Abstract—Double patterning lithography (DPL) is in current production for memory products, and is widely viewed as inevitable for logic products at the 32nm node. DPL decomposes and prints the shapes of a critical-layer layout in two exposures. In traditional single-exposure lithography, adjacent identical layout features will have identical mean critical dimension (CD), and spatially correlated CD variations. However, with DPL, adjacent features can have distinct mean CDs, and uncorrelated CD variations. This introduces a new set of ‘bimodal’ challenges for timing analysis and optimization. We assess the potential impact of DPL on timing analysis error and guardbanding, and find that the traditional ‘unimodal’ characterization and analysis framework may not be viable for DPL. For example, using 45nm models, we find that different DPL mask layout solutions can cause 50ps skew in clock distribution that is unseen by traditional analyses. Different mask layouts can also result in 20% or more change in timing path delays. Such results lead to insights into physical design optimizations for clock and data path placement and mask coloring that can help mitigate the error and guardband costs of DPL.

I. INTRODUCTION

Double Patterning Lithography (DPL) [2] [3] allows 32nm half-pitch logic patterning using 193nm ArF lithography tools. DPL partitions a critical-layer layout into two mask layouts and exposures, each with relaxed critical pitch and spacing. DPL incurs a throughput overhead, and necessitates tight overlay control between the two exposures. However, there is likely no other solution for logic patterning at 32nm [1], and indeed DPL is already in production for leading-edge memory products.

In DPL, lines, or spaces between lines, are printed in two sequential processes. Thus, CDs of adjacent lines or spaces can have different mean and sigma values. The existence of two different CD populations loses the spatial correlation that is so helpful in on-chip variation aware timing analysis (as well as statistical timing analysis), and results in a ‘bimodal’ CD distribution.

Currently, three main technology options exist for DPL: double exposure, double patterning, and spacer double patterning [8], [9]. The mechanism leading to a bimodal CD distribution, and its overall significance, will differ according to the technology option. Accordingly, we now briefly review the three DPL technology options.

Double exposure. The double exposure DPL technique creates trenches at twice the resolution of normal lithography, using two successive exposure steps. Since double exposure DPL ends up printing spaces, rather than printing target line shapes, it is called a negative dual trench process [4]. One edge of a target line is formed with the first exposure, and the other edge is generated with the second exposure, as shown in Figure 1. Both edges of two adjacent lines facing each other are formed at the same time. Hence, although, e.g., an exposure dose variation can result in an edge placement error, both lines will be affected by the same amount, and CDs of adjacent lines remain identical, as shown in Figure 1(b). However, in the presence of misalignment, CDs of adjacent lines can differ by the amount of the misalignment error, as shown in Figure 1(c).

We note that while double exposure DPL entails a relatively simple process, the fact that CDs are determined by misalignment (overlay) error reduces the technique’s viability. This is because the roadmap for overlay control capability is significantly looser than the general CD control capability requirement (e.g., the 2007 ITRS predicts overlay control capability for 45nm to be as large as 9nm [10]).

Double patterning. Double patterning DPL creates lines at twice the normally achievable resolution, using a LELE (litho-etch-litho-etch) process. At the first etch step, the patterns of the first resist layer are transferred to an underlying hard mask. Photoresist is then coated onto the surface remaining after the first process, and is then exposed in the second exposure step. The flow finishes up with the hard mask that prints one line and the resist of the second exposure that prints the other line. In double patterning DPL, the two edges of a line that are printed by the first etch and the second exposure, and the two edges of the adjacent line that are printed by the second exposure and etch process, can be different; this is shown in Figure 2(a). While the first patterns are made on a perfectly flat wafer, the second resist is coated onto a topography that is a result of the overetch of the first patterning step. The topography implies greater depth of focus (DOF) variation, so that the CDs between the first and the second patterns can be different. Plasma exposure of the first line during the second etch could additionally cause CD change. For these reasons, CDs of critical features will have a bimodal distribution.

