different structurally when viewed back into the respective molecules from the oxygens donating and accepting the phospho group. For both of these reasons, an active site could not be designed so that the same constellation of amino acids is able to recognize in turn the donor and the acceptor. Consequently, the active site of adenylate kinase must form hydrogen bonds over the complete structure of both the donor of the phospho group and the acceptor for the phospho group. As a result, adenylate kinase catalyzes the direct transfer of the phospho group from donor to acceptor while both are bound simultaneously to different regions of the active site.[602] The transfer is accomplished by aligning the nucleophilic oxygen on the α-phospho group of AMP^{2-} with the bridging oxygen–phosphorus bond of the γ-phospho group of $MgATP^{2-}$ and proceeding with an in-line transfer with inversion of configuration with $MgADP^{-}$ as the leaving group.[603,604] Further evidence for this conclusion is that P^1,P^5-bis-(5′-adenosyl)pentaphosphate, a linear pentaphosphate with adenosines at each end that should mimic the transition state in the nucleophilic substitution at phosphorus, is a strong inhibitor ($K_i = 2$ nM) of the enzymatic activity,[605] and a crystallographic molecular model of this complex in the active site has been reported.[606]

The fact that enzymatic nucleophilic substitutions at phosphorus occur with inversion of configuration whenever there is no intermediate phosphoenzyme and the fact that enzymatic nucleophilic substitutions at phosphorus occur with retention of configuration when there a phosphoenzyme intermediate both require that, in these reactions, no pseudorotation can occur. All these results together lead to the conclusion that pseudorotation, which is of accepted chemical interest, is not involved in enzymatic mechanisms.

The three isotopes of oxygen have been used along with sulfur to produce **chiral thiophosphate**[592]



S **4–69** *R* **4–70**

and a method has been developed to distinguish the two enantiomers of [^{17}O,^{18}O]thiophosphate.

Each enantiomer, separately, is converted to adenosine [β,β-^{17}O, ^{18}O]-β-thiotriphosphate by using, in sequence, glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) from *O. cuniculus*, phosphoglycerate kinase from *S. cerevisiae*, adenylate kinase from *O. cuniculus*, and then phosphoglycerate kinase a second time. The diastereomers of adenosine [β,β-^{17}O, ^{18}O]-β-thiotriphosphate produced by this sequence of reactions from (*S*)-[^{17}O,^{18}O]thiophosphate have a phosphorus nuclear magnetic resonance spectrum that is different from those produced from (*R*)-[^{17}O,^{18}O]thiophosphate.[607]

The production of chiral thiophosphate and assays for its chirality have been used to determine the stereochemical consequences of reactions in which $MgATP^{2-}$ is hydrolyzed to phosphate

$$MgATP^{2-} + H_2O \rightleftharpoons H^+ + HOPO_3^{2-} + MgADP^- \quad (4\text{–}288)$$

to provide energy. The consumption of chiral thiophosphate has also been used to determine the stereochemical consequences when $MgATP^{2-}$ is synthesized from phosphate to store energy.[608] When adenosine [(*S*)-γ,γ-^{17}O,^{18}O]-γ-thiotriphosphate is hydrolyzed in $H_2{}^{16}O$ by Ca^{2+}-transporting ATPase from *O. cuniculus*, an enzyme that uses standard free energy from the hydrolysis of $MgATP^{2-}$ for the active transport of calcium across cellular membranes, the [^{17}O,^{18}O]thiophosphate produced has the *S* configuration.[609] The **retention of configuration** observed is due to a phosphorylated intermediate in the mechanism of the enzymatic reaction. The γ-phospho group of $MgATP^{2-}$ is transferred to an aspartate in the active site to produce a mixed anhydride,[610] which is then hydrolyzed by water. The **two successive steps**, each proceeding with inversion of configuration, cause the net result to be retention of configuration. When adenosine (*S*)-[γ^{18}O]-γ-thiotriphosphate, however, is hydrolyzed in $H_2{}^{17}O$ by the ATPase of myosin from *O. cuniculus*, (*S*)-[^{17}O,^{18}O]thiophosphate is produced.[611] The **inversion of configuration** observed in this case has been used as evidence that water directly hydrolyzes the $MgATP^{2-}$ on the active site of myosin in a **single step** through an in-line nucleophilic substitution at phosphorus.

When adenosine (*R*)-[γ,γ-^{17}O,^{18}O]-γ-thiotriphosphate is used as a reactant for glutamine synthetase from *S. typhimurium* (previously Equation 3–405)

$$\text{L-glutamate} + NH_3 + MgATP^{2-} \rightleftharpoons MgADP^- + HOPO_3^{2-} + \text{L-glutamine} \quad (4\text{–}289)$$

in $H_2{}^{16}O$, (*S*)-[^{16}O,^{17}O,^{18}O]thiophosphate was produced.[594] This result is consistent with in-line attack of the oxygen in the carboxy group of the reactant, L-glutamate, bound in the active site, on the immediately adjacent γ-phospho group of the reactant, $MgATP^{2-}$, also bound in the active site, with $MgADP^-$ as the leaving group. This single step in the overall reaction would proceed with inversion of configuration at phosphorus, as is usually the case. The next step in the enzymatic reaction would be the nucleophilic substitution of the phosphate at the carboxyl carbon in the resulting γ-glutamyl phosphate by the third reactant, ammonia, to produce the product, L-glutamine.[612] This step would have no effect on the chirality of the phospho group that is the leaving group during the nucleophilic substitution at the acyl carbon of the acylphosphate. The initial inversion of configuration at phosphorus explains the inversion of configuration observed for the overall reaction.

(A) Write the steps in the mechanism of the reaction catalyzed by D-serine ammonia-lyase

$$\text{D-serine} \rightleftharpoons NH_4^+ + \text{pyruvate}$$

The active site uses a prosthetic pyridoxal 5′-phosphate to perform the reaction, so your mechanism should incorporate the pyridoxal 5′-phosphate performing its usual sequence of events as well as one unusual step.

In this enzymatic reaction, the oxygen on carbon 3 of D-serine is replaced by hydrogen. D-Serine ammonia-lyase uses only D-serine [(2*R*)-serine] as a substrate, never L-serine [(2*S*)-serine]. Likewise, the enzyme D-amino-acid oxidase turns only D-serine into 3-hydroxypyruvate, never L-serine. Therefore, in a mixture of the two enantiomers of serine, only the (2*R*)-serine is a substrate for either enzyme and the (2*S*)-serine is untouched.

(*E*)-[3-^{3}H]Propenoic acid was dissolved in methanol, and solid $Ag(CH_3COO)_2$ was added, followed by Br_2. Among other products, a diastereomeric pair of [3-^{3}H]-2-bromo-3-methoxypropanoic acids was formed by anti addition to the double bond. Ammonia (NH_3) was then added to the solution to displace the Br in a concerted nucleophilic substitution with inversion of configuration. After several hours, the whole mixture was treated with HBr to remove the methyl group from the oxygen of the methoxy group by a nucleophilic substitution at the methyl group. After purification, a diastereomeric pair of [^{3}H]serines was obtained from the overall reaction.[613]

(B) Draw, in the sawhorse convention, the absolute structures of the two diastereomeric serines in the diastereomeric mixture obtained from this synthesis, and label each chiral carbon as *R* or *S*.

A portion of this diastereomeric mixture was treated with porcine D-amino-acid oxidase, and [^{3}H]-3-hydroxypyruvate was isolated. This product was treated with H_2O_2 to produce glycolate, which was then turned into glyoxylate by (*S*)-2-hydroxy-acid oxidase from *S. oleracea*. The glyoxylate contained 80% of the tritium originally in the pyruvate; the other 20% was lost as ^3H_2O by slow exchange.

A portion of the original diastereomeric mixture of [^{3}H]serines was also dissolved in ^2H_2O and treated with a mixture of D-serine ammonia-lyase from *E. coli*, pyruvate carboxylase from *G. gallus*, CO_2, $MgATP^{2-}$, malate dehydrogenase, and NADH, all in ^2H_2O. The resulting [3,3-^{2}H,^{3}H]malate was purified from the reaction. Pyruvate carboxylase replaces a hydron on pyruvate with CO_2, which is added with retention of configuration, and the enzyme prefers to remove a hydron by a factor of 3 over a deuteron. Malate dehydrogenase produces only (*S*)-malate from oxaloacetate. When the [3,3-^{2}H,^{3}H]malate was incubated with fumarate hydratase, 41% of the ^{3}H was found in the fumarate, and 58% was recovered as ^3H_2O.

(C) Draw, in the sawhorse convention, the absolute structures of the [3,3-^{2}H,^{3}H]malate, the intermediate [3,3-^{2}H,^{3}H]pyruvate, and the diastereomer of the serine that was the reactant for D-serine ammonia-lyase. Label each chiral carbon as *R* or *S*.

A portion of the original enantiomeric mixture of [^{3}H]serines obtained from the synthesis was acetylated on their amino nitrogens to produce an enantiomeric pair of [3-^{3}H]-*N*-acetylserines. This mixture was treated with porcine aminoacylase, an enzyme that hydrolyzes acetyl groups only from *N*-acetyl-L-amino acids [(2*S*)-*N*-acetyl amino acids]. The optically pure L-[3-^{3}H]serine that was formed by this enzyme was purified, and this optically pure compound was racemized only at carbon 2 to give an equal mixture of the 2*R* and 2*S* enantiomers of [3-^{3}H]serine. This final mixture contained a pair of diastereomers.

(D) Draw, in the sawhorse convention, the absolute structure of the two stereoisomers of [3-^{3}H]serine that were present in this latter diastereomeric mixture, and label each chiral carbon as *R* or *S*.

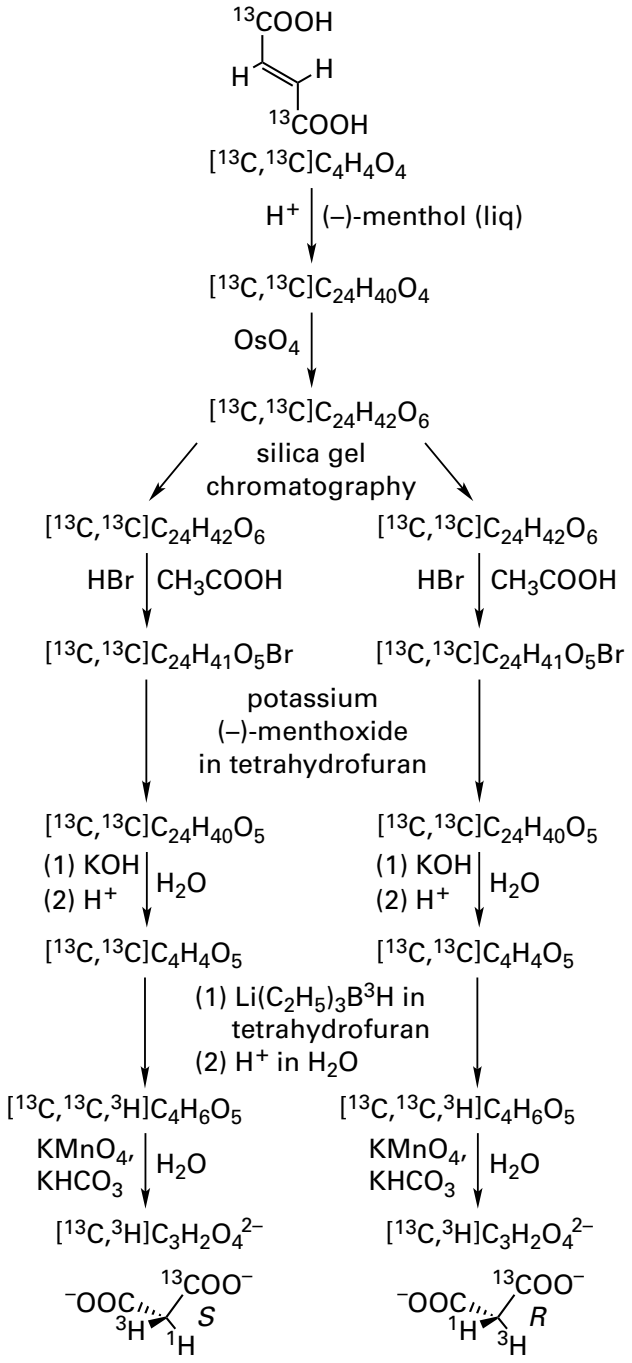
(E) When this diastereomeric mixture was treated with porcine D-amino-acid oxidase, and the [3-^{3}H]-3-hydroxypyruvate was purified and treated with H_2O_2 followed by (*S*)-2-hydroxy-acid oxidase, how much of the tritium in [3-^{3}H]-3-hydroxypyruvate was retained in the glyoxylate?

When the latter diastereomeric mixture, dissolved in ^2H_2O, was incubated with D-serine ammonia-lyase from *E. coli*, pyruvate carboxylase, CO_2, $MgATP^{2-}$, malate dehydrogenase, and NADH in ^2H_2O, [3,3-^{2}H,^{3}H]malate could be isolated. When this [3,3-^{2}H,^{3}H]malate was incubated with fumarate hydratase, 37% of the ^{3}H was released as ^3H_2O and 63% of the ^{3}H was retained in the fumarate.

(F) Refer to your mechanism for D-serine ammonia-lyase in part A and draw the dissociation of the hydroxy group from the quinonoid intermediate and addition of a hydron to the resulting carbon–carbon double bond with the proper stereochemistry based on all these results. Do these two steps result in retention or inversion of configuration at this carbon?

(G) Does the enzyme release into solution the enamine of pyruvate or pyruvate itself as the product? How can you be sure?

Problem 4–18: Draw in the sawhorse convention the structure of each intermediate product in the following synthesis of the two enantiomers of malonate.[614] In your drawings label each chiral carbon as *R* or *S*. Abbreviate menthyl as $C_{10}H_{19}$.



What is (–)-menthol and what purpose does it serve? What is potassium (–)-menthoxide and what purpose does it serve?

Problem 4–19: 2-Methylacyl-CoA dehydrogenase from *R. norvegicus* is a flavoenzyme that catalyzes the following reactions.[615]

(*S*)-2-methylbutanoyl-SCoA $\rightleftharpoons$
(*E*)-2-methylbut-2-enoyl-SCoA + 2 H^+ + 2 e^-

(*R*)-2-methylbutanoyl-SCoA $\rightleftharpoons$
2-ethylpropenoyl-SCoA + 2 H^+ + 2 e^-

2-methylpropanoyl-SCoA $\rightleftharpoons$
2-methylpropenoyl-SCoA + 2 H^+ + 2 e^-

For the moment, assume that the hydron on carbon 2 of each reactant is removed as a hydron to form the enolate and the other hydrogen is removed as a hydride by flavin in the equivalent of a β elimination.

(A) Explain the regiochemistry and stereochemistry of the products by drawing three pictures of the active site of the enzyme. In each case, the disposition of the catalytic base and the flavin in the active site must be the same, but a different one of the three reactants will be bound to it. The drawings must clearly indicate the three-dimensional dispositions of catalytic base, flavin, and reactants that explain the stereochemical results. Abbreviate coenzyme A as SCoA and disregard its detailed structure, and abbreviate flavin as HFl_{ox} and $H_2Fl_{red}^-$, as appropriate, and disregard its detailed structure. Choose a specific side chain to be the catalytic base.

(B) Explain why the enzyme is unable to catalyze the following oxidation because of an absolute stereochemical requirement.

(*R*)-2-methylbutanoyl-SCoA $\rightleftharpoons$
(*Z*)-2-methylbut-2-enoyl-SCoA + 2 H^+ + 2 e^-

The K_m for (*S*)-2-methylbutanoyl-SCoA is 20 μM. Both *n*-butanoyl-SCoA and *n*-pentanoyl-SCoA inhibit the oxidation of (*S*)-2-methylbutanoyl-SCoA. At 100 μM (*S*)-2-methylbutanoyl-SCoA, 100 μM *n*-butanoyl-SCoA inhibits the initial rate for oxidation of (*S*)-2-methylbutanoyl-SCoA by 58%, and 100 μM *n*-pentanoyl-SCoA inhibits the initial rate for oxidation of 2-methylbutanoyl-SCoA by 52%.

(C) Assume that *n*-butanoyl-SCoA and *n*-pentanoyl-SCoA are competitive inhibitors of the enzyme, and calculate the K_i for each.

n-Butanoyl-SCoA is oxidized by the enzyme at a rate only 5% that of the rate for oxidation of (*S*)-2-methylbutanoyl-SCoA when either of these reactants is present at a concentration of 100 μM. *n*-Pentanoyl-SCoA is not oxidized at all by the enzyme.

(D) Provide an explanation, consistent with both your structure of the active site in part A and the dissociation constants calculated in part C, for the fact that *n*-butanoyl-SCoA is a poor substrate and *n*-pentanoyl-SCoA is not a substrate for the enzyme.

Problem 4–20: Fatty-acid synthase system from *G. gallus*, in addition to catalyzing the internal reactions of Equations 3–495 through 3–498, also catalyzes the following homologous external reactions.

acetyl-SCoA + malonyl-SCoA + H^+ $\rightleftharpoons$
HSCoA + CO_2 + acetoacetyl-SCoA (1)

NADPH + acetoacetyl-SCoA + H^+ $\rightleftharpoons$
(*R*)-3-hydroxybutanoyl-SCoA + $NADP^+$ (2)

(*R*)-3-hydroxybutanoyl-SCoA $\rightleftharpoons$
H_2O + (*E*)-but-2-enoyl-SCoA (3)

NADPH + (*E*)-but-2-enoyl-SCoA + H^+ $\rightleftharpoons$
butanoyl-SCoA + $NADP^+$ (4)

(*E*)-But-2-enoyl-SCoA was hydrated by fatty-acid synthase system in ^2H_2O to (3*R*)-[2-^{2}H]-3-hydroxybutyryl-SCoA until equilibrium was reached (Equation 3), and the resulting (3*R*)-[2-^{2}H]-3-hydroxybutyryl-SCoA was purified. The (3*R*)-[2-^{2}H]-3-hydroxybutyryl group was transferred to benzylamine to produce *N*-benzyl-(3*R*)-[2-^{2}H]-3-hydroxybutyramide. The nuclear magnetic resonance spectrum of this product displayed a doublet at 2.4 ppm that was assigned to the proton on carbon 2 of the (3*R*)-[2-^{2}H]-3-hydroxybutyryl group.[491] The doublet integrated with a magnitude of only one proton, which is consistent with the conclusion that carbon 2 had both a hydrogen and a deuterium attached to it.

(A) Which proton on the 3-hydroxybutyryl group is responsible for splitting the absorption of the single proton on carbon 2 into a doublet?

The coupling constant for splitting the absorption of the proton on carbon 2 was 5.5 Hz. When the enzymatic reaction was brought to equilibrium with (3*R*)-[2,2-$^2H_2$]-3-hydroxybutyryl-SCoA in H_2O, the resulting *N*-benzyl-(3*R*)-[2-^{2}H]-3-hydroxybutyramide again displayed a doublet in its nuclear magnetic spectrum at 2.4 ppm, but the coupling constant was 8.4 Hz.

(B) In the spectrum of the first product that has a doublet with a coupling constant of 5.5 Hz, no contribution from a doublet with a coupling constant of 8.4 Hz was detected, and in the spectrum of the second product with a doublet with a coupling constant of 8.4 Hz, no contribution from a doublet with a coupling constant of 5.5 Hz could be detected. What does this observation demonstrate about the stereochemical purity of the two products?

(C) When (*E*)-2,3-epoxybutyric acid was reduced with sodium borodeuteride (NaB^2H_4) in ^2H_2O, the diastereomeric [2-^{2}H]-3-hydroxybutyric acid produced also displayed a doublet in its nuclear magnetic resonance spectrum at 2.5 ppm. The doublet integrated with a magnitude of one proton.[616] This doublet had a coupling constant of 9.0 Hz. What is the absolute stereochemistry at carbon 2 of (3*R*)-[2-^{2}H]-3-hydroxybutyric acid in this racemic synthetic product?

(D) Assume that the (3*R*)-[2-^{2}H]-3-hydroxybutyryl group on *N*-benzyl-(3*R*)-[2-^{2}H]-3-hydroxybutyramide that displayed a doublet with a coupling constant of 8.4 Hz had the same absolute stereochemistry as the (3*R*)-[2-^{2}H]-3-hydroxybutyric acid synthesized in part C, the doublet of which had a coupling constant of 9.0, and assume that the enzymatic product that displayed a doublet with a coupling constant of 5.5 Hz had the opposite stereochemistry at carbon 2. Write a chemical reaction with all reactants and products in the proper stereochemistry that describes the enzymatic hydration of (*E*)-but-2-enoyl-SCoA. Is this a syn addition or an anti addition?

(E) Write the chemical mechanism for the reaction of Equation 1 (the external homologue of Equation 3–495), in which malonyl-SCoA contributes carbons 1 and 2 of the acetoacetyl-SCoA and acetyl-SCoA contributes carbons 3 and 4.

Malonyl-SCoA is produced from acetyl-SCoA in a reaction catalyzed by acetyl-CoA carboxylase

$$\begin{aligned} MgATP^{2-} + HCO_3^- + \\ \text{acetyl-SCoA} \rightleftharpoons MgADP^- + HOPO_3^{2-} \\ + H^+ + \text{malonyl-SCoA} \end{aligned}$$

that uses biotin as a prosthetic group. As is the case with propionyl-CoA carboxylase (Equation 4–261), a hydrogen on acetyl-SCoA is replaced by the carboxy group from 1-(*N*-carboxy)biotin (Equation 4–262) with retention of configuration.

(F) If (*R*)-[^{2}H,^{3}H]acetyl-SCoA were carboxylated by acetyl-CoA carboxylase, what would be the stereochemistry of the [^{2}H,^{3}H]malonyl-SCoA produced?

When (*R*)-[^{2}H,^{3}H]acetyl-SCoA was incubated with acetyl-CoA carboxylase from *G. gallus* and fatty-acid synthase system simultaneously, the butyryl-SCoA produced[617] retained 30.4% of the tritium at carbon 2. When (*S*)-[^{2}H,^{3}H]acetyl-SCoA was incubated with this mixture of enzymes, the butyryl-SCoA retained 34.3% of the tritium at carbon 2. When racemic [2-^{3}H]acetyl-SCoA was incubated with this mixture of enzymes, the butyryl-SCoA retained 32.3% of the tritium at carbon 2.

(G) The first hydrogen is removed from carbon 2 of the original acetyl-SCoA by acetyl-CoA carboxylase. At which step is the second hydrogen removed? What is the absolute stereochemistry of this step?

(H) Draw, with correct stereochemistry, reactants and products for the reaction of Equation 1 if it were performed with (*R*)-[^{3}H]malonyl-SCoA and unlabeled acetyl-SCoA. Does the reaction of Equation 1 proceed with retention of configuration, inversion of configuration, syn addition, or anti addition? Only one answer is correct.

The hydrogen added as a hydron from solution in Equation 4 is added to carbon 2 of (*E*)-but-2-enoyl-SCoA, and the hydrogen added as a hydride, ultimately from NADPH, is added to carbon 3 of (*E*)-but-2-enoyl-SCoA. When the reaction of Equation 4 is carried out in ^2H_2O, with unlabeled (*E*)-but-2-enoyl-SCoA and unlabeled NADPH, the absorption assigned to the two protons on carbon 2 in the nuclear magnetic resonance spectrum of the

N-benzylbutyramide, derived from the butyryl-SCoA produced in the reaction, integrates with a magnitude of only one proton.

Porcine acyl-CoA dehydrogenase (Equation 4–147) converts butyryl-SCoA to (*E*)-but-2-enoyl-SCoA by removing the *pro-R* hydrogen[618] from carbon 3 and the *pro-R* hydrogen[619] from carbon 2. The butyryl-SCoA formed during the enzymatic conversion in ^2H_2O was isolated and then incubated with acyl-CoA dehydrogenase in ^1H_2O. None (<10%) of the deuterium incorporated by fatty-acid synthase system was lost upon this second incubation. The product formed during conversion of (*E*)-but-2-enoyl-SCoA to butyryl-SCoA with [^{3}H]NADPH (Equation 4) was isolated and then incubated with acyl-CoA dehydrogenase. Most of the tritium (83%) incorporated by fatty-acid synthase system (Equation 4) was lost during the second incubation.

(I) Draw a mechanism with proper stereochemistry for Equation 4 if it were carried out in ^2H_2O with [^{3}H]NADPH. The mechanism should proceed through a reasonable enol intermediate.

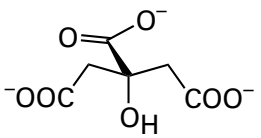
(J) Does the reaction of Equation 4 proceed with syn addition or anti addition?

Problem 4–21: Imidazoleglycerol-phosphate dehydratase, histidinol-phosphate transaminase, and histidinol-phosphatase from *E. coli* in sequence convert D-*erythro*-1-(imidazol-4-yl)glycerol phosphate in ^2H_2O into [3-^{2}H]-L-histidinol. The peak of absorption from the only proton on carbon 3 of the product in its nuclear magnetic resonance spectrum has the same chemical shift as that for the protons on carbon 3 in an equimolar mixture of (2*S*,3*S*)-[3-^{2}H]histidinol and (2*R*,3*R*)-[3-^{2}H]histidinol prepared synthetically, which was the same chemical shift as the peak of absorption from one of the two protons on carbon 3 of unlabeled L-histidinol. When [3-^{2}H]-D-*erythro*-1-(imidazol-4-yl)glycerol phosphate was used as the initial reactant with the three enzymes in ^1H_2O, the absorption from the only proton on carbon 3 of the resulting [3-^{2}H]-L-histidinol had a chemical shift equal to that of the other proton on carbon 3 of unlabeled L-histidinol.[620] Write a two-step mechanism for imidazoleglycerol-phosphate dehydratase, showing the stereochemistry of each step.

Problem 4–22: At pH 7, tyrosine 2,3-aminomutase from *C. crocatus* converts (2*S*)-[3,3-$^2H_2$]-L-tyrosine into a 3:1 mixture of (2*S*,3*R*)-[2,3-$^2H_2$]-3-amino-3-(4-hydroxyphenyl)propanoate and (2*R*,3*S*)-[2,3-$^2H_2$]-3-amino-3-(4-hydroxyphenyl)propanoate.[505] There is a prosthetic pyridoxal 5′-diphosphate in the active site that forms an external pyridoximine with the amino group of the reactant to convert it to a good leaving group and, once it has left, an adequate nucleophile. The reaction proceeds by an elimination followed by an addition with 3-(4-hydroxyphenyl)propenoic acid as an intermediate. Write a mechanism for the reaction that explains the stereochemical results, in particular why two products are produced from the same reactant. Substrates, intermediates, and catalytic acid–bases in your mechanism should be drawn so that their relative orientation is clearly indicated because the relative orientations determine the stereochemistry.

Problem 4–23: Citrate (*Re*)-synthase adds the enol of acetyl-SCoA to the *Re* face of oxaloacetate to produce citrate in which the *pro*-3*R* carboxymethyl group is derived from acetyl-SCoA.[461] Citrate (*Si*)-synthase (Equation 4–224) adds the enol of acetyl-SCoA to the *Si* face of oxaloacetate to produce citrate in which the *pro*-3*S* carboxymethyl group is derived from acetyl-SCoA.[460] Citrate (*pro*-3*S*)-lyase cleaves citrate to oxaloacetate and acetate by removing the *pro*-3*S* carboxymethyl group.

(A) Copy the structure of citrate



and identify the *pro*-3*S* and *pro*-3*R* carboxymethyl groups.

(B) If [3-^{14}C]oxaloacetate were converted to citrate by citrate (*Re*)-synthase and the [^{14}C]citrate produced were converted to oxaloacetate by citrate (*pro*-3*S*) lyase, which final product would be radioactive?

Two specimens of [^{3}H]malate were synthesized. [^{3}H]Malate, specimen 1, was made by incubating fumarate with fumarate hydratase in ^3H_2O. [^{3}H]Malate, specimen 2, was made by incubating [2,3-$^3H_2$]fumarate with fumarate hydratase in ^1H_2O. [^{3}H]Malate, specimen 1, was incubated with

malate dehydrogenase, NAD^+, acetyl-SCoA, and citrate (*Re*)-synthase from *Clostridium acidurici*. The [^{3}H]citrate produced was incubated with citrate (*pro*-3*S*)-lyase in ^2H_2O, and the [^{3}H,^{2}H]acetate produced was incubated with $MgATP^{2-}$, acetate kinase, phosphate acetyltransferase, HSCoA, glyoxylate, and malate synthase. The [^{3}H,^{2}H]malate produced in this last reaction retained 61% of its tritium upon incubation with fumarate hydratase in ^1H_2O. [^{3}H]Malate, specimen 2, was submitted to the same cycle of reactions, and the [^{3}H,^{2}H]malate produced lost 56% of its tritium upon incubation with fumarate hydratase in ^1H_2O.[574]

(C) Write out each step in this cycle that begins with [^{3}H]malate, specimen 1. Show proper stereochemistry at each step unambiguously.

(D) Draw the mechanism of the reaction of citrate (*pro*-3*S*)-lyase operating in ^2H_2O with the stereochemistry defined by these experiments on [^{3}H]citrate derived from [^{3}H]malate, specimen 1. Indicate stereochemistry unambiguously in your drawings. Use an enol as the leaving group, and hydronate the enol stereochemically on carbon while it is in the active site. Does the reaction proceed with inversion or retention of configuration at carbon 2 of acetate?

(E) Draw the mechanism for the reaction of citrate (*pro*-3*S*)-lyase, with proper stereochemistry, operating in ^2H_2O on [^{3}H]citrate derived from [^{3}H]malate, specimen 2.

(*R*)-[^{2}H,^{3}H]Acetyl-SCoA was incubated with citrate (*Si*)-synthase, and the [^{2}H,^{3}H]citrate produced was cleaved by citrate (*pro*-3*S*)-lyase to [^{2}H,^{3}H]acetate. The [^{2}H,^{3}H]acetate produced was converted to [^{3}H,^{2}H]malate by incubation with $MgATP^{2-}$, acetate kinase, phosphate acetyltransferase, SHCoA, glyoxylate, and malate synthase. The [^{3}H,^{2}H]malate produced retained 65% of its tritium upon incubation with fumarate hydratase. When the complete cycle was repeated with (*S*)-[2,2-^{2}H,^{3}H]acetyl-SCoA, the [^{3}H,^{2}H]malate produced lost 60% of its tritium upon incubation with fumarate hydratase.[574]

(F) Draw, with proper stereochemistry, the mechanism of the reaction catalyzed by citrate (*Si*)-synthase operating on (*R*)-[^{2}H,^{3}H]acetyl-SCoA. Use a stereochemically generated enol as the nucleophile. Does the reaction proceed with retention or inversion of configuration?

Problem 4–24: The unhydrated, carbonyl forms of the substrates are the only ones recognized by triosephosphate isomerase (Equation 4–46) from *O. cuniculus*, although they are the minor forms present in aqueous solution.

(A, B) Draw, with proper stereochemistry where necessary, two possible chemical mechanisms for this reaction and label them A and B. Mechanism A must involve hydron transfers only, while mechanism B must involve a 1,2-hydride migration.

When glycerone phosphate and glyceraldehyde 3-phosphate were incubated with the enzyme in ^3H_2O, tritium was incorporated into the glycerone phosphate.[621]

		specific activity (cpm μatom^{-1})	
compound	isomerase (units)	^3H_2O	compound
experiment 1			
glycerone phosphate	none	699	0
glyceraldehyde 3-phosphate	none	699	0
experiment 2			
glycerone phosphate	1600	278	303
experiment 3			
glycerone phosphate	475	3590	3150

When [^{3}H]glycerone phosphate (777 cpm μmol^{-1}) obtained in a similar experiment was oxidized to 2-phosphoglycolate and formaldehyde with periodate, the formaldehyde was radioactive (835 cpm μmol^{-1}), but the 2-phosphoglycolate was not.

(C) How many hydrogens on which carbon of glycerone phosphate are equilibrated by the enzyme with ^3H_2O during catalysis?

The intention of the next series of experiments[521] was to establish the stereochemistry of this incorporation of tritium into glycerone phosphate. To make this assessment, the absolute stereochemistry of (*S*)-2-hydroxy-acid oxidase from *N. tabacum* was determined. This enzyme catalyzes the reaction

$$O_2 + \underset{\text{glycolate}}{HOCH_2COO^-} \rightleftharpoons H_2O_2 + \underset{\text{glyoxylate}}{OCHCOO^-}$$

(*S*)-2-Hydroxy-acid oxidase readily converts (*S*)-lactate into pyruvate but fails entirely to catalyze the same reaction with (*R*)-lactate. Bovine L-lactate dehydrogenase (Equation 4–204) will convert glyoxylate and NAD^3H into NAD^+ and [^{3}H]glycolate (78,050 cpm μmol^{-1}). When this [^{3}H]glycolate is turned into glyoxylate by (*S*)-2-hydroxy-acid oxidase, all the ^3H ($\leq$100 cpm μmol^{-1} remains) is lost to the solution. Notice that glycolate and lactate differ only by a methyl group.

(D) Indicate, on a stereochemically unambiguous drawing of glycolate, which hydrogen is removed by (*S*)-2-hydroxy-acid oxidase.

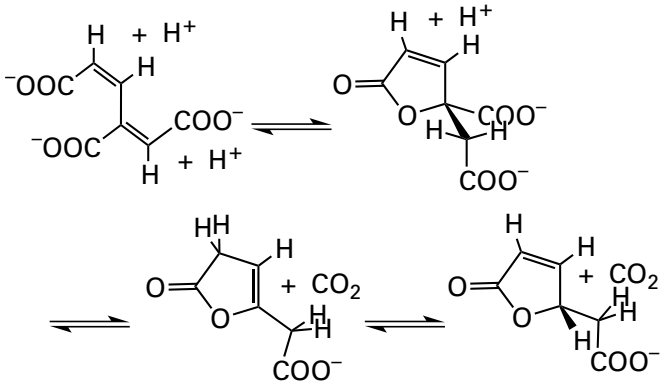
A sample of [^{3}H]glycerone phosphate (24,000 cpm μmol^{-1}), prepared as in part C above, was dephosphorylated to glycerone, which was oxidized to glycolate, formaldehyde, and CO_2 by careful treatment with periodate. The [^{3}H]glycolate from this mixture (10,800 cpm $\mu mol^{-1)}$ was isolated and turned into glyoxylate with (*S*)-2-hydroxy-acid oxidase. The specific radioactivity of the resulting glyoxylate was 188 cpm μmol^{-1}.

(E) Why was the specific radioactivity of glycolate half that of glycerone phosphate?

(F) Indicate, on a stereochemically unambiguous drawing of glycerone phosphate, the hydrogen or hydrogens equilibrated with ^3H_2O by triose-phosphate isomerase.

(G) Which mechanism, A or B, is consistent with these observations?

Problem 4–25: The three enzymes 3-carboxy-*cis,cis*-muconate cycloisomerase, 4-carboxymuconolactone decarboxylase, and muconolactone Δ-isomerase from *P. putida* convert *cis,cis*-butadiene-1,2,4-tricarboxylate into (*S*)-5-oxo-2,5-dihydrofuran-2-acetate



When *cis,cis*-butadiene-1,2,4-tricarboxylate is mixed with all three enzymes in ^2H_2O, the product of the combined sequence of reactions is (2*S*)-[4-^{2}H]-5-oxo-2,5-dihydrofuran-2-[(*R*)-[^{2}H]acetate].[622]

(A) What is the stereochemistry of addition in the first reaction?

(B) What is the stereochemistry of hydron transfers in the third reaction? [Hint: How many protiums are there in the starting material and how many in the final product?]

(C) What is the stereochemistry of the second reaction?

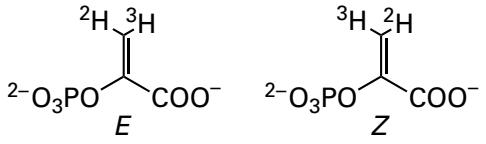
Problem 4–26: [1-^{3}H]-D-Glucose was converted to [1,1-^{3}H,^{2}H]fructose 6-phosphate with hexokinase and glucose-6-phosphate isomerase in ^2H_2O. [1-^{3}H]-D-Mannose was converted to [1,1-^{3}H,^{2}H]fructose 6-phosphate with hexokinase and mannose-6-phosphate isomerase in ^2H_2O. The two respective stereoisomers of [1,1-^{3}H,^{2}H]fructose 6-phosphate produced were of opposite stereochemistry at carbon 1.[520]

(A) Assume that the enzymatic mechanisms for triose-phosphate isomerase, D-glucose-6-phosphate isomerase, and mannose-6-phosphate isomerase are all the same. From your knowledge of the active site of triose-phosphate isomerase, draw two mechanisms, one for glucose-6-phosphate isomerase and one for mannose-6-phosphate isomerase, that explain why the stereochemistries at carbon 1 of the two stereoisomers of [1,1-^{3}H,^{2}H]fructose 6-phosphate are opposite to each other. Use the same amino acids as are found in the active site of triose-phosphate isomerase in the same roles as acid–base catalysts.

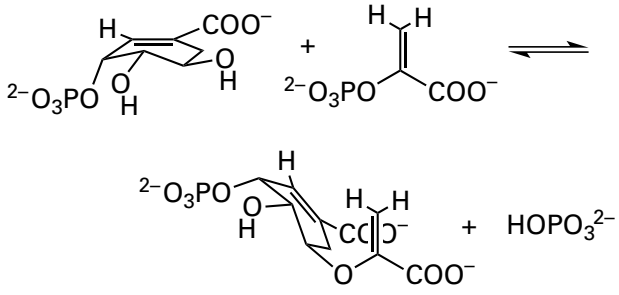
(B) Explain how deuterium was introduced at carbon 1 of each fructose 6-phosphate and why, after a sufficient time at equilibrium, the percent deuterium in the proper location on carbon 1 of fructose 6-phosphate should become equivalent to the percent deuterium for each atom of hydrogen in ^2H_2O.

(C) What are the absolute stereochemistries at carbon 1 of the [1,1-^{3}H,^{2}H]fructose 6-phosphates from [1-^{3}H]-D-glucose and [1-^{3}H]-D-mannose, respectively?

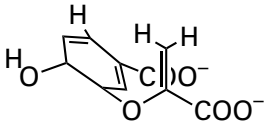
The two stereoisomers of [1,1-^{3}H,^{2}H]fructose 6-phosphate were separately incubated with 6-phosphofructokinase and fructose-bisphosphate aldolase (Equation 4–210), and the two stereoisomers of [1,1-^{3}H,^{2}H]glycerone 1-phosphate were isolated. These stereoisomers of [1,1-^{3}H,^{2}H]glycerone 1-phosphate were converted to the *E* and *Z* stereoisomers of [^{3}H,^{2}H]phospho*enol*pyruvate, respectively[543,579]



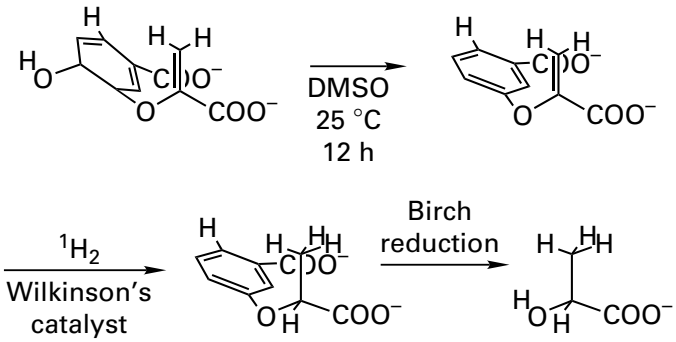
by incubation with triose-phosphate isomerase, glyceraldehyde-3-phosphate dehydrogenase in the presence of arsenate, bisphosphoglycerate mutase, and phosphopyruvate hydratase. Each stereoisomer of [^{3}H,^{2}H]phospho*enol*pyruvate was incubated separately with 3-phosphoshikimate 1-carboxyvinyltransferase from *K. aerogenes* and 3-phosphoshikimate



The 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate was converted to chorismate



with chorismate synthase, also from *K. aerogenes*. The chorismate was converted to lactate by the following sequence of chemical reactions.



Wilkinson's catalyst performs a syn addition of H_2 to a double bond and ultimately produces both the 2*S* and the 2*R* enantiomers of lactate because it does not distinguish one face of the carbon–carbon double bond from the other. The (2*S*)-lactate was eliminated by incubation with (*S*)-lactate dehydrogenase (Equation 4–204), and the stereochemically pure (2*R*)-lactate was submitted to Kuhn–Roth oxidation to produce chiral [^{3}H,^{2}H]acetate. When 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate derived from (*E*)-[^{3}H,^{2}H]phospho*enol*pyruvate was submitted to this sequence, (*R*)-[^{3}H,^{2}H]acetate was the preferential product. When 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate derived from (*Z*)-[^{3}H,^{2}H]phospho*enol*pyruvate was submitted to this sequence, (*S*)-[^{3}H,^{2}H]acetate was the preferential product.[580]

(D) Show by drawing the proper stereochemistry of every product between phospho*enol*pyruvate and acetate, including both lactates, why these two results demonstrate that (*E*)-[^{3}H,^{2}H]phospho*enol*pyruvate yields (*E*)-[5,5-^{3}H,^{2}H]-5-*O*-(1-carboxyvinyl)-3-phosphoshikimate and (*Z*)-[^{3}H,^{2}H]phospho*enol*pyruvate yields (*Z*)-[5,5-^{3}H,^{2}H]-5-*O*-(1-carboxyvinyl)-3-phosphoshikimate.

(E) Explain why the (*S*)-lactate was eliminated before Kuhn–Roth oxidation was performed.

(F) Draw a mechanism for 3-phosphoshikimate 1-carboxyvinyltransferase with correct stereochemistry for addition of shikimate 3-phosphate to phospho*enol*pyruvate and removal of phosphate to produce 5-*O*-(1-carboxyvinyl)-3-phosphoshikimate. Assume that a hydron is added to and removed from phospho*enol*pyruvate by the same acid–base in the active site and that, as has been demonstrated,

addition of a hydron and removal of that same hydron is in preference to addition and removal of a deuteron or a triton and that this explains why chiral acetate is the final product. Your mechanism must explain the observed retention of configuration in the product. Provide specific amino acids of your own choice as acid–base catalysts of these two steps.

Problem 4–27: When D-glyceraldehyde is used in place of glycerol, glycerol kinase (Equation 4–283)

$$MgATP^{2-} + \text{glycerol} \rightleftharpoons \text{sn-glycerol-3-phosphate} + MgADP^{-}$$

from *E. coli* becomes an ATPase that hydrolyzes $MgATP^{2-}$ (Equation 4–288). When adenosine (*R*)-[γ,γ-^{17}O,^{18}O]-γ-thiotriphosphate is used as a reactant for this adventitious ATPase, (*S*)-[^{17}O,^{18}O]thiophosphate is the product.[623] Write a mechanism for this ATPase that explains the stereochemistry.

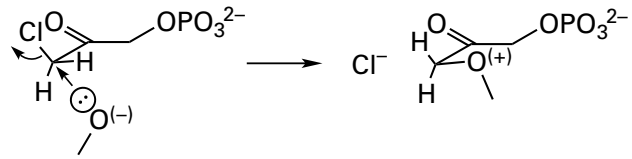
Labeling of Active Sites

The acid–bases catalyzing the reactions that occur within the active site of an enzyme are usually the side chains of amino acids within the sequence of the folded polypeptide. The particular amino acid that acts as a catalytic acid–base in a specific step in the mechanism of the enzyme can be identified with an active-site label. An active-site label can be used to locate the active site of an enzyme and identify a catalytic acid–base within that active site in a crystallographic molecular model. And an active-site label can be used to inactivate a particular enzyme within a mixture of different enzymes or, in ideal situations, in cytoplasm.

An active-site label is a reagent that has been designed to associate specifically, noncovalently, and in a defined orientation within the active site of a particular enzyme at the location normally occupied by a substrate and then modify covalently a particular catalytic acid–base or particular side chain that participates in association of a substrate with the active site. Because there are nucleophilic side chains but no electrophilic side chains on the amino acids in a protein, an active-site label is almost always **designed to position an electrophile adjacent to a catalytic acid–base or another nucleophilic side chain**. The electrophilic center on the active-site label, when it is bound in the active site, reacts covalently with the lone pair of electrons on the conjugate base of the side chain of the catalytic acid–base.

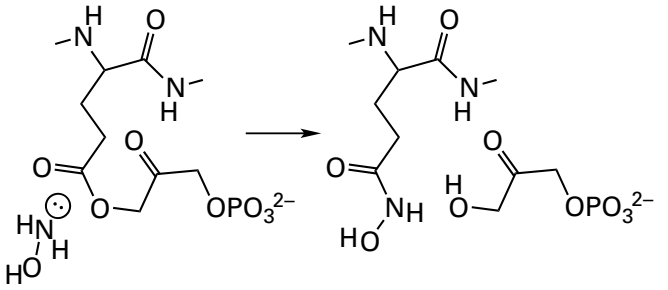
The usual sequence of events in the labeling of an active site is a description of the kinetic characteristics of the inactivation and the covalent modification of the enzyme, followed by identification of the amino acid that is modified by isolating and sequencing a peptide containing the modified amino acid. Ultimately, the role of the side chain of that amino acid in the mechanism of the enzyme is defined crystallographically.

Before crystallographic molecular models of triose-phosphate isomerase (Equation 4–46) were available, it was presumed that a catalytic base in the active site of the enzyme was responsible for removing a hydron from carbon 3 of glycerone phosphate during its conversion to D-glyceraldehyde 3-phosphate. To identify the catalytic base, the reagents 3-iodo-, 3-bromo-, and 3-chloro-1-hydroxypropan-2-one phosphate were synthesized. Each reagent, when it is bound in the active site, should place an electrophilic alkyl halide adjacent to that catalytic base, $-O^{(-)}$



(4–290)

If these reagents are capable of alkylating the actual catalytic base, they should have inactivated the enzyme irreversibly, and it was observed that each did inactivate triose-phosphate isomerase from *O. cuniculus* in a pseudo-first-order reaction (Figure 4–35).[624] 3-Chloro-1-hydroxypropan-2-one [^{32}P]phosphate was prepared, and triose-phosphate isomerase was modified with this reagent. The modified enzyme was then denatured and digested with trypsin. Only one radioactive peptide was observed upon peptide mapping. This tryptic peptide was purified, and its sequence of amino acids was found to be WVLAYEPVWAIGTGK. When the modified peptide was treated with hydroxylamine, the hydroxamate of glutamic acid was identified as the product



(4–291)

Therefore, the glutamate in this peptide was the nucleophile that had been alkylated by the reagent. The sequence of amino acids for the peptide identifies the glutamate as Glutamate 165[625] in triosephosphate isomerase from *O. cuniculus*. From the results of several such experiments, Glutamate 165 was deduced to be the base responsible for removing the hydron from carbon during the enzymatic reaction. This conclusion about the enzyme from *O. cuniculus* was subsequently confirmed by X-ray crystallography (Figure 3–37)[626] of the enzyme from *S. cerevisiae* (52% identity; 0.4 gap percent)* and site-directed mutation.[627]

There are many **electrophiles that have been incorporated into active-site labels**. In addition to alkyl chlorides,[628] alkyl bromides,[629-640] and alkyl iodides,[641] such as those used to modify triose-phosphate isomerase, alkyl fluorides[628,642,643] *O*-acetylalcohols,[628] sulfate esters,[644] oxiranes,[645-650] aziridines,[651,652] *N,N*-dimethylaziridinium ions,[653,654] aldehydes,[655], vicinal diones,[656-666] α,β-unsaturated imines,[667] and 2-methylenecyclopropyl groups[668] have been used as the electrophiles incorporated into analogues of various substrates. Electrophilic analogues of carboxy groups or acyl groups, or analogues of tetrahedral intermediates in their reactions, such as α-diazoketones,[669,670] fluorophosphono groups,[671] or phenylphosphono groups,[672] have been used as electrophiles in analogues of substrates to modify catalytic bases in an active site that would normally associate with or react with carboxy groups or acyl groups on its substrates. *S*-(4-Bromo-2,3-dioxobutyl)thiophosphate, which positions a vicinal dione in the location that would be occupied by the second phospho group in diphosphate, can be incorporated into nucleotides to position the vicinal dione adjacent to the guanidinio group of an arginine that would be a ligand for that phospho group in the active site.[666] This latter active-site label is a member of a large class of electrophiles designed to modify amino acids in active sites with which nucleotides or coenzymes containing nucleotides associate.[665]

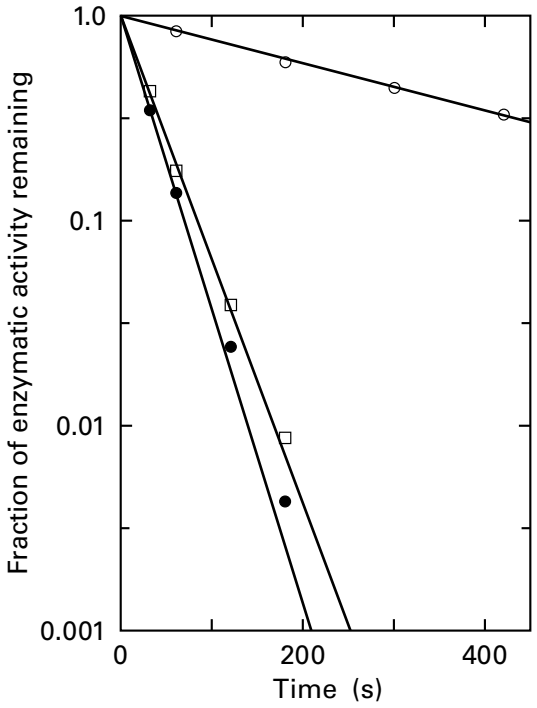


Figure 4–35: Inactivation of triose-phosphate isomerase from *O. cuniculus* by 3-halo-1-hydroxypropan-2-one phosphates.[624] Mixtures containing 0.9 μM active sites of triose-phosphate isomerase in 0.1 M imidazolium chloride, pH 6.5, at 2 °C were prepared with either 10 μM 3-iodo-1-hydroxy-2-propanone phosphate (○), 10 μM 3-chloro-1-hydroxy-2-propanone phosphate (□), or 10 μM 3-bromo-1-hydroxy-2-propanone phosphate (●). At the times indicated, 0.1 mL samples from each mixture were removed and diluted into 4.9 mL of 10 mM 2-sulfanylethanol in 0.02 M triethanolammonium chloride at pH 7.9, to discharge rapidly the respective halopropanone. These quenched samples were then assayed for enzymatic activity. The common logarithm of the fraction of enzymatic activity remaining is plotted as a function of the time (seconds) the enzyme was exposed to the halopropanone before alkylation of the active site was halted by the quenching solution. The data were fit directly with Equation 4–298 to obtain values for $k_{i,app}$ (0.0027 s^{-1}, 0.027 s^{-1}, and 0.033 s^{-1} for iodo, chloro, and bromo reagents, respectively). These values were then used to draw the lines in the figure.

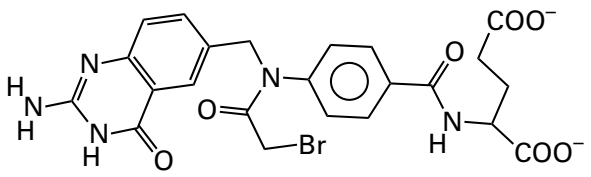
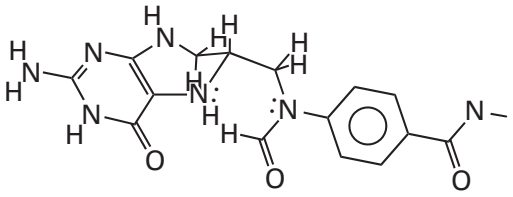
There are also **simple, widely applicable bis-electrophiles**, such as bromoacetyl bromide, that can be incorporated covalently into more complex substrates or analogues of substrates to create active-site labels. For example, bromoacetyl bromide could be used to acylate 5,8-dideazafolate to produce 10-(bromoacetyl)-5,8-dideazafolate (**4–71**)[673]

*The homologue of Glutamate 165 in the enzyme from *O. cuniclus* is Glutamate 164 in the enzyme from *S. cerevisiae*.



4–71

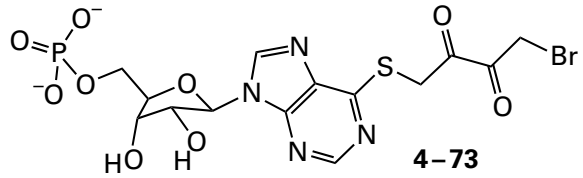
an analogue of 10-formyltetrahydrofolate



4–72

This analogue modifies the carboxy group of the catalytic acid, Aspartate 144[674] of phosphoribosylglycinamide formyltranferase from *E. coli*, that forms a hydrogen bond to the acyl oxygen of the formyl group in 10-formyltetrahydrofolate to improve the electrophilicity of that acyl group in the formyl transfer catalyzed by the enzyme.[675]

An example of the use of such a biselectrophile to synthesize an active-site label that **modifies an amino acid providing a ligand to a substrate** is the alkylation of 6-sulfanylpurine ribonucleoside 5′-monophosphate by 1,4-dibromobutane-2,3-dione to produce the nucleotide



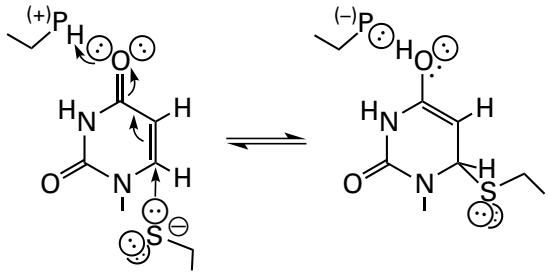
4–73

This active-site label is an analogue of N^6-(1,2-dicarboxyethyl)-AMP,[663,665] one substrate for adenylosuccinate synthase

$$N^6\text{-(}S\text{-1,2-dicarboxyethyl)-AMP}^- + \mathrm{HOPO_3^{2-}} + \mathrm{MgGDP^-} \rightleftharpoons \text{L-aspartate} + \mathrm{MgGTP^{2-}} + \text{inosine monophosphate} \quad (4\text{–}292)$$

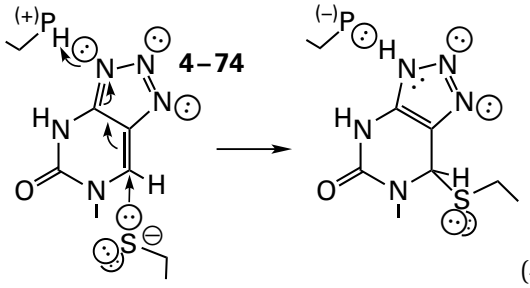
from *E. coli*. Nucleotide **4–73** modifies the guanidinio group of Arginine 303 that forms a hydrogen bond to the distal 2-carboxy group of the usual substrate, N^6-(*S*-1,2-dicarboxyethyl)-AMP, in the active site of the enzyme.[676] This carboxy group is not a catalytic acid–base.

It is also possible to **alter an electrophile already present in a substrate** to convert it into an active-site label. As part of its normal mechanism, thymidylate synthase forms a covalent adduct between the sulfido group of a cysteine in its active site and the 5,6-double bond of 2′-deoxyuridine 5′-monophosphate



(4–293)

1-(β-D-2′-Deoxyribofuranosyl)-3-azapurin-2-one 5′-monophosphate (**4–74**) is an active-site label that capitalizes on the existence of this nucleophilic addition to an α,β-unsaturated amide[677]



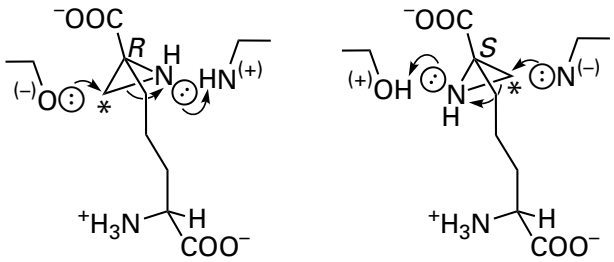
4–74

(4–294)

The aromatization of the triazole causes the nucleophilic addition to be kinetically irreversible and causes the active-site label to inactivate the enzyme from *L. casei*. Other strategies have been used to produce analogues of substrates that become aromatic during their covalent modification of the respective targeted enzymes, and hence modify the enzyme irreversibly.[678,679]

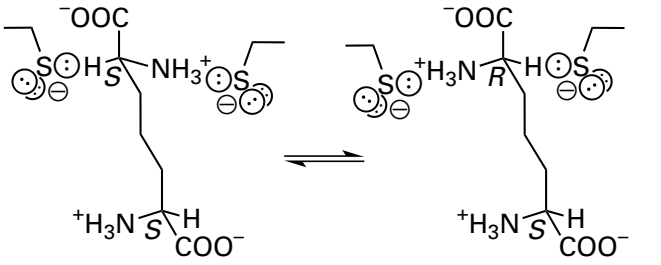
Natural products, the role of which is to inactivate enzymes in organisms other than the one producing that natural product, can contain electrophilic functional groups such as oxiranes[650] that alkylate catalytic bases in the active sites of the enzymes inactivated. They are **natural active-site labels**.

The **exact location that the electrophilic center occupies** when the active-site label is associated specifically with the active site can affect the outcome of the modification and provide additional information.[680] For example, both (2*R*,6*S*) and (2*S*,6*S*) enantiomers of 2-(4-amino-4-carboxybutyl)aziridene-2-carboxylate (**4–76**)



4–75 **4–76**

where the asterisks indicate the electrophilic carbon, were synthesized as active-site labels for diaminopimelate epimerase



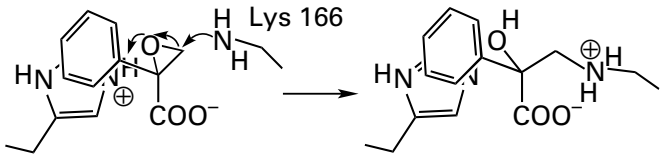
(4–295)

These two diastereomers should place an electrophilic carbon adjacent to the base responsible for removing the hydron from (2*S*,6*S*)-diaminopimelate and adjacent to the base responsible for removing the hydron from (2*R*,6*S*)-diaminopimelate, respectively, in the normal reaction.[681,682] Diaminopimelate epimerase from *Haemophilus influenzae*[652] and diaminopimelate epimerase from *A. thaliana*[654] (39% identity; 1.8 gap percent) were modified by these two active-site labels. In crystallographic molecular models of the modified enzymes, it can be seen that (2*R*)-aziridine **4–75** has alkylated the sulfanyl groups of the homologous cysteines in these two enzymes responsible for removing the hydron from (2*S*,6*S*)-diaminopimelate. Likewise, (2*S*)-aziridine **4–76** has alkylated the sulfanyl groups of the homologous cysteines in these two enzymes responsible for removing the hydron from (2*R*,6*S*)-diaminopimelate in the normal enzymatic reaction.

Glutamate racemase from *Limosilactobacillus fermentum* also uses two cysteines as catalytic acid–bases[683] for its epimerization that are situated on the two sides of the α carbon of D-glutamate.[684] Only one of these cysteines, however, is modified by the analogous racemic aziridine 2-(2-amino-2-carboxyethyl)aziridene-2-carboxylate.[651]

Mandelate racemase also catalyzes an epimerization (Equation 4–252), and (*R*)-2-phenyloxirane-2-carboxylate (**4–77**)* is an active-site label that inactivates the enzyme from *P. putida*[558] by alkylating Lysine 166

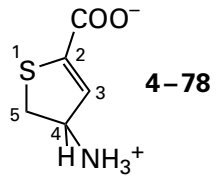
4–77



(4–296)

(*S*)-2-Phenyloxirane-2-carboxylate does not inactivate the enzyme or modify the active site because it places the electrophilic carbon 3 of the oxirane on the opposite side of the plane of 2-phenylacetate, distant from the amino group of the lysine, and the imidazolyl group at this location is perhaps not nucleophilic enough or not properly oriented.

Active-site labels can also modify prosthetic groups in the active site rather than catalytic acid–bases. For example, (*R*)-4-amino-4,5-dihydrothiophenecarboxylic acid

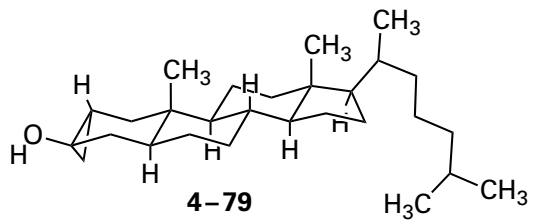


4–78

inactivates D-amino-acid transaminase from *Bacillus* by covalently modifying the prosthetic pyridoxal phosphate. The external pyridoximine is formed between the active-site label and the prosthetic pyridoxal 5′-phosphate. Hydrons are removed from carbons 4 and 5 of 4-amino-4,5-dihydrothiophenecarboxylic acid by the usual steps (see Equations 4–258 and 4–259) to produce the aromatic thiophene, which is so stable that further reaction cannot occur. In this instance the stable, aromatic product of the reaction was identified crystallographically.[678]

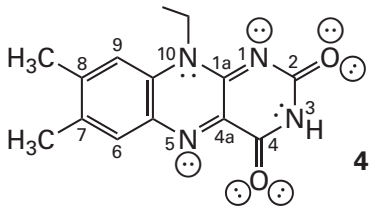
2α,3α-Cyclopropano-5α-cholestan-3β-ol

*Note that the priorities for assigning *R* and *S* reverse in going from the amino acid to the aziridine in the case of diaminopimelate epimerase and from the mandelate to the oxirane in the case of mandelate racemase.



4–79

is an active-site label for the flavoenzyme cholesterol oxidase from *Streptomyces*.[685] It covalently modifies the isoalloxazine ring of the prosthetic flavin (previously **2–42**)



4–80

at carbon 6, and the product of the reaction is consistent with dehydronation of the 3-hydroxy group of 2α,3α-cyclopropano-5α-cholestan-3β-ol by a catalytic base on the enzyme, heterolytic opening of the adjacent cyclopropane to produce a nucleophilic primary carbanion of the secondary carbon of the cyclopropane, and nucleophilic addition of that carbanion to the flavin. *N*-(Cyclopropyl)glycine is a mechanism-based label for sarcosine oxidase from *Bacillus*.[686] In this instance, however, it is thought that the oxidized prosthetic flavin (**4–80**) in the active site removes one electron from the lone pair of electrons on the nitrogen of *N*-(cyclopropyl)glycine, the cyclopropyl ring opens homolytically rather than heterolytically, and the primary radical at carbon 3 of the propanal in the resulting imine with the amino group of glycine colligates with the radical of flavin semiquinone formed upon transfer of the electron. The product of the radical colligation is an adduct that has been alkylated at carbon 4a of the flavin by carbon 3 of propanal.[687]

In one sense, however, the modifications of these prosthetic groups did not identify them as participants in the respective reaction because that fact was already known.

There are several criteria that should be met before a reagent synthesized as an active-site label can be designated as capable of modifying the enzyme while it is bound in place of a substrate within the active site. First, the rate of the reaction between enzyme and active-site label should display saturation as a function of the concentration of the active-site label, just as association of the substrate being mimicked does. Second, a natural substrate or competitive inhibitor of the enzyme should competitively inhibit the inactivation produced by the active-site label. Third, the inhibition constant K_i for a substrate or competitive inhibitor of the inactivation produced by an active-site label should be the same as the Michaelis constant of the substrate or the dissociation constant of the competitive inhibitor from the active site in the absence of the active-site label. Fourth, at short times before covalent modification occurs, the active-site label should be a competitive inhibitor of the normal enzymatic reaction with respect to the reactant that it resembles. Fifth, the inhibition constant K_i for this reversible competitive inhibition of the normal enzymatic reaction by the active-site label should be the same as the dissociation constant from the active site that governs its irreversible inactivation of the enzymatic activity. Sixth, if the behavior of the specificity constant k_A for reactant A that is being mimicked by the active-site label is pH-dependent, decreasing below a pK_a for a catalytic base involved in the reaction (as in Figure 4–10A–D), and the active-site label is thought to modify that same base, then the pH–rate profile for the rate constant of inactivation should be governed by the same pK_a. Seventh, the covalent incorporation of active-site label into the protein should be proportional to the loss of enzymatic activity, and the stoichiometry of incorporation at full inactivation should be 1.0 mol (mol of active sites)$^{-1}$. The first criterion shows that the active-site label binds to the enzyme before it can inactivate the enzyme. The next five criteria connect this binding to the normal binding of substrates or competitive inhibitors to the active site. The last criterion is consistent with the hope that the only significant covalent modification of the protein occurs while the electrophile is occupying the active site in the proper orientation.

The **criterion of saturation** can be explained by an examination of the rate equations for specific labeling. If an active-site label (ASL) first associates with the active site of an enzyme and then modifies a catalytic group within the active site, it follows that

$$\mathrm{E} + \mathrm{ASL} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}ASL} \xrightarrow{k_i} \mathrm{E{-}ASL} \qquad (4\text{–}297)$$

where k_i is the rate constant for inactivation and E–ASL is the enzyme that has been modified covalently and irreversibly by the active-site label. If the

concentration of active-site label is in large molar excess over the concentration of active sites in the solution and if the active-site label is lost from the solution only by reaction with the active site, then its concentration will remain essentially constant throughout the reaction. In this case, it can be shown[688] that

$$\frac{[E]_0 - [E\text{–}ASL]}{[E]_0} = e^{-k_{i,app}\,t} \tag{4–298}$$

where $[E]_0$ is the initial total concentration of enzyme

$$k_{i,app} = \frac{k_i\,k_{ASL}[ASL]}{k_i + k_{ASL}[ASL]} \tag{4–299}$$

and

$$k_{ASL} = \frac{k_i\,k_1}{k_i + k_{-1}} \tag{4–300}$$

If covalent modification by the active-site label is the only reason that enzymatic activity is disappearing, the term $([E]_0 - [E\text{–}ASL])\,[E]_0^{-1}$ is equal to the fraction of enzymatic activity remaining at a particular time.

The **disappearance of enzymatic activity** is followed in the experiment by removing samples of enzyme from the solution containing the active-site label at various times and immediately diluting each sample or otherwise quenching the inactivation while performing an assay of the remaining enzymatic activity.

The observed fraction of enzymatic activity remaining as a function of time can be fit directly to an exponential equation by usual least-squares analysis to obtain the rate constant $k_{i,app}$. Just as in the case of the effects of pH on the rate of an enzymatic reaction, however, it is easier to evaluate visually how well the data satisfies the exponential equation if the natural logarithm of the fraction of enzymatic activity remaining is plotted as a function of time[640]

$$\ln\left(\frac{[E]_0 - [E\text{–}ASL]}{[E]_0}\right) = -k_{i,app}\,t \tag{4–301}$$

By this criterion, the inactivations of triose-phosphate isomerase by 3-halo-1-hydroxypropan-2-one phosphates are **pseudo-first-order reactions** (Figure 4–35) as predicted by Equation 4–298.

Because the covalent reaction leading to inactivation is usually slow, $k_{-1} >> k_i$ and

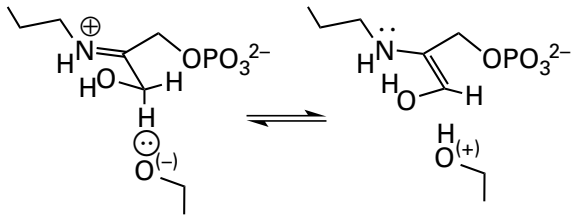
$$k_i\,k_{ASL}^{-1} \cong \frac{k_{-1}}{k_1} = K_{dASL} = \frac{[ASL][E]}{[E{\cdot}ASL]} \tag{4–302}$$

where K_{dASL} is the dissociation constant for the complex between the active-site label and the active site, so the apparent first-order rate constant for the inactivation

$$k_{i,app} = \frac{k_i[ASL]}{[ASL] + K_{dASL}} \tag{4–303}$$

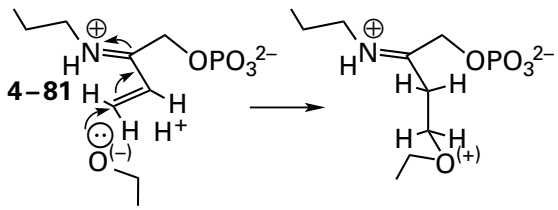
The **behavior of the observed pseudo-first-order rate constant of inactivation**, $k_{i,app}$, as a function of the molar concentration of active-site label (Equation 4–299) demonstrates saturation.[640]

One step in the reaction catalyzed by fructose-bisphosphate aldolase (Equation 4–210) is formation of an enamine of glycerone phosphate. The enamine (Figure 4–36) is formed from the imine between glycerone phosphate and a lysine on the enzyme by removal of a hydron from carbon 3



(4–304)

1-Hydroxy-2-oxobut-3-ene phosphate was synthesized as an active-site label for fructose-bisphosphate aldolase.[667] 1-Hydroxy-2-oxobut-3-ene phosphate, when bound to the active site as the analogous adduct of the same lysine (**4–81**), should place an electrophilic α,β-unsaturated imine adjacent to the amino acid responsible for removing the hydron in the normal reaction, and a Michael addition should result



(4–305)

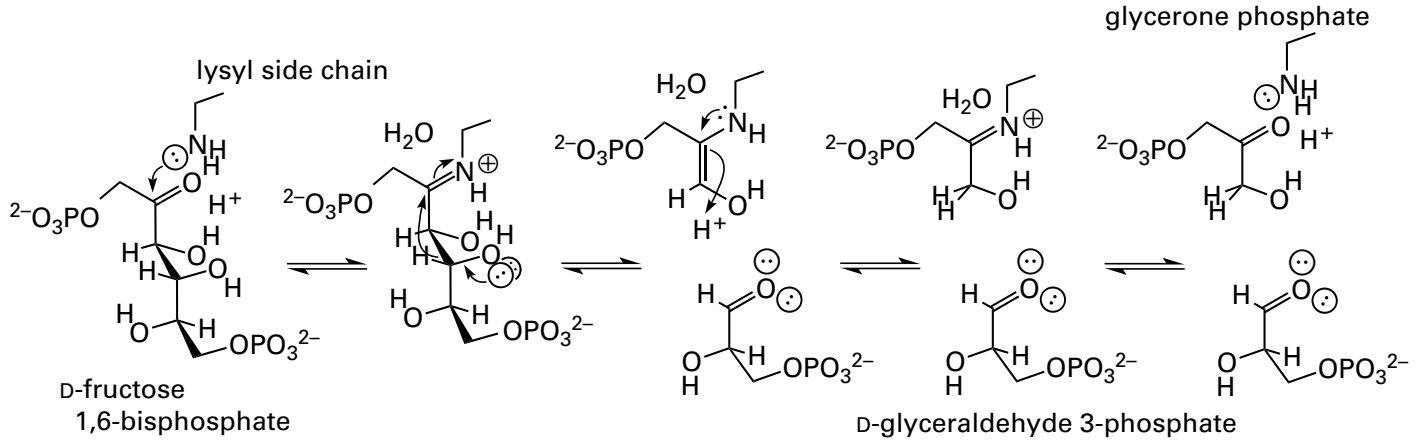


Figure 4–36: Steps in the retroaldol condensation catalyzed by fructose-bisphosphate aldolase. The amino group of a lysine in the active site adds to the carbonyl in D-fructose 1,6-bisphosphate to give the iminium, with the hemiketal as an intermediate. The bond between carbons 3 and 4, weakened by the iminium at carbon 2, breaks to give the enamine and D-glyceraldehyde 3-phosphate, one of the products of the retroaldol condensation. The enamine is hydronated at its basic carbon to give the iminium, and the iminium is hydrolyzed to give glycerone phosphate, the other product.

When 1-hydroxy-2-oxobut-3-ene phosphate was added to a solution of fructose-bisphosphate aldolase from *O. cuniculus* and samples were withdrawn at various intervals and diluted to dissociate the reversibly bound inhibitor, the enzymatic activity was observed to disappear irreversibly in a pseudo-first-order process.[689] From these measurements, observed pseudo-first-order rate constants of inactivation were obtained by fitting Equation 4–298 to the data. When these observed rate constants of inactivation are plotted as a function of the concentration of active-site label, saturation is observed (Figure 4–37).[689] The continuous curve drawn in the figure is defined by Equation 4–303 with $k_i = 0.11\ s^{-1}$ and $K_{dASL} = 100\ \mu M$. Therefore, the observed behavior is consistent with a kinetic mechanism in which the active-site label binds to the active site before covalently modifying it.

Often an active-site label is an active enough electrophile to react with the water or other bases in the solution. In this instance, the **total concentration of active-site label decreases systematically during the reaction**, and the activity of the enzyme does not decrease in a simple first-order reaction.[641] The initial rate of decrease in the enzymatic activity could be used as $k_{i,app}$ in Equation 4–299, but it is often technically difficult to make this measurement accurately at short times. The situation, however, can be viewed as a competition for the reagent between the nucleophile in the active site and nucleophiles in the solution. Under these circumstances, the final yield of modified enzyme after all

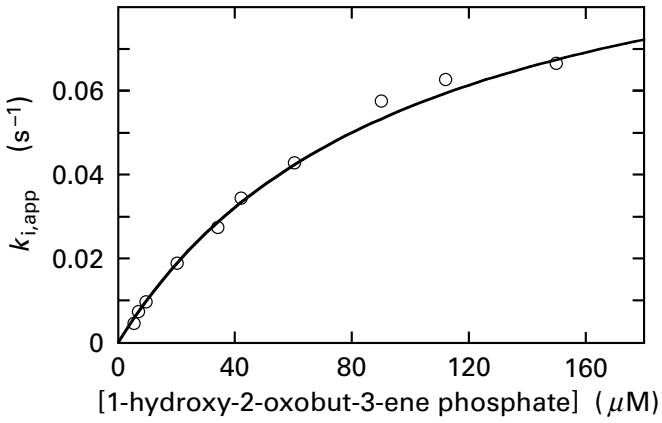

Figure 4–37: Behavior of the observed pseudo-first-order rate constant for inactivation of fructose-bisphosphate aldolase by 1-hydroxy-2-oxobut-3-ene phosphate as a function of the concentration of active-site label.[689] Mixtures were prepared containing various concentrations of 1-hydroxy-2-oxobut-3-ene phosphate at pH 7.0 and 37 °C. The reaction was initiated in each case by adding fructose-bisphosphate aldolase. Samples (50 μL) were removed at various times (at intervals of about 1 min) and were diluted immediately into an assay mixture (750 μL) for measuring enzymatic activity. The initial rate of the enzymatic reaction was measured continuously at 340 nm by coupling the production of triose phosphates to the reduction of NADH with triose-phosphate isomerase and glycerol-3-phosphate dehydrogenase. The initial rate of enzymatic activity was plotted as a function of the time of exposure to 1-hydroxy-2-oxobut-3-ene phosphate, and an observed pseudo-first-order rate constant of inactivation, $k_{i,app}$, was calculated from the time course for each concentration of active-site label. The observed pseudo-first-order rate constants, $k_{i,app}$ (second^{-1}), are plotted as a function of the concentration of 1-hydroxybut-3-en-2-one phosphate (micromolar). The curve drawn in the figure is that defined by Equation 4–303 with $k_i = 0.11\ s^{-1}$ and $K_{dASL} = 99\ \mu M$.

the active-site label has been quenched by reacting with the solution, the yield at infinite time, can be expressed as a fraction of the amount of enzyme originally present. This fractional yield, $\alpha_{E-ASL\infty}$, is simply the enzymatic activity at the end of the reaction divided by the enzymatic activity at the start of the reaction.

If the active site cannot recognize the product of the reaction between the active-site label and the solution, it can be shown[690] that

$$\ln(1 - \alpha_{E-ASL\infty}) = \frac{k_i}{k_D} \ln\left(\frac{K_{dASL}}{[ASL]_0 + K_{dASL}}\right) \quad (4–306)$$

where k_D is the first-order rate constant for the reaction in which the active-site label is destroyed by reaction with the solution, k_i is the first-order rate constant for its reaction with the active site, $[ASL]_0$ is the initial molar concentration of active-site label, and K_{dASL} is its dissociation constant from the active site.

If the active site, however, can bind the product of the reaction between the active-site label and the solution, then as product builds up, it will compete with the active-site label for the active site but be unable to modify it covalently. If the product has the same dissociation constant, K_{dASL}, as the active-site label itself and the initial concentration of the active-site label is always in large excess over the concentration of sites, then it can be shown that

$$\ln(1 - \alpha_{E-ASL\infty}) = -\frac{k_i}{k_D}\left(\frac{[ASL]_0}{[ASL]_0 + K_{dASL}}\right) \quad (4–307)$$

Whether the reaction behaves as described by Equation 4–306 or 4–307, which define significantly different behavior, makes the decision as to whether or not the product of reaction of the active-site label with the solution is able to associate with the active site. From Equation 4–306 or 4–307, it can then be ascertained whether or not the reaction between the active site and the active-site label displays saturation,[690] and a dissociation constant for the active-site label from the enzyme can be determined.

The **criterion of competition by a substrate or competitive inhibitor and the criterion of identity between the respective inhibition constant and either the Michaelis constant of the substrate or the dissociation constant of the competitive inhibitor** are explained by examining an expanded kinetic mechanism for specific labeling. If an active-site label binds in the active site at the same location as the substrate it was designed to resemble before modifying the enzyme, then that substrate should decrease the rate of modification by occupying the active site in its stead. For example, addition of the natural substrate glycerone phosphate at increasing concentrations causes the rate of inactivation of fructose-bisphosphate aldolase by 1-hydroxy-2-oxo-but-3-ene phosphate (Equation 4–305) to decrease accordingly.[689]

If natural reactant A and the active-site label are competing for the same location within the active site and if the concentration of reactant remains relatively constant during the inactivation even though it is being converted to product, then a simple kinetic mechanism for the competition is

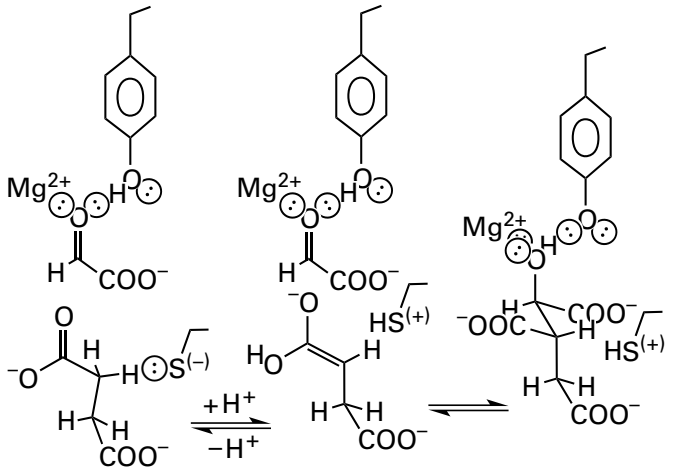
$$\begin{array}{c} E{-}ASL + A \xleftarrow{k_i} E{\cdot}ASL + A \overset{K_{dASL}}{\rightleftharpoons} \\ ASL + E + A \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} ASL + E{\cdot}A \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} \\ ASL + E{\cdot}Z \xrightarrow{k_7} ASL + E + Z \end{array} \quad (4–308)$$

Under these circumstances, or analogous circumstances dictated by the established kinetic mechanism for a particular enzymatic reaction, the derivation of the rate equation from the kinetic mechanism leads to the conclusion[691] that the observed pseudo-first-order rate constant for irreversible inactivation

$$k_{i,app} = \frac{k_i [ASL]}{K_{dASL}\left(\frac{[A] + K_{mA}}{K_{mA}}\right) + [ASL]} \quad (4–309)$$

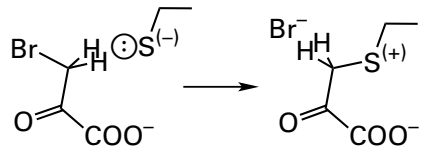
where K_{mA} is the Michaelis constant for turnover of reactant A in the absence of active-site label. It follows that reactant A, which is being mimicked by the active-site label, is a competitive inhibitor of labeling, with a competitive inhibition constant equal to its Michaelis constant.

Isocitrate lyase performs an aldol condensation between succinate and glyoxylate to produce isocitrate[692]



(4–310)

3-Bromopyruvate has a carboxylato group that should occupy one of the three subsites for carboxylato groups on the two substrates and may position an electrophile



(4–311)

in the vicinity of the catalytic base $^{(-)}$⊙S– responsible for removing the hydron from carbon 2 of succinate. It was selected, for the sake of convenience, as an active-site label for isocitrate lyase.[629] 3-Bromopyruvate inactivates isocitrate lyase from *Vogesella indigofera* in a pseudo-first-order reaction, and the observed pseudo-first-order rate constants of inactivation for various concentrations of the active-site label, 3-bromopyruvate, and the reactant, (2*R*,3*S*)-isocitrate, were determined.

When reciprocals of the observed rate constants for inactivation, $k_{i,app}$, were plotted as a function of reciprocals of the concentrations of 3-bromopyruvate at two fixed concentrations of isocitrate, competitive inhibition of the inactivation was observed (Figure 4–38).[629] The inhibition constant for isocitrate as a competitive inhibitor of the inactivation, calculated from the data directly, was 90 μM, which compares favorably to the Michaelis constant of 110 μM for isocitrate as a reactant for the enzyme. The **coincidence of the inhibition constant and the Michaelis constant** demonstrates that isocitrate binds to the same site on the enzyme when it is a reactant as when it is a competitive inhibitor of the irreversible inactivation caused by 3-bromopyruvate.

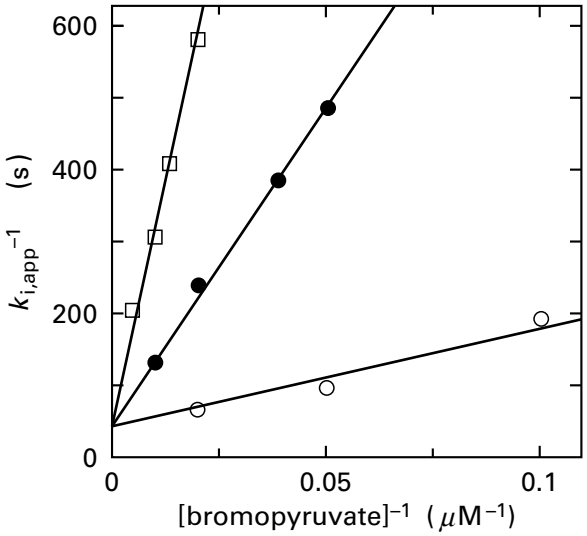


Figure 4–38: Competition between isocitrate and 3-bromopyruvate during the inactivation of isocitrate lyase from *V. indigofera*.[629] Mixtures containing various concentrations of 3-bromopyruvate and 0.5 mM isocitrate (●), 2.0 mM isocitrate (□), or no isocitrate (○) were prepared at pH 7.7 and 30 °C. Enzyme was added to initiate the inactivation. For each mixture, inactivation of the enzyme was followed as a function of time, and pseudo-first-order rate constants of inactivation were calculated from the loss of activity over the first half-time of the reaction. The reciprocals of the observed rate constants for inactivation, $k_{i,app}^{-1}$ (second^{-1}), derived from these time courses are plotted as a function of the reciprocals of the concentrations of 3-bromopyruvate (Brpyr), [bromopyruvate]$^{-1}$ (micromolar^{-1}), in the mixtures after addition of the enzyme. The lines drawn are those defined by the reciprocal of Equation 4–309 for k_i = 0.016 min^{-1}, $K_{m,isc}$ = 90 μM, and $K_{d,Brpyr}$ = 30 μM.

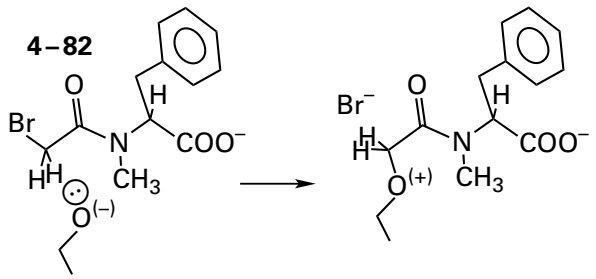
Therefore, 3-bromopyruvate alkylates the enzyme while it is bound at the active site in a portion of the location occupied by isocitrate.

For enzymes with more than one reactant, if the turnover of reactant A is prevented by leaving out reactant B or reactant C or both of them during the inactivation by an active-site label designed to resemble reactant A, then the Michaelis constant in Equation 4–309 is replaced by the dissociation constant of reactant A from the active site, K_{dA}, in the absence of reactant B or reactant C or both of them. For example, glycerone phosphate (reactant A) in the absence of glyceraldehyde 3-phosphate (reactant B) is a competitive inhibitor of the irreversible inactivation of fructose-bisphosphate aldolase caused by 1-hydroxy-2-oxobut-3-ene phosphate (Equation 4–305). Values for the various pseudo-first-order rate constants of inactivation were used to calculate the inhibition constant of glycerone phosphate for inactivation of the enzyme. The value

calculated (1.4 μM) was close enough to the value for the dissociation constant (4.5 μM) for glycerone phosphate from the active site under different circumstances for the authors to conclude that inactivation was occurring within the active site.[689]

A **competitive inhibitor** of the normal enzymatic reaction can also be used to demonstrate the specificity of an active-site label. *N*-Bromoacetyl-*N*-methyl-L-phenylalanine (**4–82**; BramF) was synthesized as an active-site label for carboxypeptidase A.[630] In the normal enzymatic reaction of carboxypeptidase A (Equation 4–172), a catalytic base, $-O\odot^{(-)}$, must remove a hydron from the water that adds to the acyl carbon, and *N*-bromoacetyl-*N*-methyl-L-phenylalanine was designed to modify this catalytic base



(4–312)

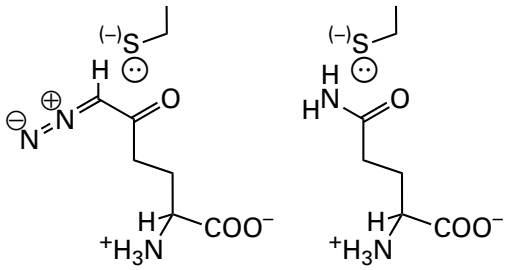
N-Bromoacetyl-*N*-methyl-L-phenylalanine inactivated the enzyme in a pseudo-first-order process, and the observed rate constants displayed saturation (K_{dBramF} = 5 mM). A competitive inhibitor of the enzyme, 2-phenylacetate, competitively inhibited the irreversible inactivation produced by *N*-bromoacetyl-*N*-methyl-L-phenylalanine. The inhibition constant for 2-phenylacetate as a competitive inhibitor of inactivation (1.1 mM) was in reasonable agreement with its inhibition constant as a competitive inhibitor of enzymatic activity (0.4 mM), and this agreement was used as evidence that the inactivation occurred while the active-site label was bound to the active site of the enzyme.

The **criterion that the active-site label should be a competitive inhibitor of the normal enzymatic reaction and the criterion that it should have the same inhibition constant as its dissociation constant** when it is irreversibly inactivating the enzyme are self-evident. The rate at which an active-site label modifies an enzyme is usually slow (Figures 4–35 and 4–37) compared to the rates at which it associates and dissociates from the active site and the rate at which normal reactants are converted to normal products. This difference in rates means that the initial rate of the enzymatic reaction can usually be measured in the presence of the active-site label over an interval short enough that significant inactivation has not yet occurred. In this way, the ultimately irreversible inhibitor can be assessed for its **ability to inhibit the enzymatic reaction reversibly.** If the active-site label does enter the active site before it reacts with the enzyme, then it should be a competitive inhibitor with respect to the reactant that it resembles. If the covalent inactivation is from the same position it occupies as a competitive inhibitor, then its competitive inhibition constant should be the same as its dissociation constant for inactivation.

Amidophosphoribosyltransferase

$$\text{manganese 5-phospho-}\alpha\text{-D-ribose 1-diphosphate} + \text{L-glutamine} + H_2O \rightleftharpoons \text{L-glutamate} + H^+ + MnOPO_3PO_3^{2-} + \text{5-phospho-}\beta\text{-D-ribosylamine} \quad (4\text{–}313)$$

transfers the ammonia produced by hydrolysis of L-glutamine at the active site for glutaminase through a tunnel[693] to 5-phospho-α-D-ribose 1-diphosphate, where the ammonia participates in a nucleophilic substitution at carbon 1 with diphosphate as the leaving group. 6-Diazo-5-oxo-(*S*)-2-aminohexanoic acid (**4–83**) was chosen[669] as an active-site label to modify any base involved in hydrolysis of L-glutamine (**4–84**) at the active site for glutaminase because it should place a diazoketone adjacent to such a base



6-Diazo-5-oxo-(*S*)-2-aminohexanoic acid inactivates amidophosphoribosyltransferase from *G. gallus* irreversibly, and at short times it is a reversible competitive inhibitor of the normal enzymatic reaction with respect to L-glutamine. Its inhibition constant as a reversible competitive inhibitor (K_{iDon} = 20 μM) is close to its dissociation constant as an irreversible active-site label (K_{dDon} = 30 μM), and this coincidence is evidence that the irreversible modification occurs while 6-diazo-5-oxo-(*S*)-2-amino-

hexanoic acid is occupying the active site for glutaminase in place of L-glutamine.

When 5-phospho-α-D-ribose 1-diphosphate is present at saturation and occupying the other active site on amidophosphoribosyltransferase that is responsible for the nucleophilic substitution of ammonia by the diphospho group, the rate for inactivation by 6-diazo-5-oxo-(*S*)-2-aminohexanoic acid of the glutaminase increases 15-fold. This fact suggests that there must be a conformational change in the enzyme that causes the active site for deamination of L-glutamine to become more efficient when 5-phospho-α-D-ribose 1-diphosphate has associated with the active site for amination. This communication between the active sites could be a way to prevent molecules of ammonia from piling up in the tunnel and leaking into the solution, leading to the nonproductive, and energetically wasteful, hydrolysis of L-glutamine, and the change in rate of inactivation has revealed this adaptation.

The usual purpose of active-site labeling is to modify the conjugate base of a catalytic acid–base involved in the catalytic mechanism of an enzyme. The **criterion that the same pK_a should govern the steady-state kinetics and the inactivation by an active-site label** connects the pK_a for the catalytic acid–base that is revealed in the pH–rate profile for a steady-state rate constant and the pK_a for the catalytic acid–base that is modified by the active-site label. The kinetic mechanism of Equation 4–297 can be expanded[636] to include acid dissociations of the base being modified, which is nucleophilic only when it is unhydronated

$$\begin{array}{ccccc} EH^{(+)} + ASL & & EH^{(+)}\cdot ASL & & \\ \Big\downarrow\uparrow K_{aE} & & \Big\downarrow\uparrow K_{aE\cdot ASL} & & \\ H^+ & & H^+ & & \\ + & & + & & \\ E^{(-)} + ASL & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & E^{(-)}\cdot ASL & \xrightarrow{k_i} & E\text{–}ASL \end{array} \qquad (4\text{–}314)$$

from which it follows that

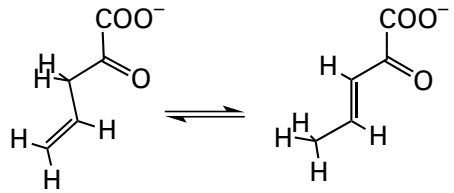
$$k_{ASL,app} = k_{ASL}\left(\frac{K_{aE}}{[H^+] + K_{aE}}\right) \qquad (4\text{–}315)$$

and

$$k_{i,app} = k_i\left(\frac{K_{aE\cdot ASL}}{[H^+] + K_{aE\cdot ASL}}\right) \qquad (4\text{–}316)$$

The rate constants $k_{ASL,app}$ and $k_{i,app}$ are the observed values at a given pH, and k_{ASL} and k_i are asymptotic values for these rate constants (Equation 4–299) at values of pH greater than pK_{aE} and p$K_{aE\cdot ASL}$, respectively, where rate constants become invariant with pH (as in Figure 4–10A–D). Because **the conjugate base of the catalytic acid–base is the nucleophile** that adds to the electrophilic center in the active-site label, the rate of inactivation decreases below a particular value of pK_a as the conjugate base is hydronated. At values of pH greater than that pK_a, all the active sites contain the unhydronated conjugate base.

