Inclusive Charged-Particle Distribution in Nearly Threefold-Symmetric
Three-Jet Events at $E_{\text{c.m.}} = 29$ GeV

(Received 11 September 1985)

We report a measurement of the inclusive charged-particle distribution for gluon jets derived from nearly threefold-symmetric three-jet events taken at center-of-mass energy of 29 GeV in $e^+ e^-$ annihilation. The charged-particle spectrum for these jets is observed to fall off more rapidly than those of quark jets of the same energy.

PACS numbers: 13.65.+i

Quantum chromodynamics (QCD) successfully accounts for many features observed in high-energy $e^+ e^-$ annihilation data, examples of which include violation of scaling in inclusive particle distributions, jet broadening, and multijet events. In the world of QCD, the sources of the experimentally observed jets are quarks and gluons. Jets initiated by quarks or antiquarks have been studied in great detail in various experiments. However, little is known experimentally about jets which originate from high-energy gluons. Bartel et al. have presented evidence that particle distributions in three-jet events which originate from hard-gluon bremsstrahlung ($e^+ e^- \rightarrow q\bar{q}g$) are only described by models in which gluon jets have a broader and softer fragmentation than quark jets of the same energy. Suggestions of differences between quark and gluon jets are now also reported by Ghez et al. for $p\bar{p}$ collisions.

In this Letter, we study inclusive charged-particle production in three-jet events with nearly threefold symmetry under the assumption that the distributions originate from two quark jets and one gluon jet. Although the production of such symmetric events is small, this requirement has the following advantages: All three jets have nearly the same energy ($\approx \frac{1}{3} E_{\text{c.m.}}$ where $E_{\text{c.m.}}$ is the center-of-mass energy), the jets have the best possible angular separation, and the gluon jet has a relatively high energy. It has been shown that quark and gluon jets do not fragment totally independently in an event, but these results indicate that it is mainly the soft particles which are affected, whereas the high-momentum particles are produced nearly independently. Hence, it is interesting to compare the particle distributions of the above mentioned three-jet events with distributions of events originating from quark jets having the same jet energies.

The data sample used in this measurement was collected on the PEP storage ring at SLAC by the Mark II detector at $E_{\text{c.m.}} = 29$ GeV. The total integrated luminosity of 215 pb$^{-1}$ corresponds to the production of approximately 90,000 hadronic events. A precise measurement of the inclusive charged-particle cross section for all events was presented in an earlier paper from a subset of these data.

The Mark II detector has been described in detail elsewhere. Both the inner and main drift chambers are used in charged-track reconstruction and provide a momentum resolution of $(\delta p/p)^2 = 0.025^2 + (0.01p)^2$ (p is the particle momentum in GeV/c). The track-selection criteria are the following: A well-reconstructed charged track has to pass within 1.6 mm in radius (distance of closest approach) and 60 mm in z from the event vertex and have at least 100 MeV/c of transverse momentum. The measured momentum is corrected for energy loss in the material in front of the tracking chambers with the assumption that the particle is a pion. Neutral particles assumed to be photons are detected by the central-region lead–liquid-argon calorimeter modules, which are 14 radiation lengths in depth. A neutral cluster with energy greater than 150 MeV and a distance (at the radius of the shower counter) of more than 300 mm from the closest charged track is defined as a photon.

Hadronic events were selected by the requirement of at least five well-reconstructed charged tracks, a total charged energy greater than 27.5%, and a total charged and neutral energy greater than 55% of $E_{\text{c.m.}}$.

The eigenvalues of the sphericity tensor are used to classify the events according to their shape in momentum space. For each event the eigenvalues \( Q_1, Q_2, \) and \( Q_3 \) (\( Q_1 < Q_2 < Q_3 \)) and the corresponding principal axes \( q_1, q_2, \) and \( q_3 \) of the momentum ellipsoid are calculated. The sphericity axis \( q_3 \) is required to have an angle \( \Theta_3 \) with respect to the beam axis such that \( |\cos \Theta_3| < 0.7 \). Obvious two-jet events with normalized eigenvalues \( Q_1 < 0.06 \) and \( Q_2 - Q_1 < 0.05 \) are excluded. A cluster algorithm, which uses the vector momenta of charged and neutral particles, is used to partition the data into \( n \)-jet events. Only the three-jet events are retained. Each jet is required to have at least 2 GeV of observed energy and to contain at least three (charged or neutral) particles.