Unlike the double exposure process, double patterning DPL will have two different CD populations due to the CD control error, as shown in Figure 2(b). Since misalignment error just shifts the line, without changing the linewidth, misalignment itself does not matter; this is illustrated in Figure 2(c). The 2007 ITRS [10]
roadmap indicates that CD control capability is much better than overlay control capability (e.g., the CD control target for 45nm is 1.9nm). We thus expect that double patterning will have smaller CD difference between adjacent lines than double exposure.

Fig. 2. LELE double patterning DPL.

Spacer double patterning. The third DPL technology option is due to [8], [9], who proposed another methodology of double patterning by use of sacrificial spacer technology. Figure 3 shows a conceptual flow of the spacer double patterning DPL process. Similar to LELE double patterning, spacer double patterning prints target lines instead of edges. Therefore, given a well-controlled spacer generation and etch process, the CD difference between adjacent lines can be maintained to be as small as the CD control capability, even in the presence of misalignment error.

Fig. 3. Sacrificial spacer double patterning DPL.

The remainder of our paper is organized as follows. In Section II, we describe the ‘bimodal challenge’ from DPL. In Section III, we experimentally assess the impact of bimodal CD distribution on timing delay and slack. Section IV then describes potential courses of action for the industry as standards and flows are evolved to address the bimodal challenge, and finally, Section V gives conclusions.

II. THE ‘BIMODAL CHALLENGE’

Figure 4(a) shows a bimodal CD distribution for 32nm technology measured from 24 wafers processed by DPL [4]. Figure 4(b) shows a simplified illustration of the bimodal CD distribution, in which two CD groups have independent mean and sigma values. The bimodal CD distribution affects design timing as follows.

Loss of spatial correlation. The existence of two independent CD populations in a design take away the presumptions of spatial correlation that has always been used to reduce pessimism in corner-based timing analysis. For example, consider two closely placed, identical inverters made with different steps of double patterning DPL – i.e., one inverter is made by the first litho-etch step and the other is made by the second litho-etch step. These two inverters can have different gate CDs, so that their electrical characteristics, such as delay and power, can also be extremely different from each other despite being adjacent in the same die.

In general, within-die variations are taken into account by on-chip variation (OCV) models or by statistical timing analysis flows. Bimodal CD distribution can also be treated as an additional variation source. However, the important problem that we address in this work is that the size of the variation from the bimodal CD distribution can be very large, e.g., over 8% of mean CD difference between the groups, as shown in Figure 4(a); therefore, designers must consider more extreme within-die variations during timing optimization as a direct consequence of DPL.

Increase of overall CD variation. Unless the two CD populations have the same mean values, overall CD variation must be increased with DPL. Dusa et al. propose the use of a unimodal representation pooled from the bimodal CD distribution [4], specifically,

\[3\sigma_{CD,pooled}^2 = \left(\frac{3\sigma_{CD,G1}}{2}\right)^2 + \left(\frac{3\sigma_{CD,G2}}{2}\right)^2 + \left(\frac{3}{2}(\mu_{CD,G1} - \mu_{CD,G2})\right)^2\]  

(1)

where G1 and G2 are the two different groups of CD populations. Dusa et al. observed about 20% of 3σ CD variation to the mean CD from the pooled CD model for 32nm DPL process. Table I shows, for various CD mean differences between G1 and G2, the CD mean and sigma values for the bimodal distribution, and for the corresponding unimodal distributions as calculated using Equation (1) for 50nm target CD.

As seen in the table, overall CD variation of the unimodal representation in Column 4 increases with the increasing mean difference between CD groups. This increased variation will necessarily increase the guardband of the process; Jeong et al. [7] recently showed how this in turn will worsen optimization and design closure runtimes, as well as standard design metrics such as area, wirelength, violations, etc.

To deal with the challenges presented by the bimodal CD distribution, novel timing analysis and optimization methodologies are required. In the following, we assess the potential timing analysis problems inherent in DPL designs, and propose bimodal-aware timing analysis and timing optimization methodologies.