3-Bromopyruvate (Equation 4–311) inactivates 2-hydroxymuconate tautomerase



(4–317)

from *P. putida*.[694] Upon entering the active site, 3-bromopyruvate (Brpyr) should place the alkyl bromide immediately adjacent to the base in the active site responsible for removing the hydron from carbon 3 of 2-oxopent-4-enoate during its tautomerization by the enzyme. The inactivation by 3-bromopyruvate was followed as a function of pH (Figure 4–39A).[636,645] The observed rate constant for the inactivation, $k_{Brpyr,app}$ (Equation 4–299), that was produced by 3-bromopyruvate decreased below a pK_a of 6.7 ± 0.3. This pK_a should be the pK_a in the empty active site of the free enzyme (Equation 4–315) for the base that is alkylated by 3-bromopyruvate. It was found that 3-bromopyruvate alkylates the amino-terminal proline of the enzyme,[636] which has been shown, by nuclear magnetic resonance spectroscopy,[116] to have a pK_a of 6.4 ± 0.2 in the unoccupied enzyme. The specificity constant $k_{OPE,app}$ for the enzymatically catalyzed tautomerization of 2-oxopent-4-enoate (OPE) decreases below a pK_a of 6.2 ± 0.3. The fact that all these values of pK_a are identical within the errors of measurement is consistent with two conclusions: first, that 3-bromopyruvate inactivates the enzyme by alkylating the catalytic base that is responsible for the decrease in

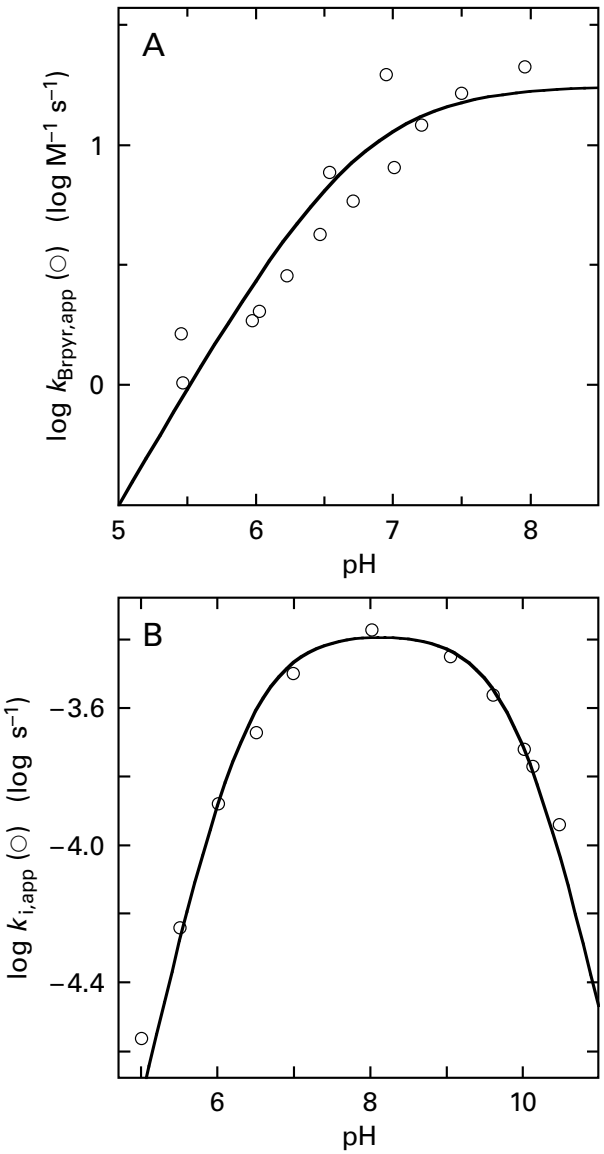


Figure 4–39: Dependence on pH of the common logarithms of the rate constants for inactivation by active-site labels. (**A**) Inactivation of 2-hydroxymuconate tautomerase from *P. putida* by 3-bromopyruvate.[636] Solutions containing 0.45–4.5 mM 3-bromopyruvate were prepared at various values of pH buffered with 0.1 M sodium phosphate at 23 °C . Inactivation of the enzyme was initiated by adding enzyme to 1.7 μM in active sites and was followed by withdrawing samples at appropriate times, diluting the sample 200-fold, and performing an assay for enzymatic activity. The observed pseudo-first-order rate constants of inactivation for each value of pH and each concentration of 3-bromopyruvate were determined from a nonlinear least-squares fit of the data for the loss in enzymatic activity as a function of time to Equation 4–298. These observed rate constants as a function of the concentrations of 3-bromopyruvate (Brpyr) for each pH were then fit to Equation 4–299 to obtain values for $k_{Brpyr,app}$. The common logarithms of these values for $k_{Brpyr,app}$ (molar^{-1} second^{-1}) are plotted as a function of the pH of the solution in which the inactivation occurred. The curve fit to the data is that for Equation 4–89, with $k_{Brpyr,app}$ substituted for $k_{0,app}$ and k_{Brpyr} substituted for k_0. The resulting parameters of the fit are pK_a = 6.74 and k_{Brpyr} = 17.7 M^{-1} s^{-1}. (**B**) Inactivation of glucose-6-phosphate isomerase from *S. cerevisiae* by 1,2-anhydro-D-mannitol 6-phosphate.[645] Solutions containing 2 or 4 mM (2*R*)-1,2-anhydro-D-mannitol 6-phosphate were prepared at various values of pH buffered with sodium acetate, imidazolium chloride, triethanolammonium chloride, or sodium glycinate at 25 °C. The two concentrations of reagent chosen were known to be saturating for the active site, and the fact that the rates of inactivation were the same for each verified this expectation. Inactivation of the enzyme was initiated by adding yeast glucose-6-phosphate isomerase and was followed by withdrawing samples at appropriate times, diluting the sample 100-fold with cold assay buffer, and performing an assay for enzymatic activity. The observed pseudo-first-order rate constants of inactivation, $k_{i,app}$, for each value of pH and each concentration of the epoxide were obtained by plotting the common logarithms of the residual enzymatic activity as a function of time. The common logarithms of these rate constants, log $k_{i,app}$ (second^{-1}), are plotted as a function of pH. The curve fit to the data is that for Equation 4–96, with $k_{i,app}$ substituted for $k_{0,app}$ and k_i substituted for k_0. The resulting parameters of the fit are pK_{a1} = 6.34, pK_{a2} = 9.95, and k_i = 1.5 h^{-1}.

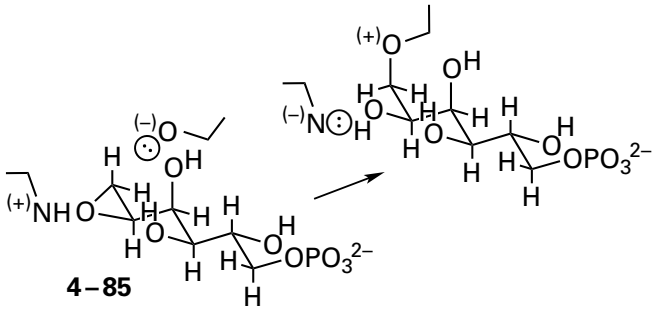
the specificity constant for tautomerization of 2-oxopent-4-enoate below a pK_a of 6.2; and second, that the catalytic base responsible for this decrease in the specificity constant and also responsible for removing the hydron from carbon 3 of 2-oxohex-4-enedioate (Equation 4–317) is the amino-terminal proline of the enzyme.

The reaction catalyzed by glucose-6-phosphate isomerase

D-glucose 6-phosphate ⇌ D-fructose 6-phosphate (4–318)

proceeds through a *cis*-enediol, as does that catalyzed by triose-phosphate isomerase (Equations 4–46 and 4–55 and Figure 3–37). The *cis*-enediol in this case is the conjugate base of both D-glucose 6-phosphate and D-fructose 6-phosphate. To produce this common conjugate base, a catalytic base is necessary to remove a hydron from carbon 1 of D-glucose 6-phosphate or carbon 2 of D-fructose 6-phosphate, and the conjugate acid of this base is necessary to add a hydron to carbon 2 or carbon 1, respectively, of the resulting enediol. Catalytic acid–bases are also necessary to operate on the oxygens on carbons 1 and 2 to stabilize the enolate (see Figure 3–37).

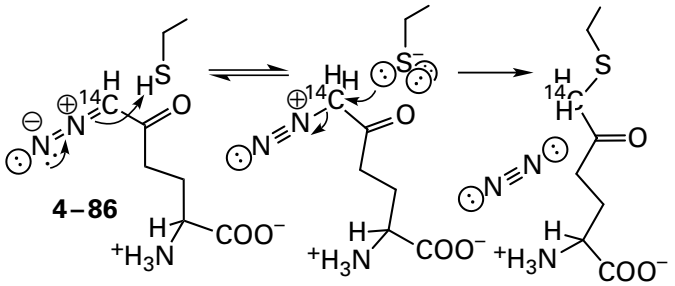
The oxirane 1,2-anhydro-D-mannitol 6-phosphate (**4–85**) was chosen[645] as an active-site label for glucose-6-phosphate isomerase



(4–319)

Under catalysis by –NH$^{(+)}$, the catalytic acid responsible for adding the hydron to oxygen in the normal reaction, the epoxide should alkylate –O$\odot^{(-)}$, the catalytic base responsible for removing the hydron from carbon. Rate constants at saturation, $k_{\text{anMP,app}}$ (Equation 4–299), for the irreversible inactivation of glucose-6-phosphate isomerase from *S. cerevisiae* caused by 1,2-anhydro-D-mannitol 6-phosphate (anMP) were determined as a function of pH (Figure 4–39B).[645] The two values of pK_a (6.3 and 10.0) are thought to correspond to the microscopic pK_a of the conjugate acid of the catalytic base responsible for the nucleophilic substitution resulting in inactivation and the microscopic pK_a for the catalytic acid that hydronates the oxygen of the epoxide, respectively. Because values of pK_a measured are for the active site occupied by the epoxide, they should be closest to values of pK_a for the active site occupied by reactant and hence values of pK_a governing the behavior of the catalytic constant. The catalytic constant of the enzymatic reaction has a similar dependence on pH with apparent values for pK_a of 6.6 and 9.8. Acid dissociation constants that govern the inactivation of the enzyme by the epoxide, however, are uncomplicated by rate constants of other steps in the catalytic reaction, and they should be more direct measurements of actual acid dissociation constants for these amino acids within the active site when it is occupied by 1,2-anhydro-D-mannitol 6-phosphate or by either substrate.

The criterion that covalent incorporation of the active-site label into the protein should be **proportional to the loss of enzymatic activity** and that the **stoichiometry of incorporation** at full inactivation should be 1.0 mol (mol of active sites)$^{-1}$ ensures that the major modified peptide that will be derived from digestion of the enzyme will be the peptide containing the amino acid the modification of which led to the inactivation of the enzyme.[640] For example, amidophosphoribosyltransferase from *B. subtilis* (Equation 4–313) is irreversibly inactivated by [6-^{14}C]-6-diazo-5-oxo-(*S*)-2-aminohexanoic acid (**4–86**), an electrophilic analogue of the substrate L-glutamine. [6-^{14}C]-6-Diazo-5-oxo-(*S*)-2-aminohexanoic acid is a diazoketone that covalently modifies an adjacent acid when it is bound in an active site. The covalent incorporation results from a nucleophilic substitution with the conjugate base of the acid after the acid has hydronated carbon 6 of the active-site label. Molecular nitrogen is the leaving group[669,670]



(4–320)

Both the covalent incorporation of the radioactive reagent into amidophosphoribosyltransferase and the irreversible loss of enzymatic activity were followed as a function of time in the same samples. A close correlation between these two properties was observed (Figure 4–40).[695] The incorporation of radioactivity into the protein rises as the enzymatic activity falls (Figure 4–40A). The fraction of enzymatic activity lost is directly proportional to the moles of carbon-14 incorporated into the protein (Figure 4–40B). The **extrapolated value for incorporation at full inactivation** was 0.85 mole of reagent for every mole of protomer, and hence every mole of active sites, estimated to be in the solution.

When intact, fully inactivated amidophosphoribosyltransferase covalently modified by [6-^{14}C]-6-diazo-5-oxo-(*S*)-2-aminohexanoic acid was submitted to Edman degradation, all the carbon-14 that had been incorporated was released in the first cycle. This result identified the sulfido group of the amino-terminal cysteine in the amino-terminal domain of the enzyme as the nucleophile that had been modified. The amino-terminal cysteine in the homologous (36% identity; 3.0 gap percent) amino-terminal glutaminase domain in amidophosphoribosyltransferase from *E. coli* is also alkylated specifically by 6-diazo-5-oxo-(*S*)-2-aminohexanoic acid,[696] and the sulfanyl group of this cysteine has been identified as the nucleophile releasing ammonia from L-glutamine by nucleophilic substitution to form a thioester, which is subsequently hydrolyzed to regenerate the sulfanyl group.[693,697-700]

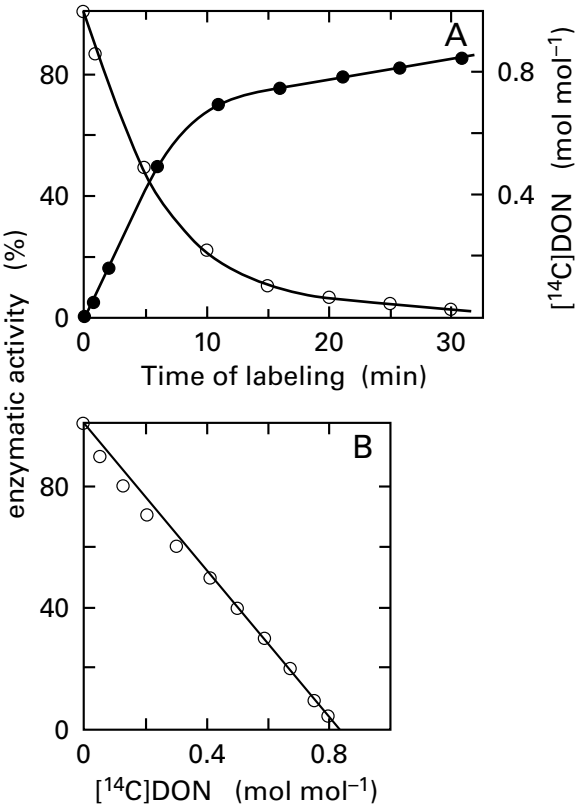


Figure 4–40: Incorporation of [6-^{14}C]-6-diazo-5-oxo-(*S*)-2-aminohexanoic acid into amidophosphoribosyltransferase from *B. subtilis*.[695] A solution containing 10 μM [6-^{14}C]-6-dazo-5-oxo-(*S*)-2-aminohexanoic acid, 7.5 mM $MgCl_2$, and 5 mM 5-phosphoribosyl 1-diphosphate was prepared at pH 7.5 and 37 °C. Amidophosphoribosyltransferase (5 μM final concentration of active sites) was added to initiate the reaction. At the noted times, samples (10 μL) were removed for assay of enzymatic activity, and other samples (75 μL) were removed and quenched with 175 μL of 10% trichloroacetic acid at 0 °C. Serum albumin (0.1 mg) was added to each of these latter samples as a coprecipitant. It was assumed that the precipitated carbon-14 was attached covalently to the amidophosphoribosyltransferase. After 4 h, the precipitates in the latter samples were washed with ethanol, dissolved in 1 M NaOH, neutralized with HCl, and submitted to scintillation counting. (**A**) Enzymatic activity (○), as a percentage of initial activity, and covalent incorporation of carbon-14 into protein (●), as moles of [6-^{14}C]-6-diazo-5-oxo-(*S*)-2-aminohexanoic acid ([^{14}C]DON) incorporated for each mole of active sites in the solution, are presented as a function of time (minutes). (**B**) Enzymatic activity (○), as a percentage of initial activity, is plotted as a function of the covalent incorporation of [6-^{14}C]-6-diazo-5-oxo-(*S*)-2-aminohexanoic acid, in moles of incorporation for each mole of active sites.

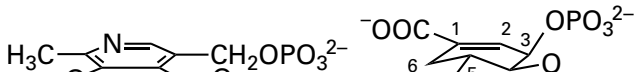
Pyridoxal 5′-phosphate (**4–87**) is electrophilic at its aldehyde. It forms unstable pyridoximines with primary amines, just as it forms external pyridoximines during the normal reactions catalyzed by enzymes that use it as a prosthetic group (Equation 4–258). Pyridoximines of primary amines can be reduced with borohydride, BH_4^-, or cyanoborohydride, $N{\equiv}CBH_3^-$, to the corresponding, stable secondary amines. Pyridoxal 5′-phosphate only vaguely resembles 3-phosphoshikimate (**4–88**)



Nevertheless, it is an active-site label for 3-phosphoshikimate 1-carboxyvinyltransferase (previously Equation 3–262)

phospho*enol*pyruvate + 3-phosphoshikimate
$\rightleftharpoons$ phosphate +
5-*O*-(1-carboxyvinyl)-3-phosphoshikimate
(4–321)

from *E. coli* (see Problem 4–26) that satisfies most of the criteria for specific active-site labeling.[655] 3-Phosphoshikimate 1-carboxyvinyltransferase was mixed with a solution of pyridoxal 5′-phosphate, and samples were removed at consecutive intervals and reduced with $[^3H]BH_4^-$. The irreversible, covalent incorporation of [4′-^{3}H]pyridoxamine 5′-phosphate into the protein was directly proportional to the loss of enzymatic activity, and at complete inactivation, 1.0 mole of pyridoxal 5′-phosphate was incorporated for every mole of protomer of the enzyme in the solution. When the fully inactivated enzyme, reduced with $[^3H]BH_4^-$, was digested with trypsin, only one of the resulting tryptic peptides was radioactive. This peptide had the sequence VDGTINLPGSX*XVSNR, where the asterisk denotes the cycle of Edman degradation in which a radioactive amino acid was released. This sequence identifies the labeled amino acid as Lysine 22 in the complete sequence of the enzyme.

In the crystallographic molecular model between 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli* and 3-phosphoshikimate and 2-(phosphonomethylamino)acetic acid, an enzymatically inactive analogue of phospho*enol*pyruvate, Lysine 22 forms a hydrogen bond (0.28 nm) to the 5-hydroxy group of 3-phosphoshikimate (**4–88**).[701] In crystallographic molecular models of 3-phosphoshikimate

1-carboxyvinyltransferase from both *E. coli* and *Agrobacterium* and several analogues of the tetrahedral intermediate in the enzymatic reaction, Lysine 22 has been identified as the catalytic base that removes the hydron from the 5-hydroxy group of 3-phosphoshikimate to increase the nucleophilicity of the oxygen and initiate transfer of the 1-carboxyvinyl group to this hydroxy group in the first step of the enzymatic reaction.[702] Pyridoxal 5-phosphate, binding in place of 3-phosphoshikimate, serendipitously places its electrophilic aldehyde adjacent to the amino group of this catalytic lysine and modifies it.

As was the case for amidophosphoribosyltransferase (Figure 4–40B), extrapolated values for the moles of reagent incorporated into the protein at complete inactivation are **rarely the hoped-for value of 1.0 mol (mol of active sites)$^{-1}$**. In situations[639] when it is 1.0 mol mol^{-1}, such as that for the incorporation of [4′-^{3}H]pyridoxamino 5′-phosphate into 3-phosphoshikimate 1-carboxyvinyltransferase, the agreement with expectation is probably only by chance. First, an incorporation in excess of 1.0 mol (mol of active sites)$^{-1}$ may only mean that **the electrophile is reactive enough to modify other amino acids** at random on the surface of the protein present in the solution in addition to the targeted catalytic base in the active site of interest. Second, an extrapolated value for incorporation at full inactivation significantly different from 1.0 mol mol^{-1} can also be due to inaccuracies in estimation of the concentration of active sites in the solution because the concentration of active sites is almost always estimated from the concentration of total protein in the preparations, and it is quite **difficult to measure the concentration of protein in any solution** accurately.[703] Third, even if the concentration of protein has been measured accurately, **inactive molecules of enzyme in the solution** and other contaminating proteins will cause the estimate of the concentration of active sites in the solution to be too high. All the foregoing problems probably apply to every measurement of covalent incorporation of an active-site label into an enzyme, so it is remarkable, and perhaps suspicious, that the extrapolated values for incorporation at full inactivation obtained are so often so close to 1.0 mol mol^{-1}.

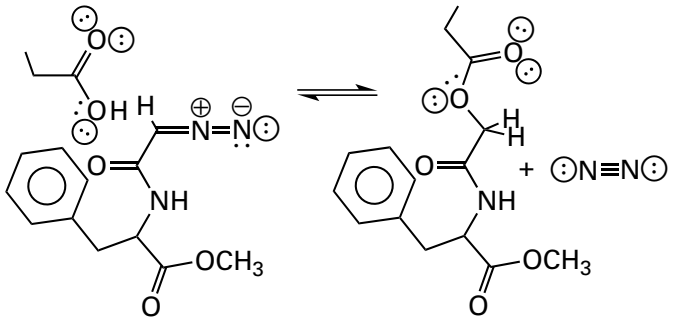
This last criterion of active-site labeling is confirmatory when it is fulfilled, but it is not a requirement for a modification that occurs specifically in an active site. An extrapolated value for incorporation at full inactivation that is greater than 1.0 or a percent of inactivation that is not directly proportional to incorporation of the active-site label does not rule out the possibility that the reagent did inactivate the enzyme while it was bound in place of a substrate within the active site. The product of the reaction that occurred within the active site can be distinguished from products of other reactions that occurred outside the active site by **changes in the yield of these products in response to ligands for the active site**. The yield of the product of modification from within the active site will decrease significantly when the amino acid involved is protected from modification by adding substrates or competitive inhibitors, but the yield of the products of modification at other amino acids outside the active site should be unaffected by these additions.

When bovine carboxypeptidase A (Equation 4–172) was modified to complete inactivation with *N*-([1-^{14}C]bromoacetyl)-*N*-methyl-L-phenylalanine (Equation 4–312), 2 moles of the reagent were incorporated for every mole of enzyme.[704] Two cyanogen bromide fragments of the protein became radioactive during the modification. When the modification was repeated under the same conditions but in the presence of the competitive inhibitor L-phenylalanine, only 10% of the enzymatic activity was lost, and incorporation of radioactivity into one of the two fragments decreased 10-fold while incorporation into the other was unchanged. This experiment was sufficient to identify the fragment containing the amino acid modified from within the active site. This **ability of substrates or competitive inhibitors to protect a particular peptide against incorporation of the active-site label** is a further necessary criterion to demonstrate that a peptide which has been isolated contains the amino acid from the active site the modification of which was correlated with the inactivation.

A determination of the position of the modified amino acid in the sequence of amino acids for an enzyme connects the results of active-site labeling to the structure of the protein.[641] For example, the modification of triose-phosphate isomerase identified Glutamate 165 as a catalytic acid–base, the modification of amidophosphoribosyltransferase identified the amino-terminal cysteine as a catalytic acid–base, and the modification of 3-phosphoshikimate 1-carboxyvinyltransferase identified Lysine 22 as a catalytic acid–base.

When porcine pepsin, an enzyme that catalyzes the hydrolysis of peptide bonds in peptides and proteins, was completely inactivated with the active-site label *N*-(diazo[^{14}C]acetyl)-L-phenylalanine methyl ester, 1.0 mole of the reagent was incorporated for

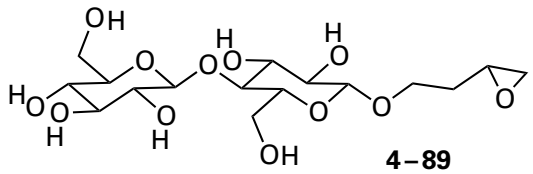
every mole of enzyme.[705] The modified protein was digested with pepsin, and a radioactive peptide was partially purified by chromatography. The peptide was then purified to homogeneity by two-dimensional diagonal electrophoresis. The peptides were submitted to electrophoresis in one dimension, treated with triethylamine, and submitted to electrophoresis again in the orthogonal dimension. Only one peptide, which was radioactive after the first separation, changed its mobility and moved off the diagonal. The isolated peptide, which no longer was labeled, was found to be IVDTGTS. It was concluded that the (diazoacetyl)-L-phenylalanine, while it was in the active site, had formed an ester with Aspartate 215 in the sequence of amino acids for the protein



(4–322)

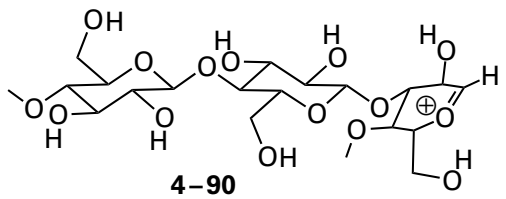
Such an ester is susceptible to aminolysis by ethylamine.

The active-site label 3,4-epoxybutyl β-D-cellobiose



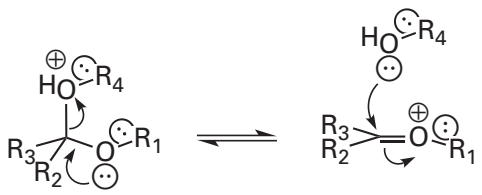
4–89

(molar mass = 412.39 g mol^{-1}) should place an electrophilic epoxy group adjacent to a catalytic acid–base responsible for either stabilizing an intermediate oxocarbenium ion



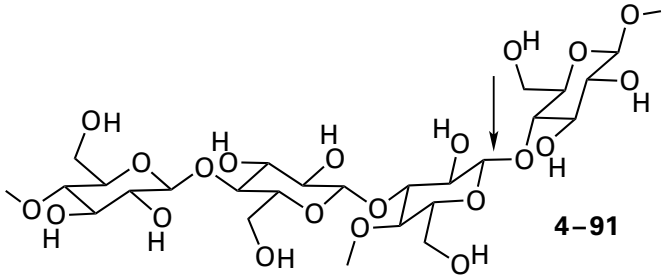
4–90

or adding a hydron to the leaving hydroxy group (previously Equation 1–23)



(4–323)

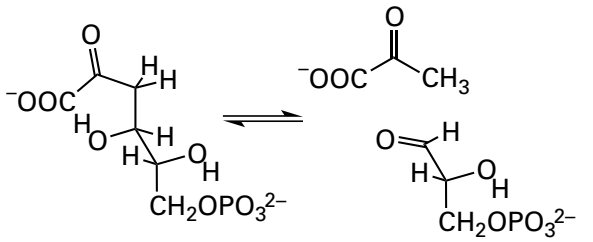
and removing a hydron from water during the hydrolysis of (β1,3)-(β1,4)-glucan



4–91

catalyzed by licheninase, where the arrow marks the site of hydrolysis. When licheninase from *B. amyloliquefaciens* was inactivated with 3,4-epoxybutyl β-[^{14}C]cellobiose, 1.1 mole of the [^{14}C]active-site label was incorporated for each mole of enzyme, and almost all the molecules of enzyme increased in mass by 412 unified atomic mass units (major) or 825 unified atomic mass units (minor), upon mass spectrometry. When the modified protein was digested separately by glutamyl endopeptidase and trypsin, the sequences of amino acids and mass spectrometry of the resulting radioactive peptides obtained from the digests identified Glutamate 105 as the modified amino acid.[648]

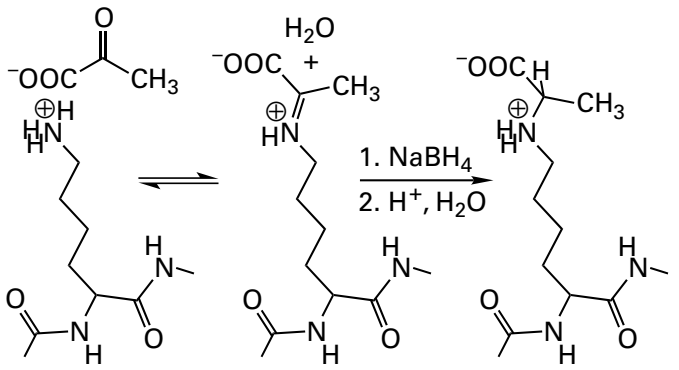
Complications can arise when **the product of a modification is too unstable** to survive the digestion, chromatography, and sequencing required to identify the amino acid modified. For example, 2-dehydro-3-deoxy-phosphogluconate aldolase from *Pseudomonas* catalyzes the aldol condensation



(4–324)

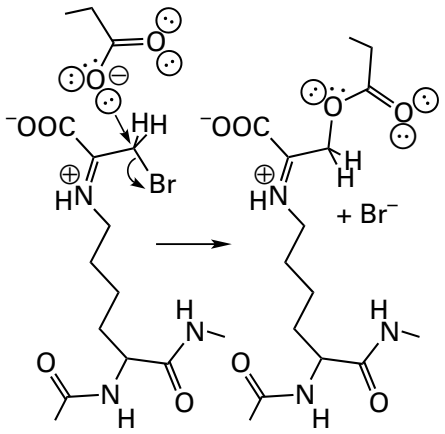
An imine between a lysine in the active site and the 2-oxo group on 2-dehydro-3-deoxyphosphogluconate is formed during the enzymatic reaction to facilitate the retroaldol condensation.[706] Therefore,

an imine between the same lysine and pyruvate forms as a step in the aldol condensation, and this imine can be identified by reducing it with sodium borohydride[707]



(4–325)

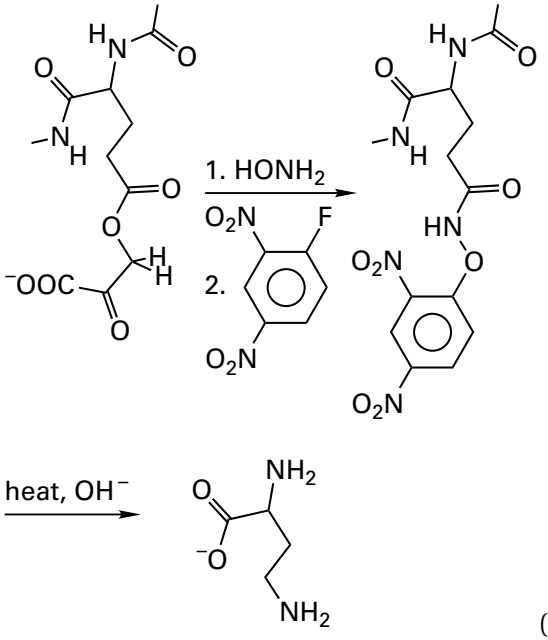
When 3-bromopyruvate is mixed with enzyme, not only does the imine form with the carbonyl of 3-bromopyruvate, but the primary bromide in the resulting imine alkylates another amino acid in the vicinity. When 2-dehydro-3-deoxy-phosphogluconate aldolase that had been inactivated with [^{14}C]-3-bromopyruvate but not reduced with sodium borohydride was digested with trypsin, a radioactive tryptic peptide could be purified to homogeneity.[637] The sequence of this peptide was TLEVTLR, which tentatively identified Glutamate 56 in the complete sequence of the protein[708] as the alkylated nucleophile



(4–326)

but all the [^{14}C]-3-hydroxypyruvate, presumably esterified to Glutamate 56, was lost at the first step of sequencing due to hydrolysis of the ester.

To confirm that the [^{14}C]-3-hydroxypyruvate actually was esterified to the glutamate as a result of the active-site labeling prior to sequencing, the isolated, radioactive peptide was submitted to a Lossen rearrangement, which requires that an ester be present



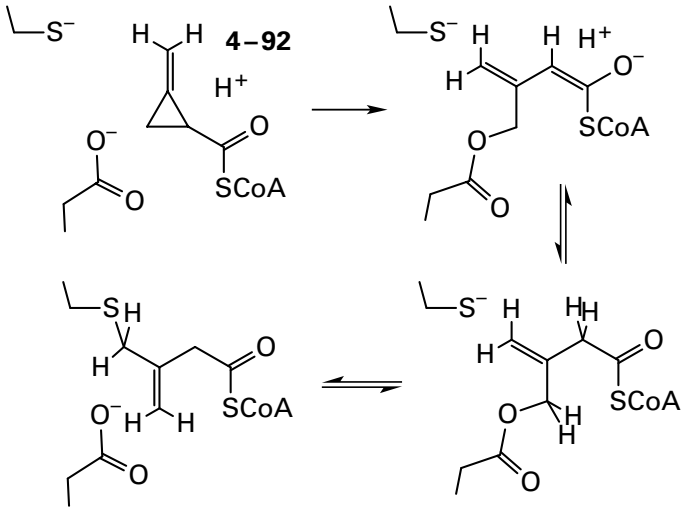
(4–327)

The recovery of 2,4-diaminobutyrate (0.8 mol mol^{-1}) could only be explained if the glutamate in the radioactive peptide was esterified.[637] After the Lossen rearrangement, the peptide was no longer intact, so it could not be sequenced to show that 2,4-diaminobutyrate had replaced glutamate, but there is no other amino acid in the peptide that could have been converted into 2,4-diaminobutyrate. Consequently, it could be concluded that Glutamate 56 had been modified by esterification.

After this discussion of historical examples of identification of labeled amino acids in the sequence of a modified protein, it should be mentioned that advances in mass spectrometry have rendered many of the specific approaches described so far obsolete. Consequently, they are presented not as examples of what would now be done, but as examples of the knowledge gained by identifying a particular amino acid as the site of modification.

Although it is not a frequent occurrence, the group covalently modifying a catalytic acid–base can **move to another amino acid** in the active site that is not a catalytic acid–base. For example, (2-methylenecyclopropyl)formyl-SCoA (**4–92**) inactivates bovine enoyl-CoA hydratase (Equation 4–236) in a reaction that satisfies many of the criteria of active-site labeling.[709] The tryptic peptide modified by the active-site label was ALGGGXEL, where X was the modified amino acid released in that cycle of sequencing.[710] Consequently, the 2-methylenecyclopropyl group had modified Cysteine 114 in the sequence

of amino acids for the enzyme. A mutant of the enzyme, however, in which Cysteine 114 had been changed to alanine, had a catalytic constant and a specificity constant for crotonyl-SCoA that were only 60% and 50%, respectively, of the values for the wild-type enzyme. Furthermore, (2-methylenecyclopropyl)formyl-SCoA inactivated the mutant in a reaction that resulted in modification of Glutamate 115 rather than the missing cysteine.[668] It was concluded that the catalytic acid–base was actually Glutamate 115 and that, after the initial modification of Glutamate 115, the resulting vinyl ester migrated to the sulfido group of Cysteine 114



(4–328)

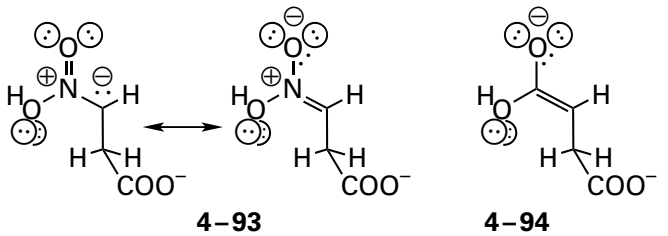
Although the migration should be a pseudosymmetric, reversible reaction, the equilibrium strongly favors the sulfide over the ester. The sulfido group is a strong nucleophile and a poor leaving group while the carboxylate is a weak nucleophile and a good leaving group.

The amino acid in the sequence of the protein that has been modified can also be identified directly in a crystallographic molecular model of the modified enzyme. For example, (1*S*,3*S*)-3-amino-4-(perfluoropropan-2-ylidene)cyclopentane-1-carboxylate inactivates human ornithine aminotransferase. Its 3-amino group forms an external pyridoximine with the prosthetic pyridoxal 5′-phosphate in the active site and positions the perfluoropropan-2-ylidene group, which is turned into an electrophile by the external pyridoximine, adjacent to a catalytic acid–base in the active site and modifies it. A crystallographic molecular model of the modified enzyme identified the structure of the product of modification and identified Lysine 292, a lysine other than the one that forms the internal pyridoximine (Equation 4–129), as the modified amino acid.[711] The product observed crystallographically was consistent with the mass spectrum of the modified enzyme, but the mass spectrum alone would not have identified the product. It is possible that chemical identification of the amino acid modified by an active-site label has been rendered obsolete by advances in the ease with which crystallography can be performed.

As with the active-site labeling of triosephosphate isomerase, diaminopimelate epimerase, 3-phosphoshikimate 1-carboxyvinyltransferase, and ornithine aminotransferase, the success of an active-site label in identifying a catalytic acid–base that participates in the catalysis accomplished by an active site relies on crystallography.

The catalytic roles of the acid–bases of particular amino acids the conjugate bases of which are modified by electrophilic active-site labels are verified crystallographically.[649,670,671,712-714] It is usually the case that the crystallographic molecular model that provides this assignment is for the same enzyme from a different species because crystallization is usually serendipitous and the serendipity depends on the source of the enzyme.

3-Bromopyruvate inactivates isocitrate lyase (Equation 4–310) from *V. indigofera* (Figure 4–38).[629] 3-Bromopyruvate also inactivates[715] the homologous (73% identity; 0.7 gap percent) isocitrate lyase from *E. coli* by alkylating the sulfido group of Cysteine 195 (Equation 4–311), and it inactivates the homologous (63% identity; 0.7 gap percent) isocitrate lyase from *M. tuberculosis* by alkylating the homologous Cysteine 191.[692] There is a mutant of isocitrate lyase from *M. tuberculosis* in which this cysteine has been mutated to serine. In a crystallographic molecular model[692] of a complex between this mutant enzyme and glyoxylate and the *aci*-nitro tautomer of 3-nitropropionate (**4–93**)



4–93 **4–94**

which is an inactive, isosteric, and isoelectronic analogue of the *gem*-enediolate of succinate (**4–94**), the γ-oxygen of the serine replacing Cysteine 191 is in the location necessary to remove the correct

hydron[716] from succinate and is only 0.29 nm from carbon 3 on the 3-nitropropionate. Presumably, the γ-oxygen forms a hydrogen bond with the anionic carbon of the *aci*-nitro tautomer of nitropropionate. In the normal enzymatic reaction, the sulfido group of the unmutated cysteine would be the catalytic base that removes the correct hydron from succinate (Equation 4–310) with the assistance of the adjacent carboxylato group of Aspartate 108, with which it forms a hydrogen bond, and the acidic molecule of water on a nearby Mg^{2+}, with which the same oxygen on the carboxylato group forms a hydrogen bond.

N-Bromoacetyl-*N*-methyl-L-phenylalanine (Equation 4–312) alkylates Glutamate 270 of bovine carboxypeptidase A.[704] This glutamate has been assigned crystallographically as the catalytic base that removes the hydron from the molecule of water that adds to the acyl carbon to initiate hydrolysis of the peptide bond (Equation 4–172).[234,259]

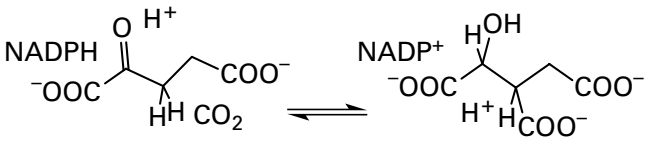
1,2-Anhydro-D-mannitol 6-phosphate (**4–85** in Equation 4–319) alkylates Glutamate 366 of glucose-6-phosphate isomerase from *S. cerevisiae*.[645] The homologous glutamate, Glutamate 357 in the active site of glucose-6-phosphate isomerase from *O. cuniculus* (59% identity; 0.7 gap percent), has been assigned crystallographically[717] as the catalytic base that transfers the hydron between carbons 1 and 2 of the hexose 6-phosphates in a role analogous to that played by Glutamate 164 in triose-phosphate isomerase from *S. cerevisiae* (Equations 4–46 and 4–55 and Figure 3–37).

(Diazoacetyl)-L-phenylalanine modifies Aspartate 215 in the sequence of amino acids for porcine pepsin (Equation 4–322). In the crystallographic molecular model of a complex between human pepsin (86% identity; 0 gap percent) and a phosphonate analogue of the tetrahedral intermediate in hydrolysis of a peptide that would be a normal reactant for the enzyme,[718] it can be seen that the homologous aspartate, Aspartate 215, is responsible for removing a hydron from the molecule of water that adds nucleophilically to the acyl carbon of the amide that is to be hydrolyzed when it occupies the active site to produce the tetrahedral intermediate in the hydrolysis.

Glutamate 156 in 2-dehydro-3-deoxyphosphogluconate aldolase from *Pseudomonas* is modified by 3-bromopyruvate (Equation 4–326). In a crystallographic molecular model[719] of 2-dehydro-3-deoxyphosphogluconate aldolase from *E. coli* (45% identity; 0 gap percent), in which the active site is occupied by the hemiaminal between pyruvate and the side chain of a lysine, and in a crystallographic molecular model of 2-dehydro-3-deoxy-phosphogluconate aldolase from *Thermotoga maritima* (29% identity; 2.5 gap percent), in which the active site is occupied by the imine between pyruvate and the side chain of a homologous lysine, the homologous glutamates are in a location in which they could easily be alkylated by the imine between 3-bromopyruvate and the lysine (Equation 4–326). In each case, however, in what appears to be the complex competent for catalysis, the carboxy group of the glutamate is too far (0.47 and 0.58 nm, respectively) from the methyl group of pyruvate to be the catalytic base that removes one of the hydrons from the methyl group on the pyruvyl group to form the enolate during the normal aldol condensation, as Glutamate 164 removes the hydron from carbon in the active sites of triosephosphate isomerase (Equation 4–55). Rather, the role that has been assigned to these two glutamates, homologous to Glutamate 156 in 2-dehydro-3-deoxy-phosphogluconate aldolase from *Pseudomonas*, is to hydronate the oxygen of the oxo group of pyruvate to increase its electrophilicity during formation of the hemiaminal and then to hydronate the hydroxy group of the hemiaminal to improve its ability to leave to form the necessary imine (Figure 1–7) between lysine and pyruvate.

The **crystallographic molecular models of actual products of active-site labeling**, in addition to sometimes identifying the product of a particular modification, have been used to provide the first identification of the active site in the molecular model and to identify catalytic bases. For example, the 4-hydroxy-3-(γ-glutamyl)butyl β-D-cellobiose in the crystallographic molecular model of licheninase from *Bacillus macerans* that had been modified by 3,4-epoxybutyl β-D-cellobiose (**4–89**) provided the first identification of the active site of the enzyme and its catalytic functional groups.[720] These assignments were later verified in the crystallographic molecular model of the complex between a β-glucan tetrasaccharide and a mutant of the enzyme in which the two catalytic glutamates had been mutated to glutamines.[721]

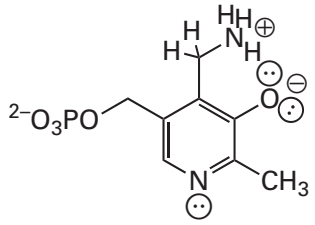
Although they are designed to label the active sites of enzymes and they inactivate those enzymes in reactions satisfying the criteria of active-site labeling, there are apparent active-site labels that do not actually modify catalytic amino acids or even amino acids in the active site of an enzyme. For example, 3-bromo-2-oxoglutarate was chosen as an active-site label for isocitrate dehydrogenase ($NADP^+$)



(4–329)

because it is an electrophilic analogue that differs from the natural substrate, 2-oxoglutarate, only by addition of a bromine. The hydroxy group at carbon 2 of isocitrate is converted in the active site to an oxo group by $NADP^+$, and the resulting 3-carboxy-2-oxoglutarate is decarboxylated by the enzyme at carbon 3 to form 2-oxoglutarate. When it is bound in the active site, 3-bromo-2-oxoglutarate should place an electrophile in the location where the catalytic acid–bases that facilitate decarboxylation from carbon 3 of 3-carboxy-2-oxoglutarate are located. Its inactivation of the porcine enzyme is an archetype of active-site labeling, satisfying most of the accepted criteria.[632] Nevertheless, in crystallographic molecular models of the complexes between the porcine α_2 dimer and isocitrate,[722] between the human α_2 dimer and $NADP^+$ and isocitrate,[723] and between the human α_2 dimer and isocitrate (Protein Data Bank 5YFN), the closest sulfanyl group of the two Cysteines 379 in each dimer, which are the nucleophiles alkylated by the reagent,[724] is 2.2 nm away from carbon 3 of isocitrate, the carbon from which modification of the enzyme was supposedly proceeding. Each Cysteine 379 is also 1.1 nm away from the closest atom on the two molecules of $NADP^+$ in the crystallographic molecular model of the complex between the human α_2 dimer and $NADP^+$ and isocitrate. Consequently, it is unclear how modification of these cysteines by 3-bromo-2-oxo-glutarate even leads to inactivation.

A possible explanation of how the modification of an amino acid distant from the active site could nevertheless lead to an inactivation of the enzyme that satisfies the criteria of active-site labeling is **syncatalytic modification**.[725] Cysteine 390 of porcine aspartate transaminase (Equation 4–108) is on the surface of the protein, 1.2 nm from carbon 4a of the prosthetic pyridoxal phosphate in the active site of the enzyme.[187] When an external pyridoximine (Figure 2–2) is formed in the active site between the prosthetic pyridoxal 5′-phosphate and an amino acid that is a reactant for the enzyme, the rate of reaction of the sulfido group of this cysteine with nonspecific electrophiles increases 20–80-fold, and the enzyme alkylated at this cysteine by any electrophile has lost more than 95% of its activity.[726] The reason for this loss of activity is probably that the enzyme can no longer accomplish the conformational change required to pass from an open to a closed conformation[187] upon association of the reactants when this cysteine is modified. Inactivation of the enzyme by 3-bromopyruvate satisfies several criteria of successful active-site labeling.[633] This inactivation, however, results from the fact that 3-bromopyruvate can be mistaken for 2-oxoglutarate and act as a reactant for the pyridoxamine form of the enzyme (previously **2–16**)



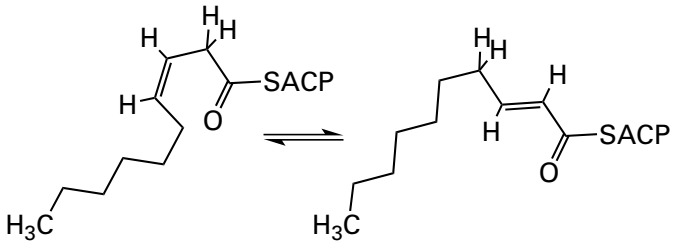
4–95

While one molecule of 3-bromopyruvate is bound in the active site, the active site closes and the rate at which the sulfido group of Cysteine 390 is alkylated by another molecule of 3-bromopyruvate free in the solution increases as usual.[725] The kinetic properties of this increase in the rate of alkylation upon closure of the active site around the 3-bromopyruvate masquerade as several of the criteria of active-site labeling.

Another explanation for modification of an enzyme outside the active site that nevertheless leads to inactivation that displays several of the criteria of active-site labeling is that the **enzyme catalytically transforms the intended active-site label into a more electrophilic reagent** that is released into the solution and then inactivates the enzyme. For example, the active site of phospho*enol*pyruvate carboxylase from *Zea mays* converts electrophilically inactive (*Z*)-3-bromophospho*enol*pyruvate into electrophilic 3-bromopyruvate that then inactivates the enzyme.[727] Because the production of 3-bromopyruvate is enzymatically catalyzed, it and the resulting inactivation display, in retrospect falsely, several of the criteria of successful active-site labeling.[631] Such a conversion of a weakly electrophilic reagent into a strongly electrophilic reagent by the active site of the enzyme is one major drawback of mechanism-based labeling.

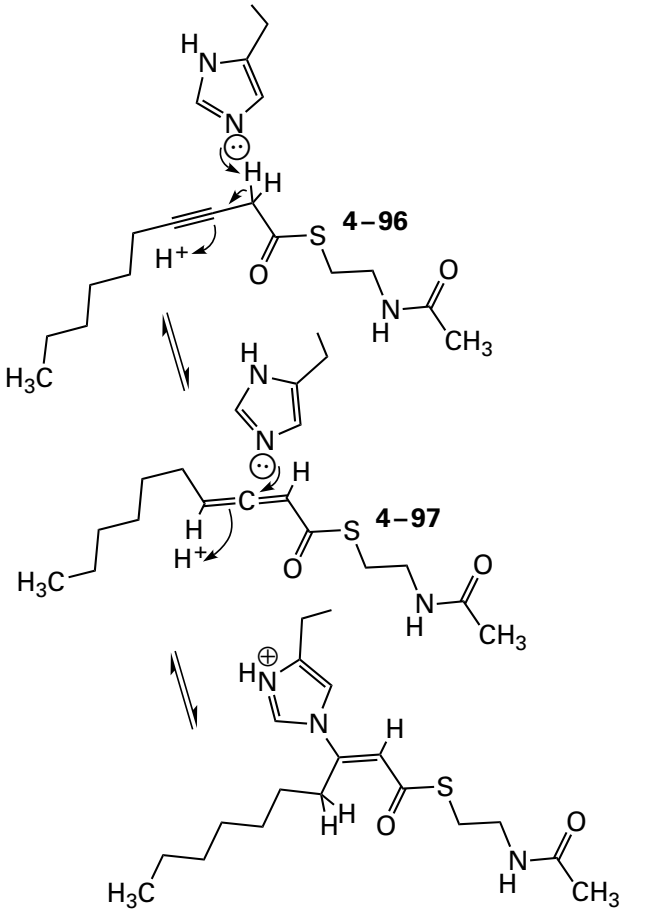
A mechanism-based label[728] is an active-site label that must be chemically altered at the active site, in a reaction resembling the one normally catalyzed by the enzyme, before it can modify a catalytic acid–base or side chain in the active site. For example, although its triple bond is not electro-

philic, dec-3-ynoyl-*N*-acetylcysteamine (**4–96**) behaves as an irreversible, covalent inhibitor for 3-hydroxydecanoyl-[acyl-carrier-protein] dehydratase from *E. coli*.[729] One of the reactions normally catalyzed by this enzyme is the tautomerization



(4–330)

Dec-3-ynoyl-*N*-acetylcysteamine inactivates the enzyme by first being converted in the active site to the electrophilic **allene** deca-2,3-dienoyl-*N*-acetylcysteamine (**4–97**)[729,730]

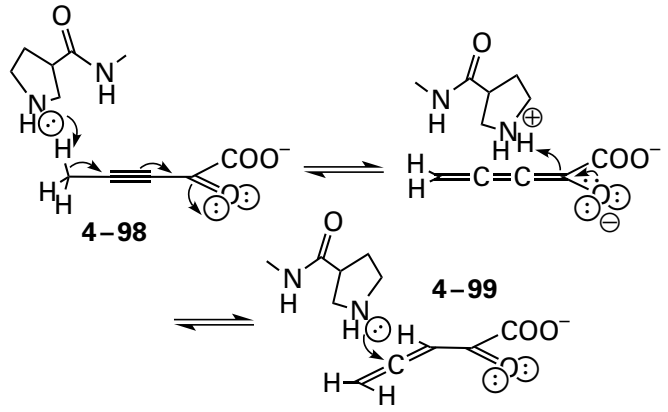


(4–331)

in a reaction that mimics the normal enzymatic reaction. Deca-2,3-dienoyl-*N*-acetylcysteamine then modifies Histidine 70 of the protein.[731] In the crystallographic molecular model of the enzyme modified by dec-3-ynoyl-*N*-acetylcysteamine,[730] the dec-2-enoyl-*N*-acetylcysteamine covalently attached at carbon 3 to Histidine 70 was used to identify and map the active site and to assign Histidine 70 as the catalytic base that removes the hydron from carbon 2 of the substrate (Equation 4–331) before any complexes of the enzyme with substrates or inhibitors were submitted to crystallography. The molecular model of the modified enzyme verified that, in the product of the modification, the double bond was between carbons 2 and 3 as drawn, conjugated to the acyl oxo group, which is the equilibrium product, rather than between carbons 3 and 4 of the decenoyl group, which would have been the kinetic product of the modification.

Acyl-carrier protein, rather than just *N*-acetylcysteamine, acylated with a dec-3-ynoyl group has also been synthesized and used to crosslink acyl-carrier protein from *E. coli* to 3-hydroxyacyl-[acyl-carrier-protein] dehydratase from *E. coli*.[732]

Ethynylene mechanism-based labels have also been used to modify other enzymes that, like 3-hydroxydecanoyl-[acyl-carrier-protein] dehydratase, proceed through intermediate enols or enolates. These enols or enolates are necessarily formed when a catalytic base removes a hydron from the carbon α to a carbonyl or acyl group, and the acidity at that carbon is required to turn the ethyne into the allene. For example, 2-hydroxymuconate tautomerase removes the hydron from carbon 5 of the reactant 2-oxo-(*E*)-pent-3-enoate to form (2*Z*)-2-hydroxy-2,4-pentadienoate (Equation 4–131). The active site of the enzyme mistakes 2-oxopent-3-ynoate (**4–98**) for the reactant, removes a hydron from carbon 5 of 2-oxopent-3-ynoate to form the cumulene, and adds a hydron to carbon 3 to produce 2-oxopenta-3,4-diene (**4–99**)



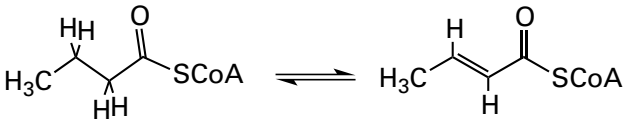
(4–332)

which is the allene that modifies the amino group of amino-terminal proline in the enzyme from

P. putida.[733] In the crystallographic molecular model of the modified enzyme, the position of the resulting 2-oxopent-3-enyl group that is covalently attached at carbon 3 to the amino-terminal proline was used to identify and map the active site.[262]

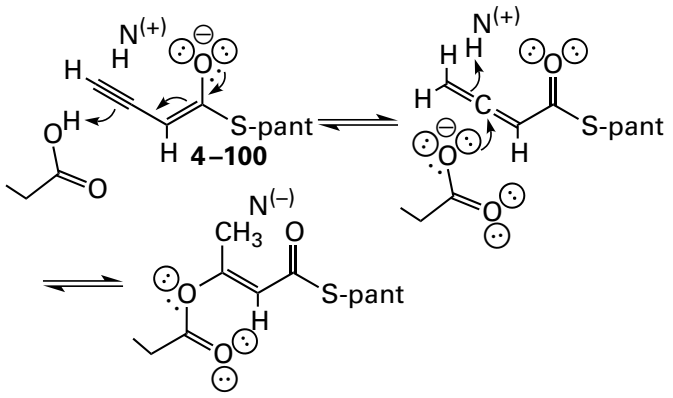
The inactivation of 2-hydroxymuconate tautomerase by 3-bromopyruvate results from a nucleophilic substitution at a carbon positioned in the active site at the location of carbon 3 in its substrates;[694] the inactivation of 2-hydroxymuconate tautomerase by 2-oxopent-3-ynoate results from a nucleophilic substitution at carbon positioned in the active site at the location of carbon 4 in its substrates (Equation 4–332); and the inactivation of 2-hydroxymuconate tautomerase by 5-bromo-(3*E*)-2-oxohex-3-enedioate results from a nucleophilic substitution at carbon positioned in the active site at the location of carbon 5 in its substrates.[117] In each alkylation, the nucleophile that is modified is the amino group of the amino-terminal proline. These three observations together illustrate the ability of the amino-terminal proline to move among these three carbons in the various substrates for the enzyme and act at a catalytic acid–base at each location at the appropriate times.

The flavoenzyme butyryl-CoA dehydrogenase catalyzes the oxidation of butyryl-SCoA



(4–333)

It is believed that this reaction passes through an enolate, formed by removal of the acidic hydron at carbon 2 of butyryl-SCoA, and that two electrons are then transferred from the electron-rich enolate to the prosthetic flavin. If an enolate is the intermediate, then locating an ethynyl group immediately adjacent to carbon 2 of the acyl-SCoA should permit formation of an allene



(4–334)

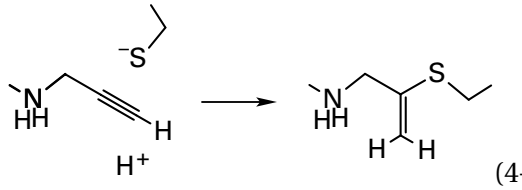
that should be able to react with the catalytic base responsible for removing the hydron from carbon 2.* When (3-pentynoyl)pantetheine (**4–100**) was incubated with butyryl-CoA dehydrogenase from *Megasphaera elsdenii*, the enzyme was irreversibly inactivated coincidently with covalent incorporation of the mechanism-based label into the protein.[734] The catalytic base modified by (3-pentynoyl)pante-theine is Glutamate 367.[735]

In the crystallographic molecular model of the complex between butyryl-CoA dehydrogenase from *M. elsdenii* and acetoacetyl-SCoA,[736] the distance between carbon 2 of acetoacetyl-SCoA and one oxygen in the carboxy group of Glutamate 367 (0.39 nm) is equal to the sum (0.38 nm) of the van der Waals radii of oxygen (0.15 nm) and hydrogen (0.115 nm) and the length of a carbon–hydrogen bond (0.11 nm), the distance of van der Waals contact. Carbon 2 of acetoacetyl-SCoA is the analogue of carbon 2 in butyryl-SCoA from which a hydron is removed during the normal reaction to create the enolate. This same oxygen, however, is within the distance of van der Waals contact with carbon 4 of acetoacetyl-SCoA (0.36 nm), analogous to carbon 4 of the (3-pentynoyl)-pantetheine to which a hydron must be added to create the allene. The distance (0.36 nm) between the same oxygen in the carboxy group of Glutamate 367 and carbon 3 of acetoacetyl-SCoA, analogous to the electrophilic carbon of the allene to which the oxygen of Glutamate 367 adds, is close to the sum of the van der Waals radii of carbon (0.175 nm) and oxygen (0.15 nm). It seems reasonable that, to accomplish the mechanism-based labeling,

*In Equation 4–334, the product of nucleophilic addition to the allene is shown as the conjugated but-2-enoyl adduct, again the equilibrium product. When the carboxylato group adds to the central carbon of the allene, the more stable intermediate would be the enolate, in which the negative charge ends up on the acyl oxygen. Hydronation of this intermediate enolate would give the but-3-enoyl adduct, the kinetic product.

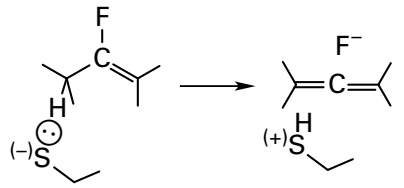
this oxygen in the carboxy group of Glutamate 367 removes the hydron from carbon 2, adds the hydron to carbon 4, and then adds to carbon 3 of the resulting allene.

Usually, an ethynylene active-site label is designed with the ethynylene group a methylene away from an oxo group, so it is converted by the targeted active site into an allene, the electrophile with which a nucleophile in the active site then reacts (Equation 4–331). In at least one case, however, an ethynylene group not a methylene away from an oxo group was used as an active-site label, and the sulfido group of a cysteine in the active site added nucleophilically directly to the ethynylene[737]



(4–335)

Like an ethynylene group, a 1-fluorovinyl group on a carbon from which an enzyme removes a hydron can be incorporated into a homologue of a substrate to produce a mechanism-based label that, upon removal of that hydron, then eliminates a fluoride ion to produce an allene



(4–336)

For example, the *N*-pyridoxylimine of vinylglycine (**4–55**, Equation 4–260) is an intermediate in the reaction catalyzed by tryptophan synthase. The enzyme from *S. typhimurium* is inactivated by (1-fluorovinyl)glycine in a reaction that satisfies several of the criteria of active-site labeling.[738] Upon formation of the external pyridoximine of (1-fluorovinyl)glycine, a catalytic base in the active site removes the hydron on the α carbon, the fluoride leaves, and the resulting allene modifies a catalytic acid–base in the active site.

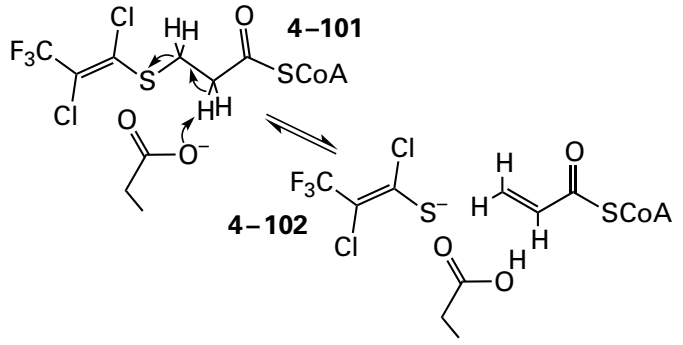
A rather unusual mechanism-based label was synthesized for benzoylformate decarboxylase from *P. putida*. This enzyme decarboxylates 2-oxo-2-phenylacetate (benzoylformate) by forming the usual adduct between its 2-oxo group and the conjugate base of the prosthetic thiamine diphosphate in the active site. In the mechanism-based label 1-phosphonobenzaldehyde, the carboxylato group of 2-oxo-2-phenylacetate is replaced by a phosphono group. Instead of producing carbon dioxide from the carboxylato group, the active site produces monomeric metaphosphate from the phosphono group in an electrophilic elimination that mimics a decarboxylation. The monomeric metaphosphate phosphorylates Serine 26, which is adjacent to the thiamine diphosphate in the active site, and this modification inactivates the enzyme.[739]

The original scenario for mechanism-based labeling was that an unreactive analogue of one of the substrates, the mechanism-based label, would associate with the active site because it was mistaken for the normal reactant in the enzymatic reaction, and it would be converted to an electrophile so reactive that it would modify the enzyme before it could leave the active site.[729] Few electrophiles, however, are so reactive. Furthermore, it is difficult to distinguish the situation in which the electrophile, once it is formed on the active site of one molecule of enzyme, alkylates that molecule of enzyme before it dissociates from the active site from the situation in which one molecule of the enzyme simply produces the electrophile, which dissociates as a free product that then inactivates another molecule of enzyme from solution as a normal active-site label. In the case of 3-hydroxydecanoyl-[acyl-carrier-protein] dehydratase, deca-2,3-dienoyl-*N*-acetylcysteamine, which is the electrophile produced by the active site (Equation 4–331), is itself far superior at inactivating the enzyme than the alkyne when it is added directly to the solution rather than being produced on an active site.[731]

This latter scenario has probably played out in almost every instance of mechanism-based inactivation. The **active site converts the mechanism-based label into a strong electrophile that dissociates from the active site** before there is sufficient time for it to modify a catalytic base in the active site in which it is formed. This is probably what happens during the modifications of 3-hydroxydecanoyl-[acyl-carrier-protein] dehydratase, butyryl-CoA dehydrogenase, and 2-hydroxymuconate tautomerase during their inactivation by the respective alkynes. If so, in each case, the enzyme has simply serendipitously identified the respective allene as as an effective active-site label. In each instance, the crystallographically verified modification of a catalytic base probably results from the fact that the respective allene is an effective and specific active-site label so that even though it is released into the solution from

one active site, it still returns to modify another active site with high specificity.

There is, however, a problem when the electrophile is produced by the enzyme and released into solution, as occurred in the attempt to use (*Z*)-3-bromophospho*enol*pyruvate to label phospho*enol*pyruvate carboxylase. In this instance, the 3-bromopyruvate produced from (*Z*)-3-bromophospho*enol*pyruvate by the active site dissociated into the solution and modified the enzyme nonspecifically. Allyl alcohol inactivates alcohol dehydrogenase (Equation 4–158) because it is converted by the enzyme to acrolein. The acrolein, however, dissociates from the active site and then inactivates the enzyme nonspecifically from solution.[740] 5,6-Dichloro-7,7,7-trifluoro-4-thiahept-5-enoyl-SCoA (**4–101**) inactivates enoyl-CoA hydratase from *R. norvegicus* because the enzyme converts it to 1,2-dichloro-3,3,3-trifluoroprop-1-enethiolate (**4–102**)



(4–337)

which is an unstable precursor to the electrophilic thioketene or thionoacyl fluoride. This precursor or one of the electrophiles, however, rather than reacting with a catalytic base in the active site, dissociates into the solution. From the solution, it modifies Cysteines 62 and 111 of the enzyme,[741] which are distant from the location in the active site where 1,2-dichloro-3,3,3-trifluoroprop-1-enethiolate is created,[742] and these nonspecific modifications inactivate the enzyme.

As was demonstrated experimentally with 3-hydroxydecanoyl-[acyl-carrier-protein] dehydratase, in such situations, the strong electrophile that has dissociated from the active site into the solution becomes indistinguishable from the same compound if it were added directly to the solution, with the exception that its **specificity is more difficult to verify**. The reason for this difficulty is that it is hard to distinguish effects of competitive inhibitors and substrates on production of the activated inhibitor from their effects on modification of the enzyme by that activated inhibitor that has dissociated into the solution. For example, the inactivation of 4-oxalocrotonate dehydrogenase by 2-oxopent-3-ynoate (Equation 4–332) shows a pseudo-first-order rate that displays saturation ($K_I = 30\ \mu M$, $k_i = 0.31\ s^{-1}$), and its rate decreases when the substrate, (3*E*)-2-oxo-3-pentenedioate, is present.[733] These criteria of specificity, however, may only be features of the kinetics of the enzymatic production and dissociation into the solution of 2-oxopenta-2,3-dienoate, the actual active-site label.

A mechanism-based label is designed to enter the active site and be converted to a strong electrophile. To enable some understanding of the inactivation that it produces, the electrophilic product of the enzymatic conversion of the label can be positively identified and both the **rate of its production and the rate of inactivation** can be measured. For example, ethyl vinyl sulfide inactivates murine thioether *S*-methyltransferase

alkyl alkyl sulfide + *S*-adenosylmethionine ⇌ *S*-adenosylhomocysteine + methyl alkyl alkylsulfonium (4–338)

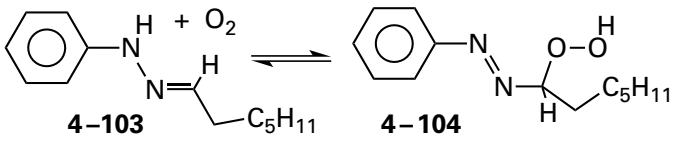
As expected, the inactive ethyl vinyl sulfide is methylated by the enzyme to form the actual electrophile, methyl ethyl vinylsulfonium ion, that then inactivates the enzyme.[743] For every 100 moles of methyl ethyl vinylsulfonium ion produced by the enzyme, however, only one mole of enzyme is inactivated. From this result, it is clear that the electrophile produced by the active site seldom inactivates the enzyme before it dissociates into the solution.

Aryldialkylphosphatase from *Brevundimonas diminuta* is inactivated by hex-1-ynyl diethyl phosphate. The inactivation levels off at a maximum yield at long times as the presumed electrophile produced by the active site, the ketene hex-1-en-1-one, participates in a rapid nucleophilic addition with water. The maximum yield of inactivation is a linear function of the initial concentration of hex-1-ynyl diethyl phosphate, but to reach complete inactivation requires 500 moles of hex-1-ynyl diethyl phosphate for every mole of enzyme.[744]

Bovine dopamine β-monooxygenase is inactivated by 3-aminomethyl-3-(4-hydroxyphenyl)propyne. The intended reactive intermediate that should be responsible for enzymatic inactivation is 3-aminomethyl-3-(4-hydroxyphenyl)propa-1,2-dien-1-yl radical, formed by abstraction of a hydrogen atom from carbon 3 of the active-site label by the pros-

thetic copper ion in the active site. This radical either inactivates the enzyme or is converted innocuously, in a reaction homologous to the normal enzymatic reaction, into 3-aminomethyl-3-hydroxy-3-(4-hydroxyphenyl)propyne, a product as unreactive as the original 3-aminomethyl-3-(4-hydroxyphenyl)propyne. Only 2.5 moles of 3-aminomethyl-3-hydroxy-3-(4-hydroxyphenyl)propyne are produced by the enzyme for every mole of enzyme inactivated,[680] so it was presumed that at least a fraction of the 3-aminomethyl-3-(4-hydroxyphenyl)propa-1,2-dien-1-yl radical inactivated the enzyme while still associated with the active site at which it was produced.

n-Hexanal phenylhydrazone (**4–103**) is converted by linoleate 13*S*-lipoxygenase from *G. max* into its α-azoperoxide (**4–104**)



(4–339)

which inactivates the enzyme. From the kinetics of the inactivation, the yield of peroxide **4–104** after full inactivation as a function of the initial concentration of phenylhydrazone **4–103**, and the effect of scavengers on the yield of inactivated enzyme, it could be concluded that 20% of the inactivation observed was due to reaction of peroxide **4–104** before it dissociated from the enzyme and 80% of the inactivation was due to reassociation of peroxide **4–104** from solution.[745] This last investigation shows that it is possible to determine what is actually happening in a mechanism-based labeling.

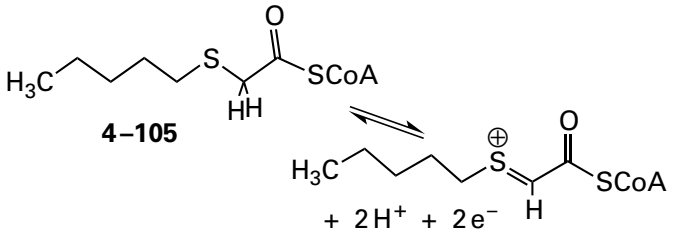
As in these experiments with linoleate 13*S*-lipoxygenase, one way to prevent the released electrophile from inactivating the enzyme from solution, rather than before it can leave the active site, is to add a **scavenger** to the solution that intercepts the electrophile after it dissociates from the active site. For example, one observation demonstrating that acrolein was inactivating alcohol dehydrogenase after it had been released from the active site was that dithiothreitol prevented the inactivation of the enzyme by allyl alcohol. 2-Aminobut-3-enoic acid inactivates porcine aspartate transaminase (Equation 4–108) irreversibly. The enzyme, in a reaction analogous to its nominal reaction, produces 2-oxobut-3-enoic acid, an electrophilic Michael acceptor that could have been acting as an active-site label from the solution, but 2-sulfanylethanol, which scavenges 2-oxobut-3-enoic acid by Michael addition to its α,β-unsaturated carbonyl, has no effect on inactivation of the enzyme.[746] Consequently, it was assumed that 2-aminobut-3-enoic acid was the species inactivating the enzyme as a true mechanism-based label. Adding a scavenger, however, will preclude the serendipitous, successful identification of a specific and useful active-site label that is produced by an enzyme from a mechanism-based label, as occurred in the case of modification of 3-hydroxydecanoyl-[acyl-carrier-protein] dehydratase by dec-3-ynoyl-*N*-acetylcysteamine.

As with the inactivation of aryldialkylphosphatase by hex-1-ynyl diethyl phosphate, another way to avoid the ambiguity resulting from dissociation of the electrophile and at the same time prevent the dissociated electrophile from modifying the protein from solution is to design a mechanism-based label that **produces an electrophile that reacts with water** rapidly after it is released from the active site. For example, while it is in the active site, 3-thiaoctanoyl-SCoA (**4–105**) is converted by the flavoenzyme porcine medium-chain acyl-CoA dehydrogenase (previously Equation 2–114)

octanoyl-SCoA +
oxidized electron-transfer flavoprotein
⇌ *trans*-oct-2-enoyl-SCoA +
reduced electron-transfer flavoprotein

(4–340)

into an *S*-alkylthiocarbonyl cation



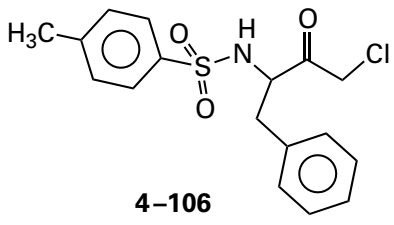
(4–341)

that is electrophilic at its α carbon. The *S*-alkylthiocarbonyl cation is rapidly hydrolyzed when it dissociates from the enzyme. In an exception to the general rule, however, and in spite of the ingenious design of a mechanism-based label electrophilic enough to be scavenged by water, the *S*-alkylthiocarbonyl cation is so electrophilic that only 1 mole of 3-thiaoctanoyl-SCoA for every mole of enzyme is sufficient to produce complete inactivation.[747] Therefore, this reagent is actually a mechanism-based label that does react before dissociating from the active site. The carboxy group of Glutamate 376 is

modified in the labeling, and the carboxy group has been assigned crystallographically to be the catalytic base that removes the hydron from the α carbon of octanoyl-SCoA to produce the enolate in the normal reaction catalyzed by the enzyme.[748]

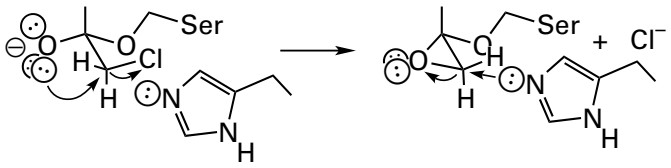
As was probably the case with inactivation of aspartate transaminase by 2-aminobut-3-enoic acid, another way to avoid the ambiguity between mechanism-based labeling and simple active-site labeling by the product of turnover of the label is to design a **mechanism-based inhibitor that remains bound tightly or even covalently to the active site** after it has been activated.[740] For example, human persulfide dioxygenase uses O_2 to oxidize *S*-sulfanylglutathione, a persulfide between the sulfanyl group of glutathione and hydrogen sulfide, to glutathione and sulfite. The oxidation occurs at a prosthetic iron ion in the active site. During the oxidation, there is an oxidized intermediate in which the sulfino group in *S*-sulfinoglutathione is a tightly bound ligand to the prosthetic Fe^{2+}. This intermediate then undergoes a nucleophilic substitution at the sulfur of the sulfino group, with a molecule of water as the nucleophile and the sulfanyl group of the glutathione as a leaving group. L-γ-Glutamyl-L-homocysteinylglycine, a derivative of glutathione in which L-cysteine is replaced by L-homocysteine, was designed to be a mechanism-based inhibitor. In the inhibitor, the distal sulfur of the reactant *S*-sulfanylglutathione has been replaced with carbon so that hydrolysis at the sulfino group of *S*-sulfinoglutathione cannot occur, and it is locked on the active site inhibiting the enzyme.[749] This inactivation is stoichiometric—one L-γ-glutamyl-L-homocysteinylglycine inactivates one molecule of enzyme—but no catalytic acid–base is modified, only the Fe^{2+}.

Some of the earliest mechanism-based labels were **chloromethyl ketones**, such as 1-chloro-2-oxo-3-(toluenesulfonyl)amino-4-phenylbutane[750]



4–106

that vaguely resemble a segment of polypeptide and that inactivate serine endopeptidases, such as chymotrypsin. The serine in the active site of a serine endopeptidase normally forms an intermediate ester from the amido group at the site of cleavage (Figure 3–6) in the first step in hydrolysis of a peptide bond in the polypeptide that is the reactant for the enzyme. The same serine forms the oxyanionic conjugate base of the hemiacetal between the serine in the active site and the 2-carbonyl group of the chloromethyl ketone,[751] locking it onto the active site of the enzyme



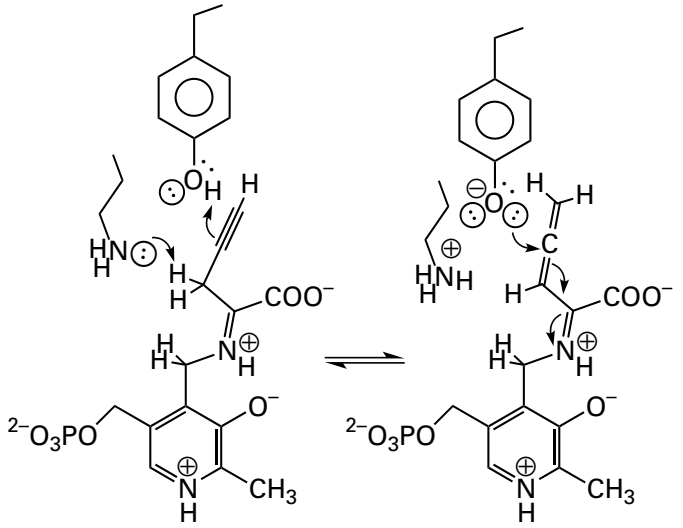
(4–342)

with its anionic oxygen in the oxyanion hole. This oxyanion then displaces the chloro group to form the 2-alkoxyepoxide,[752] and the imidazolyl group of the histidine, which is the catalytic base responsible for removing the hydron from the serine and the hydron from the water hydrolyzing the acyl enzyme, is then alkylated irreversibly by the epoxyether in a concerted nucleophilic substitution.[753,754] These two nucleophilic substitutions proceed with net retention of configuration resulting from two inversions at carbon 1 of the original chloromethyl ketone.[752] The ether between the serine and the epoxide (product in Equation 4–342) locks the electrophile on the active site, so it cannot dissociate.

Another way a mechanism-based label can be locked covalently in the active site is formation of a covalent adduct with a prosthetic pyridoxal 5′-phosphate. A number of **mechanism-based labels for enzymes that use pyridoxal 5′-phosphate** as a prosthetic group have been synthesized. One of these is 2-aminobut-3-enoic acid, which inactivates porcine aspartate transaminase as a true mechanism-based label. Each label is locked onto the active site because it has a primary amino group that forms an external pyridoximine, quinonoid intermediate, or *N*-pyridoxylimine with the prosthetic pyridoxal 5′-phosphate (Figure 2–2 and Equation 4–258). Nonspecific labeling is also avoided because, although the adduct formed between pyridoxal 5′-phosphate and the label is electrophilic, the ultimate product released into the solution, when the electrophilic adduct fails to label a catalytic base, is usually not a strong electrophile.

Ethynylene mechanism-based labels have been used for active sites containing prosthetic pyridoxal 5′-phosphates. For example, 2-amino-4-pentynoic acid[755] is a mechanism-based inhibitor of cystathionine γ-synthase (Equation 4–257) from

S. typhimurium.[756] The inactivation is thought to result from formation of the allene



(4–343)

by acid–base reactions analogous to those of the normal mechanism (Equations 4–258 and 4–259). In this case, the allene that is formed, is attached covalently to the pyridoxamine phosphate as the *N*-pyridoxylimine of propadienylglycine. The electrophilic, covalently attached allene can then alkylate one of the catalytic bases within the active site. Even so, 4 moles of 2-aminopent-4-ynoic acid was required to inactivate 1 mole of active sites, and it has been shown that after the mechanism-based inhibitor is converted at the active site, the majority of the reagent (75%) is released as an unidentified product into the solution before it can inactivate the enzyme directly. In the related enzyme human cystathionine γ-lyase (39% identity; 0.5 gap percent)

2-ammoniobut-2-enoate + L-cysteine
$\rightleftharpoons$ L-cystathionine

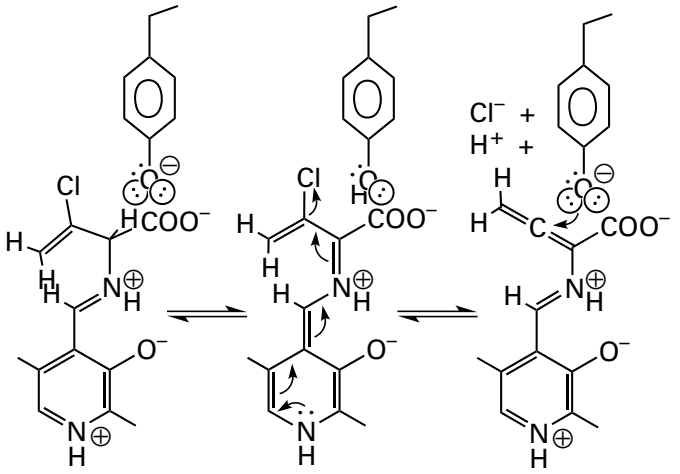
(4–344)

2-aminopent-4-ynoic acid specifically labels Tyrosine 114 in the active site,[757] which is in the homologous position of Tyrosine 101 in the sequence of amino acids for cystathionine γ-synthase from *S. typhimurium,* and Tyrosine 101 has been assigned crystallographically as the catalytic acid–base that hydronates and dehydronates the γcarbon of the normal substrates in the active site of cystathionine γ-synthase from *N. tabacum* (33% identity; 1.3 gap percent).[537]

(*R*)-2-Amino-3-chlorobut-3-enoate is an irreversible inhibitor of alanine racemase from *E. coli*[758,759]

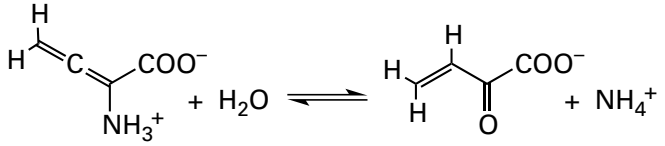
L-alanine $\rightleftharpoons$ D-alanine (4–345)

It forms an external pyridoximine that is converted in the quinonoid intermediate, following the usual removal of the αhydron catalyzed by the enzyme (Equation 4–258), into an electrophilic allene



(4–346)

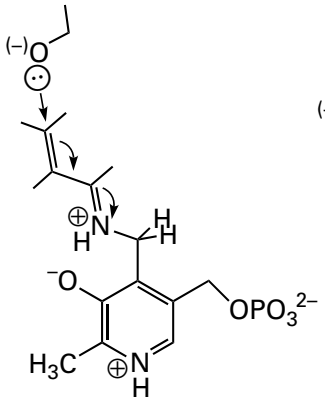
that specifically modifies Tyrosine 253 in the active site of the enzyme.[759] In this instance, the 4-oxidophenyl group of Tyrosine 253 is the catalytic base responsible for removing the αhydron[760] from L-alanine[761] after it has formed an external pyridoximine. The enzyme turns over 2.2 moles of 2-amino-3-chlorobut-3-enoic acid for every mole of enzyme inactivated,[759] but the product of this turnover, 2-aminobuta-2,3-dienoic acid, which would be a strong electrophile, is scavenged by being immediately hydrolyzed to the weak electrophile 2-oxobut-3-enoic acid[746]



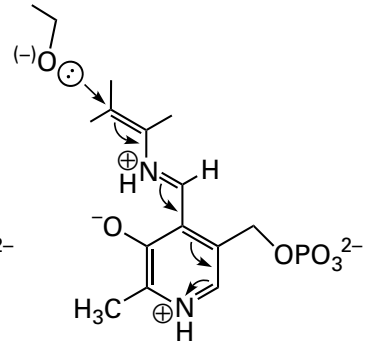
(4–347)

There is an alternate route to the same α,β-allene of an external pyridoximine by using the more paradigmatic α-ethynyl analogue of a substrate for the enzyme.[762]

Two other **electrophilic adducts of pyridoxal phosphate** (**4–107** and **4–108**)



4–107

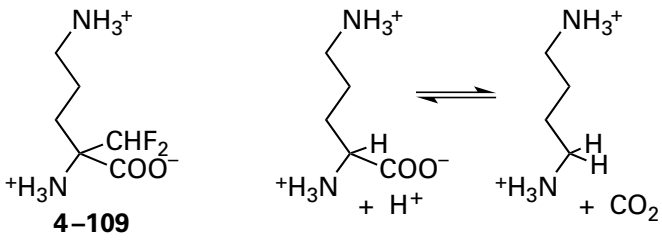


4–108

can be generated by using the mechanism-based label appropriate to the reaction that is performed by a particular enzyme with a prosthetic pyridoxal 5′-phosphate in its active site. The functional groups at the α, β, and γcarbons of these adducts depend upon the mechanism-based inhibitor used, which in turn is determined by the reaction catalyzed by the enzyme.

N-Pyridoxylimine **4–107**, with methyl groups on the α and γcarbons, is the electrophile produced by using 2-aminobut-3-enoic acid as a mechanism-based inhibitor[746] by the usual dehydronation of the αcarbon and the usual hydronation of the aldehydic carbon of the resulting quinonoid intermediate (Equation 4–258). The product released into solution from this adduct is the inert saturated carbonyl compound 2-oxobutanoic acid.[763] 2-Aminobut-3-enoic acid is converted to 2-oxobutanoic acid that dissociates into the solution from the active site of 1-aminocyclopropane-1-carboxylate synthase from *Malus domestica* 500 times more often than the electrophilic adduct **4–107** inactivates the enzyme. The electrophilic adduct specifically alkylates a catalytic base in the active site of the enzyme.[763]

External pyridoximine **4–108**, which places the electrophilic carbon–carbon double bond one atom closer to the pyridoxyl group, is produced by using an analogue of the substrate in which a good leaving group such as a fluorine,[628,642,762,764-766] chlorine,[628,764] acetyl group, or sulfate[644,767] is synthetically placed on a carbon next to the carbon on which the primary amino group is located. For example, α-(difluoromethyl)ornithine (**4–109**)



4–109

(4–348)

is a mechanism-based label for ornithine decarboxylase (Equation 4–348) from *R. norvegicus*.[762] Following the decarboxylation of its external pyridoximine to form the quinonoid intermediate (see Equation 4–256), the fluorine on the βcarbon is eliminated in a normal βelimination from a quinonoid intermediate. The result of βelimination is the electrophilic adduct (**4–108** with a 3-aminopropyl group on the αcarbon and fluorine and hydrogen on the βcarbon) of the prosthetic pyridoxal 5′-phosphate in the active site. This particular adduct is the electrophile that modifies Cysteine 360.[643] Cysteine 360 is immediately adjacent (3.5 nm) to what would be the αcarbon in the adduct between the prosthetic pyridoxal 5′-phosphate and 1-aminooxy-3-aminopropane in the crystallographic molecular model of human ornithine decarboxylase (92% identity; 0 gap percent).[768] The product released from the electrophilic adduct **4–108** in this instance is 5-amino-1-fluoro-2-oxopentane, which is only weakly electrophilic.

Unfortunately, however, unlike the example of the successful modification of ornithine decarboxylase with α-(difluoromethyl)ornithine just described, in most instances where the electrophilic external pyridoximine of an enamine, such as **4–108,** is produced by elimination of a good leaving group, it does not react with a catalytic base in the active site. Instead, the respective enamine is released by transimination with the usual lysine (Figure 2–2). The now nucleophilic enamine, before it dissociates from the active site, inserts into the adjacent electrophilic carbon 4′ of the internal lysylpyridoximine to inactivate the enzyme by **labeling the pyridoxal 5′-phosphate**,[628,644,766] which is already known to be a catalytic player. For example, 3-amino-4-fluorocyclopentanecarboxylate is a general active-site label for enzymes that have a prosthetic pyridoxal 5′-phosphate in their active sites. The amino group

forms an external pyridoximine, and the fluorine leaves to produce the external pyridoximine of the enamine, 3-aminocyclopent-3-enylcarboxylate. Upon transimination, carbon 4 of 3-aminocyclopent-3-enylcarboxylate adds irreversibly to carbon 4′ of the internal lysylpyridoximine in an aldol condensation.[769] A covalent modification of carbon 4′ of the internal lysylpyridoximine occurs even when α-(difluoromethyl)ornithine modifies human ornithine aminotransferase[770] rather than ornithine decarboxylase from *R. norvegicus* (91% identity; 0 gap percent).

Even when an enzyme, such as enoyl-CoA hydratase (Equation 4–337), converts a mechanism-based label into a reactive but nonspecific electrophile that dissociates before it can react and is not hydrolyzed, the electrophile, although no longer associated with functional groups mimicking those on a substrate, nevertheless may serendipitously enter another active site and modify a catalytic base because that catalytic base is unusually reactive.

Bases performing catalytic roles in the active sites of enzymes often display exceptional nucleophilicity and react readily with an unexceptional and undirected electrophile that should otherwise react nonspecifically with every nucleophilic amino acid in the protein. Presumably, this results from the fact that these exceptional nucleophiles are found in special environments that are tailored to their assignments in the enzymatic reaction.

When pancreatic ribonuclease (Equation 4–104) was mixed with a molar excess of iodoacetate (8 mol mol^{-1}), the enzymatic activity was lost rapidly. When most of the inactivation had occurred, products were separated chromatographically (Figure 4–41).[771] Aside from some remaining, unalkylated enzyme, only two products were isolated. One was shown to be alkylated only at nitrogen 1 of Histidine 119; the other was shown to be alkylated only at nitrogen 3 of Histidine 12. Neither of the other two histidines in the enzyme, Histidine 48 and Histidine 105, nor any other nucleophilic amino acid, had been alkylated significantly under these circumstances even though iodoacetate is a promiscuous, nonspecific electrophile. These results demonstrate that both Histidine 119 and Histidine 12 in native pancreatic ribonuclease are exceptionally nucleophilic. Furthermore, no bisalkylated product was isolated, and this result suggested that once one of the histidines had reacted, the other became much less nucleophilic. This observation was later explained by the fact that Histidine 12 and Histidine 119 are adjacent to each other in the active site of the enzyme,[151] and

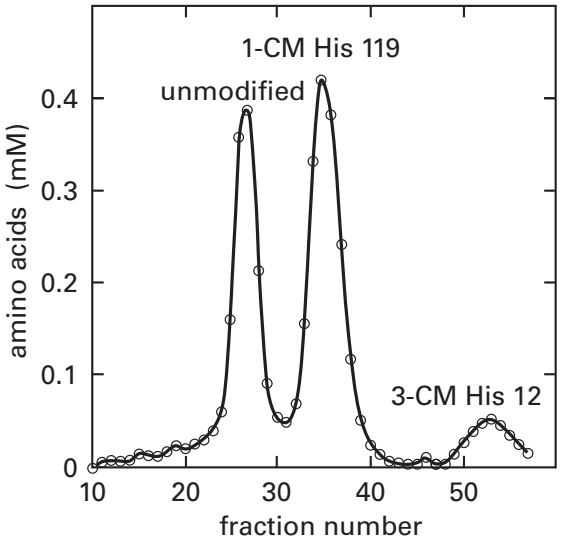


Figure 4–41: Separation of the two monoalkylated derivatives of bovine pancreatic ribonuclease produced by alkylation of the enzyme with iodoacetic acid.[771] A solution containing 16 mM iodoacetic acid and 2 mM pancreatic ribonuclease was prepared at pH 5.5 and 25 °C. After 2 h, the solution was brought to 0.2 M in sodium phosphate at pH 6.5, and it was immediately submitted to cation-exchange chromatography on a column of Amberlite IRC 50 (0.9 × 30 cm) eluted with 0.2 M sodium phosphate, pH 6.5. The several products were located by an alkaline ninhydrin assay that registers the concentration of amino groups in an alkaline hydrolysis of the protein and hence the approximate concentration (millimolar, based on the extinction coefficient for leucine in the assay) of total amino acids in each fraction. The concentration of amino groups (millimolar) is presented as a function of the number of the fraction of eluent collected. Each fraction contained 1 mL. The products were identified as unmodified pancreatic ribonuclease (unmodified), pancreatic ribonuclease carboxymethylated at nitrogen 1 of Histidine 119 (1-CM His 119), and pancreatic ribonuclease carboxymethylated at nitrogen 3 of Histidine 12 (3-CM His 12). The identification was performed by tryptic digestion of each component and subsequent identification of carboxymethylated peptides by chromatography.

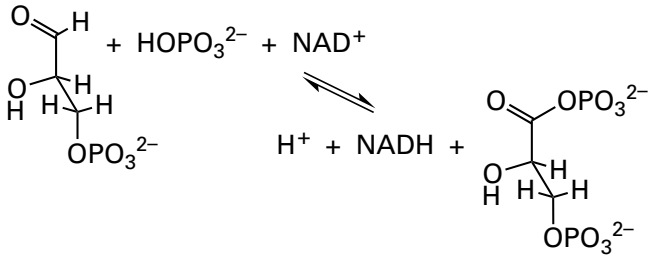
steric hindrance prevents alkylation of one of them after the other has become alkylated. The product alkylated at Histidine 119 was completely inactive (<1% activity remaining), but the product alkylated at Histidine 12, although significantly inhibited, retained 7% of the enzymatic activity of native pancreatic ribonuclease. At the time, this result suggested that Histidine 12 might not be involved in the mechanism of the reaction as an essential catalytic acid–base,[771] and this suggestion was later confirmed crystallographically.[152]

The disadvantage of using **reagents for the general modification of particular types of amino acids** to identify amino acids within an active site is that the electrophile has **unbiased access to all the amino acids on the surface of the protein** as well as

those in the active site, rather than being carried into the active site and juxtaposed to a particular amino acid or being created within the active site during turnover. Nevertheless, various reagents for the general modification of particular types of amino acids have been used to identify exceptionally reactive amino acids, the modification of which inactivates the respective enzyme. For example, when bovine phospholipase A_2 was methylated with the reactive electrophile methyl 4-toluenesulfonate, a product could be isolated chromatographically that had been N-methylated exclusively at Histidine 48 and that retained only 1% of the activity of the original enzyme.[772] Histidine 48 is the catalytic base that removes a hydron from the molecule of water that hydrolyzes the ester within the glycerolipid that is a reactant for the enzyme.[773]

When glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) (previously Equation 3–32)



(4–349)

from *O. cuniculus* was mixed with a concentration of [^{14}C]iodoacetic acid equivalent to the total concentration of cysteine in the protein, the enzymatic activity was rapidly lost. After the inactivation was complete and the reaction was terminated, the protein was digested with trypsin. Only one radioactive tryptic peptide was produced in significant yield by the digestion, and it could be shown that the sulfido group of only Cysteine 149, of the four cysteines present in the protein, had been alkylated significantly by iodoacetic acid.[774] Cysteine 149 is the cysteine that forms the hemithioacetal with glyceraldehyde 3-phosphate during the normal enzymatic reaction,[775] and its exceptional nucleophilicity, as demonstrated by its apparently exclusive reaction with iodoacetic acid, may be essential for this role in the mechanism. If so, this essentiality would be the reason for the specificity of the alkylation in this instance.