The jet axes are defined by the vector sum of the particle momenta within each jet. On the assumption of three massless partons the jet energies \( E_j \) are calculated from the angles between the jet axes projected onto the event plane \( (q_2, q_3) \). To require almost threefold symmetry for the three-jet events, all three angles between the jet axes are required to lie between 100° and 140°. After these selection criteria the data sample consists of 560 events, corresponding to about 0.5% of all hadronic events.

Monte Carlo calculations using models containing QCD plus fragmentation estimate a background of \((0.4 \pm 0.2)\%\), mainly from the process \( e^+e^- \rightarrow q\bar{q}\gamma \) where some low-momentum charged particles are produced in the direction of the photon, thereby simulating a third jet. The model calculations show further that the fraction of heavy quarks in this sample is the same fraction as for all hadronic events.

The inclusive charged-particle distribution is analyzed in terms of the fractional momentum \( x_i = p_i/E_j \), where \( p_i \) is the momentum of particle \( i \), and \( E_j \) the energy of the jet to which it is assigned. The fact that all three jets have nearly the same energy, implies that a wrong assignment of a particle to a jet is not a severe problem.

Corrections for detector inefficiencies were computed from Monte Carlo simulations based on three different models for QCD plus fragmentation: the independent-parton-fragmentation model of Ali et al. and the Lund string model, both of which employ parton emission to second order in \( \alpha_s \), and the QCD cluster model of Marchesini and Webber, which uses leading-logarithm evolution for the parton showering including soft-gluon interferences and cluster decay for the final hadronization. As a first step, Monte Carlo events were generated without QED radiative effects and passed through the above-mentioned cuts to yield \( N_{\text{gen}} \) events. These events yield the distribution \( n_{\text{gen}}(x) \) of all long-lived, charged particles with lifetimes greater than \( 3 \times 10^{-10} \) s, produced either at the primary vertex or from the decay of short-lived particles including \( K \) and \( \Lambda \). Secondly, events were generated with QED radiative effects included and traced through the detector. Energy loss, multiple scattering, photon conversion, and nuclear interactions in the material of the detector as well as decays were taken into account. This information was then converted into the measured quantities, such as drift times and pulse heights, taking the properties of the apparatus into account. The events were then passed through the same reconstruction algorithms and analysis used for the real data, yielding \( N_{\text{det}} \) accepted events and producing the particle distribution \( n_{\text{det}}(x) \). The correction factors \( C(x) \) are calculated as

\[
C(x) = \frac{n_{\text{det}}(x)}{n_{\text{gen}}(x)} \frac{n_{\text{gen}}(x)}{N_{\text{gen}}} \quad \text{(1)}
\]

\( C(x) \) increases slightly from 0.85 at low \( x \) values to 0.92 at high \( x \) values.

To determine the systematic uncertainties in the correction, the different models were used and the cuts on \( \cos \Theta_3 \) and the angles between the jet axes were varied slightly. As an additional check, the axis corresponding to the smallest eigenvalue of the sphericity tensor \( (q_3) \) was restricted to \( |\cos \Theta_3| > 0.7 \) with respect to the beam axis, so that the total event plane is in the well-instrumented area of the detector. The uncertainty in the correction factor is estimated to vary from \( \pm 0.03 \) at low \( x \) to \( \pm 0.10 \) for \( x > 0.5 \). Figure 1 shows the corrected \( x \) distribution (filled circles), where the errors include both statistics and the uncertainty in the correction factor.

To compare this \( x \) distribution originating from events containing two quark jets and one gluon jet, each with approximately 9 GeV of energy, with \( x \) dis-

![Figure 1](image-url)
tributions coming from events containing two quark jets each with about 9 GeV, we use the published data from Bender et al.\textsuperscript{14} at $E_{\text{c.m.}} = 29$ GeV, Bartel et al.\textsuperscript{15} and Brandelik et al.\textsuperscript{16} both at $E_{\text{c.m.}} = 14, 22,$ and 34 GeV, and Patrick et al.\textsuperscript{4} (Mark II) at $E_{\text{c.m.}} = 5.2, 6.5,$ and 29 GeV. In Fig. 2 all of these cross sections are presented in the form $(1/N_{\text{jet} \sigma_{\text{tot}}}) d\sigma/dx$ vs $E_{\text{c.m.}}/N_{\text{jet}}$ where $N_{\text{jet}}$, the number of jets, is set to two. Within a fixed $x$ interval, all of the data points with $N_{\text{jet}} = 2$ are fitted by the form suggested by QCD\textsuperscript{17}:

$$\frac{1}{\sigma_{\text{tot}}} \frac{d\sigma}{dx} = c_1(x) \left[ 1 + c_2(x) \ln(s) \right],$$

where $c_1(x)$ and $c_2(x)$ are free parameters. The resulting fits are represented by the curves in Fig. 2. Large deviations between the different data points are only visible for low $x$ values, probably because of higher background problems for low-momentum tracks.

The cross section of the symmetric three-jet events with $N_{\text{jet}} = 3$ is also plotted in Fig. 2. The deviations between these points and the fitted curves (or the data points with $N_{\text{jet}} = 2$ themselves) suggest a different slope in the $x$ distribution between two-jet and three-jet events of the same jet energy.

The results of the fits within the twelve intervals from Fig. 2 are used to interpolate the cross section at $E_{\text{c.m.}} = 19.3$ GeV. This is shown in Fig. 1 as a dashed curve. The three-jet distribution is observed to fall off faster than that of quark jets, indicated by the curve.

To extract to first approximation an inclusive charged-particle distribution for a gluon jet of $E = 9$ GeV energy, we adopted the following Ansatz:

$$\frac{1}{\sigma_{\text{tot}}} \frac{d\sigma}{dx} \text{(gluon jets)} = \frac{1}{\sigma_{\text{tot}}} \frac{d\sigma}{dx} \text{(three \text{- jet events, } E_{\text{c.m.}} = 29 GeV)}$$

$$- \frac{1}{\sigma_{\text{tot}}} \frac{d\sigma}{dx} \text{(all events, } E_{\text{c.m.}} = 19.3 \text{ GeV}),$$

where for the events at $E_{\text{c.m.}} = 19.3$ GeV the fit results are again used. This cross section is also shown in Fig. 1 (open circles).

Another way of displaying the data is to calculate the ratio

$$r(x) = \frac{(3\sigma_{\text{tot}})(d\sigma/dx)(\text{three-jet events, } E_{\text{c.m.}} = 29 \text{ GeV})}{(1/2\sigma_{\text{tot}})(d\sigma/dx)(\text{all events, } E_{\text{c.m.}} = 19.3 \text{ GeV})}$$

as a function of $x$, which is shown in Fig. 3.

For comparison, the results of calculations for the three models are also indicated in Fig. 3. The quantity $r(x)$ is used for comparison with the models because many of the model parameters and inputs governing the fragmentation are common to the three-jet final state at 29 GeV and the two-jet final state at 19.3 GeV. The effects of the inadequacies in the model features are greatly reduced when the ratio is taken and hence $r(x)$ should be relatively insensitive to how the models are optimized. We have checked that $r(x)$ stays relatively stable in the three models even if the $x$ distributions themselves are changed drastically by adjustment of the model features governing the fragmentation process.

The model of Ali et al. and Lund model do not account well for the trend of the data. A large part of the disagreement comes from the fact that these models use finite order (second order) for the parton generation. The numerator in $r(x)$ receives only one order of parton radiation because the first-order process is used to generate the three-parton state. The differences between the two models themselves are mainly due to different assumptions about the gluon fragmentation and the method used to distinguish between two-, three-, and four-parton events.

On the other hand, the model of Marchesini and
Webber, which uses leading-logarithm evolution for the parton radiation, accounting for multiple-parton emission in a more complete way, represents the trend of the data well.

In conclusion, we have measured the $x$ distribution for charged particles in nearly threefold-symmetric three-jet events produced in $e^+e^-$ annihilation at 29 GeV. On the assumption that these events originate from the quark-antiquark-gluon parton state and using published data on $x$ distributions from quark fragmentation, we have obtained the $x$ distribution for gluon jets of 9 GeV energy. When compared with quark jets of the same energy, the gluon $x$ distribution appears to fall off more rapidly for $x > 0.4$.

We would like to thank T. Sjöstrand for fruitful discussions about the different models. This work was supported in part by the U. S. 9Model calculations show that the reproduction of the original parton energy is improved by use of $E_j$ instead of just $E_{cm}/3$. The resolution for $E_j$ is about 1 GeV.