### III. IMPACTS OF BIMODAL CD DISTRIBUTION ON TIMING

In this section, we analyze the timing problems that arise from a bimodal CD distribution. In our discussion, we refer to the different CD distributions as corresponding to the different colorings (i.e., mask exposures) of the gate polys in a cell layout. In DPL coloring, adjacent minimum-pitch poly lines must be colored differently. Thus, a cell can have (at least) two basic versions according to its coloring sequence, as shown in Figure 5. To distinguish between these different colorings, we use $M_{12}$ (respectively, $M_{21}$) to refer to a cell in which the first or leftmost$^1$ poly is colored by CD group 1 (respectively, CD group 2), the second poly is colored by CD group 2 (CD group 1), and so on. It is important to note that regardless of whether a cell has an odd number of polys or an even number of polys, there will exist two different colorings for the cell, based on which color is assigned to the first (leftmost) poly. We discuss two key impacts of the bimodal CD distribution: on path delay variation, and on timing slack variation.

![Fig. 5. Example of two different DPL colorings for a NOR3 cell.](image-url)

#### A. Path Delay Variation in DPL

Every cell instance in a design can be colored differently according to its location and the surrounding cell instances. Therefore, instances of the same master cell in a timing path can be differently colored, and can have different electrical behaviors. As mentioned in Section II above, due to the loss of the spatial correlation between differently colored cells, delays across cell types ($M_{12}$ and $M_{21}$) in a path can vary randomly or with less correlation, even while cells of the same type coloring have strong correlation. Finding the path delay variation of a timing path in the presence of bimodal CD distribution requires solution of the following problem formulation.

**Bimodal Path Delay Variation Analysis:** Given $m$ cells $g_i$ of $M_{12}$ type and $n$ cells $q_j$ of $M_{21}$ type in a timing path, determine the delay variation of the timing path, subject to the constraints:

(a) $\min_{i,j} \text{cov}(g_i, g_j) > \max_{i,j} \text{cov}(g_i, q_j)\)

(b) $\min_{i,j} \text{cov}(q_i, q_j) > \max_{i,j} \text{cov}(g_i, q_j)\)

According to the constraints, the covariance between cells in the same group is larger than than the covariance between cells in different groups.

The delay variation of a delay path is:

$$\sigma^2(d(path)) = \sigma^2(\sum_i (d(g_i))) + \sum_i \sigma^2(d(g_i)) + 2 \sum_{i,j} \text{cov}(g_i, g_j) + 2 \sum_{i,j} \text{cov}(g_i, q_j) + 2 \sum_{i,j} \text{cov}(q_i, q_j)$$

From Equation (2), since $\text{cov}(g_i, q_j)$ is small (e.g., zero in the case of no correlation), the path delay variation for a path composed of uncorrelated different types of cells is smaller than that of a path composed of only correlated cells.

Recall that for the DPL process, patterns are first partitioned into two groups, and that the two groups are each assigned a distinct color. The constraint is that same-color patterns should not be placed within the minimum distance that is permitted by the litho and etch equipment. According to the placement locations, orientations and the neighboring cells, a cell can be colored in different ways. Figure 6 shows the delay variation of 4-stage inverter chains (a) and buffer chains (b), for all possible colorings of cells. We measure the delay of the timing paths across the four combinations of extreme CD corners (Min and Max CD values for each CD group). Note that even for such a simple timing path, the number of required timing analyses in the DPL regime increases exponentially with the number of stages.

For this experiment, we use the 45nm bulk CMOS SPICE model from the University of Arizona’s Predictive Technology Model website [11] and 45nm circuits from NANGATE’s Open Cell Libraries [12]. We assume the CD values of each CD group have perfect spatial correlation, only to isolate the impact of bimodality as well as to reduce the number of experiments. The number of configurations of each path, accounting for different colorings and process corners, is $4 \cdot 2^4 = 64$. Table II shows all possible process corners (Column 1), and all possible coloring sequences (Column 2), in the 4-stage inverter and buffer chains.