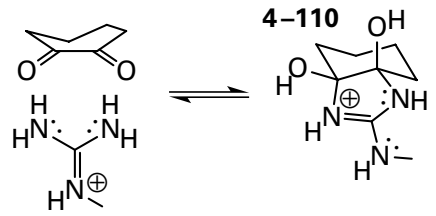
There are other examples of inactivations caused by the **exclusive modification of particularly nucleophilic amino acids** in active sites. 1,3-Dibromoacetone, a bifunctional alkylating agent, crosslinks Cysteine 25 and Histidine 159 in the active site[776] of papain to inactivate the enzyme.[777,778] Dicyclohexylcarbodiimide exclusively and selectively crosslinks Aspartate 184 and Lysine 72 within the active site of porcine non-specific serine/threonine protein kinase to inactivate the enzyme.[779]

The modification of a single arginine in a subunit of bovine ornithine carbamoyltransferase by butanedione led to inactivation of the enzyme,[780] and the exclusive arylation of one exceptionally reactive lysine, the apparent pK_a of which is 8.0, with trinitrobenzenesulfonate led to inactivation of bovine isocitrate dehydrogenase (NAD^+).[781] Addition of the respective substrates to the solution prevents both of these modifications and the accompanying inactivation of the respective enzyme. Such **protection by a substrate or inhibitor** for the enzyme against the modification of a particular amino acid by a nonspecific electrophile is often the only criterion suggesting that the modification is labeling a nucleophile in the active site.

It is usually unclear why a particular amino acid in a protein is extraordinarily reactive relative to other amino acids of the same type in the same protein. One possibility already mentioned is that the enzymatic reaction requires that the nucleophile be particularly reactive. Even though the nucleophile in the active site is not particularly reactive and the reagent bears no resemblance to a substrate or ligand, it nevertheless may be guided by the high concentration of donors and acceptors for hydrogen bonds within an active site to bind, preferentially but adventitiously, adjacent to the nucleophile with which it reacts. Other acid–bases clustered together in an active site in the vicinity of the nucleophile that is modified may act as catalytic acid–bases to catalyze the modification reaction itself even though the electrophilic reagent does not associate with the active site and modifies the nucleophile in a random encounter complex.

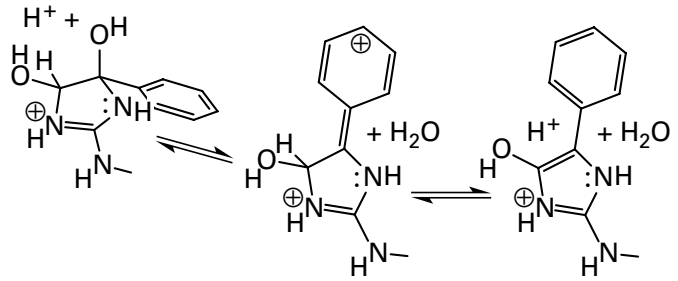
There is also the broader question of **why the nonspecific modification of a particularly reactive nucleophilic amino acid causes the inactivation of an enzyme**. So far, examples of modifications of catalytic acid–bases that produce inactivation have been presented, but there are other reasons for the inactivation caused by a nonspecific reagent.

Cyclohexane-1,2-dione[659] and 2,3-dioxobutane[657,658] have been shown to react with the guanidinio group on L-arginine to produce the bicyclic adduct **4–110**[656]



(4–350)

This adduct is formed reversibly but can be stabilized by adding borate,[658] which forms a borocycle with the vicinal hydroxy groups in the adduct. 1-Phenyl-2,3-dioxobutane is another vicinal dione that modifies arginines[660-662] and forms a stable 4-hydroxy-5-phenylimidazol-2-yl group



(4–351)

(+116 unified atomic mass units) with the arginine[782] in a dehydration that is not possible with a fully saturated adduct such as **4–110**. 1-Phenyl-2,3-dioxobutane has been widely used to modify arginines in active sites. A 4-bromo-2,3-dioxobutyl group can be attached to nucleophilic atoms in various substrates and ligands by using 1,4-dibromo-2,3-dioxobutane.[665,666] The bromine in the 4-bromo-2,3-dioxobutyl group stabilizes the adduct of the vicinal dione with the guanidinio group enough that the adduct with an arginine in an active site survives digestion and chromatography.[663,664]

When fructose-bisphosphate aldolase (Equation 4–210 and Figure 4–36) from *O. cuniculus* was mixed with cyclohexane-1,2-dione in sodium borate buffer, the enzymatic activity was rapidly lost.[783] When glycerone phosphate or fructose 1,6-bisphosphate was present, however, no activity was lost. During this modification of the enzyme, less than 2 moles of cyclohexane-1,2-dione was incorporated for each mole of the polypeptide comprising the enzyme even though cyclohexane-1,2-dione is not an active-site label. Only one tryptic peptide in a digest of the enzyme modified with [^{14}C]cyclohexane-1,2-dione incorporated radioactivity to a significant level (Figure 4–42A),[783] and the incorporation into this peptide was prevented by addition of fructose 1,6-bisphosphate (Figure 4–42B). The remainder of

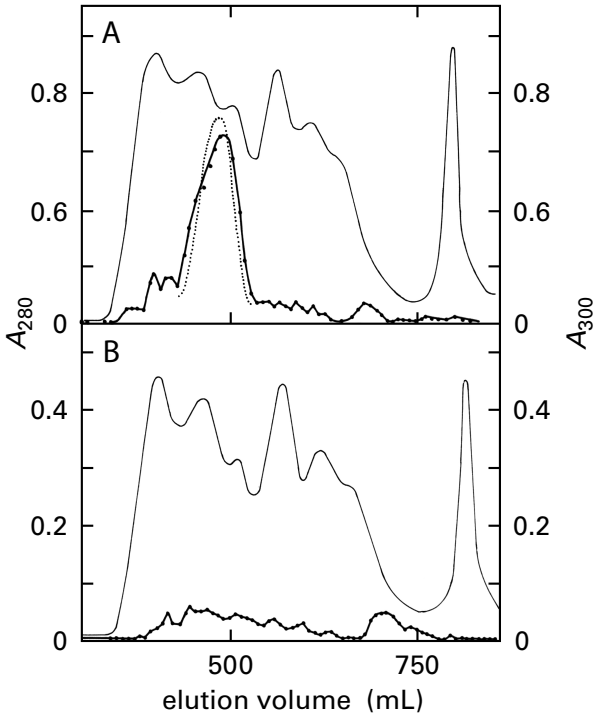


Figure 4–42: Distribution of N^{ω},N^{ω}-(1,2-dihydroxycyclohexyl)-arginine side chains among the tryptic peptides of rabbit muscle fructose-bisphosphate aldolase inactivated with cyclohexane-1,2-dione.[783] Two solutions (60 mL) containing 50 mM cyclohexane-1,2-dione and 0.1 M sodium borate at pH 8.0 and 25 °C were prepared. One of the two solutions contained 5 mM fructose 1,6-bisphosphate to protect the active site. The inactivation was initiated by adding fructose-bisphosphate aldolase (0.2 mM final concentration in protomers) and was allowed to proceed until the residual enzymatic activity in the unprotected sample was 10%, and in the protected sample, 90%. The pH of the two solutions was dropped to 4, and both were dialyzed into deionized water and submitted to performic acid oxidation. The protein was then submitted to digestion by trypsin. The resulting tryptic peptides were submitted to chromatography by size exclusion on Sephadex G-25 in 30% acetic acid. The absorbance of the effluent at 280 nm was monitored continuously. Samples were removed from the various fractions to assay for cyclohexane-1,2-dione released from modified arginines by treatment at alkaline pH. The released cyclohexane-1,2-dione in samples exposed to alkaline pH was assayed by its reaction with (trimethylamino)acetohydrazide, which forms an adduct with vicinal diones that absorbs at 300 nm. The absorbance at 280 nm (thin line) and the absorbance of the adduct at 300 nm (thick line or dashed line) are plotted as a function of the elution volume (milliliters) from the chromatographic column (3 × 140 cm). (**A**) Unprotected product. (**B**) Product from enzyme protected with 5 mM fructose 1,6-bisphosphate.

the incorporation was spread over a number of other peptides indiscriminately. The selectively modified peptide was isolated and sequenced, and from these results it could be concluded that modification of Arginine 148 had inactivated the enzyme. Only Arginine 148, of the 15 arginines present in the enzyme, reacted appreciably with cyclohexane-

1,2-dione under these circumstances even though cyclohexane-1,2-dione is an uncharged, nonspecific reagent for arginines in general.

In the crystallographic molecular model of the complex between fructose-bisphosphate aldolase from *O. cuniculus* and fructose 1,6-bisphosphate, Arginine 148 is near the 6-phospho group of the substrate, well away from the catalytic center of the active site in the immediate vicinity of carbons 3 and 4, and forms a hydrogen bond to a molecule of water that in turn forms a hydrogen bond to the 6-phospho group.[784] Consequently, the arginine is neither a catalytic acid–base nor directly associated with a bound substrate. Nevertheless, modification of Arginine 148 by a bulky cyclohexane-1,2-dione and the accompanying borocycle should **sterically hinder the association of substrates** fructose 1,6-bisphosphate and D-glyceraldehyde 3-phosphate with the active site and prevent catalysis. Conversely, association of either of these substrates should prevent the modification of Arginine 148 by cyclohexane-1,2-dione.

A nonspecific electrophile can also **sterically hinder the access of substrates to an active site** upon its incorporation. For example, at the entrance to the active site of *S*-formylglutathione hydrolase from *A. thaliana*, there is a cysteine the modification of which sterically blocks access to the active site.[785]

There are other instances in which the **steric bulk of a nonspecific electrophile** affects the outcome of inactivation of an enzyme. The sulfido group of Cysteine 565 in native bovine aconitate hydratase is exceptionally nucleophilic and can be modified exclusively with several electrophiles.[786,787] When its sulfanyl group is alkylated with phenacyl bromide, a bulky electrophile, enzymatic activity is completely abolished, but when it is simply methylated, one of the least bulky alterations possible, enzymatic activity is inhibited by only 50%.[788] In the crystallographic molecular model of a complex between a mutant of porcine aconitate hydratase (98% identity; 0 gap percent) and isocitrate,[789] Cysteine 565 is too far away (1.6 nm) from the nearest atom of isocitrate to have a direct steric effect on the enzymatic reaction, as was the case in the modification of fructose-bisphosphate aldolase by cyclohexane-1,2-dione. It is more likely that the bulky phenacyl group **hinders a conformational change**, such as the closing of the active site around one substrate for the enzyme, and that that conformational change is required for catalysis. The small methyl group is not bulky enough to affect the conformational change. A similar difference between complete inactivation upon alkylation with a bulky group and only partial inactivation upon alkylation with a methyl group is observed for modification of the sulfido group of Cysteine 16 in phosphoribulokinase from *S. oleracea*[790]

As the result with aconitate hydratase illustrates, **the question of whether or not an exceptionally nucleophilic amino acid is located within the active site**, even though it inactivates the enzyme, is one that cannot be settled in experiments that only examine the kinetics of inactivation and identify the amino acid modified. Usually, in experiments of this type, only two observations are available. First, the enzymatic activity is irreversibly and completely, or almost completely, inhibited when only 1–2 moles of reagent have become incorporated for every mole of active sites. Second, when a substrate, inhibitor, or ligand is present, the enzyme is protected against inactivation, and incorporation of the reagent is blocked.

Regarding the first observation, there are ways an enzyme can be inactivated other than through modification at the active site. The alkylation of Cysteine 565 in aconitate hydratase probably prevents a conformational change required for enzymatic activity. The modification of Cysteine 45 in porcine glutathione transferase produces an inactive enzyme[791,792] even though its sulfanyl group is 1.9 nm from the active site.[793] In the conformation of the enzyme induced by the association of substrates, Cysteine 45 is buried in a hydrophobic pocket and inaccessible to the solution. If it were modified with a bulky functional group, it would be sterically unable to enter this pocket, and the conformational change required for the active site to close around substrates would be prevented.

Regarding the second observation, the protection of a particular amino acid in an enzyme by a substrate or inhibitor against modification by an electrophile does not prove that the amino acid is located within the active site. For example, modification of the carboxy group of Aspartate 176 in glucan 1,4-α-glucosidase from *Aspergillus awamori* by 1-ethyl-3-(4-azonia-4,4-dimethylpentyl)carbodiimide is prevented by association of the inhibitor acarbose with the active site,[794] even though its carboxy group is 0.9 nm from the nearest atom in this particular inhibitor.[795] The reason that the enzyme is protected from reaction with the carbodiimide is that this carboxy group becomes incorporated into a network of hydrogen bonds created by binding of the inhibitor to the active site. When tryptophan synthase from *E. coli* was irreversibly inactivated with 1-phenyl-2,3-dioxobutane, 1 mole of arginine was modified for each mole of inactive enzyme, and the

modification responsible for the inhibition occurred at Arginine 148 in the β subunit.[796] Because the enzyme could be protected from irreversible inhibition by pyridoxal phosphate and L-serine but not by pyridoxal phosphate alone, and because 1-phenyl-2,3-dioxobutane was a competitive inhibitor with respect to serine in the normal enzymatic reaction, it was concluded that serine binds to Arginine 148 within the active site during catalysis. In the crystallographic molecular model of the β_2 dimer of tryptophan synthase in complex with pyridoxal 5-phosphate, however, the guanidinio group of Arginine 148 is 1.5 nm away from the 4′ carbon of the pyridoxal phosphate[797] Consequently, it cannot be a ligand to the serine.

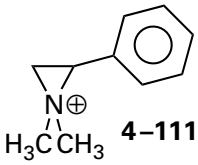
It is usually difficult to decide whether the residual enzymatic activity present after modification of an enzyme represents the modified enzyme itself or enzyme that is as yet unmodified. This distinction is important because if the actually modified enzyme still possesses significant enzymatic activity, then the amino acid that has been modified must not be essential for catalysis. When human carbonic anhydrase 1 was alkylated with iodoacetate, Histidine 200 was modified to produce an enzyme that, depending on the pH, had 3–15% the catalytic constant of the native enzyme.[798] From these results, it was concluded that Histidine 200 is not essential for enzymatic activity, even though its alkylation does inhibit the enzyme extensively. Histidine 200, however, as in the case of Histidine 12 in pancreatic ribonuclease, is in the active site of the enzyme,[799] and its imidazolyl group is probably catalytic. It is possible that alkylation of its π nitrogen, which is directed away from the site of catalysis, would still permit its τ nitrogen to participate in catalysis, albeit less effectively.

When 2-nitro-5-(thiocyanato)benzoate was used to inactivate 3-oxoacid-CoA transferase, it produced two products, one enzymatically inactive and the other still enzymatically active. It was demonstrated that in each product the sulfido group of the same cysteine had been modified. In the enzymatically active product, however, the cysteine was cyanylated, while in the enzymatically inactive product, it had been oxidized by formation of a mixed disulfide with the 2-nitro-5-thiobenzoate that is a product of cyanylation. In the latter instance, in which the mixed disulfide is far bulkier than the cyanylated sulfanyl group, the inactivation was a steric effect. If only the enzymatically inactive product had been obtained, it might have been concluded, incorrectly, that this cysteine was essential for enzymatic activity.[800]

The strategy of active-site labeling and mechanism-based labeling, in which a reagent is designed to associate specifically with an active site and identify a particular catalytic base–acid responsible for removal or addition of a particular hydron, can be expanded to encompass reagents that are intended simply to identify amino acids in the vicinity of an active site or a site for the binding of a ligand by specifically associating with an active site or binding site and bringing a covalently attached electrophile into its vicinity even though the amino acid or amino acids modified by that electrophile are not catalytic functional groups.

An affinity label is a compound that contains a reactive center and that is designed to resemble the substrate of an enzyme or ligand for a protein so closely that it will bind specifically to the active site or binding site, and while it is bound the reactive center will covalently modify an amino acid in or near the site. If the reagent is designed with the intention of placing the electrophile immediately adjacent to a catalytic acid–base in the normal mechanism of an enzymatic reaction, the affinity label is an active-site label. Often, however, a reagent intended to be an active-site label modifies a nucleophilic side chain that is not involved in the catalytic mechanism and is only near the location at which catalysis occurs, in which case the active-site label is in fact a more general affinity label.[801] In many experiments, however, information about functional groups in the enzymatic mechanism is irrelevant; the actual intention of the labeling is the identification of any amino acid in the vicinity of the active site or the binding site for a particular ligand or, in many cases, simply the identification of the protein to which the ligand binds.

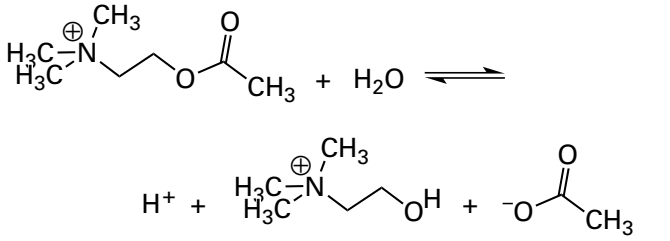
This difference in intent, in part, distinguishes more general affinity labeling from specific active-site labeling. For example, the electrophilic *N,N*-dimethyl-2-phenylaziridium cation



4–111

was used as an affinity label for acetylcholinesterase from *Torpedo californica*. Rather than labeling a catalytic base in the active site that was responsible

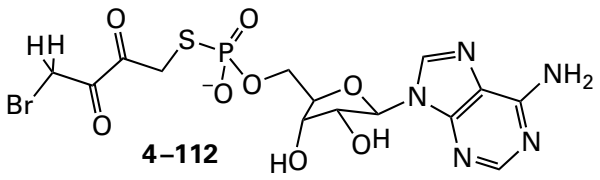
for the hydrolysis of acetylcholine, the intention was to modify the amino acids that form the **pocket for the quaternary ammonio group** in acetylcholine (previously Equation 3–341)



(4–352)

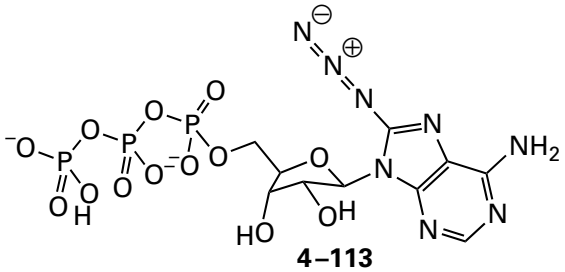
The aziridium participated in an electrophilic aromatic substitution of the indolinyl group of Tryptophan 84,[653] which is one of the three aromatic amino acids that form the pocket for the quaternary ammonium cation,[802] which associates through π–cation interactions.

In many instances, the intended target of the affinity labeling is not an active site at all but the **site for binding a ligand that is not catalytically altered** by the enzyme or the site for binding a ligand on a nonenzymatic protein. For example, adenosine 5′-*O*-[*S*-4-bromo-2,3-dioxobutyl)thiophosphate



4–112

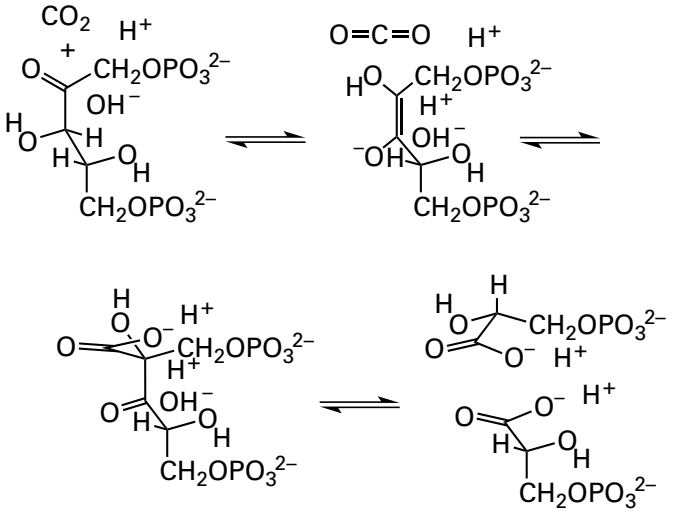
was used as a label for the modification of one side chain forming the binding site for ADP^{3-}, an activator of bovine glutamate dehydrogenase [$NAD(P)^+$] that is not catalytically involved in the enzymatic oxidation–reduction. It covalently modifies Arginine 459 in the enzyme,[664] which forms a hydrogen bond to the β-phosphate of ADP^{3-} in a crystallographic molecular model[803] of the complex between the enzyme and ADP^{3-}. 8-Azidoadenosine triphosphate



4–113

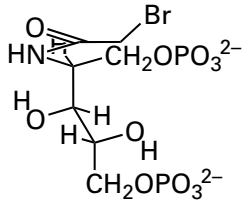
was used as an affinity label for the noncatalytic binding site for ATP^{4-} on actin from *O. cuniculus*. It was photolytically converted to the nitrene while the label was bound in the site on this nonenzymatic protein, and the electrophilic nitrene modified Lysine 336,[804] which is immediately adjacent to carbon 8 of ATP^{4-} in the crystallographic molecular model[805] of the complex between actin and ATP^{4-}.

Usually, a portion of an affinity label is designed to bind to the site, and a different portion, often quite distinct or even quite distant from the portion that binds, provides the electrophile, diradical, or some other group capable of modifying amino acids in the protein. If the designer is lucky, association of the portion of the affinity label responsible for specificity will position the portion performing the covalent modification close enough to a suitable side chain. For example, ribulose-bisphosphate carboxylase (previously Equation 3–424)



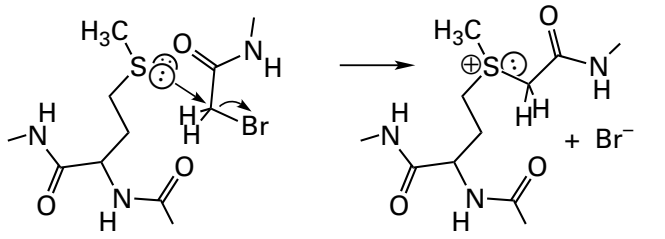
(4–353)

catalyzes the carboxylation of the enediolate of D-ribulose 1,5-bisphosphate.[806,807] Although there should be two or more catalytic base–acids involved in a Claisen condensation, none should be in the vicinity of the electrophilic carbon of *N*-bromoacetyl-2-amino-2-deoxypentitol 1,5-bisphosphate



4–114

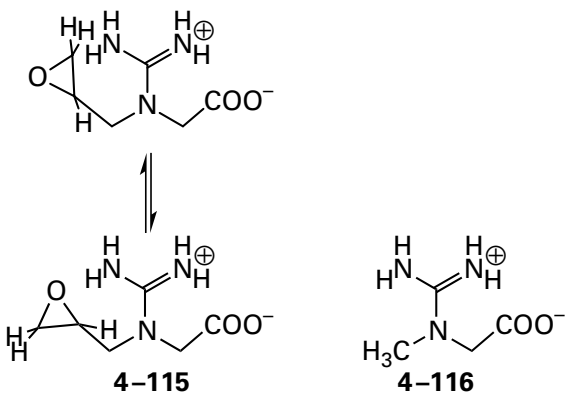
when it binds to the active site of the enzyme in place of the substrate. Nevertheless, *N*-bromoacetyl-2-amino-2-deoxypentitol 1,5-bisphosphate irreversibly inactivates ribulose-bisphosphate carboxylase from *R. rubrum* in a reaction the properties of which meet all the criteria for specific labeling within the active site.[808] It was shown that the covalently modified amino acid was methionine



(4–354)

Since methionine cannot act as a catalytic acid or base or as an acceptor or donor for a hydrogen bond, the conclusion reached from these observations is that this methionine is, by chance, **one of the amino acids within or immediately adjacent to the active site**. In the sequence of amino acids for ribulose-bisphosphate carboxylase from *R. rubrum*, Methionine 115 takes the place of Phenylalanine 125 in the enzyme (Figure 3–53) from *S. oleracea* (27% identity; 2.5 gap percent). In the crystallographic molecular model of the enzyme from *R. rubrum* in a complex with D-ribulose 1,5-bisphosphate,[809] Methionine 115 is the closest methionine and in the same location relative to D-ribulose 1,5-bisphosphate as it is in the active site of the enzyme from *S. oleracea*. There are no atoms from the protein between it and D-ribulose 1,5-bisphosphate, but its sulfur is 1.1 nm from carbon 2, which seems a stretch.

An affinity label for creatine kinase, *N*-(2,3-epoxypropyl)-*N*-amidinoglycine (**4–115**)[810]



4–115 **4–116**

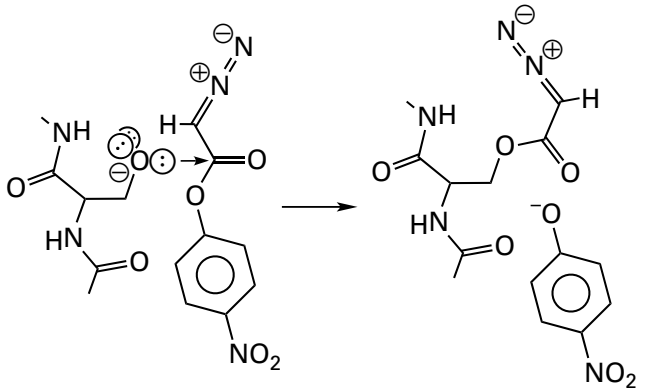
tacks an epoxide onto the *N*-methyl group in the substrate creatine (**4–116**). This point of attachment places the electrophilic distal carbon of the epoxide at what seems to be a significant remove from the site of phosphorylation, which occurs at one of the distal amidino nitrogens of the creatine. This fact suggested that the reagent was modifying an amino acid only in the vicinity of the active site. Cysteine 282 in creatine kinase from *O. cuniculus* is the site of modification.[811] In the crystallographic molecular model between creatine kinase from *O. cuniculus* and creatine, nitrate, and $MgADP^-$, the sulfur of Cysteine 282 is 0.56 nm from any of the atoms involved in the nucleophilic substitution at phosphorus,[812] which would be consistent with this conclusion that it is not a catalytic acid–base.

In this crystallographic molecular model of the analogue for the transition state (see Figure 3–41), however, the sulfido group of Cysteine 282 is only 0.32 nm from the other distal nitrogen in creatine, the one that is uninvolved directly in the reactions, so it could be increasing the nucleophilicity of the distal nitrogen that is involved. The orientation of the sulfido group of Cysteine 282 with respect to the distal nitrogen is not proper for a hydrogen bond, and the sulfido group participates in three proper hydrogen bonds with an amido nitrogen–hydrogen from the polypeptide, the hydroxy group of a serine, and a molecule of water. Nevertheless, the sulfido group of Cysteine 282, by electron repulsion, could shift electron density in the π molecular orbital system of the guanidinio group from the lobe over the nitrogen adjacent to it to the lobe on the nitrogen that is phosphorylated and make that lobe a more nucleophilic participant in the nucleophilic substitution at phosphorus catalyzed by the enzyme.[813] From the orientation of the participants in the crystallographic molecular model of the complex between creatine kinase from *O. cuniculus* and creatine, nitrate, and $MgADP^-$ and the complex between the related (46% identity; 2 gap percent) arginine kinase from *Limulus polyphemus* and L-arginine, $MgADP^-$, and nitrate (Figure 3–41), it can be seen that this lobe in the π molecular orbital system of the guanidinio group is the nucleophile, not a localized lone pair of electrons in the plane of the conjugate base of the guanidinio group. In the active site of arginine kinase from *L. polyphemus*, the homologous sulfido group on the homologous cysteine is in a similar location.[814]

As was the case with *N*-bromoacetyl-2-amino-2-deoxypentitol 1,5-bisphosphate, the methyl group on creatine to which the epoxide is attached seems too distant (0.61 nm) in the molecular model from the sulfido group of Cysteine 282 that is modified,

and it would be positioned on the opposite side of the guanidinio group, which would lie between it and the sulfido group. There is a rotational isomer (**4–115**) that places the electrophilic carbon immediately adjacent to one of the distal nitrogens, but according to the molecular model, the nitrogen is the nucleophile in the nucleophilic substitution at phosphorus. The labeling was performed in the absence of adenine nucleotide, and the combination of $MgADP^-$ and nitrate, in the absence of creatine, prevents the modification.[810] For both of these reasons, it seems reasonable to assume that the complex between the active site and *N*-(2,3-epoxy-propyl)-*N*-amidinoglycine that is responsible for the modification is the one in which the *N*-methyl-guanidinio group is flipped over relative to its competent orientation in the crystallographic molecular model, in part because this flipped disposition would be precluded when $MgATP^{2-}$ and nitrate are bound, and hence their presence should prevent the modification.

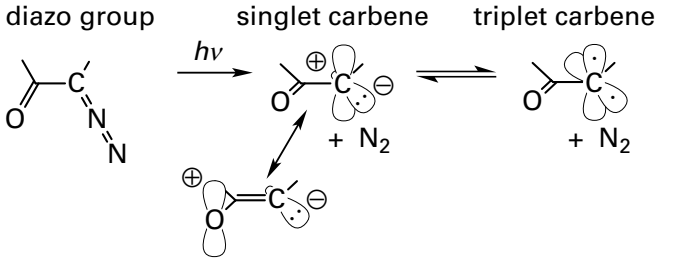
It is possible to perform affinity labeling with **a reagent attached covalently within the active site**. A diazoacetyl group was transesterified onto Serine 195 in chymotrypsin to form a stable acyl intermediate[815] by taking advantage of the first step in the normal enzymatic reaction (Figure 3–6)



(4–355)

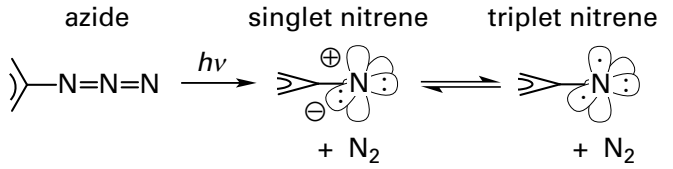
Upon photolysis, a carbene was formed that inserted at random into any one of several oxygen–hydrogen bonds of amino acids surrounding the active site.

8-Azidoadenosine triphosphate (**4–113**) and 4-nitrophenyl diazoacetate (Equation 4–355) are examples of a large class of **photoaffinity labels** that have been widely used to perform affinity labeling. These photoaffinity labels usually contain either a diazoketone or a diazo ester[816] or an azido group.[817] When a diazoketone or diazo ester is photolyzed, a **carbene** is formed



(4–356)

and when an azido group is photolyzed, a **nitrene** is formed



(4–357)

Both carbenes and nitrenes are dramatically electron-deficient. A carbene has only six valence electrons around the single carbon, and a nitrene has only six valence electrons around the single nitrogen.

A carbene or nitrene can react either as a **singlet electrophile**, in which the two nonbonding electrons occupy only one atomic orbital on carbon or nitrogen, or as a **triplet diradical**, in which each of two nonbonding σ atomic orbitals on carbon or nitrogen, respectively, are occupied by one of two unpaired electrons. The singlet state of a carbene or a nitrene has a vacant atomic orbital at carbon or nitrogen, respectively, and consequently it is a strong electrophile that can form a covalent bond with a nucleophilic atom that has a lone pair of electrons in a simple nucleophilic addition, followed by hydronation of the resulting carbanion or azanide. The triplet diradical is capable of abstracting a hydrogen from an atom in its vicinity to produce a radical at that atom and a single radical on the former carbon of the carbene or nitrogen of the nitrene, and then the two adjacent radicals can colligate to form a covalent bond between the carbon or nitrogen of the carbene or nitrene and the atom from which hydrogen was abstracted. Because the reactants in both photochemical dissociations—the diazoketone or diazoacetyl group and the azido group and their respective photochemically excited states—are singlets and molecular nitrogen is a singlet, the initial products of the photolysis are the respective singlets. Each singlet then equilibrates (Equations 4–356 and 4–357) with the triplet state, which is usually the more stable state, by intersystem crossing.

Table 4–1: Affinity Labels

enzyme or protein	substrate or ligand mimicked	affinity label
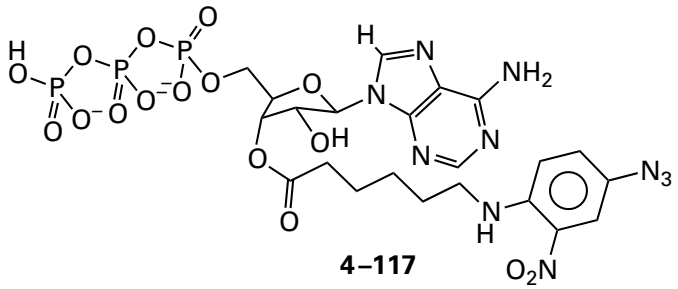
pyruvate kinase[823]	ADP^{3-}	tryptophan synthase[824]	tryptophan	cytochrome bo_3 ubiquinol oxidase[825]	ubiquinone	acyl-CoA oxidase[826]	stearoyl-SCoA	procollagen-proline 3-dioxygenase[827]	procollagen	immunoglobulin G anti-estradiol[828]	estradiol	β-adrenergic receptor [829]	benzylpindolol	
Although there is an example of insertion of a carbene into a carbon–hydrogen bond, albeit at low yield,[818] the majority of the products from modification within active sites or binding sites in proteins by either carbenes[816] or nitrenes[804,817,819,820] are consistent with nucleophilic addition of an oxygen, nitrogen, or sulfur to the respective singlet electrophile. This regioselectivity is observed even when the vast majority of the covalent bonds surrounding a nitrene or carbene are carbon–hydrogen bonds.[821,822]

There are many examples of the use of affinity labels (Table 4–1).[665,823-829] Rather than being used to identify a particular amino acid or set of amino acids in a protein, affinity labels have frequently been **used to identify a particular protein or region within the sequence of amino acids for a protein**[830,831] that contains or comprises the active site or binding site of interest. Although functional groups capable of alkylation, acylation, or sulfonylation are often used as the electrophiles, the most common choice, when the affinity label is not being used as an active-site label, has been an aryl azide (Equation 4–357). This choice increases the chance that a sufficiently reactive nucleophile will be encountered by the electrophile. Nevertheless, it is still necessary that a nucleophile, however unreactive, be accessible to the nitrene resulting from the photolysis. To increase the probability of this juxtaposition, the aryl azide can be attached flexibly to the portion of the reagent conferring specificity so that it can reach several side chains in the vicinity of the active site or binding site, as in the aryl azide



4–117

that was used to modify amino acids surrounding the active site of myosin ATPase (Equation 4–288).[832]

A few of the natural substrates and ligands for enzymes and proteins are themselves photochemically active, and upon photolysis they are converted into products that can covalently modify a site to which they are bound. For example, magnesium thymidine triphosphate modifies Histidine 881 in DNA-directed DNA polymerase I from *E. coli* when it is photolyzed with ultraviolet light while bound at the catalytic site for deoxynucleoside triphosphates on the enzyme.[833]

Derivatives of large nucleic acids that position a group capable of modifying amino acids in a protein with which the nucleic acid associates have been used as affinity labels. For example, the precursor to $tRNA^{Phe}$ into which either 4-thiouridine or 5-bromouridine had been incorporated at each position occupied by uridine was used to modify photolytically RNA ligase (ATP) from *S. cerevisiae* and identify all the uracils in $tRNA^{Phe}$ that come in contact with the enzyme.[834] A 1-pyrrolidinyl ester, which is able to modify the amino group on a lysine, was attached in turn to four different cytosines in $tRNA^{fMet}$. In each instance, the 1-pyrrolidinyl ester was at the end of a long chain of 17 atoms, the bonds between which are free to rotate, permitting the electrophile to survey a wide area on the adjacent surface of the enzyme. Each affinity label modified a different lysine in methionine—tRNA ligase from *E. coli*, and the tryptic peptides containing each modification were isolated and sequenced to identify each site of modification in the sequence of amino acids in the enzyme.[835]

The ribose at the 3′ end of a transfer RNA, which is the only ribosyl group in the nucleic acid with vicinal hydroxy groups, can be oxidized exclusively with periodate, and a dialdehyde is produced from the ribose. This dialdehyde is able to form an imine with the amino group of a lysine in a protein, which can then be reduced with cyanoborohydride.[836] Oxidized $tRNA^{Ala}$ specifically modifies Lysine 73 in alanine—tRNA ligase from *E. coli*.[837] In the crystallographic molecular model of the complex between alanine—tRNA ligase from *Archaeoglobus fulgidus* (24% identity; 2.3 gap percent) and $tRNA^{Ala}$, the leucine that occupies the same position in the aligned sequences as Lysine 73 is immediately adjacent to the 3′ end of the tRNA.[838] It obviously is not a catalytic acid–base, and since Lysine 73 is not conserved, it also is probably not a catalytic acid–base.

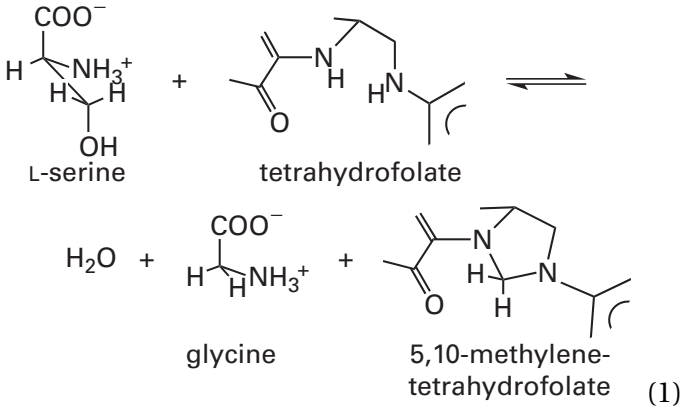
Problem 4–28: Glycine hydroxymethyltransferase (previously Equation 2–10) uses pyridoxal phosphate as a prosthetic group in its active site to catalyze the reversible interconversion of glycine and L-serine.



(1)

This reaction is the major source of 5,10-methylene-tetrahydrofolate in mammals. The enzyme also carries out the following transformations.

L-allothreonine $\rightleftharpoons$ acetaldehyde + glycine (2)

L-3-phenylserine $\rightleftharpoons$ benzaldehyde + glycine (3)

aminomalonate + H^+ $\rightleftharpoons$ CO_2 + glycine (4)

L-2-methylserine + tetrahydrofolate $\rightleftharpoons$ H_2O + D-alanine + 5,10-methylenetetrahydrofolate (5)

D-alanine + internal pyridoximine + H_2O $\rightleftharpoons$ lysyl side chain + pyruvate + pyridoxamine (6)

R-2-amino-3-fluoropropionate (D-fluoroalanine) + H_2O $\rightleftharpoons$ F^- + H^+ + pyruvate + NH_4^+ (7)

(A) Write the common mechanism for each of these seven reactions that explains each outcome, both the chemistry and the stereochemistry. Make it clear that each mechanism is just a variation of the common theme. Start with the external pyridoximine of each amine. In every step of each mechanism, write out only the imino carbon and the imino nitrogen of the pyridoximine and the remainder of the respective adduct. Abbreviate the tetrahydrofolate as in Equation 1. Indicate acids and bases as $HN^{(+)}$and $\odot O^{(-)}$ to save time.

(B) Explain the following results from a study[642] of the reaction in Equation 7

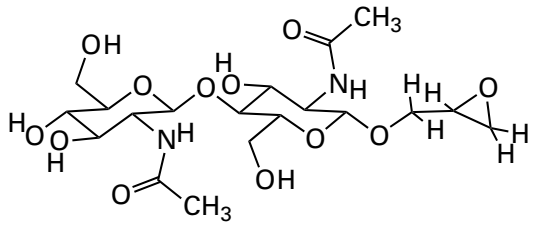
reactant	k_{FA} (M^{-1} s^{-1})
D-[2-^{1}H]fluoroalanine	0.37
D-[2-^{2}H]fluoroalanine	0.07

where k_{FA} is the specificity constant for the respective fluoroalanine (FA). When tetrahydrofolate is present, D-fluoroalanine is turned into pyruvate 100 times faster than L-fluoroalanine is turned into pyruvate. The normal substrate for the enzyme, however, is L-serine.

(C) Draw two structures, side by side, of adducts formed at the active sites between pyridoxal phosphate and D-fluoroalanine and between pyridoxal phosphate and L-serine, respectively, that explain why D-fluoroalanine is the preferred substrate over L-fluoroalanine but L-serine is the preferred substrate over D-serine.

(D) Draw a chemical mechanism involving a nucleophilic amino acid side chain, $-S\odot^{(-)}$, in the active site to explain one way the enzyme could become irreversibly inactivated while it is performing the reaction in Equation 7.

Problem 4–29: 2′,3′-Epoxypropyl β-di(*N*-acetyl-D-glucosamine)glycoside



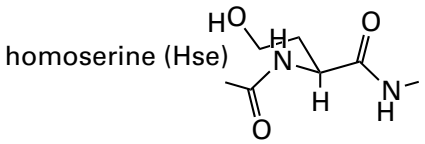
was synthesized as an active-site label for lysozyme (Figure 3–27) from *G. gallus*. After binding to the active site, 2′,3′-epoxypropyl β-di(*N*-acetyl-D-glucosamine)glycoside reacts with the enzyme to form a covalent derivative that is inactive and that contains 1 mole of the label attached to Aspartate 52 for each mole of the enzyme.[646]

(A) Write the chemical mechanism for the reaction between Aspartate 52 and 2′,3′-epoxypropyl β-di(*N*-acetyl-D-glucosamine)glycoside.
(B) Use steric arguments to predict which electrophilic carbon in the epoxide is the most likely electrophile.

Lysozyme, which had been modified by 2′,3′-epoxypropyl β-di(*N*-acetyl-D-glucosamine)glycoside and rendered inactive, was crystallized, and a crystallographic molecular model was constructed.[646]

(C) Which subsites (Figure 3–27) on the inactive lysozyme molecule were occupied by the two *N*-acetyl-D-glucosamino groups of the affinity label?

When the covalently modified enzyme was reduced with $NaBH_4$, the ester was reduced to an alcohol and a derivative of lysozyme with homoserine at position 52 resulted.[839]



(D) Lysozyme(Hse52) is catalytically inactive but binds hexasaccharide substrates such as $(GlcNAc)_6$ with the same affinity as the native enzyme. Explain this observation.

Problem 4–30: Aldolases are enzymes that catalyze aldol condensations such as those in Equations 4–278 and 4–324 and Figures 4–26 and 4–36. It has been shown that when a ketone that is a substrate is mixed with its aldolase and allowed to equilibrate, and then the mixture is treated with $NaBH_4$ (a mild reducing reagent), a lysine in the protein is irreversibly modified and a secondary amine resulting from reduction of the imine of the ketone with that lysine (Equation 4–325) can be isolated from a hydrolysate of the protein. This result is evidence for the existence of the respective imine of a lysine in the active site.

(A) Write out the steps involved in an aldolase mechanism. Where are hydrons rearranged?

2-Dehydro-3-deoxyphosphogluconate aldolase (Equation 4–324) from *Pseudomonas* was mixed with pyruvate in the presence of ^3H_2O and equilibrated for the times noted in the table.[706] Following the reaction, pyruvate was purified on an ion-exchange column, and fractions were examined for the incorporation of tritium.

enzyme	time (h)	$\frac{\mu mol\ of\ ^3H}{\mu mol\ of\ pyruvate}$
none	1	<0.005
boiled	1	<0.005
active	1	0.585
none	16	0.073
active	16	2.310

(B) To which carbon in pyruvate is tritium added? How does this process fit into the overall mechanism? Draw what you think is occurring at the active site, and explain the super-stoichiometry of the incorporation. Include hydron donors and acceptors.

2-Dehydro-3-deoxyphosphogluconate aldolase was mixed with 1 mM 3-bromopyruvate at pH 6. Samples were removed at various intervals and immediately diluted 200-fold into a solution at pH 8 to hydrolyze the 3-bromopyruvate. The enzyme, following this dilution procedure, was then assayed for aldolase activity.[691]

time of initial incubation with bromopyruvate (min)	enzymatic activity remaining (%)
0	100
1	78
2	65
3	50
4	41
5	28

The 3-bromopyruvate irreversibly inactivates the enzyme.

(C) Why was 3-bromopyruvate chosen? Examine your diagram for the enzyme mechanism. What group is the intended target of 3-bromopyruvate, and what type of chemical reaction should be occurring?

(D) Assume that the kinetic mechanism of Equation 4–297 describes this inactivation and that

$$\frac{d[\text{E–ASL}]}{dt} \equiv v_i = k_i[\text{E}\cdot\text{ASL}]$$

and show that

$$\frac{d[\text{E–ASL}]}{dt} = \frac{k_i([\text{E}]_0 - [\text{E–ASL}])\,k_{ASL}[\text{ASL}]}{k_i + k_{ASL}[\text{ASL}]}$$

where k_{ASL} is defined by Equation 4–300.

(E) Show by integration that Equation 4–298 describes the inactivation.

(F) Show that the reaction corresponds to this expectation by plotting the data from the table in the form of Equation 4–298 or in its common logarithmic form, Equation 4–301. Assume that the concentration of 3-bromopyruvate, [ASL], is 1 mM at all times t, because $[\text{E}]_0 \ll [\text{ASL}]$.

(G) If $t_{½}$ is defined as the time required to inactivate half the enzyme, show that

$$t_{½} = \ln 2\left(\frac{k_{ASL}^{-1} + k_i^{-1}[\text{ASL}]}{[\text{ASL}]}\right)$$

Values of $t_{½}$ for several 3-bromopyruvate concentrations were calculated from curves such as the one you drew earlier.[691]

[bromopyruvate] (mM)	$t_{½}$ (s)
0.21	330
0.30	250
0.46	190
0.89	140
1.5	100
3.5	80

(H) Do these data conform to expectations? Explain.

(I) What are numerical values for k_{ASL} and k_i?

If 3-bromopyruvate is binding to the active site of 2-dehydro-3-deoxyphosphogluconate aldolase at the same position as pyruvate, then pyruvate should protect the enzyme. The following values for $t_{½}$ were measured when 6 mM pyruvate was present in addition to 3-bromopyruvate.[691]

[bromopyruvate] (mM)	$t_{½}$ (s)
5	500
10	280
20	170

(J) What kind of an inhibitor is pyruvate with respect to the inactivation caused by 3-bromopyruvate? Is this observation expected? Why?

Radioactive [^{14}C]-3-bromopyruvate was synthesized by direct bromination of [^{14}C]pyruvate. 2-Dehydro-3-deoxy-D-gluconate 6-phosphate was incubated at pH 6 for 20 min in the presence of 1 mM unradioactive 3-bromopyruvate and 40 mM pyruvate. The enzyme was dialyzed exhaustively and then treated with 1 mM [^{14}C]-3-bromopyruvate at pH 6 in the absence of pyruvate for 20 min. The enzyme was precipitated 3–4 times with $(NH_4)_2SO_4$ until constant counts per minute of ^{14}C (milligram of precipitated protein)$^{-1}$ were obtained. It was found that 90% of the activity had disappeared and 1.1 mol of ^{14}C (mol of enzyme protomer)$^{-1}$ had been covalently incorporated. When the radioactive protein was incubated with 0.5 M NaOH or unfolded in 10 M urea and reacted with hydroxylamine, 90–95% of the radioactivity was removed from the protein. Ethers, phenol ethers, and secondary amines are all stable under these conditions. When the ^{14}C-labeled

protein was hydrolyzed in 6 M HCl at 100 °C for 24 h, 99% of the ^{14}C was released as hydroxypyruvic acid.[634]

(K) What type of amino acid side chain has probably reacted covalently with 3-bromopyruvate to inactivate the enzyme?

[^{14}C]-2-Dehydro-3-deoxy-D-gluconate 6-phosphate aldolase that had been inactivated with [^{14}C]-3-bromopyruvate was prepared and divided into two fractions. One fraction was unfolded with 1% sodium dodecyl sulfate. Both native and unfolded [^{14}C]aldolase were then reacted with $NaBH_4$ for 30 min at 50 °C. When these two fractions were hydrolyzed in 6 M HCl, the unfolded sample yielded only [^{14}C]glyceric acid, but the hydrolysate of the native enzyme contained a new [^{14}C]amino acid (60% yield). When enzyme, purified from bacteria grown on [^{3}H]-L-lysine, was reacted with [^{14}C]-3-bromopyruvate, reduced, and hydrolyzed, the new amino acid contained both ^{14}C and ^{3}H in a 1:1 molar ratio.[634]

(L) What is this novel amino acid, and what occurred during inactivation and then reduction?

(M) Look again at your diagram of hydron movements during the aldolase reaction. Notice that during the retroaldol dissociation a hydron is removed from the hydroxy group on carbon 4 of 2-dehydro-3-deoxy-6-phospho-D-gluconate, but during the reverse reaction a hydron is removed from the methyl group of carbon 3 of pyruvate. Consider the amino acid that performs this function. What is there about its functional group that makes it particularly suitable?

Problem 4–31: 2,3-Epoxypropanol 1-phosphate, glycidol phosphate (GcP), is an irreversible inhibitor of triose-phosphate isomerase (Equations 4–46 and 4–55 and Figure 3–37). When glycidol phosphate is added to a solution of triose-phosphate isomerase from *O. cuniculus*, in large excess over the concentration of enzyme, the enzymatic activity disappears in a pseudo-first-order fashion such that a plot of log([active enzyme]) against time (Equation 4–301) is linear, and a rate constant, $k_{i,app}$, could be obtained from the slope. It was found that $k_{i,app}$ varied with the concentration of glycidol phosphate and was affected by addition of a competitive inhibitor of the enzymatic activity, glycerol 1-phosphate.[647]

[glycidol phosphate] (mM)	$k_{i,app}$ ($s^{-1} \times 10^6$)	
	enzyme alone	enzyme + 0.3 mM glycerol 1-phosphate
0.15	6.4	
0.3	12.0	
0.6	18.4	
1.2	28.7	14.0
1.9	37.5	20.7
3.8		34.0
5.2		49.3

(A) Plot these data in an informative format and determine K_{dGcP}, the dissociation constant of glycidol phosphate from the active site, and K_{dGoP}, the dissociation constant of glycerol 1-phosphate.

(B) What two features of the kinetics of inactivation lead to the conclusion that glycidol phosphate is an active-site label?

(C) What participant in Equation 4–55 is reacting with glycidol phosphate?

When the enzyme was fully inactivated, 0.9 ± 0.1 mol of [^{32}P]glycidol phosphate (mol of active sites)$^{-1}$ was incorporated into the protein.[840] The radioactive protein was digested with pepsin, and a radioactive peptide was isolated. Upon hydrolysis, the amino acid composition of the peptide was

amino acid	mol of amino acids (100 mol of total amino acids)$^{-1}$
Glu	20
Pro	22
Ala	18
Val	21
Tyr	19

The optical density of the peptide at 280 nm was 5800 M^{-1} cm^{-1}.

(D) Find this peptide in the sequence of triose-phosphate isomerase from *O. cuniculus* and write out its sequence.

This peptide was radioactive (^{32}P) and lost its radioactivity upon either alkali treatment, which will not cleave phosphate esters, or phosphatase

treatment, which will. The same peptide was isolated from unmodified enzyme and from enzyme modified with 2,3-epoxypropan-1-ol (glycidol) and $HOPO_3^{2-}$. Upon electrophoresis, the following behavior was observed

peptide	electrophoretic mobility (relative to aspartate) pH 6.5	electrophoretic mobility (relative to serine) pH 1.9
unlabeled	–0.21	+0.43
labeled with glycidol phosphate	–0.27	0
labeled with glycidol + $HOPO_3^{2-}$	0	+0.42

(E) Which amino acid in the peptide had reacted with glycidol phosphate?

Problem 4–32: 3-Hydroxydecanoyl-[acyl-carrier-protein] dehydratase from *E. coli* can catalyze both of the following reactions.[841]

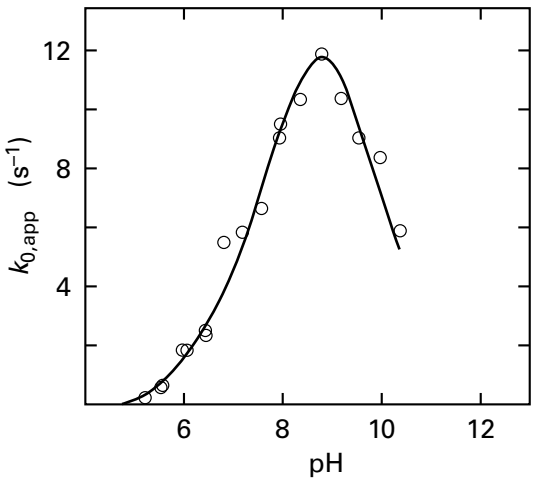
(R)-3-hydroxydecanoyl-SACP $\rightleftharpoons$ H_2O + *trans*-dec-2-enoyl-SACP $\rightleftharpoons$ H_2O + *cis*-dec-3-enoyl-SACP

The abbreviation SACP is for acyl-carrier protein, a small protein in which the sulfanyl group of a prosthetic 4′-phosphopantetheine forms a thioester with the respective fatty acids. Substrates that are thioesters of *N*-acetylcysteamine (SNAC) are as effective as substrates for the enzyme as the thioesters of acyl-carrier protein.

(A) Provide a mechanistic reason to explain why the enzyme cannot convert (*R*)-3-hydroxydecanoyl-SACP directly into *cis*-dec-3-enoyl-SACP.

(B) If any one of the substrates were mixed with a high enough concentration of the enzyme in D_2O, so that the three reactions catalyzed by the enzyme come to equilibrium faster than nonenzymatic hydron exchange could occur, then deuterium would be incorporated by the enzyme into some or all of the three substrates. Assume that the dehydration is trans and that the hydron is moved across the face of the intermediate in the second reaction from carbon 4 to carbon 2. How many deuteriums should incorporated into each of the three substrates, and what are the absolute stereochemistries of each deuterated substrate?

The effect of pH on the catalytic constant of the enzyme, k_0, for isomerization of *cis*-dec-3-enoyl-SNAC to *trans*-dec-2-enoyl-SNAC was measured at various values of pH and at constant temperature (30 °C) and ionic strength (0.05 M).[842]



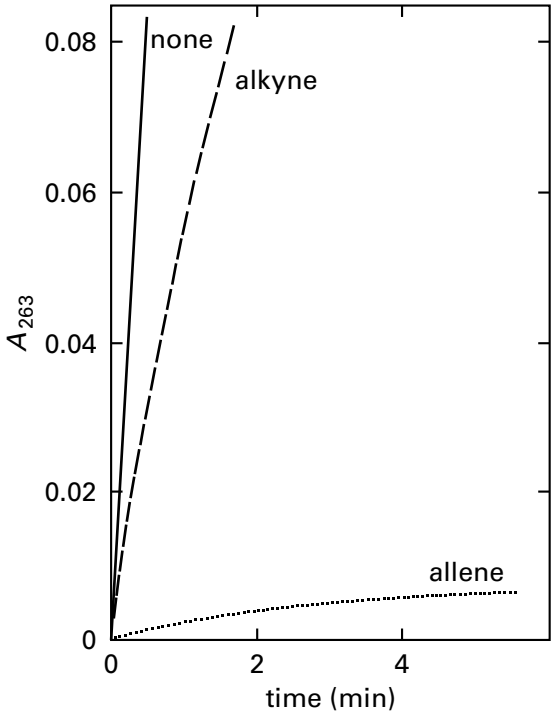
Reactions were initiated by addition of 4 μg of dehydratase to cuvettes containing 1.0 mL of substrate, the concentration of which had been determined by measuring absorbance at 232 nm. Product formation was monitored by measuring A_{263}. Values for k_0 were calculated from double-reciprocal plots of the data at each pH. At least 10 different substrate concentrations were used for each point. The buffer systems were sodium acetate, imidazolium chloride, potassium phosphate, tris(hydroxymethyl)aminomethane hydrochloride, and sodium glycinate.

(C) Write a mechanism for isomerization of *cis*-dec-3-enoyl-SNAC as it occurs within the active site of the enzyme. Your mechanism must contain the explanation for the behavior observed in the figure. Use amino acid side chains of your choice to act as catalytic side chains. Choose a different one for each role to distinguish them in later answers.

(D) Explain the observed effect of pH on k_0 observed in the preceding figure in terms of acid dissociations of the catalytic acids and catalytic bases that you chose in part C. Consider both the free enzyme and the enzyme–

substrate complex. Remember that in this particular experiment *cis*-dec-3-enoyl-SNAC is the substrate.

Both dec-3-ynoyl-SNAC (alkyne) and deca-2,3-dienoyl-SNAC (allene) are irreversible inhibitors of the enzyme.[729]

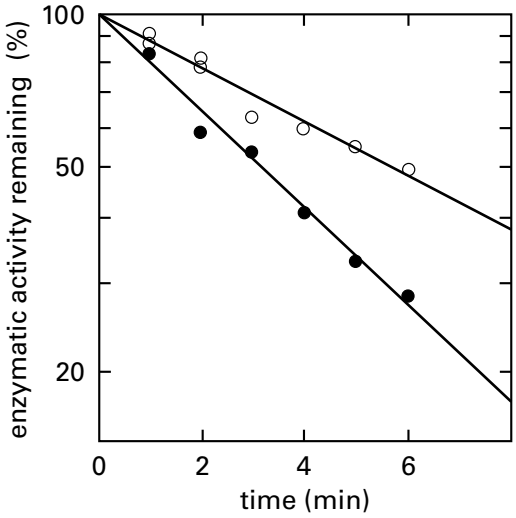


To a cuvette containing 10 μM of the respective inhibitor and 400 μM *cis*-dec-3-enoyl-SNAC in 0.01 M potassium phosphate at pH 7.0 was added 6 μg of purified 3-hydroxydecanoyl-[acyl-carrier-protein] dehydratase at zero time. The rate of *trans*-2-decenoyl-SNAC production was measured spectrophotometrically by absorbance at 263 nm (A_{263}).

(E) Write the nucleophilic addition that explains why one of these compounds is so much more reactive than the other. Use one of the nucleophiles in your active site for the addition.

(F) Draw at least two possible products of the reaction of deca-2,3-dienoyl-SNAC with amino acid side chains in the active site that you constructed in the answer to part B.

2,2-Dideuterodec-3-ynoyl-SNAC was synthesized as well as dec-3-ynoyl-SNAC, and these two compounds were tested together as inactivators of the enzyme.[729] To cuvettes containing 0.5 mL of potassium phosphate at pH 6.0 and an ionic strength of 0.05 M were added, to a final concentration of 8 μM, either dec-3-ynoyl-SNAC (●) or 2,2-dideuterodec-3-ynoyl-SNAC (○) and, at zero time, 33 μg of dehydrase. At various times, 0.5 mL of 3.1×10^{-4} M *cis*-dec-3-enoyl-SNAC in the same buffer was added, and the initial rate of product formation was recorded. The degree of inactivation was based on comparison with a similar reaction to which no ethynylene thioester had been added. Since the amount of ethynylene thioester was present at a 60-fold molar excess over dehydrase, the inactivation data were treated in a first-order manner.



The deuterium kinetic isotope effect observed ($^{H}k/^{D}k = 2.60$) is similar in magnitude to that seen for 2,2-dideutero-3-hydroxydecanoyl-SNAC during its dehydration to *trans*-2-decanoyl-SNAC ($^{H}k/^{D}k = 2.25$). 2-Deuterodeca-2,3-dienoyl-SNAC, however, shows no isotope effect during its inactivation of the enzyme.

(G) What does the deuterium kinetic isotope effect suggest that the enzyme must be doing to dec-3-ynoyl-SNAC before this active-site label can inactivate the enzyme?

(H) What must dec-3-ynoyl-SNAC be turned into before it can inactivate the enzyme?

(I) Incorporate the mechanism for this transformation into your active site from part B.

(J) Write an overall mechanism that incorporates the three reactions naturally catalyzed by the enzyme, inactivation by the allene, and mechanism-based inactivation by the alkyne.

(K) Is the enzyme catalyzing its natural reaction through an enolate, through an intermediate carbenium ion, or by a concerted mechanism?

Problem 4–33: The following mechanism-based labels[679,843-846] were designed to modify the noted enzymes.

enzymatic reaction or enzyme	mechanism-based label
cis-3-chloropropenoate ⇌ 3-oxopropanoate	
4-aminobutyrate transaminase	isopentenyl-diphosphate Δ-isomerase	glutaryl-SCoA ⇌ CO_2 + crotonyl-SCoA + 2 e^-	thymidylate synthase	
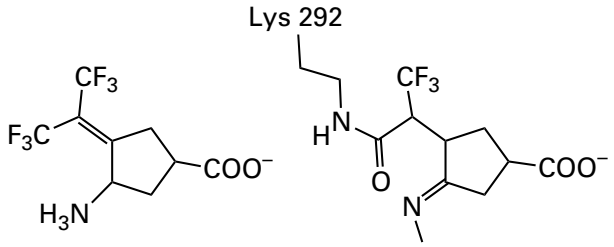
(A) Draw the structure of the substrate for each enzyme that the mechanism-based label is designed to mimic.

(B) Draw the structure of each electrophile that the respective enzyme produces from each mechanism-based label. The electrophile in each case is produced in the same step or sequence of steps through which the enzyme takes the substrate that the mechanism-based label mimics.

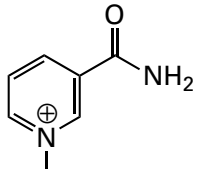
Problem 4–34: (1*S*,3*S*)-3-Amino-4-(perfluoropropan-2-ylidene)cyclopentane-1-carboxylate



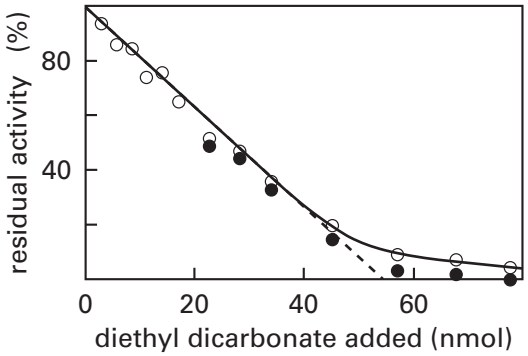
inactivates human ornithine aminotransferase.[711] The product of the reaction has been identified in a crystallographic molecular model of the modified enzyme as the amide between the amino group of Lysine 292 and the N^3-(5′-phosphopyridoxyl)imine of (1*S*)-3-imino-4-(3,3,3-trifluoro-1-carboxypropan-2-yl)cyclopentane-1-carboxylate, and the identification was verified by the mass spectrum of the inactivated enzyme. In the initial step of the reaction, the 3-amino group of the (1*S*,3*S*)-3-amino-4-(perfluoropropan-2-ylidene)cyclopentane-1-carboxylate forms the external pyridoximine with the prosthetic pyridoxal 5′-phosphate in the active site. Write a mechanism for formation of the amide from the perfluoropropan-2-ylidene that involves the 5′-phosphopyridoxyl group in every step except the last one.

Problem 4–35: L-Lactate dehydrogenase catalyzes the reaction of Equation 4–204.

(A) Write a chemical mechanism for the oxidation–reduction as it would occur in the active site, using $HN^{(+)}$ and $\odot O^{(-)}$ to indicate any necessary acid or base. Abbreviate NAD^+ as



Porcine L-lactate dehydrogenase is inactivated irreversibly by the nonspecific electrophile diethyl dicarbonate.[847]

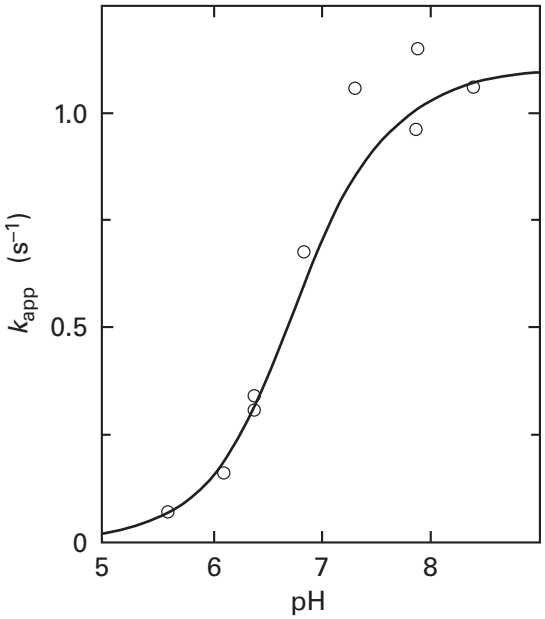


Freshly diluted samples of diethyl dicarbonate were added to solutions of enzyme (56 nmol of subunits) in 0.08 mL of 0.1 M sodium phosphate at pH 6.0 and 20 °C. After 1 min, the enzyme was diluted 200-fold into ice-cold buffer, and a sample was used to measure the enzymatic activity about 5 min after the initial addition of diethyl dicarbonate. The percentage of residual activity is expressed relative to that of an untreated control (○), and the percentage of residual activity, after being corrected for the reactivation (about 5%) that occurs during the 5 min necessary to assay the enzyme, is expressed as a percentage, relative to that of that of an untreated control (●).

(B) Explain why this experiment was done, what the results demonstrate, and why there must be one particularly reactive amino acid in the protein.
(C) Write a kinetic mechanism for the reaction between the nucleophilic form of the enzyme and diethyl dicarbonate. Do not solve the rate equation.
(D) Why is the observed rate of the reaction kinetically first-order when the inactivation of the enzyme is followed as a function of time, and what is the observed rate constant equal to in terms of your kinetic mechanism?

The rate of reaction of diethyl dicarbonate was measured by rapidly mixing a solution of 30 μM L-lactate dehydrogenase in sodium diphosphate at pH 8.4 and an ionic strength of 150 mM with an equal volume of a solution of 11 mM diethyl dicarbonate and following at an absorbance of 251 nm. The product of the reaction between diethyl dicarbonate and the amino acid in the active site absorbs most strongly at 251 nm.

The concentrations of both L-lactate dehydrogenase and diethyl dicarbonate and the ionic strength were kept constant in a series of experiments in which the pH was varied systematically. The apparent first-order rate constant for the change in absorbance at 251 nm was determined for each pH.[847]



The observed first-order rate constant for the reaction is plotted as a function of the pH. The concentration of enzyme after mixing was 15 μM, and that of diethyl dicarbonate was 5.5 mM. Buffers were sodium diphosphate.

(E) Write a kinetic mechanism for this inactivation describing it as the carbonylation of the conjugate base of an amino acid on the protein. Incorporate acid dissociation of the conjugate acid of that amino acid in your mechanism. Derive an equation for the observed first-order rate constant, k_{app}, in terms of the intrinsic rate constant, k_{DD}, between diethyl dicarbonate and the conjugate base of the amino acid and the acid dissociation constant, K_{aNH}, of the amino acid.
(F) What is the pK_a of the nucleophilic amino acid?

Catalytic Acid–Bases in Crystallographic Molecular Models

It would seem that, when a crystallographic molecular model of the empty active site of a particular enzyme became available, the catalytic acid–bases involved in the enzymatic mechanism could be identified immediately by inspection. Unfortunately, this hope has not been realized. The reasons for the almost universal ambiguity that accompanies crystallographic molecular models of empty active sites are

that there are usually too many acid–bases, that they are too flexible, and that there are many heteroatoms that do not seem to be possible catalytic acid–bases that turn out to be. The reason that there are too many acid–bases in an active site is that substrates, in addition to presenting to the active site the hydrons that must be removed and the lone pairs of electrons that must be hydronated for the reaction to occur, also have significant numbers of donors and acceptors for hydrogen bonds, and these must be occupied by acceptors and donors from the active site. These acceptors and donors within the active site are usually acid–bases in their own right, and they are indistinguishable chemically from the catalytic acid–bases.

Consequently, the active site must be occupied by an informative set of ligands that identifies the catalytic acid–bases responsible for the hydron transfers necessary for the enzymatic reaction.

The most informative ligands are the **complete set of substrates in a complex with the enzyme** in which reactants and products are in rapid equilibrium with each other within the active site. For example, the crystallographic molecular model (Figure 3–36) of the complex between murine cytidine deaminase and a cytidine, a water, a uridine, and an ammonia in equilibrium with each other clearly identifies one oxygen of the carboxylato group of Glutamate 67 as the catalytic base that removes the hydron from hydroxide on the Zn^{2+} (0.28 nm) while it adds as the nucleophile to cytidine in the direction of hydrolysis. Removal of this hydron turns the hydroxide into the oxyanion still coordinated to the Zn^{2+} in the tetrahedral intermediate to provide push. The resulting carboxy group on Glutamate 67 then becomes the catalytic acid that adds the hydron to the amino group in the tetrahedral intermediate at carbon 4, as is required to permit the nitrogen to leave as ammonia. By microscopic reversibility, this same oxygen in the carboxylato group of Glutamate 67 must be the catalytic base that removes the hydron from ammonia (0.29 nm) while it adds as the nucleophile to uridine and then adds that hydron to the oxyanion coordinated to the Zn^{2+} in the resulting tetrahedral intermediate in the direction of aminolysis so that it can leave as a zinc hydroxide. In each case, this catalytic oxygen moves from oxygen to nitrogen and nitrogen to oxygen by pivoting on the hydrogen bond of its other oxygen to nitrogen 3 of cytidine (0.29 nm) or uridine (0.27 nm).[848] While the carboxy group is pivoting, the hydron within this stationary hydrogen bond that acts as the pivot moves from the oxygen to nitrogen 3 as the other oxygen of the carboxy group removes the hydron from the hydroxide group; and in reverse, the hydron within the hydrogen bond moves from nitrogen 3 to the oxygen as the other oxygen of the carboxy group adds the hydron to the oxygen of the oxyanion in the tetrahedral intermediate.

The crystallographic molecular model of phosphopyruvate hydratase (Equation 4–128) from *S. cerevisiae* and an equilibrium mixture (Figure 3–35) of its three substrates—phospho*enol*pyruvate, water, and 2-phospho-D-glycerate—unambiguously identifies the amino group of Lysine 345 (0.32 nm) as the catalytic base responsible for removing the hydron from carbon 2 of 2-phospho-D-glycerate during the anti elimination and the catalytic acid responsible for adding a hydron to carbon 2 during the anti addition (Figure 4–43).[544,849-851] Oxygens from the carboxy groups of Glutamate 168 (0.24 nm) and Glutamate 211 (0.26 nm) form hydrogen bonds to the 3-hydroxy group. One of the glutamates is the catalytic acid responsible for hydronating the leaving hydroxy group during the anti elimination and the catalytic base responsible for removing a hydron from a molecule of water during the anti addition.

In most instances, however, the equilibrium within an **active site favors the set of substrates on one side of the equation** over the set on the other side when together they occupy the active site. For example, in the case of nicotinate-nucleotide—dimethylbenzimidazole phosphoribosyltransferase from *S. typhimurium* (Figure 3–31), in a complex with its substrates at equilibrium within the active site, nicotinate and α-ribazole 5′-phosphate are the favored pair. In this case, Glutamate 317 can be assigned the role of hydronating nitrogen 3 of the benzimidazolyl group (0.26 nm) in α-ribazole 5′-phosphate to improve its ability as a leaving group. The crystallographic molecular model of the complex between triose-phosphate isomerase (Equations 4–46 and 4–55) from *S. cerevisiae* and glycerone phosphate and D-glyceraldehyde 3-phosphate (Figure 3–37) identifies unambiguously one of the two oxygens of the carboxy group of Glutamate 164 as the catalytic base that transfers the hydron between the two carbons. Even though the equilibrium in the active site favors glycerone phosphate,[852] the oxygen is equidistant from the two carbons (0.3 and 0.3 nm) in the complex.

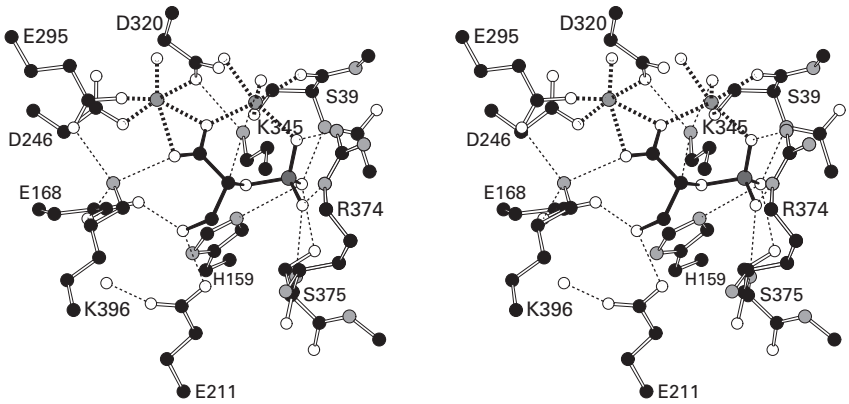


Figure 4–43: Stereodrawing[134] of the crystallographic molecular model of the active site of phosphopyruvate hydratase from *S. cerevisiae* occupied by an equilibrium mixture of 2-phospho-D-glycerate and phospho*enol*pyruvate and H_2O.[544] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, the large dark gray atom is a phosphorus, and the two small dark gray spheres are magnesium ions surrounded by their ligands. Crystals of the enzyme were grown from solutions of phosphopyruvate hydratase (0.3 mM in active sites), 2 mM phospho*enol*pyruvate, 2 mM $MgCl_2$, 15% PEG 8000, 0.25 M KCl, and 50 mM potassium 3-[4-(2-hydroxyethyl)piperazin-1-yl]propane-1-sulfonate at pH 8.0. The omit maps of electron density from these crystals were consistent with the conclusion that an equilibrium mixture of phospho*enol*pyruvate and H_2O and 2-phospho-D-glycerate occupies the active sites in the crystals (Figure 3–35).[851] For simplicity, however, only a molecule of 2-phospho-D-glycerate is drawn (black bonds). The two catalytic Mg^{2+} in the active site, their eleven ligands, and the catalytic acid–bases participating in the reaction were also chosen for inclusion in the drawing, as well as the donors for hydrogen bonds forming the cup for the phospho group of the substrates. This cup anchors the substrates in the active site by their respective phospho groups as they are interconverted at equilibrium.

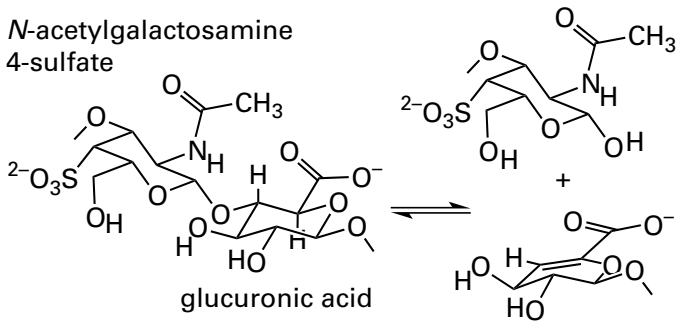
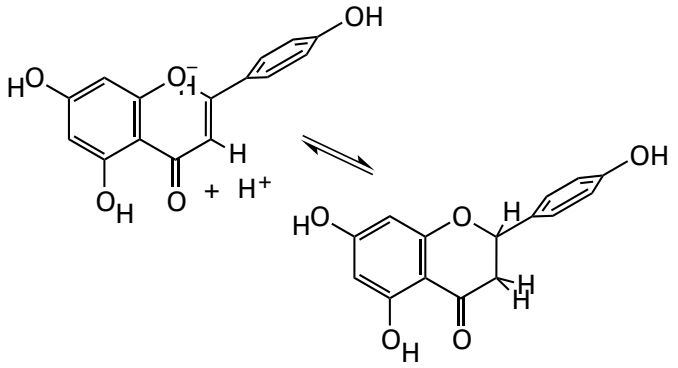
Chondroitin AC lyase from *Paenarthrobacter aurescens* catalyzes a syn elimination to cleave the polymer chondroitin sulfate between one of its *N*-acetylgalactosamine 4-sulfates and one of its glucuronic acids



(4–358)

In a crystallographic molecular model of a complex between a tetrasaccharide of chondroitin sulfate and the enzyme (Figure 4–44),[853] the equilibrium in the active site favors uncleaved reactant, and no electron density is observed for the two separate disaccharides that would be products of the elimination occupying the active site simultaneously. The distance (0.29 nm) between the oxygen of the 4-oxidophenyl group of Tyrosine 242 and carbon 5 of the glucuronic acid, from which the hydron is removed during the elimination, is well within the sum (0.38 nm) of the van der Waals radii of oxygen (0.15 nm) and hydrogen (0.115 nm) and the length of a carbon–hydrogen bond (0.11 nm). The plane of its phenyl ring is oriented such that the lone pair of electrons on the oxygen of its 4-oxidophenyl group, which is in the same plane as the ring, points directly at the carbon–hydrogen bond. The oxygen of the 4-oxidophenyl group of Tyrosine 242 is also only 0.31 nm from the oxygen of the leaving group on carbon 1 of *N*-acetylgalactosamine 4-sulfate. Consequently, during the elimination, the hydron is removed from carbon 5 of glucuronic acid by the oxygen of the 4-oxidophenyl group of Tyrosine 242 to produce the *gem*-enediolate at the 6-carboxy group of glucuronic acid, which is hydronated on one of its two enolate oxygens by Histidine 233 during removal of the hydron. The 4-hydroxyphenyl group then rotates around the bond between carbons β and γ of Tyrosine 242 to swing over and hydronate the leaving oxygen on carbon 1 of *N*-acetylgalactosamine 4-sulfate.

Chalcone isomerase from *M. sativa* catalyzes nucleophilic addition of a weakly basic ($pK_a < 8.4$) phenolate oxygen to an α,β-unsaturated carbonyl



(4–359)

presumably by the usual β addition with an enol as an intermediate. In the crystallographic molecular model of the complex between substrates and the active enzyme, the equilibrium within the active site favors the cyclized adduct.[854] The electron-releasing 4-hydroxyphenyl group on the β carbon of the α,β-unsaturated carbonyl (upper right-hand corner in the respective drawings in Equation 4–359) is rotated by the active site out of conjugation with the α,β-unsaturated carbonyl to prevent the decrease of its electrophilicity by electron donation. The carbonyl oxygen accepts a hydrogen bond from a molecule of water that is a participant in a compound acid formed from a network of hydrogen bonds consisting of that molecule of water, another molecule of water, two oxygens of the 4-oxidophenyl groups from Tyrosines 106 and 152, and the ammonio group of Lysine 97. Together these participants in the compound acid hydronate the carbonyl oxygen, forming the enol during addition of the nucleophilic phenolate oxygen. The hydrogen bond is between the hydron on the immediately adjacent molecule of water in the compound acid and the π system of the carbonyl oxygen, rather than either of its two lone pairs, and the effect of this hydrogen bond is to increase the electrophilicity of the β carbon in the α,β-unsaturated carbonyl to encourage addition of the weak nucleophile.

It is also possible to create an equilibrium between **an intermediate in the reaction** and a substrate that represents one step in a multistep reaction. The nucleophilic addition catalyzed by hydroxymethylglutaryl-CoA synthase

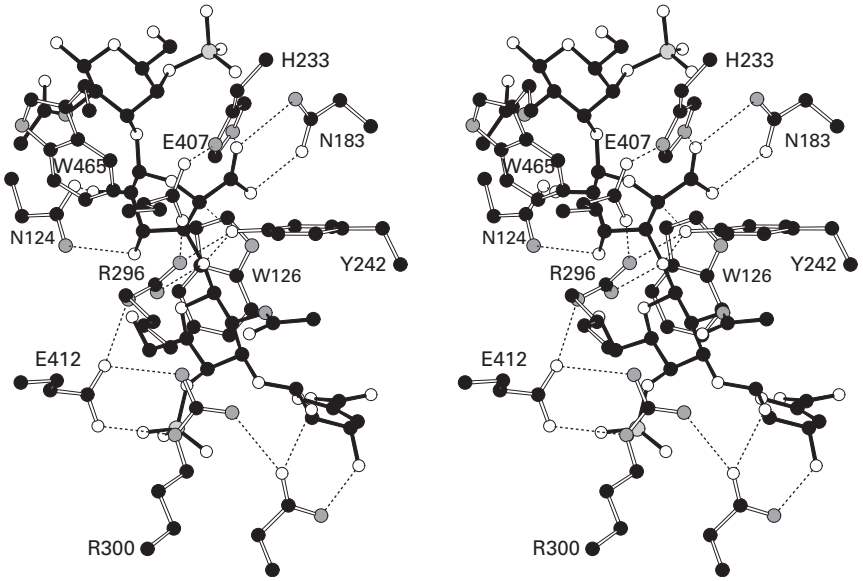


Figure 4–44: Stereodrawing[134] of the crystallographic molecular model of the active site of chondroitin AC lyase from *P. aurescens* occupied by the tetrasaccharide 4-deoxy-α-L-*threo*-hex-4-enuronosyl-(β1,3)-*N*-acetyl-2-deoxy-2-amino-4-sulfato-D-galactosyl-(β1,4)-D-glucuronosyl-(β1,3)-*N*-acetyl-2-deoxy-2-amino-4-sulfato-D-galactose (black bonds).[853] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and large light gray atoms are the sulfurs of the two sulfates. Crystals of the enzyme were suspended in a solution containing 5 mM tetrasaccacharide for 30 s and then rapidly frozen to around 100 K. The omit maps of electron density from the resulting crystals were consistent with the presence of intact molecules of tetrasaccharide in the active sites in the crystals. If the soaking was prolonged, only the disaccharide 4-deoxy-α-L-*threo*-hex-4-enuronosyl-(β1,3)-*N*-acetyl-2-deoxy-2-amino-4-sulfato-D-galactose, which is one of the products of hydrolysis, was present in the active site in the same location its glycosyl groups occupy in the complex with the intact reactant. Consequently, it was concluded that the enzyme was active in the crystal and that the tetrasaccharide in the active site was the favored substrate in the equilibrium catalyzed by the enzyme. The catalytic acid–bases participating in the reaction, Tyrosine 242 and Histidine 233, and donors and acceptors for hydrogen bonds to the tetrasaccharide were chosen for inclusion in the drawing, as well as the indolyl groups of two tryptophans the hydrophobic faces of which stack against the hydrophobic faces of two of the glycosyl groups in the tetrasaccharide. The 4-oxidophenyl group of Tyrosine 242 is responsible for removing a hydron from carbon, and it is connected to the carbon that it services by thinner dashed line to indicate that it may or may not participate in a hydrogen bond with this carbon.

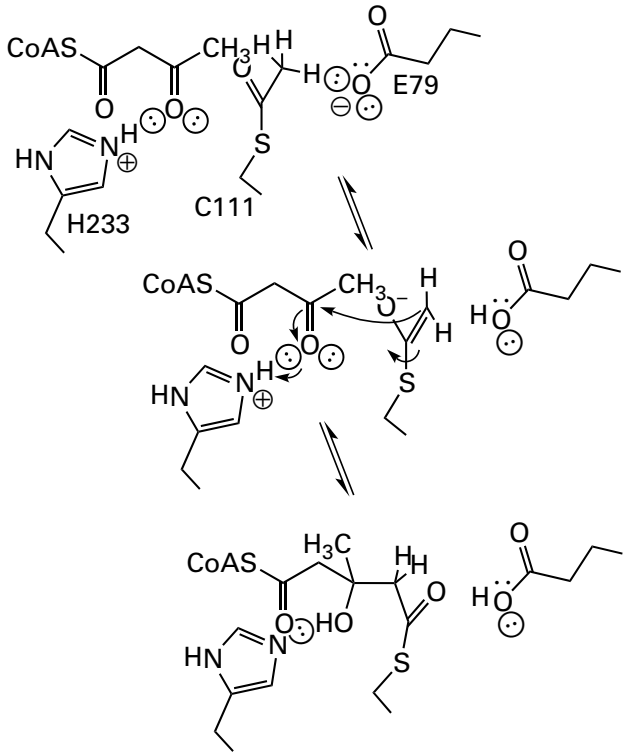
acetyl-SCoA + acetoacetyl-SCoA + H_2O $\rightleftharpoons$ H^+ + HSCoA + (*S*)-3-hydroxy-3-methylglutaryl-SCoA (4–360)

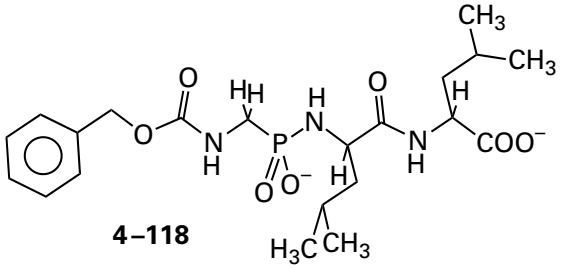
displays ping-pong kinetics[855] and proceeds through two separate steps. In the first step, acetyl-SCoA acetylates the sulfanyl group of a cysteine in the active site.[856,857] In the second step, the enolate of the acetylated cysteine adds to the 3-oxo group of acetoacetyl-SCoA, and the resulting thioester of cysteine is hydrolyzed. In the crystal of the complex between acetoacetyl-SCoA and hydroxymethylglutaryl-CoA synthase from *S. aureus* (Equation 4–361) that had been acetylated on Cysteine 111, the equilibrium between acetyl enzyme and acetoacetyl-SCoA and unacetylated enzyme and (*S*)-3-hydroxy-3-methylglutaryl-SCoA is established with about equal concentrations of reactants and products.[858] In the crystallographic molecular model, it can be seen that the carboxylato group of Glutamate 79 (0.30 nm) is the base that removes the hydron from the acetyl group on Cysteine 111, and the imidazolio group of Histidine 233 (0.31 nm) is the acid that hydronates the 3-oxo group of acetoacetyl-SCoA



(4–361)

during nucleophilic addition of the enolate to the carbonyl.

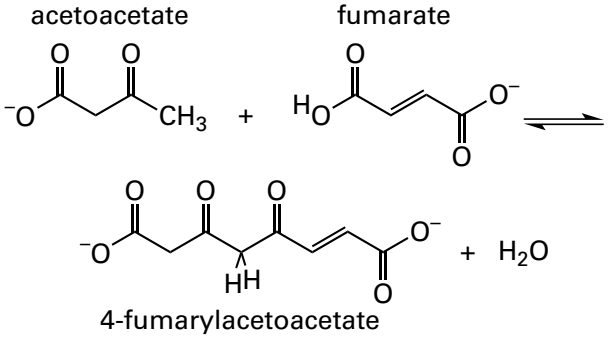
The only structures in which the catalytic acid–bases are revealed unambiguously are the transition states themselves, but these, by definition, are inaccessible to crystallography. By the Hammond postulate,[859] however, crystallographic molecular models of **complexes between analogues for intermediates of high energy and active sites** are close representations of transition states. For example, the crystallographic molecular model (Figure 3–42) of the complex between thermolysin from *Bacillus thermoproteolyticus* and phosphonamidate



4–118

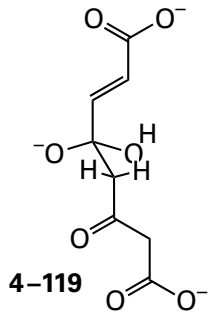
which mimics the tetrahedral intermediate in the enzymatic reaction, clearly identifies the composite catalytic base formed from the side chains of Histidine 231 and Aspartate 226 as the catalytic base (0.32 nm) that removes the hydron from the molecule of water that is bound to Zn^{2+} and that adds nucleophilically to the acyl carbon of the peptide bond hydrolyzed by the enzyme. The molecular model also identifies the carboxy group of Glutamate 143 as the catalytic acid (0.34 nm) that performs the inescapable hydronation of the amino group that leaves the resulting tetrahedral intermediate in the hydrolysis. The crystallographic molecular model of the complex between the phosphatase encoded by the BT4131 gene of *Bacteroides thetaiotaomicron* and vanadate (Figure 3–43), which mimics the phosphorane that is the intermediate in the hydrolysis catalyzed by this enzyme, clearly identifies the carboxy group of Aspartate 10 as the catalytic base (0.27 nm) that removes the hydron from the nucleophilic molecule of water or the catalytic acid that adds a hydron to the leaving group in reverse.

Fumarylacetoacetase catalyzes a Claisen condensation

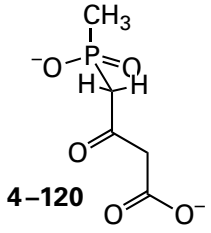


(4–362)

that passes through a tetrahedral intermediate (**4–119**)



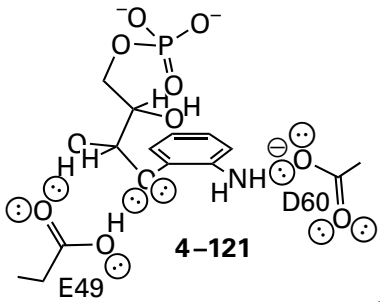
4–119



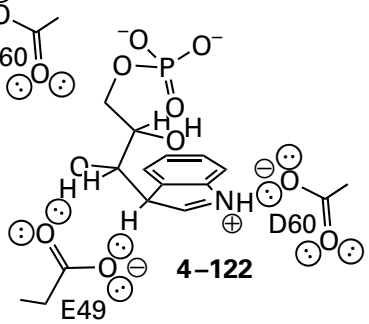
4–120

This tetrahedral intermediate is mimicked by 4-(hydroxymethylphosphinoyl)-3-oxobutanoate (**4–120**). In the crystallographic molecular model of the murine enzyme in a complex with phosphinate **4–120**,[860] the distance (0.42 nm) between the nitrogen of the amino group of Lysine 253 and methylene carbon 4 of the analogue of the intermediate is close to the sum (0.39 nm) of the van der Waals radii of nitrogen (0.16 nm) and hydrogen (0.115 nm) and the length of a carbon–hydrogen bond (0.11 nm). This amino group has been assigned as the catalytic base that removes the hydron from the methyl group of acetoacetate (Equation 4–362)[861] to form its enolate, the oxyanion of which is a ligand to a Ca^{2+}. The hole for the other oxyanion in the enzymatic reaction, that of intermediate **4–119**, is formed by the ammonio group of Lysine 253, the guanidinio group of Arginine 237, and the amido group of Glutamine 240. The hydroxy group that is analogous to the leaving group from intermediate **4–119** during the final step of the Claisen condensation forms a hydrogen bond with the imidazolyl group of Histidine 133 (0.27 nm) in the complex with the analogue of the intermediate and has been assigned as the catalytic acid that is responsible for its hydronation to enhance its ability to leave as a molecule of water

There is a crystallographic molecular model (Figure 4–45)[862] of the complex between (*R*)-1-(2-aminophenoxy)glycerol 3-phosphate (**4–121**)

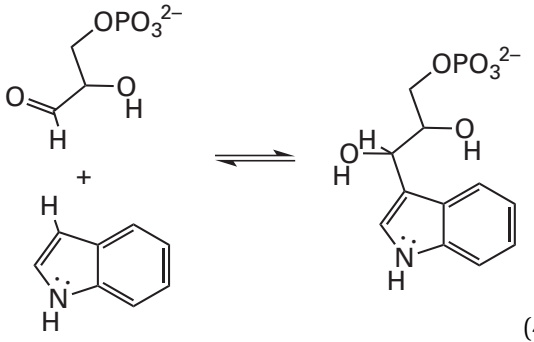


4–121



4–122

and the active site for indole-3-glycerol-phosphate lyase within tryptophan synthase from *S. typhimurium*, which condenses indole and D-glyceraldehyde 3-phosphate (previously Equation 3–524)



(4–363)

Hemiacetal **4–121** is an analogue of intermediate **4–122** in addition of the enamine in the pyrrolyl group of the indole to the carbonyl group of D-glyceraldehyde 3-phosphate catalyzed by the enzyme. In this molecular model, Glutamic Acid 49 is identified as the catalytic acid that hydronates the carbonyl oxygen of glyceraldehyde 3-phosphate to increase its electrophilicity and also the catalytic base, after the hydronation, that accepts the hydron that is removed from the indolyl group to restore the aromaticity. The molecular model also identifies Aspartate 60 as the catalytic base that stabilizes the cationic iminium nitrogen in the intermediate formed after addition of the enamine, perhaps by fleetingly dehydronating it. In the crystallographic molecular model of the complex between the enzyme

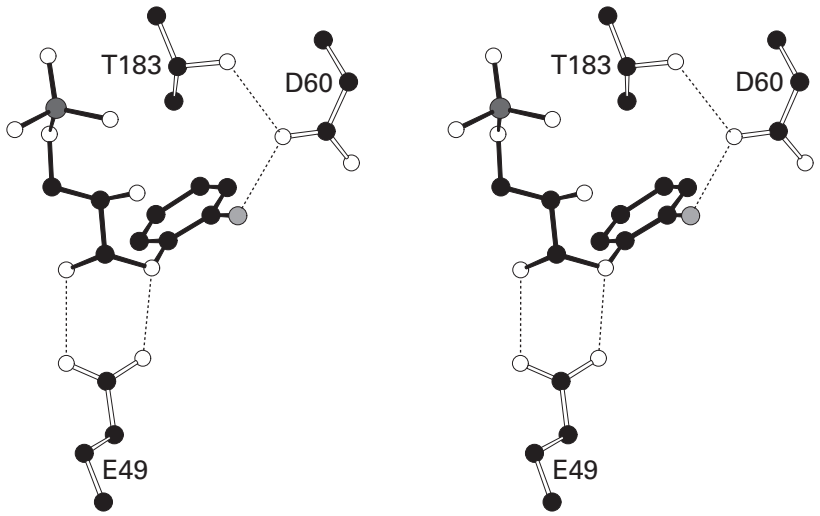


Figure 4–45: Stereodrawing[134] of the crystallographic molecular model of catalytic acid–bases in the active site of tryptophan synthase from *S. typhimurium* occupied by the hemiacetal (*R*)-1-(2-aminophenoxy)glycerol 3-phosphate.[862] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large dark gray atom is a phosphorus. Crystals of the enzyme and crystals of solid 2-aminophenol to achieve saturation were suspended in a solution containing 70 mM D-glyceraldehyde 3-phosphate, 20% (w/v) PEG 8000, 20% (v/v) glycerol, and 75 mM 2-[bis(2-hydroxyethyl)amino]acetate at pH 7.8 for 20 min and then rapidly frozen. The omit maps of electron density from the resulting crystals were consistent with molecules of (*R*)-1-(2-aminophenoxy)glycerol 3-phosphate (black bonds), the hemiacetal of D-glyceraldehyde 3-phosphate and 2-aminophenol, occupying the active sites of the enzyme in the crystals. Only the catalytic acid–bases participating in the reaction, Glutamate 49 and Aspartate 60, as well as Threonine 183, which positions the carboxy group of Aspartate 60, were chosen for inclusion in the drawing.