We assume the CD variation within each CD group to be 2nm, which is comparable to the ITRS predicted value for CD control in the 45nm node, i.e., 1.9nm [10]. Finally, we measure the delay

$^1$As noted in the earlier review of double exposure DPL technology, since overlay control in the 45nm node is 9nm, it is hard to use the negative double exposure process in light of the CD variation requirement. Hence, we do not consider the negative correlation between CD groups that would result with double exposure DPL, and we assume that CD variation is determined only by CD control capability.
of the 64 different path configurations while sweeping the mean difference between CD group1 and CD group2 from 0nm to 6nm. We also compare the delay estimated from the pooled unimodal CD model (ref. Table I) with those from the actual bimodal CD model. The upper Figure 6(a) shows the delay variation of a buffer chain, while the lower figure (b) shows the delay variation of an inverter chain. The x-axis shows the different coloring sequences of cells, and the legends in the figure show the combinations of the process corners for each CD group, i.e., MAX-MAX, MIN-MIN, MIN-MAX and MAX-MIN. From this study, we observe that for most cases, the delay values are within the boundary of the delay at the MAX-MAX and MIN-MIN corners, and that most results from bimodal analysis are within the window established by the pooled unimodal model. However, not all cases are covered by the pooled model when the mean CD difference between the two groups is 0nm. In addition, delay variation increases when the mean difference between the two CD groups increases.

Note that the delay variation of pooled unimodal cases becomes significantly larger than that for the bimodal cases, when the mean CD difference becomes nonzero, as shown in Figure 6(b). This immediately raises the question as to whether the pessimism of a pooled unimodal delay model (i.e., today’s standard practice) will be too costly in the DPL regime. We also observe that for skewed processes (MAX-MIN or MIN-MAX), delay variation across all the path configurations is larger than for MAX-MAX or MIN-MIN.

Figure 7 shows delay variations of a 16-stage inverter chain, normalized to mean values. Here, only four (out of $2^{16}$) path colorings are studied: (i) M1-only, (ii) M1-M2-M1-... alternation, (iii) M2-M1-M2-... alternation, and (iv) M2-only. As is implied by Equation (2), the alternatively colored paths show smaller variations. This suggests the possibility of 'self-compensation' - in the sense of deliberate balancing of cell colorings in timing paths - to reduce delay variation.\(^3\)

B. Timing Slack Variation in DPL

While path delay variation can be reduced by the bimodal CD distribution, we find a very different situation with variation of timing slack - which is the most important parameter for design timing. Timing slack $T_{slack}$ of the design is defined by

$$T_{slack} = T_{clock} + T_{cycle} - T_{data}$$

The variation of the timing slack is calculated by

$$\sigma^2_{T_{slack}} = \sigma^2_{T_{clock}} + \sigma^2_{T_{data}} - 2\text{cov}(T_{clock}, T_{data})$$

The upper Figure 6(a) shows the delay variation of a buffer chain, while the lower figure (b) shows the delay variation of an inverter chain. The x-axis shows the different coloring sequences of cells, and the legends in the figure show the combinations of the process corners for each CD group, i.e., MAX-MAX, MIN-MIN, MIN-MAX and MAX-MIN. From this study, we observe that for most cases, the delay values are within the boundary of the delay at the MAX-MAX and MIN-MIN corners, and that most results from bimodal analysis are within the window established by the pooled unimodal model. However, not all cases are covered by the pooled model when the mean CD difference between the two groups is 0nm. In addition, delay variation increases when the mean difference between the two CD groups increases.

Table II: Path configurations for 4-stage inverter and buffer chains.
the covariance term will be reduced to zero, so that timing slack variation becomes a sum of clock path and data path variations. To meet signoff timing constraints with this increased slack variation in DPL, designs will require more stringent and difficult timing optimization.

We illustrate this concept with Figure 8, which portrays the slack calculation for the traditional single-exposure process in (a), and for the DPL process in (b). In this simple example, we assume that nominal delay of both clock and data path are 10ns, and, following the analysis of path delay variation in Equation (2), we assume that DPL has smaller delay variation than the single exposure, e.g., ±5ns for single exposure and ±2ns for DPL.