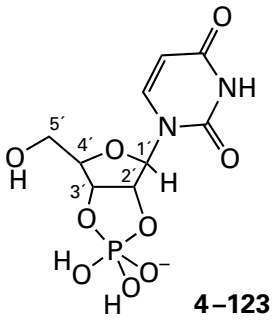
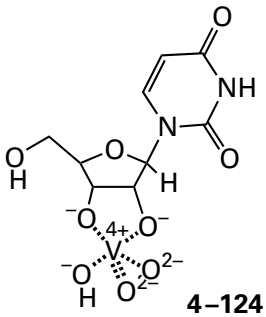
and 3-(indol-3-yl)propanol phosphate, an analogue of the substrate 1-*C*-(indol-3-yl)glycerol 3-phosphate (product in Equation 4–363) rather than the intermediate, Aspartate 60 forms a hydrogen bond (0.28 nm) with nitrogen 1 of the indolyl group[863] that is to become the iminium nitrogen during hydronation at carbon 3 of the indolyl group, which is the first step in the reverse reaction.

In aqueous solutions, oxovanadium(IV) usually forms octahedral complexes with its oxo group and five oxygens from its other ligands at the six octahedral positions, but complexes in which only five oxygens surround the vanadium(IV) have also been observed. A complex between uridine and oxovanadium(IV) was found to inhibit bovine ribonuclease competitively (K_i = 10 μM).[864] Ribonuclease, as the second half of its complete mechanism, catalyzes the hydrolysis of nucleoside 2′,3′-cyclic phosphates (Equation 4–104). During that reaction, phosphorane **4–123** should be formed in which the leaving group, the oxygen of the hydroxy group on carbon 2′, should be at an apical position in a trigonal bipyramid



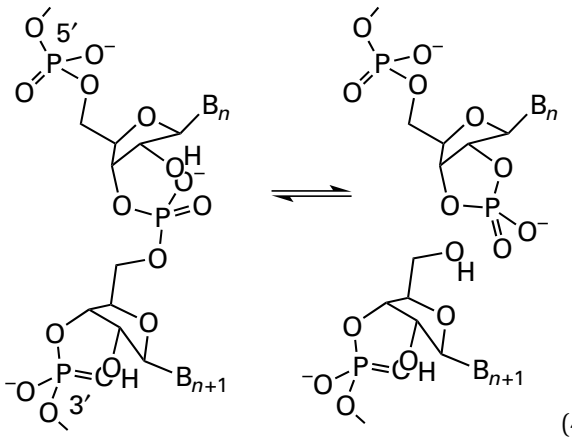
4–123



4–124

As originally proposed,[864] it was seen in the subsequent crystallographic molecular model that the strong inhibition observed with the complex between oxovanadium(IV) and uridine results from binding to the active site of the pentacoordinate complex **4–124** between uridine, vanadate, and water (Figure 4–46)[152,865] that mimics the phosphorane.*

This crystallographic molecular model between bovine ribonuclease and uridine 2′,3′-cyclic vanadate identifies Lysine 41 as the catalytic base responsible for that removes the hydron from the 2′-hydroxy group during the first half of the cleavage of a molecule of RNA



(4–364)

that produces the 2′,3′-cyclic phosphate; and it also identifies Lysine 41 as the catalytic acid that hydronates the leaving 2′-oxygen during the subsequent hydrolysis of the 2′,3′-cyclic phosphate (Equation 4–104) that constitutes the second half of the complete reaction. In addition, this molecular model identifies Histidine 119 as the catalytic acid that hydronates the leaving 5′-hydroxy group during the initial cleavage of a molecule of RNA (Equation 4–364) and also the catalytic base that removes the hydron from a molecule of water during hydrolysis of the resulting 2′,3′-cyclic phosphate. These assignments follow from the fact that these two oxygens at the axial positions in the vanadyl complex are acceptors in hydrogen bonds with the side chains of these two amino acids. The role of Histidine 12 is to stabilize the phosphorane by forming a hydrogen bond with one of the axial oxygens.

Crystallographic molecular models of inert complexes between one reactant and one product, in which **a group normally transferred between two reactants is missing**, also identify acid–bases catalyzing the reaction. For example, in the complex between guanidinoacetate *N*-methyltransferase from *R. norvegicus* and *S*-adenosyl-L-homocysteine and guanidinoacetate (Figure 3–34), which is missing the methyl group that is transferred in the normal reaction between these two substrates, it can be seen that a carboxylato oxygen of Aspartate 134 is the catalytic base (0.30 nm) responsible for removing a hydron from the guanidino nitrogen of guanidinoacetate to turn it into a nucleophile. In the complex between human 2,4-dienoyl-CoA reductase [(3*E*)-enoyl-CoA-producing] and $NADP^+$ and hexa-2,4-dienoyl-SCoA, the hydride transferred between NADPH and hexa-2,4-dienoyl-SCoA in the normal reaction is missing. The crystallographic molecular model[866] identifies Tyrosine 199 as the catalytic acid (0.25 nm) that hydronates the acyl oxygen to increase

*The van der Waals radius of vanadium (0.179 nm) is the same as that of phosphorus (0.180 nm).

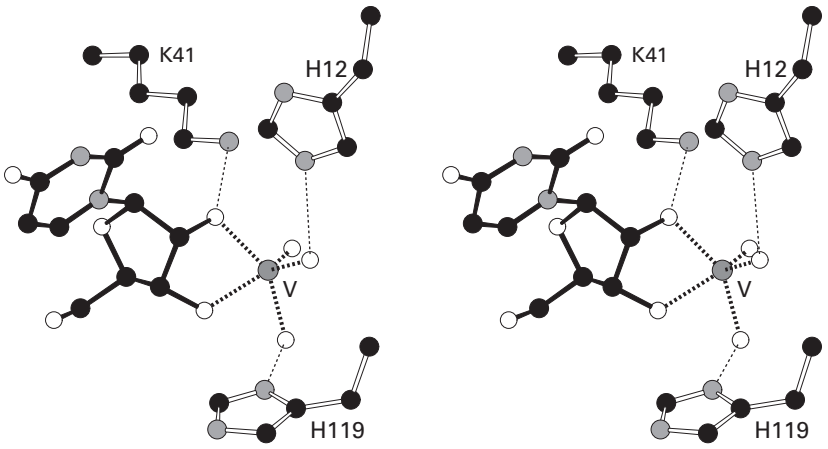


Figure 4–46: Stereodrawing[134] of the crystallographic molecular model of catalytic acid–bases in the active site of bovine pancreatic ribonuclease occupied by uridine 2′,3′-cyclic vanadate, an analogue of the phosphorane that is an intermediate in the reaction.[865] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the dark gray sphere is a vanadium ion surrounded by its ligands. Crystals of bovine pancreatic ribonuclease were produced in 43% (v/v) 2-methyl-2-propanol at pH 5.3; transferred to a solution of 15 mM ammonium uridyl vanadate, 60 mM NH_4VO_3, 50% (v/v) 2-methyl-2-propanol, and 25 mM imidazole at pH 6.2; and soaked for 10 days. Omit maps of electron density from the resulting crystals were consistent with the presence of a molecule of uridine 2′,3′-cyclic vanadate (**4–124**, solid bonds) in each active site in the crystals. Only the key catalytic acid–bases participating in the reaction—Histidine 12, Histidine 119, and Lysine 41—were chosen for inclusion in the drawing.

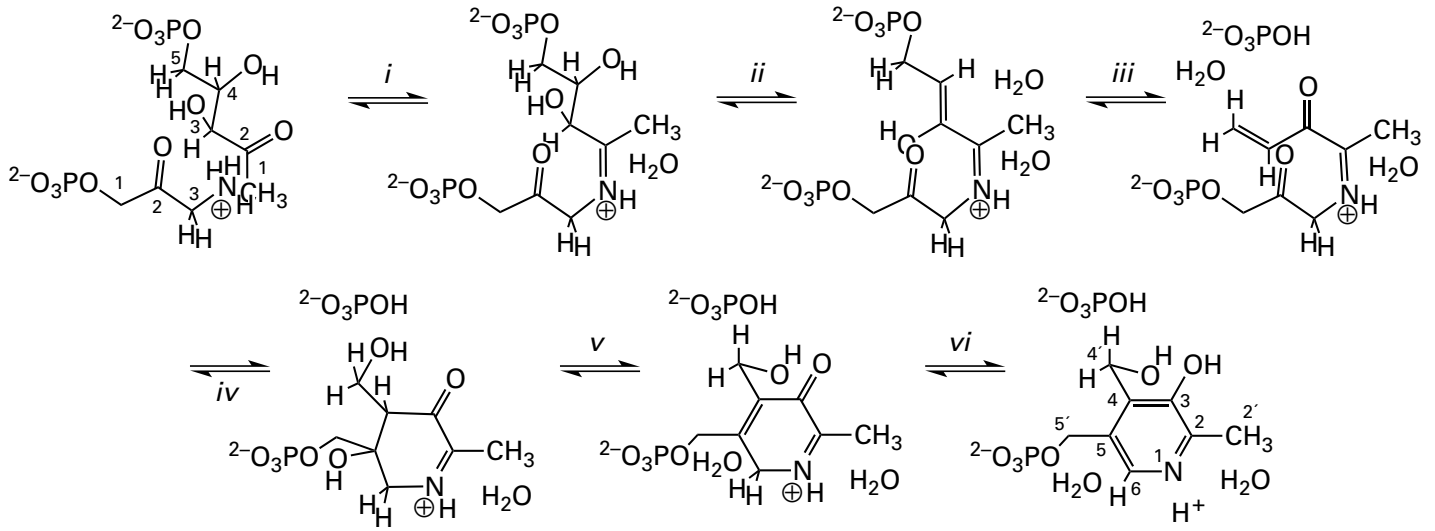

Figure 4–47: Steps in the mechanism for the reaction catalyzed by pyridoxine 5′-phosphate synthase.[867] The reactants for the direction shown are 1-deoxy-D-xylulose 5-phosphate (upper right in first panel) and 3-amino-2-oxopropyl phosphate (lower left in first panel). (*i*) Nucleophilic addition of the amino group to the 2-oxo group of 1-deoxy-D-xylulose 5-phosphate produces the iminium. (*ii*) Dehydration produces the *α,β*-unsaturated iminium, the enol in which then undergoes (*iii*) *β* elimination of phosphate to produce the *α,β*-unsaturated ketone. (*iv*) Addition of hydroxide, which takes the place of the phosphate that left, to the distal carbon of the *α,β*-unsaturated ketone produces the enolate, the anionic carbon of which adds to the ketone across the way to cyclize the intermediate and produce the six-membered ring. (*v*) Dehydration then produces the second unsaturation in the ring, followed by (*vi*) tautomerization of the newly formed *α,β*-unsaturated ketone by removal of its *γ* hydron to aromatize the ring and produce pyridoxine 5′-phosphate.

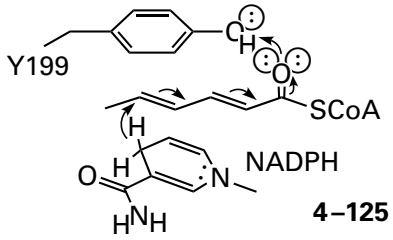
the electrophilicity of carbon 5 of hexa-2,4-dienoyl-SCoA for the hydride from NADPH



4–125

For enzymes with two reactants, the crystallographic molecular model of an **inert complex between the enzyme and one reactant and an analogue of the other** can identify catalytic acid–bases operating on the actual reactant and can tentatively identify those acting on groups in common between the other reactant that has been substituted by the analogue. For example, pyridoxine 5′-phosphate synthase catalyzes a reaction

1-deoxy-D-xylulose 5-phosphate +
3-amino-2-oxopropyl phosphate $\rightleftharpoons$
pyridoxine 5′-phosphate + phosphate + 2 H_2O (4–365)

that proceeds through five intermediates (Figure 4–47).[867] Each step between one intermediate and the next requires both a catalytic base and a catalytic acid. In the crystallographic molecular model of an inert complex between the enzyme from *E. coli* and 1-deoxy-D-xylulose 5-phosphate and D-glycerol phosphate [(*R*)-2,3-dihydroxypropyl phosphate], which is an analogue of the normal substrate 3-amino-2-oxopropyl phosphate, the catalytic acids and bases for the first steps in the mechanism line up along 1-deoxy-D-xylulose (Figure 4–48A). In the crystallographic molecular model of an enzymatically active complex between the enzyme and pyridoxine 5′-phosphate, phosphate, and water, which are the substrates favored by the equilibrium in the active site, the catalytic acids and bases for the last steps in the mechanism line up around pyridoxine 5′-phosphate and phosphate (Figure 4–48B).[868] These two models together assign the catalytic acids and bases responsible for all six of the individual steps (Figure 4–47).

In the first crystallographic molecular model (Figure 4–48A), it can be seen that Glutamate 72 consecutively removes the two hydrons from the 3-ammonio group of 3-ammonio-2-oxopropyl phosphate, represented by the 3-hydroxy group of

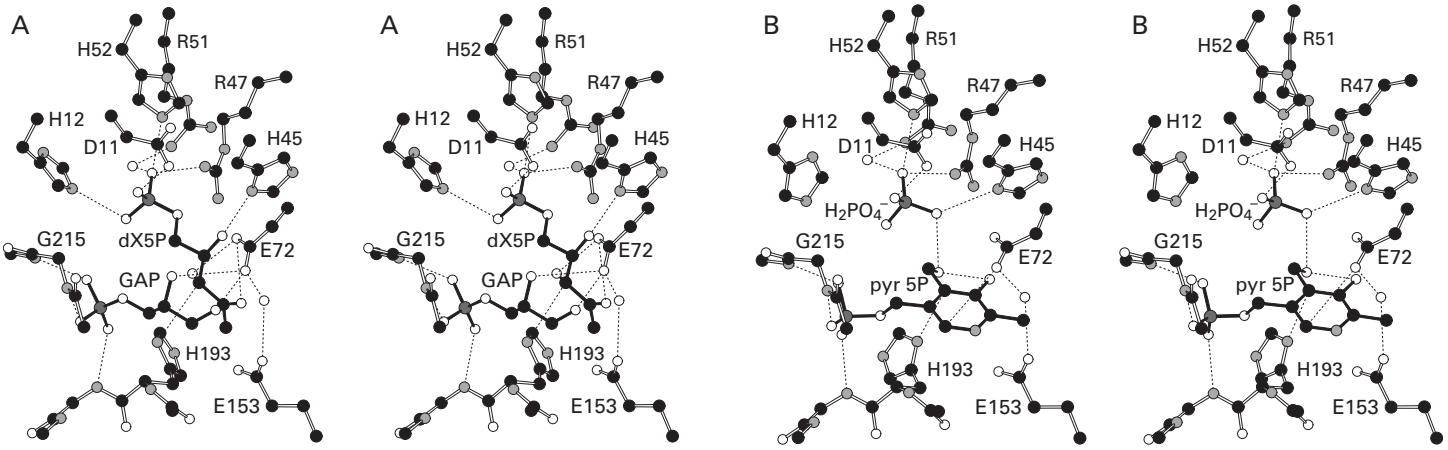


Figure 4–48: Stereodrawings[134] of crystallographic molecular models of the active site of pyridoxine 5′-phosphate synthase from *E. coli* occupied by (**A**) the substrate 1-deoxy-D-xylulose 5-phosphate (dX5P) and glyceraldehyde 3-phosphate (GAP), an analogue of the cosubstrate 3-amino-2-oxopropyl phosphate, or by (**B**) the substrate pyridoxine 5′-phosphate (pyr 5P) and its cosubstrate, phosphate ($H_2PO_4^-$).[868] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the two large dark gray atoms are atoms of phosphorus. The enzyme was overexpressed in *E. coli*, purified, and crystallized from 10% poly(ethylene glycol) and 2 M NaCl at pH 8.0, and the crystals were then isolated and soaked in a solution of (**A**) 2.5 mM 1-deoxy-D-xylulose 5-phosphate and 2.5 mM glyceraldehyde 3-phosphate for 4 h or (**B**) 5 mM pyridoxine 5′-phosphate, 5 mM glyceraldehyde 3-phosphate, and $H_2PO_4^-$ for 1 h. The three substrates and the analogue in the resulting crystallographic molecular models of Panels A and B are anchored firmly in the active sites by the respective phospho groups sitting in their cups of donors for hydrogen bonds. The catalytic acid–bases are shown in the drawing forming hydrogen bonds to the heteroatoms that they service. Acid–bases responsible for removing hydrons from carbon are connected to the carbons that they service by thinner dashed lines (one in Panel A and two in Panel B) to indicate that they may or may not participate in hydrogen bonds with those carbons.

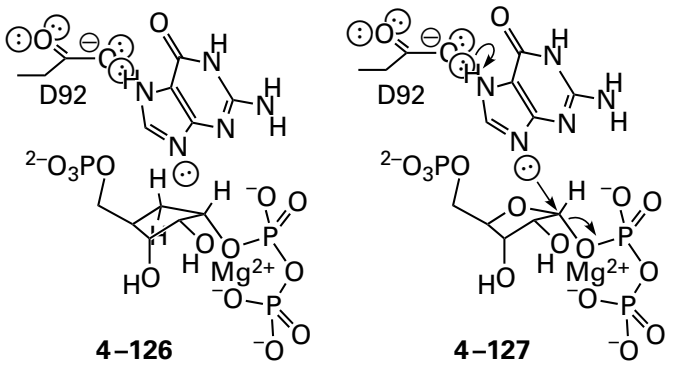
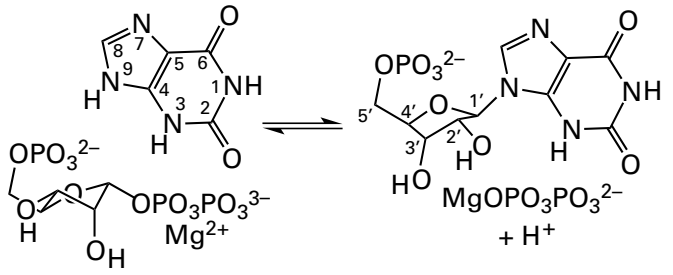
glycerol phosphate (0.24 nm)*, and transfers them consecutively to the 2-carbonyl oxygen of 1-deoxy-D-xylulose 5-phosphate (0.34 nm) that leaves as water in step *i*. Histidine 193 removes the hydron from former carbon 3 of 1-deoxy-D-xylulose 5-phosphate (0.37 nm), and Histidine 45 hydronates the former 4-hydroxy group (0.26 nm) that leaves as water in step *ii*. Glutamate 72 removes the hydron from the former 3-hydroxy group (0.29 nm) of 1-deoxy-D-xylulose 5-phosphate in step *iii*, and Glutamate 72 then hydronates the former carbonyl group of 3-amino-2-oxopropyl phosphate, represented by the 2-hydroxy group (0.34 nm) of the glycerol phosphate, in step *iv*.

In the second crystallographic molecular model (Figure 4–48B), it can be seen that Histidine 45 hydronates the oxygen of the phosphate (0.31 nm) that leaves in step *iii* and that the composite base formed from Histidine 45 and the oxygen of that phosphate removes the hydron from the molecule of water that becomes the eventual 4′-hydroxy group (0.29 nm) of pyridoxine 5′-phosphate in step *iv*. Glutamate 72 then adds a hydron, perhaps shuttled from Glutamate 153, to the hydroxy group that leaves as water, and Histidine 193 removes the hydron from carbon (0.41 nm) in step *v*. A hydron is then relayed from Histidine 45 through the oxygen (0.31 nm) of the phosphate and the 4′-hydroxy group (0.29 nm) of pyridoxine 5′-phosphate to the carbonyl that becomes the 3-hydroxy group (0.25 nm) of pyridoxine 5′-phosphate, and Glutamate 72 removes the hydron from carbon 6 (0.37 nm) of the soon-to-become pyridoxine 5′-phosphate in step *vi*.

Analogue **4–126** of 5-phospho-α-D-ribofuranose 1-diphosphate (**4–127**)[869,870]



because it lacks the oxygen that stabilizes the transition state resembling an oxocarbenium ion in the enzymatic reaction, is not a substrate for xanthine phosphoribosyltransferase



(4–366)

from *E. coli* (see Equations 3–251 and 3–398).

From an examination of the crystallographic molecular model[870] of a complex of the enzyme with analogue **4–126** and guanine, which is also a substrate for the enzyme, one oxygen of the carboxy group of Aspartate 92 can be assigned as the catalytic acid (0.26 nm) that hydronates nitrogen 7 of xanthine or guanine to stabilize the tautomer with a hydron on nitrogen 7 rather than nitrogen 9. The only catalytic base in the vicinity of nitrogen 9 that could remove a hydron from it and in turn stabilize the same tautomer, which lacks a hydron on nitrogen 9 as required by the reaction (**4–127**), is the oxygen (0.39 nm away) on the α-phospho group of the magnesium diphosphate of analogue **4–126**. The hydron or the lone pair of electrons on nitrogen 9 in the molecular model is pointed straight at this oxygen. Neither of the nonbonding oxygens on the α-phospho group is a ligand to the Mg^{2+}. Nevertheless, the α-phospho group on the usual substrate, 5-phospho-α-D-ribofuranose 1-diphosphate, should be a rather weak base ($pK_a \cong 2$), but once nitrogen 7 is hydronated, the hydron on nitrogen 9 should be a fairly strong acid ($pK_a \cong 4$), and when analogue **4–126** is bound in the active site, the α-phospho group is exposed over most of its surface to the aqueous phase, which would serve as a sink to which it could transfer the hydron. As the reaction proceeds, the carboxylato group of Aspartate 92 acts as a catalytic base that removes the hydron from nitrogen 7 and increases the nucleophilicity of the lone pair of electrons on nitrogen 9. Nitrogen 7 of guanine is homologous to nitrogen 3 of 5,6-dimethylbenzimidazole in the reaction catalyzed by nicotinate-nucleotide—dimethylbenzimidazole phosphoribosyltransferase (Figure 3–31) from which a carboxylato

*The numbers in parentheses are the distances in the relevant crystallographic molecular model, either that in Panel A or that in Panel B, between the two atoms between which a hydron is transferred during the steps in the enzymatic reaction.

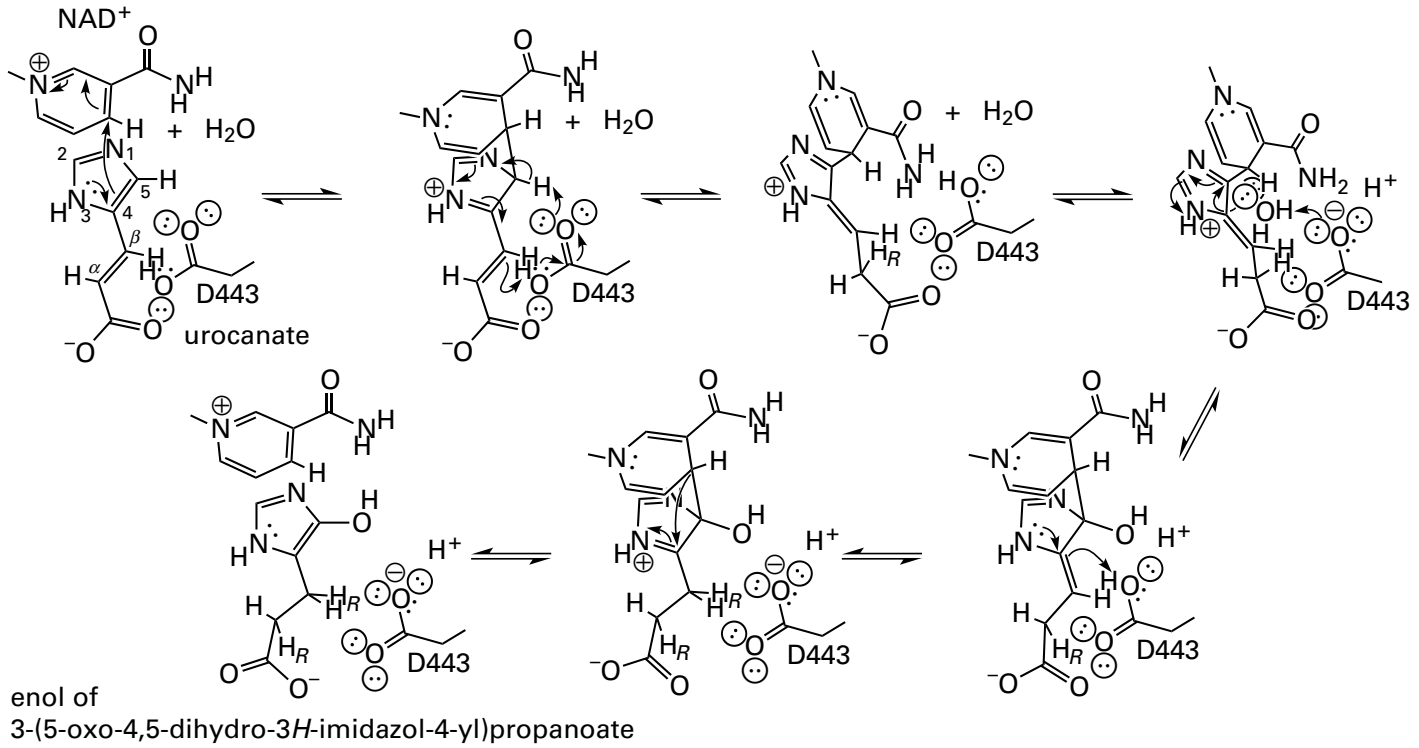


Figure 4–49: Steps in the mechanism for the reaction catalyzed by urocanate hydratase.[871] The reactants for the direction shown are urocanate and water, and the enzyme has a tightly bound NAD^+ as a prosthetic group in its active site. Nucleophilic addition of carbon 4 in the electron-rich imidazolyl group in urocanate to the electrophilic carbon 4 of NAD^+ initiates the reaction. In the resulting adduct, the aromaticity of the imidazolyl group is broken so that it has become two imines linked head to tail. The next step is a tautomerization to produce the exocyclic enamine of one of these imines. A molecule of water then adds nucleophilically to the imino carbon of the other imine to produce a hemiaminal next to a now-neutral enamine. The enamine is hydronated on its carbanionic carbon to produce the corresponding iminium. The parallel π system of this iminium withdraws electrons from the bond to the nicotinamide, and it breaks heterolytically to regenerate NAD^+ and the enol of the product, 3-(5-oxo-4,5-dihydro-3*H*-imidazol-4-yl)propanoate. Every hydron transfer is catalyzed by the carboxy group of Aspartate 443 in the enzyme from *P. putida* (Figure 4–50).

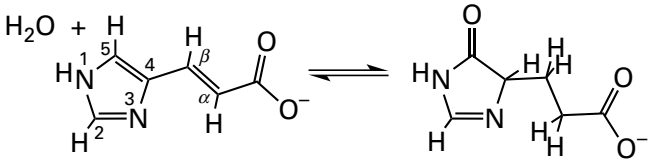
group removes a hydron to increase the nucleophilicity of the other nitrogen in the imidazolyl group.

Crystallographic molecular models of **complexes between inactive mutants and the usual substrates** can identify catalytic acids and bases. The crystallographic molecular model of the complex between an inactive mutant of phosphoserine phosphatase from *Methanocaldococcus jannaschii*, and the usual reactant *O*-phospho-L-serine (Figure 3–56) identifies Aspartate 13 as the catalytic acid that hydronates the β-oxygen of the L-seryl group to ensure its ability to leave from phosphorus. In the normal reaction catalyzed by the enzyme, the phospho group is transferred to the carboxy group of Aspartate 11, which has been changed to asparagine in the mutant, causing it to be inactive.

A less drastic change results from the mutation of Arginine 455 in the active site of urocanate hydratase (previously Equation 1–84)



(4–367)

from *P. putida*. The guanidinio group of Arginine 455 is not a catalytic acid–base. Rather, in the unmutated active site of this enzyme, it sterically pushes on carbon 2 of the nicotinamide ring in the prosthetic nicotinamide adenine dinucleotide that is within the active site. When the guanidinio group is removed by mutation, the nicotinamide ring relaxes and tilts away from its proper position for its electrophilic addition to the urocanate (Figure 4–49),[871] and the mutant is catalytically inactive. Crystallographic molecular models of the unliganded native enzyme and of the mutant enzyme with its active site occupied by urocanate were prepared. In a hybrid molecular model (Figure 4–50)[872] of the active site

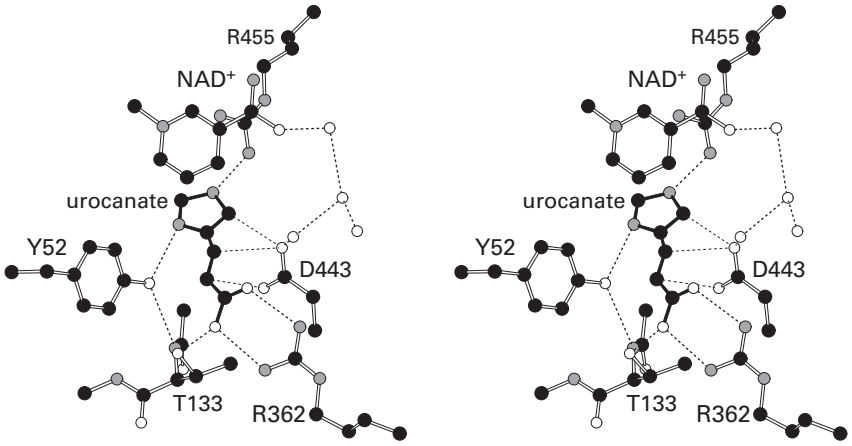


Figure 4–50: Stereodrawing[134] of the crystallographic molecular model of the active site of urocanate hydratase from *P. putida* occupied by the substrate urocanate.[872] Black atoms are carbons, white atoms are oxygens, and small gray atoms are nitrogens. Genes for both the native enzyme and an enzymatically inactive mutant in which Arginine 455 had been changed to alanine were overexpressed in *E. coli*. The two enzymes were purified and crystallized from 12% (w/v) poly(ethylene glycol) 8000, 90 mM sodium acetate, and 50 mM sodium cacodylate at pH 5.8. Crystals of the mutant were soaked in a solution of 10 mM urocanate. In the molecular model of the active site of the native enzyme, Arginine 455 was seen to be sterically tilting the ring of NAD^+, a tightly bound prosthetic group in the active site of the enzyme, into a conformation believed to be required for activity. In the active site of the molecular model of the mutant enzyme soaked in the solution of urocanate, electron density for urocanate could be observed in the active site. The drawing was made by combining urocanate, three molecules of water, and the side chains of Tyrosine 52, Threonine 133, Arginine 362, and Aspartate 443 from the molecular model of the active site of the mutant enzyme with NAD^+, a molecule of water, and the side chain of Arginine 455 from the molecular model of the native unoccupied enzyme. Consequently, the tilt produced by the arginine, which does not occur in the mutant, is depicted in the drawing. The most active acid–base catalyzing the reaction (Figure 4–49) is the carboxy group of Aspartate 443, which adds and removes hydrons from the three carbons connected to it in the drawing by thin dashed lines. The carboxy group swings between the two upper carbon atoms and to the molecule of water that is a substrate in the reaction by rotating around the α,β bond and swings up to the lower carbon by rotating around the β,γ bond. Tyrosine 52 ensures that nitrogen 3 of the imidazolyl group remains hydronated during the reaction, and Arginine 455 ensures that nitrogen 1 remains unhydronated. The four molecules of water clustered at the top right are connected directly to the solution and represent the source of the water that is a substrate in the reaction.

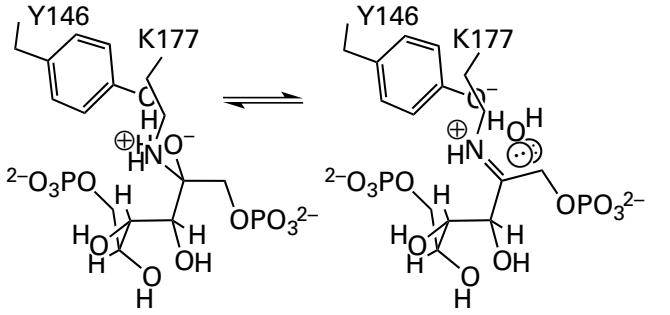
constructed from the model of the mutant protein occupied by urocanate and the model of the native enzyme, it can be seen that the carboxy group of Aspartate 443 is positioned to perform by itself all four of the hydron transfers required by the mechanism of the enzyme (Figure 4–49). It was known from stereochemical experiments that hydrons from the solution assumed the *pro-R* positions on carbons 2 and 3 of the product 3-(5-oxo-4,5-dihydro-3*H*-imidazol-4-yl)propanoate.[873] The stereochemical observations agree with the location of the carboxy group of Aspartate 443 in the model and serve to confirm its identity as the catalytic acid–base.

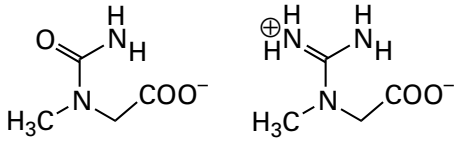
When Tyrosine 146 in fructose-bisphosphate aldolase from *Thermoproteus tenax* is mutated to phenylalanine, the enzyme is inactivated. In the normal reaction catalyzed by the enzyme (Figure 4–36), Lysine 177 forms an imine with the carbonyl carbon of fructose 1,6-bisphosphate in a nucleophilic substitution. In a crystallographic molecular model of the complex between the inactive enzyme and fructose 1,6-bisphosphate,[874] the enzymatic reaction is stalled at the zwitterion of the hemiaminal between the carbonyl of fructose 1,6-bisphosphate and the amino group of Lysine 177 in the active site (see Figure 1–7). The enzymatic reaction stalls at the zwitterion of the hemiaminal because Tyrosine 146, which has been mutated, is normally responsible for hydronating the oxygen of the hemiaminal and then shuttling a hydron from the ammonio group of Lysine 177 to the same oxygen so that it can leave as water to produce the iminium*



(4–368)

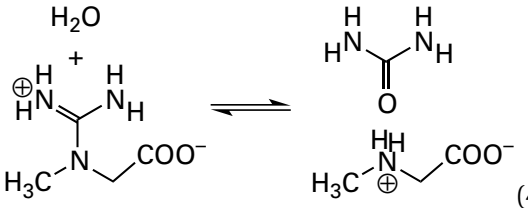
The fact that the enzymatic reaction stalls at this step is another example of the impossibility of transferring a hydron intramolecularly between two heteroatoms that are attached to the same carbon.

For enzymes with only one reactant and one product, other than water, crystallographic molecular models of **complexes between the enzyme and an inactive analogue of the sole reactant or product** can identify catalytic acid–bases. For example, the complex between creatinase from *P. putida* and carbamoyl sarcosine (**4–128**)



4–128 **4–129**

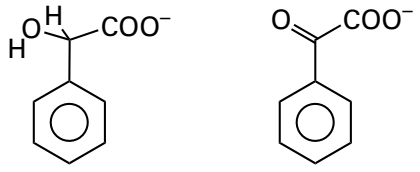
an inactive analogue of creatine (**4–129**) identifies the imidazolyl group of Histidine 232 as the catalytic base that removes the hydron from a fixed molecule of water in the active site to promote its nucleophilic addition to the guanidinio carbon in the hydrolysis catalyzed by the enzyme



(4–369)

and then as the catalytic acid that hydronates the nitrogen of the *N*-methylglycine that leaves from the tetrahedral intermediate.[875]

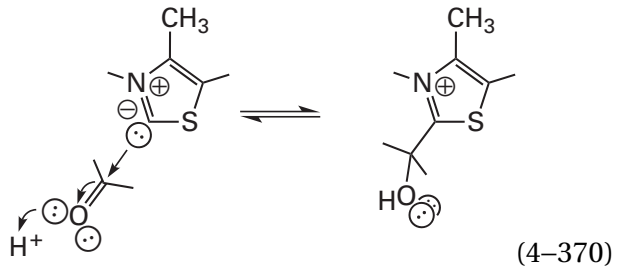
R-Mandelate (**4–130**)



4–130 **4–131**

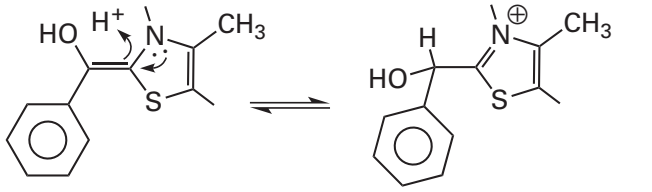
is an analogue of benzoylformate (**4–131**), which is decarboxylated to benzaldehyde by benzoylformate decarboxylase, an enzyme that uses thiamine diphosphate as a prosthetic group. The crystallographic molecular model of a complex between the enzyme from *P. putida* and *R*-mandelate identifies Histidine 70 as the catalytic acid that hydronates the carbonyl group of benzoylformate (**4–131**) during nucleophilic addition of the ylide of thiamine diphosphate (previously Equation 2–49)

*Carbon 4 of the phenylalanine is equidistant (0.42 nm) from the oxygen and the nitrogen of the hemiaminal and oriented so that, if it had a hydroxy group, as it does in Tyrosine 146, that hydroxy group would sit between the oxygen and the nitrogen of the hemiaminal within the length of a hydrogen bond to each.



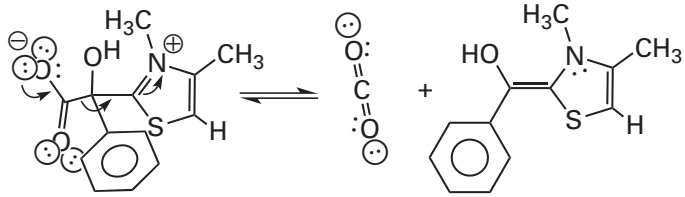
(4–370)

and Histidine 281 as the catalytic acid that hydronates the eventual carbonyl carbon of the incipient benzaldehyde



(4–371)

following the decarboxylation[876] (see Equations 2–51 and 2–54)



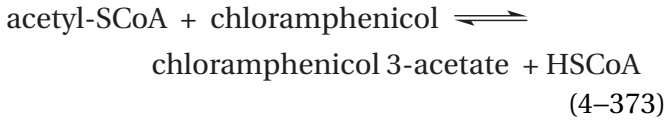
(4–372)

When Histidine 70 is mutated to alanine, the rate constant $k_0\,K_m^{-1}$ decreases by a factor of 18,000, and when Histidine 281 is mutated to alanine, it decreases by a factor of 800.

If an enzyme has two reactants, it is often possible to form a **complex with just one of the two reactants.** The crystallographic molecular model of such a complex, however, **can be misleading** because in many instances the active site is not fully assembled, nor are the catalytic groups properly aligned, until the protein closes around both reactants. For example, when ribulose-bisphosphate carboxylase (Equation 4–353) from *S. oleracea* associates with D-ribulose 1,5-bisphosphate and not with CO_2,[877] the active site fails to close completely around the substrate as it does when it closes around 2-carboxyarabinitol,[878] an analogue of the carboxylated enolate of D-ribulose 1,5-bisphosphate, the central intermediate in the mechanism of the reaction. Consequently, the identification of the N^6-carboxy group of carboxylated Lysine 201, acting alone, as the base that removes the hydron from carbon 3 of D-ribulose 1,5-bisphosphate (0.31 nm) to form the enolate in the first step in the reaction is equivocal. The proximate oxygen of the carboxy group on N^6-carboxylysine, because the other oxygen is a ligand to a Mg^{2+}, would be a weak base indeed ($pK_a < -2$). One possible solution to this problem is that a composite base could form between the proximate oxygen of the carboxy group and the τ nitrogen of Histidine 327 (0.36 nm) upon closure of the active site, and the oxygen of the carboxy group could relay the basicity of the imidazolio group.

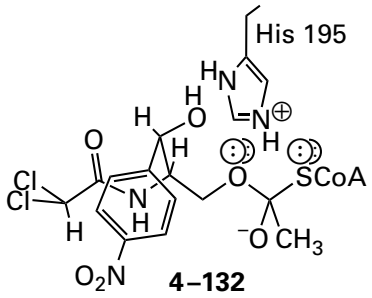
In the active site[719] of 2-dehydro-3-deoxyphosphogluconate aldolase from *E. coli* (Equation 4–324), when only pyruvate is present, the equilibrium for formation of the imine of pyruvate (Equation 4–325) lies in favor of the hemiaminal (see Figure 1–7), so the key question of which base removes the hydron from carbon 3 of the imine of pyruvate cannot be answered.

Such observations, however, **need not be equivocal.** In the crystallographic molecular model of the complex between chloramphenicol *O*-acetyltransferase



(4–373)

from *E. coli* and chloramphenicol in the absence of acetyl-SCoA, the imidazolyl group of Histidine 195 forms a hydrogen bond with the 3-hydroxy group of chloramphenicol to which the acetyl group is transferred. This hydrogen bond identifies Histidine 195 as the catalytic base that removes the hydron from the hydroxy group to enhance its nucleophilicity during formation of the tetrahedral intermediate in the reaction.[879] In the crystallographic molecular model of a complex between chloramphenicol *O*-acetyltransferase and coenzyme A in the absence of chloramphenicol 3-acetate, the same imidazolyl group forms a hydrogen bond with the sulfanyl group of the coenzyme A.[880] Taken together, these two observations suggest that this imidazolyl group, because it can form a hydrogen bond with each substrate when it is present alone, is responsible for hydronating either the oxygen or the sulfur in the tetrahedral intermediate



4–132

to make one or the other the leaving group. In addition, the imidazolyl group of Histidine 195 removes either the hydron from the hydroxy group of chloramphenicol or the hydron from the sulfanyl group of coenzyme A to produce the respective nucleophile during the two forward and two reverse routes to formation of the tetrahedral intermediate.

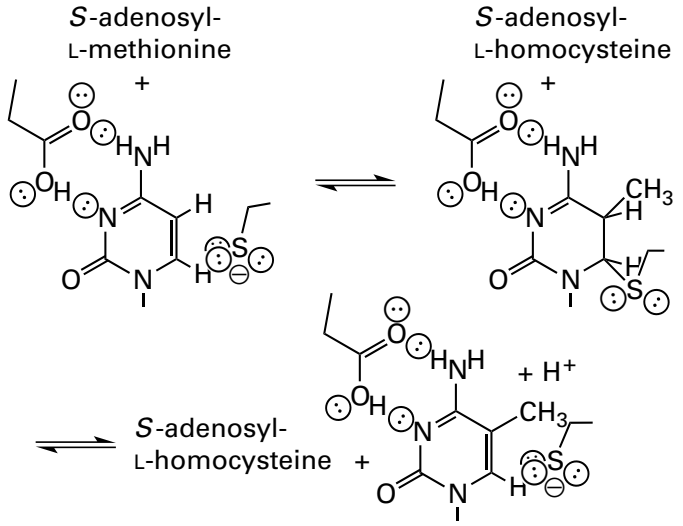
In the crystallographic molecular model of the complex between glucose 1-dehydrogenase [$NAD(P)^+$]

$$\beta\text{-D-glucopyranose} + NADP^+ \rightleftharpoons \text{D-glucono-1,5-lactone} + NADPH + H^+ \quad (4\text{–}374)$$

from *Thermoplasma acidophilum* and an alternate substrate, D-mannose, in the absence of NAD^+, Tyrosine 145 forms a hydrogen bond with the 1-hydroxy group of D-mannose, which probably identifies it as the catalytic base that removes the hydron during the enzymatically catalyzed oxidation by NAD^+ of D-mannose to D-mannono-1,5-lactone.[881]

There are **acid–bases other than the side chains of amino acids** in the polypeptide that accept and donate hydrons. The most common is a molecule of **water**. That molecule of water can be fixed in the active site by several donors and acceptors for hydrogen bonds,[581] or it may be an unfixed molecule of water in an exposed region of the active site, such as a wide opening to the solution[882] or simply due to the fact that the active site is only a depression on the surface of the enzyme, fully exposed on one side, as is the active site of xanthine phosphoribosyltransferase. As also in the case of xanthine phosphoribosyltransferase, a phospho group on a substrate (see Figure 3–44) or a phosphate that is itself a substrate (Figure 4–48B) can act as a catalytic acid–base. The phospho group on the prosthetic pyridoxal 5′-phosphate in glycogen phosphorylase, which is neither a substrate nor a direct participant in any step in the reaction catalyzed by the enzyme, acts as a catalytic acid–base that transfers a hydron to and from an oxygen on the phosphate that is a substrate in the reaction.[883] In this instance, a rather complicated prosthetic group is used by the active site only for its phospho group.

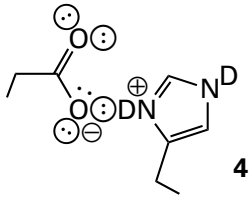
There are many **temporary hydronations at steps in the enzymatic reaction**. In the temporary nucleophilic addition of the sulfanyl group of Cysteine 81 to carbon 6 of cytosine



(4–375)

in the methylation of carbon 5 of cytosines in DNA by *S*-adenosyl-L-methionine catalyzed by DNA (cytosine-5-)-methyltransferase from *Haemophilus parahaemolyticus*, Glutamic Acid 119 transiently hydronates nitrogen 3 of the *N*-acylamidine in cytosine during nucleophilic addition of the sulfanyl group to carbon 6 to increase its electrophilicity, dehydronates nitrogen 3 during addition of the electrophilic methyl group from *S*-adenosyl-L-methionine to increase the nucleophilicity of the resulting *gem*-enediamine, and then rehydronates the nitrogen to acidify the hydron on carbon 5 following the methylation, and then dehydronates the nitrogen so that its πlone pair of electrons can push out the sulfanyl group during the final elimination.[884]

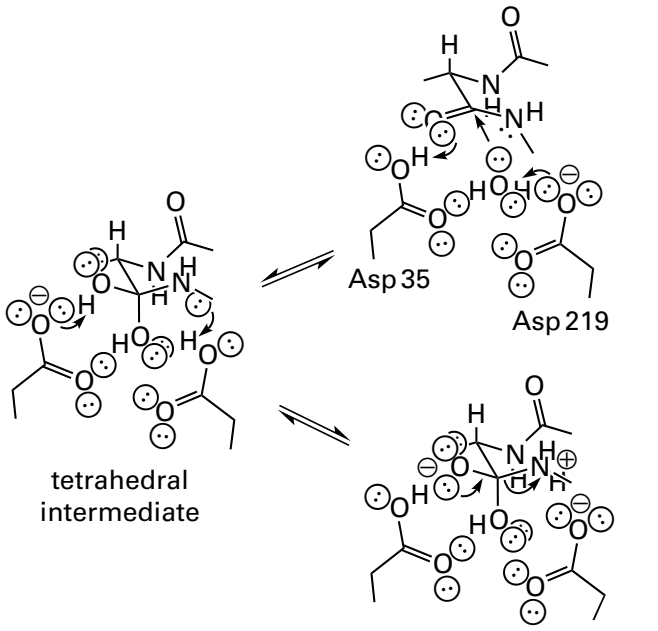
In crystallographic molecular models obtained from **neutron diffraction** of deuterated protein[135,885,886] or crystallography from the diffraction of X-rays at **short Bragg spacing**[887,888] or a combination of the two,[889,890] the **deuterons or hydrons on catalytic acid–bases in an active site can be observed directly**. For example, in the imidazolyl-carboxy composite acid–base in bovine trypsin (Equation 4–134), the deuteron in the hydrogen bond between the imidazolyl group and the carboxy group in the molecular model derived from a map of scattering density from neutron diffraction is on the imidazolyl group, even when it is the cationic imidazolium, rather than the carboxy group



4–133

as expected from the respective values of pK_a.[135] The same is true of the imidazolyl-carboxy composite base in α-lytic endopeptidase from *Lysobacter enzymogenes*[891] and the one in xylose isomerase from *Streptomyces rubiginosus*.[892] In the unoccupied active site of cysteine endopeptidase from severe acute respiratory syndrome coronavirus 2, within the hydrogen bond between the nucleophilic sulfido group of Cysteine 145 and the imidazolio group of Histidine 41, the map of scattering density from neutron diffraction clearly shows the deuteron on the nitrogen of the imidazolyl group.[893] In the X-ray crystallographic molecular model (0.088 nm Bragg spacing) of the complex between β-lactamase CTX-M-9 from *E. coli* and a phosphate anion (Figure 4–51), an analogue of the tetrahedral intermediate in the enzymatic reaction, the hydron relayed by the hydroxy group of Serine 130 from the 6-ammonio group of Lysine 234 to the atom in the analogue representing the leaving nitrogen sits on the serine in the hydrogen bond with that oxygen on the phosphate, again as expected from the respective values of pK_a. All three hydrons on the ammonio group of Lysine 234 and the hydron on the hydroxy group of Serine 130 can be observed.[894]

Aspartic endopeptidases (pepsins) hydrolyze the amide of a peptide bond by catalyzing the nucleophilic substitution of a molecule of water for the amino group in the amide without a covalent intermediate (Figure 1–10). In a crystallographic molecular model from neutron diffraction of a deuterated complex between the aspartic endopeptidase endothiapepsin from *Cryphonectria parasitica* and an analogue of the tetrahedral intermediate, the deuteronation states of the carboxy groups on both catalytic aspartates, Aspartates 35 and 219, can be observed directly.[890] Aspartate 219 is deuteronated in the complex and Aspartate 35 is not deuteronated (but is the carboxylate), and the complex is an analogue of the tetrahedral intermediate, not the Michaelis complex. For these reasons, Aspartate 219 can be assigned as the catalytic base that removes the hydron from the molecule of water that adds to the amido group to form the tetrahedral intermediate. Aspartate 35 must be either the catalytic acid that hydronates the oxyanion of the tetrahedral intermediate



(4–376)

or the catalytic acid that deuteronates the homologous oxygen in the analogue of the tetrahedral intermediate but merely participates in an oxyanion hole for the actual intermediate in the enzymatic reaction.

The assignments of these roles, based on the locations of the deuterons in the crystallographic molecular model of endothiapepsin from neutron diffraction, are consistent with several other crystallographic observations. The molecule of water that is shared by the two carboxy groups in the active site before the reactant associates and that adds nucleophilically to the amido group of the peptide bond can be observed in the crystallographic molecular model[895] of unoccupied porcine pepsin (25% identity; 3.8 gap percent). This model identifies the location of that molecule of water in the Michaelis complex. In a crystallographic molecular model of a complex between HIV-1 retropepsin, encoded in the genome of human immunodeficiency virus, and an inert analogue of a peptide that is hydrolyzed by the enzyme, the carboxy group on the aspartate homologous to Aspartate 219 (Equation 4–376) is positioned to hydronate the leaving nitrogen.[896] In a crystallographic molecular model of a complex between HIV-1 retropepsin[897] and an actual tetrahedral intermediate, the aspartate homologous to Aspartate 219 forms a hydrogen bond with the amino group in the tetrahedral intermediate while retaining

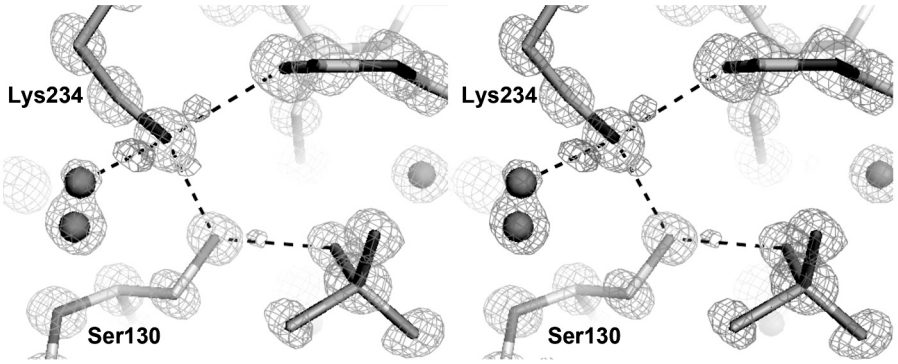


Figure 4–51: Crystallographic molecular model of β-lactamase CTX-M-9 from *E. coli* superposed on the map of electron density.[894] A data set from crystals of the enzyme was collected to Bragg spacing of 0.088 nm and submitted to molecular replacement. The polypeptide was inserted into the initial map of electron density and submitted to refinement. In the end there were three data sets: the observed amplitudes, F_o; the best estimates of the phases following the refinement, α_c; and the amplitudes calculated from the final refined molecular model, F_c. A data set $2F_o - F_c$ was created by subtracting the value for each calculated amplitude from twice the value for the respective observed amplitude, and a map of electron density was calculated from this data set and α_c. The resulting map gave the features of electron density centered on each of the heavy atoms of the molecular model in the drawing and represents the electron density from each of these atoms. A data set $F_o - F_c$ was created by subtracting the value for each calculated amplitude from the value for the respective observed amplitude, and a map of electron density was calculated from this data set and α_c. The resulting map gave three small features of electron density arranged tetrahedrally around the 6-ammonio group of Lysine 234 and a single small feature of electron density at one of the tetrahedral positions next to the oxygen of Serine 130. These four small features of electron density arise from the hydrons at these positions in the active site of β-lactamase CTX-M-9 but not in the refined crystallographic molecular model. They appear because they represent information about electron density within the crystal that is not represented in the molecular model. It can be seen that, within the composite acid–base formed from a molecule of water that is in equilibrium between two fixed positions, the 6-ammonio group of Lysine 234, and the hydroxy group of Serine 130, the hydron in the hydrogen bond between the ammonio group and the hydroxy group is located on the ammonio group. In the hydrogen bond between the 6-ammonio group and an acyl oxygen in the polypeptide backbone (upper right), the hydron, as expected, is on the 6-ammonio group, and in the hydrogen bond to the peripatetic molecule of water, the hydron is also on the 6-ammonio group. There is a phosphate occupying the location (lower right) at which the lactam hydrolyzed by the enzyme would be located in the Michaelis complex, and in the hydrogen bond between one of its oxygens and the hydroxy group of Serine 130, the hydron is, as expected, on the hydroxy group. Reprinted with permission from reference 894. Copyright 2007 American Chemical Society. https://doi.org/10.1021/ja0712064

its hydrogen bond with the oxygen that was the molecule of water, a fact that demonstrates its ability to remove a hydron from the water and then add a hydron to the nitrogen (Equation 4–376). In a crystallographic molecular model of a complex between HIV-1 retropepsin and the two products of the reaction,[897] the aspartate homologous to Aspartate 219 retains its contact with the nitrogen that it has just hydronated as the acceptor in a hydrogen bond with the amino group after it has left the tetrahedral intermediate.

As has already been noted, active sites use composite acid–bases. The simplest of all acids in aqueous solution, the hydronium ion, is itself a composite acid of at least four molecules of water and a hydron, all participating in a complex of hydrogen bonds.[898-907] In the composite acid of four waters and a hydron that may be the smallest hydronium ion, there are six equivalent hydrogens on the periphery, any one of which is acidic. In the simplest composite base of four molecules of water lacking one hydron, there are six lone pairs of basic electrons on the periphery, any one of which is basic. These two composite acid–bases are believed to be responsible for the fact that a hydronium as a catalytic acid in solution is often more acidic than its corrected pK_a would suggest (Figure 4–5B) and the fact that a hydroxide as a catalytic acid is often more basic than its corrected pK_a would suggest. Given the precedent of hydronium and hydroxide, it is not surprising that catalytic acid–bases in an active site are often composites of several side chains and often fixed molecules of water. In a composite acid–base in an active site, one or two heteroatoms on the periphery of the composite acid–base and immediately adjacent to a substrate are catalytic.

The first composite acid–base that was observed crystallographically is the one formed from the imidazolyl group of Histidine 57 and the carboxy group of Aspartate 102 in bovine chymotrypsin (Equation 4–134).[908] The proximal nitrogen on the imidazolyl group in this composite acid–base is responsible for removing the hydron from the hydroxy group on Serine 195 during its nucleophilic addition to a peptide bond (Figure 3–6).

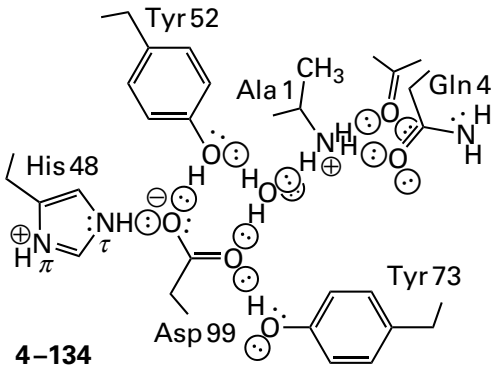
Imidazolyl-carboxy* composite acid–bases have been identified in many active sites. For example, **imidazolyl-carboxy composite acid–bases** remove the hydron from the nucleophilic molecule of water bound to Zn^{2+} in thermolysin (His 231 and Asp 226 in Figure 3–42), and they remove the hydrons from the respective hydroxy groups on the carbons oxidized by L-lactate dehydrogenase (Equation 4–204)[909] and malate dehydrogenase[910]

$$(S)\text{-malate} + NAD^+ \rightleftharpoons NADH + H^+ + \text{oxaloacetate} \qquad (4\text{–}377)$$

As is the case in the active site of chymotrypsin, a number of serine endopeptidases, carboxypeptidases D,[911] lipases,[912-914] esterases,[915] and phospholipases[916] use an imidazolyl-carboxy composite base to remove a hydron from serine, cysteine,[917] or a molecule of water[916] during their nucleophilic additions to the respective acyl derivatives hydrolyzed by these enzymes. The active sites of formamidase from *Helicobacter pylori*[918] and β-lactamase from *S. aureus*,[919] however, use 6-amino-carboxy composite bases, formed from the amino group of lysine and the carboxy group of glutamate or aspartate, to remove a hydron from the sulfanyl group of cysteine and the hydroxy group of serine, respectively, during their nucleophilic additions to the respective acyl derivatives. Composite acid–bases are so common among the hydrolases of acyl compounds that the absence of a composite acid–base in one of these enzymes is considered peculiar.[920,921] Two imidazolyl-carboxy composite acids are used to hydronate one of the equatorial oxygens in an intermediate phosphorane and to hydronate the leaving oxygen from that intermediate phosphorane, respectively, in bovine deoxyribonuclease I.[922] Imidazolyl-carboxy composite acid–bases are also used to add a hydron to a carbonyl oxygen[909,923] and even to remove a hydron from carbon.[924-926]

In some instances, an imidazolyl-carboxy composite acid–base is extended further.[266] For example, in porcine phospholipase A_2, the composite acid–base, the catalytic hydron of which is on the π nitrogen of Histidine 48,[927] has the extended structure[916]

*__Proximal__ refers to positions in the composite acid–base nearer to the point where the catalytic hydron is transferred back and forth between acid–base and substrate, and **distal** refers to positions in the composite acid–base farther from the point at which the catalytic hydron is transferred, respectively. The functional groups in the composite acid–base are written from proximal to distal.



4–134

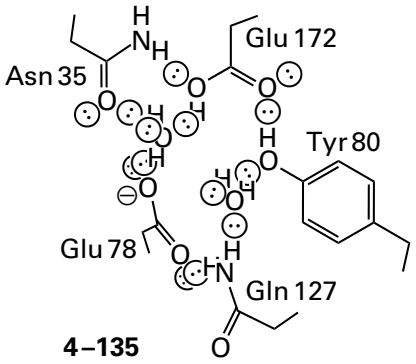
Mutation of both tyrosines to phenylalanines, however, decreases the rate constant $k_0 K_m^{-1}$ by only a factor of 7 while mutating the aspartate to asparagine decreases it by a factor of 1200.[928] The results of these mutations suggest that in many instances the purpose of the more distal participants in an extended composite acid–base may be structural rather than catalytic, as seems to be the case in the original composite acid–base, the one in the active site of chymotrypsin, in which the carboxy group is responsible only for orienting the imidazolyl group rather than significantly affecting its pK_a or effectiveness as a catalyst.[136,139]

As in the active sites of formamidase and β-lactamase, there are many composite acid–bases other than imidazolyl-carboxy ones. An imidazolyl-carbamoyl composite acid–base between histidine and asparagine removes the hydron from the nucleophilic sulfanyl group of a cysteine in the active site of actinidain from *Actinidia chinensis*,[929] and the two imido hydrogens of the carbamoyl group of the asparagine are buried respectively in the two π electron clouds of two tryptophans.[930] A carboxy-guanidinio composite acid–base removes the hydron from the nucleophilic molecule of water in the active site of the phosphatase encoded by the BT4131 gene of *B. thetaiotaomicron* (Asp10 and Arg45 in Figure 3–43). In the active site of chondroitin AC lyase (Equation 4–358 and Figure 4–44), the 4-hydroxyphenyl group (Tyrosine 242) responsible for the transfer of the hydron is the proximal participant in a composite acid–base. It is connected through a guanidinio group (Arginine 296) to two carboxy groups (Glutamate 412 and Glutamate 407), another guanidinio group (Arginine 300) and an imidazolyl group (Histidine 233). When the proximal guanidinio group on Arginine 296 is removed by mutation, the activity of the enzyme decreases by a factor of 100.[931] In the active site of pyruvate carboxylase from *Rhizobium etli*, the carboxylato group on Glutamate 305, which is responsible for removing a hydron from bicarbonate during the carboxylation of the prosthetic biotin, is the proximal participant in a composite acid–base with a carboxy group on Glutamate 218 and the imidazolyl group of Histidine 216. When any one of these three amino acids is mutated, the catalytic constant of the enzyme decreases by a similar factor (50–100),[932] a result suggesting that their effects on catalysis are concerted.

In the crystallographic molecular model[933] of asparaginase from *E. coli* in a complex with aspartate, one of its substrates, but not the cosubstrate ammonia, there is a continuous network of hydrogen bonds surrounding the substrate that consists of, in order, the side chains of Threonine 89, Lysine 162, Aspartate 90, Asparagine 248, Glutamate 283, Tyrosine 25, and Threonine 12. Calculations suggest that the amino group of Lysine 162, the hydroxy group of Threonine 89, and the hydroxy group of Threonine 12 within this extensive composite catalytic acid–base in turn transfer hydrons to and from substrates and the tetrahedral intermediate in three steps comprising the nucleophilic substitution catalyzed by the enzyme.[934]

Aside from their role in **orienting the heteroatom of the catalytic acid–base** that actually participates in transfer of the hydron to or from a substrate, a role that is usually essential, composite acid–bases, by combining several acid–bases of different intrinsic pK_a, participate in **adjusting the pK_a for that heteroatom**. In the unfolded polypeptide that folds to become the enzyme, the donors and acceptors for hydrogen bonds on the side chain in which the eventually catalytic heteroatom is located, including those on that heteroatom itself, are occupied by molecules of water, and this normal, unheralded network of hydrogen bonds determines in part the pK_a for the heteroatom in the unfolded polypeptide; in fact, this network determines in part the pK_a for any acid–base in solution. When these molecules of water are replaced as donors and acceptors in hydrogen bonds by other acid–bases during folding of the polypeptide and subsequent association of substrates, the pK_a changes for the heteroatom that is the ultimate catalytic acid–base.

When the polypeptide of endo-1,4-β-xylanase from *B. circulans* folds to produce the active site, the pK_a for the catalytic carboxy group of Glutamate 172 shifts from 4.3, the value it has when fully exposed to bulk water,[32] to 6.7.[124] When it is in the native active site, Glutamate 172 forms hydrogen bonds with Tyrosine 80, Asparagine 35, and a molecule of water to connect it to a large composite acid–base



4–135

When Tyrosine 80 is mutated to phenylalanine, the pK_a for the carboxy group of Glutamate 172 increases to 7.9[157] because there is no longer an acidic donor of a hydrogen bond to the distal oxygen of the carboxy group, although an unresolved, less acidic (pK_a = 15.7) molecule of water may take its place. When Asparagine 35, the carboxamido group of which donates a hydrogen bond to the proximal oxygen of the carboxy group of Glutamate 172, is changed to aspartate, the pK_a for the carboxy group rises to 8.4, presumably because the neutral amido group that is the donor of the hydrogen bond (**4–135**) has been replaced by an anionic carboxylato group. The observed increase in the pK_a of Glutamate 172 from 4.3 to 6.7 upon folding, however, is due mainly to the juxtaposition of the anionic, catalytic carboxylato group of Glutamate 78,[124] which is linked to the carboxy group of Glutamate 172 through a molecule of water (**4–135**) at the pH that is optimal for enzymatic activity. This molecule of water is replaced by the oxygen that is the leaving group in the substrate upon its association with the active site so that Glutamic Acid 172 can hydronate that leaving group during hydrolysis of a xylan.[123,935]

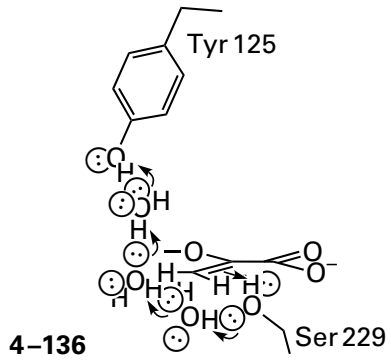
When the polypeptide of glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) from *E. coli* folds to produce the active site, the pK_a for the catalytic sulfanyl group of Cysteine 149 should have increased from its value of 8.7 when immersed in bulk water[32] because of a decrease in the relative permittivity from that of liquid water. In this instance, however, a hydrogen bond between the sulfanyl group of Cysteine 149 and the imidazolyl group of Histidine 176[936] maintains the pK_a for the sulfanyl group at 8.6 to facilitate its dehydronation.[937]

The evolution of a composite acid–base by natural selection is a special case, albeit a more obvious example, of the **ability of the active site to adjust the acidity and basicity of a catalytic acid–base**, and a crystallographic molecular model often identifies the reasons for this adjustment. For example, as has already been mentioned, the decrease in pK_a for the 6-amino group of Lysine 115 in acetoacetate decarboxylase from *C. acetobutylicum* from 10.5 to 6.0 (Figure 4–15) is not due to the proximity of Lysine 116, as was originally proposed.[938] Instead, the decrease is the result of Lysine 115 being situated in a hydrophobic region of low relative permittivity in the native enzyme.[165]

When a polypeptide folds and a donor or acceptor for a hydrogen bond on a particular heteroatom within its sequence of amino acids retains a molecule of water* or that fixed molecule of water is replaced by the hydroxy group of serine, threonine, or a substrate, there is no direct effect of that retention or that isoergonic substitution on the pK_a for that heteroatomic donor or acceptor in the native protein, even though other features of the active site, such as its relative permittivity, usually do affect the pK_a. Nevertheless, the **retained molecule of water or the hydroxy group replacing it can relay the acidity or basicity of the heteroatom** to a bound substrate or to another acid–base, much as the molecules of water in a hydronium ion or a hydroxide ion in solution can relay its acidity or basicity, respectively, or a hydron wire can relay a hydron. For example, the hydroxy group on the substrate pyridoxine 5-phosphate (Figure 4–48B) relays the hydron from the phosphate-imidazolyl composite acid in which Histidine 45 is a participant to the carbonyl oxygen on 2-methyl-3-oxo-4-hydroxymethyl-5-phosphomethyl-3,6-dihydropyridine (step *vi*, Figure 4–47) to catalyze its aromatization. A molecule of water relays the acidity of the amino-terminal ammonio group to the carboxy group of Aspartate 99 in the composite acid–base in phospholipase A_2 (**4–134**). A molecule of water relays the basicity of the carboxylato group of Glutamate 78 to the carboxy group of Glutamate 172 (**4–135**) in the empty active site of endo-1,4-β-xylanase from *B. circulans*.

The hydron on Tyrosine 125 in the active site of UDP-*N*-acetylmuramate dehydrogenase (Equation 4–239) is relayed through three molecules of water and the hydroxy group of Serine 229

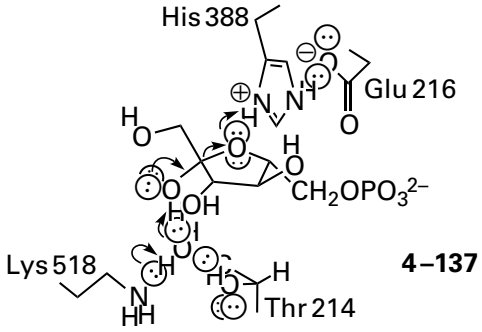
*It should be reiterated that *the* same molecule of water is not retained, only *a* molecule of water, which is constantly exchanging.



4–136

to hydronate carbon 1 of the enolpyruvyl group on the substrate, UDP-*N*-acetyl-3-*O*-(1-carboxyvinyl)-α-D-glucosamine, as the hydride is added to carbon 2 of the 1-carboxyvinyl group.[513] When that serine is mutated to alanine,[939] interrupting the relay, the rate of the reaction catalyzed by the enzyme decreases by a factor of 10^7.

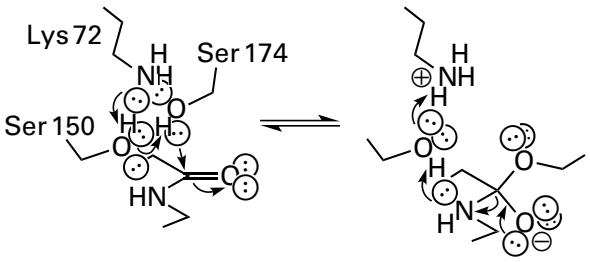
A single molecule of water relays the basicity of Lysine 518 during removal of a hydron from the 2-hydroxy group of α-D-fructofuranose 6-phosphate



4–137

during the opening of the furanose catalyzed by glucose-6-phosphate isomerase from *O. cuniculus*.[940]

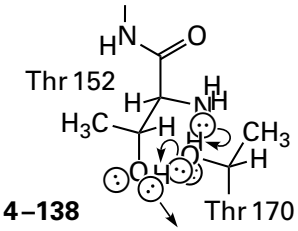
The enzyme 6-aminohexanoate-cyclic-dimer hydrolase from *Arthrobacter* hydrolyzes one of the two identical amides in 1,8-diazacyclotetradecane-2,9-dione, the tetradecacyclic, diamido dimer of two 6-aminohexanoates. In its active site, the hydroxy group of Serine 150 first relays the basicity of the amino group of Lysine 72 to remove the hydron from the hydroxy group of Serine 174



(4–378)

during its nucleophilic addition to the acyl carbon of the amido group. The hydroxy group of Serine 150 then relays the acidity of the resulting ammonio group of Lysine 72 to hydronate the amino nitrogen of the tetrahedral intermediate, permitting it to be the leaving group.[941] When either Serine 150 (the central relay) or Lysine 72 (the catalytic acid–base) is mutated to alanine, enzymatic activity decreases by a factor of greater than 4000.

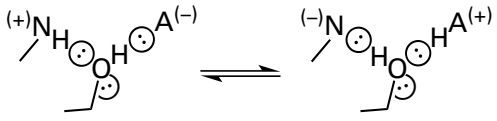
In the active site of N^4-(β-*N*-acetylglucosaminyl)-L-asparaginase from *Elizabethkingia miricola*, the hydroxy group of Threonine 170 relays the basicity of the amino-terminal amino group of Threonine 152, which is exposed during an endopeptidolytic cleavage that activates the enzyme, to remove a hydron from the hydroxy group of Threonine 152[942]



4–138

during its nucleophilic addition to the acyl carbon of the amido group in the reactant N^4-(β-*N*-acetylglucosaminyl)-L-asparagine. The amino-terminal amino group cannot remove the hydron on the hydroxy group effectively on its own because only three atoms separate its nitrogen from the hydron.

When a molecule of water or the hydroxy group on a serine or threonine relays the acidity or basicity of a catalytic acid–base, –NH, in a composite catalytic acid–base to or from a lone pair of electrons on reactant A, a tautomerization occurs



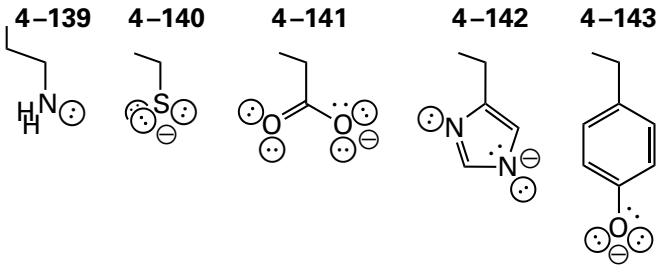
(4–379)

Since there is a hydroxy group in both reactant and product, the standard free energy change for the reaction is about the same as that for the reaction in which the catalytic acid–base would have directly transferred a hydron to and from the substrate. In this sense, the acidity in the forward reaction or the basicity in the reverse reaction is relayed. A hydrogen bond between the conjugate acid of the catalytic acid–base, $-NH^{(+)}$, and a hydroxy group, in the absence of hydron transfer, however, increases the acidity of the hydron on the hydroxy group only

slightly. Likewise, a hydrogen bond between the conjugate base of reactant A, $\odot A^{(-)}$, and the hydroxy group increases the basicity of one lone pair on the hydroxy group only slightly. Consequently, the fraction of the acidity or basicity relayed in the transition state is determined by the extent to which the hydrons are transferred to and from the hydroxy group to the reactant in the transition state. If the hydrons have been transferred almost completely in the transition state, the acidity or basicity has been fully relayed. If they are transferred only partially, then the acidity or basicity is only partially relayed.

The positions of basic lone pairs of electrons and acidic hydrons are revealed by the orientations of catalytic bases and catalytic acids on side chains of the amino acids, respectively, relative to hydrons to be removed from a substrate and lone pairs of electrons to be hydronated on a substrate. In most of the crystallographic molecular models discussed so far and in most others, neither hydrons nor lone pairs of electrons in hydrogen bonds are features in the map of electron density, yet they are there. An acidic hydrogen on a heteroatom in the side chain of an amino acid, although it is engaged in a covalent bond with the heteroatom, can be thought of as a hydron occupying a lone pair of electrons. Consequently, although the location of the hydron in the hydrogen bond cannot be observed in a crystallographic molecular model, the position of the lone pair in a hydrogen bond between a catalytic base and a hydron on a substrate, or the position of a hydron in a hydrogen bond between a catalytic acid and a lone pair on a substrate, are the same. All that remains ambiguous is the location of the hydron.

Leaving aside the question of their orientation in an aprotic solvent or the gas phase, the orientation of the lone pairs on the conjugate bases of the **five most common catalytic acid–bases** among the side chains of the amino acids when they are participating in hydrogen bonding, which they must be to be catalytic acid–bases and which they do when fully exposed to the solution when the polypeptide is unfolded, can be drawn



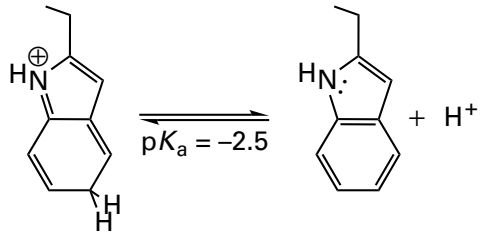
In both the amino group (**4–139**) of lysine and the sulfanyl group (**4–140**) of cysteine, the lone pairs and acidic hydrons are directed tetrahedrally from the heteroatom. This disposition is also true of the amino terminus of the polypeptide, which is sometimes used as a catalytic acid–base. In the carboxylato groups (**4–141**) of glutamate and aspartate, the imidazolyl group (**4–142**) of histidine, and the 4-hydroxyphenyl group (**4–143**) of tyrosine, the lone pairs are in the respective σ planes of these groups sandwiched between the respective π systems, and they are directed trigonally from their heteroatoms. Each side chain has **more than one lone pair of electrons or more than one acidic hydron,** giving it several orientational options and also allowing it to accept one hydron while it is donating another, as when it is a participant in a hydron wire or a composite catalytic acid–base.

The amino group (**4–139**) of lysine, the sulfanyl group (**4–140**) of cysteine, and the 4-hydroxyphenyl group (**4–143**) of tyrosine are particularly adept at removing a hydron from one atom and then pivoting to add a hydron to another atom that is two atoms removed from the first (Figure 4–44, Equation 4–368). This adeptness results from the freedom of nitrogen and sulfur to rotate around the carbon–nitrogen bond and the carbon–sulfur bond, respectively, and also from the collinearity of oxygen in the 4-hydroxyphenyl group with the β-carbon–γ-carbon bond of tyrosine. In a carboxy group, the two oxygens are symmetrically arrayed about the axis of the carbon–carbon bond, but rotation around that bond can have a much wider span. A rotation of 180° around this bond interchanges the two oxygens. Usually, however, one of the oxygens removes a hydron, pivots through a small arc, and then donates a hydron, as in the active site of triose-phosphate isomerase (Equation 4–55), where the carboxy group transfers the hydron between two adjacent carbons. Even though both nitrogens of an imidazolyl group in an enzyme almost always participate in hydrogen bonds, usually only one of the two nitrogens in a catalytic imidazolyl group functions as the acid–base, (Figures 3–37, 3–42, 4–46, and 4–48 and

4–132), and it often pivots on the noncatalytic hydrogen bond to service more than one atom. Lysine has the advantage that its 6-amino group is at the end of a flexible tether that allows it to move around more widely and more freely.

When it is participating in the transfer of a hydron, **each catalytic acid–base** must be oriented such that the atom in the substrate, the heteroatom in the side chain, the hydron being transferred, and the lone pairs of electrons on substrate and side chain between which it is being transferred are as **collinear** as possible. These components are not always precisely collinear because of the extreme steric challenges faced by natural selection in folding a polypeptide to create an active site, but they are usually remarkably close to collinear given these challenges. When you are examining the following stereodrawings from crystallographic molecular models and reexamining the stereodrawings you have already seen, pay particular attention to these orientations. Keep in mind the hybridization of the lone pairs in situations in which hydrogen bonding is occurring and the locations of the hydrons, usually unobserved, on the oxygens, nitrogens, sulfurs, and carbons in the molecular models.

Crystallographic molecular models of informative complexes have delineated the extensive group of catalytic acid–bases that are available to an enzyme for providing or removing a hydron during its catalysis. The set is diverse. In addition to the most common catalytic acid–bases (**4–139** to **4–143**) as well as molecules of water, there is a set of **less common catalytic acid–bases** such as the guanidinio group of arginine[943] and the hydroxy groups of serines[432,464,513] and threonines. Perhaps the most unexpected catalytic base is the indolyl group of tryptophan



(4–380)

Like pyrrole, the indolyl group hydronates on any one of its carbons with a macroscopic pK_a of –2.5,[944] which is, within experimental error, the same as the pK_a for hydronation of the hydroxy group in serine.[388] The indolyl group of tryptophan has been proposed to be the base that removes a hydron adjacent to a carbenium ion to produce an alkene.[945] Any of the more conventional bases would be alkylated irreversibly by a carbenium ion. The hydron on the nitrogen in the indolyl group of tryptophan is a very weak acid (pK_a = 16), as is the hydron on the nitrogen in pyrrole (pK_a = 17), and it is seldom used as a catalytic acid–base, but when it is, advantage is taken of its weakness.

The present set of crystallographic molecular models of informative complexes has identified the types of catalytic acid–bases used for particular types of hydron transfer. These purposes range in necessity from the apparently unnecessary—acting as the donor of a hydrogen bond to a chloro group to enhance its ability as a leaving group—to the absolutely necessary—removing or adding a hydron from or to carbon. The unexpected result is how broad a spectrum of acid–bases have been called upon for each purpose, from the easiest to the most difficult.

In almost every chemical reaction catalyzed by an enzyme, there are hydron transfers between substrates and catalytic acid–bases in the active site or molecules of water in a region of the active site exposed to the solution or connected to the solution by a hydron wire. In order to understand the acid–base catalysis being performed by a particular active site, **each of its catalytic acid–bases must be identified and their roles defined**. To make this identification and establish this definition, an understanding of what the reaction requires is essential. Although the roles of the side chains in enzymatic reactions have been tabulated in a general sense,[946,947] these tabulations have not been dissected into **specific chemical roles**, such as removing a hydron from a hydroxy group in one direction and adding a hydron to the same oxygen in the other direction or removing a hydron from carbon in one direction and adding a hydron to the same carbon in the other direction. Each bidirectional role is chemically distinct and should be discussed systematically.

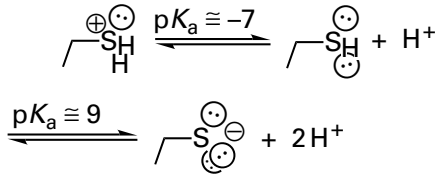
In most enzymatic reactions, **hydrons are transferred back and forth between two heteroatoms**: one on a substrate and another on a catalytic acid–base. Heteroatoms on substrates that participate in an enzymatic reaction usually participate as **nucleophiles and leaving groups**. When a heteroatom on a substrate acts in one direction as a nucleophile, it is a leaving group in the other direction, and vice versa. For the same type of heteroatom in a substrate, be it sulfur, oxygen, or nitrogen, the nucleophilicity of one of its lone pairs of electrons increases as the pK_a for its conjugate acid increases, and the ability

of the same heteroatom to leave decreases as the pK_a for its conjugate acid increases. Consequently, as discussed before, the measure of the nucleophilicity of a lone pair of electrons on a heteroatom in a substrate is the pK_a for its conjugate acid, and the measure of the ability of a leaving group to leave is the pK_a for the conjugate acid of the leaving group after it has left. When, however, the difficulty of hydronating a leaving group to improve its ability to leave is considered, that difficulty is measured by the pK_a for the conjugate acid of the leaving group while it is still in the reactant before it leaves. In the following discussion, unless otherwise defined, values of pK_a listed are for the conjugate acid of the nucleophile and the conjugate acid of the leaving group, either before or after it has left depending on the situation. Values of pK_a listed[948] are approximate because they depend significantly on the actual substituents on the particular type of heteroatom.

Strong heteroatomic nucleophiles in substrates, because they are usually hydronated at neutral pH, require a catalytic base to dehydronate them before or while they are adding to an electrophile. A strong nucleophile in the direction of addition is a poor leaving group in the direction of dissociation. Because a catalytic base is required to remove a hydron from a strong nucleophile on the approach to a transition state, by microscopic reversibility, the conjugate acid of that catalytic base will hydronate that same atom as it leaves, which will automatically improve the poor leaving group. These reciprocal requirements explain why, **in most dissociations of weak leaving groups and nucleophilic additions of strong nucleophiles, the active site provides a catalytic acid–base for the heteroatom that is leaving and adding**. It follows that, in a transition state within an active site catalyzing such a reaction, there is usually a catalytic acid–base that forms a hydrogen bond to a heteroatom that is about to leave or has just entered the transition state. This hydrogen bond in the transition state—between the heteroatom of the catalytic acid–base and the heteroatom that was or will be in the substrate and that will be or was the heteroatom of the leaving group or the nucleophile—lowers the standard free energy of formation of the transition state.

Weak heteroatomic nucleophiles, because their conjugate acids are strong, are usually unhydronated at neutral pH. Consequently, they should not require a catalytic base to ensure that they are unhydronated in the ground state. Weak heteroatomic nucleophiles in reverse are good leaving groups. In instances in which the leaving group is a good one and hence the nucleophile is a weak one and a catalytic acid–base should be unnecessary in both directions, one is nevertheless often provided even though it would seem to be counterproductive. If the catalytic acid hydronates the leaving group, then its conjugate acid must donate a hydrogen bond to the weakly basic nucleophile. This hydrogen bond would lower the nucleophilicity of the weak nucleophile from which a hydron does not have to be removed because it is already unhydronated in solution. In such cases, the catalytic acid base is probably used to orient the nucleophile by forming a hydrogen bond with it. For example, **chlorine in an alkyl chloride** is an excellent heteroatomic leaving group (p$K_{aHCl} = -7$) and should not need a catalytic acid, and it is a poor nucleophile in the other direction, the nucleophilicity of which would be decreased by the donor of a hydrogen bond. In haloalkane dehalogenase from *Xanthobacter autotrophicus*, however, the nitrogen–hydrogens in the indolyl groups of two **tryptophans** (p$K_a = 16$) donate their hydrons to the chloride as it leaves from a haloalkane.[949,950] In this instance, the nucleophile displacing the chloride is the carboxy group of an aspartate in the active site, which is a weak nucleophile, so acid catalysis of this nucleophilic substitution at chlorine is appropriate but the two acids in this case are weak ones so that their effect on the nucleophile is minimal.

Sulfur in a sulfanyl group

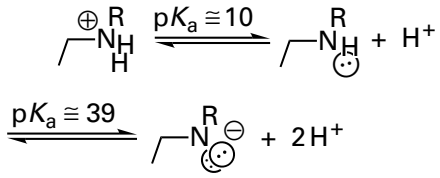


(4–381)

would seem also to need little assistance as a leaving group or a nucleophile. A sulfanyl group has a fairly low pK_a (p$K_a = 9$) and is, consequently, a decent leaving group; the pK_a of the conjugate acid of the sulfur in a sulfide (where one H in Equation 4–381 is a carbon) is quite low (p$K_a = -7$), making it difficult to hydronate before or as it leaves; and the unhydronated sulfido group, because it is in the third row, is a stronger nucleophile than its pK_a would suggest, so removal of a hydron should not be necessary. Yet catalytic acid–bases are almost always supplied. For example, in hydroxymethylglutaryl-CoA synthase (Equation 4–360) from *S. aureus*, the carboxy group of **Glutamate** 79 removes the hydron from the sulfanyl

group of Cysteine 111 (0.34 nm)* during its nucleophilic substitution on acetyl-SCoA. In chloramphenicol *O*-acetyltransferase from *E. coli*, **Histidine** 195 performs a similar role (**4–132**). In formamidase from *H. pylori*, a 6-amino group from lysine and a carboxy group from glutamate form a **lysyl-glutamyl composite base** that removes the hydron from the sulfanyl group of a cysteine during its nucleophilic addition to formamide.[918] In glyceraldehyde-3-phosphate dehydrogenase from *E. coli*, Histidine 176, by providing a catalytic imidazolyl group, ensures that the sulfanyl group of Cysteine 149 is unhydronated and properly oriented during its nucleophilic addition to the aldehyde of glyceraldehyde-3-phosphate.[936] In the human glutathione transferases, the 4-hydroxyphenyl group of **Tyrosine** 7 removes the hydron from the nucleophilic sulfanyl group in glutathione that participates in nucleophilic additions performed by these enzymes.[951,952] These examples indicate how eclectic is the choice of a catalytic acid–base, at least for removing a hydron from a sulfanyl group or adding a hydron to the sulfur in a leaving group.

Nitrogen in an amino group (–NH_2) or a secondary amino group (–NRH)



(4–382)

where R can be either a hydrogen or a carbon, rarely leaves a saturated carbon but often leaves carbon in a tetrahedral intermediate or participates in a tetrahedral intermediate by adding nucleophilically to a carbonyl or acyl group. Regardless of the type of carbon from which it leaves, a nitrogen in an amino or alkylamino group must be hydronated and cationic before it can leave (Figure 1–10) because the respective azanide anion, H_2N^- or RHN^-, is an exceptionally strong base ($pK_a = 39$) and hence an exceptionally poor leaving group. Whenever an amino or alkylamino group is **leaving carbon**, the active site must provide a catalytic acid to hydronate the nitrogen before or during the step in which the carbon–nitrogen bond is broken. This requirement is inescapable but also relatively simple to fulfill because an amino or alkylamino group, the conjugate acids of which have values for pK_a of 10, is easily hydronated by any of the catalytic acids available, and the resulting hydronated cationic ammonio or alkylammonio group, in contradistinction to, for example, a hydronated cationic oxygen, is a weak acid and remains hydronated as long as it takes to reach the transition state.

In the other direction (Figure 1–10), when ammonia or an alkylamine **adds to carbon**, it is always as ammonia or the neutral alkylamine (Figure 1–7), which are, respectively, the only accessible species in which the respective nitrogen has a nucleophilic σ lone pair of electrons. Consequently, if the amine enters the active site as the ammonium cation ($pK_a = 10$), there must be a catalytic base ready to remove its hydron before the nucleophilic addition. This participant is often the same catalytic base that removes a second hydron from the amino group as the reaction progresses. Consequently, if the same catalytic base performs both functions, it must either dissociate the hydron it took from the entering ammonium, if the nucleophilic addition is to a saturated carbon, or pass the hydron over to the oxyanion formed during addition of an amino group to a carbonyl or acyl carbon (left path of the tautomerization in Figure 1–7) because it must again be a base to dehydronate the again-ammonio group a second time. In reverse, the conjugate acid of this base would have to hydronate a leaving amino group, which is inescapable, so that it can leave as the amine. Furthermore if dehydronation of the initial ammonio group is required before the nucleophilic addition, then, by microscopic reversibility, it must be hydronated again after it leaves. The catalytic base that just hydronated the leaving group must gain a hydron from somewhere, usually from the atom of the nucleophile that just produced a tetrahedral intermediate, so that it can hydronate the amino group again after it has dissociated as the leaving group.

Formation of the iminium required for the retro-aldol condensation catalyzed by fructose-bisphosphate aldolase from *T. tenax* illustrates these consecutive roles in the two directions. The 4-oxidophenyl group of **Tyrosine** 146 has to remove a hydron from the 6-ammonio group of Lysine 177 before its nitrogen can add nucleophilically to the carbonyl of fructose 1,6-bisphosphate (Equation 4–368), and the resulting 4-hydroxyphenyl group either hydronates the resulting oxyanion of the former carbonyl oxygen in the resulting hemi-

*There is controversy surrounding the question of whether or not sulfanyl groups participate in hydrogen bonds, but this oxygen–sulfur distance is well within the sum (0.40 nm) of a hydrogen–sulfur bond (0.135 nm) and the van der Waals radii of hydrogen (0.115 nm) and oxygen (0.15 nm).

aminal or hydronates the carbonyl oxygen as the amino group is adding to the carbonyl group to form the hemiaminal. The second hydron is then shuttled by the 4-oxidophenyl group from the ammonio group in the hemiaminal to the resulting hydroxy group that is leaving as a molecule of water to give the lysyl imine. In reverse, the 4-oxidophenyl group of Tyrosine 146 removes a hydron from the molecule of water, before or as the water is adding to the lysyl iminium; the resulting 4-hydroxyphenyl group then transfers the hydron to the lone pair of electrons on the nitrogen in the resulting hemiaminal to create a leaving group; and then the resulting 4-oxidophenyl group removes a hydron from the hydroxy group in hemiaminal to give the oxyanion that provides the push to dissociate the amino group. The 4-hydroxyphenyl group then transfers the hydron to the amino group to give the 6-ammonio group of Lysine 177.

A large array of catalytic acid–bases are called upon to be the necessary catalytic acid–bases in reactions in which an amino group is the nucleophile in one direction and the leaving group in the other. **Glutamic Acid** 143 must hydronate the alkylamino group before it can leave as an amine from the tetrahedral intermediate during the reaction catalyzed by thermolysin from *B. thermoproteolyticus* (Figure 3–42). Aspartic Acid 126 must hydronate the alkylamino group before it can leave as an amine from the tetrahedral intermediate in the reaction catalyzed by endothiapepsin from *C. parasitica* (Equation 4–376). The carboxylato group of **Glutamate** 72 has to remove a hydron from the 3-ammonio group of 3-ammonio-2-oxopropyl phosphate before its nitrogen can add nucleophilically to carbonyl carbon 2 of 1-deoxy-D-xylulose during first step in the reaction (Equation 4–365) catalyzed by pyridoxine 5′-phosphate synthase from *E. coli* (Figure 4–48A). **Serine** 150 must relay the acidity of the 6-ammonio group of **Lysine** 72 to hydronate the alkylamino group before it can leave as an amine from the tetrahedral intermediate in the reaction catalyzed by 6-aminohexanoate-cyclic-dimer hydrolase from *Arthrobacter* (Equation 4–378). The **amino-terminal α-ammonio group** of the protein must hydronate the amino group before it can leave as ammonia from the tetrahedral intermediate in the hydrolysis catalyzed by the active site in the glutaminase domain (previously Equation 3–528)

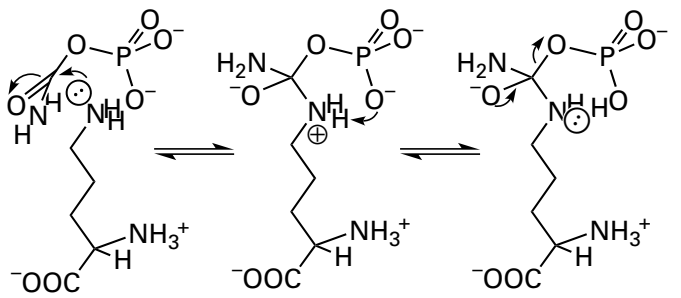
$$\text{L-glutamine} + H_2O \rightleftharpoons \text{L-glutamate} + NH_4^+$$

(4–383)

of asparagine synthase (glutamine-hydrolyzing) from *E. coli*.[953] **Histidine** 232 must hydronate the dialkylamino group before it can leave as the dialkyl secondary amine *N*-methylglycine from the tetrahedral intermediate in the reaction catalyzed by creatinase from *P. putida* (Equation 4–369),[875] and the imidazolyl group of Histidine 141 has to remove the hydron from the 6-ammonio group of GDP-4-amino-4,6-dideoxy-α-D-mannose in the active site of GDP-perosamine *N*-acetyltransferase from *Caulobacter vibrioides* before it can add to the acyl carbon of acetyl-SCoA to initiate the acetyl transfer catalyzed by the enzyme.[954] In the first step of the nucleophilic substitution catalyzed by arginine dihydrolase from *Synechocystis*, Histidine 248 must hydronate one of the two amino groups before it can leave as ammonia from a tetrahedral intermediate in which the four substituents are all heteroatoms: the sulfur of Cysteine 365 and the three nitrogens in the guanidinio group of the substrate L-arginine to which the sulfido group of the cysteine has added nucleophilically.[955] The **phenolate oxygen of a lysylpyridoximine** or some other base has to remove a hydron from the α-ammonio group of the substrate before its nitrogen can add nucleophilically to the iminium carbon of an internal lysylpyridoximine (Figure 2–2), and the resulting conjugate acid of the phenolate oxygen or of the other base hydronates the amino group of the former iminium nitrogen of the internal lysylpyridoximine before it can shuttle the second hydron between the two nitrogens in the tetrahedral intermediate.

Histidine 57 in bovine trypsin is the histidine in the **imidazolyl-carboxy composite acid–base** that is homologous to the one in chymotrypsin (Equation 4–134). After Histidine 57 has removed the hydron from Serine 194 during formation of the tetrahedral intermediate, its imidazolyl group pivots around to the alkylamino group in the tetrahedral intermediate and hydronates the nitrogen before it can leave during the acylation of Serine 194 catalyzed by the enzyme (Figure 3–6).[135,956]

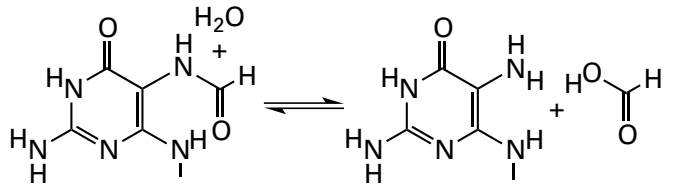
In the nucleophilic substitution catalyzed by ornithine carbamoyltransferase from *E. coli*, the side chain of an amino acid does not act as a catalytic base, but **one oxygen of the phospho group** of the reactant, carbamoyl phosphate[957]



(4–384)

is conveniently positioned 4 atoms away. Ornithine binds to the enzyme as the neutral zwitterion with a nucleophilic 5-amino group that adds directly to the carbonato carbon of carbamoyl phosphate.[109] The phospho group of carbamoyl phosphate then removes the *pro-S* hydron from the now-ammonio nitrogen in the tetrahedral intermediate to make the phosphate the preferred leaving group.[957] The hydrogen bond between phosphoryl oxygen and ammonio group in the tetrahedral intermediate forms a five-membered ring, which is ideal for the transfer of a hydron. Removal of this hydron is unavoidable because only after it is dehydronated can the amino group become the required secondary ureido nitrogen in L-citrulline.

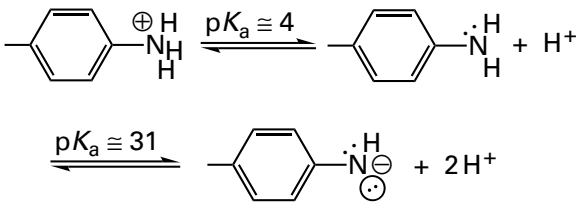
The choices by natural selection of an acid–base for the role of removing a hydron from an ammonio group or adding a hydron to an amine seem arbitrary. In the examples just cited, a carboxy group, an amino terminus, an imidazolyl group, a 4-hydroxyphenyl group, a composite hydroxy-6-amino group, and a phospho group have been chosen as catalytic acid–bases. In GTP cyclohydrolase I from *E. coli*, Histidine 179 hydronates the vinylamine that leaves from the tetrahedral intermediate in the latter of two consecutive hydrolyses catalyzed by the enzyme[958]



(4–385)

In the unrelated GTP cyclohydrolase II from *E. coli*, however, which catalyzes exactly the same hydrolysis, Tyrosine 105 hydronates the same nitrogen.[959]

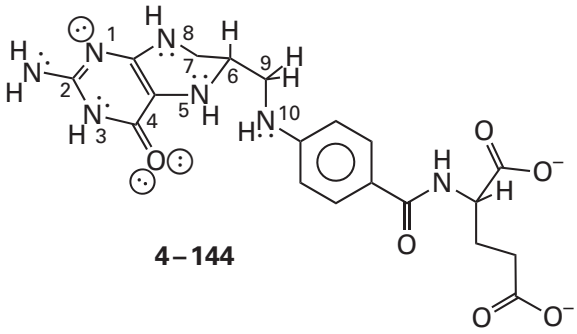
Nitrogen in an aniline



(4–386)

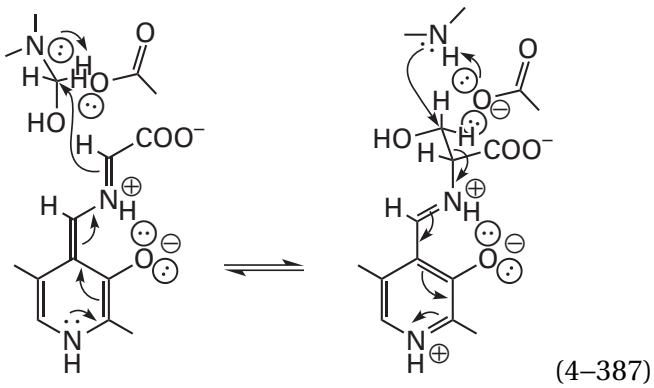
is a poor nucleophile but likely to be unhydronated at neutral pH. In the role of a leaving group, however, the nitrogen in a neutral anilino group inescapably requires a catalytic acid to hydronate it because the anilino anion is an impermissible leaving group ($pK_a = 31$). This hydronation of the leaving nitrogen is not such an inescapable requirement as the one for nitrogen in an amino group, but it is nevertheless imperative.

Both nitrogen 5 and nitrogen 10 of **tetrahydrofolate** (previously **1–81**)



4 – 144

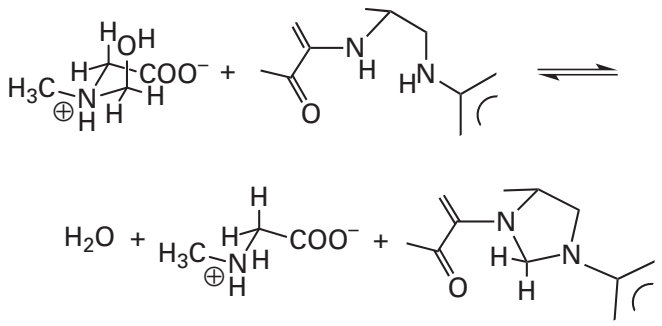
are anilino nitrogens on the basis of acid dissociation constants of their conjugate acids,[960] and they require a catalytic acid to add a hydron to them before they can leave. By microscopic reversibility, in the reverse reaction the resulting catalytic base removes a hydron from the anilino nitrogen as it adds and thus increases its nucleophilicity. For example, when the α carbon of the quininoid intermediate of glycine is adding to the hydroxymethyl group of the hydrate of N^5-methylenetetrahydrofolate, the anilino nitrogen 5 of tetrahydrofolate must be hydronated in order to leave



(4–387)

and this role is fulfilled by the carboxy group of **Glutamate** 75 in the active site of murine glycine hydroxymethyltransferase.[961] In the reverse reaction, the carboxylato group of Glutamate 75 removes the hydron from nitrogen 5 to improve its nucleophilicity.

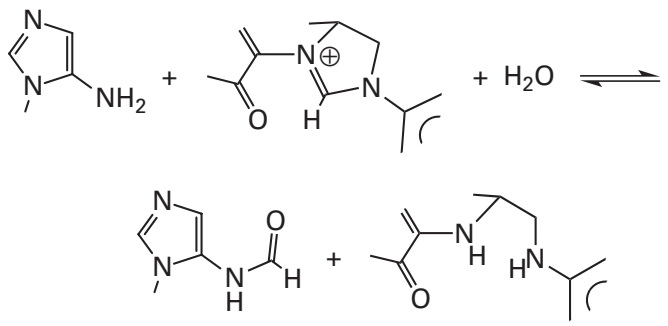
When either anilino nitrogen in tetrahydrofolate enters into or leaves from the successive intermediates in the enzymatic **transfer of a methenyl to or from tetrahydrofolate**



(4–388)

a catalytic acid–base hydronates or dehydronates the respective nitrogens. In the second half of the reaction catalyzed by dimethylglycine dehydrogenase (Equation 4–388) from *A. globiformis*, the carboxy group of **Aspartate** 552 dehydronates nitrogen 10 of tetrahydrofolate, and the 4-oxidophenyl group of the conjugate base of **Tyrosine** 651, through a hydron wire (0.33, 0.26, and 0.28 nm) of two molecules of water, dehydronates nitrogen 5.[962]

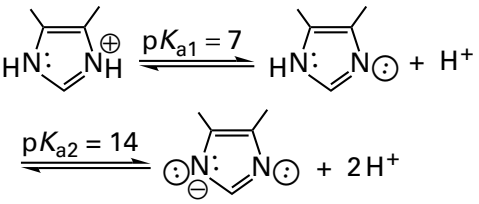
Furthermore, when either anilino nitrogen leaves from or enters into the tetrahedral intermediate in the enzymatic **transfer of a formyl group to or from tetrahydrofolate**



(4–389)

a catalytic acid–base must hydronate or dehydronate the respective nitrogens. In phosphoribosylaminoimidazolecarboxamide formyltransferase from *G. gallus*, the 6-ammonio group of **Lysine** 267 plays at least one of these roles, and perhaps the hydroxy group of **Serine** 451 plays the other.[963]

Nitrogen in the imidazolyl group of an imidazole

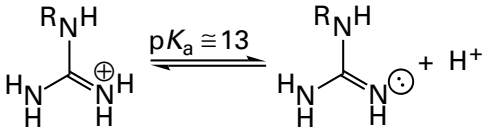


(4–390)

a benzimidazole ($pK_{a1} = 5$, $pK_{a2} = 13$) or the imidazolyl group of a purine such as adenine ($pK_{a1} = 4$, $pK_{a2} = 10$) or guanine ($pK_a = 3$, $pK_a = 9$) is a poor to middling leaving group when it is unhydronated on the distal nitrogen. As has already been noted, the ability of nitrogen in a covalent bond with carbon to leave is usually improved by providing a catalytic acid to hydronate the other, distal nitrogen in the imidazolyl group ($pK_a = 7$), the benzimidazolyl group ($pK_a = 5$), or the adeninyl ($pK_a = 4$) or guaninyl group ($pK_a = 3$), the one that is not leaving.[964,965] For example, **Glutamic Acid** 317 hydronates the other nitrogen in dimethylbenzimidazole as it leaves in the reaction catalyzed by nicotinate-nucleotide—dimethylbenzimidazole phosphoribosyltransferase from *S. typhimurium* (Figure 3–31). Aspartate 92 removes the hydron from the distal nitrogen in the imidazolyl group as guanine adds to 5-phospho-α-D-ribose 1-diphosphate in the active site of xanthine phosphoribosyltransferase from *E. coli* (**4–127**), and **Aspartic Acid** 137 adds a hydron to the distal nitrogen in the imidazolyl group when hypoxanthine or guanine leaves during the reaction catalyzed by human hypoxanthine phosphoribosyltransferase (Figure 3–38). The **carboxy-terminal carboxy group** of Tyrosine 158 in the active site of

nucleoside deoxyribosyltransferase from *Lactobacillus helveticus* hydronates the distal nitrogen in the imidazolyl group of an adenine that is a leaving group from a reactant while the other oxygen of the carboxy group is pinned in a hydrogen bond to the amido group on carbon 6 of the adenine.[966]

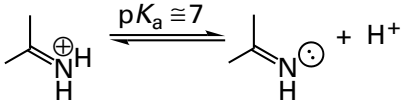
Nitrogen in a guanidinio group



(4–391)

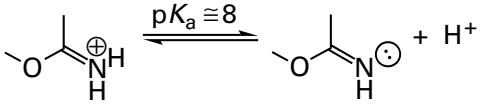
where R can be a carbon or a hydrogen, is a strong nucleophile when it is the neutral, unhydronated conjugate base, but for the same reason it is unlikely to be unhydronated at neutral pH. It follows that even when a guanidinio group is the hydronated, cationic conjugate acid, it is a poor leaving group. In the active site of guanidinoacetate *N*-methyltransferase from *R. norvegicus* (Figure 3–34), Aspartate 134 removes the hydron from the guanidinio nitrogen to unveil its nucleophilic σ lone pair of electrons that can participate in a concerted nucleophilic substitution at the methyl group of *S*-adenosyl-L-methionine. In the reverse reaction, Aspartate 134 must hydronate the same nitrogen as it is leaving to improve its ability as a leaving group. It has already been noted, however, that in the active sites of creatine kinase and arginine kinase (Figure 3–41), the electrons in the π molecular orbital system are the nucleophile, rather than a lone pair of electrons in the plane of the guanidino group of the conjugate base, and Aspartate 134 in guanidinoacetate *N*-methyltransferase is also not situated within the plane of the guanidinio group.

During addition **of a nucleophile to an imine**



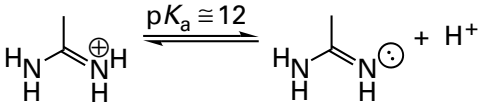
(4–392)

an imidoester



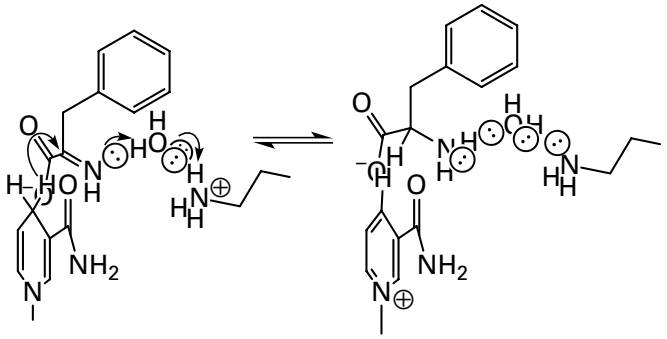
(4–393)

or an amidine



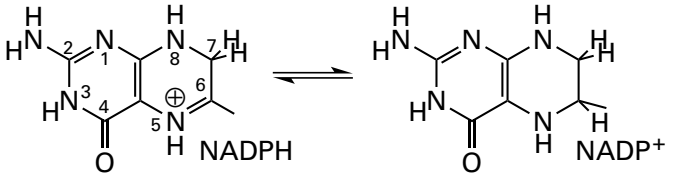
(4–394)

the imino nitrogen in each of these reactants must be hydronated, either before or during the addition to the carbonyl or acyl carbon that forms the respective tetrahedral intermediate. Otherwise an azanide (p$K_a = 39$) or an anilino anion (p$K_a = 31$), which are both more basic than an oxyanion (p$K_a = 15$), would be formed. As with nucleophilic addition to a carbonyl or acyl carbon, one of the simplest examples of such a nucleophilic addition is the addition of a hydride to an imino group catalyzed by a dehydrogenase or reductase.[967,968] For example, a molecule of water (0.26 nm) relays the hydron from Lysine 78 (0.26 nm) in the active site of phenylalanine dehydrogenase from *Rhodococcus* to the imino nitrogen in 2-imino-3-phenylpropionate either before or while a hydride is transferred stereospecifically from NADH to carbon 2 to reduce 2-imino-3-phenylpropionate to L-phenylalanine[969]



(4–395)

One of the most puzzling instances of this requirement for hydronation upon hydride transfer is the as yet unanswered question of what catalytic acid in the active site of dihydrofolate reductase (Equation 4–148) could hydronate nitrogen 5 during addition of a hydride by NADPH to carbon 6 of dihydrofolate



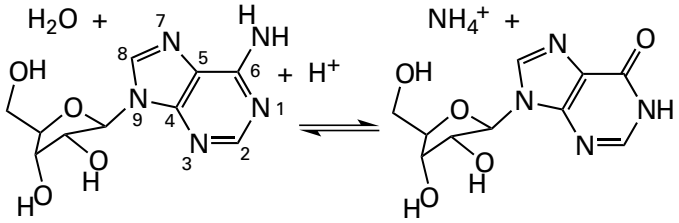
(4–396)

to give tetrahydrofolate.[970,971] Again, the requirement that nitrogen 5 be hydronated must be unavoidable because, if the nitrogen were not hydronated,

the anionic conjugate base of an aniline would be formed. The answer to the question is probably that the dihydrofolate has to enter the active site as the conjugate acid at nitrogen 5 ($pK_a = 4.82$), which is present in solution at reasonable levels, before the reaction can proceed. When dihydrofolate enters the active site as the conjugate base at nitrogen 5, hydride transfer cannot occur, and it simply dissociates.

Tyrosine 146 in fructose-bisphosphate aldolase from *T. tenax* (Equation 4–368) has to ensure that the nitrogen of the lysylimine of glycerone phosphate remains hydronated while a hydron is removed from carbon 3, because an azanide anion would be formed during removal of the hydron from carbon if the imine were not hydronated.

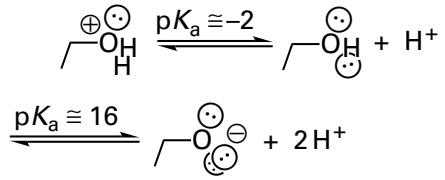
In the nucleophilic substitution catalyzed by murine adenosine deaminase



(4–397)

nitrogen 1 is hydronated by Glutamic Acid 217 to make the amidine in the adenine more electrophilic and avoid an anionic nitrogen in the tetrahedral intermediate either before or during nucleophilic addition of the hydroxy group of water to carbon 6.[972]

Oxygen in a hydroxy group



(4–398)

because its pK_a is so large, is a poor leaving group, and although hydroxide and alkoxide anions are strong nucleophiles, water and hydroxy groups are almost completely neutral at neutral pH. Consequently, a catalytic acid is required to hydronate a leaving oxygen in a hydroxy or alkoxy group. In the other direction, the conjugate catalytic base of that catalytic acid is required to remove a hydron from the corresponding water or hydroxy group to make it a nucleophile. Unlike the situation with a chloro group or even a guanidino group, these are inescapable requirements. Furthermore, one would expect that because hydronating an oxygen that is leaving is difficult and removing the hydron from a hydroxy group or a molecule of water that is adding is also difficult, only certain catalytic acid–bases would be capable of these responsibilities. Again, however, the choice of catalytic acid–bases made by natural selection is curiously eclectic.

The imidazolyl group of **Histidine** 322 must hydronate the hydroxy group of (*S*,*S*)-tartrate while that hydroxy group is leaving as water during the elimination catalyzed by D(–)-tartrate dehydratase from *B. japonicum* (Equation 4–267). The imidazolyl group of Histidine 231 must remove the hydron from the molecule of water while it adds nucleophilically to the acyl carbon of the peptide bond during the hydrolysis catalyzed by thermolysin (Figure 3–42). Histidine 195 must remove a hydron from the primary hydroxy group of chloramphenicol while it is adding nucleophilically to the acyl carbon of acetyl-SCoA in the active site of chloramphenicol *O*-acetyltransferase from *E. coli* (**4–132**). The imidazolyl group of Histidine 45 must hydronate the 4-hydroxy group while it leaves as water, and the **phospho-imidazolyl composite** base must remove a hydron from the molecule of water as it adds to carbon 5 during the reaction catalyzed by pyridoxine 5′-phosphate synthase from *E. coli* (Figures 4–47 and 4–48). The **imidazolyl-carboxy composite** acid must hydronate the furanose oxygen of α-D-fructofuranose 6-phosphate during the ring opening catalyzed by glucose-6-phosphate isomerase (**4–137**). The imidazolyl-carboxy composite base (Equation 4–134) must remove the hydron from the hydroxy group of Serine 195 (see **4–39** and the second stereodrawing in Problem 3–30) in bovine chymotrypsin while it adds nucleophilically to the acyl carbon of a peptide bond during the hydrolysis (Figure 3–6) catalyzed by the enzyme.

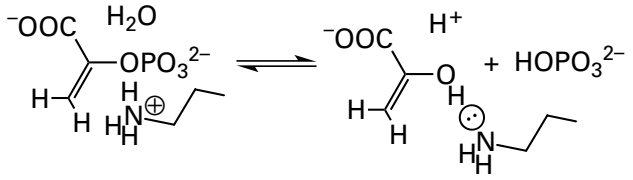
The carboxy group of **Glutamate** 211 or Glutamate 168 (Figure 4–43)—or possibly the imidazolyl group of Histidine 373 (not shown in Figure 4–43)—must hydronate the 3-hydroxy group of 2-phospho-D-glycerate while it is leaving as water during the elimination catalyzed by phosphopyruvate hydratase (Equation 4–128) from *S. cerevisiae*. Aspartate 215 must remove a hydron from the molecule of water while it adds nucleophilically to the acyl carbon of a peptide bond during the hydrolysis catalyzed by endothiapepsin from *C. parasitica* (Equation 4–376). Aspartate 443 must remove a hydron from the molecule of water while it adds nucleophilically to the imidazolyl group during the reaction catalyzed by

urocanate hydratase from *P. putida* (Figures 4–49 and 4–50).

The 4-hydroxyphenyl group of **Tyrosine** 146 must shuttle two hydrons to the oxyanion in the tetrahedral intermediate so that it can leave as water during formation of the imine in the reaction catalyzed by fructose-bisphosphate aldolase from *T. tenax* (Equation 4–368). The 4-hydroxyphenyl group of Tyrosine 242 must hydronate the oxygen of the glycosidic linkage to *N*-acetylgalactosaminyl 4-sulfate while that oxygen is leaving during the elimination catalyzed by chondroitin AC lyase from *P. aurescens* (Equation 4–358 and Figure 4–44).

An ester between the hydroxy group of Threonine 12 and the β-carboxy group of L-aspartate is a covalent acyl intermediate in hydrolysis of L-asparagine catalyzed by asparaginase from *E. coli*. The basicity of the 4-oxidophenyl group of Tyrosine 25 in the active site is relayed through a molecule of water that removes a hydron from a second molecule of water. This second molecule of water is the nucleophile that adds to the acyl intermediate to form the tetrahedral intermediate, which has been observed in a crystallographic molecular model.[973] The resulting 4-hydroxyphenyl group of Tyrosine 25 then hydronates the oxygen of Threonine 12 as the hydron on the hydroxy group of the tetrahedral intermediate, which was the molecule of water, is transferred through the intervening molecule of water to the 4-hydroxyphenyl group. This transfer of a hydron allows the developing oxido group in the tetrahedral intermediate to provide push while the hydroxy group of Threonine 12 being hydronated leaves. In the transition state, a hydron is leaving the 4-hydroxyphenyl group as another hydron is arriving from the relay, and a hydron is leaving the relay as another hydron is arriving.

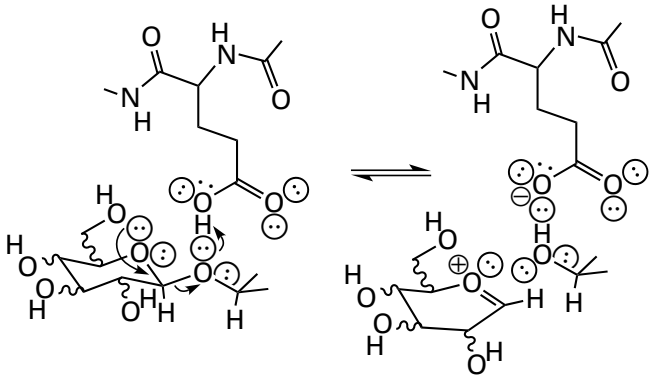
The guanidinio group of **Arginine** 241 must hydronate the oxygen of the glycosidic linkage to an α-L-guluronoyl group while that oxygen is leaving during the elimination catalyzed by guluronate-specific alginate lyase from *Paraglaciecola chathamensis*.[974] **Serine** 150 must relay the basicity of **Lysine** 72 to remove a hydron from Serine 174 while it adds to the acyl oxygen of the substrate during the hydrolysis catalyzed by 6-aminohexanoate-cyclic-dimer hydrolase from *Arthrobacter* (Equation 4–378). The 6-ammonio group of Lysine 207 directly hydronates the oxygen on carbon 2 of phosph*enol*pyruvate while it leaves phosphorus during the hydrolytic nucleophilic substitution at phosphorus that forms the enol of pyruvate



(4–399)

during the aldol condensation catalyzed by 3-deoxy-7-phosphoheptulonate synthase from *T. maritima*.[975]

Glycosidases are enzymes that hydrolyze *O*-glycosyl oligosaccharides and polysaccharides. In most glycosidases, a carboxy group—usually in the side chain of a **glutamic acid**,[795,976-983] such as Glutamate 35 in lysozyme (Figure 3–27) from *G. gallus*, but occasionally[984] in the side chain of an **aspartic acid**—performs the necessary hydronation of oxygen in the alkoxy group in the monosaccharide toward the reducing end of the oligosaccharide while it is leaving from the acetal or ketal that is the glycosidic linkage



(4–400)

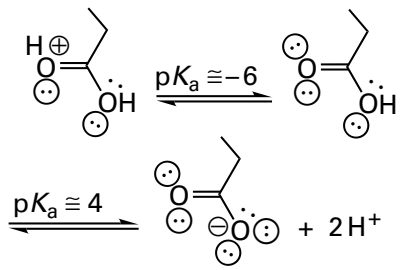
The oxygen of the carboxy group is positioned so that it forms a hydrogen bond with an sp^3-hybridized lone pair on the oxygen of the acetal and an sp^3-hybridized lone pair on the hydroxy group of the alcohol that leaves.[985] In the absence of hydronation, the alkoxide would have to be the leaving group, which would make dissociation difficult. In the unoccupied active site of lysozyme, Glutamate 35 has a pK_a of 6.0, and in the unoccupied active site of endo-1,4-β-xylanase from *B. circulans*, Glutamate 172, which hydronates the leaving group in this glycosidase,[935] has a pK_a of 6.7. These values are too high for the respective acids to hydronate the oxygen of the acetal (pK_a = –2) in the ground state before it leaves, so it must be the case that hydronation occurs as it leaves.

In most glycosidases, the leaving group dissociates from the active site and a molecule of water takes its place. The carboxylato group on the same

glutamate or aspartate then removes a hydron while the molecule of water adds nucleophilically, in the reverse of Equation 4–400, resulting in **retention of configuration** at the glycosidic carbon.

There are also glycosidases, however, that hydrolyze oligosaccharides and polysaccharides with **inversion of configuration** at the glycosidic carbon to produce, for example, an α glycoside from a β oligosaccharide or polysaccharide.[986,987] In these enzymes, a catalytic carboxy group from glutamate or aspartate still hydronates the leaving group (Equation 4–400), but a second carboxylato group acts as a catalytic base, performing the necessary removal of a hydron from a fixed molecule of water or hydroxy group on the opposite side of the glycosidic carbon from the leaving group. That molecule of water or that hydroxy group adds nucleophilically to the glycosidic carbon either during or immediately after dissociation of the leaving group and while this other carboxylato group is removing one of its hydrons.[976,984,988] In at least one inverting glycosidase, the required role of removing this hydron has been assumed by the 4-hydroxyphenyl group of a tyrosine rather than a carboxylato group.[983]

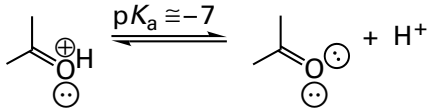
Oxygen in a carboxy group



(4–401)

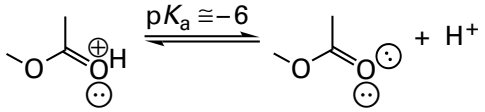
is a weak nucleophile, but it is usually already unhydronated and anionic at neutral pH. Oxygen in a carboxy group is also an excellent leaving group. Nevertheless, as a nucleophile and as a leaving group, it is usually provided with a catalytic acid–base by the active site. For example, in phosphatase from *B. thetaiotaomicron* (Figure 3–43), **Lysine** 188 provides a hydrogen bond (0.29 nm) to enhance the ability of the oxygen in the carboxy group of Aspartate 8 to leave the phosphorane that is the intermediate in the reaction. The 4-hydroxyphenyl group of **Tyrosine** 163 in cystathionine γ-synthase from *N. tabacum* provides a hydrogen bond for the oxygen of the succinyl group that leaves from O^4-succinyl-L-homoserine (Equation 4–259) as well as providing a hydrogen bond for the sulfur of the L-cysteine that leaves from cystathionine in the reverse reaction (Equation 4–257).[537]

The **oxygen in a carbonyl**



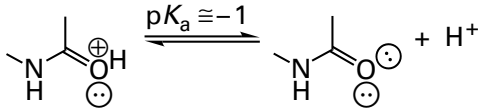
(4–402)

an ester



(4–403)

or **an amide**[989]

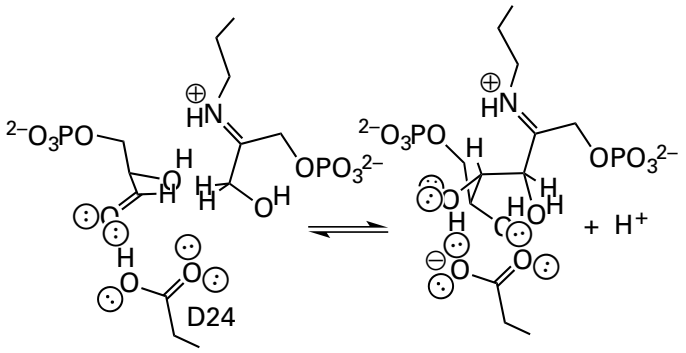


(4–404)

cannot be hydronated by any available catalytic acid in an active site. Nevertheless, when it is to become a hydroxy group in the product, the **oxyanion that results from nucleophilic addition to a carbonyl, ester, or amide** is almost always hydronated by a catalytic acid in an active site as it is being formed. One of the simplest examples is an oxygen that becomes a hydroxy group upon nucleophilic addition of a hydride to a carbonyl or acyl carbon catalyzed by a dehydrogenase or reductase. For example, in the active site of porcine lactate hydrogenase (Equation 4–204), **Histidine** 195 hydronates the developing oxyanion while NADH adds a hydride to the carbonyl of pyruvate.[909] In the active site of sorbose reductase from *Gluconobacter frateurii*, a hydron wire culminating in **Tyrosine** 157 hydronates the developing oxyanion as NADPH adds a hydride to the carbonyl of L-sorbose.[990] In the active site of dTDP-glucose 4,6-dehydratase from *E. coli*, however, Tyrosine 160 by itself dehydronates the developing carbonyl group as the prosthetic NAD^+ in the active site removes a hydride from carbon 4 of dTDP-α-D-glucose.[991] In the active site of human glycerol-3-phosphate dehydrogenase (NAD^+), the ammonio groups from **Lysine**s 120 and 204 form hydrogen bonds with the oxygen of the carbonyl in glycerone phosphate that is reduced.[992]

When the carbanionic carbon of an enolate, enol, or enamine is added to a carbonyl carbon to convert it to an alcohol, a catalytic acid is supplied to hydronate the oxygen. For example, during the aldol condensation between the lysyl enamine of glycerone phosphate and D-glyceraldehyde 3-phosphate, **Aspartic Acid** 24 in the active site of fructose-

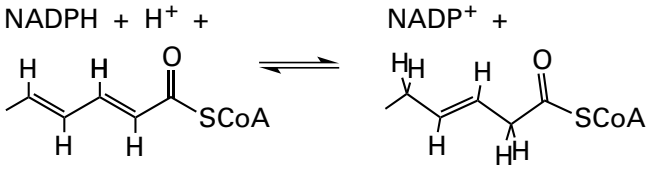
bisphosphate aldolase (Equation 4–210) from *T. tenax* hydronates the oxygen of the carbonyl in D-glyceraldehyde 3-phosphate that eventually becomes the 4-hydroxy group in D-fructose 1,6-bisphosphate[874]



(4–405)

Glutamic Acid 49 in the active site of indole-3-glycerol-phosphate lyase within tryptophan synthase (**4–122**) hydronates the oxygen of the carbonyl of glyceraldehyde 3-phosphate (Figure 4–45) that becomes a hydroxy group during nucleophilic addition of the enamine of indole to that carbonyl carbon (Equation 4–363).

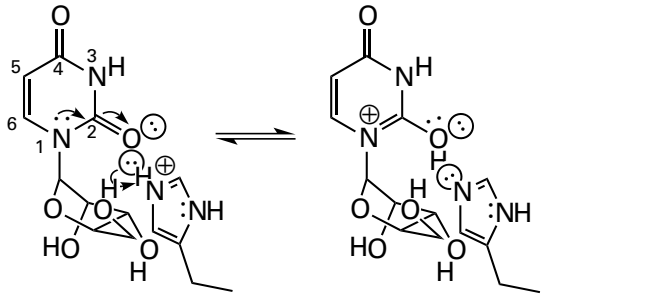
Even when the **oxyanion formed from a nucleophilic addition is transient** and will become an unhydronated carbonyl or acyl group in the product, a catalytic acid is sometimes provided rather than the far more common oxyanion hole. For example, in chalcone isomerase from *M. sativa* (Equation 4–359), the acidity of Tyrosine 106 is relayed through a molecule of water to hydronate the carbonyl oxygen during nucleophilic addition to the α,β-unsaturated carbonyl;[854] in the active site of hydroxymethylglutaryl-CoA synthase from *S. aureus* (Equation 4–360), Histidine 233 transiently hydronates the acyl oxygen of acetoacetyl-SCoA during nucleophilic addition of the enolate of acetyl-SCoA (Equation 4–361);[858] and in endothiapepsin from *C. parasitica* (Equation 4–376), Aspartic Acid 32 hydronates the acyl oxygen of the peptide bond during nucleophilic addition of a molecule of water. In the nucleophilic addition of a hydride catalyzed by human 2,4-dienoyl-CoA reductase (NADPH)



(4–406)

the acyl oxygen of a dienoyl-SCoA, which transiently becomes the oxygen of an enol, is hydronated by Tyrosine 199 (see **4–125**).[866]

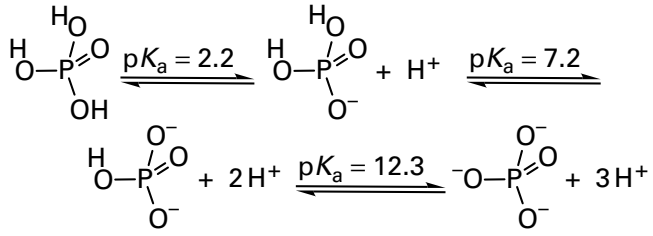
Nitrogen 1 of a pyrimidine such as cytosine ($pK_a = 8$), uracil ($pK_a = 10$), or thymine can be turned into a better leaving group by hydronating the carbonylbis(azanediyl) oxygen on carbon 2



(4–407)

as in the active site of ribosylpyrimidine nucleosidase from *E. coli*.[993] Furthermore, if an acceptor for a hydrogen bond with the hydron on nitrogen 3 and a donor for a hydrogen bond with the oxygen on carbon 4 of uridine (Equation 4–407) are provided by the active site, in addition to hydronating the oxygen on carbon 2, then these three catalytic acid–bases increase the concentration of the unstable tautomer of uridine in which the ring is an aromatic 2,4-dihydroxypyrimidinio group.[994] This tautomer simulates the pyridinio group in an *N*-alkylpyridinium, which is an excellent leaving group. In the case of cytidine, all that is needed is to hydronate the oxygen on carbon 2 to produce the aromatic 4-amino-2-hydroxypyrimidinio group. A similar way in which an active site can make guanine a better leaving group is to hydronate the amido oxygen on carbon 6, as does the hydron on the carboxy group of Glutamate 201, which is relayed through a molecule of water, in the active site of bovine purine-nucleoside phosphorylase.[995]

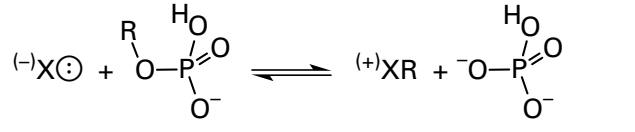
Oxygen in hydrogen phosphate dianion, $HOPO_3^{2-}$



(4–408)

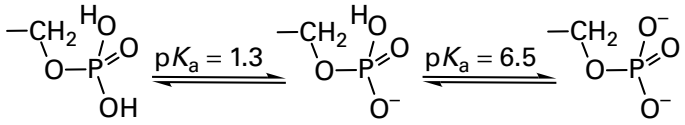
is more nucleophilic than a carboxy group. The pK_a for its conjugate acid, dihydrogen phosphate

monoanion, $HOPO_3H^-$, is 7.2, so at neutral pH there should be a significant fraction of the phosphate in a solution present as the nucleophilic dianion. Because the pK_a for its conjugate acid is 7.2, hydrogen phosphate dianion, without further assistance, is a good leaving group from the carbon in a monoanionic hydrogen phosphomonoester, $ROPO_3H^-$



(4–409)

Because its pK_a is around 6.5, at neutral pH a significant fraction of the phospho group in a phosphomonoester should be the monoanionic hydrogen phosphomonoester



(4–410)

as required. Because a phosphate trianion (pK_a = 12.3) cannot leave from a completely unhydronated dianionic phosphomonoester, $ROPO_3^{2-}$, which should be the major fraction of a phosphomonoester at neutral pH, at least one of the two nonbridging oxygens in a phosphomonoester must be kept hydronated (Equation 4–409) if a phospho group is to function as a leaving group.

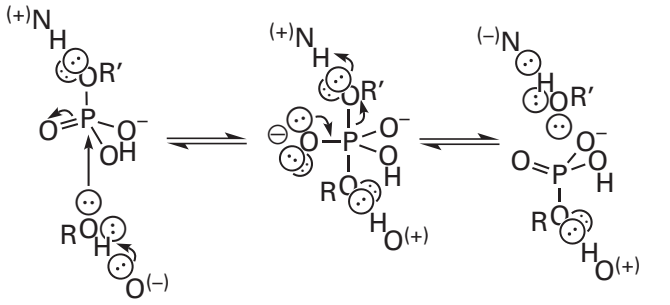
Regardless of the fact that hydrogen phosphate dianion by itself is a good nucleophile, a catalytic acid–base is usually supplied to orient that oxygen by a hydrogen bond and to **ensure that the oxygen that is the nucleophile is unhydronated**, and a conjugate base is often supplied to ensure that its other hydron (pK_a = 12.3) is removed as the nucleophilic substitution proceeds. For example, in the active site of glycogen phosphorylase from *O. cuniculus*, phosphate is the nucleophile in a nucleophilic substitution at carbon in which it replaces, at carbon 1 of a D-glucosyl group, the 4-hydroxy group of an adjacent D-glucosyl group in glycogen, poly(α1,4)-D-glucose. Lysine 574, Arginine 569, and an amido nitrogen–hydrogen from the polypeptide, by forming hydrogen bonds, ensure that two oxygens of the phosphate remain unhydronated during the reaction. The remaining, hydronated oxygen of the phosphate dianion (Equation 4–408) hydronates the leaving 4-hydroxy group of the D-glucosyl group (0.29 nm) while one of the other, previously anionic, oxygens of the phosphate is hydronated, to avoid formation of the trianion of phosphate, by the phospho group of a prosthetic pyridoxal 5′-phosphate (0.27 nm) in the active site as the 4-hydroxy group of the D-glucosyl group leaves to form the oxocarbenium ion. The nucleophilic oxygen in the resulting dianion of the phosphate, which just gave its hydron to the leaving group and which remains unhydronated because of hydrogen bonds to Lysine 574 and Arginine 569, then adds to the oxocarbenium ion at carbon 1 of the other D-glucosyl group as the phospho group of pyridoxal 5′-phosphate removes the hydron it just added to the phosphate to increase the nucleophilicity of the dianion.[996]

Regardless of the fact that hydrogen phosphate dianion by itself is a good leaving group (pK_a = 7.2), from carbon, catalytic acids are usually supplied both to **hydronate the bridging oxygen leaving from a monoanionic phosphomonoester** and to ensure that at least one of its nonbridging oxygens remains hydronated to ensure its ability to leave. For example, the imidazolyl groups of Histidine 12 and Histidine 52 and the carboxy group of Aspartate 11, acting in concert, ensure that the phospho group of 1-deoxy-D-xylulose 5-phosphate in the active site of pyridoxine 5′-phosphate synthase from *E. coli* remains at least monoanionic (Figure 4–48A), but the imidazolyl group of **Histidine** 45 hydronates the phospho oxygen that actually leaves (Figure 4–48B). The acidity of a composite acid formed from the carboxy group of the substrate and the imidazolyl group of Histidine 110 is relayed through three molecules of water to the phospho oxygen that leaves carbon 3 during the elimination catalyzed by chorismate synthase (Equation 4–250) from *S. pneumoniae*.[298] In (2*E*,6*E*)-farnesyl diphosphate synthase (Figure 3–44),[515] **Lysine** 202 provides a hydrogen bond to the oxygen of the diphosphate that actually leaves from the carbon of geranyl diphosphate to produce the methylalkylallyl carbenium ion (see Figure 1–26), even though the diphosphate has three Mg^{2+} as ligands.

The many nucleophilic substitutions at phosphorus catalyzed by enzymes almost always involve the transfer of a phospho group from one oxygen to another oxygen. In many of these instances, one or both oxygens are hydroxy groups on carbon or one is a hydroxy group on carbon and the other is a a hydroxy group on a molecule of water. In these cases, **a catalytic acid must be provided to hydronate the weakly acidic oxygen that is leaving, and a catalytic base must be provided to remove a hydron**

from the weakly basic hydroxy group while it is adding as a nucleophile. For example, the carboxy group of **Aspartate** 13 must hydronate the oxygen of serine phosphate while it leaves during the nucleophilic substitution at phosphorus catalyzed by phosphoserine phosphatase from *M. jannaschii* (Figure 3–56). In many instances, however, one or both oxygens are bound to phosphorus. In these cases, the conjugate acid of the leaving group or the nucleophilic oxygen, or both of them, are respectively acidic enough to leave or basic enough to add without assistance. Nevertheless, a catalytic acid is often provided to hydronate the oxygen that is leaving, and a catalytic base is provided to ensure that the nucleophilic oxygen is unhydronated.

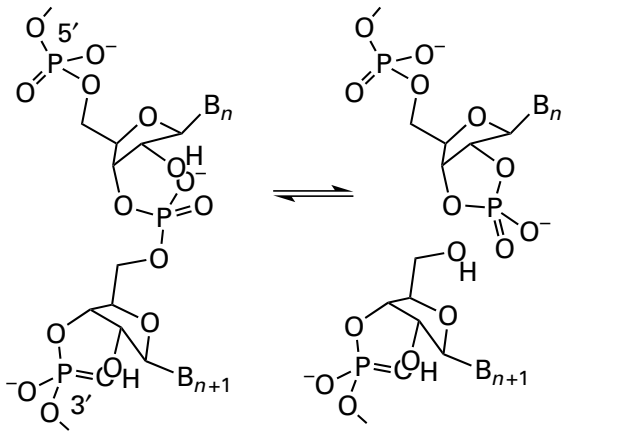
Catalytic acid–bases are provided for the oxygens that leave from and add to phosphorus, regardless of whether the nucleophilic substitution is associative with a **phosphorane** as an intermediate



(4–411)

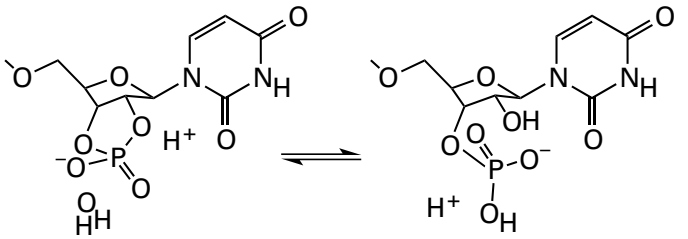
or dissociative with **monomeric metaphosphate** as an intermediate (see Figure 3–41). As with almost all classes of nucleophilic substitution, many if not most of the actual transition states fall between the two extremes of phosphorane and monomeric metaphosphate.

The active site of bovine **pancreatic ribonuclease** (Figure 4–46) is a paradigm of the requirements for catalytic acid–bases in nucleophilic substitutions at phosphorus. In the first step of the reaction, a molecule of RNA is cleaved to produce the 2′,3′-cyclic phosphate



(4–412)

In the second step, the 2′,3′-cyclic phosphate is hydrolyzed



(4–413)

In these two steps, either the intermediates[997] are fully formed phosphoranes (Equation 4–411),[998] as they are in the alkaline hydrolyses of uridine 3′-phosphate esters in solution,[999] or the transition states[1000,1001] are phosphoranes with partial bonds at their axial positions. It is most likely that both of them are intact phosphoranes because, as in nucleophilic substitutions at phosphorus in solution that proceed through intermediate phosphoranes,[1002] all three oxygens involved in the two successive nucleophilic substitutions in the active site of ribonuclease, the two hydroxy groups and the molecule of water, are weak bases.

In the two halves of the full hydrolysis, the roles of the two catalytic acid–bases at the axial positions are switched. During the first half (Equation 4–412), the imidazolyl group of Histidine 119 ($^{(+)}$NH in Equation 4–411) hydronates the leaving 5′-hydroxy group (Figure 4–46), and the 6-ammonio group of Lysine 41 (⊙O$^{(-)}$ in Equation 4–411) removes the hydron from the 2′-hydroxy group that adds nucleophilically to the phosphorus. During the hydrolysis of 2′,3′-cyclic phosphodiester (Equation 4–413), the 6-ammonio group of Lysine 41 ($^{(+)}$NH in Equation 4–411) hydronates the leaving 2′-hydroxy group (Figure 4–46), and the imidazolyl group of Histidine 119 (⊙O$^{(-)}$ in Equation 4–411)

removes the hydron from the molecule of water that adds nucleophilically to phosphorus. When Lysine 41 is replaced by cysteine, the rate constant $k_0 K_m^{-1}$ for hydrolysis of RNA catalyzed by the enzyme decreases by a factor of 100,000;[1003] and when Histidine 119 is replaced by alanine, it decreases by a factor of 8000.[1004]

From the crystallographic molecular model for the complex between bovine pancreatic ribonuclease and the vanadyl analogue of the phosphorane (Figure 4–46), a crystallographic molecular model from neutron diffraction of the same complex,[152] a crystallographic molecular model of the complex between bovine pancreatic ribonuclease and uridine 5′-phosphate,[1005] a crystallographic molecular model of the complex between bovine pancreatic ribonuclease and uridine 3′-phosphate,[1006] and the pH–rate behavior of the enzyme (Figure 4–11), the following description of the two nucleophilic substitutions at phosphorus performed by the active site of pancreatic ribonuclease can be formulated.*

The reactant ribonucleic acid (Equation 4–412) enters the active site with the two nonbridging oxygens on the phosphodiester that will be cleaved sharing, as usual, the equivalent of a charge number of –1, and they remain at that charge number until the reaction commences. Before the first nucleophilic substitution at phosphorus, the imidazolio group on Histidine 119 must be hydronated as the cationic conjugate acid, the imidazolyl group on Histidine 12 must be unhydronated as the neutral conjugate base, and the ammonio group on Lysine 41 must be hydronated as the conjugate acid. Before addition of the nucleophile itself commences, one of the nitrogen–hydrogen bonds of the cationic ammonio group on Lysine 41 forms a hydrogen bond with one of the two lone pairs of electrons on the oxygen of the 2′-hydroxy group from the ribose in the 5′-nucleotide; the unhydronated lone pair of electrons on the proximal nitrogen of the neutral imidazolyl group on Histidine 12 forms a hydrogen bond with the hydrogen of the same 2′-hydroxy group;[1005] and the nitrogen–hydrogen bond of the cationic imidazolio group of Histidine 119 forms a hydrogen bond with the leaving 5′-oxygen from the ribose in the 3′-nucleotide esterified to the phospho group at which the cleavage will occur. The hydron in the hydrogen bond between the neutral imidazolyl group on Histidine 12 and the 2′-hydroxy group moves from oxygen to nitrogen at the same time that the hydron in the hydrogen bond between the ammonio group on Lysine 41 and the 2′-hydroxy group moves from nitrogen to oxygen. The now-cationic imidazolio group on Histidine 12 swings away from the 2′-hydroxy group,* and its nitrogen–hydrogen bond forms a hydrogen bond (Figure 4–46) with one of the lone pairs of electrons on the closest of the two nonbridging oxygens of the phospho group.[1006]

The empty lone pair of electrons on the 2′-hydroxy group from the ribose in the 5′-nucleotide, which was released as the imidazolio group of Histidine 12 swung away, adds nucleophilically to phosphorus. The bond between this oxygen and phosphorus forms at the same time that the hydron in the hydrogen bond between this oxygen and the amino group of Lysine 41 is moving from oxygen to nitrogen (first step in the reverse of Equation 4–411) and the hydron in the hydrogen bond between the imidazolio group of Histidine 12 and the nonbridging oxygen is moving from nitrogen to oxygen. Formation of the covalent bond between the oxygen at the 2′-position on the ribose in the 5′-nucleotide and phosphorus produces the phosphorane (the intermediate in Equation 4–411). The two axial oxygens of the phosphorane are the oxygen at the 2′-position of the ribose in the 5′-nucleotide and the oxygen at the 5′-position of the ribose in the 3′-nucleotide. The three equatorial positions are occupied by the two nonbridging oxygens, one of which has been hydronated by the imidazolio group of Histidine 12, and the oxygen at the 3′-position on the ribose in the 5′-nucleotide (Figure 4–46).

In the phosphorane (Equation 4–411), the neutral imidazolyl group of Histidine 12 is forming a hydrogen bond with the nearest neutral, hydronated equatorial oxygen of the phosphorane; the cationic ammonio group of Lysine 41 is forming a hydrogen bond with the uncharged oxygen at the 2′-position on the ribose in the 5′-nucleotide that is at one axial position in the phosphorane; and the cationic imidazolio group of Histidine 119 is forming a hydrogen bond with the uncharged oxygen that is about to leave the 5′-position of the ribose in the 3′-nucleotide at the other axial position in the phosphorane.

The next step is dissociation of the phosphorane. As the bond between phosphorus in the phosphorane and the 5′-oxygen of the ribose of the leaving nucleo-

*While you proceed through the discussion, view Figure 4–46.

*It has also been proposed that the imidazolyl group of Histidine 12 remains hydrogen-bonded to the 2′-oxygen and is the catalytic base that dehydronates it, rather than Lysine 41.[1007] This proposal, however, disagrees with the disposition of catalytic acid–bases in the vanadyl complex.

tide is breaking, the hydron in the bond between the imidazolio group of Histidine 12 and the equatorial oxygen is moving from oxygen to nitrogen, and the hydron in the hydrogen bond between the imidazolio group of Histidine 119 and the 5′-oxygen is moving from nitrogen to oxygen. Consequently, when the bond between oxygen and phosphorus has broken, there is now a hydrogen bond between the neutral imidazolyl group of Histidine 119 and the 5′-hydroxy group from the ribose in the 3′-nucleotide. The 3′-fragment of RNA departs from the active site as one product of the reaction (Equation 4–412) because it is no longer attached covalently to phosphorus.

At this point, the other product is the nucleoside 2′,3′-cyclic phosphate (Equation 4–412). Its negatively charged nonbridging oxygen forms a hydrogen bond with the cationic imidazolio group of Histidine 12 (Figure 4–11), and the uncharged oxygen from the 2′-position of its ribose forms a hydrogen bond with the cationic ammonio group of Lysine 41. Forget for the moment that this cyclic nucleotide can leave the active site at this point and enter the active site of another molecule of pancreatic ribonuclease.

A molecule of water enters the active site and occupies a location identical to the location that had been occupied by the 5′-hydroxy group from the ribose in the 3′-nucleotide that just left, and one of its two hydrons forms an identical hydrogen bond to the lone pair of electrons on the nitrogen of the neutral imidazolyl group of Histidine 119 (Figure 4–11). At this point the roles of the amino group of Lysine 41 and the imidazolyl group of Histidine 119 reverse. The nucleoside 2′,3′-cyclic phosphate still has one of its negatively charged, nonbridging oxygens forming a hydrogen bond to the cationic imidazolio group of Histidine 12 and the uncharged oxygen from the 2′-position of its ribose forming a hydrogen bond to the cationic ammonio group of Lysine 41. As the bond between phosphorus and the oxygen of water that will become an axial oxygen in the second phosphorane is forming, the hydron in the hydrogen bond between the imidazolio group of Histidine 12 and the nonbridging oxygen is moving from nitrogen to oxygen, and the hydron in the hydrogen bond between that molecule of water and the imidazolyl group of Histidine 119 is moving from oxygen to nitrogen.

When the axial bond has formed and the phosphorane occupies the active site, there is a hydrogen bond between the cationic imidazolio group of Histidine 119 and one of the lone pairs of electrons of the hydroxy group that was in the molecule of water but is now one of the axial oxygens of the resulting phosphorane. The other axial oxygen of the phosphorane is the 2′-oxygen of the ribose. The three equatorial positions are occupied by the two nonbridging oxygens and the oxygen at the 3′-position of the nucleotide (Figure 4–46). In the phosphorane, the neutral imidazolyl group on Histidine 12 forms a hydrogen bond with the nearest hydronated, neutral nonbridging oxygens of the phosphorane; and the cationic ammonio group on Lysine 41 forms a hydrogen bond with the uncharged oxygen at the 2′-position of the ribose in the phosphorane.[152]

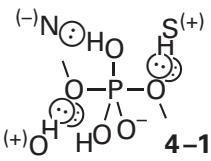
The next step is dissociation of the phosphorane. As the bond between the phosphorus and the 2′-oxygen of the ribose is breaking, the hydron in the hydrogen bond between the neutral oxygen at the 2′-position and the nitrogen of the cationic ammonio group of Lysine 41 is moving from nitrogen to oxygen, and the hydron in the hydrogen bond between the imidazolyl group of Histidine 12 and the nonbridging oxygen is moving from oxygen to nitrogen. When the dissociation of the 2′-oxygen is complete, there is a hydrogen bond between the anionic nonbridging oxygen of the phospho group on the 3′-oxygen of the ribose and the cationic imidazolio group of Histidine 12, and there is also a hydrogen bond between the now 2′-hydroxy group of the ribose and the amino group of Lysine 41. The overall reaction is now complete.

Transfer of the hydron in the hydrogen bond from the ammonio group of Lysine 41 to the 2′-oxygen that is leaving during the hydrolysis of uridine 2′,3′-cyclic phosphate occurs at the point on the reaction coordinate at which the pK_a for the conjugate acid of that oxygen equals the pK_a for the ammonio group. In the phosphorane, the pK_a for the conjugate acid of the 2′-oxygen in the hydrogen bond to the ammonio group of Lysine 41 is less than 0. After the 2′-oxygen has become the 2′-hydroxy group in a hydrogen bond to the amino group of Lysine 41 following its dissociation from phosphorus, the pK_a is around 14. Consequently, as the reaction proceeds along the reaction coordinate in the direction of dissociation of the 2′-oxygen from phosphorus, the hydrogen bond between the ammonio group (p$K_a \cong 11$) and 2′-oxygen increases in enthalpy of formation by about -1.3 kJ mol^{-1} for each unit of increase in pK_a for the congugate acid of the 2′-oxygen, until its pK_a equals than of the ammonio group.[1008] There is no additional increase in enthalpy of formation when the pK_a for the ammonio group

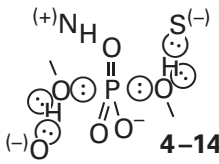
is equal to that of the conjugate acid of the oxygen,[1009,1010] especially because the two heteroatoms are different. The increase in enthalpy of formation of this hydrogen bond as the reaction moves along the reaction coordinate lowers the height of the transition state relative to the ground state and promotes catalysis.

This **increase in enthalpy of formation of a hydrogen bond** as the reaction progresses, however, also occurs during general acid catalysis in aqueous solution. Consequently, it cannot be a factor in explaining the increase in the rate of reaction in the active site relative to that same reaction under general acid catalysis in solution because the same effect is operating in each situation. Furthermore, one would expect that this increase in enthalpy of formation due to the increasing strength of the hydrogen bond as the reaction proceeds along the reaction coordinate would be diminished by changing the catalytic acid—in the case of pancreatic ribonuclease, the ammonio group—to an acid of lower pK_a. This expected decrease, however, must be less than the increase in rate that would be caused by the increased acidity of the conjugate acid because rates of reactions in solution always increase as one general acid catalyst is replaced by another that is a stronger acid. The larger the Brønsted coefficient of the reaction is, the larger is this increase in rate. The increase in enthalpy of formation of the hydrogen bond cannot appreciably increase the rate of the reaction in the active site relative to the same reaction under general acid catalysis in water, and this increase in enthalpy is not so consequential as the absolute acidity of the acid catalyst. These two facts apply to any transfer of a hydron within a hydrogen bond during acid or base catalysis that is coincident with formation and dissociation of covalent bonds while passing along a reaction coordinate in an active site or in solution.

The other requirement for catalytic acid–bases in the transition state or transition states of a nucleophilic substitution at phosphorus



4–145



4–146

in addition to the requirements at the nucleophile and the leaving group (the acid–bases OH and SH), is manifest at **the equatorial oxygens on phosphorus** in the intermediate or the transition state. A phosphorane (**4–145**) and a monomeric metaphosphate sandwiched between two hydroxy groups (**4–146**) are the two extremes in a spectrum of transition states or intermediates in a nucleophilic substitution at phosphorus. When a phospho group is transferred between two poor leaving groups, such as two hydroxy groups on alkyl carbons or a hydroxy group on carbon and water (as in pancreatic ribonuclease), a phosphorane will usually be the intermediate, or there will be a transition state closely resembling a phosphorane. When a phospho group is transferred between two good leaving groups, such as two nucleoside diphosphates or a nucleoside diphosphate and a carboxylate, monomeric metaphosphate will usually be the intermediate, or there will be a transition state closely resembling monomeric metaphosphate. In the former instance, the leaving group is too poor an acid to leave before the nucleophile adds; in the latter instance, the leaving group is such a good acid that it leaves before the nucleophile can add.

In the former case, **a phosphomonoester or phosphodiester becomes a monoanionic phosphorane (4–146)** or its equivalent. A phosphorane is required to be at least a monoanion because the pK_a of a fully hydronated phosphorane is around 9 and because the oxyanion must be present to push out one or the other of the leaving groups at its axial positions. When the nucleophile adds to a phosphoester to create a phosphorane, it pushes a negative elementary charge out onto one of the oxygens, which is the automatic origin of the one negative elementary charge in the phosphorane. Consequently, the conjugate acid, $^{(+)}$NH in **4–145**, of at least one acid–base is required to hydronate the inescapable oxyanion on the phosphomonoester (pK_{a1} between 1 and 2) or phosphodiester (pK_a also between 1 and 2). This hydronation also guarantees that the phospho group is electrophilic either before or during the nucleophilic addition of a weak nucleophile. The same acid–base is required to guarantee that the phosphorane is dehydronated either before or while the poor leaving group departs from it to increase the push on phosphorus. In pancreatic ribonuclease, which has both phosphodiesters and phosphomonoesters as substrates, the acid–base that performs this role of hydronating and dehydronating a nonbridging oxygen is Histidine 12. When this histidine is mutated to alanine[1004] rather than simply being carboxymethylated, the rate constant $k_0\,K_m^{-1}$ for the enzymatic reaction decreases by a factor of 17,000. While a phosphodiester must enter the active site as the monoanion, a phosphomonoester can enter

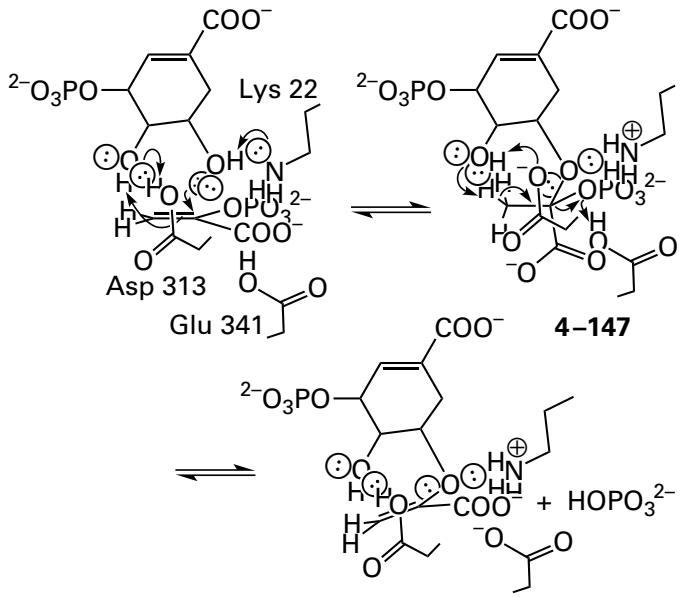
the active site as either a monoanion or dianion. If the phosphomonoester ($pK_{a2} \cong 6$) enters the active site as a monoanion, then only that one acid–base is required at one of the equatorial oxygens, but if it enters as a dianion, a second acid–base is required so that both anionic oxygens can be hydronated during the nucleophilic addition.

In the latter case, **a phosphomonoester becomes a monoanionic monomeric metaphosphate** or its equivalent. Monomeric metaphosphate ($pK_a \cong -11$) must always be monoanionic, and there must be the equivalent of an oxyanionic hole to accommodate the anion. Either a phosphomonoester must enter the active site as the unhydronated dianion or there must be a catalytic acid–base, $^{(-)}$N⊙ in **4–146**, in the active site to remove the hydron from the hydronated monoanion. Because the next step in the nucleophilic substitution at phosphorus is usually equivalent to the first step in reverse, either the product of the nucleophilic substitution must be the unhydronated dianion or there must be a catalytic acid–base responsible for hydronating it to give a monoanionic product. Because it must always be monoanionic, monomeric metaphosphate cannot be an intermediate in a nucleophilic substitution at phosphorus in a phosphodiester.

Acetate kinase from *Methanosarcina thermophila*[1011] is one of the enzymes most likely to have monomeric metaphosphate for an intermediate, and both acetyl phosphate (pK_a for the monoanion is around 1) in one direction and $MgATP^{2-}$ in the other direction enter the active site unhydronated. The crystallographic molecular model for the active site of arginine kinase, however, strongly indicates that the nucleophilic substitution at phosphorus must pass through monomeric metaphosphate (Figure 3–41).[814] In this case, one equatorial oxygen of monomeric metaphosphate participates in hydrogen bonds with the guanidinio group of an arginine and the amido group of an asparagine, each of the other two oxygens participates in a hydrogen bond with one of the guanidinio nitrogens of the same arginine, and one of these two oxygens is also a ligand to the Mg^{2+} that entered the active site on $MgATP^{2-}$. These ligands form an extensive cationic oxyanion hole. The lack of a catalytic acid–base at the equatorial oxygens suggests that one is unneeded. Rather, the arginines surrounding the phospho group that participates in the nucleophilic substitution ensure that both arginine phosphate (pK_a for the monoanionic phosphoramidate is 9.6) and $MgATP^{2-}$ enter the active site as dianions at the phospho group involved in the reaction. In the active site of adenylate kinase from *E. coli*,[603,606] which transfers a phospho group between a monophosphate and a diphosphate and should pass through monomeric metaphosphate, the equatorial oxygens accept hydrogen bonds from two guanidinio groups of two arginines.

In other instances, the catalytic acid–bases that form hydrogen bonds to equatorial oxygens are the 6-ammonio groups of lysine,[1012-1020] which are competent catalytic acid–bases; or the guanidinio groups of arginines,[1021-1024] one or more guanidinio groups and a metallic dication,[1025] or two or more metallic dications,[1026] all of which are unlikely catalytic acid–bases. It has been shown, however, that although catalytic acid–bases provided for the equatorial oxygens increase rates of the respective enzymatic reactions, they do not seem to change the degree to which the nucleophilic substitution at phosphorus is associative or dissociative.[1027]

The slowest and most difficult hydron to remove or add is a hydron on carbon. In the reaction catalyzed by 3-phosphoshikimate 1-carboxyvinyltransferase (Equation 4–321; Problem 4–26) from *E. coli*, the 5-hydroxy group of shikimate 3-phosphate is added to phospho*enol*pyruvate, and hydrogen phosphate is eliminated from the resulting adduct[1028,1029]



(4–414)

In both the elimination that takes place in the second step in the forward direction of Equation 4–414 and the elimination that takes place in the first step in reverse, a hydron is **removed from a methyl carbon that is not adjacent to a carbonyl or an acyl carbon**, probably the least acidic carbon–hydrogen bond in enzymatically catalyzed reactions. This remarkable

feat in each elimination from tetrahedral intermediate **4–147**, however, is performed by the 4-hydroxy group of shikimate 3-phosphate, the oxygen of which is only 0.31 nm from the methyl carbon of the enol pyruvyl group in tetrahedral intermediate **4–147**.[1029] In each elimination, this hydroxy group relays the basicity of the anionic carboxylato group of Aspartate 313. The same 4-hydroxy group, now relaying the acidity of the neutral carboxy group of Aspartate 313, must also accomplish the difficult hydronation of the methylene carbon of phospho*enol*-pyruvate during the addition that takes place in the first step in the forward direction, and it must hydronate the methylene carbon of the carboxyvinyl group in the addition that takes place in the second step in reverse.[702,1030] Another example of the ability of an active site to remove a hydron from a methyl carbon that is not adjacent to a carbonyl or acyl carbon is the removal of the hydron from the methyl group of *S*-adenosyl-L-methionine by the active site of carboxy-*S*-adenosyl-L-methionine synthase from *E. coli*.[1031]

3-Phosphoshikimate 1-carboxyvinyltransferase and carboxy-*S*-adenosyl-L-methionine synthase are two of the few exceptions, however, to the rule that when a hydron is removed from carbon by a catalytic base in the active site, that hydron is removed from a carbon immediately adjacent to a carbonyl carbon, acyl carbon, imido carbon, or imine or from a carbon conjugated to one of these groups, and addition of a hydron to carbon is to a carbon in an enol or enolate or to an enamine or to the carbon in a carbon–carbon bond conjugated to an enol, enolate, or enamine.

The **hydron on a carbon immediately adjacent to a carbonyl carbon, acyl carbon, imido carbon, or imine** is acidic, and its acid dissociation constant is usually in a reasonable range (Figure 1–23) that widely encompasses the acid dissociation constant for a hydroxy group. Nevertheless, the slowest and most difficult transfer of a hydron in biochemical reactions is the transfer of a hydron from and to carbon, for reasons already discussed in the first chapter. Removal of an acidic hydron from carbon is slow and difficult even for a base as strong as hydroxide, and addition of a hydron to nucleophilic carbon is also slow and difficult even for an acid as strong as hydronium. Hydroxide is a stronger base and hydronium is a stronger acid than any of the catalytic acid–bases available in an active site.

The kinetic difficulty of removing a hydron from carbon, and the fact that the Brønsted coefficient for general bases that remove a hydron from carbon in solution is 0.8,[1032-1034] would suggest that only the strongest bases available are used by an enzyme for this role. This expectation has proven to be mistaken. **Almost every catalytic base available has been chosen** at one time or another for what natural selection seems to find a simple task. For example, to remove a hydron from carbon, a **carboxylato group** is used by triose-phosphate isomerase (Figure 3–37), by tryptophan synthase (**4–122**),[863] by hydroxymethylglutaryl-CoA synthase (Equation 4–361), and by urocanate hydratase (Figure 4–50); a **6-amino group** is used by phosphopyruvate hydratase (Figure 4–43) and the enzymes that are related to it (Equations 4–126 and 4–266 through 4–269); an **imidazolyl group** is used by mandelate racemase (Equation 4–126) and its cousin glucarate dehydratase (Equation 4–266); an imidazolyl group and a carboxylato group are used by pyridoxine 5′-phosphate synthase (Figure 4–48); and a **4-oxidophenyl group** is used by chondroitin AC lyase from *P. aurescens* (Equation 4–358 and Figure 4–44). There are many examples of carboxylato groups of aspartates and glutamates, formally the weakest bases available, that remove hydrons from carbon,[1035-1037] as well as imidazolyl groups of histidines,[226,876,925,1038,1039] **sulfido groups** of cysteines,[652,654,1040-1042] 4-oxidophenyl groups of tyrosines,[761,1043] 6-amino groups of lysines,[1044-1046] **amino-terminal α-amino groups** (**4–53**),[1047-1049] and even **guanidinio groups** of arginines.[943,1050,1051]

In the reverse direction of each removal of a hydron from carbon, a hydron is added to the carbon from which it is removed in the forward direction, so each catalytic acid–base has been chosen by natural selection for both roles. Addition of a hydron to carbon is so difficult that it is also surprising that all these catalytic acids are capable of accomplishing this role effectively, rather than only the most acidic. A choice of the most acidic catalytic acid, however, for addition of a hydron to carbon would mean that the least basic catalytic base had been chosen for removal of a hydron from carbon in the other direction. The solution to this conundrum is to remember that the only relevant ability of a catalytic acid–base is its ability to lower the standard free energy of formation of the transition state for the step in question, and by microscopic reversibility, the same transition state is passed through in either direction.

In the active site of fumarate hydratase (Equation 4–226) from *M. tuberculosis*, the alkoxide of **Serine** 318, conveniently stabilized in a classic oxyanion hole, removes the hydron from carbon 3 of (*S*)-malate (Figure 4–27).[464] In the active site of the

related ethylenediamine-*N,N′*-disuccinate lyase from *Chelativorans*, the alkoxide of Serine 280, within a homologous sequence of amino acids[1052] and also stabilized in a classic oxyanion hole, removes the hydron from carbon 3 of one of the succinyl groups in ethylenediamine-*N,N′*-disuccinate.[1053] An alkoxide is a strong base. Nevertheless, each hydroxy group is forced up against the carbon–hydrogen bond so strongly (0.32 and 0.30 nm, respectively, between carbon and oxygen) by the oxyanion hole that there is no space to accommodate an atom larger than its oxygen. When Serine 318 in fumarate hydratase from *M. tuberculosis* is mutated to cysteine, the enzyme is inactivated. The cysteinate anion would be a satisfactory base, but the sulfur is too large (0.36 nm compared to 0.30 nm for oxygen). This rather unusual use of the alkoxide of serine as the catalytic base that removes a hydron from carbon is found in the large family of enzymes of which fumarate hydratase and ethylenediamine-*N,N′*-disuccinate lyase are members.[1052]

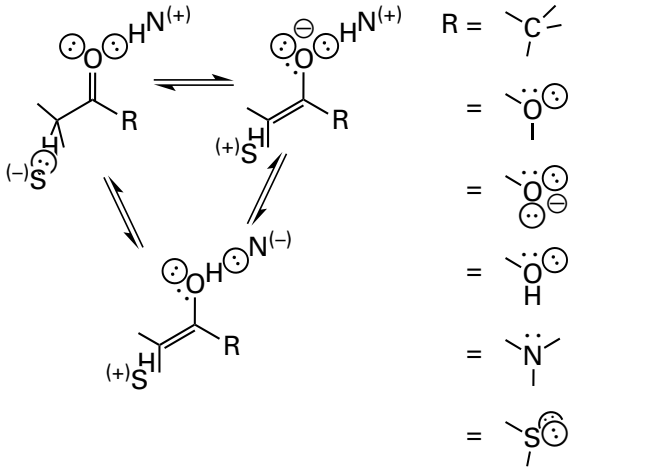
Rather than acting directly as a catalytic base, the basicity of the side chain of an amino acid,[513] a base on a substrate,[1054] or a base on a prosthetic group in the active site[1055] can also be **relayed through the neutral hydroxy group** of threonine or serine or through a molecule[1056] or two molecules of water.[1057] When this occurs, a lone pair of electrons on a neutral hydroxy group or molecule of water, which is even less basic than one on a carboxylato group, can nevertheless formally remove a hydron from carbon. In the active site of 1,4-dihydroxy-2-naphthoyl-CoA synthase from *E. coli*, a bicarbonate, bound in the active site from solution, acts as a catalytic base that removes a hydron from carbon.[275]

During the dehydration catalyzed by 2-oxo-4-carboxy-3-hexenedioate hydratase from *Sphingobium*, the carboxy group of Glutamate 284 in the active site forms a hydrogen bond with the 4-hydroxy group in (4*S*)-2-oxo-4-carboxy-4-hydroxyhexanedioate, the substrate that dominates the equilibrium for this addition–elimination within the active site in the crystallographic molecular model (Figure 4–29),[487] and the carboxy group is responsible for hydronating this hydroxy group in the direction of elimination. It is also the only catalytic acid–base in the vicinity of the hydron on carbon 3, which is removed during the dehydration, so it must also be responsible for this dehydronation. One might think that the reaction could be concerted, with the carboxy group adding a hydron to the hydroxy group while it removes the hydron from carbon 3, but this concerted removal would require that the acyl oxygen in the carboxy group ($pK_a = -7$) act as the base that removes a hydron from carbon because the other oxygen in the carboxy group has to be hydronated to add a hydron to the hydroxy group. The reaction could be stepwise, but the first step must be removal of the hydron from carbon 3 by the basic unhydronated carboxylato group to produce the enolate. For both steric reasons and a consideration of hydrogen bonding, however, it seems that the now-carboxy group could not flip over, carrying the hydron with it, to hydronate the hydroxy group. It is also possible that only one oxygen of the carboxy group is involved in a transfer of the hydron from carbon 3 to the hydroxy group because the oxygen forming the hydrogen bond to the hydroxy group is the same distance (0.34 nm) from carbon 3 as the other oxygen, but the angle between it and carbon 3 is much less appropriate for the transfer of a hydron. Each oxygen of the carboxy group, however, forms hydrogen bonds to a molecule of water, and each fixed molecule of water is in direct contact with the solution. Consequently, it is also possible that hydron on the carboxy group that was just removed from carbon 3 to form the enolate is shuttled into the solution while a hydron is shuttled from the solution onto the other oxygen of the carboxy group so that it can hydronate the hydroxy group. This example illustrates the fact that it is often difficult to be sure of how hydrons move during what seems to be a simple reaction, even when a crystallographic molecular model of high accuracy for the complex between an unmutated active site and the full complement of substrates at equilibrium is available.

It may be the case that the basicities of the various side chains, when they are acting as catalytic bases in active sites that remove a hydron from carbon, are much more similar to each other than the acid dissociation constants of their conjugate acids in solution would suggest. There may well be **shifts in pK_a caused by the lower relative permittivity** of the surroundings after the active site has closed around its substrates, isolating them and one of these catalytic bases from the high relative permittivity of the surrounding water. Anionic carboxylato groups become neutral when they remove a hydron from carbon, and neutral amino and guanidino groups become cationic when they remove a hydron from carbon. Consequently, in an environment of low relative permittivity, carboxylato groups of aspartates and glutamates are more basic, and amino groups of lysines and guanidino groups of arginines are less basic than they are in water. Such shifts in the values of pK_a for the conjugate acids would explain

the low pK_a for the catalytic lysine (pK_a = 6.0) in the active site of acetoacetate decarboxylase from *C. acetobutylicum*[938] and the high pK_a for the catalytic glutamic acid (pK_a = 6.7) in the active site of endo-1,4-β-xylanase. Carboxylato groups, amino groups, and guanidino groups are the outliers in the complete spectrum of basicity, so they would require the most adjustment, but the low relative permittivity of an active site also would make an imidazolyl group less basic (as is does to an amino or guanidino group) and would make a 4-oxidophenyl group more basic (as it does to a carboxylato group).*

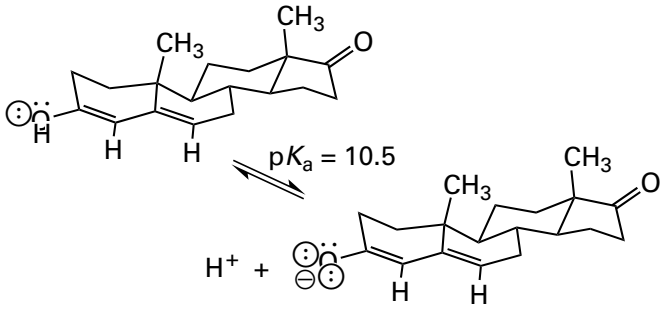
When a hydron is removed from carbon adjacent to a carbonyl or acyl carbon, an **enolate or enol** is formed



(4–415)

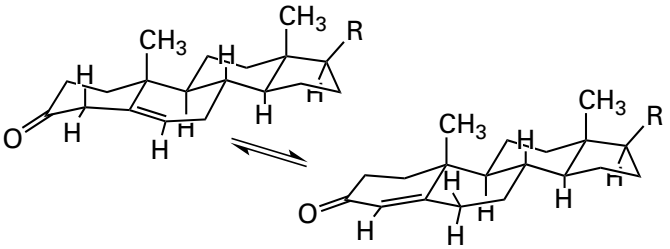
The enzyme always provides a **mechanism to stabilize an enolate**, either by providing hydrogen bonds from within an oxyanion hole for the oxyanion of the enolate or by hydronating the enolate on its oxyanion while it is being formed to produce the enol. It is possible that the enolate can be stabilized sufficiently that the rate for removal of a hydron from the α carbon by a mediocre base can be significantly increased. As has already been mentioned, however, the carbonyl oxygen (pK_a = –7) or acyl oxygen (pK_a = –6) cannot be hydronated to improve the acidity at carbon before the enolization proceeds.

The enolate



(4–416)

that is the intermediate in the reaction catalyzed by steroid Δ-isomerase



(4–417)

is produced by removal of the hydron from carbon 4 of the 3-oxo-Δ^5-steroid that is the reactant, the carbon adjacent to the carbonyl group. This intermediate illustrates the issues addressed by natural selection when stabilizing an transient enolate. Either the enolate (Equation 4–416) or the enol can be formed when a hydron is removed from carbon 4 of the steroid (pK_a = 12.8) by Aspartate 40 in the active site of the enzyme from *P. putida*.[1058] In the next step of the reaction, the enolate or enol is hydronated on carbon 6. The pK_a for the conjugate acid of the oxyanion in the enolate is 10.5 (Figure 1–23). If a strong acid were used to stabilize this intermediate enolate by hydronating its oxyanion while it was being formed to produce the enol, the weak conjugate base of that acid would not provide much kinetic assistance in dehydronating the hydroxy group of the enol in the second step when the hydron is being added to carbon 6 to form the α,β-unsaturated ketone,* and addition of a hydron to carbon would also be difficult. If a weak acid were used, such as an oxyanion hole, the oxyanion of the enolate would not be hydronated during removal of the hydron from carbon in the first step, but the enolate formed in the first step would be stabilized only by one or more hydrogen bonds from weak acids.

*In the case of a 4-oxidophenyl group, however, the effect of the relative permittivity would be diminished because the negative charge would be delocalized over the ring.

*The conversion of an enol to its keto form is almost always exergonic and therefore requires little thermodynamic assistance, but the issue in catalysis is kinetic assistance.

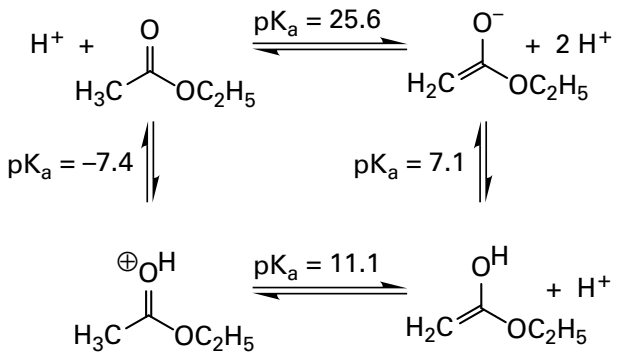
Consequently, in stabilizing any enolate formed from a reactant, which then returns to a carbonyl in the product, a compromise must be made between creating an enol by hydronation of the carbonyl or acyl oxygen as the hydron is removed from carbon and forming hydrogen bonds to the oxyanion of the enolate that results from dehydronation. If the enolate is hydronated as the hydron is removed from carbon, the act of removing the hydron gets the maximum kinetic assistance. If one or more donors of hydrogen bonds are provided, the return to the oxo group in the second step is less difficult because it does not require dehydronation of the enol. The conjugate acids of most oxyanions of enolates have a pK_a in the range 8–12 (Figure 1–23). Consequently, depending on the requirements of the reaction, it is not difficult for the enzyme either to hydronate the enolate or to provide a hole for its oxyanion. In the case of steroid Δ-isomerase, the hydron that must be removed from carbon is fairly acidic (pK_a = 12.8), and the oxyanion of the enolate is formed from an oxo oxygen that must return to an oxo oxygen in the second step of the reaction.

The active site of steroid Δ-isomerase seems to compromise. In the active site of steroid Δ-isomerase from *P. putida*, the 3-oxo group of the ketosteroid that is the reactant accepts hydrogen bonds from the carboxy group of Aspartate 103 and the 4-hydroxyphenyl group of Tyrosine 16.[1059,1060] The 4-hydroxy group of Tyrosine 16 is the proximal hydroxy group of a composite acid–base formed from 4-hydroxy groups of three tyrosines,[1061] but it is surrounded by three methyl groups from three methionines on one side and a valine and an isoleucine on the other,[1060] which should significantly raise its pK_a. The pK_a for the carboxy group of Aspartate 103 is greater than 9,[1062] probably because it is surrounded by the side chains of the same three methionines, a phenylalanine, a valine, and an alanine. The values of pK_a for both Tyrosine 16 and Aspartate 103, although perhaps higher, are in the vicinity of the pK_a for the enol (10.5). It seems as though, in this instance, natural selection may have matched values of pK_a for the enol, the carboxy group, and the 4-hydroxyphenyl group. Consequently, it is difficult to decide if the 4-hydroxyphenyl group or the carboxy group in the complex with the oxyanion of the dienolate hydronates the enolate to stabilize it while it is being formed or if these two catalytic acids simply create an oxyanion hole that provides two hydrogen bonds to the enolate to stabilize it.

The active site of steroid Δ-isomerase from *P. putida* binds various phenolates, in part by providing an oxyanion hole formed by the carboxy group of Aspartate 103 and the 4-hydroxyphenyl group of Tyrosine 16 into which the respective phenolate oxyanion inserts.[1063] Phenols with values of pK_a up to 9.7 occupy this oxyanion hole as the respective phenolates, and their oxygens are not hydronated by the oxyanion hole. These observations suggest that the intermediate is the enolate (Equation 4–416). If, however, the pK_a of Tyrosine 16 is lowered by replacing it semisynthetically in turn with one of three fluorotyrosines, there is no statistically significant change in either the catalytic constant or the specificity constant for estr-5(10)-ene-3,17-dione.[1064] These observations suggest that the intermediate, even when the tyrosine is unmodified, is the enol.

There is another way to look at this situation. Before Aspartate 40 removes the hydron from carbon 4, which is the difficult step in the reaction, its carboxylato group bears a delocalized negative elementary charge. After the hydron is removed, that negative elementary charge is either delocalized in the enolate, delocalized over the ring of the 4-oxidophenyl group of Tyrosine 16, or delocalized in the carboxylato group of Aspartate 103, depending on which is the more stable tautomer of the active site occupied by the intermediate. It may well be that the choice between these delocalized options is determined by the relative permittivity in the immediate vicinity of each possible anion.

The hydron on carbon 4 of a 3-oxo-Δ^5-steroid (Equation 4–417) is a particularly acidic hydron because its dissociation creates an enolate conjugated to a carbon–carbon double bond (Equation 4–416). Most hydrons on carbons adjacent to a carbonyl or acyl carbon are much less acidic. In such cases, the decision **whether or not the enolate should be hydronated** during removal of the hydron should be influenced by this poor acidity. Consider the dehydronation of the α carbon of ethyl acetate



(4–418)

If the acyl oxygen is not hydronated, the pK_a for the adjacent carbon–hydrogen bond is 25.6, but if the oxygen is first hydronated, its pK_a is 11.1. Hydronation leads to a dramatic increase in acidity. In solution, of course, the pH at which the acyl oxygen is hydronated (pH < –7.4) and the pH at which the carbon of the hydronated ester has dissociated a hydron to form the enol (pH > 11.1) are so different from one another that these two steps cannot occur in the order of hydronation followed by dehydronation, even though such a scenario explains in part the specific acid catalysis of aldol condensations involving ethyl acetate.

On an active site, where there is no pH, if a catalytic acid forms a hydrogen bond to the carbonyl or acyl oxygen and a catalytic base is placed adjacent to the carbon–hydrogen bond, and if the active site waits long enough, the oxygen can be hydronated before the hydron is removed. The question is whether or not the wait is longer than the wait necessary for the transition state to be achieved by **hydronating the oxygen while the hydron is being transferred** to the catalytic base. If the wait to hydronate the carbonyl or acyl oxygen is too long, the obvious advantage of hydronating the oxygen *before* the hydron is transferred (Equation 4–418) is nevertheless the reason that hydronating the oxygen *while* the hydron is being transferred is advantageous, just not so advantageous as hydronating it first, if that were even possible.

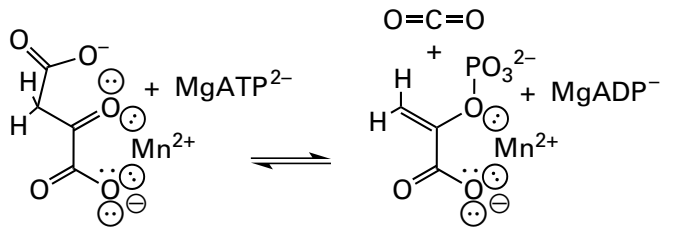
In triose-phosphate isomerase from *S. cerevisiae* (Equations 4–46 and 4–55 and Figure 3–37), either Lysine 11 or Histidine 94 probably hydronates the 2-oxo group of glycerone phosphate and Histidine 94 probably hydronates the 1-oxo group of glyceraldehyde 3-phosphate during removal of the hydron from either carbon 3 or carbon 2, producing the respective enol as the intermediate. These assignments are reasonable because these two hydrons are difficult to remove (Figure 1–23) and because one of the oxygens is eventually going to leave the active site as a hydroxy group on the product anyway.

In the active site of pyridoxine 5′-phosphate synthase, a hydron is removed from carbon 4 of one of the intermediates (step *v* in Figure 4–47), and as the hydron is removed from carbon, the 4′-hydroxy group of the intermediate (Figure 4–48B) probably relays a hydron from the imidazolyl group of Histidine 45 through an oxygen of the phospho group to hydronate the developing oxyanion while the hydron is removed, because removal of the hydron from carbon is also difficult in this instance. During removal of a hydron from carbon 6 (step *vi* in Figure 4–47), the 4′-hydroxy group of the intermediate (Figure 4–48B) again relays a hydron from the imidazolyl group of Histidine 45 through an oxygen of the phospho group to hydronate the developing oxyanion either while the hydron is being removed from carbon or immediately after it has been removed, because the oxygen becomes a hydroxy group in the product.

In the active site of citrate (*Si*)-synthase (Equation 4–224, Problem 4–23) from *G. gallus*, Aspartate 375 removes a hydron from the methyl group of the substrate, acetyl-SCoA,[462,1065] so that its enol can participate in the aldol condensation with the carbonyl of oxaloacetate that produces citrate. Histidine 274 simultaneously hydronates the acyl oxygen of acetyl-SCoA as the hydron is removed to give the enol of acetyl-SCoA, which is the intermediate in the enzymatic reaction.[1066]

In 2-hydroxymuconate tautomerase (Equation 4–317), however, the guanidinio group of Arginine 39 probably just provides a hydrogen bond to **create an oxyanion hole** for stabilizing the enolate formed during removal of the hydron from carbon 3 of the substrate by the amino-terminal proline of the enzyme (**4–53**). In this instance, again, the hydron is quite acidic (p$K_a \cong 13$) because its dissociation creates an enolate conjugated to a carbon–carbon double bond and the oxyanion in the enolate is not basic enough to remove a hydron from a guanidinio group (Figure 1–23). In the active site of hydroxymethylglutaryl-CoA synthase from *S. aureus* (Equation 4–361), the oxyanion of the enolate of acetylated Cysteine 111, even though the cysteinyl thioester is much less acidic at carbon (p$K_a = 21$), is also stabilized not by hydronation but by a hydrogen bond from an amido nitrogen–hydrogen of the polypeptide backbone and perhaps a hydrogen bond—if formation of such a hydrogen bond is even possible—from the acidic hydron on acetoacetyl-SCoA.[858] The oxyanion of the enolate remains unhydronated (the pK_a of the enol is 8) and becomes an acyl oxygen after nucleophilic addition of the carbanionic carbon to acetoacetyl-SCoA. In the active site of allantoin racemase from *K. pneumoniae*, the oxyanion of the enolate of allantoin is stabilized by a classic oxyanion hole formed from two amido nitrogen–hydrogens pointed directly at the oxygen.[1042]

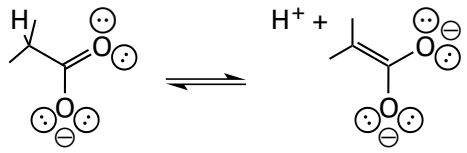
There are instances in which hydronating an enolate is clearly counterproductive. For example, during the reaction catalyzed by phospho*enol*pyruvate carboxykinase[1067]



(4–419)

the enolate formed upon decarboxylation of oxaloacetate must remain nucleophilic at its oxygen in order to add to the γ-phospho group of $MgATP^{2-}$, so instead of being hydronated, it is coordinated to a Mn^{2+} so that it retains most of its nucleophilicity.[1068,1069]

Because of its excess negative charge, **one of the most difficult enolates to produce is the *gem*-enediolate** produced by removal of a hydron ($pK_a \cong 33$; Figure 1–23) from a carbon adjacent to a carboxylato group



(4–420)

Hydronating one of the two oxygens prior to removal of the hydron is the equivalent of turning a carboxylato group into an ester, so **hydronation of one oxygen** lowers the pK_a for the acidic carbon by more than 7 units (Figure 1–23). It follows that at least one oxygen of an incipient *gem*-enediolate should be hydronated by a catalytic acid in the active site and forced to stay hydronated before removal of the hydron from the α carbon. For example, in the active site of porcine aconitate hydratase (Figure 3–52), the 3-carboxylato group of isocitrate becomes the *gem*-enediolate upon removal of a hydron from carbon 3 of isocitrate during the elimination that turns isocitrate into *cis*-aconitate. The 3-carboxylato group is hydronated by a molecule of water (0.29 nm) that is a ligand to a hexacoordinate[1070] Fe^{2+} in the prosthetic [4Fe–4S] iron–sulfur cluster in the active site of the enzyme.[1054] This molecule of water, although it is itself a competent catalytic acid ($pK_a = 10$), relays a hydron from the imidazolyl group (0.26 nm) of Histidine 167 or the carboxy group of Aspartate 165 (0.26 nm) so that it remains a molecule of water. The fact that the hydron is added to the oxygen in an orientation normal to the plane of the 3-carboxylato group causes the hydrogen bond between the resulting hydronated oxygen of the carboxy group and the molecule of water on Fe^{2+} to be parallel to the π molecular orbital system of the carbon–oxygen double bond to the other oxygen of the carboxy group. This disposition ensures that there is no conjugation between the hydronated oxygen and the carbon–oxygen double bond, so that it becomes the equivalent of a simple carbonyl group or thioester, which also lowers the pK_a for the α carbon significantly (Figure 1–23).

The conjugate acid of the remaining oxyanion in a *gem*-enediolate produced by removing a hydron on the carbon adjacent to a now-neutral carboxy group has a pK_a around 7 (Figure 1–23) so that it can be hydronated or it can be stabilized by a hydrogen bond or an oxyanion hole, depending on the situation. In the case of porcine aconitate hydratase, the other oxygen is in an oxyanion hole formed from two amido nitrogen–hydrogens from two peptide bonds (0.29 and 0.30 nm) and the hydroxy group of Serine 642 (0.29 nm).

In the active site of ulvan lyase from *Alteromonas*, one oxygen of the carboxylato group that is to become a *gem*-enediolate on the oligosaccharide that is the substrate forms a hydrogen bond with the imidazolyl group of Histidine 144, which probably hydronates the carboxylato group before the hydron is removed from the α carbon by the imidazolyl group of Histidine 123 to form the *gem*-enediolate and initiate the elimination catalyzed by the enzyme.[1071] The two oxygens of the carboxylato group also form hydrogen bonds with the two ω-nitrogen–hydrogens of the guanidinio group of Arginine 236. These hydrogen bonds to the cationic guanidinio group should provide even more stabilization to the monoanionic *gem*-enediolate after it forms following hydronation of the carboxylato group by the imidazolyl group.