For a design to operate correctly, data signals must be carried from one flip-flop (launching flip-flop) to the next flip-flop (capturing flip-flop) once per each clock cycle. The timing slacks for setup and hold time are defined by:

- setup timing slack

\[ T_{\text{AAT,setup}} = T_{\text{launch}} + T_{\text{data}} \] (5)

\[ T_{\text{RAT,setup}} = T_{\text{capture}} + T_{\text{cycle}} - T_{\text{setup}} \] (6)

\[ T_{\text{slack,setup}} = T_{\text{RAT,setup}} - T_{\text{AAT,setup}} \] (7)

\[ = (T_{\text{capture}} - T_{\text{launch}}) + T_{\text{cycle}} - T_{\text{setup}} - T_{\text{data}} \geq 0 \]

- hold timing slack

\[ T_{\text{AAT,hold}} = T_{\text{launch}} + T_{\text{data}} \] (8)

\[ T_{\text{RAT,hold}} = T_{\text{capture}} + T_{\text{hold}} \] (9)

\[ T_{\text{slack,hold}} = T_{\text{RAT,hold}} - T_{\text{AAT,hold}} \] (10)

\[ = (T_{\text{launch}} - T_{\text{capture}}) + T_{\text{data}} - T_{\text{hold}} \leq 0 \]

The difference of delays between launching and capturing clock paths, i.e., clock skew, plays an important role in both the setup and hold timing slacks. If \( T_{\text{capture}} \) is greater (resp. smaller) than \( T_{\text{launch}} \), this increases (decreases) setup time slack but decreases (increases) hold time slack regardless of data path delay. Therefore, however well one optimizes the circuit to have zero slack, an unbalanced clock network can create clock skew and cause timing problems by either setup or hold time violations. Figure 9 shows the maximum skew that occurs as a result of the bimodal CD distribution, across the path coloring cases shown in Table III. Note that the clock skew is originally designed to be zero. Intuitively, we can expect that there is no clock skew when the coloring configurations of both clock paths are the same, i.e., Cases 1, 2 and 5. However, even when the mean difference between two CD groups is zero, Cases 3 and 4 show substantial clock skew due to the different coloring of launching and capturing clock paths, and the skew increases when the mean CD difference increases. The maximum clock skews of Cases 3 and 4 with 0nm mean CD difference are 22.7ps for each, and these skews increase up to 52.2ps and 53.4ps, respectively, with 6nm mean difference. Another implication of Figure 9 is that the pooled unimodal CD representation cannot

We use the standard acronyms of AAT for actual arrival time, and RAT for required arrival time.
discern the potential skew-related timing problems in DPL designs, even though the pooled model accounts for the physical distribution of CDs, and is very pessimistic with respect to CD corners. This is because the pooled CD model cannot distinguish the colorings of paths.

IV. IMPLICATIONS OF BIMODAL CD DISTRIBUTION TO DESIGN PROCESS

DPL can double the resolution of optical lithography, in comparison to the traditional single-exposure process, and is a likely technology solution for 32nm patterning. However, our results strongly suggest that to incorporate DPL into production, the bimodal CD distribution must be dealt with accurately in both analysis and optimization. Even as the traditional timing flow undergoes substantial changes today, DPL-awareness appears to be a looming key issue. In this section, we give some considerations for future courses of action by which the industry can respond to bimodal and uncorrelated distributions of device behaviors in the DPL context.

1. Device and device parameter extraction. With respect to device modeling and device parameter extraction, the device parameters of the process must capture the reality of bimodal CD variation. Existing methodology and infrastructure allows modeling via a pooled unimodal CD model, but our timing analyses in Section III show that the pooled unimodal description is likely too pessimistic. As noted above, the cost of guardband pessimism can be high [7]. Production methodology at 32nm should permit each printed transistor (finger) to independently reference the appropriate model card. To correctly extract devices from the layout, another mask layer is required to distinguish transistors in G1 and G2, and each type of device must correspond to its model within the bimodal-aware SPICE modeling. Orthogonally, accurate control and measurement of mean difference between the two CD populations are required to reduce pessimism.