It most cases, however, it seems that active sites are not so logical. For example, in the active site of chondroitin AC lyase from *P. aurescens* (Equation 4–358 and Figure 4–44), one of the oxygens of the carboxy group that becomes the *gem*-enediolate does accept a hydrogen bond from the imidazolyl group of Histidine 233, which at first glance seems to be a catalytic acid. The two oxygens of the carboxylato group, however, participate in two hydrogen bonds (0.27 and 0.31 nm) with the carbamoyl group of Asparagine 183. In the map of electron density, it cannot be determined which atom in the carbamoyl group is nitrogen and which is oxygen. If the amido group of the carbamoyl group forms the hydrogen bond (0.31 nm) with the oxygen that forms a hydrogen bond with the imidazolyl group, which is the choice made by the authors, then the acyl oxygen

of the carbamoyl group must form the hydrogen bond (0.27 nm) with the other oxygen of the carboxylato group, which must have been hydronated before that hydrogen bond formed because a hydrogen bond must have a hydron. In this instance, the oxygen of the carboxylato group that forms a hydrogen bond with the imidazolyl group could be hydronated by the imidazolyl group either in the ground state or in the transition state to form the enediol. If, however, the acyl oxygen of the carbamoyl group forms the hydrogen bond with the oxygen that forms a hydrogen bond with the imidazolyl group, then that oxygen of the carboxylato group must be hydronated, but the hydron must be directed toward the carbamoyl oxygen rather than the imidazolyl group. In addition, the imidazolyl group must be the imidizolium because a hydrogen bond requires a hydron, and that hydron must be on the nitrogen. In this instance, the amido group of the carbamoyl group must form a hydrogen bond with the other oxygen of the carboxylato group, which is probably not hydronated. In neither case does a catalytic acid hydronate one oxygen of the anionic carboxylato group prior to enolization, even though either disposition does guarantee that it becomes hydronated.

The *gem*-enediolate in the active site of proline racemase from *Trypanosoma cruzi* is stabilized in two **oxyanion holes** that together provide four peptide amido nitrogen–hydrogens and the hydroxy group of threonine as donors for two hydrogen bonds to one oxygen and three hydrogen bonds to the other.[1072] A similar arrangement of two oxyanion holes, in which there are two hydroxy groups and an amido nitrogen–hydrogen for each oxyanion, is found in the active site of fumarate hydratase from *M. tuberculosis* (Figure 4–27) and other members of the family of homologous enzymes to which it belongs.[464,1052] In both cases, it is possible that one oxygen on the *gem*-enediolate is a strong enough base to remove the hydron from one of these donors, which all have values of pK_a between 14 and 15, while the hydron is being removed from carbon, but this remains unlikely (Figure 1–23). If neither oxygen removes a hydron from a donor, then the active site removes a hydron from a carbon α to a carboxylato group without hydronating one of its oxygens prior to removal of the hydron or on the approach to the transition state. It has been suggested that one way the active site of these enzymes could stabilize the *gem*-enediolate instead of hydronating it would be to hold the carbon and the two oxygens of the carboxy group and the two adjacent carbons of the respective substrate in the same plane.

Formation of a hydrogen bond between a reasonably strong catalytic acid and the oxygen in a carbonyl or acyl group should lower the pK_a for the hydron on the α carbon (Equation 4–418). Nevertheless, even for the more acidic α carbons with fairly low values of pK_a, removal of their hydrons, even by a base as strong as hydroxide, is slow and difficult. Likewise, even for the more basic carbons in enols, enolates, and enamines, the conjugate acids of which have fairly high values of pK_a, addition of a hydron, even by an acid as strong as hydronium, is slow and difficult. These observations in solution beg the question of **how an active site is able to remove a hydron rapidly from carbon**, even a poorly acidic carbon, or to add a hydron rapidly to carbon, even a poorly basic carbon, with such ease, even with the relatively weak catalytic bases and acids that it generally uses. One explanation is that **steric effects engendered by the active site compress the catalytic base or the catalytic acid against the carbon–hydrogen bond or the trigonal carbon**, respectively, to bring the complex closer to the transition state for transfer of the hydron.

In crystallographic molecular models of enzymatically active complexes between the active site and a complete complement of substrates at equilibrium within an enzyme that removes a hydron from and adds a hydron to a carbon, the **distance between that carbon and the heteroatom of the base** that removes the hydron or the acid that adds the hydron is usually shorter than the sum (0.38–0.41 nm) of the van der Waals radii of hydrogen (0.115 nm); the heteroatom, oxygen (0.15 nm), nitrogen (0.16 nm), or sulfur (0.18 nm); and the length of a carbon–hydrogen bond (0.11 nm). For example, for the enzymatically active complex of triosephosphate isomerase from *S. cerevisiae* and glycerone phosphate (Equations 4–46 and 4–55 and Figure 3–37), the distance between the oxygen of the carboxylato group and the carbon is 0.31 nm; for the enzymatically active complex of phosphopyruvate hydratase from *S. cerevisiae* (Figure 4–43), the distance between the nitrogen of the amino group and the carbon is 0.32 nm; for the enzymatically active complex of chondroitin AC lyase from *P. aurescens* (Equation 4–358 and Figure 4–44), the distance between the oxygen of the 4-hydroxyphenyl group and the carbon is 0.29 nm; for the enzymatically active complex of hydroxymethylglutaryl-CoA synthase from *S. aureus* (Equation 4–361), the distance between the oxygen of the carboxylato group and the carbon is 0.30 nm;[858] for the enzymatically active complex of fumarate hydratase from *M. tuberculosis*

(Figure 4–27), the distance between the oxyanion of Serine C319 and the carbon is 0.32 nm;[464] and for the enzymatically active complex of pyridoxine 5′-phosphate synthase from *E. coli* (Figure 4–48B), the distance between the oxygen of the carboxylato group and the carbon is 0.37 nm. In the active site of an enzymatically inactive mutant of 3-phosphoshikimate 1-carboxyvinyltransferase (Equation 4–321; Problem 4–26) from *E. coli* and its tetrahedral intermediate, the distance between the hydroxy group of the intermediate and the carbon from which it remove a hydron (Equation 4–414) is 0.31 nm.[1029]

In a crystallographic molecular model of the complex between steroid Δ-isomerase (Equation 4–417) from *C. testosteroni* and androst-4-ene-3,17-dione,[1073] which is one substrate of the enzymatic reaction, the distance between the carboxylato oxygen of Aspartate 38 and carbon 4, the carbon from which this oxygen removes a hydron from the reactant androst-5-ene-3,17-dione or adds a hydron to the product androst-4-ene-3,17-dione to give the intermediate enolate, is 0.27 nm. There are at least 29 crystallographic molecular models of complexes between steroid Δ-isomerase from *P. putida* (32% identity; 1.6 gap percent) and equilenin, an analogue of the intermediate dienol (Equation 4–416) in which the A and B rings are an aromatic 2-hydroxynaphthyl group. In these models, the distances between the oxygen of Aspartate 38, responsible for transferring the hydron between carbons 4 and 6, and the carbon analogous to carbon 4 varied between 0.31 and 0.36 nm, and the distances between the oxygen and carbon 6 varied between 0.30 and 0.38 nm.[1074] All these distances are less than the distance of van der Waals contact (0.39 nm) expected for a hydrogen on an oxygen and the π molecular orbital system of a naphthyl group (0.17 nm).[1075] Consequently, in these complexes that resemble the acceptor of the hydron by the intermediate in the addition, rather than the donor of the hydron by the substrate in the elimination, the catalytic acid is also compressed against the carbon.

One caveat concerning such conclusions about these apparent compressions is that the positions in a particular crystallographic molecular model of the carbon and the heteroatom between which a hydron is transferred may not be defined with sufficient accuracy to support them. In the collection of 29 crystallographic molecular models of complexes between steroid Δ-isomerase from *P. putida* and equilenin, the mean deviation of the position for both the oxygen atom of Aspartate 103 and the oxygen atom of Tyrosine 16, which together form the oxyanion hole for the dienolate, from their mean position in the aligned models is only 0.02 nm.[1074] These two oxygens do not have to move during the enzymatic reaction, and they are remarkably fixed in position by the methionines, the valine, the isoleucine, the phenylalanine, and the alanine that surround them as well as the strands of polypeptide, and this steric confinement is reflected in the crystallographic molecular models. The side chain of Aspartate 40, like the side chain of Glutamate 164 in the active site of triose-phosphate isomerase (Equations 4–46 and 4–55 and Figure 3–37), has to transfer a hydron between carbons 4 and 6 of the substrate, which are even farther apart. Consequently, the mean deviation of the position for the oxygen atom of the carboxy group in Aspartate 103 that transfers the hydron from its mean position in the aligned models is 0.1 nm. Nevertheless, the oxygen is never more than 0.38 nm from both carbons and usually significantly less. The oxygen, in turn, is confined within these boundaries by the side chains of an alanine, a phenylalanine, a valine, and a methionine that surround it. All these considerations suggest that the distances observed in crystallographic molecular models between a catalytic acid–base and the carbon from which it adds or removes a hydron are accurate descriptions of the compression applied by the active site to facilitate the transfer of the hydron to or from the carbon.

The oxygen of the carboxylato group of Aspartate 103 is compressed against carbon 4 in the complex between the active site of steroid Δ-isomerase from *C. testosteroni* and androst-4-ene-3,17-dione in part by a steric interaction (0.36 nm) between its other oxygen and the methyl group of Alanine 114. When Alanine 114 is mutated to glycine, a mutation that eliminates the methyl group (0.15 nm) and relieves the compression, the value of the catalytic constant for the reactant estr-5(10)-ene-3,17-dione decreases by a factor of 225.[1076] For comparison, when Tyrosine 16 in steroid Δ-isomerase from *P. putida* was mutated to phenylalanine or when Aspartate 103 was mutated to leucine, the catalytic constants for the reactant estr-5(10)-ene-3,17-dione decreased by factors of 17,000 and 230. These are the two catalytic acid–bases that stabilize the intermediate enolate by directly providing hydrogen bonds or an oxyanion hole to its oxygen rather than engendering a steric effect.

It is hard to avoid the conclusion that all these observations of distances less than van der Waals contact represent an **intentional compression of the heteroatoms of the catalytic acid–bases against the**

respective carbon–hydrogen bonds accomplished by steric effects within the active site. In solution, there are large differences between rates for the transfer of a hydron between two heteroatoms and rates for the transfer of a hydron between a carbon atom and a heteroatom. It has been argued that a significant portion of this difference results from the fact that in the former instance a preexisting hydrogen bond decreases the distance between the two heteroatoms, and hence the barrier to hydron transfer, while no such decrease can occur in the latter instance in which a hydrogen bond cannot form.[1077] Consequently, compressing the distance between the heteroatom of a base and the carbon atom by an active site should accomplish much the same thing that is accomplished in solution by a hydrogen bond, and it should significantly accelerate the otherwise slow transfer of a hydron from carbon. It has also been proposed, however, that hydrogen bonds can actually form between an acidic carbon–hydrogen bond and a heteroatom.[1078] If such a hydrogen bond can form, then the short distances observed could be the result of their formation, a process that should achieve the same objective.

In **the transition state for transfer of a hydron from carbon to a heteroatom**, the distance between carbon and heteroatom is significantly shorter than the distance between these two atoms upon their van der Waals contact in the ground state. For example, it has been calculated that in the transition state for transfer of a hydron from carbon 2 of D-glyceraldehyde 3-phosphate to the oxygen of the catalytic carboxy group in the active site of triose-phosphate isomerase (Equations 4–46 and 4–55 and Figure 3–37), the distance between carbon and oxygen should be 0.27 nm; and in the transition state for transfer of a hydron from carbon 3 of glycerone phosphate to the oxygen of the carboxy group, the distance between carbon and oxygen should also be 0.27 nm.[1079] These two distances are less than the compressed distance (0.31 nm) observed in the crystallographic molecular model of the enzyme while it is catalyzing its reaction. Nevertheless, the enzyme has compressed the distance from that of van der Waals contact (0.38 nm) in the direction of the transition state, and this compression would be an example of the use of strain to catalyze the reaction.

In crystallographic molecular models of complexes between enzymes and substrates or analogues of intermediates in an enzymatic reaction, there are also many instances of hydrogen bonds between two heteroatoms that are shorter than expected. For example, in the enzymatically active complex of triose-phosphate isomerase (Figure 3–37), the distance between the τ nitrogen of Histidine 94 and the 2-oxo group of the substrate is 0.26 nm; in the complex between steroid Δ-isomerase (Equation 4–417) from *P. putida* and equilenin, a phenolic analogue of the actual dienol intermediate in the enzymatic reaction (Equation 4–416), the distance between the oxygen of the 4-oxidophenyl group of Tyrosine 16 and the phenolic oxygen of the analogue is 0.25 nm, and the distance between the oxygen in the carboxy group of Aspartate 103 and the same phenolic oxygen on the analogue is also 0.25 nm;[712] and in a complex between penicillopepsin from *Penicillium janthinellum* and an analogue of the tetrahedral intermediate in the enzymatic reaction, the distance between an oxygen of Aspartate 33 and an oxygen of the analogue is 0.24 nm.[1080] In the complex between bovine chymotrypsin and an analogue of the tetrahedral intermediate in the enzymatic reaction, the distance (0.26 nm) between the π nitrogen of Histidine 57 and the oxygen in the carboxy group of Aspartate 102 within the imidazolyl-carboxy composite acid–base (Equation 4–134) is thought to be shorter than that of an unconstrained hydrogen bond.[1081-1083] One explanation for the shorter lengths in complexes between active sites and analogues for intermediates in the enzymatic reactions is that these complexes are unnatural and the analogues necessarily contain atoms of a different type in place of one or more of the atoms in the natural intermediate. These differences will produce steric effects not present in the natural intermediate that could cause the observed shortening.

One almost always unexamined question, however, relevant to these observations of short hydrogen bonds is **what would be the unconstrained lengths of these specific hydrogen bonds**. Most tabulated values for the lengths of unconstrained hydrogen bonds are those between two acids or between two bases. For example, the lengths of hydrogen bonds[1084] between two carboxylic acids are 0.26 ± 0.1 nm, those between two phenols are 0.27 ± 0.1 nm, those between the nitrogen–hydrogen of an amide and the acyl oxygen of the same amide are 0.29 ± 0.1 nm, and those between two amines are 0.31 ± 0.1 nm. In all these instances, the difference between the pK_a of the donor and the pK_a of the acceptor is large. For example, in the hydrogen bond between two carboxylic acids, the pK_a of the donor is around 5 while the pK_a of the acceptor is around –6, and in the hydrogen bond between two amines, the pK_a of the

donor is around 40 while the pK_a of the acceptor is around 10.

It is known, however, that hydrogen bonds between an acid as a donor and the conjugate base of that acid as an acceptor, in which the difference in pK_a between donor and acceptor is 0, are about 0.02–0.03 nm shorter[1085] than the hydrogen bonds between two molecules of the same conjugate acid or the same conjugate base. For example, the bond length for the hydrogen bond between an amine and its ammonium is around 0.28 nm. The bond length for the hydrogen bond between a phenol and its phenolate anion is around 0.245 nm. This distance is almost identical to the length of the hydrogen bond between the phenolic oxygen of Tyrosine 103 and the phenolate oxygen of equilenin in the active site of steroid Δ-isomerase, two phenols of almost the same pK_a. The bond length for a carboxylic acid and its conjugate base is also around 0.245 nm. This distance is almost identical to the bond length (0.248 nm) between the carboxy group of Aspartate 103 and the phenolate oxygen of equilenin,[712] two oxygens also with closely matched values of pK_a, and it is also almost identical to the bond length of the hydrogen bond between Aspartate 24 and Aspartate 15 in the crystallographic molecular model of human protein deglycase DJ-1, which was thought to be shorter than expected.[1086] In an extensive compilation of the lengths of hydrogen bonds in small molecules in solution and in crystallographic molecular models,[1087] it was shown that the length of the bonds decreased linearly with the difference in pK_a between donor and acceptor, reaching a minimum when the pK_a of the donor was equal to the pK_a of the conjugate acid of the acceptor. For hydrogen bonds between two oxygens, the length decreased from 0.29 nm to a minimum of 0.245 nm; for hydrogen bonds between nitrogen and oxygen, the length decreased from 0.30 nm to a minimum of 0.255 nm; and for hydrogen bonds between two nitrogens, the length decreased from 0.31 nm to a minimum of 0.27 nm,* in agreement with the earlier, far more limited compilation.[1085]

Although unconstrained bond lengths for even one of the short hydrogen bonds observed in crystallographic molecular models between a native active site and its substrates or an analogue of an intermediate or between two side chains within a protein cannot be ascertained, it is likely that they are almost the same as those observed in the molecular model, and the conclusion that active sites or protein molecules often compress hydrogen bonds between two heteroatoms may be mistaken.

Some of these bond lengths for hydrogen bonds between two heteroatoms, however, may actually be shorter than the unconstrained length. In a compilation[1086] of all the hydrogen bonds in the Protein Data Bank between a carboxylato group and a carboxy group on the side chains of aspartates and glutamates, which are usually hydrogen bonds between an acid and its conjugate base, 85% of these hydrogen bonds were longer than 0.245 nm, but 15% were shorter than 0.245 nm. The most likely explanation for these shorter-than-unconstrained hydrogen bonds in the native structures of these proteins, as well as those observed between substrates and analogues of intermediates and catalytic acid–bases, is **adventitious steric compression**. The almost impossible process of folding a polypeptide to form an active site in which catalytic groups are properly arrayed around the associated substrates cannot always accommodate hydrogen bonds of unconstrained length. Some pushing, pulling and shoving must take place. In fact, there are more hydrogen bonds in these complexes that are longer than the unconstrained length than there are hydrogen bonds that are shorter, but the longer ones go unremarked. To compress a hydrogen bond by 0.02 nm decreases its strength by only around 3 kJ mol^{-1}, which is only about 15% of its energy of formation.[1088] A shortening of another 0.01 nm would result in a further loss of only 4 kJ mol^{-1}.

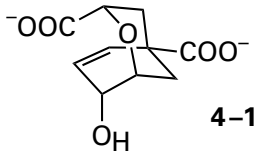
Adventitiously compressed hydrogen bonds between heteroatomic donors and acceptors should be less stable than if they were uncompressed, but the compression may nevertheless accelerate transfer of the hydron between donor and acceptor, a possibility that has been dwelled upon. In most cases, however, transfer of a hydron between two heteroatoms is extremely rapid (Figure 1–1), and unless the difference in pK_a between donor and acceptor is remarkably large, no acceleration should be required. Consequently, any acceleration arising from the observed compression should be inconsequential to natural selection.

The donors and acceptors for hydrogen bonds on the molecules of water, side chains, and polypeptide backbone within an active site that participate in hydrogen bonds with substrates and with

*In all the instances that were tabulated, there was no obvious discontinuous decrease in the length of hydrogen bonds when the difference in pK_a reached 0, and consequently there is no evidence for shorter, stronger "low-barrier" hydrogen bonds in this situation, just as there was no obvious decrease in the dissociation constant of a hydrogen bond in the same situation.[1009]

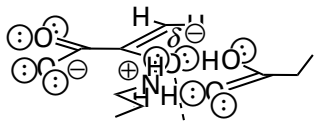
transition states for the enzymatic reaction are usually identified by crystallographic molecular models. These functional groups form direct, unambiguous contacts with substrates that can be observed unambiguously in models of appropriate complexes. They unquestionably participate in either the association of substrates with the active site or catalysis itself. Other adjacent functional groups that do not make direct contact with substrates but that may participate in catalysis can also be identified in molecular models. One way in which such action at a distance can be performed is electrostatically. It seems to be the case that, in addition to positioning donors and acceptors for hydrogen bonds, enzymatic active sites also position charged side chains to produce appropriate electrostatic fields that stabilize the transition state and thereby increase the rate of the enzymatic reaction.

Electrostatic catalysis is enhancement of the rate of a reaction that results from the electrostatic field created by the formal elementary charge of one or several nearby functional groups. For example, the transition state of the reaction catalyzed by chorismate mutase (Equation 4–218) involves a separation of charge (Figure 1–30). The separation of charge creates a dipole, and any electrostatic field that stabilizes the dipole will stabilize the transition state and increase the rate of the enzymatic reaction. In an analogue of the transition state in chorismate mutase, the ether oxygen in bicyclic ether



4–148

accepts hydrogen bonds from the ammonio group of a lysine and the carboxy group of a glutamate in the crystallographic molecular models of its complexes with the chorismate mutases from *S. cerevisiae*[1089] and from *E. coli*.[1090] The former hydrogen bond would position the ammonio group of the lysine adjacent to the oxygen

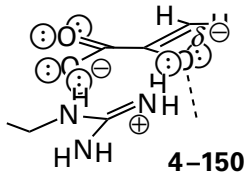


4–149

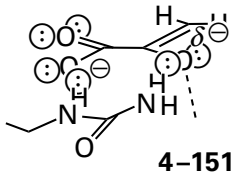
in each substrate for the enzyme, chorismate and prephenate. In chorismate mutase from *M. tuberculosis*, the ether oxygen in **4–148** accepts hydrogen bonds from the ammonio group of a lysine and the amido group of a glutamine.[1091]

Because the ether oxygen of the analogue is at the location at which the negative charge is concentrated in the transition state, it has been proposed that the positive elementary charges of these lysines stabilize the transition state electrostatically. The hydrogen bonds from these electropositive donors suggest that in the transition state for this reaction, as expected, the bond between the oxygen and the allyl carbon is dissociating heterolytically and that the oxygen, therefore, increases in negative charge as the transition state is approached.

In the chorismate mutase from *B. subtilis*, which is unrelated to the aforementioned chorismate mutases and hence a test of this proposal, Arginine 90 is at the same location in the crystallographic molecular model of the complex between the enzyme and bicyclic ether **4–148** as the lysine in the other enzymes. This arginine is the donor in the only hydrogen bond to the ether oxygen in the analogue of the transition state, and it also forms a hydrogen bond to the carboxy group of the analogue.[1092] Again, these two hydrogen bonds would position the guanidinio group of the arginine adjacent to the oxygen



4–150



4–151

in each substrate for the enzyme, chorismate and prephenate. When this arginine is replaced by site-directed mutation with a citrulline (**4–151**), which is isosteric to arginine but lacks the positive elementary charge, the value for rate constant $k_0\,K_m^{-1}$ decreases by a factor of 50,000.[1093] In crystallographic molecular models of **4–148** complexed with the mutated enzyme and with the unmutated enzyme, citrulline superposes precisely with arginine[1094] and forms the same two hydrogen bonds (**4–151**) as arginine. These observations are consistent with the conclusion that the catalytic role of arginine in the native enzyme is to stabilize electrostatically the charge developing on the oxygen in the transition state (Figure 1–30) rather than simply to provide hydrogen bonds.

If, during hydrolysis of the acetal in the glycosidic linkage by the active site of lysozyme, the true intermediate is an oxocarbenium ion because the nearby anionic carboxylato group of Aspartate 52 is sterically prevented from adding to the carbon of the oxycarbenium ion despite sitting next to it, then the carboxylato group is stabilizing the oxocarbenium ion electrostatically. It has been proposed that the oxocarbenium ion that is an intermediate in the hydrolysis of poly(ADP-ribose) by poly(ADP-ribose) glycohydrolase from *Thermomonospora curvata* is stabilized electrostatically by the anionic, nonbridging oxygen on the α-phospho group of the ADP-D-ribosyl leaving group. In the crystallographic molecular model of the complex between the enzyme and ADP-D-ribose,[1095] this anionic oxygen is only 0.41 nm away from oxygen 4′ in the ribosyl ring, which is the oxygen onto which formal positive elementary charge in the oxocarbenium ion is delocalized. The anionic oxygen on the α-phospho group is held firmly and is unable to approach any closer than 0.45 nm to carbon 1′ of ADP-D-ribose, so it cannot stabilize the oxocarbenium ion covalently.

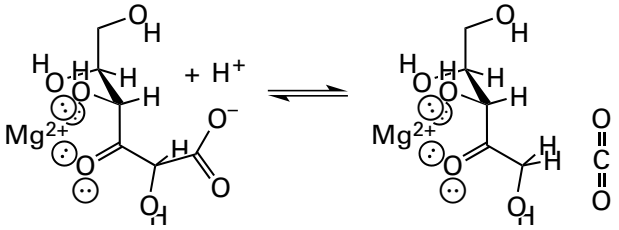
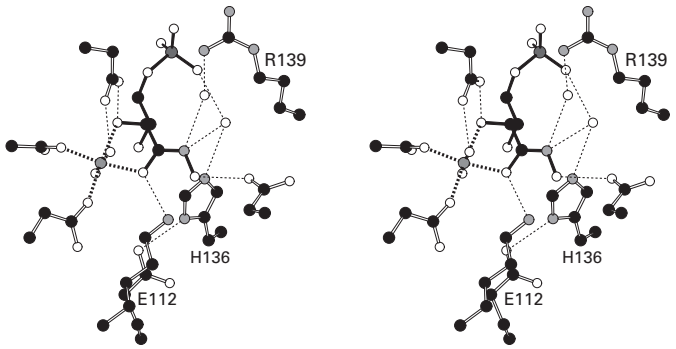
Problem 4–36: 3-Dehydro-L-gulonate-6-phosphate decarboxylase from *E. coli* catalyzes the reaction



in which a carboxy group is replaced by a hydron.

(A) Write a mechanism for this reaction that proceeds through a *cis*-enediol intermediate.

When the enzymatic reaction is run in ^2H_2O with the wild-type enzyme, both L-(1*S*)-[1-^{2}H]xylulose and L-(1*R*)-[1-^{2}H]xylulose are produced in a 2:1 molar ratio. When the enzymatic reaction is run in ^2H_2O with a mutant in which Glutamate 112 has been changed to glutamine and Histidine 136 has been changed to alanine, L-(1*R*)-[1-^{2}H]xylulose is the exclusive product (>90%). When the enzymatic reaction is run in ^2H_2O with a mutant in which Arginine 139 has been changed to valine, L-(1*S*)-[1-^{2}H]xylulose is the exclusive (>95%) product.[1096]



The figure is a stereodrawing of the superposition of two portions of a crystallographic molecular model of a complex between the enzyme and (2*R*,3*S*)-*N*,2,3,4-tetrahydroxybutanamide, a hydroxamate that is an analogue of the *cis*-enediol intermediate.[1097] The asymmetric unit of the crystal is the dimer, and both active sites in the asymmetric unit are occupied by the hydroxamate. Each active site also contains a fixed molecule of water that forms a hydrogen bond to the nitrogen of the hydroxamate, but the the water occupies different locations in the two active sites of the dimer. The drawing includes both molecules of water, positioned in their respective locations in the two active sites in the asymmetric unit. This positioning was achieved

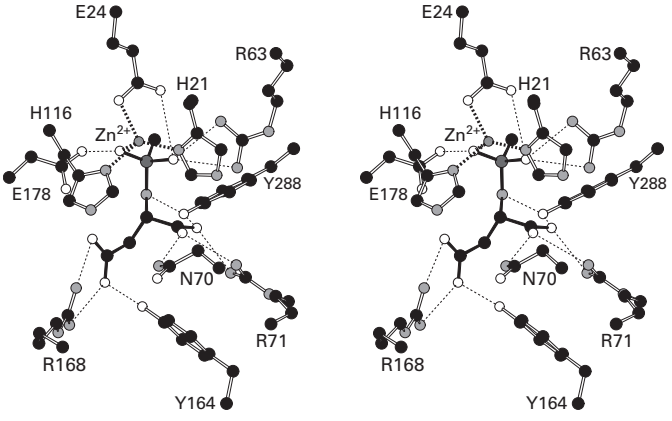
by superposing one of the occupied active sites in the asymmetric unit with its molecule of water with only the molecule of water in the other active site. It seems that both molecules of water cannot be in the same active site at the same time, probably because of steric exclusion.

(B) Draw the structure of the *cis*-enediol intermediate that is formed from 3-dehydro-L-gulonate 6-phosphate and (2*R*,3*S*)-*N*,2,3,4-tetrahydroxybutanamide side by side in the same orientation.
(C) What is the complete description of the acid that hydronates the *cis*-enediol on the *Si* face of carbon 1 in the normal enzymatic reaction?
(D) What is the complete description of the acid that hydronates the *cis*-enediol on the *Re* face of carbon 1 in the normal enzymatic reaction?
(E) Explain the stereochemical observations. In your explanation, discuss the difference in the positions of the molecules of water in the two active sites. This discussion should indicate your understanding of the difference between an enzyme in a crystal and an enzyme in solution.

Problem 4–37: Aspartoacylase catalyzes the nucleophilic substitution

N-acetyl-L-aspartate + H_2O $\rightleftharpoons$ acetate + L-aspartate

(A) Write a step-by-step mechanism for this hydrolysis.



The figure is a stereodrawing of a crystallographic molecular model of the active site of human aspartoacylase occupied by *N*-[hydroxy(methyl)phosphinyl)-L-aspartate.[1098]

(B) Draw the structure of *N*-[hydroxy(methyl)phosphinyl)-L-aspartate.
(C) Why is *N*-[hydroxy(methyl)phosphinyl)-L-aspartate a potent competitive inhibitor of the enzymatic reaction?

What is the role of each of the following in the enzymatic hydrolysis?

(D) The imidazolyl group of Histidine 21
(E) The carboxylato group of Glutamate 24
(F) The carboxamido group of Asparagine 70
(G) The guanidinio group of Arginine 71
(H) The imidazolyl group of Histidine 116
(I) The 4-hydroxyphenyl group of Tyrosine 164
(J) The guanidinio group of Arginine 168
(K) The carboxylate group of Glutamate 178
(L) The 4-hydroxyphenyl group of Tyrosine 288
(M) The Zn^{2+} cation

Metalloenzymes

A limited set of metallic cations is incorporated into proteins as prosthetic groups or transient occupants of their active sites and participate in their function. These are the cations of magnesium, potassium, calcium, vanadium, manganese, iron, cobalt, nickel, copper, zinc, molybdenum, cadmium, and tungsten. Because of their several accessible oxidation states, the transition metals iron and copper, and occasionally manganese, are used as carriers of single electrons (Chapter 2). In this role, they alternate between oxidation states such as Fe^{2+} and Fe^{3+} or Cu^{+} and Cu^{2+}. The metallic cations of cobalt with different formal oxidation states are used enzymatically within the respective cobalamins (Figure 2–67). The cations of the transition metals vanadium, manganese, iron, nickel, copper, molybdenum, and tungsten catalyze reactions involving molecular hydrogen, molecular nitrogen, or molecular oxygen (Chapter 2), and their oxidation states are required to change in these roles. The metallic dications Mn^{2+}, Fe^{2+}, Co^{2+}, and Ni^{2+}, however, are also used by enzymes in situations in which a change in oxidation state is not required and in fact must be avoided; if such a change is encountered adventitiously, it

must be corrected. Cations of the alkaline earth metals magnesium and calcium and the transition metals zinc and cadmium occur naturally only in the dicationic oxidation state as Mg^{2+}, Ca^{2+}, Zn^{2+}, and Cd^{2+}. When they perform enzymatic roles as solely metallic dications, Mg^{2+}, Ca^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, and Cd^{2+} usually act as Lewis acids and are, in effect, **surrogate hydrons.** In this role, they fulfill a catalytic requirement in an enzymatic reaction that would otherwise be fulfilled by a hydron from a catalytic Brønsted acid.

Because a metallic dication is larger than a hydron and consequently has a lower density of positive charge, each of them is **less acidic than a hydron**. This difference in acidity can be quantified. It has already been noted that H^+ and H_3O^+ are used as shorthand for the actual cation $[H(OH_2)_n]^+$, where n is variously depicted as having a value between 4 and 21. Values for m in the homologous complexes of water with a metallic dication, $[Me(OH_2)_m]^{2+}$, are between 4 and 9. As a result, $[H(OH_2)_n]^+$ and $[Me(OH_2)_m]^{2+}$ are analogous Brønsted acids, and their **values of pK_a** can be compared. The hydronium cation, $[H(OH_2)_n]^+$, as a Brønsted acid, displays a pK_a for the reaction

$$H^+(OH_2)_n \rightleftharpoons H^+ + HOH(OH_2)_{n-1} \quad (4\text{–}421)$$

of –1.75. Metallic dications, $[Me(OH_2)_m]^{2+}$, in dilute aqueous solution acting as Brønsted acids display analogous values of pK_a for the reaction

$$Me^{2+}(OH_2)_m \rightleftharpoons H^+ + MeOH^+(OH_2)_{m-1} \quad (4\text{–}422)$$

These values of pK_a, as well as those for metallic trications, have been determined in water for metallic cations that act as Lewis acids in metalloenzymes (Table 4–2).[1099-1101] From these values of pK_a, it can be concluded that none of these metallic cations, even the trications, is so effective as a hydron at lowering the acid dissociation constant of the cluster of water that surrounds it and that a hydron is a stronger Lewis acid than any of these metallic cations.

The advantage of a metallic dication, however, is that at neutral pH the molar concentration of hydronium is very small, while the molar concentration of the complex between water and a metallic cation will be equal to the free molar concentration of that metallic cation. There is also another advantage to this weakness of acidity. When a hydron occupies a lone pair of electrons on a nitrogen, oxygen, or sulfur, the other lone pairs on that nitrogen, oxygen, or sulfur become poorer nucleophiles. When, however, a metallic dication occupies one of the lone pairs of electrons, rather than a hydron, the other lone pairs retain much of their nucleophilicity.

Because it is larger than a hydron, a metallic cation is usually **surrounded in its inner sphere of coordination by four or more ligands**. Metallic cations used catalytically as prosthetic Lewis acids within the active sites of enzymes in aqueous solution are at all times surrounded by Lewis bases. The strongest Lewis bases present in biological fluids are the lone pairs of electrons on oxygen, nitrogen, and sulfur. A hydron is also a Lewis acid, and in biological fluids every acidic hydron is always surrounded by lone pairs of electrons on oxygen, nitrogen, or sulfur. A hydron is so small, however, that it can accommodate as ligands only two Lewis bases at a time in one hydrogen bond. Because a metallic cation has core electrons, it is larger than a hydron and can sterically accommodate more Lewis bases simultaneously. The metallic cations incorporated into enzymes are always surrounded by four to nine lone pairs of electrons from oxygen, nitrogen, sulfur, or a halide whether they are in the active site or in the solution before they enter the active site. These four to nine lone pairs of electrons coordinate the metallic dication.

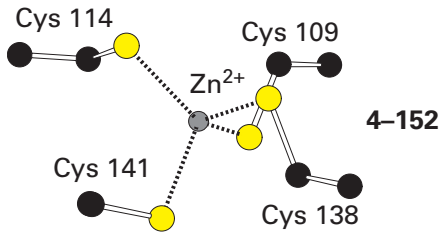
Table 4–2: Acid Dissociation Constants for Aquo Complexes of Metallic Cations[1099-1101]

cation	pK_a	cation	pK_a
K^+	>15[a]	Cd^+	10.1[b]
Ca^{2+}	12.7[a]	Ni^{2+}	9.9[b]
Mg^{2+}	11.4[a]	Co^{2+}	9.6[a,b]
Mn^{2+}	10.6[a,b]	Zn^{2+}	9.0[b]
Fe^{2+}	10.1[a]	Fe^{3+}	2.3[a,b]
		Co^{3+}	0.7[a]

[a]Reference 1101. [b]Reference 1099.

The preference of a metallic cation for a particular type of lone pair of electrons is usually discussed in terms of **hardness** or **softness** of the Lewis acid and the Lewis base.[1102] The rule is that hard acids prefer hard bases and soft acids prefer soft bases. Of the metallic dications acting catalytically in active sites as Lewis acids, K^+, Mg^{2+}, Ca^{2+}, and Mn^{2+} are hard Lewis acids; Fe^{2+}, Co^{2+}, Ni^{2+}, and Zn^{2+} are borderline; and Cd^{2+} is soft. For the commonly encountered bases, lone pairs of electrons on oxygen are harder than lone pairs of electrons on nitrogen, which are harder than lone pairs of electrons on sulfur. These rankings, for example, are consistent with the fact that Ca^{2+} has a strong preference for lone pairs of electrons on oxygen while Zn^{2+} and Co^{2+} have a preference for lone pairs of electrons on sulfur. It also explains why the bases on metallothionein, a protein responsible for chelating soft, toxic cations of heavy metals such as Hg^{2+}, Cd^{2+}, and Pb^{2+}, are entirely the soft sulfanyl groups of cysteine side chains in the protein.

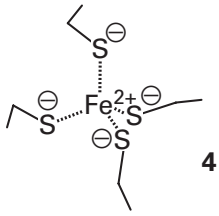
The Lewis bases surrounding a metallic cation in solution are held by interactions the characteristics of which span the spectrum between ionic and covalent. **Ionic interactions** are created by electrostatic forces between the metallic cation and an anion or the dipole on a ligand. If the forces were entirely ionic, the number and orientation of the Lewis bases around the cation would be determined solely by steric considerations. The larger the cation or the smaller the bases, the more bases should be gathered. Usually, the interactions between hard metallic cations and hard bases are close to being purely ionic. The calcium dication is an example of a hard, ionic metallic cation, and it is also large. When it is bound to a protein or when it is in the solution that surrounds the protein, Ca^{2+} is coordinated by six to nine lone pairs of electrons, invariably from oxygen atoms,[1103] which are the hardest of bases. The number and orientation of these lone pairs of electrons from the atoms of oxygen around the calcium depend entirely on the size and shape of the bases that provide the lone pairs, as well as any steric constraint upon those bases.[1104] The Zn^{2+} in the crystallographic molecular model[1105,1106] of aspartate carbamoyltransferase



4–152

from *E. coli*, however, is a good example of a metallic cation participating in almost purely **covalent bonds**. In this arrangement, a borderline metallic cation bonds covalently to four soft bases. When the ligands coordinating the dication of a transition metal form covalent bonds in such a tetrahedral geometry, the empty valence 4*s* orbital of the transition metal and its three empty valence 4*p* orbitals form four sp^3 hybrid orbitals, each of which is occupied by a lone pair of electrons from one of the four soft bases that are ligands to the metallic dication to form the four mostly covalent bonds.*

Zinc dication has 10 valence electrons that occupy its five 3*d* orbitals and **completely fill the *d* shell**, and this completion causes the 3*d* electrons to be unavailable for covalent bonding.† In the case of Fe^{2+} in reduced rubredoxin (previously **2–63**)



4–153

the metallic dication has only 6 valence electrons, which fill the five 3*d* orbitals. The 3*d* electrons in Fe^{2+}, unlike those in Zn^{2+}, can participate in covalent bonding because, like the valence electrons on a carbon, nitrogen, or oxygen atom, **the *d* shell they occupy is unfilled**. Consequently, in the case of Fe^{2+}, both the partially filled 3*d* orbitals and the unfilled 4*s* and 4*p* orbitals are all available for covalent bonding.

The major structural difference, as opposed to electronic difference, between ionic interactions and

*A comprehensive description of the covalency of the interactions between metallic dications and their ligands is beyond the scope of this discussion and not germane to the participation of metallic dications as Lewis acids in enzymatic reactions. As before, in drawings, all interactions will be considered to be intermediate between ionic and covalent and will be designated by thick dotted lines. The two examples here are close to the extremes of ionic and covalent.

†The electrons occupying all these orbitals cannot be distinguished in terms of their origins, but giving them arbitrary origins makes the counting easier.

covalent bonds is the **directional properties of the arrangements of ligands**. Covalent bonds usually position the participating atoms in strict geometric orientations, such as tetrahedral in the case of Zn^{2+} in **4–152**, while ionic interactions are malleable, resembling pigs at a trough. The fact that covalent bonds involving metals are so reliable is reflected by the practice of geometrically restricting them during crystallographic refinement, as is done for bonds involving carbon, nitrogen, and oxygen. For example, in the initial crystallographic molecular model of aspartate carbamoyltransferase built directly from the unrefined map of electron density, the arrangement of sulfurs around the Zn^{2+} was constrained to tetrahedral geometry, just as all sp^3 carbons were, in all subsequent refinements.[1107] This practice can be dangerous, however, particularly if the metallic cation is harder or if the ligands to the metallic cation are harder, less covalent bases.[1108] In such intermediate cases, various mixtures of ionic and covalent behavior are observed. The main structural indication of such deviations from covalent behavior is the loss of directional ligation.

When a metallic cation leaves the solution and is incorporated into an active site, it exchanges some or all of the lone pairs of electrons from the ligands that coordinated it in solution for lone pairs of electrons provided by the polypeptide backbone or the side chains of the protein. The **coordination observed within the active site** is somewhat characteristic of the type of cation, but similar dications are often accommodated by natural selection with indistinguishable coordinations.

Potassium ion, K^+, is the hard monocation of an alkali metal. It is so hard that it is always surrounded by lone pairs of electrons from oxygens, the hardest bases. Potassium ion is the largest of all the metallic cations that are incorporated naturally into molecules of protein, and it is the only monovalent metallic cation used catalytically as a Lewis acid by enzymes. It has a large enough ionic radius (Table 4–3)* to accommodate as many as eight lone pairs of electrons from oxygens, and because K^+ is so hard, the association is entirely ionic.

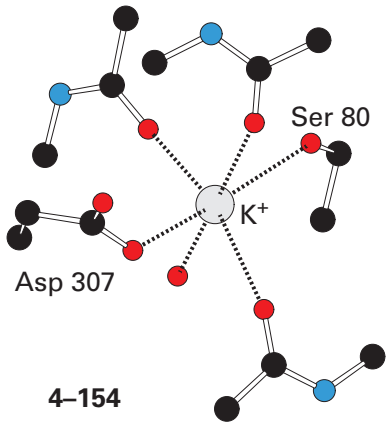
A typical arrangement of ligands coordinating K^+ when it is bound in an enzyme occurs in 2,2-dialkylglycine decarboxylase (pyruvate) from *Burkholderia cepacia*[1110]

*Even though an ion is obviously not a hard sphere but a continuous distribution of electron density that decreases with distance from the nucleus, effective ionic radii[1109] are commonly used to quantify the dimensions of this distribution.

Table 4–3: Effective Ionic Radii of Metallic Cations Used by Enzymes as Lewis Acids[1109]

cation	ionic radius (nm)	cation	ionic radius (nm)
K^+	0.14	Fe^{2+} (ls)[a]	0.061
Mg^{2+}	0.072	Fe^{2+} (hs)[b]	0.078
Ca^{2+}	0.11	Ni^{2+}	0.06
Mn^{2+}	0.083	Zn^{2+}	0.07
Co^{2+} (ls)[a]	0.065	Cd^{2+}	0.09
Co^{2+} (hs)[b]	0.075		

[a]Low-spin state. [b]High-spin state.



4–154

The six ligands are three acyl oxygens from the peptide backbone, an oxygen in the carboxy group of Aspartate 307, the hydroxy group from Serine 80, and a molecule of water. In the occupied active site of [formate-*C*-acetyltransferase]-activating enzyme from *E. coli* occupied by its substrate L-methionine, the K^+ that activates the enzymatic activity[1111] is coordinated by five ligands—two oxygens, one from each of two carboxy groups from two aspartates, the acyl oxygen of a peptide bond, the hydroxy group of threonine, and the carboxylato group of L-methionine—but no molecules of water.[1112] The number of fixed **molecules of water remaining on K^+** following its incorporation into a protein varies[1113,1114] from none, as in the occupied active sites of [formate-*C*-acetyltransferase]-activating enzyme and carbam-

oyl-phosphate synthase (glutamine-hydrolyzing) from *E. coli*,[1115] to five, as in a mutant of UDP-glucose–hexose-1-phosphate uridylyltransferase from *E. coli*.[1116]

Potassium ion is present in cytoplasm at concentrations of 0.1–0.8 M, making it the **dominant cation in all cells**. Because its presence is as reliable as that of water, it is not surprising that, just as are molecules of water, ions of potassium are incorporated structurally into many proteins. It is also not surprising that many enzymatic reactions are inhibited partially or fully by removal of K^+ from solution,[1117] as they would be if water were removed. In most instances, this inhibition of enzymatic activity results from the fact that, as with 2,2-dialkylglycine decarboxylase (pyruvate) and carbamoyl-phosphate synthase, a K^+ is bound so close to the active site that its removal disrupts the structure of the active site.

There are, however, a few instances in which an oxygen on a substrate that is involved closely in the enzymatic reaction becomes a ligand to K^+ upon association with the active site, and the K^+ performs a **catalytic role**. For example, pyruvate kinase (Equation 4–275) has an absolute requirement for a monovalent cation to catalyze its reaction.[1118] Although ammonium and rubidium cations can fulfill this role as well, in the cytoplasm, where neither of these other ions is present in significant concentration, K^+ is the cation involved in normal catalysis. In steady-state kinetic measurements of the reaction catalyzed by pyruvate kinase, K^+ behaves as if it were one reactant in a multireactant mechanism.[1119] In the crystallographic molecular model of the active site of pyruvate kinase from *O. cuniculus* occupied by K^+, $MgATP^{2-}$, and oxalate (an analogue of the enol of pyruvate),[581] one nonbridging oxygen of the γ-phospho group of $MgATP^{2-}$ is one of the six oxygens that coordinate the K^+ (Figure 4–52). During the nucleophilic substitution at phosphorus catalyzed by the enzyme, this K^+ ensures that the γ-phospho group of $MgATP^{2-}$ remains dianionic and stabilizes the intermediate monomeric metaphosphate or phosphorane.

The enzymatic activity of [formate-*C*-acetyltransferase]-activating enzyme from *E. coli* is activated 10-fold by K^+. It is also activated[1111] by Li^+, Na^+, NH_4^+, and Rb^+. Because, however, K^+ is the most effective and because these other monovalent cations are not present at significant concentrations, in the cytoplasm it must be K^+ that activates the enzyme. When this active site is occupied by the substrate *S*-adenosyl-L-methionine,[1112] the carboxy group of *S*-adenosyl-L-methionine is a monodentate ligand to K^+. Because the carboxy group is distant from *S*-adenosyl-methysulfanyl group of L-methionine, which is the functional group participating in catalysis, the only role for K^+ in this case is to contribute to the recognition of *S*-adenosyl-L-methionine.

With a few exceptions such as pyruvate kinase, where it is involved only peripherally in catalysis, K^+ usually has a structural role in the protein. The K^+ in 2,2-dialkylglycine decarboxylase (**4–154**) and the K^+ in carbamoyl-phosphate synthase (glutamine-hydrolyzing) from *E. coli*[1115] are examples of K^+ in a structural role. Potassium ion is seldom used catalytically because its large size and low density of charge cause it to be the **weakest of the Lewis acids** (Table 4–2). Consequently, the remainder of the discussion will focus on only the metallic dications that are used almost exclusively as Lewis acids in catalytic roles.

The divalent metallic cations used as Lewis acids in the active sites of enzymes each have particular properties.

Magnesium ion, Mg^{2+}, is a hard, small, alkaline earth, metallic dication. Because it is hard, it is almost[1120] always coordinated by lone pairs of electrons from atoms of oxygen. Because it is small (Table 4–3) and therefore has a high density of charge, Mg^{2+} gathers as many oxygen ligands as it can. It almost always ends up with six lone pairs from six oxygens arranged octahedrally. This octahedral arrangement is not, however, the result of covalence. It is a consequence of the fact that the sterically least repulsive way to crowd six oxygens around a cation with such a small ionic radius is octahedrally. In its preferred coordination, with six lone pairs from six atoms of oxygen in an octahedral arrangement, the interatomic distances between Mg^{2+} and the atoms of oxygen (0.20–0.21 nm) are shorter and much less variable than those (0.23–0.26 nm) for Ca^{2+}, its larger sibling. Even these short and less variable distances are probably the result of steric effects. If each atom of oxygen is only 0.205 nm from Mg^{2+}, then the distance between each oxygen and its four neighbors in the octahedral array must be 0.29 nm, which is the distance for van der Waals contact. Consequently, the distance between the cation and its ligands is as short as it can be if six of them are gathered around it. Because of the shorter distance between the metallic cation and the oxygens, the acidity of Mg^{2+} is somewhat stronger than that of Ca^{2+} (Table 4–2).

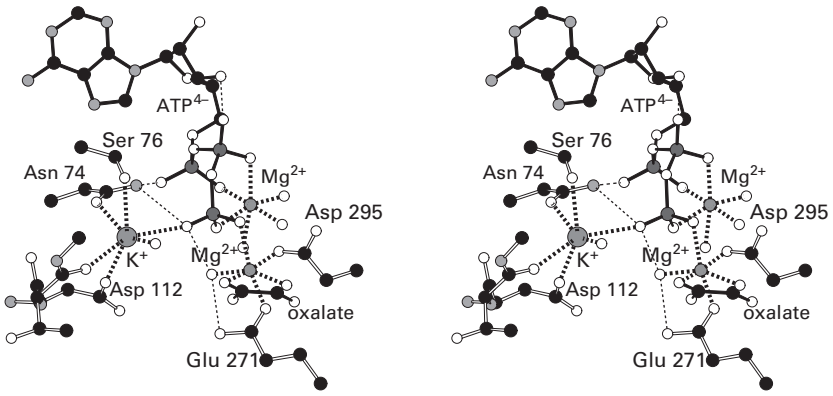


Figure 4–52: Stereodrawing[134] of the crystallographic molecular model of the active site of pyruvate kinase from *O. cuniculus* occupied by K^+, the substrate $MgATP^{2-}$, and oxalate, an analogue of the intermediate enolate of pyruvate that is the nucleophile or leaving group, respectively, in the reaction.[581] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the three large dark gray atoms are three atoms of phosphorus. The smaller dark gray spheres are two magnesium ions surrounded by their ligands, and the larger dark gray sphere is a potassium ion surrounded by its ligands. The enzyme was purified from muscle of *O. cuniculus* and crystallized from 7.8% (w/v) poly(ethylene glycol) 8000, 0.16 M KCl, 5 mM $MgCl_2$, 5 mM ATP^{4-}, 1 mM oxalate, and 50 mM succinate at pH 6.0. Electron density for $MgATP^{2-}$, K^+, oxalate, and an additional Mg^{2+} could be observed in the active site. Molecules of water and side chains of the amino acids that are ligands to K^+ and the other Mg^{2+} are included. The two carboxy groups of the oxalate are monodentate ligands to the other Mg^{2+}.

Magnesium ion is the only metallic dication present at significant free concentration in cytoplasm (Table 4–4). As a result, a prominent role for free Mg^{2+} in the cytoplasm of a cell is to form **complexes with oligophosphates**. The paradigm of such a complex is $MgATP^{2-}$, which is the predominant form[1122] of adenosine triphosphate present in solution in cytoplasm. In $MgATP^{2-}$, three coordination sites on Mg^{2+} are occupied by oxygens of phosphates and the other three by waters.[1123] When the complex associates with the active site of an enzyme, the three sites occupied by water can retain their aquo ligands or become occupied by Lewis bases from the active site. When the waters on Mg^{2+} are not replaced by ligands from the enzyme, donors and acceptors from the protein often form hydrogen bonds to these fixed molecules of water that remain associated with Mg^{2+}.[1124] In the active site of pyruvate kinase (Figure 4–52), the $MgATP^{2-}$ that is bound retains all three of the fixed molecules of water on Mg^{2+} (the upper Mg^{2+} in the drawing) that it had in solution as well as the three oxygens from ATP^{4-}. The structure of this $MgATP^{2-}$ in the active site of pyruvate kinase is almost identical* to the structure of free $MgATP^{2-}$ that has been crystallized from solution.[1123] This fact suggests that the $MgATP^{2-}$ in the active site of pyruvate kinase is little changed upon associating with the enzyme and simply carries Mg^{2+} into the active site as if there were covalent bonds between the three oxygens and Mg^{2+}.

One advantage of using magnesium rather than a hydron as the Lewis acid neutralizing ATP^{4-} is that **more of the oxygens are neutralized**. At pH 7, the predominant forms of free ATP are the unhydronated form (ATP^{4-}) and the monohydronated form ($HATP^{3-}$) in about equal proportions.[1122] In $MgATP^{2-}$, the predominant form of the magnesium complex, however, two oxyanions are fully neutralized by Mg^{2+}.

Another advantage is that the **triphosphate is rigidified by the chelation**, which hinders free rotation around the bonds between the atoms of phosphorus and the bridging oxygens. This rigidification of $MgATP^{2-}$ significantly restricts the conformations that it can assume while still in solution. This decrease in the number of conformations in turn decreases the entropic barrier for association of $MgATP^{2-}$ with an active site, as long as the active site is complementary to the set of these conformations. Because an active site is rigid, the $MgATP^{2-}$ is required to assume a single conformation once it is bound.

Table 4–4: Free Concentrations of Metallic Cations in Cytoplasm[1121]

cation	free concentration[a]	cation	free concentration[a]
K^+	100 mM	Ni^{2+}	<1 nm
Mg^{2+}	1 mM	Zn^{2+}	10 pM
Ca^{2+}	0.1 μM	Co^{2+}	<1 nm
Mn^{2+}	0.1 μM	Cu^{2+}	<10 fM
Fe^{2+}	0.1 μM		

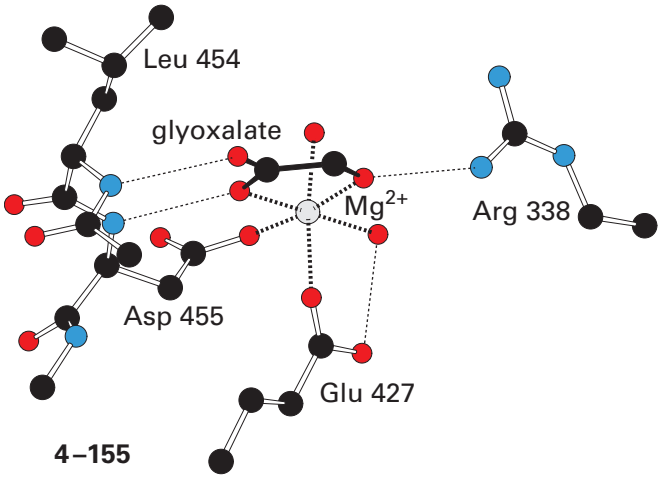
[a]These concentrations are estimates believed to be accurate to within a factor of 10. In most cases, they are not based on direct measurements of free concentration.

Other **nucleoside triphosphates**, such as $MgGTP^{2-}$, $MgCTP^{2-}$, $MgUTP^{2-}$, and $MgdTTP^{2-}$, also enter active sites coordinated[1012] to Mg^{2+}, as do nucleoside diphosphates such as adenosine diphosphate,[1015,1125,1126] thiamine diphosphate,[1127] and diphosphate itself.[1128,1129] In at least one instance, Mg_2ATP seems to have been the substrate that entered the active site.[1024]

The free concentration of Mg^{2+} in the cytoplasm and intracellular compartments is around 1 mM,[1130] Although this free concentration is well below the free concentration of K^+, it is still fairly high, and it does not fluctuate significantly. As a result, natural selection has sometimes incorporated Mg^{2+} into an enzyme in a purely structural role simply because it was an available structural component. An example is the Mg^{2+} in alcohol dehydrogenase ($NADP^+$) from *L. brevis* that is coordinated by the acyl oxygens of two glutamines and four molecules of water.[1131] Even though this bound Mg^{2+} is greater than 1 nm from the active site and not involved in catalysis, its removal completely inactivates the enzyme.

A **typical arrangement of the ligands** coordinating Mg^{2+} that is not coordinated by an oligophosphate occurs in the active site of malate synthase from *E. coli*[1132]

*The complex between the triphosphate of ATP^{4-} and Mg^{2+} in $MgATP^{2-}$ crystallized from solution is, within the triphosphate, the same enantiomer as that in the active site of pyruvate kinase, but the conformations of one of the two six-membered rings around Mg^{2+} are slightly different in the two complexes within the asymmetric unit.



The Mg^{2+} is octahedrally coordinated by two oxygens of carboxy groups, one from Aspartate 455 and one from Glutamate 427; two molecules of water; and two oxygens in glyoxylate, one substrate in the enzymatic reaction (Equation 4–271). This arrangement of ligands is almost identical to that for the Mg^{2+} that did not arrive in the active site of pyruvate kinase on $MgATP^{2-}$ (the lower Mg^{2+} in Figure 4–52), if it is realized that the bridging oxygen between the β-phosphate and the γ-phospho group of $MgATP^{2-}$ in the active site of pyruvate kinase occupies the same position as a molecule of water in the active site of malate synthase.

The two Mg^{2+} in the active site of phosphopyruvate hydratase from *S. cerevisiae* (Figure 4–43) are additional paradigms. The one on the right is coordinated by the hydroxy group and the amido oxygen of Serine 39, two molecules of water, and the oxygen from a carboxy group and an oxygen from a phospho group in the substrate. The one on the left is coordinated by three oxygens from carboxy groups, one from Aspartate 246, one from Glutamate 295, and one from Aspartate 320; a molecule of water; and the two oxygens on the carboxy group of the substrate. These latter two oxygens are an example of the frequent use of a carboxy group as a **bidentate ligand** to a metallic cation, and one of them is in turn a ligand to both Mg^{2+}. Usually there are two, three, or four oxygens from the carboxy groups of aspartates or glutamates, or one or more carboxy groups from substrates and one, two, or three molecules of water or hydroxy groups coordinating Mg^{2+} in an active site.[692,1133-1135] Even though they are usually considered to be carboxylato groups in the absence of evidence, **whether or not the carboxy groups are hydronated on their other oxygens** is generally unknown, but in most instances some or most of them are probably unhydronated and anionic. When Mg^{2+} is acting as a Lewis acid, one or two of the ligands are oxygens from the substrate, one or both of which is a Lewis base acted upon by Mg^{2+} in its catalytic role.

If Mg^{2+} is bound to the active site in the absence of substrate, the positions to be occupied by oxygens from a substrate after it has associated are occupied by fixed molecules of water before it associates. This hydration is commonly the case for the sites on any metallic dication. In the absence of substrate, **the sites to be occupied by the substrate are usually occupied by water**, as are the donors and acceptors for hydrogen bonds that will form with a substrate in any active site.

Calcium ion, Ca^{2+}, is another hard, alkaline earth, metallic dication. Like Mg^{2+}, Ca^{2+} participates in purely ionic interactions. Because it has a significantly larger ionic radius than Mg^{2+} (Table 4–3), the ligands around the cation are not so sterically crowded. Consequently, there are fewer geometric requirements, and Ca^{2+} can be coordinated by as many as nine lone pairs of electrons. Calcium has an even lower affinity for nitrogen[1103] than Mg^{2+}, so the lone pairs of electrons that are its **ligands are**

When Ca^{2+} is bound to proteins, it often **serves in a structural role**[1136-1138] by gathering around itself oxygens from the polypeptide, its side chains, and molecules of water (Figure 4–53).[1139] These associations are highly specific, but the specificity is provided by the distribution of oxygens within the protein and the donors and acceptors for hydrogen bonds between the protein and associated molecules of water, not by the calcium. Although its free concentration in present-day cytoplasm is low (Table 4–4),[1130,1140] the free concentration of Ca^{2+} may have been significantly higher, close to that of its concentration in present-day seawater (10 mM), when it was first being incorporated structurally into the proteins of primitive organisms and before it assumed a role in cellular signaling that required its free concentration in cytoplasm to be maintained at these low levels. The **more flexible steric requirements** for Ca^{2+} may also give it advantages in a purely structural role.

Calcium ion, however, can also play a **catalytic role as a Lewis acid** in enzymatic reactions.[1022,1141]

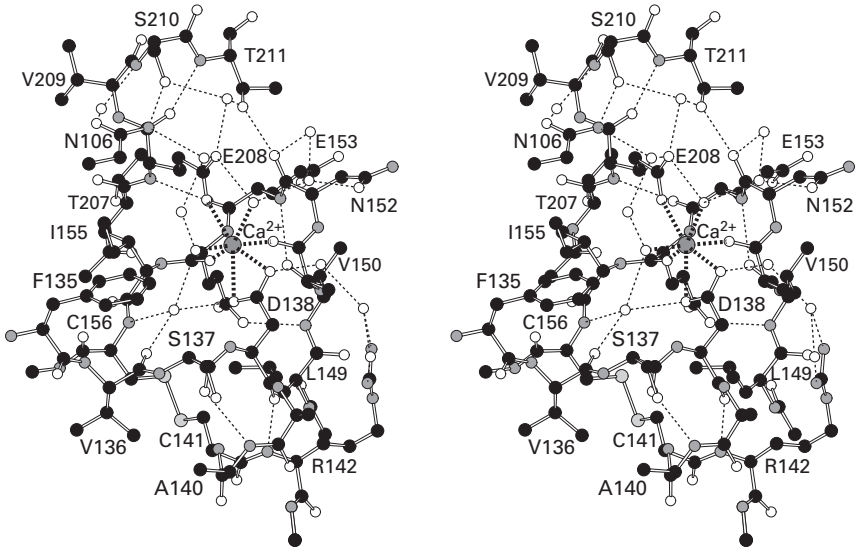


Figure 4–53: Stereodrawing[134] of the crystallographic molecular model of the site in which a Ca^{2+} is coordinated in trypsin from the bacterium *S. griseus*.[1139] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, large light gray atoms are sulfurs, and the large dark gray sphere is a calcium ion surrounded by its ligands. Crystals were grown in solutions of the purified protein (10–15 mg mL^{-1}) in 10 mM calcium acetate at pH 6.2 by varying the concentration of ammonium sulfate. Reflections from four isomorphous replacements were collected to Bragg spacing of 0.28 nm, and a data set was collected from crystals of the native enzyme to Bragg spacing of 0.17 nm. The phases were estimated from multiple isomorphous replacements and also from molecular replacement using molecular models of bovine trypsin (31% identity; 3.1 gap percent) and bovine chymotrypsin (30% identity; 4.0 gap percent) as guides. The site at which Ca^{2+} is coordinated is distant from the active site in which the nucleophilic serine, Serine 172, as well as Aspartate 82 and Histidine 37 are located, so the Ca^{2+} performs only a structural role. It is located in a pocket on the surface of the protein, and the view in the drawing is into the pocket from the solution.

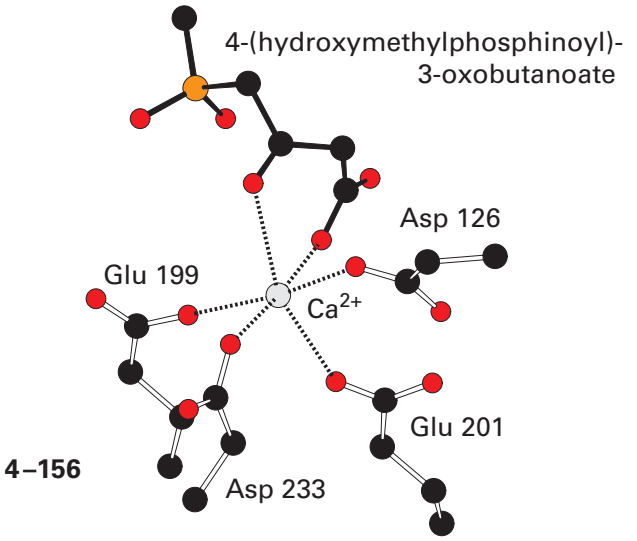
It performs that role in the active site of murine fumarylacetoacetase (Equation 4–362).[860] In this instance



Ca^{2+} is coordinated monodentally by five carboxy oxygens, one from each carboxy group in two aspartates and two glutamates and one oxygen from the carboxy group of 4-(hydroxymethylphosphinoyl)-3-oxobutanoate (**4–120**), an analogue of the tetrahedral intermediate that is formed by nucleophilic addition of the peripheral enolate of acetoacetate to a carboxy group of the fumarate. The carbonyl group of 4-(hydroxymethylphosphinoyl)-3-oxobutanoate represents the oxyanion of the enolate, which is stabilized by Ca^{2+} in the usual reaction. In the active sites of both micrococcal nuclease from *S. aureus*[1021] and diisopropyl fluorophosphatase from *Loligo vulgaris*,[1142] a Ca^{2+} acts catalytically as a Lewis acid. In both active sites, the Lewis base on the substrate that is a ligand to Ca^{2+} is the oxygen of a phospho group. The Ca^{2+} forms only this one contact with the substrate, and its role appears to be the neutralization of negative charge that develops on the oxygen as the phosphorane is formed during the reaction.

Calcium dication is not used often in the role of a Lewis acid because its acidity is weak (Table 4–2). Nevertheless, it is sometimes used as a Lewis acid, and perhaps in these situations weak acidity may actually be advantageous, just as the weak acidity of an oxyanion hole is often advantageous. Its inability to form sterically reliable interactions and thereby provide a firm anchor to distort substrates may also be a drawback. It has already been noted, however, that the Ca^{2+} in the cluster of four manganese ions and a Ca^{2+} (Figure 2–59) in the active site of photosystem II at which water is oxidized to molecular oxygen has exploited this lack of firm coordination to permit molecules of water to rotate across the surface of the Ca^{2+} as they are fed into the cluster of manganese ions to be oxidized,[1143,1144] as if on a conveyer belt.

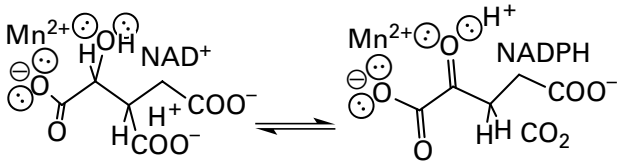
Manganese dication, Mn^{2+}, is a transition metallic cation rather than an alkaline earth metallic cation. Nevertheless, like Mg^{2+}, Mn^{2+} is also hard and small, although less hard than Mg^{2+}. Its ionic radius (Table 4–3) is only about 10% larger than that of Mg^{2+}, so it has a similar density of charge and size, and for all the same reasons, Mn^{2+} usually gathers six ligands octahedrally around itself. Each of these six ligands, as with all ligands to metallic dications, directs a lone pair of electrons, and hence the dipole associated with that lone pair of electrons, toward Mn^{2+}.

Because it is the **ion of a transition metal**, Mn^{2+}, unlike Mg^{2+}, has **electrons in 3*d* orbitals**. Manganese dication has a half-filled d^5 electronic configuration in which its five valence electrons are distributed one into each of the five 3*d* orbitals (Figure 2–24). In octahedral coordination, the 3*d* orbitals have orientations that cause the two singly occupied orbitals that are aligned with its six ligands ($3d_{z^2}$ and $3d_{x^2-y^2}$) to increase in energy because of electron repulsion and the three singly occupied orbitals that are not aligned with the ligands ($3d_{xy}$, $3d_{xz}$, and $3d_{yz}$) to decrease in energy, relative to a situation in which the sum of the electric fields of the ligands is redistributed mathematically as a uniform spherical field. These increases and decreases in energy result from the fact that the dipoles and elementary charges of the ligands are discretely oriented rather than distributed over a uniform spherical field. Their sum is the **ligand field stabilization** provided by the ligands. Because its five 3*d* electrons are evenly distributed over the five 3*d* orbitals, the increases and decreases in energy nearly cancel, and the ligand field stabilization for octahedrally coordinated Mn^{2+} is negligible. This lack of ligand field stabilization and the fact that the two orbitals aligned with the ligands, $3d_{z^2}$ and $3d_{x^2-y^2}$, are each occupied by an electron makes the bonding between Mn^{2+} and its ligands predominantly ionic, similar to the bonding between Mg^{2+} and its ligands. Consequently, as with Mg^{2+}, the main reason for the octahedral coordination around Mn^{2+} is steric.

While Mg^{2+}, both in solution and when bound to the active site of an enzyme, prefers oxygen ligands, particularly the oxygens of carboxy groups, the softer metallic dication Mn^{2+} in solution forms complexes with both nitrogen bases and oxygen

bases such as ammonia, imidazole, 1,2-diaminoethane, water, alcohols, carboxylates, the carbonyl oxygens of ketones and aldehydes, and the acyl oxygens of amides. Oxygen bases and nitrogen bases are roughly equivalent in their affinities for Mn^{2+}. In aqueous solution, the hexaammonium complex is observed only at concentrations of ammonia greater than 2 M; hexaimidazole salts can be crystallized from anhydrous ethanol. Like those for Mg^{2+}, all these complexes between unhindered bases and Mn^{2+} are hexacoordinate and octahedral. In these complexes, mixtures of various ligands around manganese can occur. For example, each of the species $[Mn(OH_2)_n(NH_3)_{6-n}]^{2+}$ with $0 < n \leq 6$ is observed in mixtures of ammonia and water. When Mn^{2+} is engaged catalytically as a Lewis acid in an enzymatic reaction, it is complexed octahedrally by Lewis bases from amino acids in the active site, molecules of water, and substrates.

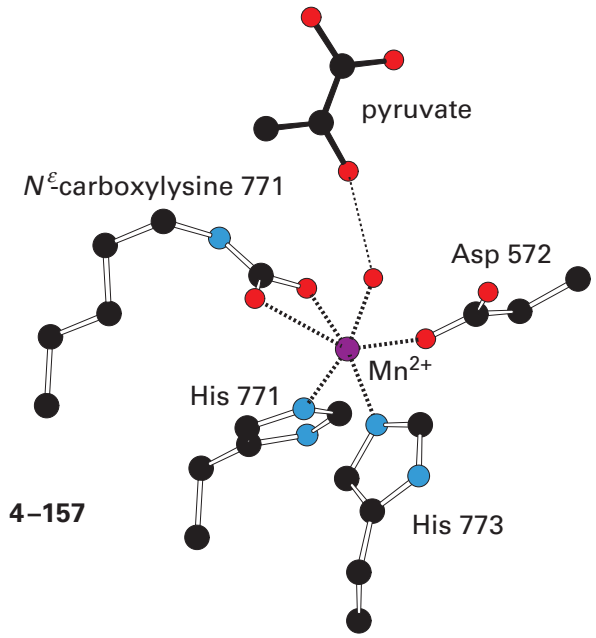
As does Mg^{2+}, Mn^{2+} can form a complex in solution with one of the nominal reactants to produce the actual reactant entering the active site from the solution. For example, the requirement for Mn^{2+} in kinetic studies of the reduction catalyzed by isocitrate dehydrogenase (NAD^+)



(4–423)

results from the fact that the actual reactant entering the active site is the complex between Mn^{2+} and the isocitrate dianion,[722,1145] and Mn^{2+} enters the active site within this complex just as Mg^{2+} often enters active sites in a complex with an oligophosphate. Because Mg^{2+}, however, was able to substitute for Mn^{2+} in this role, albeit with a lower catalytic constant, it may be the case that in cytoplasm, where the concentration of Mn^{2+} is quite low (Table 4–4), Mg^{2+} is the ligand to the isocitrate that enters the active site.

A typical arrangement of ligands coordinating Mn^{2+} when it is acting as a Lewis acid in an active site occurs in human pyruvate carboxylase[1146,1147]



In the crystallographic molecular model, pyruvate, which is one of the six substrates for the enzyme

$$MgATP^{2-} + HOCO_2^- + \text{pyruvate} \rightleftharpoons H^+ + MgADP^- + HOPO_3^{2-} + \text{oxaloacetate}$$

(4–424)

is bound to the active site. The Mn^{2+} is coordinated by imidazolyl groups from Histidines 771 and 773, a carboxylato oxygen from Aspartate 572, the two oxygens of the N^6-carboxy group on Lysine 741, and a molecule of water* that sits between the carbonyl oxygen of pyruvate and Mn^{2+} and connects them.

Iron dication, Fe^{2+}, is a small dication that is borderline in hardness. It is a d^6 transition metallic dication, and its six valence electrons are distributed over five 3*d* orbitals (Figure 2–24). Unlike Mn^{2+}, in which the five 3*d* electrons are all unpaired, causing the ion to have significant unpaired electron spin, Fe^{2+} can exist in both low-spin and high-spin states. Low-spin Fe^{2+} usually adopts octahedral coordination with significant covalent character while high-spin Fe^{2+} exhibits more varied coordination with more ionic character.

Whether Fe^{2+} adopts a high-spin or low-spin state depends on the orientation of its ligands and

*There are no waters in the crystallographic molecular model of the human enzyme, so the molecule of water shown is a ligand to the metal and forms a hydrogen bond to the pyruvate found in the same location in the crystallographic molecular model of the homologous (46% identity; 0.6 gap percent) enzyme from *R. etli*.[1148]

whether they are strong or weak field ligands. These latter designations depend on the magnitude of the effect of a particular ligand on the energy of the ligand field. When octahedrally coordinated Fe^{2+} is in its **high-spin state** (Figure 2–25), two of its six valence electrons as a pair occupy one of the 3*d* orbitals ($3d_{xy}$, $3d_{xz}$, or $3d_{yz}$) that is of low energy because it does not align with any of the ligands. The other four valence electrons are distributed over the other four 3*d* orbitals: the remaining two of the $3d_{xy}$, $3d_{xz}$, and $3d_{yz}$ orbitals of lower energy and the $3d_{z^2}$ and $3d_{x^2-y^2}$ orbitals of higher energy that do align with the ligands. When octahedrally coordinated Fe^{2+} is in its **low-spin state**, its six valence electrons, in three pairs, occupy the three 3*d* orbitals of lower energy ($3d_{xy}$, $3d_{xz}$, or $3d_{yz}$) that are not aligned with the ligands. The 3*d* orbitals that align with the ligands, $3d_{z^2}$ and $3d_{x^2-y^2}$, are empty so that electron repulsion is minimized. The stronger the effect of the ligands is on the ligand field, the stronger will be the electron repulsion exerted by the ligands, and the more favorable will be the low-spin state. When Fe^{2+} is not octahedrally coordinated, the disposition of its 3*d* electrons, and hence its spin state, is determined more subtly, but strong field ligands usually promote octahedral coordination with a low-spin state because in this situation maximum ligand field stabilization is achieved. Because antibonding orbitals on Fe^{2+} are occupied by the lone pairs of electrons of the ligands when Fe^{2+} is in the high-spin state, pentacoordination or tetracoordination is preferred for high-spin Fe^{2+}, but that preference is not absolute. In an active site, steric effects are often more relevant to the distribution of ligands around Fe^{2+} than the electronic effects of the ligand field.

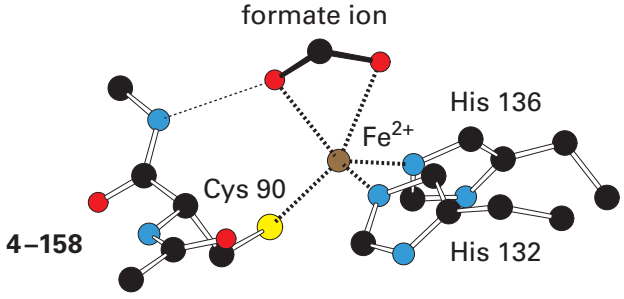
The high-spin state of octahedral Fe^{2+}, like the high-spin state of octahedral Mn^{2+}, does not have much ligand field stabilization. The fact that the two orbitals aligned with the ligands, $3d_{z^2}$ and $3d_{x^2-y^2}$, are each occupied by an electron precludes covalent bonding and makes the bonding of Fe^{2+} with its ligands predominantly ionic. The low-spin state of octahedral Fe^{2+} has maximum ligand field stabilization because the valence electrons are not aligned with the ligands and the lone pairs of the ligands are aligned with empty $3d_{z^2}$ and $3d_{x^2-y^2}$ orbitals. Because of this alignment, when Fe^{2+} is in the low-spin state, its interactions with its ligands have more of a covalent character.

When Fe^{2+} is used as a Lewis acid in an active site, one significant difference between its high-spin and low-spin states is ionic radius (Table 4–3). In the high-spin state of Fe^{2+}, its radius is larger by almost 0.02 nm, so its ligands are coordinated less tightly, as well as more ionically, and they are **more easily substituted**. In the low-spin state of Fe^{2+}, its ligands are coordinated more tightly, as well as more covalently, and they are **more inert to substitution**. These differences are consequential when substrates for the enzyme must become ligands to Fe^{2+} for the reaction catalyzed to proceed.

Iron dication is significantly softer than either Mn^{2+} or Mg^{2+}, so **its ligands are far more eclectic**. For example, in the crystallographic molecular model of peptide deformylase

N-formyl-L-methionyl peptide + H_2O $\rightleftharpoons$ formate + L-methionyl peptide (4–425)

from *E. coli*[121] in a complex with its substrate formate, the Fe^{2+} that acts as a Lewis acid in the reaction catalyzed by the enzyme[1149] is pentacoordinated by five ligands[1150]



4–158

the imidazolyl groups of Histidines 132 and 136, the sulfanyl group of Cysteine 90, and the two oxygens of formate.

In addition to the covalency of the interactions of its empty 3*d* orbitals with its ligands in the low-spin state, Fe^{2+} can also participate with soft ligands in coordinations that have even more covalency. In these more covalent bonds, the lone pairs of electrons from four ligands fill the four vacant sp^3 orbitals formed from the vacant 4*s* orbital and the three vacant 4*p* orbitals of the dication. Consequently, as is the case with Zn^{2+} in aspartate carbamoyltransferase (**4–152**), this **primarily covalent bonding** always occurs with **tetrahedral coordination**. For example, the four Fe^{2+} in a tetranuclear [4Fe–4S] iron–sulfur cluster (Figure 2–21),* which form covalent bonds with sulfides and sulfanyl groups, are tetrahedrally

*Note the difference in tetrahedrality between the iron ions and the sulfide anions in the distorted cube.

coordinated. In these tetrahedral complexes, ligand field stabilization is negligible.

In the active site of aconitate hydratase (Figure 3–52), one of the four irons in the [4Fe–4S] cluster is missing the usual ligand from the sulfanyl group of a cysteine and is held in the active site only by the three inorganic sulfides. The requirement of aconitate hydratase to be activated with Fe^{2+} to observe enzymatic activity results from the fact that this loosely held Fe^{2+} readily dissociates from the iron–sulfur cluster and must be replaced.[1151] The enzyme is inactive if the cluster has lost this fourth iron. The absence of the sulfanyl group as a ligand to this Fe^{2+} in the cluster, however, although it labilizes the Fe^{2+}, permits the coordination of this Fe^{2+} in the tetranuclear [4Fe–4S] iron–sulfur cluster to expand from tetracoordinate to hexacoordinate when substrates are bound. This hexacoordinate Fe^{2+} provides an example of how important steric effects are in the orientation of ligands coordinating a metallic dication. The three sulfur atoms of the sulfides are significantly larger than the three oxygen atoms in the shell of coordination. As a result, the usual octahedral array around this Fe^{2+} is significantly distorted. The three vertices at which the atoms of sulfur are located move farther apart, increasing the angles between them, and force the three oxygens to move closer together, decreasing the angles between them. When the substrate isocitrate is bound to the hexacoordinate Fe^{2+} in aconitate hydratase (Figure 3–52) and when the substrate citrate is bound to the same Fe^{2+}, each provides a hydroxy group and a carboxylato group as ligands while the third open site is occupied by the molecule of water. When either substrate is bound, the hexacoordinate Fe^{2+} is in the high-spin state.[1070] In this high-spin state, substrates can enter and leave the coordination sphere of Fe^{2+} rapidly enough for catalysis to proceed.

Cobalt dication, Co^{2+}, has ionic radii (Table 4–3) indistinguishable from those of Fe^{2+}, and it is also borderline in hardness. It is a d^7 transition metallic dication, and its seven valence electrons are distributed over five $3d$ orbitals (Figure 2–24). Like Fe^{2+}, Co^{2+} can exist in both low-spin and high-spin states, but unlike Fe^{2+}, in its low-spin state it still has one unpaired electron in one of its $3d$ orbitals (see Figure 2–25). It is as acidic as most of the transition metallic dications (Table 4–2) and exchanges ligands as rapidly as Fe^{2+} (Table 4–5). Metalloenzymes, however, seldom[1152] have Co^{2+} as their naturally occurring prosthetic metallic dication, perhaps because of its extremely low free concentration in cytoplasm (Table 4–4), but it can often substitute effectively in the laboratory for the naturally occurring prosthetic metallic dication in a particular enzyme.

Table 4–5: Rates of Exchange of Water Bound in an Inner-Sphere Complex of a Metallic Cation at 25 °C[1153,1154]

cation	rate constant[a] (μs^{-1})	cation	rate constant[a] (μs^{-1})
K^+	4000	Zn^{2+}	30
Mg^{2+}	0.6	Co^{2+}	1
Ca^{2+}	>10000	Cu^{2+}	5000
Mn^{2+}	20	Fe^{3+}	2×10^{-4}
Fe^{2+}	3	Co^{3+}	1×10^{-7}
Ni^{2+}	0.03	Cr^{3+}	7×10^{-13}

[a]For the reaction
$[Me(OH_2)_m]^{n+} + H_2O^* \rightarrow [Me(OH_2)_{m-1}(O^*H_2)]^{n+} + H_2O$

Nickel dication, Ni^{2+}, is a small transition metallic dication that is also borderline in hardness. Its ionic radius is similar to that of low-spin Fe^{2+} (Table 4–3). Nickel dication has eight electrons in its five $3d$ orbitals (Figure 2–24). In octahedral coordination, the $3d_{xy}$, $3d_{xz}$, and $3d_{yz}$ orbitals are doubly occupied, and the $3d_{z^2}$ and $3d_{x^2-y^2}$ orbitals are each occupied by an unpaired electron. The doubly occupied $3d_{xy}$, $3d_{xz}$, and $3d_{yz}$ orbitals do provide significant ligand field stabilization in favor of octahedral coordination, but the singly occupied $3d_{z^2}$ and $3d_{x^2-y^2}$ orbitals are destabilizing, causing ligand field stabilization in fully octahedral coordination to be weak.

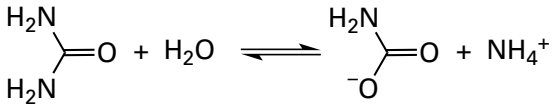
Both the fact that the orbitals oriented toward the ligands are singly occupied and the fact that it has more valence electrons make Ni^{2+} more reluctant to participate in fully occupied octahedral coordination because of electron repulsion. This reluctance and the lack of ligand field stabilization means that Ni^{2+} is **often coordinated by fewer than six ligands**. If one octahedral site is vacant, then **square pyramidal pentacoordination** results. If two octahedral sites are vacant, then **square planar tetracoordination** results. For example, when Ni^{2+} is in an enforced square planar coordination, as in coenzyme F_{430} (**4–61**), the two axial positions can be unoccupied (square planar tetracoordinate), one can be occupied (square pyramidal pentacoordinate), or both can

be occupied (octahedral hexacoordinate), depending on the strength of the ligands available.

In the Ni^{2+} state of the superoxide dismutases from *Streptomyces seoulensis*[1155] and *S. coelicolor*,[1156] the ligands coordinating Ni^{2+} are the sulfido groups of two cysteines and the unhydronated amido nitrogens of two peptide bonds. These ligands produce strong fields that would destabilize an octahedral coordination. In this instance, the four ligands are in a square planar array and both axial positions are unoccupied. In a square planar coordination, strong field ligands, such as dehydronated amido nitrogens of peptide bonds and sulfido groups, promote a **low-spin state** for Ni^{2+} in which the axial $3d_{z^2}$ orbital is doubly occupied and the $3d_{x^2-y^2}$ orbital, oriented toward the ligands, is vacant.[1157] The stability of this configuration is the reason that unconstrained, low-spin Ni^{2+} is nearly always square planar. In this low-spin state, axial ligands, if they are present, are only weakly associated.

Although a square planar coordination, such as those just described, that increases in covalency with softer ligands is common with Ni^{2+}, other dispositions of ligands are possible. For example, in the reduced nickel–iron hydrogenases, Ni^{2+} is coordinated with four sulfanyl groups from four cysteines in a distorted square planar array in which one of the four sulfurs is bent up away from the plane of the other three until it is almost normal to the plane.[1158,1159] This disposition of ligands is neither a tetrahedral nor a square planar arrangement. It must result from **steric effects** exerted by the active site.

There is a binuclear cluster of two Ni^{2+} in the active site of urease



(4–426)

In the crystallographic molecular model of the enzyme from *Sporosarcina pasteurii* in a complex wih phosphorodiamidate, an analogue of the tetrahedral intermediate in the reaction (Figure 4–54),[1160] each Ni^{2+} is coordinated by two imidazolyl groups from two histidines and one of the two oxygens from the carboxy group on N^6-carboxy-Lysine 219. One oxygen of phosphorodiamidate is a μ-oxo ligand between the two Ni^{2+}. The other oxygen is a ligand to one Ni^{2+}, and one nitrogen is a ligand to the other Ni^{2+}. One Ni^{2+} has these five ligands in a sterically distorted square pyramidal coordination; the other Ni^{2+} has an oxygen of the carboxy group of Aspartate 362 as a sixth ligand in a sterically distorted octahedral coordination.

Zinc dication, Zn^{2+}, is a small transition metallic cation that is borderline in hardness. Its ionic radius (Table 4–3) is indistinguishable from those of Mg^{2+}, Fe^{2+}, and Ni^{2+} and somewhat smaller than that of Mn^{2+}. It is a d^{10} metallic cation, so all five of its $3d$ orbitals are occupied by pairs of electrons, a configuration that fills the $3d$ shell. Because the $3d$ shell is fully occupied, there is only a low-spin state. It has already been noted that Zn^{2+} is able to form tetrahedral, mostly covalent complexes (**4–152**) by using the sp^3 hybrids of its vacant $4s$ and $4p$ orbitals.

Zinc dication is the **most versatile metallic cation functioning as a Lewis acid** in the active sites of metalloenzymes. Its versatility in this role arises from its stability to oxidation and reduction because its $3d$ orbitals are fully occupied; its ability to form tetracoordinate, pentacoordinate, and hexacoordinate complexes with Lewis bases; and its ability to be coordinated with lone pairs from oxygen, nitrogen, and sulfur. Often two or three of these rather different bases coordinate the Zn^{2+} in an active site. When Zn^{2+} is coordinated by four sulfurs (**4–152**), which are soft bases, the interaction is usually tetrahedral and almost entirely covalent. The complex between Zn^{2+} and the harder base ammonia, $[Zn(NH_3)_4]^{2+}$, is also tetracoordinate and tetrahedral. This tetrahedral coordination of Zn^{2+} is observed when Zn^{2+} forms complexes with 1,2-diaminoethane, cyclic lactams, and imidazole. As the ligands become harder, however, geometries become more variable as the bonding becomes less covalent and tetrahedral and more ionic and flexible. For example, the complex $[Zn(OH_2)_6]^{2+}$ between Zn^{2+} and water, a hard base, is hexacoordinate and octahedral for the same reasons that ligands around Mg^{2+}, a metallic dication of the same radius, are octahedral. As hydrons are removed, however, and the donor strength of the ligands increases, covalency becomes more favorable because of decreases in ligand field stabilization, and the coordination decreases to four ligands, as $[Zn(OH)_3(OH_2)]^-$.

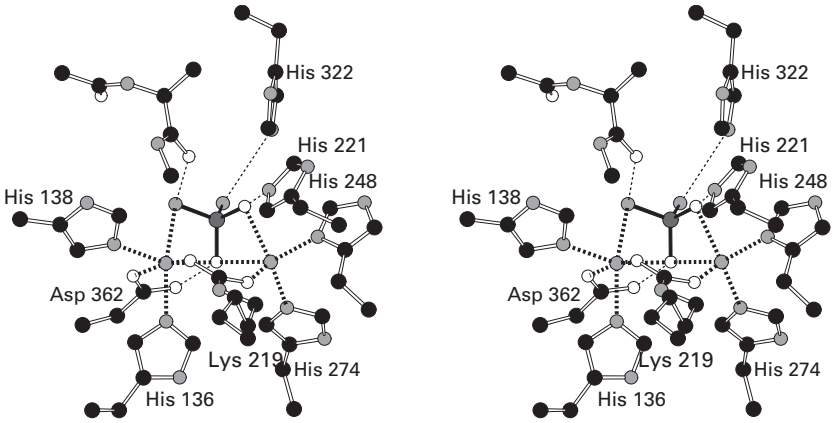


Figure 4–54: Stereodrawing[134] of the crystallographic molecular model of the active site of urease from *S. pasteurii* occupied by two Ni^{2+} and phosphorodiamidate (**4–76**), a analogue of the tetrahedral intermediate in the enzymatic reaction.[1160] Black atoms are carbons, white atoms are oxygens, small gray atoms are nitrogens, and the large dark gray atom is an atom of phosphorus. The small dark gray spheres are the nickel ions surrounded by their ligands. The enzyme was purified from cytoplasm of *S. pasteurii* and crystallized from 1 M $(NH_4)_2SO_4$, 4 mM phosphorodiamidate, 10 mM 2-ammonio-2-hydroxymethylpropane-1,3-diol, and 50 mM citrate at pH 7. Electron density for phosphoramidate and two Ni^{2+} could be observed in the active site. The molecular model of phosphorodiamidate is in the center of the figure. The hexacoordinate Ni^{2+} has as four of its monodentate ligands the imidazolyl groups of Histidines 136 and 138, an oxygen from the carboxylato group of Aspartate 362, and an amido nitrogen of phosphorodiamidate. The pentacoordinate Ni^{2+} has as three of its monodentate ligands the imidazolyl groups of Histidines 248 and 274 and an oxygen from the phosphorodiamidate. One oxygen of phosphorodiamidate is a μ-oxo ligand between the two Ni^{2+}, and each Ni^{2+} is coordinated by one of the two oxygens from the carboxy group on *N*-carboxy-Lysine 219. Histidine 322 forms a hydrogen bond with one of the nitrogens in the phosphorodiamidate, and the acyl oxygen of a peptide bond in the polypeptide forms a hydrogen bond with the other nitrogen.

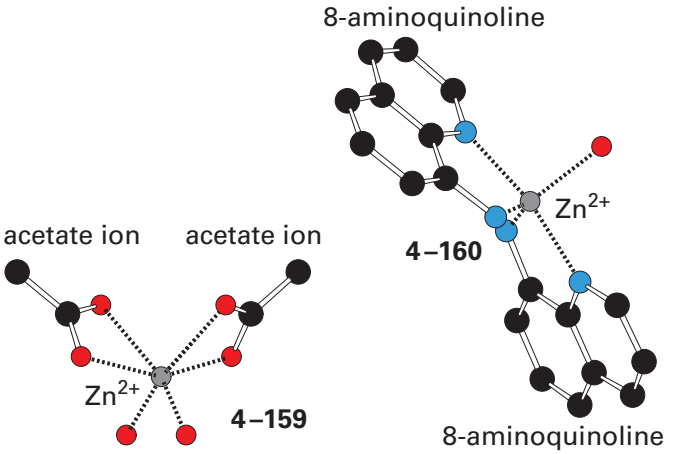
A distorted octahedral complex (**4–159**) forms with two acetates[1161,1162]



The zinc ion forms a trigonal bipyramidal pentacoordinate complex with, among other ligands, 8-aminoquinoline **4–160**.[1163] In this case, the four nitrogens from two aminoquinolines and a molecule of water are the five Lewis bases that generate the complex $[Zn(N_2C_9H_8)_2(OH_2)]^{2+}$.

The ability of Zn^{2+} to be coordinated effectively by lone pairs on nitrogen, oxygen, and sulfur is also exploited in the association of substrates. For example, the amido nitrogen in cyanamide becomes a ligand to the prosthetic Zn^{2+} in the active site of cyanamide hydratase from *S. cerevisiae* during its hydration;[1164] the acyl oxygen in a peptide bond becomes a ligand to the prosthetic Zn^{2+} in the active site of thermolysin (Figure 3–42) during its hydrolysis by a molecule of water, the oxygen of which is also a ligand to Zn^{2+}; and the sulfanyl group of a cysteine in a substrate becomes a ligand to the prosthetic Zn^{2+} in the active site of protein farnesyltransferase from *S. cerevisiae* during its farnesylation.[1165]

There is no typical arrangement for the ligands coordinating Zn^{2+} when it is bound in an active site (Figure 4–55).[1166-1173] Examples from its eclectic set of **mononuclear coordinations** in the active sites of enzymes are two imidazolyl groups, the oxygen from a monodentate carboxy group, and the oxygen of what was the molecule of water that added nucleophilically to the acyl oxygen of the peptide bond of the substrate in the active site of thermolysin (Figure 3–42); three sulfanyl groups and a molecule of water or the 4-oxo oxygen of uridine in cytidine deaminase (Figure 3–36); two sulfanyl groups, an imidazolyl group, and a molecule of water in GTP cyclohydrolase I from *E. coli*;[1174] three imidazolyl groups and an oxygen from the substrate bicarbonate in human carbonic anhydrase 1 (Figure 4–55A);[1169] three imidazolyl groups and the two oxygens of the *cis*-enediol intermediate in fructose-bisphosphate aldolase from *M. tuberculosis* (Figure 4–55B);[1171] the oxygen from a carboxy group, the acyl oxygen from the γ-carbamoyl group of a glutamine, an imidazolyl group, and the two oxygens from an analogue of the *cis*-enediol intermediate in human lactoylglutathione lyase (Figure 4–55C);[1167] and an imidazolyl group, the two oxygens of a bidentate carboxylato group, an oxygen from another carboxy group, a sulfanyl group, and the carbonyl oxygen from the substrate D-arabinose 5-phosphate in 3-deoxy-8-phosphooctulonate synthase from *A. aeolicus* (Figure 4–55D).[1168] Adjacent to the active site in isopentenyl-diphosphate Δ-isomerase from *E. coli*, there is a structural Zn^{2+} hexacoordinated by three imidazolyl groups, bidentately by the two oxygens of a carboxylato group, and monodentately by one oxygen of another carboxy group.[1175,1176] The tetracoordinate Zn^{2+} in aspartate carbamoyltransferase (**4–152**) is distant from the active site and performs only a structural role.