2. Cell characterization. Cell characterization strategies must also change to accommodate DPL. Each cell master has at least two distinct instantiations in silicon (M12 type and M21 type) that require modeling. And, despite availability of bimodal-aware SPICE models, we do not know the relation of CD means in the two coloring groups until after the actual manufacturing process is complete. Thus, DPL requires (1) more guardbanding and/or (2) a new methodology to characterize electrical properties such as delay, power, etc. of DPL circuits.

- A conservative but simple method to reduce the impact of the bimodal CD distribution on the entire design process is to model bimodal as unimodal. The already-cited pooled unimodal CD model from [4] can be useful, and today’s conventional flow can still be used. However, as shown in Section III, the pooled unimodal model gives too pessimistic a guardband, which can lead to significant overdesign. Furthermore, as we demonstrated above, the pooled unimodal model cannot capture the potential timing problems caused by uncorrelated data and clock delay variations; to deal with this kind of variation would require an even more pessimistic guardband and even more overdesign.
- A realistic but complex method to closely capture actual bimodality without undue guardbanding is to make two independent timing libraries for M12 and M21 type cells. Our results above show that delay of the MAX-MAX combination for CD groups G1 and G2 dominates other combinations for the worst-case delay, and that delay of the MIN-MIN combination dominates other combinations for best-case delay. Hence, for combinational cells it may be reasonable to use the larger (smaller) of the the M12 and M21 delays in the MAX-MAX (MIN-MIN) corner as the worst (best) delay corner of a given
5. Timing analysis. For sequential cells, e.g., latches and flip-flops, it is unclear which process combination gives the worst or best behavior. ‘D-Q’ and ‘CK-Q’ delay can be maximized (minimized) at the MAX-MAX (MIN-MIN) corner, but hazard timing margins such as setup and hold may take on worst values at different combinations of process corners, since these result from racing between clock and data path within a cell. Measurement of delay and hazard timing margin across process corners requires further study.

4. Timing optimization. For bimodal-aware timing optimization, we can split a timing graph into three pieces: data path, clock path and sequential cells. From our experiments in Section III, we notice that alternative coloring is a good way to reduce delay variation as well as the worst delays of both clock and data paths. However, we also note that making alternative coloring can increase coloring conflicts with neighboring cells that are already colored. Although this problem is out of the scope of this paper, we may fix this problem by perturbing placement by use of remaining white space, i.e., increasing distance between conflicting cells. For clock paths, if we can use the same type of coloring for all cells in the clock network (thus exploiting spatial correlation maximally), we can further reduce clock variation as well as slack variation. For sequential cells, balancing delay and hazard timing margin across combinations of bimodal process corners appears to be an open and challenging research topic.

5. Timing analysis. More generally, the loss of spatial correlation - such that instances of the same master cell, placed closely together, behave quite differently - represents a significant change to timing analysis and optimization. New statistical and deterministic timing analysis methodology, comprehending transistor-level spatial correlation, will be required.

V. CONCLUSIONS AND ONGOING WORK

Double Patterning Lithography (DPL) allows 32nm half-pitch logic patterning using 193nm ArF lithography tools, and is already in production for leading-edge memory products. However, the associated ‘bimodal’ CD distribution and loss of spatial correlation between color (exposure) groups has far-reaching impacts on circuit properties that are neither well-defined nor well-studied. In this paper, we have given both analytic and empirical assessments of the potential impact of DPL on timing analysis error and guardbanding; we observe that the traditional ‘unimodal’ characterization and analysis framework may not be viable for DPL. For example, our analyses demonstrate that different mask layouts can result in 20% or more change in timing path delays. Based on our observations, we have proposed potential solutions for each step of the design process. Our next goal is to provide more accurate, efficient and practical solutions for the ‘bimodal-aware’ challenges in timing analysis and circuit design optimization.