Many zinc metalloenzymes have **dinuclear clusters of Zn^{2+}, often bridged by a single atom** of one of the ligands. One example is the dinuclear cluster of two Zn^{2+} in the active site of aryldialkylphosphatase from *B. diminuta* (Figure 4–55E).[1166,1177] One pentacoordinated Zn^{2+} is coordinated by two imidazolyl groups and the oxygen of a carboxy group, and the other is coordinated by two imidazolyl groups and the phospho oxygen of diisopropyl methylphosphonate, an analogue of a substrate. In addition, a μ-hydroxide, located between the two Zn^{2+} and bridging them, provides one lone pair to each Zn^{2+}, and the carboxylato group of an N^6-carboxylysine provides one oxygen as a ligand to one Zn^{2+} and the other oxygen as a ligand to the other Zn^{2+}. In the active site of succinyl-diaminopimelate desuccinylase from *H. influenzae* (Figure 4–55F),[1170] each of the two pentacoordinated Zn^{2+} is coordinated by an imidazolyl group and bidentately by the two oxygens of a carboxylato group. In addition, a μ-hydroxide, located between the two Zn^{2+} and bridging them, provides one lone pair to each Zn^{2+}, and the carboxylato group of an aspartate provides one oxygen as a ligand to one Zn^{2+} and the other oxygen as a ligand to the other Zn^{2}.

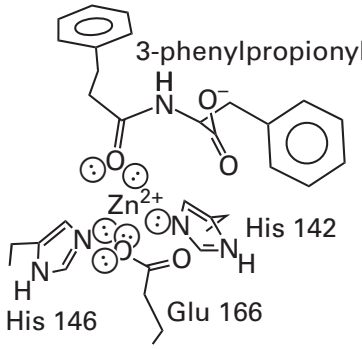
Figure 4–55: Ligands to zinc dications in drawings[134] of the crystallographic molecular models for the active sites of metalloenzymes. Black atoms are carbons, white atoms are oxygens, small darker gray atoms are nitrogens, large lighter gray atoms are sulfurs, and large dark gray atoms are atoms of phosphorus. The small dark gray spheres are zinc ions surrounded by their ligands. (**A**) The Zn^{2+} in the active site of human carbonic anhydrase 1, which is occupied with its substrate bicarbonate, has as its four tetrahedrally arrayed ligands the imidazolyl groups of Histidines 94, 96, and 119 and one of the oxyanions from bicarbonate.[1169] (**B**) The Zn^{2+} in the active site of fructose-bisphosphate aldolase from *M. tuberculosis*, which is occupied with what has been assigned as the *cis*-enediolate of its substrate glycerone phosphate, has as its five ligands the imidazolyl groups of Histidine 96, 212, and 252 and the two oxygens from the *cis*-enediolate.[1171] (**C**) The Zn^{2+} in the active site of human lactoylglutathione lyase, which is occupied with *S*-(*N*-hydroxy-*N*-4-iodophenylcarbamoyl)glutathione, an analogue of the *S*-(*cis*-enediolato) intermediate in the enzymatic reaction, has as its five ligands the oxygens of the amido group of Glutamine 33 and the carboxylato group of Glutamate 99 from one subunit of the enzyme, the imidazolyl group of Histidine 126 from the other subunit, and the two oxygens of the *N*-hydroxycarbamoyl group that are homologues of the two oxygens of the *S*-(*cis*-enediolato) intermediate. Only the side chain of the *S*-(*N*-hydroxycarbamoyl)cysteinyl portion of the analogue without the iodophenyl group is drawn.[1167] (**D**) The Zn^{2+} in the active site of 3-deoxy-8-phosphooctulonate synthase from *A. aeolicus*, which is occupied with the substrates phospho*enol*-pyruvate and D-arabinose 5-phosphate, has as its six ligands the sulfanyl group of Cysteine 11, the imidazolyl group of Histidine 185, the two oxygens of the carboxylato group of Glutamate 222, the carboxylato group of Aspartate 233, and the oxo oxygen of the D-arabinose 5-phosphate.[1168] (**E**) One of the two Zn^{2+} in the active site of aryldialkylphosphatase from *B. diminuta*, which is occupied with diisopropyl methylphosphonate (an analogue of a phosphotriester substrate) has as three of its ligands the imidazolyl groups of Histidines 201 and 230 and the phospho oxygen of the diisopropyl methylphosphonate. The other Zn^{2+} has as three of its ligands the oxyanion of the carboxylato group of Aspartate 301 and the imidazolyl groups of Histidines 55 and 57. A μ-hydroxide is located between the two Zn^{2+} and serves as a ligand to each ion. Each oxygen of the carboxylato group of *N*-carboxy-Lysine 169 provides a ligand[1166,1173] to one of the Zn^{2+}. (**F**) One of the two Zn^{2+} in the active site of succinyl-diaminopimelate desuccinylase from *H. influenzae* has as three of its ligands the two oxygens of the carboxylato group of Glutamate 163 and the imidazolyl group of Histidine 67. The other Zn^{2+} has as three of its ligands the two oxygens of the carboxylato group of Glutamate 135 and the imidazolyl group of Histidine 349. A μ-hydroxide is located between the two Zn^{2+} and serves as a ligand to each ion. Each oxygen of the carboxylato group of Aspartate 100 provides a ligand[1170] to one of the Zn^{2+}. (**G**) One of the two Zn^{2+} in the active site of bovine leucyl aminopeptidase, which is occupied by 1-amino-3-methylpropylphosphonate (an analogue of the tetrahedral intermediate) has as three of its ligands the 6-amino group of Lysine 282, the carboxylato group of Aspartate 305, and the amino group of 1-amino-3-methylpropylphosphonate. The other Zn^{2+} has as three of its ligands the carboxylato group of Aspartate 364, the amido oxygen of the peptide bond following Aspartate 364, and one of the phospho oxygens of 1-amino-3-methylpropylphosphonate. A carboxylato oxygen of Aspartate 287 and a phospho oxygen of 1-amino-3-methylpropylphosphonate are μ-oxo ligands located between the two Zn^{2+}, and each oxygen acts as a ligand to each Zn^{2+}. Each oxygen of the carboxylato group of Glutamate 366 provides a ligand[1172] to one of the Zn^{2+}.

In the active site of bovine leucyl aminopeptidase (Figure 4–55G),[1172] one of the hexacoordinated Zn^{2+} is coordinated by one oxygen from an aspartate and its peptidyl acyl oxygen as well as an oxygen from the phosphonyl group of 1-amino-3-methylpropylphosphonate, an analogue of the tetrahedral intermediate in the enzymatic hydrolysis; and the other hexacoordinated Zn^{2+} is coordinated by the 6-amino group of a lysine, the amino group of 1-amino-3-methylpropylphosphonate, and the oxygen of the carboxylato group of an aspartate. In addition, one carboxylato oxygen of an aspartate and one phospho oxygen of 1-amino-3-methylpropylphosphonate are located between the two Zn^{2+} and provide bridging ligands to both; and the carboxylato group of a glutamate provides one oxygen as a ligand to one Zn^{2+} and the other oxygen as a ligand to the other Zn^{2+}.

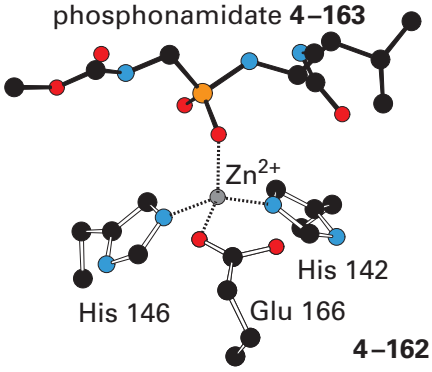
In the complete collection of these examples of Zn^{2+} in active sites (Figure 4–55), there are tetracoordinate, pentacoordinate, and hexacoordinate arrangements that are more or less sterically distorted from the paradigmatic tetrahedral, trigonal bipyramidal, tetragonal pyramidal, and octahedral geometries, respectively, and lone pairs of electrons on sp^3 and sp^2 oxygens, sp^3 and sp^2 nitrogens, and sp^3 sulfurs serve as ligands. One conclusion from this promiscuity is that the identities of **ligands to Zn^{2+} in active sites are in part arbitrary**. For example, the homologous (26% identity; 2.7 gap percent) murine cytidine deaminases from *Mus musculus* (Figure 3–36) and *E. coli*[1178] and the unrelated cytosine deaminase from *E. coli*[1179] all use a single Zn^{2+} as a Lewis acid to catalyze the same reaction. The Zn^{2+} is coordinated in the murine enzyme by three sulfanyl groups,[848] in the homologous enzyme from *E. coli* by two sulfanyl groups and an imidazolyl group, and in the nonhomologous enzyme from *E. coli* by three imidazolyl groups. Two of the three sulfanyl groups in the murine enzyme are acceptors for hydrogen bonds from the guanidinio group of an arginine, which may modulate their field strengths.[1180]

It also seems that **the number of ligands to Zn^{2+} is flexible**. For example, the ability of Zn^{2+} to alternate between tetracoordination and pentacoordination while bound as a Lewis acid in the active site of an enzyme has been demonstrated in studies of thermolysin (Figure 3–42). In the crystallographic molecular model of the unoccupied active site in the native enzyme, the Zn^{2+} is **pentacoordinate**. Histidines 142 and 146 each provide a lone pair of electrons, Glutamate 166 provides two lone pairs of electrons as a bidentate ligand, and the fifth position is occupied by a molecule of water.[1181,1182] There are several different complexes in which the active site of thermolysin is occupied by ligands. The first (**4–161**) is a complex with the competitive inhibitor 3-phenylpropionyl-L-phenylalanine



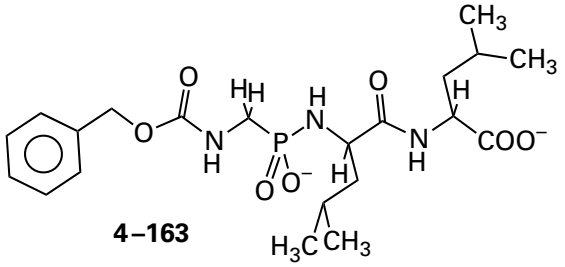
4–161

phosphonamidate **4–163**



4–162

in which the peptide bond is intact.[1183] Figure 3–42 and **4–162** depict a second complex between the active site of thermolysin and a phosphonamidate (previously **3–83**)

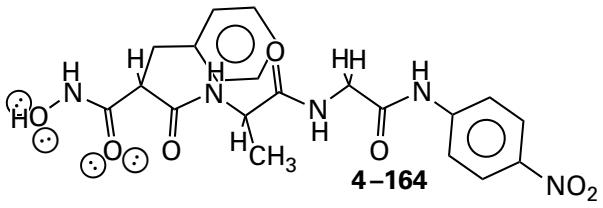


4–163

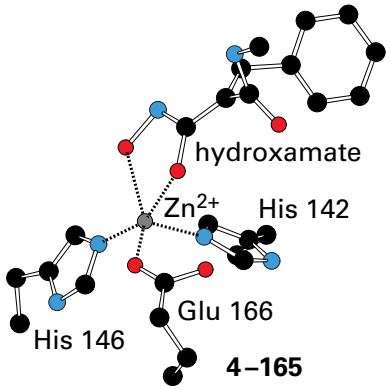
an analogue of the tetrahedral intermediate.[1184] There is a third complex of the active site of thermolysin with *N*-(1-carboxy-3-phenylpropyl)-L-leucyl-L-tryptophan, an analogue of the carboxy terminus of the amino-terminal product of hydrolysis of a peptide bond.[1185] In crystallographic molecular models of these three complexes, Glutamate 166 has become a monodentate ligand at only one of its oxygens. The molecule of water in the unliganded enzyme has been replaced by a monodentate ligand—the acyl oxygen of 3-phenylpropionyl-L-phenylalanine (**4–161**), the oxyanion of phosphonamidate **4–163** (**4–162**), or the carboxylato group of the carboxy terminus—and the Zn^{2+} has become **tetracoordinate**.

Each complex, representing in turn three major intermediates in the enzymatic reaction, has almost identical tetrahedral tetracoordination (**4–162**). Dissociation of the other oxygen of the carboxy group of Glutamate 166 from the Zn^{2+} is probably the result of a steric effect. Each bulky ligand—attached to the active site in multiple locations, as are the actual substrates and intermediates in the normal enzymatic reaction—draws the zinc toward itself into a location that can no longer accommodate bidentate coordination by the carboxy group of Glutamate 166.

Hydroxamate **4–164**



4–164

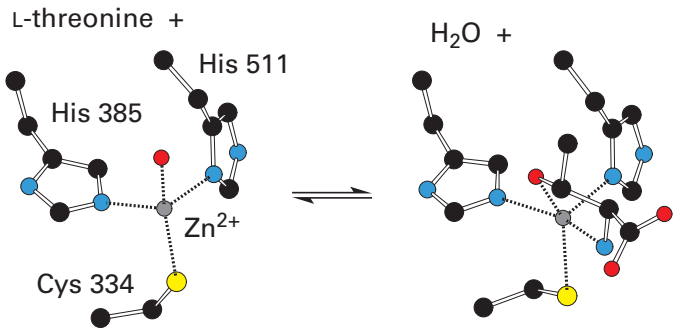


4–165

is also a competitive inhibitor for the enzyme. In the crystallographic molecular model of the complex with the active site,[1108] the hydroxamate provides two ligands to Zn^{2+}—a lone pair of electrons from the acyl oxygen and a lone pair of electrons on the

oxygen in the hydroxy group of the hydroxamate—to accomplish its pentacoordination (**4–165**). This complex probably represents the Michaelis complex between a polypeptide and the active site. The acyl oxygen of the peptide bond in the Michaelis complex is represented by the acyl oxygen of the hydroxamate. The molecule of water that was bound to the Zn^{2+} before association of the polypeptide, which will add nucleophilically to the acyl carbon of the peptide bond in the next step to form the tetrahedral intermediate, is represented by the hydroxy group of the hydroxamate. In this complex, Glutamate 166 is also a monodentate ligand and the pentacoordination is different from the pentacoordination in the unoccupied active site.

In the active site of threonine–tRNA ligase from *E. coli*, the Zn^{2+} that recognizes the L-threonine is tetracoordinate in the unoccupied state with a sulfanyl, two imidazolyl groups, and a molecule of water as ligands



(4–427)

When the L-threonine, however, occupies the active site, both its hydroxy group and its amino group are ligands to the Zn^{2+}, making it pentacoordinate in a distorted tetragonal pyramid.[1186]

Cadmium is in the same group, immediately below zinc in the periodic table, so **cadmium dication**, Cd^{2+}, is a larger and hence softer transition metallic cation than Zn^{2+}. Nevertheless, it is used instead of Zn^{2+} in carbonic anhydrase from *Thalassiosira weissflogii*, which can live in regions of the ocean with very low levels of Zn^{2+}. The Cd^{2+} is coordinated in the resting enzyme in this rare if not exclusive appearance by two sulfanyl groups, an imidazolyl group, and two molecules of water.[1187]

One might imagine that there would be little doubt as to which of the metallic dications just described are incorporated into a particular metalloenzyme to fulfill its particular role when the enzyme is in the cytoplasm, the solution in which it has evolved, but unfortunately, in many instances it is difficult, if not impossible, to ascertain this seemingly simple fact.

There are **enzymes that retain one or more metallic dications** as a part of their structure as they are being purified and also retain their full enzymatic activity throughout. For example, Zn^{2+}, which is the native metallic dication in the active site of *N*-acetylglucosamine-6-phosphate deacetylase from *E. coli*,[1188] is retained during purification. When fructose-bisphosphate aldolase is purified from *S. cerevisiae*, the enzyme is found to contain one tightly bound Zn^{2+} for each active site (Figure 4–55B).[1189] If the Zn^{2+} is removed from the enzyme, its enzymatic activity is lost.[1190] Purified thermolysin (Figure 3–42),[1191] cytidine deaminase (Figure 3–36),[1178] carbonic anhydrase (Figure 4–55A),[1192] lactoylglutathione lyase (Figure 4–55C),[1193] 3-deoxy-8-phosphooctulonate synthase (Figure 4–55D),[1194] aryldialkylphosphatase (Figure 4–55E),[1177] succinyl-diaminopimelate desuccinylase (Figure 4–55F),[1195] and leucyl aminopeptidase (Figure 4–55G)[1196] are other examples of metalloenzymes that retain their Zn^{2+} during purification to homogeneity. Urease (Figure 4–54)[1197,1198] retains its Ni^{2+}, and pyruvate carboxylase from *G. gallus*[1146] retains its Mn^{2+}. Because they seem to be permanent participants in the active site, these metallic dications that purify with the enzyme can be considered to be **prosthetic**.

The Zn^{2+} in the active site of native *N*-acetylglucosamine-6-phosphate deactylase can be removed and replaced with Cd^{2+}, Co^{2+}, Mn^{2+}, Fe^{2+}, or Ni^{2+}, each of which reactivates the enzyme[1199] to catalytic constants about the same as that for Zn^{2+}. Fructose-bisphosphate aldolase in which the native Zn^{2+} has been replaced by Ni^{2+}, Cu^{2+}, or Mg^{2+} is inactive (<0.5% activity).[1190] When, however, the Zn^{2+} is replaced[1189] by Co^{2+}, Fe^{2+}, or Mn^{2+}, the enzyme regains activity, but its catalytic constant has decreased by factors of 2, 2.7, and 7, respectively,[1190] relative to the enzyme in which Zn^{2+} has been reincorporated. Even though a limited number of replacements are permitted, there can be little doubt that the metallic dication normally incorporated into *N*-acetylglucosamine-6-phosphate deactylase and fructose-bisphosphate aldolase is Zn^{2+}, because that dication is still present following purification.

Several of the enzymes that retain their metallic dications during purification because they are so tightly bound in the active site require specific **chaperones that are essential for the incorporation of the metallic dications** during their folding and maturation.[1200] Metallochaperones are able to bind tightly metallic dications that are present at extremely

low free concentrations in the cytoplasm (Table 4–4), such as Ni^{2+}, Zn^{2+}, and Cu^{2+}, and deliver them to the folding metalloenzyme for insertion into their active sites.[1201] For example, a chaperone produced by expression of the *UreE* genes in bacteria is able to bind Ni^{2+} tightly and participate in its incorporation into urease,[1202,1203] the active site of which contains a dinuclear cluster of Ni^{2+}. The fact that such an elaborate system is required to incorporate the metallic dication in the first place suggests that once a metal is incorporated into an active site by a metallochaperone, it will remain incorporated throughout the lifetime of the enzyme.

There is one caveat concerning identification of the metallic cation that is bound so tightly that it copurifies with the enzyme. In the past, when an enzyme retained its cytoplasmic metallic cation, a definitive identification of that prosthetic metallic cation was usually made by standard qualitative and quantitative inorganic analysis. One difficulty with this approach is that significant amounts of protein are needed and are usually lost during the procedure. Methods that require less protein, such as mass spectrometry, X-ray absorption spectroscopy,[1204] X-ray fluorescence,[1205] and particle-induced X-ray emission,[1206] can be used to make identifications when the presence of a metallic cation is suspected. A difficulty arises when a metallic cation that is yet to be identified is observed in a crystallographic molecular model. There are procedures for identifying it provisionally by varying the wavelength of the X-rays used to determine the map of electron density through the absorption edges of the various metals.[1207] It has been noted, however, that when identification of the metallic cation in an active site is made based only on crystallography, that identification is often incorrect.[1206]

There are other **metalloenzymes that require a metallic dication to be added to the solution** after they have been purified as well as during their purification before they display any catalytic activity, but they are themselves, following purification, devoid of any metallic dication. In these situations, either the metallic dication present in the active site when the enzyme is in the cytoplasm is bound weakly and dissociates as the enzyme is purified, or the procedures for purifying the enzyme are so harsh that they promote dissociation of an otherwise tightly bound metallic dication. For **enzymes that lose their metallic dications** during purification, it is unlikely that metallochaperones are involved in incorporating the metal during the folding of their polypeptides because the metallic dications are probably dissociating and associating constantly. In this case, association with the active site is an equilibrium between bound metallic dication and metallic dication free in the cytoplasm. Because, in this instance, the metallic dications are not permanent or even semipermanent participants in the active site, although they are cofactors, they are obviously not prosthetic.

For enzymes in this class, when they are in the cytoplasm under normal circumstances, it is possible that the sites at which the required metallic dications are coordinated are occupied because the concentrations of those metallic dications in the cytoplasm are high enough to saturate those sites, and their association with the preferred metallic dication is specific enough to exclude significant association of other metallic dications. It is also possible, however, that many of these enzymes with loosely bound catalytic metallic dications are able to use more than one particular metallic dication for effective catalysis in the cytoplasm.

When phosphoglucomutase is purified from muscle of *O. cuniculus*, it contains no metallic dications, but its enzymatic activity displays an **absolute requirement** for one (activity in the absence of metallic dication is <0.001% that in the presence of Mg^{2+}).[1208] The requirement for a metallic dication can be fulfilled by Mg^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, or Zn^{2+}. Although the relative capacity of each metallic dication to reactivate the enzyme varies with temperature and pH,[1209] Mg^{2+}, Ni^{2+}, and Co^{2+} are almost equally effective at restoring a high catalytic constant, while the catalytic constants of the enzyme reconstituted with Mn^{2+} and Zn^{2+} are much less. Purified 3-dehydroquinate synthase from *Aspergillus nidulans* requires addition of a metallic dication before it will catalyze its enzymatic reaction, and the requirement can be fulfilled[1210] by Zn^{2+} and Co^{2+} and to a lesser extent by Fe^{2+} and Ni^{2+}. In addition, Eu^{3+} and Sm^{3+}, which are definitely nonphysiological metallic dications, work almost as well as Zn^{2+} and Co^{2+}. The requirement for a metallic dication displayed by *N*-formylmethionylaminoacyl-tRNA deformylase from *E. coli*[1211] can be fulfilled only by Mn^{2+} and Ni^{2+}.

Either **the catalytic constant or the specificity constant for a substrate can differ**, depending on the metallic dication that is chosen to occupy the active site and activate the enzymatic reaction. For example, when Co^{2+} is used as the prosthetic metal in the active site of 3-dehydroquinate synthase from *E. coli*,[1212] its catalytic constant is 14 s^{-1}, but when Zn^{2+} is used,[1152] it is 7 s^{-1}; with Ni^{2+}, it is 3.3 s^{-1}; with Cd^{2+}, it is 1.7 s^{-1}; with Mn^{2+}, it is 1.4 s^{-1};

and with Cu^{2+}, it is 1.3 s^{-1}. When Co^{2+} is the prosthetic metal in the active site of xylose isomerase from *Piromyces*,[1213] its specificity constant for xylose is 3300 M^{-1} s^{-1}; with Mn^{2+}, it is 1100 M^{-1} s^{-1}; with Mg^{2+}, it is 270 M^{-1} s^{-1}; and with Ca^{2+}, it is 0.2 M^{-1} s^{-1}. The apparent dissociation constant for the metallic dication can also vary widely. For xylose isomerase from *Piromyces*, the apparent dissociation constants for Mn^{2+}, Co^{2+}, Mg^{2+}, and Ca^{2+} are 1.4, 6.5, 100, and 160 μM, respectively.

In at least one instance, there seems to be a linear correlation between standard free energy of association with the active site for nine metallic dications that activate an enzyme and density of charge for the respective dication.[1214] In most instances, however, there seems to be **little rationale for which metallic dications are effective** at performing the role of a Lewis acid in the active site of an enzyme that loses its native metallic dication during purification. The distinction between dications that are effective and those that are not may arise from subtle differences in the arrangement of ligands that coordinate the metallic dication. For example, mammalian lactoylglutathione lyase (Figure 4–55C) retains its Zn^{2+} during purification.[1193] The homologous enzyme from *E. coli* (38% identity; 2.3 gap percent) loses its metallic dication during purification and can use Ni^{2+}, Co^{2+}, and Mn^{2+} as catalytic Lewis acids but not Zn^{2+}.[1215] The difference in the two enzymes is the identity and arrangement of the ligands coordinating the respective metallic dications.[1216]

When an enzyme loses its metallic dication during purification, the question that arises is **which metallic dication performs the role of a Lewis acid in the active site when the enzyme is in the cytoplasm**. Estimates of free concentrations* of the metallic dications in cytoplasm (Table 4–4)[1130] can provide limits on which metallic dication may be functioning physiologically.† For example, the Michaelis constants for Mg^{2+} and Mn^{2+} for the initial rate of the reaction catalyzed by phosphopyruvate hydratase from *S. cerevisiae* are 0.50 mM and 5 μM, respectively, while the catalytic constants of the enzyme are about the same for the two dications.[1217] Because the free concentration of Mg^{2+} in cytoplasm is about 10,000 times higher than the free concentration of Mn^{2+} (Table 4–4), only about 1% of the total activity of the enzyme in the cytoplasm should result from active sites using Mn^{2+}. Dimethylsulfoniopropionate lyase from *Pelagibacter ubique* requires a metallic dication for enzymatic activity, and that requirement can be filled by Ni^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Zn^{2}, and Cu^{2+}. Because Ni^{2+} gives the highest specific activity of all these metallic dications and is present in seawater at relatively high concentrations, it was concluded that Ni^{2+} is the metallic dication normally present in the active site.[1218] In the case of xylose isomerase from *Piromyces*, it was concluded that, in the cytoplasm, each active site of the enzyme was occupied by one of several different metallic dications.[1213]

There is a group of enzymes that can **use as their required Lewis acid either Mg^{2+} or Mn^{2+}**, two hard metallic dications of small, almost equivalent ionic radius (Table 4–3) and acidity (Table 4–2) but significantly different rates of exchange (Table 4–5). Phosphopyruvate hydratase (Equation 4–128) from *S. cerevisiae*,[1217] pyruvate kinase from *O. cuniculus*,[1219-1221] and mandelate racemase (Equation 4–126) from *P. putida*[1222] are typical members of this group. For xylose isomerase from *Streptomyces violaceoruber*, the Michaelis constant for Mg^{2+}, K_{mMg}, is the same[1223] as that for Mn^{2+}, but the catalytic constant when the enzyme is using Mg^{2+} as its Lewis acid is 5 times greater than when it is using Mn^{2+}. For xylose isomerase from *L. brevis* (23% identity; 2.2 gap percent), however, only Mn^{2+}, not Mg^{2+}, is catalytically effective.[1224]

When Mg^{2+} is able to fulfill the role of a Lewis acid in the active site of a metalloenzyme that has lost its native metallic dication, Mg^{2+} usually performs that role in the cytoplasm as well. For example, in the cytoplasm, Mg^{2+} is probably the metallic dication responsible for all the activity of phosphoglucomutase.[1209] 3-Deoxy-8-phosphooctulonate synthase from *A. aeolicus* requires a metallic dication for its catalysis, and the requirement can be fulfilled by Cd^{2+}, Mn^{2+}, Co^{2+}, or Ni^{2+} and to a lesser extent Cu^{2+}, Zn^{2+}, and Mg^{2+}.[1225] Even though much higher concentrations of Mg^{2+} are required to activate the enzyme than most of the other dications, the concentration of Mg^{2+} in cytoplasm is also much

*These estimates of free concentrations are imprecise because metallic dications are usually bound tightly to proteins, nucleic acids, and carbohydrates in the cytoplasm. Consequently, the free concentration of any one of these dications, the concentration that is relevant to an equilibrium constant for association with an active site, is only a small fraction of its total concentration, which is usually the only precisely known value. The imprecision in these estimates of free concentration for metallic dications other than Mg^{2+} is thought to be plus or minus a factor of 10.[1130]

†Cadmium dication, Cd^{2+}, and the dications and trications of the other soft metals are almost always toxic, and there usually are physiological mechanisms for keeping their free concentrations in cytoplasm at vanishingly low levels.

higher. Consequently, in the cytoplasm, active sites using Mg^{2+} as the Lewis acid are probably responsible for most of the enzymatic activity, with the remainder coming from active sites using Mn^{2+}. Glutamine synthetase from *E. coli* is controlled[1226] by the adenylation of Tyrosine 397. Unadenylated enzyme can use only Mg^{2+} as a Lewis acid[1227] (K_{mMg} = 17 mM)[1228] while adenylated enzyme can use only Mn^{2+} (K_{mMn} = 1.7 mM), and the catalytic constant for unadenylated enzyme using Mg^{2+} is 4 times that for adenylated enzyme using Mn^{2+}. From values for Michaelis constants, catalytic constants, and free concentrations of Mg^{2+} and Mn^{2+} (Table 4–4), it can be concluded that, in the cytoplasm, even though the activity of the adenylated enzyme at saturating concentrations of Mn^{2+} is significant, the adenylated enzyme is essentially inactive relative to the unadenylated enzyme. Phospho*enol*-pyruvate carboxykinase (ATP), however, has been shown to require both Mg^{2+} and Mn^{2+} for effective catalysis:[1229-1231] the Mg^{2+} enters the active site as $MgATP^{2-}$ while the Mn^{2+} acts as a Lewis acid to catalyze the reaction.[1232]

When Mg^{2+} cannot perform the role of a Lewis acid in a metalloenzyme that can use one of several other metallic dications, the metallic dication performing that role in the cytoplasm is harder to identify. Because the free concentration of Ni^{2+} in cytoplasm is vanishingly small (Table 4–4), *N*-formylmethionylaminoacyl-tRNA deformylase[1211] must use Mn^{2+}. *S*-Ribosyl homocysteine lyase can use Fe^{2+}, Zn^{2+}, and Co^{2+} as a required Lewis acid in its active site but must use Fe^{2+} in the cytoplasm because only Fe^{2+} produces enzymatic activity with the same stability to temperature and oxidation and the same K_m for its substrate *S*-(5-deoxy-D-ribos-5-yl)-L-homocysteine as the enzymatic activity in a homogenate of cells.[1233] In addition, Fe^{2+} is at a higher free concentration in cytoplasm than Co^{2+} and Zn^{2+}. Methionyl aminopeptidase from *E. coli* can use Mn^{2+}, Fe^{2+}, Zn^{2+}, and Co^{2+} as a required Lewis acid,[1234,1235] but only the enzyme operating with Fe^{2+} has the same pattern of inhibition for a set of six synthetic inhibitors as the enzyme in a homogenate of cells.[1236] In addition, the total cellular concentration of iron increases about 5 times more than those of the other metals when the enzyme is overexpressed in bacteria.[1235] This latter fact can be explained if the free concentration of Fe^{2+} in the cytoplasm remains constant, as expected, and the excess in the total concentration of Fe^{2+} is that bound to the enzyme. Phosphoprotein phosphatase from bacteriophage λ can use Mn^{2+}, Fe^{2+}, Zn^{2+}, and Co^{2+} as well as nonphysiological Ga^{3+} as a Lewis acid in its active site,[1237,1238] but the total concentration of manganese in cells of *E. coli* overexpressing the enzyme increases 4 times more than those of the other metals.[1239]

When the question of which metallic dication performs the role of Lewis acid in the cytoplasm remains unanswered, metallic dications that eventually turn out **not to be the ones used physiologically** are often used experimentally. For example, *S*-ribosylhomocysteine lyase from *B. subtilis* was crystallized with Co^{2+} coordinated in its active site[1240] to obtain the initial crystallographic molecular model, rather than the Fe^{2+} that was eventually shown to be the cytoplasmic metallic dication. Before it was known that Fe^{2+} was the native Lewis acid, methionyl aminopeptidase from *E. coli* was crystallized with Co^{2+} coordinated in its active site[1241,1242] rather than Fe^{2+}, the cytoplasmic metallic dication, to obtain the initial crystallographic molecular model. Experiments to screen pharmacological inhibitors of methionyl aminopeptidase also used the enzyme with Co^{2+} in its active site, but potent inhibitors of the enzymatic activity elicited by Co^{2+} unfortunately had little effect on the cellular enzymatic activity.[1236]

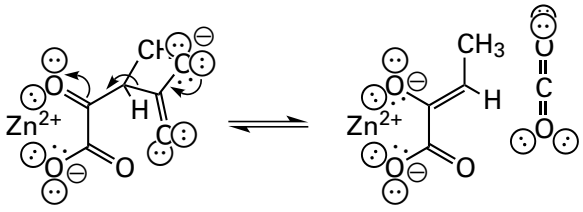
Although it does lead to uncertainty as to which metallic dication is used by an enzyme in its native cytoplasm, the chemical lesson to be learned from the promiscuity displayed by many purified metalloenzymes, regardless of which dication plays that role in the cytoplasm, is that **it often does not really matter what metallic dication is used as a Lewis acid**. This fact, which is a common observation, seems counterintuitive, given the significant differences in electronic configuration and effects of ligand field among the divalent metallic dications. As has been noted, even metalloenzymes that retain their metallic dication during purification can be promiscuous. Often the tightly bound, physiological metallic dication can be removed and replaced with other metallic dications that can also promote catalytic activity.[1243-1246] One conclusion from this frequent promiscuity of metalloenzymes is that the number of 3*d* electrons and their distribution in the five 3*d* orbitals is of little consequence for effective catalysis in metalloenzymes. All that seems to be of consequence is that the metallic cation be dicationic and be able to occupy the available coordination.

Now that the chemical characteristics of the individual metallic dications and the difficulty of determining the cytoplasmic actor in many instances have been discussed, the roles of the metallic dicat-

ions incorporated into an active site or into the protein surrounding the active site can be described.

There are metallic dications in enzymes that do not perform catalytic roles but that are nevertheless required for their functions. The Mg^{2+} in alcohol dehydrogenase ($NADP^+$) from *L. brevis*, the Ca^{2+} in trypsin from *Streptomyces griseus* (Figure 4–53), and the Zn^{2+} in aspartate carbamoyltransferase (**4–152**) are examples of metallic dications incorporated into enzymes in an **exclusively structural role.** In these instances the metallic dication, by drawing together several ligands from the polypeptide, determines the structure of the protein in its vicinity. Such a structural role should be distinguished from a catalytic role in which the metallic dication is a direct participant in catalysis performed by the active site. In the absence of an informative crystallographic molecular model, it is often difficult to distinguish whether the requirement for a metallic dication for the expression of enzymatic activity results from its participation in a structural role or a catalytic role.

In those instances in which **a metallic cation has a catalytic function**, the catalysis is classified as outer-sphere or inner-sphere. **Outer-sphere catalysis** at a catalytic metallic cation occurs when ligands coordinated to the metallic cation are the catalysts rather than the metallic cation itself. An example of outer-sphere catalysis would be a molecule of water, the pK_a of which has been lowered by the metallic cation (Table 4–2), acting as a catalytic Brønsted acid–base. **Inner-sphere catalysis** at a catalytic metallic cation occurs when one or more reactants become inner-sphere ligands to a catalytic metallic cation and, during their coordination, participate in the reaction. For example, it has been shown[1247] that metallic dications such as Zn^{2+} or Cu^{2+} can increase the rate constants for decarboxylation of β-oxo carboxylic acids by factors of at least 100 if the β-oxo carboxylic acid is designed to promote formation of a complex with the dication and if the complex coordinates the metallic dication directly to the oxygen of the developing enolate



(4–428)

In these examples of inner-sphere catalysis, Zn^{2+} or Cu^{2+} serves the role of a weak hydron by forming a more weakly acidified (Table 4–2) analogue of an enol.

A **molecule of water bound to a metallic dication often acts as an outer-sphere, catalytic Brønsted acid** in an active site to hydronate a substrate, or its conjugate base, a hydroxide bound to the metallic dication, acts as a catalytic Brønsted base that removes a hydron from a substrate. For example, in the active site of 4-hydroxy-2-oxoheptanedioate aldolase from *E. coli*, a molecule of water on the prosthetic metallic dication acts as a catalytic acid that hydronates the carbonyl oxygen of the succinate semialdehyde that is the electrophile in the aldol condensation catalyzed by the enzyme. In addition, a hydroxide on the metallic dication acts as a base that removes a hydron from the 4-hydroxy group in 4-hydroxy-2-oxoheptanedioate in a retroaldol dissociation.[1248] In such a situation, all the ligands to the metallic dication remain as they were, and no exchange of ligands at the metallic dication is required for the reaction to proceed.

Molecules of water on metallic dications have **a variety of values of pK_a** (Table 4–2), a fact that would seem to make them attractive candidates for outer-sphere Brønsted acid–bases in enzymatic active sites. For example, the molecule of water on the Mn^{2+} in the active site of pyruvate carboxylase (**4–157**) is a catalytic Brønsted acid. The anionic 2-oxido oxygen of the enolate of pyruvate that is the intermediate in this reaction is in the outer sphere of the octahedrally coordinated Mn^{2+}, and it participates in a hydrogen bond with the molecule of water that is in the inner sphere.[1148] The pK_a for this molecule of water—were it on $Mn^{2+}(H_2O)_6$ rather than Mn^{2+} coordinated by two imidazolyl groups, a carboxy group, a bidentate carboxylato group, and the molecule of water itself—would be 10.6 (Table 4–2), close to the pK_a for the enol of pyruvate, which is 11.6 (Figure 1–23). Consequently, it is impossible to tell whether or not the molecule of water hydronates the enolate. Were the enolate to remain unhydronated, the carbanionic carbon would more readily add nucleophilically to the electrophilic carbon dioxide or the electrophilic 1-(*N*-carboxy)biotin (Equation 4–262); were the enolate hydronated during its formation, it would be easier for the catalytic base in the active site to remove the hydron from the pyruvate.

In the active site of 3-deoxy-*manno*-octulosonate cytidyltransferase from *E. coli*, $Mg^{2+}{\cdot}OH^-$ acts as a Brønsted base to remove a hydron from the anomeric

2-hydroxy group on the pyranose of 3-deoxy-D-*manno*-octulosonate. The resulting oxyanion then adds nucleophilically to the phosphorus of the α-phospho group of $MgCTP^{2-}$, with magnesium diphosphate as the leaving group, during the formation of CMP-3-deoxy-D-*manno*-octulosonate.[1249] In the active site of isopentenyl-diphosphate Δ-isomerase from *E. coli*, a hexacoordinated Zn^{2+} has one oxygen of the carboxy group of Glutamate 116 as its sixth ligand. The pK_a for the conjugate acid of the other oxygen of the carboxy group of Glutamate 116, which acts as a Brønsted acid in the reaction catalyzed by the enzyme, must be lowered significantly by the Zn^{2+}.[1176]

Such outer-sphere acid–bases, however, regardless of their appeal in the abstract, are seldom used in enzymatic active sites, perhaps because they are more complicated than the simple side chain of an amino acid.

In most cases, **the role of a catalytic metallic dication in an active site is to be a Lewis acid**. If the dication is to act as a Lewis acid, it must directly coordinate a lone pair of electrons on a substrate or an intermediate in the enzymatic reaction. Consequently, when the metallic dication is acting as a Lewis acid, the catalysis it provides must be **inner-sphere**. In nonenzymatic reactions in solution in which a metallic dication participates as a Lewis acid, the base on the reactant that is acidified is almost always bound in direct coordination to the metallic dication.

When a metallic dication acts as an inner-sphere Lewis acid in an enzymatic reaction, the first step is the **exchange of its ligands**. If the metallic dication is to be an inner-sphere, catalytic Lewis acid, the ligand or ligands from the reactant must exchange with the ligand or ligands at the catalytic position or positions that are already on the cation. In addition, the ligand or ligands on the next reactant, or other ligands in solution, must exchange at the dication with the ligand or ligands from the product in order to release product and maintain turnover of molecules of reactant. Therefore, an important feature of the ability of a metallic dication to act directly as a Lewis acid in an enzymatic reaction is the rate at which the ligands surrounding that dication can be exchanged (Table 4–5).*

Rates of exchange for Ca^{2+}, Mn^{2+}, Zn^{2+}, and Co^{2+} are rapid (>1 μs^{-1}) and could be accommodated easily during an enzymatic reaction. The rate of exchange for Mg^{2+}, however, is slow and, given that Mg^{2+} is often used as an inner-sphere Lewis acid, this fact suggests that catalysis of the exchange of ligands or the use of coordinations that promote exchange might be required. The rate of exchange for Fe^{2+} is reasonably fast, but the rate of exchange for Ni^{2+} is slow. In the particular environment of an active site, in which the equilibrium between the low-spin and high-spin state for metallic cations such as Fe^{2+}, Ni^{2+}, and Fe^{3+} shifts in response to the particular coordination that exists, rates of exchange could be hastened by coordination that favors the **high-spin state**. The same could be true for the few active sites that use Fe^{3+} as a Lewis acid because exchange rates for this metallic trication are extremely slow.

The exchange of ligands coordinating a metallic cation can be associative or dissociative. **Associative exchange** is a mechanism in which the entering ligand associates with the metallic cation, expanding its coordination, and then the leaving ligand dissociates. Associative exchange is thought to occur at the Zn^{2+} in thermolysin (Figure 3–42) when the inhibitor 3-phenylpropionyl-L-phenylalanine (**4–161**) binds.[1108] In the resting active site, the Zn^{2+} is pentacoordinate with a molecule of water as one of its ligands. The acyl oxygen of the inhibitor associates with the Zn^{2+}, pushing the molecule of water to one side and causing one oxygen of the carboxy group of Glutamate 166 to dissociate from the Zn^{2+}. This dissociation produces a pentacoordinate arrangement of ligands (**4–165**) from which the molecule of water then dissociates so that the Zn^{2+} becomes tetracoordinate (**4–162**). **Dissociative exchange** is a mechanism in which the leaving ligand dissociates from the metallic cation, contracting its coordination, and then the entering ligand occupies the open site of coordination. Ligands exchange at Mg^{2+} dissociatively because there is no room around the crowded octahedrally hexacoordinated cation for a seventh ligand to occupy.

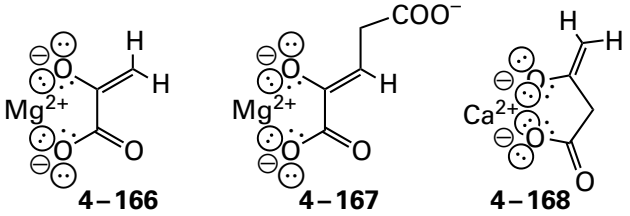
When $MgATP^{2-}$ and pyruvate enter the active site of pyruvate kinase, one oxygen of the phospho group, the oxygen of the carbonyl group, and one oxygen of the carboxy group enter the inner sphere of the catalytic Mg^{2+}, which is not the Mg^{2+} that entered on the $MgATP^{2-}$ (Equation 4–275 and Figure 4–52). Therefore, as the two substrates associate with the enzyme, these three oxygens must exchange dissociatively with three molecules of water from

*The rates of exchange tabulated are for the exchange of molecules of water from hydrated metallic cations in water. Table 4–5 is only a rough measure of actual rates of exchange in the more complicated coordinations within an active site and with ligands other than water.

the coordination shell of the already bound Mg^{2+}. This ligand exchange must not be a very rapid process (Table 4–5), and this **displacement of the molecules of water may become rate-limiting** under certain circumstances. There is an apparent pK_a of 9.2 above which both the catalytic constant and the specificity constants for pyruvate and $MgATP^{2-}$ in the steady-state kinetics of pyruvate kinase decrease. This pK_a has been assigned to dissociation of a hydron from a molecule of water bound to Mg^{2+} in the free enzyme.[1250,1251] It has been proposed that when this hydron is lost to produce a hydroxide at the magnesium, the exchange required for the oxygens on the substrates to enter the inner sphere of the bound magnesium, which is already slow, becomes too slow to support catalysis.

When a metallic dication acts as a Lewis acid in the active site of an enzyme, it **performs many of the same roles as a hydron**. Unlike a hydron, however, it is not transferred to an oxygen or a nitrogen, and it usually does not leave the active site on that oxygen or nitrogen as the metallic analogue of a hydroxy group or an amine, respectively. A metallic dication is also a weaker acid than is a hydron (Table 4–2), but this weakness is an advantage in circumstances in which a weaker acid is an improvement: for example, in a situation where a strong catalytic acid would be unhydronated. In a sense, the set of metallic dications provides natural selection with a range of surrogate hydrons of unique acidities (Table 4–2) from which to make, in some situations, a choice appropriate to the reaction being catalyzed.

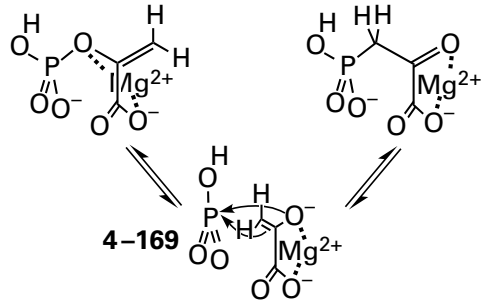
One role of a metallic dication is to **stabilize the oxyanion of an enolate**. The choice between whether to hydronate or provide an oxyanion hole for an enolate can be avoided by using a metallic dication rather than a hydron. For example, the Mg^{2+} that is coordinated by the two oxygens of oxalate in the active site of pyruvate kinase (Figure 4–52) has the homologous two oxygens of pyruvate as ligands when pyruvate occupies the active site.[1252] This Mg^{2+} must be the Lewis acid stabilizing the oxyanion of the enolate of pyruvate (**4–166**)



4–166 **4–167** **4–168**

that leaves from the phospho group of phospho*enol*pyruvate during the nucleophilic substitution at phosphorus that transfers the phospho group from phospho*enol*pyruvate to $MgADP^-$. By providing Mg^{2+}, the active site makes hydronation of the carbon of the enolate in the next step easier than if the enolate had been hydronated on its anionic oxygen. In 4-hydroxy-2-oxoheptanedioate aldolase, the enolate of the pyruvate that is a reactant in the aldol condensation catalyzed by the enzyme forms a similar complex (**4–166**) with a Mg^{2+} coordinated in the active site,[1135] but the carbanionic carbon 3 of the enolate of pyruvate in this case adds to the electrophilic carbonyl carbon of succinate semialdehyde, rather than to an electrophilic hydron as in pyruvate kinase. In the active site of isocitrate dehydrogenase ($NADP^+$) from *E. coli* (Equation 4–329), a similar complex is formed between Mg^{2+} and the enolate of 2-oxoglutarate (**4–167**) following the decarboxylation of oxalosuccinate.[1253] In a crystallographic molecular model of the active site of murine fumarylacetoacetase (**4–156**), the oxyanion of the enolate of acetoacetate is a ligand to a Ca^{2+} (**4–168**) acting as a Lewis acid to stabilize the enolate and retain its carbanionic carbon so that it can add nucleophilically to the carboxy group of fumarate in the Claisen condensation catalyzed by the enzyme (Equation 4–362).[860] In these four examples, the enolate stabilized by the metallic dication in the active site is a bidentate ligand, so two exchanges are required to form the respective complexes from reactants.

In the active site of phospho*enol*pyruvate mutase



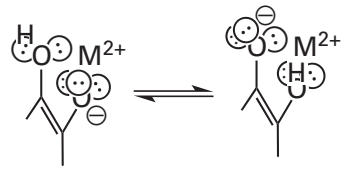
(4–429)

from *Mytilus edulis*,[1254] the enolate of pyruvate that is the intermediate is a bidentate ligand to a coordinated Mg^{2+} (**4–166**). The electrophilic phosphorus atom in the monomeric metaphosphate (**4–169**) that dissociates from phospho*enol*pyruvate to form the enolate is to the left in the orientation of the drawings in Equation 4–429 and above the plane of drawing **4–166**. The plane of the enolate is in the plane of the page in the orientation of drawing **4–166** and perpendicular to the page in the orientation of the drawing of Equation 4–429. The monomeric metaphosphate is perpendicular to the page

in the drawing of Equation 4–429, and its electrophilic phosphorus is approximately equidistant from carbanionic carbon and the anionic 2-oxido group, the two nucleophilic centers in the resulting coordinated enolate. When the carbanionic carbon adds to the monomeric metaphosphate, 3-phosphonopyruvate is formed; when the oxyanion of the enolate adds, phospho*enol*pyruvate is formed. In the former instance, the 2-oxo oxygen of 3-phosphonopyruvate ends up to the right side of the product as drawn in Equation 4–429; in the latter, the same oxygen, now in the phosphoester, ends up to the left side of phospho*enol*pyruvate as drawn in Equation 4–429.

In the complex with the enolate, the 2-oxido oxygen ends up below the plane of the page as drawn in Equation 4–429 as a ligand to the Mg^{2+}, which is also below the plane of the page, and the 2-oxido oxygen is as close as possible to the anionic oxygen of the 1-carboxylato group in the enolate, as in drawing **4–166**. During addition of either carbanionic carbon 3 or the 2-oxido oxygen to the monomeric metaphosphate, the 2-oxido oxygen is forced to move away from the anionic oxygen of the carboxylato group, and the Mg^{2+} attached to it, into the plane of the page in Equation 4–429 because the phosphorus atom is in the plane of the page. These respective pivots to the left and to the right distort the tight octahedral arrangement of ligands around Mg^{2+} (dashed lines in Equation 4–429).[1254] Consequently, the complex with either substrate is strained at Mg^{2+}, and the strain is relieved in the complex with the enolate. This relief decreases the difference in standard free energy between the coordinated substrates and the coordinated enolate intermediate.

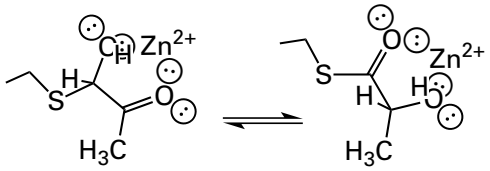
***cis*-Enediolates are stabilized** by bidentate ligation to metallic dications. These common intermediates can be separated into two groups. In the first group, an electrophile is removed from one of the two carbons to form the *cis*-enediolate, and an electrophile is added to the other carbon of the *cis*-enediolate to produce an oxo group in the product on a carbon adjacent to the oxo group in the reactant. In the second group, one electrophile is exchanged for another at the same carbon with the *cis*-enediolate as an intermediate, and the oxo group is on the same carbon in reactant and product. In the first group, a hydron must be removed from one oxygen and a hydron added to the other oxygen to form the tautomer of the *cis*-enediolate



(4–430)

where M^{2+} is a metallic ion. In the second group, no hydron is removed from or added to either oxygen.

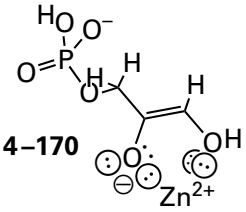
The *cis*-enediolate that is coordinated to Zn^{2+} in the active site of human lactoylglutathione lyase (Figure 4–55C) is an example of the first group of *cis*-enediolates. It is an intermediate in an isomerization



(4–431)

analogous to that catalyzed by triose-phosphate isomerase (Equations 4–46 and 4–55 and Figure 3–37), and lactoylglutathione lyase also uses glutamate to transfer the hydron between the two carbons.[1167] In this isomerization, the 2-oxo group becomes a hydroxy group and the 1-hydroxy group becomes an oxo group—and the other way around in reverse—so a hydron is added to the one oxygen and a hydron is removed from the other. Because Zn^{2+} is stabilizing the *cis*-enediolate, each hydron transfer at oxygen need not be concerted with the one at carbon. In fact, unlike the situation in the active site of triose-phosphate isomerase, in the active site of lactoylglutathione lyase, there are no obvious catalytic acid–bases forming hydrogen bonds to the two oxygens that could hydronate or dehydronate them. Lactoylglutathione lyase from *E. coli*, although clearly related to the human enzyme (34% identity; 1.4 gap percent), uses Ni^{2+} as its Lewis acid[1215] rather than Zn^{2+}.

The *cis*-enediolate that is coordinated to Zn^{2+}

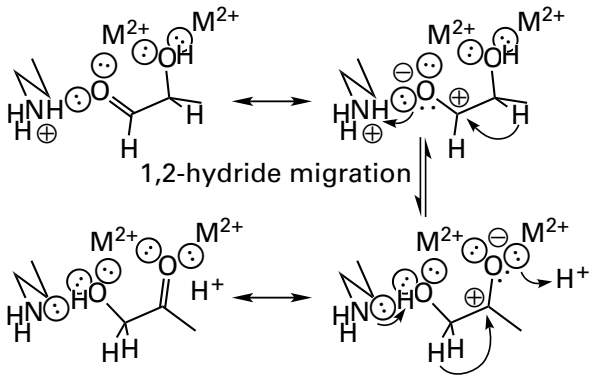


in the active site of fructose-bisphosphate aldolase (Equation 4–210) from *M. tuberculosis* (Figure 4–55B) is an example of the second group of *cis*-enediolates. The *cis*-enediolate of glycerone phosphate is formed

by removal of a hydron from carbon 3, and the carbanionic carbon 3 of the *cis*-enediolate adds nucleophilically to the carbonyl of D-glyceraldehyde 3-phosphate in the aldol condensation catalyzed by the enzyme. In this instance, the 3-hydroxy group provides a second ligand to Zn^{2+} but remains a hydroxy group throughout the reaction. No hydron must be removed from or added to either oxygen because a hydron on carbon 3 of glycerone phosphate is replaced by the carbon of a carbonyl and the oxygen in the carbonyl group of glycerone phosphate ends up as the oxygen in the carbonyl group of D-fructose bisphosphate. In rhamnulose-1-phosphate aldolase from *E. coli*, a Zn^{2+} in the active site also stabilizes the *cis*-enediolate of glycerone phosphate in a similar bidentate complex.[1255]

In the triose-phosphate isomerases, an intermediate *cis*-enediolate is formed by removal of a hydron from either carbon 1 of glycerone phosphate or carbon 2 of D-glyceraldehyde 3-phosphate by the carboxylato group of a glutamate (Figure 3–37) or its respective homologue. In xylose isomerase and L-rhamnose isomerase, however, both of which also interconvert an aldose and a ketose with the analogous stereochemistry (Equation 4–253), there is no glutamate or any other base in the appropriate location. Instead, the hydrogen that is transferred back and forth during the isomerization is, in both the aldose and the ketose, sitting up against the π cloud on one face of the indolyl group of a tryptophan and enclosed by the phenyl groups of two phenylalanines.[1256-1259] In crystallographic molecular models of the active sites of xylose isomerases[892,1120,1256,1260,1261] and rhamnose isomerase[1258,1262] from various species in complexes with substrates or intermediate analogues and catalytic[1224] or noncatalytic metallic dications, the two oxygens that are interconverted between an oxo group and a hydroxy group during the isomerizations catalyzed by these enzymes are ligands to one or both of two catalytic metallic dications, and the oxygen on carbon 1 forms a hydrogen bond with the ammonio group of a lysine. Consequently, the isomerizations must proceed by acid catalysis by these two Lewis acids and this Brønsted acid, since there is no base available.

The role of these acids at the two oxygens is to polarize in turn the carbonyl groups on substrates to promote a 1,2-hydride migration[1261]

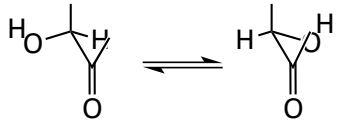


(4–432)

In solution, only about half of the nonenzymatic isomerization between aldose and ketose in strong acid,[1263] in strong base,[1264,1265] or under catalysis by Zn^{2+} at pH 6[1265] proceeds by removal of a hydron from one carbon and addition of a hydron to the other as it does in triose-phosphate isomerase (Equations 4–46 and 4–55 and Figure 3–37). The other half of the isomerizations in solution proceed by 1,2-hydride migration. The 1,2-hydride migration is analogous to the 1,2-hydride migrations and 1,2-alkyl migrations that occur in carbenium ions that are intermediate in terpene cyclizations (Figure 3–50), and the polarization of the respective carbonyl group by the acids makes its carbon resemble a carbenium ion (Equation 4–432).

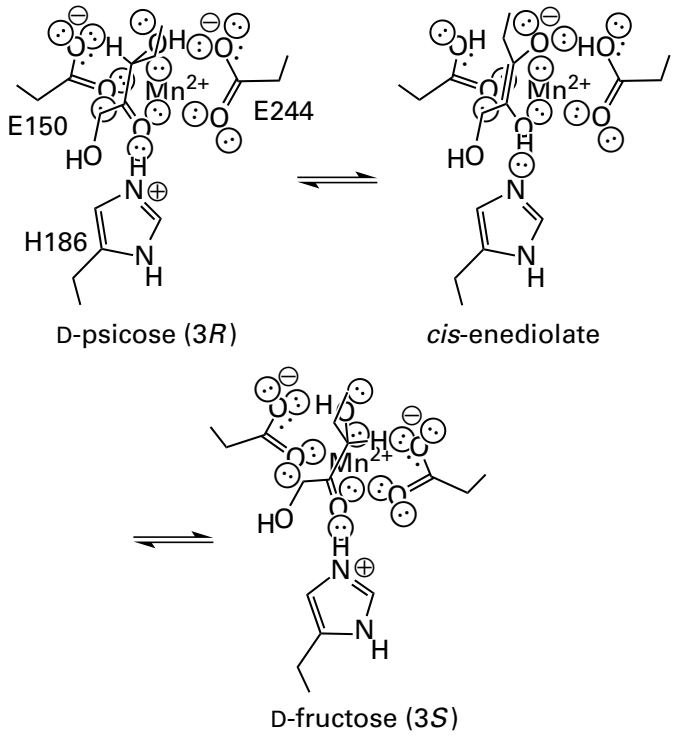
These isomerizations also require dehydronation of one oxygen and hydronation of the other. The oxygen on carbon 2 in a substrate for one of these two enzymes is dehydronated or hydronated by a fixed molecule of water that, in most cases, forms a hydrogen bond to it. Depending on the crystallographic molecular model, however, the molecule of water either is a ligand to the central metallic dication[1120,1256,1261] or forms a hydrogen bond with the 1-oxygen[1258] to relay the hydron directly. Again, the transfers of the hydrons are not necessarily concerted with the 1,2-hydride migration because the metallic dications coordinate the oxygens.

Certain **epimerases have *cis*-enediolate intermediates that are stabilized** by metallic dications. These epimerases remove either an *R* or *S* hydrogen as a hydron from an acidic carbon adjacent to a carbonyl, and then they add another hydron to the same carbon with the opposite stereochemistry[1266-1269]



(4–433)

For example, D-psicose 3-epimerase from *A. tumefaciens* equilibrates D-psicose and D-fructose, which are epimers at carbon 3 that is adjacent to the carbonyl group at carbon 2 in the two substrates. The *cis*-enediolate intermediate in this epimerization is a bidentate ligand to the prosthetic Mn^{2+}.[1270] Two carboxylato groups, from Glutamates 244 and 150, are monodentate ligands to Mn^{2+}. Their other, unliganded oxygens are on opposite sides of the *cis*-enediolate, and these unliganded oxygens are the catalytic bases that remove the hydrons from carbon 3 in the respective ketoses and add the hydrons to one of the two faces of carbon 3 in the *cis*-enediolate



(4–434)

to accomplish the respective epimerization. When Glutamate 240 in the active site of 3-dehydro-D-guloside 4-epimerase from *E. coli*, which is homologous to Glutamate 244, was mutated to glutamine, the enzyme, although unable to perform the epimerization, was still able to exchange a deuterium from ^2H_2O at carbon 4 of the substrate α-methyl 3-dehydro-D-glucoside, presumably because Glutamate 146, the glutamate homologous to Glutamate 150, was unmutated and still able to remove the 4*S*-hydrogen on carbon 4 and replace it with a deuterium. When Glutamate 146 was mutated to glutamine, however, the enzyme was again unable to catalyze the epimerization but also was unable to exchange this hydrogen for a deuterium,[1271] presumably because the carboxy oxygen of the unmutated Glutamate 244 is located on the opposite side of carbon 4 in α-methyl 3-dehydro-D-glucoside from the 4*S*-hydrogen.

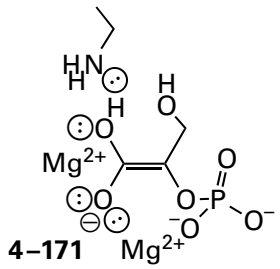
In the intermediate *cis*-enediolate resulting from either dehydronation in the active site of D-psicose 3-epimerase, a hydron has been added to the oxygen on carbon 2 that was the carbonyl oxygen by the imidazolium of Histidine 186. Hydronation at the oxygen of the *cis*-enediolate on carbon 2 during removal of the hydron from carbon 3 by the unliganded oxygen of one of the carboxylato groups produces a neutral *cis*-enediol. A hydron is then removed from the 3-hydroxy group of the *cis*-enediol by the unliganded, unhydronated oxygen of the other carboxylato group to form the *cis*-enediolate with a 2-hydroxy group and a 3-oxido group. The resulting hydronated oxygen on this second carboxy group provides the hydron that is then added to carbon 3 of the *cis*-enediolate. The hydron that was originally removed by the other carboxy group from carbon 3 to form the *cis*-enediolate is added to the 3-oxido oxygen of the *cis*-enediolate, either before or while the hydron is being added to carbon 3 on the opposite face of the *cis*-enediolate, to complete the epimerization.[1268,1270]

In the crystallographic molecular model of the complex between D-psicose 3-epimerase from *Ruminiclostridium cellulolyticum* (61% identity; 0 gap percent) and D-psicose, the unliganded oxygen of the carboxy group of Glutamate 150 is 0.28 nm from carbon 3, well within van der Waals contact, and 0.27 nm from the oxygen of the 3-hydroxy group of D-psicose, the length of a hydrogen bond. In the complex of the enzyme with D-fructose, the oxygen of the carboxy group of Glutamate 244 is 0.29 nm from carbon 3 and 0.31 nm from the oxygen of the 3-hydroxy group of D-fructose.[1272] The carboxy group of Glutamate 150 hydronates carbon 3 of the *cis*-enediolate to form D-psicose, and the carboxy group of Glutamate 244 hydronates carbon 3 of the *cis*-enediolate to form D-fructose, so these distances are consistent with, and seem to compel, the conclusion that each glutamate transfers a hydron between oxygen and carbon. D-Tagatose 3-epimerase from *Pseudomonas cichorii* (39% identity; 0.4 gap percent) has the same disposition of Mn^{2+} and the carboxy groups of Glutamates 152 and 246 in the crystallographic molecular models of complexes with D-fructose and D-tagatose, respectively.[1268]

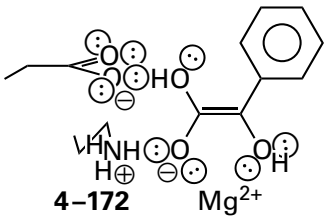
Each of the two carboxy groups in these epimerases is an example of a carboxy group that dedicates one of its oxygens to act as a ligand to a metallic

dication but uses its other oxygen for Brønsted acid–base catalysis. The metallic dication affects the pK_a for each carboxy group but also pins down one oxygen in each carboxy group so that the other oxygen on the respective **carboxy group can pivot back and forth** between carbon 3 and the oxygen on carbon 3 of the *cis*-enediolate.

***Gem*-enediolates can be stabilized** by metallic dications. For example, the *gem*-enediolate that is the intermediate[1273] in the dehydration catalyzed by phosphopyruvate hydratase (Equation 4–128) from *S. cerevisiae* is produced by removal of the hydron from carbon 2 of 2-phospho-D-glycerate by Lysine 345 (Figure 4–43) and is stabilized by two Mg^{2+} and a hydrogen bond with the amino group of Lysine 396 (**4–171**)[544]



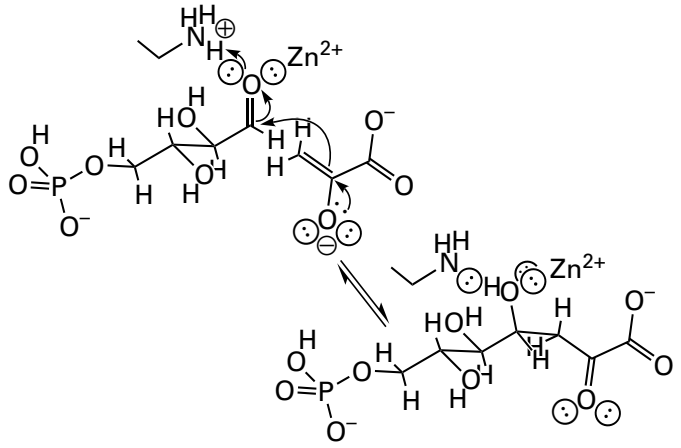
4–171



4–172

The *gem*-enediolate that is an intermediate in the racemization catalyzed by the related enzyme, mandelate racemase (Equation 4–126) is stabilized by only one Mg^{2+} but also by a hydrogen bond with the ammonio group of a lysine after being hydronated by a carboxy group (**4–172**).[212] In each instance, the substrates, before removal of the hydron from carbon to produce the *gem*-enediolate, are bidentate ligands to each Mg^{2+}. The *gem*-enediolate formed during the elimination of dimethyl sulfide from 3-dimethylsulfoniopropionate in the active site of dimethylpropiothetin dethiomethylase from *P. ubique* is a also a bidentate ligand at its two carboxy oxygens to the prosthetic Ni^{2+} in the active site.[1218] In pectate lyase 10 from *Cellvibrio japonicus*, however, which catalyzes an elimination analogous to that catalyzed by chondroitin AC lyase (Equation 4–358 and Figure 4–44), the *gem*-enediolate intermediate is a monodentate ligand to a Ca^{2+} through only one of its two carboxylato oxyanions; the other oxyanion is an acceptor for a hydrogen bond from the amido oxygen of the polypeptide, and both carboxylato oxygens form a canonical pair of hydrogen bonds with the *ω*-nitrogens of the guanidinio group of an arginine.[1050] The *gem*-enediolate that is an intermediate in the elimination catalyzed by guluronate-specific alginate lyase from *P. chathamensis* is also a monodentate ligand to a prosthetic Ca^{2+} in the active site.[974]

Metallic dications are also used to **polarize a carbonyl** (Figure 4–55D) to which an enolate[692,975,1168,1274] or a hydride[1275,1276] is to be added, to make the carbonyl more electrophilic. For example, the Mg^{2+} in malate synthase, in addition to the guanidinio group of Arginine 338 (**4–155**), polarizes the carbonyl of oxalate to which the enolate of acetyl-SCoA is added (Equation 4–272). In the active site of 3-deoxy-7-phosphoheptulonate synthase from *S. cerevisiae*, which catalyzes addition of the enolate of pyruvate to D-erythrose 4-phosphate



(4–435)

the carbonyl oxygen of D-erythrose 4-phosphate is a ligand to a metallic dication, which is probably Zn^{2+} in the native enzyme,[1277-1279] and the metallic dication polarizes the carbonyl, increasing its electrophilicity.[1274] In the active site of equine alcohol dehydrogenase (Equation 4–158), a Zn^{2+}, which is coordinated by two sulfanyl groups and an imidazolyl group, polarizes the carbonyl in a substrate, increasing its electrophilicity for the hydride transferred from NADH.[1275,1276] In the active site of the unrelated alcohol dehydrogenase from *Zymomonas mobilis*, the same function is performed by an Fe^{2+} that is tetracoordinated by three imidazolyl groups from three histidines and the oxygen of the carboxy group of an aspartate and that becomes pentacoordinated in the complex with substrates.[1280]

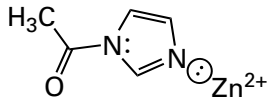
Unlike enolates in which an oxyanion stabilized by a metallic dication begins the reaction and ends the reaction as a carbonyl oxygen, in most instances in which a metallic dication **polarizes a carbonyl for nucleophilic addition**, the oxygen of the carbonyl becomes a hydroxy group, and there is usually a catalytic Brønsted acid in a hydrogen bond to the carbonyl oxygen to provide the necessary hydron.

In 3-deoxy-7-phosphoheptulonate synthase (Equation 4–435) from *S. cerevisiae*, it is the ammonio group of a lysine;[1274] in isocitrate lyase (Equation 4–310) from *M. tuberculosis*, it is the 4-hydroxyphenyl group of a tyrosine;[692] and in equine alcohol dehydrogenase, the hydroxy group of a serine relays a hydron ultimately from the imidazolium of a histidine.[1276]

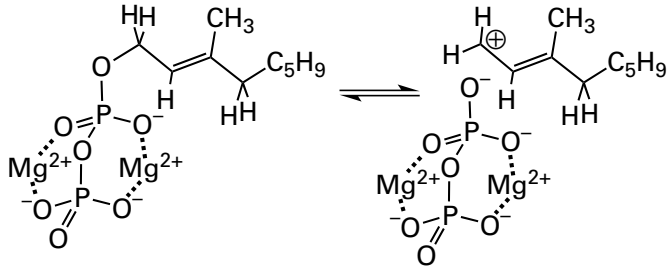
In the **reverse of each of these reactions**, by microscopic reversibility, the substrate with a hydroxy group is the reactant, and the oxygen of the hydroxy group is a ligand to the metallic dication. The Lewis acid lowers the pK_a for the hydroxy group (Table 4–2) so that the hydron can be removed more readily by the now-catalytic Brønsted base to **produce an oxyanion that pushes out the leaving nucleophile**, the enolate or the hydride, far more effectively than a lone pair of electrons on a hydroxy group. For example, pH–rate profiles of enzymatic activity indicate that there is a catalytic acid in the binary complex between NAD^+ and equine alcohol dehydrogenase with an apparent pK_a of 7.6; this acid has been assigned[1281] to the molecule of water bound to the prosthetic Zn^{2+} in the active site. Presumably, after the molecule of water has been replaced by the hydroxy group of the reactant to form the ternary Michaelis complex, the pK_a for that hydroxy group in the alcohol is also shifted into the same range by the Zn^{2+} to which it is a ligand. Upon dissociation of the hydron from this hydroxy group, the resulting oxyanion provides push to the hydride being transferred. There is a synthetic model compound containing a Zn^{2+} that is able to lower the pK_a for a secondary alcohol and accelerate its oxidation to the corresponding ketone by stabilizing the alkoxide so that it can push out the hydride.[1282] In solution, in another nonenzymatic reaction, metallic dications catalyze the decomposition of hemiaminals to aldehydes (reverse of reaction in Figure 1–7) by coordinating to their hydroxy groups, promoting dissociation of a hydron, and increasing the push that pushes out the amine.[1283]

In most cases, a carbonyl participating in an enzymatic reaction is hydronated during a nucleophilic addition to improve the electrophilicity of its carbon rather than becoming a ligand to a metallic dication. An even more common hydronation performed by an active site is one that improves the ability of a leaving group. Consequently, it is not surprising that a metallic dication can act as a Lewis acid to **improve the ability of one of its ligands to act as a leaving group**. For example, Zn^{2+} accelerates the nonenzymatic hydrolysis of *N*-acetylimidazole by coordinating with its peripheral nitrogen

4–173



to make the imidazolyl group a better leaving group.[1284] Although Mg^{2+} is a much weaker Lewis acid than the hydron (Table 4–2), the effect of its **complexation of a phospho group** is similar to the enhancement of the ability of a phosphate to act as a leaving group that would result from hydronation.[1285] For example, at high concentration (0.1 M), Mg^{2+} enhances the nonenzymatic solvolysis of geranyl diphosphate, which proceeds through dissociation of the diphospho group that produces the allyl carbenium ion



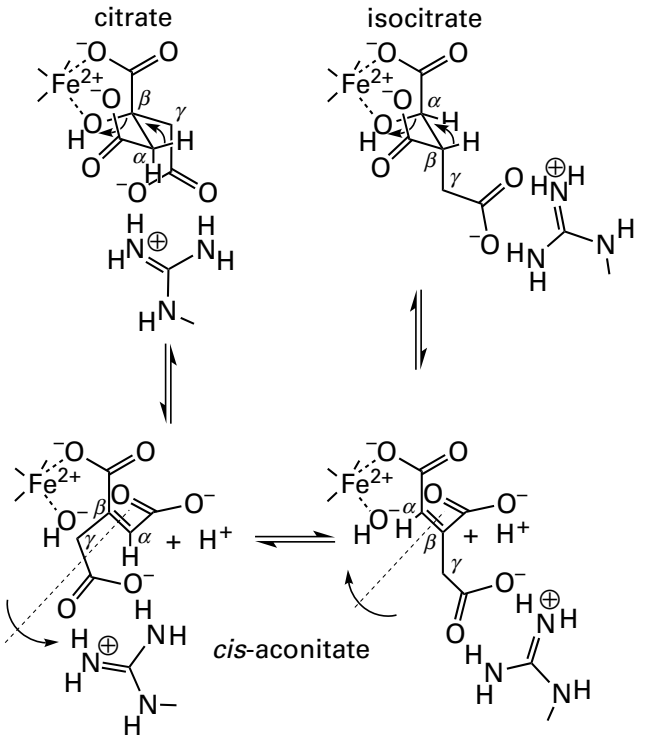
(4–436)

From a consideration of dissociation constants for the complexes between geranyl diphosphate and Mg^{2+}, it could be concluded that the form of geranyl diphosphate showing enhanced reactivity had two Mg^{2+} bound as Lewis acids to the departing diphosphate.

Such catalysis at the leaving group is observed in enzymatic reactions as well. In the nucleophilic substitution catalyzed by xanthine phosphoribosyltransferase from *E. coli*, a Mg^{2+} coordinating the leaving oxygen (**4–127**) improves its ability to leave;[870] in DNA β-glucosyltransferase from T4 bacteriophage, a Mg^{2+} coordinating the leaving oxygen of UDP^{3-} improves its ability to leave;[1286] and in methionine adenosyltransferase from *E. coli*, two Mg^{2+} coordinating the triphosphate of ATP^{4-} improve the ability of triphosphate to leave.[1287]

A hydroxy or alkoxy group on a substrate can become a ligand to a metallic dication, and the metallic dication **enhances the ability of the hydroxy or alkoxy group to leave** without the usual requirement for its oxygen to be hydronated by a Brønsted acid. For example, in the crystallographic molecular model (Figure 3–52)[1054] of the enzymatically active

complex between isocitrate and porcine aconitate hydratase (previously Equation 3–423)



(4–437)

the 2-hydroxy group, which is to leave in the elimination producing *cis*-aconitate, occupies one of the three open coordination sites on the hexacoordinate Fe^{2+} that is situated at the labile site in the tetranuclear [4Fe–4S] iron–sulfur cluster.[789] In the crystallographic molecular model[789] of the complex between citrate and an inactive mutant of bovine aconitate hydratase (98% identity; 0 gap percent), in which Serine 642 has been changed to alanine, the 3-hydroxy group, which is to leave in the elimination also producing *cis*-aconitate, occupies the same open coordination site on the hexacoordinate Fe^{2+}.

Iron dication acts as a Lewis acid in the reactions catalyzed by aconitate hydratase,[1288] maleate hydratase,[1289] fumarate hydratase A,[1290-1292] dihydroxy-acid dehydratase,[1293,1294] and L-serine ammonia-lyase.[1295] These five enzymes catalyze the hydration of 3-carboxymethyl-(*Z*)-butenedioic acid (*cis*-aconitate), (*Z*)-butenedioic acid (maleate), (*E*)-butenedioic acid (fumarate), 2-hydroxy-3-methylbutenoic acid (the enol of 3-methyl-2-oxobutanoate), and 2-amino-propenoic acid (the enamine of pyruvate), respectively. Each enzyme has a tetranuclear [4Fe–4S] iron–sulfur cluster in its active site. Each hydration proceeds by a mechanism that differs from the others only in the identity of the functional groups on the two ends of the carbon–carbon double bond.

The active site of aconitate hydratase (Figure 3–52) is a paradigm of the active site in each hydratase. Because, however, each carbon in the double bond of *cis*-aconitate is adjacent to a carboxy group that can become a *gem*-enediolate, the active site of aconitate hydratase (Equation 4–437) unlike the other enzymes in the family, adds the hydroxy group to *cis*-aconitate at one or the other of the carbons in the double bond, rather than at the only carbon adjacent to a carboxy group, and therefore produces two products, citrate and isocitrate.

During the elimination that converts isocitrate to *cis*-aconitate, a hydron is removed from carbon 3 of isocitrate to form the *gem*-enediolate at the 3-carboxy group; and during the elimination that converts citrate to *cis*-aconitate, a hydron is removed from carbon 2 of citrate to form the *gem*-enediolate at the 1-carboxy group. In each instance, the hydroxy group of the substrate that is a ligand to Fe^{2+} then leaves the *gem*-enediolate to complete the elimination of water from citrate or isocitrate, respectively, that in each case produces *cis*-aconitate. The hydroxide leaves as ferrous hydroxide, $Fe^{2+}{\cdot}OH^-$, instead of the usual situation in which it would leave as water, HOH, after being hydronated by a catalytic acid. The resulting hydroxide on Fe^{2+} participates in the respective reverse directions during the hydrations of *cis*-aconitate producing isocitrate and citrate, respectively (Equation 4–437). The Fe^{2+} lowers the pK_a for the conjugate acid of the hydroxide (Table 4–2) to around 10 so that it can remain unhydronated after it leaves and so that it can add nucleophilically to *cis*-aconitate to produce the *gem*-enediolate during the conversion of citrate to isocitrate and during the conversion of isocitrate to citrate. In order for this lowering of the pK_a for the hydroxy group to occur, the other molecule of water that is also a ligand to the iron (Figure 3–52) cannot also be a hydroxide. In fact, if it were, it could not fulfill its role in the dehydration, which is to relay the acidity of Aspartate 165 or Histidine 167 to hydronate the carboxy group that becomes the *gem*-enediolate in one of the two eliminations catalyzed by the enzyme.

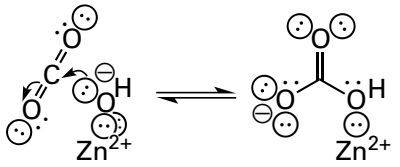
4-Hydroxy-3-methylbut-2-en-1-yl diphosphate reductase from *E. coli*, like aconitate hydratase, has a tetranuclear [4Fe–4S] iron–sulfur cluster in which one iron ion is missing the sulfanyl group of a cysteine that would normally be its ligand. This tetranuclear [4Fe–4S] iron–sulfur cluster is also prone to losing its unliganded Fe^{2+}. In a crystallographic molecular model of the native enzyme with its active site occupied by the substrate (*E*)-4-hydroxy-3-methylbut-

2-en-1-yl diphosphate,[1296] which presumably represents the Michaelis complex, the 4-hydroxy group of (*E*)-4-hydroxy-3-methylbut-2-en-1-yl diphosphate is a ligand to this Fe^{2+} in the intact [4Fe–4S] iron–sulfur cluster. If the reaction then parallels that of aconitate hydratase, the 4-hydroxy group would become the hydroxide in $Fe^{2+}OH^-$, leaving behind an allyl carbenium ion, a logical intermediate in the reaction. In this case, however, unlike in aconitate hydratase, two electrons would then be transferred, one at a time, from two reduced ferredoxins, through the the prosthetic [4Fe–4S] iron–sulfur cluster, to the allyl carbenium ion to produce an intermediate allyl radical and then isopentenyl diphosphate or dimethylallyl diphosphate, the products produced in a 5:1 ratio by the enzyme. An alternative, but more complicated, mechanism has been proposed on the basis of crystallographic molecular models of the substrate (*E*)-4-hydroxy-3-methyl-but-2-en-1-yl diphosphate occupying in turn the active sites of three site-directed mutants, rather than the native enzyme, each the mutant of one of the three side chains that form a composite acid responsible for hydronating the 4-hydroxy group as it is leaving. In these molecular models, the 4-hydroxy group has swung away from the Fe^{2+} and forms hydrogen bonds with the peripheral phospho group of diphosphate and Glutamate 126. In this alternative mechanism, Glutamate 126 hydronates the 4-hydroxy group to catalyze its departure, and the [4Fe–4S] iron–sulfur cluster acts simply as a relay of the two electrons required for the reduction catalyzed by the enzyme.[1297]

The dehydrations and hydrations catalyzed by aconitate hydratase during the conversions of citrate to isocitrate and isocitrate to citrate (Equation 4–437) are particularly apt illustrations of the fact that when a metallic dication improves the ability of a hydroxy group to leave so that it leaves as the metallic hydroxide, the metallic hydroxide is the nucleophile in the reverse of such a dissociation. A metallic dication decreases the pK_a for a molecule of water that is coordinated to it (Table 4–2) and facilitates removal of one of its hydrons by a Brønsted base or simply by dissociation of the hydron into the solution. Dissociation of the hydron from a molecule of water that is a ligand to the metallic dication produces a metallic hydroxide. There are many enzymes in which such metallic hydroxides are used in hydrations and hydrolyses.

Carbonic anhydrase (Equation 4–83) is a metalloenzyme that uses Zn^{2+} in its active site to catalyze the **hydration of carbon dioxide** to produce bicarbonate. In the crystallographic molecular model of the active site of human carbonic anhydrase 1 occupied by bicarbonate (Figure 4–55A), the Zn^{2+} is fixed in position by three imidazolyl groups positioned by the active site in orientations that together promote tetrahedral coordination. A fourth position, one unoccupied sp^3 orbital formed from the 4*s* and 4*p* atomic orbitals of the metallic dication, is occupied by one oxyanion of the bicarbonate. In the unoccupied active site of human carbonic anhydrase 1, the fourth coordinate position is occupied by a molecule of water.[1298] In the active site of the closely related human carbonic anhydrase 2 (60% identity; 0.0 gap percent), the pK_a for this molecule of water[1299-1301] is 6.8, and $Zn^{2+}\cdot OH^-$ rather than $Zn^{2+}\cdot OH_2$ is the catalytically active species.

Because one oxyanion of bicarbonate is a ligand in the inner sphere to the Zn^{2+} in carbonic anhydrase (Figure 4–55A), during the hydration, by microscopic reversibility, the hydroxide anion on Zn^{2+} must add nucleophilically to CO_2 to produce $HOCO_2^-$



(4–438)

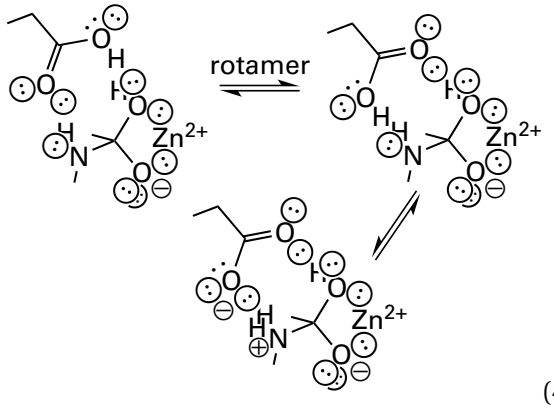
The CO_2 occupies a hydrophobic pocket in the active site of human carbonic anhydrase 2, immediately adjacent to the metallic hydroxide, before the nucleophilic addition occurs.[1299] One of the oxygens in CO_2 is in an oxyanion hole formed from a fixed molecule of water in the active site and the amido nitrogen–hydrogen of a peptide bond.[1302] A molecule of water from solution exchanges at the Zn^{2+} with bicarbonate as it vacates the active site. One hydron on this molecule of water entering form solution then dissociates into a hydron wire[1303] that connects it to the solution to form $Zn^{2+}\cdot OH^-$, prepared for the next turnover.

In most instances, a **metallic hydroxide in an active site is used for hydrolysis**. For example, in the active site of murine cytidine deaminase (Figure 3–36), the hydroxide on Zn^{2+} adds nucleophilically to the carbon of the *N*-carbamoylamidine in cytidine to produce a tetrahedral intermediate from which ammonia is the leaving group in the hydrolysis of cytidine to uridine.[1178,1304] The carboxylato group of Glutamate 67 removes the hydron from the water on Zn^{2+} to produce $Zn^{2+}\cdot OH^-$. The resulting carboxy group shuttles the hydron to the

nitrogen that will leave from the tetrahedral intermediate and then removes the hydron on the hydroxy group of the tetrahedral intermediate, which is acidic because it is still a ligand to the Zn^{2+}, to improve the push of oxygen in ejecting the ammonia. When the homologous[1178] glutamate in cytidine deaminase from *E. coli* was mutated to alanine,[199] the catalytic constant of the enzyme decreased by a factor of 10^8. The enzyme dCTP deaminase from *M. jannaschii*, which is completely unrelated but nevertheless catalyzes the same reaction, has no metallic dication in its active site, but it does use the carboxy group of a glutamate to hydronate the leaving ammonia.[1305] Adenine deaminase from *E. coli*, however, which catalyzes the homologous reaction on the *N*-carbamoylamidine in adenine, has a prosthetic diferric cluster in its active site that uses a dimetallic μ-hydroxide as the nucleophile.[1306]

Histone deacetylase 10 from *D. rerio* hydrolyzes acetyl groups from lysines in histones, which are proteins involved in assembling chromatin. A molecule of water that is a ligand to the prosthetic Zn^{2+} in the active site is the nucleophile in the nucleophilic substitution catalyzed by the enzyme. Upon association with the active site, the acyl oxygen of the acetyl group on a substrate associates with an open site on Zn^{2+}, and the 4-hydroxy group of Tyrosine 307 also forms a hydrogen bond to the acyl oxygen. Together Zn^{2+} and the 4-hydroxy group withdraw electron density from the acyl carbon, making it more electrophilic, and the 4-hydroxyphenyl group hydronates the oxygen as the tetrahedral intermediate forms by addition of the adjacent hydroxide. The imidazolyl group of Histidine 136 removes a hydron from the water either before or during its addition to the acyl carbon of the acetyl group, and the imidazolio group of Histidine 137 adds a hydron to the amino group in the resulting tetrahedral intermediate to permit the nitrogen of the 6-amino group of lysine in the reactant to leave. In the crystallographic molecular model of the active site of a mutant in which Tyrosine 307 was mutated to phenylalanine, an unhydrolyzed N-acetylated substrate occupies the active site because there is no catalytic acid to hydronate the acyl oxygen as the tetrahedral intermediate forms. In this analogue of the Michaelis complex, the τ nitrogen of Histidine 137 is pointed at the amido nitrogen that it would normally hydronate, at a distance of 0.37 nm and in the proper orientation for hydronation. In the crystallographic molecular model of the active site of a mutant in which Histidine 137 was mutated to alanine, the active site is occupied by the tetrahedral intermediate itself because there is no imidazolyl group to hydronate the leaving nitrogen, an inescapable requirement.[137] This molecular model is one of the few instances in which the actual tetrahedral intermediate in the nucleophilic substitution of an acyl derivative has been observed.

Thermolysin (Figure 3–42) is the paradigm of a metalloendopeptidase that uses a metallic hydroxide to **hydrolyze a peptide bond**. In the unoccupied active site of thermolysin, the molecule of water that occupies the fourth position on the tetrahedrally coordinated Zn^{2+} participates in a hydrogen bond with the carboxylato group of Glutamate 143.[1181,1182] The carboxylato group of Glutamate 143 is responsible for removing the acidic hydron from the molecule of water on the prosthetic Zn^{2+} to produce $Zn^{2+}{\cdot}OH^-$, which is the nucleophile in the hydrolysis, and its carboxy group is now responsible for adding the hydron to the departing nitrogen[1307]



(4–439)

This mechanism allows Zn^{2+} as well as the imidazolium of Histidine 231 (Figure 3–42) to polarize the carbon–oxygen double bond of the amido group to increase the electrophilicity of the acyl carbon. The mechanism has the disadvantage of increasing the occupancy of Zn^{2+}, which should increase the pK_a for the molecule of water and make it more difficult for the carboxylato group to remove the hydron,[1308,1309] but it has the advantage of increasing the nucleophilicity of the resulting zinc hydroxide.

Peptide deformylase from *E. coli* uses $Fe^{2+}{\cdot}OH^-$ instead of $Zn^{2+}{\cdot}OH^-$ in its active site (**4–158**)[1149] to catalyze hydrolysis of an amino-terminal formyl group on a polypeptide (Equation 4–425). The enzyme also uses the carboxylato group of a glutamate to remove a hydron from a molecule of water on Fe^{2+} to produce $Fe^{2+}{\cdot}OH^-$ and to then hydronate the leaving amino group (see Equation 4–439).[121]

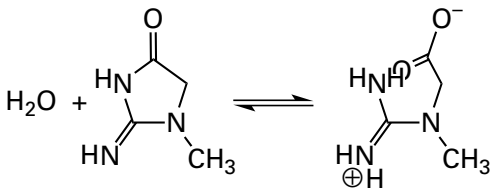
The mechanism for hydrolysis of a carboxy-terminal peptide bond in the active site of the zinc metalloenzyme bovine carboxypeptidase A (Equation 4–172) is also almost the same as that used by thermolysin. The hydron is removed from a molecule of water on Zn^{2+} by the carboxylato group of Glutamate 270, the same carboxylato group labeled by *N*-bromoacetyl-*N*-methyl-L-phenylalanine (Equation 4–312), but the carboxylato group does not seem to be properly oriented to hydronate the leaving group.[259] In the active site of GTP cyclohydrolase I from *E. coli*, which hydrolyzes the cyclic amidine in the imidazolyl ring of the guanine in $MgGTP^{2-}$, the hydron is removed from the molecule of water on Zn^{2+} by Histidine 112 while Histidine 179 hydronates the leaving group.[1174]

A metallic dication in an active site can also be used as a Lewis acid to lower the pK_a for an alcohol or thiol to ease its dehydronation, just as it is able to lower the pK_a of a molecule of water. For example, in the active site of catechol *O*-methyltransferase from *R. norvegicus*, the two ortho hydroxy groups of a catechol such as 4-(2-aminoethyl)-benzene-1,2-diol are both ligands to a Mg^{2+} that lowers the pK_a of the hydroxy group that is to be methylated by *S*-adenosyl-L-methionine, so that it is unhydronated and nucleophilic at the start of the reaction.[1310] The Zn^{2+} in the active site of protein farnesyltransferase (Equation 4–245) from *S. cerevisiae* lowers by 3 units the pK_a of the sulfanyl group of cysteine in a protein that is a substrate to which the farnesyl group is transferred during the enzymatic reaction.[1165] When the Zn^{2+} in protein farnesyltransferase from *R. norvegicus* is replaced with Cd^{2+}, a pK_a of 6.0 in the pH–rate profile for the enzyme decreases by 1.0 unit, as expected for replacement of Zn^{2+} by the softer metal.[1311] Consequently, the zinc(II) thiolate is the nucleophile in the enzymatic reaction, and the role of Zn^{2+} is to lower the pK_a for the sulfanyl group in the substrate into the physiological range.

Usually, because of the Brønsted relation, when the pK_a for the conjugate acid of a nucleophile is decreased, its nucleophilicity also decreases. There are indications that this decrease in nucleophilicity can be minimized by coordination with a metallic dication. In dimethyl sulfoxide as a solvent, the rate of nonenzymatic methyl transfer from trimethyl phosphate, $(CH_3O)_3P{=}O$, to the sulfido group of a thiolate in $Zn(SC_6H_5)_4^{2-}$ is equal to the rate for the same methyl transfer to $^-SC_6H_5$, but it is more than 100 times faster than methyl transfer to HSC_6H_5.[1312] Consequently, at least in this instance, Zn^{2+} lowers the pK_a for the sulfanyl group without affecting its nucleophilicity proportionally. When a hydron is added to a sulfido group, however, it has a dramatic effect on the nucleophilicity of sulfur. In solution, $Zn^{2+}{\cdot}OH^-$ in a synthetic, pentacoordinated complex is almost as effective as free OH^- at hydrolyzing a strained lactam and only 100 times less effective at hydrolyzing an ester,[1309] even though the pK_a for $Zn^{2+}{\cdot}OH_2$ in the complex is 8 units lower than that of H_2O the conjugate acid of OH^-. Both observations suggest that use of a metallic dication in the active site of an enzyme could be a general strategy for lowering the pK_a for one of its ligands toward the physiological range of pH without at the same time dramatically decreasing the nucleophilicity of the ligand after it has been dehydronated.[1313]

Upon associating with the active site of 5-methyltetrahydropteroyltriglutamate—homocysteine *S*-methyltransferase from *Candida albicans*,[1314] the sulfanyl group of the substrate L-homocysteine becomes a ligand on the prosthetic Zn^{2+}, and in the complex at neutral pH, the sulfido group is unhydronated.[1313] The concerted nucleophilic substitution at the 5-methyl group in 5-methyltetrahydropteroyltri-L-glutamate by the sulfido group of L-homocysteine is a difficult one because the leaving group, nitrogen 5 of tetrahydropteroyltri-L-glutamate, is an anilino nitrogen. Consequently, the sulfido group has to retain as much of its nucleophilicity as possible even though the Zn^{2+} has lowered its pK_a sufficiently to ensure that the sulfanyl group is the sulfido group, its conjugate base, at neutral pH.

***μ*-Hydroxides bridging two metallic dications** in enzymatic active sites (Figure 4–55E,F), such as the one in the active site of adenine deaminase from *E. coli*, are also used in hydrolyses.[1315-1317] For example, in the active site of creatininase



(4–440)

from *P. putida*, a *μ*-hydroxide bridging[1318] two Zn^{2+} adds nucleophilically to the acyl carbon of the (*N*-acyl-*N*′-alkyl)guanidino group in creatinine while the acyl oxygen on that carbon is a ligand to one of the Zn^{2+} to increase the electrophilicity of the carbonyl carbon. Acting as a Brønsted acid, a molecule of water on the same Zn^{2+} that coordinates the acyl oxygen hydronates the leaving nitrogen.[1319] In this

instance, the dinuclear cluster seems to do everything: provide the nucleophile, polarize the carbonyl, and hydronate the leaving group. In the active site of human glutamate carboxypeptidase II, an enzyme that hydrolyzes a peptide bond, the nucleophile in the hydrolysis that adds to the acyl carbon is a μ-hydroxide bridging two Zn^{2+}. The carboxy group of Glutamate 424 that forms a hydrogen bond with this hydroxide at one of its oxygens hydronates the leaving amino nitrogen in the tetrahedral intermediate with the hydron on its other oxygen.[1320]

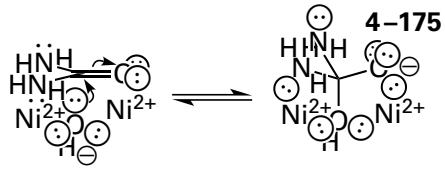
The main purpose of the two metallic dications in one of these dinuclear clusters is to **lower the pK_a for a molecule of water** bridging the two dications even more than if it were a ligand to only one dication, so that it is a μ-hydroxide sitting between them at physiological pH rather than a μ-molecule of water. For example, a synthetic mononuclear complex of Zn^{2+}, in which one ligand to the metallic dication is the hydroxy group of an aliphatic alcohol, can be induced to dimerize. In the dimer, the same hydroxy group ends up as a ligand to both Zn^{2+}. At pH 6.0, the μ-hydroxy group that sits between the two Zn^{2+} in the dimer is the unhydronated μ-alkoxide; but at pH 9.1, the μ-hydroxy group in the mononuclear complex of Zn^{2+} is still hydronated.[1321] Consequently, the μ-hydroxy group between the two Zn^{2+} must have a pK_a less than 6 while the same hydroxy group on the lone Zn^{2+}, which has the same coordination as each of the two Zn^{2+} in the dimer, must have a pK_a greater than 9. The pK_a for a molecule of the μ-water bridging the two Zn^{2+} in the active site of aryldialkylphosphatase[1322] (Figure 4–55E) is 5.8, so at pH 7, it will be a μ-hydroxide bridging the metals.

In nonenzymatic examples, even though values of pK_a for their conjugate acids, μ-molecules of water, are low, the bridging μ-hydroxides in synthetic dinuclear metallic hydroxides are **competent nucleophiles**. A synthetic dinuclear cluster of two Ni^{2+} bridged by a μ-hydroxide is able to hydrolyze urea,[1323] as does $(Ni^{2+})_2{\cdot}OH^-$ in urease (Figure 4–54). A synthetic dinuclear cluster[1324] of two Ni^{2+} bridged by a μ-hydroxide and a synthetic dinuclear cluster[1325] of two Zn^{2+} bridged by a μ-hydroxide are both able to hydrolyze amides, as does $(Zn^{2+})_2{\cdot}OH^-$ in β-lactamase[1315,1316] or $(Zn^{2+})_2{\cdot}OH^-$ in leucyl aminopeptidase (Figure 4–55G).[1160] A synthetic dinuclear cluster of two Co^{2+} bridged by a μ-hydroxide is able to hydrolyze a guanidino group,[1326] as does $(Mn^{2+})_2{\cdot}OH^-$ in the active site of arginase.[1327]

In the active site of urease (Equation 4–426)[1328] from *S. pasteurii*, which catalyzes a nucleophilic substitution at a carbonato carbon, there is a dinuclear cluster[1329] of two Ni^{2+}. When the active site is occupied by phosphorodiamidate **4–174**

4–174 **4–175**

an analogue of tetrahedral intermediate **4–175** in the enzymatic reaction, one oxygen of the phosphorodiamidate bridges the two Ni^{2+} (Figure 4–54).[1160] In the unoccupied enzyme, there is a μ-hydroxide bridging the two Ni^{2+} at the same location as the bridging oxygen of the phosphorodiamidate. From these observations, it can be concluded that the bridging hydroxide is the nucleophile that adds to the acyl carbon of the urea



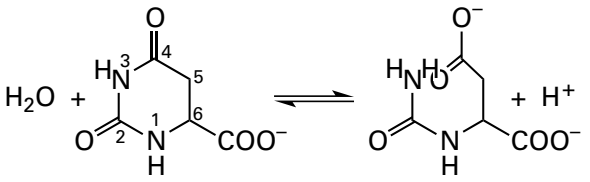
(4–441)

Because two ligand positions, one on each of the two Ni^{2+} in the active site, are occupied by the other oxygen and one nitrogen of phosphorodiamidate **4–174**, respectively (Figure 4–54), it can be concluded that one nitrogen in tetrahedral intermediate **4–175** when it is in the active site is a ligand to one Ni^{2+}, and the oxygen from urea is a ligand to the other Ni^{2+}. Each position for a ligand is occupied by a molecule of water in the unoccupied active site. Upon entering the active site, the urea exchanges with these two molecules of water. The two lone pairs of σ electrons that are ligands to the Ni^{2+} in tetrahedral intermediate **4–175** are π electrons in the urea in the Michaelis complex (Equation 4–441). As these π electrons become σ electrons in the transition state, the **strength of their ligation to the metal increases** dramatically, stabilizing the transition state and promoting catalysis.

The carboxylato group of Aspartate 362 dehydronates the μ-hydroxy group bridging the two Ni^{2+} in tetrahedral intermediate **4–175** (Equation 4–441) to give the resulting μ-oxido group the ability, along with the other oxyanion, to push out the leaving group. The ammonia that is the leaving group from the tetrahedral intermediate in urease can only leave if its nitrogen in tetrahedral intermediate **4–175** is hydronated. If the nitrogen that leaves as ammonia is the one that is a ligand to one of the Ni^{2+} (Figure

4–54), the carboxylato group of Aspartate 362 that has just dehydronated the μ-hydroxy group bridging the two Ni^{2+} in the tetrahedral intermediate (Equation 4–441) would then pivot on the ligation of its other oxygen to that Ni^{2+} and hydronate the nitrogen so that it can leave as ammonia. In this case, the carboxy group would dedicate one of its oxygens to act as a ligand to the nickel and the other oxygen to act as a catalytic acid–base, just as the carboxy groups do in the active site of D-psicose 3-epimerase (Equation 4–434). If, however, the ammonia that is the leaving group from the tetrahedral intermediate is the one that is forming a hydrogen bond with the imidazolyl group of Histidine 322 (Figure 4–54), then the imidazolyl group provides the hydron necessary to make the nitrogen a leaving group.[1330]

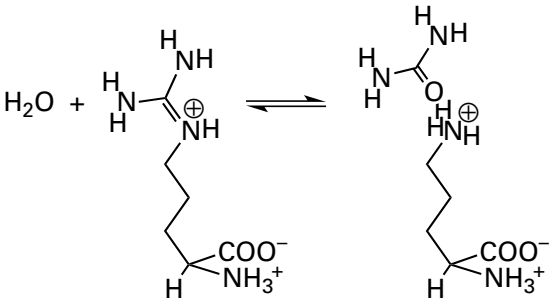
In the active site of dihydroorotase



(4–442)

from *E. coli*, which, unlike urease, catalyzes a nucleophilic substitution at an acyl carbon rather than a carbonato carbon, a μ-hydroxide bridging two Zn^{2+} adds nucleophilically to carbon 4, the acyl carbon of the (*N*-acyl-*N*-alkyl)urea in dihydroorotate, just as $(Ni^{2+})_2{\cdot}OH^-$ does to urea in urease (Equation 4–441). The acyl oxygen of carbon 4 is a ligand to one of the two Zn^{2+} in the cluster, which serves to stabilize the oxyanion in the tetrahedral intermediate, just as one of the Ni^{2+} does in urease. The carboxylato group of Aspartate 250 is a ligand to the other Zn^{2+}. It dehydronates the resulting hydroxy group of the tetrahedral intermediate, just as Aspartate 362 in urease does (Figure 4–54), and then the **carboxylato group pivots around its ligation to Zn^{2+}** and hydronates the nitrogen that is a ligand to this same Zn^{2+} in the dinuclear cluster and that leaves as the ureido group,[1331] just as the carboxylato group of Aspartate 362 in the active site of urease might do (Figure 4–54).

Human arginase catalyzes a nucleophilic substitution at a carbonato carbon, as does urease, but in arginase the carbonato carbon is part of a guanidinio group

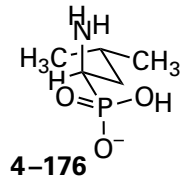


(4–443)

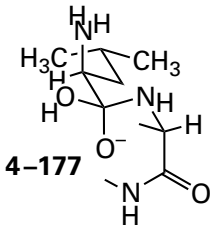
A μ-hydroxide bridging[1332,1333] two Mn^{2+} adds nucleophilically to the guanidinio carbon while one peripheral nitrogen in the guanidinio group is a ligand to one of the Mn^{2+}. The imidazolyl group of Histidine 141 then hydronates the leaving amino group in the tetrahedral intermediate to give L-ornithine,[1334-1336] just as the imidazolyl group of Histidine 322 in the active site of urease might do (Figure 4–54).

The ambiguity in assigning the leaving nitrogen in urease again illustrates the value of stereochemical information, which is necessarily lacking in this case. The uncertainty results from the fact that there are two equivalent nitrogens in tetrahedral intermediate **4–175**, either of which could represent the leaving group in the actual reaction. In the cases of dihydroorotase and arginase, as well as creatinase (**4–128**), the catalytic acids were identified when a substrate or an analogue of an intermediate was bound in the active site and the leaving group or the atom representing the leaving group could be unambiguously identified.

An uncertainty similar to that for urease exists for the complex (Figure 4–55G) between bovine leucyl aminopeptidase and 1-amino-3-methylpropylphosphonic acid (**4–176**)



4–176

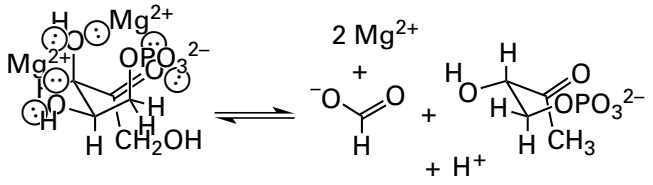


4–177

which is an analogue of tetrahedral intermediate **4–177** in the hydrolysis of a peptide bond to an amino-terminal leucine catalyzed by the enzyme. The phosphono group has two oxygens that are ligands to the two Zn^{2+}, respectively; either the one to the right or the one to the left in drawing **4–176** could represent the leaving amine.[1172] The oxygen on the right, however, is more likely the representative because the ammonio group of Lysine 262 forms a

hydrogen bond to it (Figure 4–55G), perhaps identifying that lysine as the acid that must hydronate the α-amino group before it can leave. In the crystallographic molecular model of the complex between methionyl aminopeptidase from *E. coli*, which has a dinuclear cluster of two Fe^{2+} in its active site, and 1-amino-3-(methylsulfanyl)propylphosphonic acid (the 3-methylsulfanyl analogue of **4–176**), two oxygens of this analogue of the tetrahedral intermediate, either of which may represent the leaving amine, accept hydrogen bonds from the imidazolyl groups of Histidine 79 and 178, respectively, either of which could be the unavoidable catalytic acid that hydronates the actual leaving amino group.[1242]

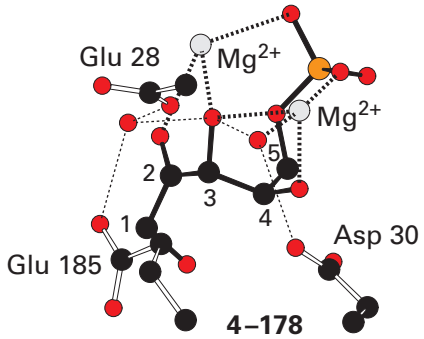
The enzymatic reaction catalyzed by 3,4-dihydroxy-2-butanone-4-phosphate synthase



(4–444)

from *M. jannaschii* is centered on the 3-hydroxy group of the D-ribulose 5-phosphate that is its substrate. On one side of the 3-hydroxy group, the reaction involves a 1,2-hydride migration to the carbonyl group of the reactant, analogous to that performed by xylose isomerase (Equation 4–432), or an isomerization analogous to that performed by triose-phosphate isomerase that involves an enolate (Equation 4–55), followed by an elimination that exploits the newly formed carbonyl at carbon 3 or the enolate itself. On the other side of the 3-hydroxy group that has now become a carbonyl, a 1,2-phosphomethide migration then occurs, analogous to a 1,2-methyl migration, followed by a retro-Claisen dissociation during which a metallic hydroxide adds to a carbonyl group.[1337] Consequently, it is one of the most unusual heterolytic reactions catalyzed by an enzyme, and a captivating puzzle to solve (Problem 4–48).

During the steps in the reaction, the oxygen on carbon 3 of D-ribulose 5-phosphate is required to be a hydroxy group, the oxyanion of an enolate, and the oxygen of a carbonyl group at various stages in the mechanism. In order to accommodate these various roles, this oxygen is coordinated by two Mg^{2+}. One Mg^{2+} is additionally coordinated by the 2-carbonyl group of D-ribulose 5-phosphate, and the other Mg^{2+} is additionally coordinated by the 4-hydroxy group of D-ribulose 5-phosphate[882,1338]



The 3-hydroxy group of D-ribulose 5-phosphate bridges the two Mg^{2+}, so it is formally equivalent to a μ-molecule of water or a μ-hydroxy group bridging the metallic dications in the usual dinuclear cluster and almost, but not quite, as acidic as a typical bridging oxygen (Table 4–2). The purpose of the two Mg^{2+} is to lower the pK_a for the hydroxy group as well as to stabilize the oxyanion of the enolate.

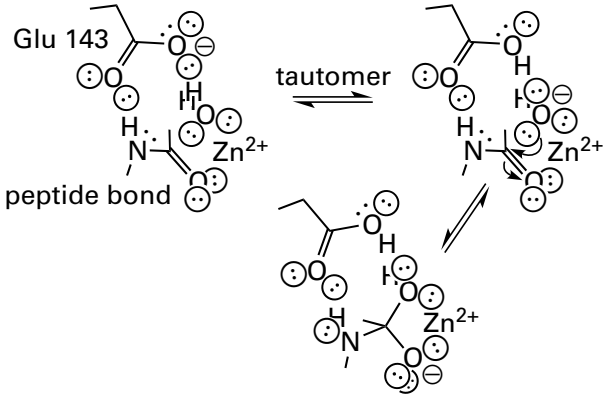
In addition to the two Mg^{2+} that are acting as the usual Lewis acids, two molecules of water form hydrogen bonds to the central 3-hydroxy group. One molecule of water also participates in a hydrogen bond with Aspartate 30, and the other molecule of water also participates in hydrogen bonds with Glutamates 28 and 185. Consequently, the central 3-hydroxy group, in addition to its covalent bond to carbon 3, is surrounded by a crowd of four ligands: two Mg^{2+} and two oxygens from the molecules of water. The molecules of water act as Brønsted acids to give and take hydrons from the oxygen on carbon 3 of D-ribulose 5-phosphate while it assumes its different roles as the reaction proceeds through its several steps. This enzymatic reaction in turn provides, in each of its steps (Problem 4–48), a paradigm of one of several of the roles played by metallic dications as Lewis acids.

In most cases, as in those that have just been discussed, the two metallic dications in a dinuclear cluster in an active site are of the same metal, but several active sites have **two different metallic dications in their dinuclear clusters**. For example, in the active site of enamidase from *E. barkeri*, which hydrolyzes the amido group in 6-oxo-1,4,5,6-tetrahydronicotinate, the dinuclear cluster consists of one Fe^{2+} and one Zn^{2+}, bridged by a μ-hydroxide.[1339]

In addition to acting as Lewis acids, metallic dications or dinuclear clusters can catalyze reactions by approximating a nucleophile and the electrophile to which it is to add in a nucleophilic substitution at carbon. For example, formate, a substrate for peptide deformylase (Equation 4–425), is a

bidendate ligand to Fe^{2+} in the crystallographic molecular model of the active site (**4–158**). This fact implies that Fe^{2+} not only lowers the pK_a for the molecule of water that is one of its ligands but also coordinates the acyl oxygen of the formyl group on an N-formylated polypeptide, the substrate in the hydrolytic direction, and consequently approximates the hydroxide to the formyl carbon to which it adds during the hydrolysis.

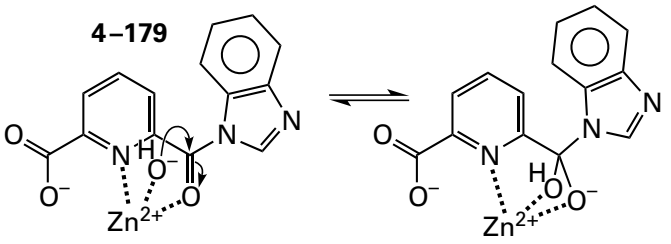
The Zn^{2+} in thermolysin can be either tetracoordinate (**4–162**) or pentacoordinate (**4–165**) in crystallographic molecular models of different complexes between inhibitors and the enzyme. This fact suggests that the acyl oxygen of the peptide bond in the normal reactant for the enzyme associates as a monodentate, fifth ligand to Zn^{2+}, pushing to one side that molecule of water, which remains as a ligand to Zn^{2+} while still forming a hydrogen bond with the carboxy group rather than leaving Zn^{2+} as it would in a dissociative exchange. The hydroxide on Zn^{2+} in the tautomer of the pentacoordinate complex would then attack nucleophilically the acyl carbon of the peptide bond that is also coordinated to Zn^{2+} through its acyl oxygen



(4–445)

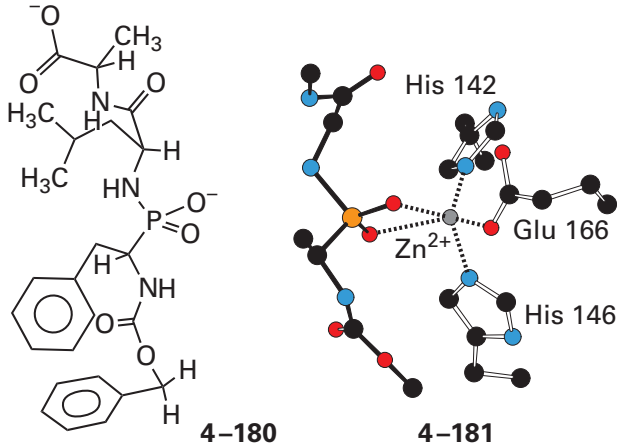
In this way, Zn^{2+} approximates the hydroxide and the acyl carbon of the peptide bond.

Metallic hydroxides are also effective in the nonenzymatic hydrolyses of substrates. The nonenzymatic hydrolysis of *N*-acylbenzimidazole **4–179**, in which the acyl group is designed to chelate Zn^{2+}, proceeds through nucleophilic addition of zinc hydroxide to the acyl group, which is also coordinated by the Zn^{2+}. In this instance, Zn^{2+} approximates the nucleophile and electrophile as well as coordinating the two oxygens of the tetrahedral intermediate[1340]



(4–446)

In both enzymatic and nonenzymatic nucleophilic substitutions at an acyl group taking place on a metallic dication, addition of the nucleophile—in the previous three instances a hydroxide on the metallic dication—to the acyl carbon, the oxygen of which is also a ligand to the dication, produces a four-membered metallocycle (zinc, oxygen, carbon, oxygen; see Equation 4–446). In the active site of thermolysin, this metallocycle, unlike the five-membered metallocycle in the complex between the active site and hydroxamate **4–165**, would be strained. In the crystallographic molecular model of the complex between thermolysin and phosphonamidate **4–180**



just such a four-membered metallocycle is formed (**4–181**).[1184] In the normal reaction, however, this metallocycle containing a pentacoordinate Zn^{2+} should break at the weakest bond, that between the hydroxy group of the tetrahedral intermediate and Zn^{2+}, to generate the tetracoordinate complex represented in Figure 3–42.

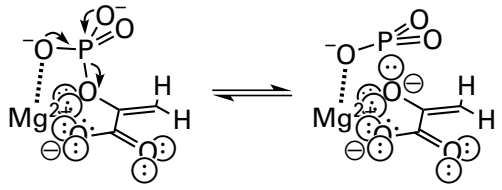
The Zn^{2+} in the active site of bovine carboxypeptidase A (Equation 4–172), just as does the Zn^{2+} in thermolysin, coordinates both the hydroxide that adds to the acyl carbon of the peptide bond and the acyl oxygen; and, in this way, it approximates the nucleophile and the electrophile. The Zn^{2+} in carboxypepidase A forms a metallocycle, analogous to that formed by Zn^{2+} in the active site of thermolysin

(**4–181**), with a phospho analogue of the tetrahedral intermediate in its enzymatic reaction.

The hydrolysis catalyzed by urease (Equation 4–441) illustrates the fact that because **a dinuclear cluster has coordination sites on two metallic dications** instead of just one, it provides more opportunities for catalysis by approximation. In the Michaelis complex between the active site of urease and urea, one Ni^{2+} coordinates the carbonato oxygen and the other Ni^{2+} coordinates one ureido nitrogen. This dinuclear coordination approximates the nucleophilic μ-hydroxide and the electrophilic carbonato carbon in the correct orientation for nucleophilic addition. In tetrahedral intermediate **4–175**, there are two metallocycles—composed of nickel, oxygen, carbon, oxygen and nickel, oxygen, carbon, nitrogen—rather than just one as in the active site of thermolysin, which has only one metallic dication. In the active sites of creatininase[1319] (Equation 4–440), dihydroorotase[1331] (Equation 4–442), arginase[1335] (Equation 4–443), leucyl aminopeptidase[1172] (**4–176**), and methionyl aminopeptidase,[1242] however, although they contain dinuclear clusters of dimetallic dications, only one dimetallic dication (rather than both) approximates the electrophile and the nucleophile by coordinating the respective acyl oxygens and the bridging μ-hydroxide. Creatininase, dihydroorotase, leucyl aminopeptidase, and methionyl aminopeptidase hydrolyze acyl derivatives rather than carbonato derivatives, so there are fewer opportunities for coordination.

Metallic dications are also used as Lewis acids in nucleophilic substitutions at phosphorus. Most nucleophilic substitution at phosphorus, unlike that catalyzed by pancreatic ribonuclease (Figure 4–46), rely on catalysis by metallic dications. For example, pyruvate kinase (Equation 4–275 and Figure 4–52) has two prosthetic Mg^{2+} in its active site when it is occupied by reactants in the productive Michaelis complex. The unliganded enzyme binds one Mg^{2+} from solution at the active site, and the second Mg^{2+} arrives complexed with ATP^{4-} or ADP^{3-}.[1341] This fact was shown by using, in place of $MgATP^{2-}$, a Cr^{3+} complex of ATP, which is a stable covalent complex almost completely inert to exchange (Table 4–5). The enzyme transferred the γ-phospho group from $CrATP^{-}$ to an analogue of *enol*pyruvate but only when Mg^{2+} was also present to occupy the site on the free enzyme for the second, uncomplexed metallic dication.

Both Mg^{2+} involved in the normal reaction catalyzed by pyruvate kinase (Equation 4–275), the one bound to free enzyme and the one brought in by $MgATP^{2-}$, have been located in maps of electron density derived from crystals of the enzyme in which the active site is occupied by substrates and inhibitors.[581,1342,1343] In the complex between the enzyme and Mg^{2+}, oxalate, and $MgATP^{2-}$, one oxygen of the phospho group that is transferred, as well as the oxygen of oxalate that represents the enol oxygen of the enol of pyruvate, are both ligands to the Mg^{2+} that is not brought in on $MgATP^{2-}$ (Figure 4–52). In the complex[1343] between the enzyme and pyruvate and Mg^{2+}, the carbonyl oxygen of pyruvate that was or that becomes the enol oxygen of phospho*enol*-pyruvate is a ligand to this same Mg^{2+} at the same position. Consequently, the role of this prosthetic Mg^{2+} that is not brought in on $MgATP^{2-}$ is to act as a Lewis acid to improve the ability of the enol oxygen to leave phosphorus during transfer of the phospho group from phospho*enol*pyruvate to $MgADP^{-}$. The intermediate in the reaction is probably monomeric metaphosphate, so this Mg^{2+}, by also coordinating one phospho oxygen, ensures that the phospho group on phospho*enol*pyruvate is dianionic, as is required to form monomeric metaphosphate, as well as to provide push to the dissociation

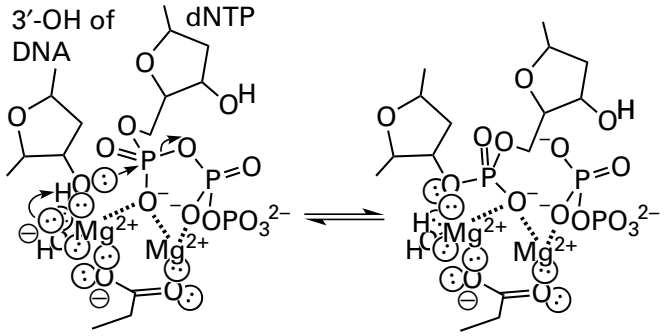


(4–447)

In the active site of phospho*enol*pyruvate carboxykinase, which catalyzes a reaction similar to that catalyzed by pyruvate kinase, one Mg^{2+} enters the active site on $MgATP^{2-}$, but Mn^{2+} rather than Mg^{2+} acts as the Lewis acid for the oxygen of the enolate of pyruvate.[1232]

In the reverse reaction catalyzed by pyruvate kinase (Equation 4–275), the role of the Mg^{2+} that is not brought into the active site on $MgATP^{2-}$ is to **stabilize the enolate and prevent its hydronation** so that its oxyanion can act as a nucleophile on phosphorus, albeit a phosphorus probably in monomeric metaphosphate. A similar role is played by the Mg^{2+} that is not brought into the active site on the nucleoside triphosphate in DNA-directed DNA polymerase β from *R. norvegicus*,[1344] DNA-directed DNA polymerase encoded by the genome of T7 bacteriophage,[1345,1346] and DNA-directed DNA polymerase encoded by the genome of hepatitis C virus.[1347] These Mg^{2+} coordinate the respective

3′-hydroxy groups that add to the α-phospho group of the next deoxynucleoside triphosphate to elongate the DNA. In each instance, this catalytic Mg^{2+} lowers the pK_a for the hydroxy group so that it can be dehydronated and act as a nucleophile at the α phosphorus



(4–448)

where 3′-OH is the 3′-hydroxy group at the end of the strand of DNA being elongated and dNTP is the deoxynucleoside triphosphate that is being added. In RNA-directed DNA polymerase from human immunodeficiency virus, this catalytic Mg^{2+} is loosely bound to the active site (K_d = 4 mM) and only associates after the magnesium nucleoside triphosphate has associated,[1348] so it is not a prosthetic Mg^{2+}.

In the case of the two Mg^{2+} in the active site of UDP-*N*-acetylglucosamine diphosphorylase

N-acetyl-α-D-glucosamine 1-phosphate^{2-} +
$MgUTP^{2-} \rightleftharpoons MgOPO_3PO_3^{2-}$ +
MgUDP-*N*-acetyl-α-D-glucosamine^{2-}

(4–449)

from *M. tuberculosis*, when it is occupied by magnesium diphosphate^{2-} and MgUDP-*N*-acetyl-α-D-glucosamine, it seems that neither Mg^{2+} fulfills a catalytic function other than entering the active site on the two substrates.[1349] The Mg^{2+} that enters on diphosphate leaves on $MgUTP^{2-}$, in which it is coordinated as the usual enantiomer at the Mg^{2+} on a triphosphate. The Mg^{2+} that enters on MgUDP-*N*-acetyl-α-D-glucosamine ends up on the phospho group of *N*-acetyl-α-D-glucosamine 1-phosphate and probably leaves on its own from the active site. Neither Mg^{2+} is coordinated by the two oxygens between which the phospho group is transferred; rather, each is coordinated by equatorial oxygens in the phosphorane or monomeric metaphosphate that is the intermediate in the nucleophilic substitution at phosphorus.

It is tempting to assign a **role for the Mg^{2+} on nucleoside triphosphates** that enter the active sites of the many enzymes like pyruvate kinase (Figure 4–52), the DNA-directed DNA polymerases, and on both substrates of UDP-*N*-acetylglucosamine diphosphorylase. In solution, addition of Mg^{2+} to an alkyl diphosphate, as opposed to a phosphodiphosphate, significantly enhances the ability of the diphosphate to act as a leaving group in a nonenzymatic nucleophilic substitution at the carbon to which it is attached.[1350] This enhancement results from the decrease in negative charge in the leaving group when it is magnesium diphosphate rather than diphosphate. The same enhancement, however, is not observed for nonenzymatic phosphorylations effected by H_2ATP^{2-}, which is a model for all nucleoside triphosphates. Most of the reactions in which magnesium nucleoside triphosphates engage are phosphorylations, and in these phosphorylations the magnesium nucleoside diphosphate is the leaving group. As has been mentioned, the major form[1122] of nucleoside triphosphates in cytoplasm, is $MgATP^{2-}$, and the Mg^{2+} probably enters the active site of an enzyme for which a nucleoside triphosphate is a substrate automatically rather than purposefully. In most instances of such a Mg^{2+} bound to oligophospho groups in a substrate, the dication ends up coordinated to one or two equatorial oxygens in the phosphorane or monomeric metaphosphate that is the intermediate in the nucleophilic substitution at phosphorus, and this coordination may enhance catalysis, albeit at the periphery. The argument for a mechanistic purpose for these Mg^{2+} could extend, but probably should not, to assigning that purpose as the reason that cellular free concentrations of Mg^{2+} are so high.

Regardless of the role played by a Mg^{2+} brought into the active site on a nucleoside triphosphate or a nucleoside diphosphate, the Mg^{2+} or other metallic dication that is not brought in by $MgATP^{2-}$ can be thought of as acting alone as a catalyst: **stabilizing the phosphorane or monomeric metaphosphate** that is an intermediate in the reaction, stabilizing the nucleophilic oxyanion in one direction, and stabilizing the leaving group in the other direction.

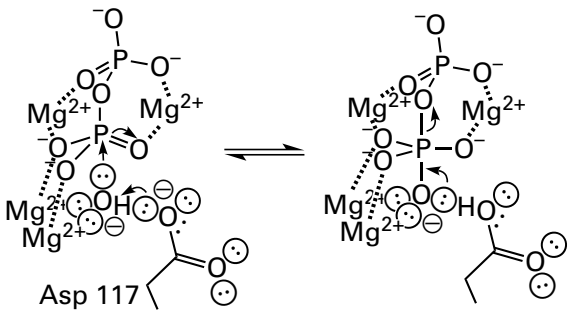
There are, however, a number of instances in which **two metallic dications**, neither of which is brought in by a substrate and both of which are bound as prosthetic groups in the active site in the absence of substrates,[1351-1354] act in concert to catalyze a nucleophilic substitution at phosphorus.

For example, in the active site of aryldialkylphosphatase (Figure 4–55E), which hydrolyzes triesters of phosphoric acid, the μ-hydroxide bridging two Zn^{2+} is the nucleophile that adds to the phosphorus of the triester. In the Michaelis complex, the single, unarylated and unalkylated phospho oxygen on the phosphotriester is a ligand to one of the Zn^{2+}, which withdraws electron density from phosphorus and makes it more electrophilic. The conjugate acid of the unliganded oxygen in the carboxy group of Aspartate 301 that is a monodentate ligand to the other Zn^{2+} is in van der Waals contact (0.39 nm) with the methyl group of diisopropyl methylphosphonate, which is an analogue of a phosphotriester and occupies the active site in the crystallographic molecular model.[1166,1354] This carboxy group hydronates the leaving group that, in a substrate, would sit in the location of the methyl group. This carboxy group also forms a hydrogen bond with the μ-hydroxide in the unoccupied active site,[1354] so it is responsible for removing a hydron from the μ-hydroxide during the nucleophilic addition to phosphorus that forms the phosphorane. The dimetallic cluster and the carboxy group of Glutamate 407 in the active site of aryldialkylphosphatase from *Sphingobium* also seem to be exclusively responsible for the nucleophilic substitution at phosphorus catalyzed by the enzyme. Therefore, the pK_a of 7.9, below which the specificity constant for the aryl dialkyl substrate paraoxon decreases, has been assigned to the hydron in the hydrogen bond between this carboxy group and the μ-hydroxide.[1355]

Two of the four Mg^{2+} in the active site of inorganic diphosphatase

$$Mg_2O_3POPO_3 + H_2O \rightleftharpoons 2\,HOPO_3^{2-} + 2\,Mg^{2+} \qquad (4\text{–}450)$$

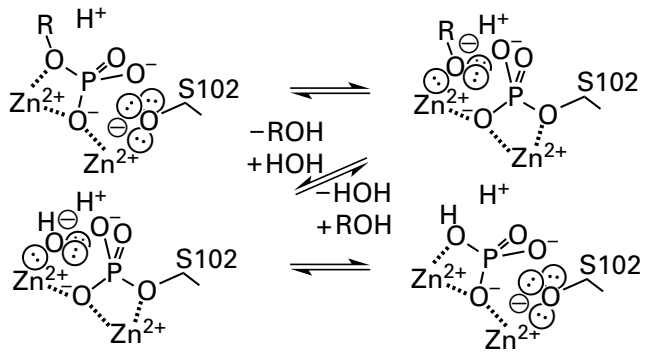
from *E. coli* when it is occupied by diphosphate are brought in with the diphosphate, but the other two are metallic dications present in the active site before the substrate binds.[1356] There is a μ-hydroxide bridging these latter two Mg^{2+}. This bridging hydroxide is the nucleophile that adds to the one phosphorus from which the other phospho group leaves during the hydrolysis catalyzed by the enzyme.[1357-1359] Aspartate 117 in inorganic diphosphatase from *S. cerevisiae* removes the hydron from this hydroxide as it adds to the electrophilic phosphorus[1358]



(4–451)

There are other **enzymes that use a μ-hydroxide bridging two metallic dications to hydrolyze phosphoesters**[1360-1362] by a mechanism in which **two oxygens on the phosphoester are ligands**, one to each metallic dication, as in the active site of inorganic diphosphatase (Equation 4–451). There is even an inorganic diphosphatase in which a μ-hydroxide bridging three metallic dications acts as the nucleophile in hydrolysis of diphosphate.[1363] In the active site of histidinol-phosphatase from *Lactococcus lactis*, which hydrolyzes the monoester L-histidinol phosphate, the nucleophile is a μ-hydroxide bridging two Zn^{2+}, and a third Zn^{2+}, not coordinated by the hydroxide, has the leaving oxygen of L-histidinol as a ligand and, as a Lewis acid, enhances its ability to leave from the phosphorane that forms upon nucleophilic addition of the hydroxide to the phospho group.[1364] In the active site of the enzyme from *Vibrio cholerae*, which is responsible for hydrolysis of the phosphodiester at the 3′-hydroxy group of adenylate in 3′,3′-cyclic guanosine monophosphate-adenosine monophosphate, there is a μ-hydroxide bridging two Fe^{2+}.[1365,1366] When either one or both Fe^{2+} are adventitiously oxidized to Fe^{3+}, the enzyme loses its catalytic activity, perhaps because exchange is so much faster at the dication than the trication. A nonenzymatic, synthetic dinuclear $(Co^{2+})_2{\cdot}OH^-$ has been shown to hydrolyze a phosphodiester[1367] by nucleophilic addition of the μ-hydroxide to phosphorus in a complex in which one nonbridging oxygen is the ligand to one Co^{2+} and the other is a ligand to the other Co^{2+}. In most cases, however, the mechanism of nucleophilic substitution at phosphorus catalyzed enzymatically by a dinuclear metallic cluster is the same as that catalyzed by alkaline phosphatase.

Alkaline phosphatase (Equation 4–284) from *E. coli* hydrolyzes a phosphomonoester by transferring the phospho group to Serine 102



(4–452)

and then transferring it to a molecule of water that enters and replaces the leaving alcohol after it dissociates.[1368] When alkaline phosphatase is hydrolyzing arylphosphomonoesters, in which the leaving groups are acidic ($pK_a \leq 10$), the transition state has considerable dissociative character,[1369] a fact suggesting the intermediate is more like monomeric metaphosphate than a phosphorane. It seems likely, however, that when alkylphosphomonoesters are hydrolyzed by the enzyme, the intermediate is closer to a phosphorane because the leaving groups are poor. In any case, vanadate (Table 3–7) forms an analogue (see **4–124**) for the two phosphoranes of Serine 102 or the two monomeric metaphosphates that are the respective intermediates in the two consecutive nucleophilic substitutions at phosphorus.

The crystallographic molecular model of the vanadyl complex with the active site (Figure 4–56)[1370] demonstrates that one of the equatorial oxygens of each phosphorane or monomeric metaphosphate in the normal reaction (phosphorus in place of vanadium) ends up bridging the two Zn^{2+} in the active site, rather than the oxygen of either the hydroxide or one of the two alkoxides that are substrates for the enzyme. The oxygen of the hydroxy group of Serine 102 is successively a nucleophile and a leaving group, the oxygen of the hydroxy group of the alcohol is successively a leaving group (Equation 4–452) and a nucleophile, and the hydroxy group of the molecule of water replacing the hydroxy group of the alcohol is successively a nucleophile and a leaving group. At one time or another, all three of these oxygens are ligands to one or the other Zn^{2+}, but never both at the same time, as the reaction progresses through the two phosphoranes or the two monomeric metaphosphates, with overall retention of configuration (Equation 4–285).[591]

The **μ-oxygen between the two Zn^{2+}** is one of the equatorial oxygens in each of the two phosphoranes or two monomeric metaphosphates that are intermediates in the overall reaction. The two Zn^{2+} may well **stabilize the negative charge that builds up on the equatorial oxygen** in the phosphorane or monomeric metaphosphate,[1371] but the role of the two Zn^{2+} in the rigid dinuclear cluster may instead be entirely that of both **approximating and orienting reactants** during the respective formations of the two phosphoranes or two monomeric metaphosphates.[107,1370,1372,1373]

One Zn^{2+} (the seryl Zn^{2+}) is also coordinated to the nucleophilic oxygen while the other Zn^{2+} (the aquo Zn^{2+}) is coordinated to the leaving oxygen in the first step of the reaction, and they switch roles in the second step. The seryl Zn^{2+} lowers the pK_a for the hydroxy group of Serine 102, one of its constant ligands, so that the hydroxy group is unhydronated and nucleophilic. The seryl Zn^{2+} then improves the ability of the oxygen of Serine 102 to leave in the next nucleophilic substitution at phosphorus. The aquo Zn^{2+} improves the ability of the hydroxy group of the alcohol, one of its exchangeable ligands, to leave. The aquo Zn^{2+} then lowers the pK_a for the molecule of water that replaces the alcohol so that it dissociates a hydron to become an unhydronated $Zn^{2+}OH^-$. There is also a Mg^{2+} in the active site that is coordinated by a carboxylato group, a hydroxy group, and four molecules of water. One of the molecules of water on this Mg^{2+} acts as the donor of a hydrogen bond to one of the other equatorial oxygens in the two consecutive phosphoranes or monomeric metaphosphates, relaying the Lewis acidity of Mg^{2+}.

The exchanges necessary for association of substrates with the prosthetic Mg^{2+} in the active site of pyruvate kinase are prevented when one water on the prosthetic Mg^{2+} dissociates its hydron and becomes a hydroxide.[1250,1251] Although Zn^{2+} exchanges its ligands more rapidly than Mg^{2+} (Table 4-5), this fact suggests that an **alkoxide anion sitting as an inner-sphere ligand on a Zn^{2+}**, rather than Mg^{2+}, such as the alkoxide that has left the phosphorane or monomeric metaphosphate in the first step of the reaction catalyzed by alkaline phosphatase (Equation 4–452 and Figure 4–56), also **cannot dissociate rapidly** from the aquo Zn^{2+}, and hence leave the active site efficiently as a product, until it is hydronated by a Brønsted acid. The most likely catalytic acid is the molecule of water 0.38 nm from the axial

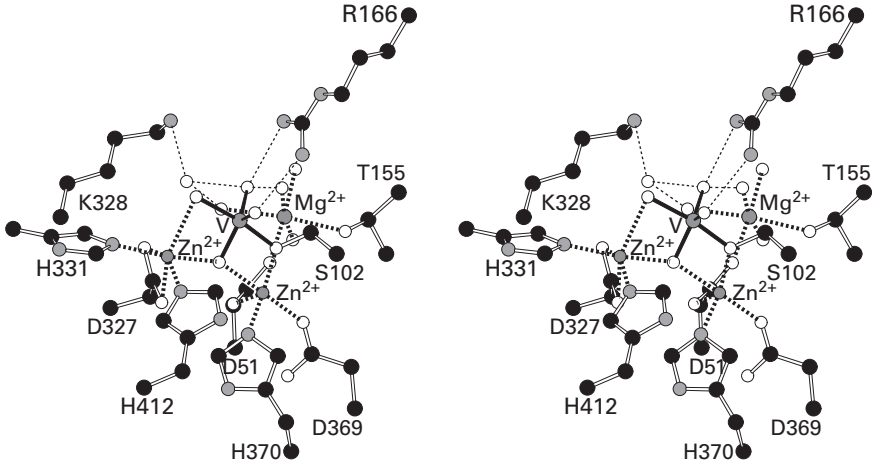


Figure 4–56: Stereodrawing[134] of the crystallographic molecular model of the active site of alkaline phosphatase from *E. coli* occupied by two Zn^{2+}, a Mg^{2+}, and a vanadyl ester (**3–63**) of Serine 102, an analogue of the phosphorane that is an intermediate in the enzymatic reaction.[1370] Black atoms are carbons, white atoms are oxygens, and small gray atoms are nitrogens. The smaller dark gray spheres are two zinc ions surrounded by their ligands, and the larger dark gray sphere is a magnesium ion surrounded by its ligands. The enzyme was purified from cytoplasm of *E. coli* that had been infected with a plasmid encoding the gene for the enzyme that overexpressed the protein and crystallized. The crystals were soaked in a solution containing 1 mM $ZnCl_2$, 10 mM $MgCl_2$, and 100 μM NH_4VO_3 and submitted to X-ray diffraction in that solution. Electron density for two Zn^{2+}, a Mg^{2+}, and a vanadyl ester of Serine 102 could be observed in each active site in the dimer that occupied the asymmetric unit. The molecular model of the vanadyl ester with its five oxygens is in the center of the figure. One of the two Zn^{2+} has as four of its ligands the imidazolyl groups of Histidines 331 and 412, an oxygen from the carboxylato group of Aspartate 327, and one of the oxygens of the vanadyl ester. The other Zn^{2+} has as four of its ligands the imidazolyl group of Histidine 370, the carboxy groups of Aspartates 51 and 369, and the esterified oxygen of Serine 102. One of the oxygens of the vanadyl group is between the two Zn^{2+}, as a ligand to each of them. The Mg^{2+} has retained four molecules of water as ligands and is held in the active site by ligation to one of the oxygens of the carboxy group of Aspartate 51 and the hydroxy group of Threonine 155.

oxygen of the vanadate, which represents the leaving alkoxide in the normal reaction. This molecule of water can form a hydrogen bond (0.26 nm) with the ammonio group of Lysine 238, or it can interact with another molecule of water that bridges the gap but is unresolved in the map of electron density. In either case, a hydron is relayed from Lysine 328 to the alkoxide, converting it to an alcohol that can readily dissociate from the aquo Zn^{2+}.

The alkoxide of Serine 102, however, which is the nucleophile that adds initially to the phosphoester to form the first phosphorane (Equation 4–452) or monomeric metaphosphate, is never required to leave the active site and could remain a metallic alkoxide even after it leaves the second phosphorane or monomeric metaphosphate in the later step of the enzymatic reaction. When it is a ligand to the seryl Zn^{2+}, the oxyanion of Serine 102 is surrounded by an oxygen in the carboxylato group of Aspartate 51 (0.38 nm) and a molecule of water (0.35 nm) that are both ligands on the Mg^{2+} that is also in the active site (Figure 4–56). When the oxyanion of Serine 102 swings away from the seryl Zn^{2+}, it forms a hydrogen bond (0.32 nm) to the hydroxy group of Threonine 155 that is also a ligand to Mg^{2+}.[1374] Because a hydroxy group or a molecule of water on Mg^{2+} is a weaker acid than a hydroxy group on Zn^{2+} (Table 4–2) neither the molecule of water nor the hydroxy group of Threonine 155, which are both permanent ligands to Mg^{2+}, can hydronate the hydroxy group of Serine 102 as long as it is a ligand to the seryl Zn^{2+}. These neighbors, which form a cup surrounding the oxyanion of Serine 102, ensure that the hydroxy group on Serine 102 remains the unhydronated, nucleophilic oxyanion when it is bound to the seryl Zn^{2+}. It is possible that this constellation is responsible for the values for pK_a of 7.4 and 7.3 in the pH–rate profiles for the enzyme below which its catalytic constant and specificity constant k_{phs} for a phospho substrate (phs), respectively, decrease.[1375] If so, these two values for pK_a, identical within the error of measurement, both represent hydronation of the oxyanion of Serine 102 as the pH is lowered and both would be the pK_a for its conjugate acid.

There are also enzymes[1376-1382] that use two Mg^{2+} or two Mn^{2+} in the same way that alkaline phosphatase uses its two Zn^{2+} to coordinate dinuclearly an equatorial oxygen in the phosphorane or monomeric metaphosphate (Figure 4–56) and to increase the electrophilicity of phosphorus in the respective phosphoesters, as well as to anchor the oxygens of the nucleophiles and leaving groups to Zn^{2+} to lower the values of pK_a for the nucleophilic oxygens and to improve, in turn, the leaving groups (Equation 4–452). In a nonenzymatic instance of catalysis by a dinuclear complex of two Zn^{2+}, the hydron dissociates from a hydroxy group on one Zn^{2+} and the resulting zinc alkoxide adds to the phosphorus of a phosphodiester that is tightly bound to the two Zn^{2+} by the two nonbridging oxygens as the first step in a nucleophilic substitution.[1383]

In most reactions in which a metallic dication is used by an active site to catalyze a nucleophilic substitution at phosphorus, the metallic dication also **catalyzes the nucleophilic addition by approximating the two reactants**. This approximation is achieved by coordination of the reactants to the metallic dication or dications. Examples are approximation of the enolate oxygen and the γ-phospho group of $MgATP^{2-}$ by the prosthetic Mg^{2+} in the active site of pyruvate kinase (Equation 4–447 and Figure 4–52); approximation of the 3′-hydroxy group and the α-phospho group of $MgdNTP^{2-}$ by the prosthetic Mg^{2+} in the active site of DNA-directed DNA polymerase (Equation 4–448); approximation of the bridging μ-hydroxide and the phosphorus in diphosphate by coordination of two phospho oxygens by the dinuclear cluster of Mg^{2+} in the active site of inorganic diphosphatase (Equation 4–451); and both approximation of the oxido group of Serine 102 and the phospho group and approximation of the nucleophilic molecule of water or an alcohol and the phospho group in the active site of alkaline phosphatase (Equation 4–452). The ability of the Mg^{2+} in $Mg^{2+}(H_2O)_5OH^-$ to approximate the respective phospho group and hydroxide by coordinating one oxygen of the phospho group has been proposed in part as an explanation for the effective catalysis exhibited by Mg^{2+} for the hydrolyses of phosphopyridiniums[1384] and phosphodiesters.[1385]

In the active site of glutamine synthetase (previously Equation 3–405)

$$\text{L-glutamate} + NH_3 + MgATP^{2-} \rightleftharpoons MgADP^- + HOPO_3^{2-} + \text{L-glutamine} \qquad (4\text{–}453)$$

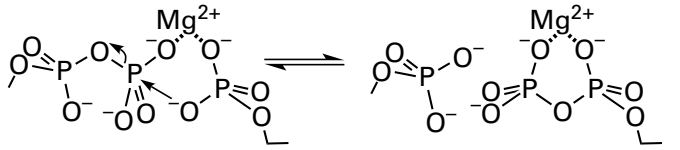
from *S. typhimurium*, a prosthetic Mg^{2+} coordinates both the γ-carboxy oxygen of L-glutamate, which is the nucleophile, and one nonbridging oxygen of the γ-phospho group of $MgATP^{2-}$, which is the electro-

phile,[1386] during transfer of the phospho group from $MgATP^{2-}$ to the γ-carboxy group. Since the carboxylato group of L-glutamate in the Michaelis complex with the active site requires no assistance to remain unhydronated and its nucleophilicity can be decreased only by being a ligand to Mg^{2+}, the role of Mg^{2+} in this case must be mainly that of approximating the nucleophilic oxygen and the phosphorus of the phospho group by having both the carboxylato group and the phospho group as inner-sphere ligands.

In all these complexes, the **metallocycle** or each of the two metallocycles that approximates the nucleophilic oxygen and phosphorus of the phospho group has four atoms: the metallic dication, the nucleophilic oxygen, the phosphorus, and its oxyanion that is a ligand to the metallic dication (Equations 4–447, 4–448, 4–451, and 4–452). In the nucleophilic substitution at phosphorus catalyzed by dTMP kinase

$$MgATP^{2-} + \text{deoxythymidine 5′-phosphate} \rightleftharpoons MgADP^{-} + \text{deoxythymidine 5′-diphosphate} \quad (4\text{–}454)$$

from *M. tuberculosis*, however, the metallocycle that brings the two phospho groups together has six atoms in its ring[1387,1388]



(4–455)

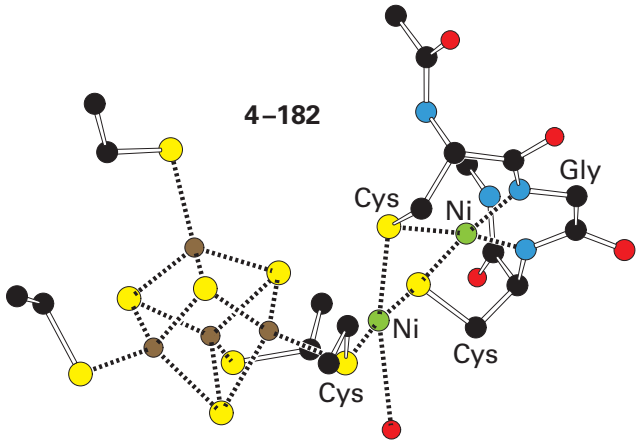
In nucleophilic additions both to an electrophilic carbon and to an electrophilic phosphorus in which metallic dications approximate nucleophile and electrophile, the electrophilic carbon and the electrophilic phosphorus are not themselves direct ligands to the respective metallic dications. The nucleophilic addition occurs at an electrophilic position one atom removed from the metallic dication, and an oxygen attached to either the electrophilic carbon or the electrophilic phosphorus is the inner-sphere ligand. There are, however, many nonenzymatic examples of **inner-sphere additions** in organometallic compounds. A Ni^{2+} in the active site of CO-methylating acetyl-CoA synthase catalyzes such an inner-sphere addition between an electrophilic carbon and the carbon of a nucleophilic methyl group and between an electrophilic carbon and the sulfur of a nucleophilic sulfido group. In each case, both the nucleophile and the electrophile are direct ligands to the metallic dication.

CO-Methylating acetyl-CoA synthase is a metalloenzyme responsible for fixing carbon monoxide in the form of acetyl-SCoA

$$\text{methyl-Co(III) corrinoid} + CO + e^{-} + {}^{-}SCoA \rightleftharpoons \text{Co(I) corrinoid} + \text{acetyl-SCoA} \quad (4\text{–}456)$$

The cobalt corrinoids are located within large (1520 aa) homodimeric $\alpha_2\beta_2$ heterotetramers.[1389,1390] Each heterotetrameric protein contains two identical sites, each of which is occupied by one cobalt corrinoid. As such, they are rather elaborate methyl-carrier proteins that supply the methyl group to CO-methylating acetyl-CoA synthase. Because the carbon and the oxygen of the acyl group in the acetyl group of acetyl-SCoA are derived from carbon monoxide itself,[1391] the enzyme simply stitches together a formal carbanide ion, a molecule of carbon monoxide, and a sulfido group, without changing them in the process other than forming bonds between them. Although there would be a two-electron oxidation were this actually what is occurring, there is no net oxidation–reduction in the complete reaction because the methyl-Co(III) corrinoid becomes a Co(I) corrinoid. Nevertheless, the cobalt corrinoid is acting neither as an oxidant nor as a reductant; rather, it is a leaving group in the forward reaction and a nucleophile in the reverse reaction, while the sulfido group is a nucleophile in the forward reaction and a leaving group in the reverse reaction. All these roles balance in the overall reaction.

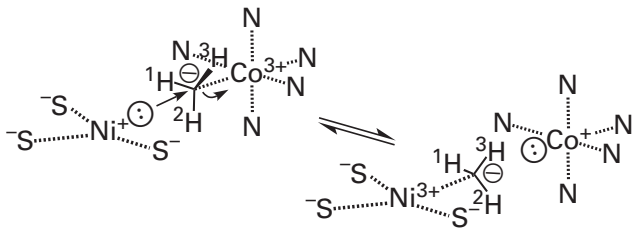
In the active site of CO-methylating acetyl-CoA synthase, there is a **dinuclear cluster of nickel ions**.[1207,1392] One of these clusters is found in the crystallographic molecular model of the active site of monomeric (732 aa) CO-methylating acetyl-CoA synthase from *Carboxydothermus hydrogenoformans*



One nickel ion in this cluster is electronically coupled to a normal [4Fe–4S] iron–sulfur cluster[1393,1394] by the sulfanyl group of a cysteine, which is a ligand in the inner spheres of both this nickel ion and one iron ion in the cluster. This **central nickel ion** is also electronically coupled to the **peripheral nickel** ion in the cluster by the sulfanyl groups of two other cysteines, each of which is a ligand in the inner spheres of both nickel ions in the dinuclear cluster.[1207,1392] The peripheral nickel ion is also gripped tightly by two amido groups, one from the carboxy-terminal cysteine and one from the glycine between the two cysteines. Because they are obviously ligands to a nickel ion (bond lengths of 0.190 and 0.188 nm), because both amido groups and the nickel are in the same plane, and because the nitrogen–hydrogen of the amido group carboxy-terminal to the carboxy-terminal cysteine is pointed at the nitrogen of the amido group of glycine, each of the two nitrogens must be the unhydronated, anionic conjugate base of the respective amido group. Consequently, the peripheral nickel ion is coordinated by two strongly basic ligands and **enfolded by the polypeptide** in a five-membered metallocycle.

The central nickel ion that is electronically coupled to both the [4Fe–4S] iron–sulfur cluster and the other nickel ion is coordinated much less tightly by the sulfanyl groups of the three cysteines performing the electronic coupling. During the purification of CO-methylating acetyl-CoA synthase, this latter, unenfolded nickel ion can dissociate, much as the Fe^{2+} in aconitate hydratase can, and be replaced adventitiously by Zn^{2+} or Cu^{2+}.[1207,1395,1396] These substitutions decrease significantly or eliminate the catalytic activity of the enzyme because the trisulfido-dinickel cluster is the active species.[1207,1392,1397]

The first step in the enzymatic reaction of CO-methylating acetyl-CoA synthase[1398] is thought[1399] to be either **association of carbon monoxide** with Ni^{+}, to give a complex in which carbon monoxide is an inner-sphere ligand,[1400-1402] or **concerted nucleophilic substitution of a nucleophilic Ni^{+}** in the cluster for the cobalt cation in methyl-Co(III) corrinoid, in which the leaving group is the nucleophilic Co(I) corrinoid[1403-1405]



(4–457)

If the carbonylation is the first step in the reaction, the methylation is the second, and vice versa. If the carbonylation is the first step, then the Ni^{+} that participates in the nucleophilic substitution (Equation 4–457) has carbon monoxide as its fourth ligand in addition to the three sulfido groups.

The Ni^{+} that is carbonylated and then methylated or methylated and then carbonylated is the central nickel ion, which shares the sulfanyl group of cysteine with the [4Fe–4S] iron–sulfur cluster (**4–182**) and is prone to dissociation and replacement with other metallic dications.[1405] In the resting enzyme, this nickel ion is Ni^{2+}. Transfer of an electron from the [4Fe–4S] iron–sulfur cluster in the entire complex **4–182,** preceding or concurrently with association of carbon monoxide, or association of the protein containing the methyl-Co(III) corrinoid, which also has a [4Fe–4S] iron–sulfur cluster that can provide the necessary electron,[1406] promotes reduction **of the central Ni^{2+} in the trisulfido-dinickel cluster to Ni^{+}**, which is the participant in either the coordination of carbon monoxide or the nucleophilic substitution. This Ni^{+} can also be produced in the active site of the enzyme from *Moorella thermoacetica* by reduction with titanium(III) citrate.[1394]

Whether association of carbon monoxide with Ni^{+} is the first or second step in the reaction of CO-methylating acetyl-CoA synthetase, carbon monoxide arrives at the active site either directly from the solution—in those enzymes that are independent proteins such as the one in *R. rubrum*—or by passing through a tunnel from the active site of anaerobic carbon monoxide dehydrogenase—in those enzymes (Figure 3–69) that are found in multienzymatic

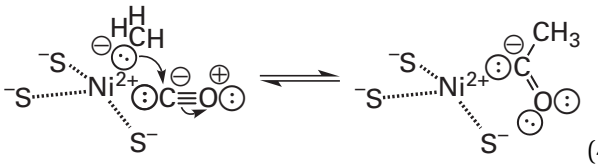
complexes, such as those in *M. thermoacetica* and *M. barkeri*. CO-Methylating acetyl-CoA synthase from *C. hydrogenoformans* can function either as an independent protein or in complex with carbon monoxide dehydrogenase.[1392] At the end of the tunnel in CO-methylating acetyl-CoA synthase from *M. thermoacetica*, immediately adjacent to the two nickel ions in the cluster, there is a cavity that can be occupied by one xenon atom and that is the proper size for a carbon monoxide.[1407] When the cavity is expanded by mutating a phenylalanine in its wall to alanine, the activity of the enzyme decreases by a factor of 10 and the cluster becomes more flexible.[1408] These facts suggest a steric requirement for the active site to hold carbon monoxide firmly during its association with the cluster.

Before CO-methylating acetyl-CoA synthase from *M. thermoacetica* has been methylated by methyl-Co(III) corrinoid, it is possible to form a complex in which one iron ion in the [4Fe–4S] iron–sulfur cluster (see **4–182**), presumably the one closest to the labile nickel ion, has been coordinated by carbon monoxide.[1409,1410] Some kinetic studies are consistent with this carbonmonoxy iron intermediate being a precursor to the acyl carbon and acyl oxygen in the product acetyl-SCoA[1411] while also being consistent with either methylation of the nickel ion or carbonylation of the iron ion being the first step in the normal enzymatic reaction.[1412] The proposal is that before it can add to the methylnickel(II), carbon monoxide must first become a ligand to the iron ion and then be transferred. The situation is complicated by the fact that carbon monoxide inhibits the enzymatic reaction,[1413] and there are other kinetic results consistent with a requirement that the methylation precedes productive association of the carbon monoxide destined to become the carbon and oxygen of the acyl group of acetyl-SCoA.[1398]

Nucleophilic substitution of Ni^+ for the Co(I) corrinoid (Equation 4–457), regardless of whether or not a carbon monoxide is associated with the Ni^+ as a fourth ligand, is a concerted in-line transfer of the methyl group[1414] between cobalt and nickel with inversion of configuration at the methyl group. Although the methyl group in methyl-Co(III) corrinoid bears a formal negative elementary charge because carbon is more electronegative than cobalt, this designation is a formal one and the methyl group on cobalt is actually electrophilic. The nucleophilic substitution requires that the nickel ion be at least as reduced as Ni^+, which is nucleophilic. The leaving group is the Co^+ in Co(I) corrinoid, which is itself (as is the case with all leaving groups) a nucleophile, but less of a nucleophile than Ni^+. Methyl transfer from Co^+ to Ni^+ (Equation 4–457) in the active site of the enzyme from *M. thermoacetica* is rapidly reversible[1415] and has an equilibrium constant of 2.3.

During the nucleophilic substitution, preceding it, or immediately following it, an electron is transferred to nickel, so the final adduct is methylnickel(II), which is diamagnetic.[1405,1415,1416] The order in which the two steps, methylation and transfer of this other electron to Ni^+, occur is not clear. The single nickel atom in a model compound, in which the nickel is Ni^0, readily reacts nucleophilically with a methyl-Co(III) corrinoid, and the product is directly methylnickel(II).[1417] This result suggests that the second electron could be transferred to Ni^+ before the nucleophilic substitution occurs to make it Ni^0, which would be even more nucleophilic. This proposal would explain the fact that paramagnetic methylnickel(III), which would be the product of the nucleophilic substitution in which Ni^+ is the nucleophile (Equation 4–457), has never been observed during the enzymatic reaction.[1399] The Ni^+, however, in the reduced state of a mutant of azurin in which the native copper cation has been replaced with a nickel ion does react with CH_3I to form an adduct, but again methylnickel(III) was not observed. It was believed that the reductant present in the solution to maintain the reduced state of Ni^+-azurin immediately reduced methylnickel(III) as it was formed to diamagnetic methylnickel(II). In this instance, the reductant present was not able to reduce Ni^+-azurin to Ni^0-azurin before the CH_3I was added to the solution, so the nickel in Ni^+-azurin must have been the nucleophile.

Regardless of whether carbonylation of nickel or methylation of nickel is the first step, after both have occurred, the product is a pentacoordinate Ni^{2+} with three sulfido groups, a formal methide ion, and carbon monoxide as the five ligands.[1418] This complex then undergoes formally a nucleophilic addition of the methide ion as the nucleophile to carbon monoxide as the electrophile

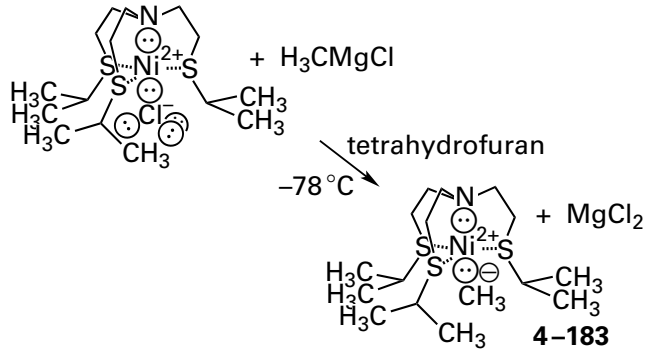


(4–458)

Both the nucleophilic carbon and the electrophilic carbon are ligands to Ni^{2+}, so this addition is a **nucleo-**

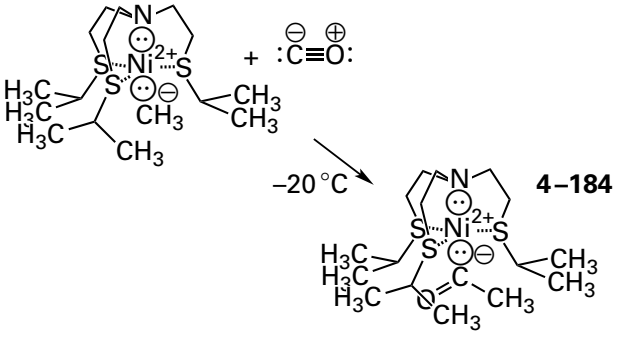
philic addition that takes place in the inner sphere of the metallic dication. This inner-sphere nucleophilic addition produces an acetylnickel(II).[1405]

There is a synthetic model reaction that replicates this methylation of carbon monoxide. A Ni^{2+}, coordinated with a ligand that provides three sulfides and a tertiary amine, was methylated with Grignard reagent



(4–459)

This methylation involves the transfer of the formal equivalent of a methide ion from a hard metal, Mg^{2+}, to a soft metal, Ni^{2+}, and as such it is not a model for the first step in the enzymatic reaction. The methylated Ni^{2+} that is the product, however, is equivalent to the methylnickel(II) produced in the enzymatic reaction. When the synthetic methylnickel(II) is mixed with carbon monoxide, an acetylnickel(II) is produced[1419]



(4–460)

Methylnickel(II) **4–183** and acetylnickel(II) **4–184** have both been crystallized, and the crystallographic molecular models verify their structures.[1420] A similar CO insertion produces an acylnickel(II) from a synthetic alkylnickel(II) in a model compound in which the nickel ion is coordinated by the two sulfido groups of a bisthiolate and a phosphine and in which the alkyl group is larger than a methyl group.[1421]

In the final chemical step in the mechanism, the acetylnickel(II) intermediate in the enzymatic reaction is subjected to a nucleophilic substitution that forms acetyl-SCoA.[1405] In this final nucleophilic substitution, the sulfido group of coenzyme A is the nucleophile and Ni^0 is the leaving group. Because Ni^0, a strong nucleophile, can be considered equivalent to an alkoxide, the acetylnickel(II) intermediate is analogous to an acetyl ester, so it could be the case that there is a tetrahedral intermediate in the reaction, with the oxyanion of the tetrahedral intermediate expelling Ni^0. When synthetic acetylnickel(II) **4–184** is mixed with phenylmethanethiol, a high yield (75%) of the corresponding acetyl thioester is obtained.[1419,1420] Because there seems to be little room for the phenylmethanethiolate to coordinate with the nickel before the acetyl group is transferred to it, it may be the case that, in this particular model system, the sulfido group of the thiolate adds directly to the acyl carbon that is a ligand to Ni^{2+}, forming a tetrahedral intermediate.

In another synthetic model system, however, in which the nickel ion is coordinated at only two sites by a bispyridine, an acetylnickel(II) can be formed by adding an equivalent of carbon monoxide to a square planar complex in which the other two sites are occupied by a methide and a thiolate. A crystallographic molecular model verifies the direct coordination of both the acetyl group and the thiolate in this product. Upon addition of excess carbon monoxide, a strong ligand for Ni^{2+}, the immediately adjacent sulfanyl group on the nickel ion adds in the inner sphere to the acetyl group to produce the acetyl thioester, which is released from the Ni^{2+} as two carbon monoxides associate with it.[1422]

This model reaction suggests that **the $^-$SCoA may first coordinate to Ni^{2+}** in the acetylnickel(II) intermediate in the enzymatic reaction, which has open sites for ligands, before adding to the acetyl group to produce acetyl-SCoA, the product of the overall enzymatic reaction (Equation 4–456). If the sulfur of the sulfido group does become a ligand to Ni^{2+}, this does not happen until the acetylnickel(II) intermediate has formed because HSCoA is the last reactant to associate with the enzyme and does so only after the acetylnickel(II) intermediate is present.[1412] If this intramolecular addition is the mechanism of the enzymatic reaction, rather than a normal nucleophilic substitution in which the nucleophile adds directly to the acyl carbon of the acyl derivative, then there are two steps in the overall mechanism in which a nucleophilic substitution between a nucleophile and an electrophile that are both ligands to Ni^{2+} occurs in the inner sphere. The difficulty with this proposal is that if the sulfido group of

coenzyme A adds to the acetyl group while both are ligands to the Ni^{2+}, then what is to prevent a sulfido group from one of the cysteines that also coordinate the Ni^{2+} from adding to the acetyl group, which would be counterproductive? In fact, in another synthetic model system, where the Ni^{2+} has a bisthiolate and a phosphine as ligands, one sulfido group of the bisthiolate also becomes acetylated upon addition of carbon monoxide,[1421] just as the sulfido group that is a substrate in the other model compound does. Somehow the active site has to prevent this unfortunate side reaction.

The steps in the reaction catalyzed by CO-methylating acetyl-CoA synthase from *M. thermoacetica* between the methylated intermediate and the final product, acetyl-SCoA, are rapidly reversible. When the enzyme is mixed with [1-^{14}C]acetyl-SCoA and [^{12}C]carbon monoxide, [^{14}C]carbon monoxide is formed continuously[1423] at a maximum rate of 440 min^{-1} at pH 6.0 and 55 °C.[1424]

In the model reaction in which acetylnickel(II) **4–184** is mixed with phenylmethanethiol to produce the acetyl thioester, the nickel ends up as Ni^0 and precipitates from the solution as nickel metal, which would certainly be counterproductive in the enzymatic reaction. In order to precipitate as nickel metal, however, the atoms of nickel must be able to collide with each other in solution, which is precluded by the fact that the nickel atoms in the enzymatic reaction are individually buried in active sites in proteins. This protection is similar to the long-term protection that an active site can provide to the sulfenic acid of a cysteine. Sulfenic acids do not exist in free solution because they immediately disproportionate to a thiol and a sulfinic acid, a disproportionation that is precluded when they are located in an active site. Because Ni^0 would be protected by the surroundings of the active site, it could be the case that Ni^0 is stable and able to participate as the nucleophile in the next round of the reaction with the next molecule of methyl-Co(III) corrinoid (see Equation 4–457) and produce methylnickel(II) directly. In this case, no source of electrons would be needed to sustain successive turnovers.

Another possibility, however, is that the [4Fe–4S] iron–sulfur cluster in cluster **4–182**, perhaps in concert with the peripheral nickel ion, instantaneously removes an electron from Ni^0 to return it to Ni^+, which then participates in the next round of the reaction. This electron would then be returned to the Ni^{3+} in methylnickel(III) during its formation or immediately after it is formed by the nucleophilic substitution (Equation 4–457). If these transfers of an electron are the actual sequence of events, the purpose of the other participants in the complete cluster would be to poise the central nickel ion by transferring an electron back and forth so that it is either Ni^+ or methylnickel(II) or acetylnickel(II) while the enzyme is turning over.

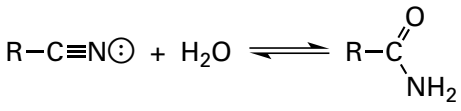
A few enzymes have metallic trications as Lewis acid catalysts in their active sites. For example, in the dinuclear[1425] cluster in the active site of purple acid phosphatase, one position is occupied by Zn^{2+}, Fe^{2+}, or Mn^{2+} depending on the species from which the enzyme is purified,[1426-1430] but the other position is always occupied by Fe^{3+}.[1431,1432] Even though all these enzymes have Fe^{3+} in their active sites, all that is required for catalysis is a metallic trication that can occupy the available coordination because Ga^{3+} can substitute effectively for Fe^{3+}.[1238]

There are at least two problems with using a metallic trication as a Lewis acid. First, the conjugate acid of an alkoxide or hydroxide that is a ligand to a metallic trication has such a low pK_a (Table 4–2) that it is a weak Brønsted base and a weak nucleophile. It is also difficult to hydronate so that it can be used as a Brønsted acid or so that it can leave the metallic trication as an alcohol or a molecule of water. Second, the exchange rates of even a neutral molecule of water at a metallic trication are so slow (Table 4–5) that association of a reactant with or dissociation of a product from the inner sphere of the trication would limit rates of catalysis. These difficulties illustrate the advantages of metallic dications for catalysis.

In the active site of alkaline phosphatase PhoX from *Pseudomonas fluorescens*, an oxide bridges two Fe^{3+} and a Ca^{2+}. In a crystallographic molecular model[1433] of a complex between the enzyme and β,γ-methylene ATP^{4-}, which is a nonhydrolyzable analogue of the substrate ATP^{4-}, two nonbridging oxygens of the γ-phosphono group are ligands to the two Fe^{3+}, and the third nonbridging oxygen is a ligand to the Ca^{2+}. The hydroxide is directed toward phosphorus and oriented for an in-line addition directly opposite the methylene group that represents the leaving group. The two Fe^{3+} are high-spin, but it is not clear how the two nonbridging oxygens are able to exchange into their inner spheres rapidly enough and how the phosphate that is the product of the hydrolysis, which would have three of its oxygens as ligands to the two Fe^{3+}, is able to dissociate rapidly enough to sustain catalysis. That the iron ions must be Fe^{3+} for catalysis to occur is demonstrated by

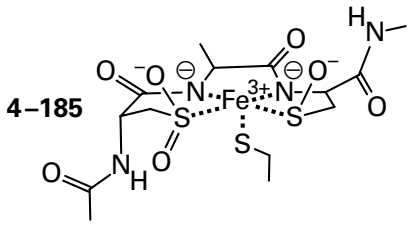
the fact that reduction of both to Fe^{2+} inactivates the enzyme.[1433]

Nitrile hydratase



(4–461)

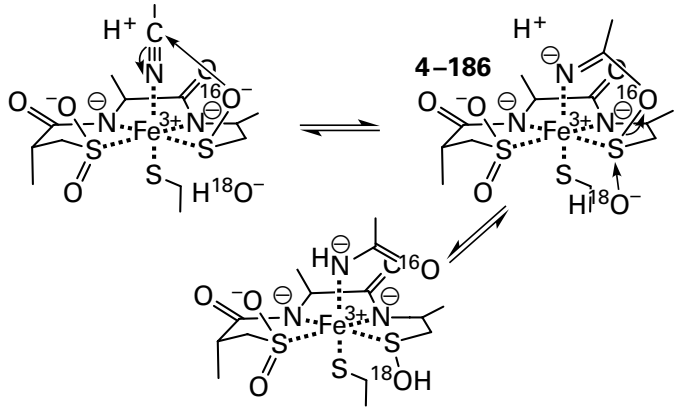
has either Co^{3+} or Fe^{3+} in its active site depending on the species from which the enzyme is purified.[1434] The enzymes with the different metallic trications, however, are very similar (40% identity; 1.0 gap percent), so they must have the same catalytic mechanism. The metallic trications in each unoccupied active site have the same ligands



4–185

which are the sulfanyl group of a cysteine; two unhydronated, negative amido nitrogens from the peptide backbone; a cysteinyl sulfinate ($-SO_2^-$); and a cysteinyl sulfenate ($-SO^-$).[1435-1439] The last ligand is an example of a sulfenate that is protected from disproportionation by being in the active site of an enzyme. The pK_a for a sulfinic acid is around 3 while that of a sulfenic acid is around 12, but the cysteinyl sulfenate has a hydrogen bond to the guanidinio group of an arginine, which should lower its pK_a.

The following mechanism has been proposed[1440] for the hydration catalyzed by the enzymes with Fe^{3+} in their active sites



(4–462)

4–186

and by extension those with Co^{3+} in their active sites. The nitrogen of the nitrile would associate with the metallic trication, and the oxyanion of the sulfenate would add nucleophilically to the carbon of the nitrile. A hydroxide would then perform a nucleophilic substitution at sulfur with the amido oxygen as the leaving group while the amido nitrogen is hydronated by a catalytic acid. The nucleophilic substitution at sulfur is analogous to the nucleophilic substitution of one sulfido group for another in a disulfide.

There are a number of observations consistent with this mechanism. Intermediate **4–186** has been observed in a crystallographic molecular model[1440] of the complex between 2,2-dimethylpropanenitrile, a hindered analogue of the substrate, and the active site of a mutant of the ferric nitrile hydratase from *Rhodococcus erythropolis* in which the arginine that forms the hydrogen bond to sulfenate has been mutated to lysine, decreasing the turnover of the enzyme by a factor of 500. Both 1-butaneboronic acid and phenylboronic acid form adducts[1441] with the oxygen of sulfenate in the active site of cobaltic nitrile hydratase from *P. thermophila.* In these adducts, the boronate is trigonal and isosteric with the amido group in intermediate **4–186**, and the only oxygen from boronic acid that remains is a ligand to the Co^{3+}, as is the nitrogen in the proposed intermediate. When cobaltic nitrile hydratase from *Streptomyces rimosus*, which has been preequilibrated in $H_2{}^{16}O$, is mixed with the nitrile toyocamycin (a natural substrate) in $H_2{}^{18}O$, the hydrated product from the first turnover contains oxygen-16 in the amide, but products from the next turnovers contain oxygen-18. During the first turnover, the enzyme itself covalently incorporates one oxygen-18, but it incorporates no further oxygen-18 in later turnovers.[1442] When iron nitrile hydratase from *Rhodococcus hoagii* was mixed rapidly with 2-methylprop-2-enenitrile, an intermediate appears with a rate constant of 60 $mM^{-1}\,s^{-1}$ and a visible absorption spectrum that has been assigned as that of a complex between nitrile and Fe^{3+} in the active site.[1443]

The problem with the proposed mechanism is rate constants and equilibrium constants. The Fe^{3+} in ferric nitrile hydratase is in the low-spin state.[1444] Ferric iron in its low-spin state and Co^{3+} are usually almost inert to ligand exchange, and since there is only one open site on the prosthetic metallic complexes in the several active sites, that exchange would have to be dissociative. The crystallographic molecular model in which intermediate **4–186** occupied the open position on Fe^{3+} was from a crystal in which each lone open site on Fe^{3+}

was occupied by a molecule of nitric oxide, and a molecule of 2,2-dimethylpropanenitrile occupied a nearby site in the outer sphere.[1440] Nitric oxide then dissociated photolytically and vacated the active site almost immediately. Nevertheless, it took the nitrile more than 25 min ($0.001\ s^{-1}$) at 20 °C to move 1 nm from the site in the outer sphere to the open site on Fe^{3+}. A synthetic complex of Fe^{3+} coordinated by three amino nitrogens and two sulfanyl groups, which is similar to the coordination in the active site of ferric nitrile hydratase, is able to associate with nitriles such as acetonitrile ($K_d = 33$ M at 2 °C; $k_{ex} = 10^5\ s^{-1}$ at 2 °C) and forms an octahedral complex with thiocyanate that could be crystallized.[1445] Most synthetic model compounds, however, with either Fe^{3+} or Co^{3+} that have similar ligands, do not associate with nitriles.[1446-1449] There is a synthetic complex of Co^{3+} that is coordinated by three amino nitrogens, an imino nitrogen, and the sulfido group of a thiolate and that was synthesized with a nitrile at the sixth position.[1450] When the complex is mixed with hydroxide, the nitrile is hydrated with a rate constant of $3\ M^{-1}\ s^{-1}$. The rate, however, for exchange of the nitrile at Co^{3+} is $0.01\ s^{-1}$ at 7 °C. The amide on Co^{3+} that is the product of nucleophilic addition of hydroxide to the nitrile is inert to exchange.

It is unclear how nitrile hydratase can accelerate the exchanges at the single open site on either Fe^{3+} or Co^{3+}, which are required for the mechanism of Equation 4–462, to accommodate rate constants for the turnover of the various enzymes. Such considerations have led to the proposition that the metallic trication, if it is involved in catalysis, must provide a Brønsted acid–base in a reaction at its outer sphere.[1437,1447]

Problem 4–38: Write a mechanism for the complete reaction catalyzed by 4-hydroxy-2-oxoheptanedioate aldolase that uses Mg^{2+} (**4–166**) as a Lewis acid in the active site.

Problem 4–39: Write a mechanism for the complete reaction catalyzed by isocitrate dehydrogenase ($NADP^+$) that uses Mg^{2+} (**4–167**) as a Lewis acid in the active site.

Problem 4–40: Write a mechanism for the complete reaction catalyzed by fumarylacetoacetase (Equation 4–362) that uses Ca^{2+} (**4–168**) as a Lewis acid in the active site.

Problem 4–41: Write a mechanism for the complete reaction catalyzed by fructose-bisphosphate aldolase (Equation 4–210) that uses Zn^{2+} (**4–170**) as a Lewis acid in the active site.

Problem 4–42: Write a mechanism for the complete reaction catalyzed by lactoylglutathione lyase (Equation 4–431) that uses Zn^{2+} (Figure 4–55C) as a Lewis acid in the active site.

Problem 4–43: Write a mechanism for the complete reaction catalyzed by malate synthase (Equation 4–271) that uses Mg^{2+} (**4–155**) as a Lewis acid in the active site.

Problem 4–44: Write a mechanism for the complete reaction catalyzed by peptide deformylase (Equation 4–425) that uses Fe^{2+} (**4–158**) as a Lewis acid in the active site.

Problem 4–45: Write a mechanism for the complete reaction catalyzed by alkaline phosphatase (Equation 4–452) that incorporates the two respective phosphoranes. Include the two Zn^{2+} in each successive structure.

Problem 4–46: The following is a direct quotation from reference 1022.

> Staphylococcal nuclease [micrococcal nuclease] catalyzes the hydrolysis of both DNA and RNA at the 5′ position of the phosphodiester bond yielding a free 5′-hydroxyl group and a 3′-phosphate monoester. The pH optimum is between 8.6 and 10.3 and varies inversely with the Ca^{2+} concentration, but at any pH rather high levels of Ca^{2+}, typically 0.01 M, are required for optimal activity. With minor exceptions, which will be discussed later, Ca^{2+} is required for activity with all substrates and cannot be replaced with other ions, although Ca^{2+} and a number of other ions do promote the binding of various inhibitors. The 5′-*p*-nitrophenyl esters of pdT and pdTp are the simplest known good substrates for the nuclease. Both these esters are hydrolized [sic] at essentially the same rate via P–O bond cleavage of the 5′–C–O–P bond, but the pdTp-based ester has a K_m showing almost two orders of magnitude tighter binding to enzyme. Both the 5′-methyl ester of pdT and thymidine 5′-fluorophosphate are poor substrates. With these simple substrates, the products of enzyme-catalyzed reaction are exclusively *p*-nitrophenyl phosphate and dT or dTp for the first two and methylphosphate or fluorophosphate plus dT for the second two …, a striking and significant contrast to the products of a nonenzymatic hydrolysis of these compounds where *p*-nitrophenol, fluoride ion, or at least some methanol along with pdT or pdTp would result. Simple diesters of phosphate are not substrates, so this enzyme is indeed a nuclease and not a general phosphodiesterase. For a series of dinucleotides, $dN^{\alpha}pdN^{\beta}$, as substrates, there is a distinct order of preference (dT > dA >> dC >> dG) for the base in the β-nucleotide position, but little base specificity in the α-position. The presence of a terminal 3′-phosphate results in a better substrate than the plain dinucleotide; a terminal 5′ phosphate results in a poorer substrate. In the presence of Ca^{2+}, or a wide variety of other metallic dications, pA, pdA, and pdT are good inhibitors ($K_i \cong 10^{-5}$); pdTp is the best known inhibitor ($K_i \cong 10^{-7}$). The binding of the nucleoside 5′-monophosphates involves a single Ca^{2+} ion; the binding of pdTp and of DNA and RNA appears to involve two. Nucleosides themselves and nucleoside 2′- or 3′-monophosphates are not inhibitory. Mapping studies of the active site region with oligonucleotides having a terminal 5′ phosphate $(pdT)_n$, show maximum binding when $n = 3$, suggesting the presence of a third, probably ionic, binding site in addition to those for the 5′- and 3′-phosphates of pdTp. Studies of the interactions among the inhibitors, the simple substrates, DNA, and RNA strongly imply a single, common binding and hydrolytic site on the nuclease, although, as noted elsewhere, there are differences between DNA and RNA as substrates that may indicate different hydrolytic mechanisms.

In the abbreviation used for mononucleotides, a p before the capital letter, such as pdT, stands for a phosphate attached to the 5′-hydroxy group of the ribose; a p after, such as dTp, stands for a phosphate attached to the 3′-hydroxy group. The d stands for 2′-deoxyribose in a 2′-deoxyribonucleotide. The capital letters stand for the various nucleosides.

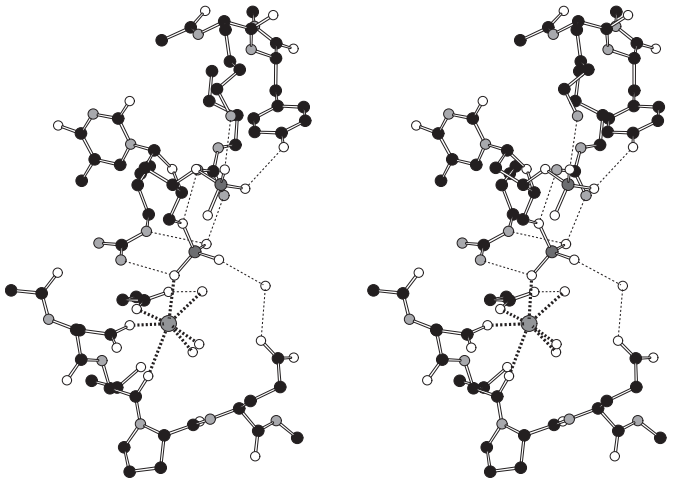
The point of the preceding brief, but fairly comprehensive, review of the enzymological properties of micrococcal nuclease is to establish that the crystal structure of the nuclease–pdTp–Ca^{2+} complex should resemble fairly closely that of the actual enzymatically active complex of micrococcal nuclease, a substrate for the enzyme, and Ca^{2+}. Because a diester will have a single negative elementary charge on the phosphate when it is associated with the hydrolytic site and pdTp has two negative elementary charges on its 5′ phosphate, some difference is, of course, to be expected.

(A) Write the mechanism for hydrolysis of the 5′-(4-nitrophenyl) ester of pdTp, as it would occur during a nonenzymatic reaction that produces 4-nitrophenol and pdTp. Draw your intermediates, for example a phosphorane, with proper stereochemistry.

(B) Why is 4-nitrophenol rather than 4-nitrophenyl phosphate the product of the nonenzymatic reaction?

(C) Write the mechanism for hydrolysis of the 5′-(4-nitrophenyl) ester of pdTp as it would occur under catalysis by micrococcal nuclease, which produces 4-nitrophenyl phosphate and dTp. Draw your intermediates with proper stereochemistry, and include catalytic acids, $HA^{(+)}$, or catalytic bases, $\odot B^{(-)}$, where appropriate.

Crystals of the complex between micrococcal nuclease, Ca^{2+}, and pdTp were submitted to diffraction, and a map of electron density from a data set with minimum Bragg spacing of 0.17 nm was obtained. A molecular model built from the sequence of the protein, the Ca^{2+}, and the known structure of the inhibitor were placed into the map. The stereodrawing of the active site



has been derived from the final refined molecular model.[1021]

(D) The various side chains, inhibitor, and prosthetic groups in the stereodrawing are not identified. Make a copy of one side of the drawing. Expand the scale so that you have plenty of room, and clearly identify with labels each side chain, the inhibitor, and the prosthetic groups. On each hydrogen bond indicated in the figure, draw a hydron next to the donor for that hydrogen bond. Attach a 4-nitrophenyl group to the appropriate oxygen.

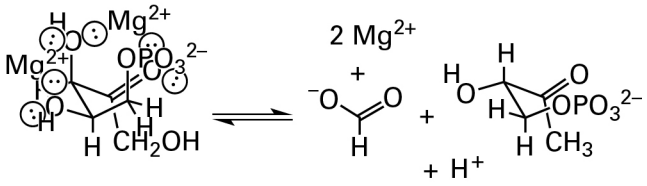
(E) What are the smaller detached, open spheres in the crystallographic molecular model?

(F) Which is the most likely molecule of water for the role of the nucleophile in hydrolysis of 5′-(4-nitrophenyl)pdTp? Write a mechanism for the hydrolysis that uses this molecule of water. What are the catalytic acid–bases activating the molecule of water?

(G) Why is 4-nitrophenyl phosphate rather than 4-nitrophenol the product of the enzymatic reaction? Invoke two rules of phosphate chemistry in your explanation. What must the active site be preventing the phosphorane from undergoing that would enable the best leaving group? Decide which would be the best leaving group by looking up values for pK_a.

(H) What is the identity of the catalytic acid that hydronates the leaving group in the mechanism that you presented in part C? Why is this choice peculiar?

Problem 4–47: 3,4-Dihydroxy-2-butanone-4-phosphate synthase is a metalloenzyme that catalyzes the conversion of D-ribulose 5-phosphate to 3,4-dihydroxybutan-2-one-4-phosphate and formate.

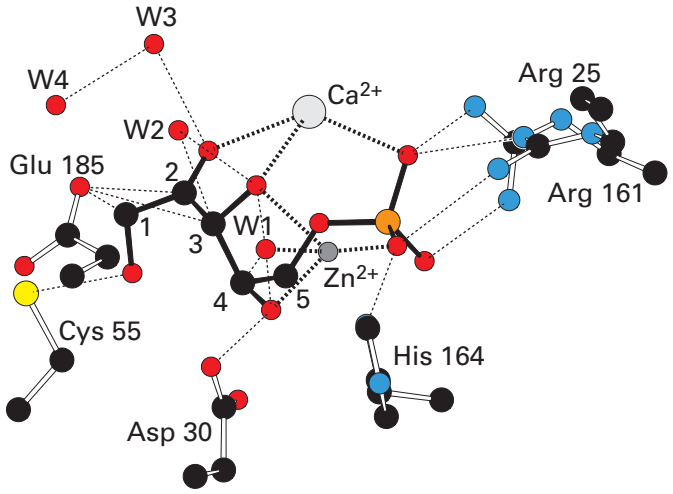


(A) Write a mechanism for the multistep transformation catalyzed by the unmutated enzyme that involves an isomerization proceeding by a 1,2-hydride migration as occurs in xylose isomerase (Equation 4–432), followed by removal of a hydron α to a carbonyl to produce an enolate, a β elimination, a hydronation, a 1,2-phosphomethide migration analogous to a 1,2-methyl migration, and a retro-Claisen condensation.[1337] (Hint: Write the mechanism in reverse first.)

(B) Write an alternative mechanism that lacks the isomerization and 1,2-hydride migration steps but includes the remaining five steps in part A. (Hint: As in part A, write the mechanism in reverse first.)

There is a crystallographic molecular model of a complex of D-ribulose 5-phosphate with a mutant of the enzyme from *M. jannaschii* in which Histidine 147 has been replaced by serine and in which one of the two Mg^{2+} normally in the active site has been replaced with Zn^{2+} and the other Mg^{2+} has been replaced by Ca^{2+} to produce an inactive enzyme. D-Ribulose 5-phosphate coordinates Ca^{2+} with its 2-oxo and 3-hydroxy groups, and it coordinates Zn^{2+} with its 3-hydroxy and 4-hydroxy groups.[882] Recall that, in the unmutated active enzyme, Ca^{2+} and Zn^{2+} are replaced by two Mg^{2+} (**4–178**).

In the following drawing



of a portion of the active site in this crystallographic molecular model, the carbons of D-ribulose 5-phosphate are numbered. The 1-hydroxy group of D-ribulose 5-phosphate forms a hydrogen bond (0.31 nm) with the sulfanyl group of Cysteine 55. The distance (0.34 nm) between carbon 1 and an oxygen in the carboxy group of Glutamate 185 is within van der Waals contact (0.38 nm). The oxygen of the 2-carbonyl group of D-ribulose 5-phosphate is coordinated to Ca^{2+} (see **4–178**) and participates in a hydrogen bond (0.27 nm) with water W3 that in turn forms a hydrogen bond (0.29 nm) with water W4 that in turn is in contact with the bulk solution. The distance (0.35 nm) between carbon 2 and the same oxygen in the carboxy group of Glutamate 185 is within van der Waals contact (0.38 nm). The 3-hydroxy group of D-ribulose 5-phosphate is coordinated to Ca^{2+} and Zn^{2+} (see **4–178**) and forms hydrogen bonds (0.31 and 0.27 nm) with both waters W1 and W2, which in turn form hydrogen bonds with carboxy groups of two glutamates and an aspartate (see **4–178**). The distance (0.32 nm) between carbon 3 and water W2 is within van der Waals contact (0.38 nm). The distance (0.35 nm) between carbon 3 and the same oxygen in the carboxy group of Glutamate 185 is within van der Waals contact (0.38 nm). The 4-hydroxy group of D-ribulose 5-phosphate is coordinated to the Zn^{2+} and forms a hydrogen bond (0.24 nm) with the carboxy group of Aspartate 30 and a hydrogen bond (0.30 nm) with water W1 that is also coordinated to that Zn^{2+}. The distance (0.39 nm) between carbon 4 and water W1 is at van der Waals contact (0.38 nm). Nitrogen τ of Histidine 147 (missing in the drawing because it is the mutated amino acid) forms a hydrogen bond (≥0.29 nm) in a crystallographic molecular model of the unmutated enzyme with the oxygen of the carboxy group of Glutamate 185 that is in contact with carbons 1, 2, and 3 of D-ribulose 5-phosphate.

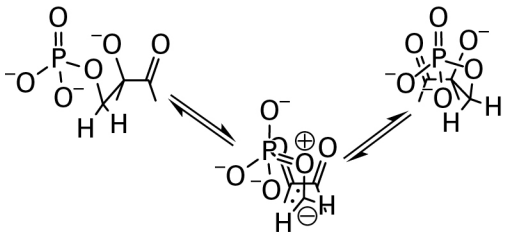
(C) Referring to the drawing from the crystallographic molecular model of the occupied active site in the mutant enzyme, the numbered side chains it contains, and the contacts just described between them and the D-ribulose 5-phosphate, identify the catalytic acid–base that performs the removal or addition of a hydron in each step of your two mechanisms whenever a hydron must be removed or added to an oxygen or a carbon.

(D) Which metallic hydroxide is the nucleophile in the retro-Claisen condensation?

(E) Why does the active site enforce the rotational isomer between carbons 3 and 4 observed in the drawing?

(F) Why does the active site enforce the rotational isomer between carbons 4 and 5 observed in the drawing?

In a 1,2-phosphomethide migration, the carbon migrating carries with it the two electrons in the bond, so formally it bears a negative elementary charge that is stabilized by conjugation to phosphorus. It migrates across the plane of a vicinal dicarbonyl. The carbon from which the phosphomethide leaves becomes a carbonyl, and the oxygen on the carbon to which it adds becomes a hydroxy group.



(G) Discuss the several ways in which the active site encourages the 1,2-phosphomethide migration both sterically and electronically.
