REVIEW OF PARTICLE PHYSICS*

Particle Data Group

Abstract

The *Review* summarizes much of particle physics and cosmology. Using data from previous editions, plus 3,283 new measurements from 899 papers, we list, evaluate, and average measured properties of gauge bosons and the recently discovered Higgs boson, leptons, quarks, mesons, and baryons. We summarize searches for hypothetical particles such as heavy neutrinos, supersymmetric and technicolor particles, axions, dark photons, etc. All the particle properties and search limits are listed in Summary Tables. We also give numerous tables, figures, formulae, and reviews of topics such as Supersymmetry, Extra Dimensions, Particle Detectors, Probability, and Statistics. Among the 112 reviews are many that are new or heavily revised including those on: Dark Energy, Higgs Boson Physics, Electroweak Model, Neutrino Cross Section Measurements, Monte Carlo Neutrino Generators, Top Quark, Dark Matter, Dynamical Electroweak Symmetry Breaking, Accelerator Physics of Colliders, High-Energy Collider Parameters, Big Bang Nucleosynthesis, Astrophysical Constants and Cosmological Parameters.

A booklet is available containing the Summary Tables and abbreviated versions of some of the other sections of this full *Review*. All tables, listings, and reviews (and errata) are also available on the Particle Data Group website: `http://pdg.lbl.gov`.

DOI: 10.1088/1674-1137/38/9/090001

The 2014 edition of *Review of Particle Physics* is published for the Particle Data Group as article 090001 in Volume 38, No. 9 of Chinese Physics C.

This edition should be cited as: K.A. Olive et al. (Particle Data Group), Chin. Phys. C, 2014, **38**(9): 090001

*The publication of the *Review of Particle Physics* is supported by the Director, Office of Science, Office of High Energy Physics of the U.S. Department of Energy under Contract No. DE–AC02–05CH11231; by the U.S. National Science Foundation under Agreement No. PHY-0652989; by the European Laboratory for Particle Physics (CERN); by an implementing arrangement between the governments of Japan (MEXT: Ministry of Education, Culture, Sports, Science and Technology) and the United States (DOE) on cooperative research and development; and by the Italian National Institute of Nuclear Physics (INFN).

HIGHLIGHTS OF THE 2014 EDITION OF THE REVIEW OF PARTICLE PHYSICS

899 new papers with 3283 new measurements

- Over 330 papers from **LHC** experiments (ATLAS, CMS, and LHCb).
- Extensive **Higgs boson** coverage from 138 papers with 258 measurements.
- **Supersymmetry**: 123 papers with major exclusions, many from LHC experiments.
- **Top quark**: 51 new papers, many from LHC experiments.
- Cosmology reviews updated to include **2013 Planck**.
- Latest from ***B*-meson** physics: 183 papers with 803 measurements, including first observation of $B_s \to \mu^+\mu^-$ from LHCb and CMS.
- Updated and new results in **neutrino mixing** on Δm^2 and mixing angle measurements, including the first Δm^2_{32} result from reactor experiment.
- Final assignment of $\mathbf{1}^{++}$ quantum numbers to the ***X*(3872)** by LHCb.
- Observation of **charmonium-like states** $X(3900)$ and $X(4020)$ (BESIII and BES3).
- Observation of **bottomonium-like states** $X(10620)$ and $X(10650)$ (Belle).
- Heavily revised Atomic-Nuclear Properties website.

112 reviews (most are revised or new)

- **New reviews** on:
  - Higgs Boson Physics
  - Dark Energy
  - Monte Carlo Neutrino Generators
  - Resonances
- **Significant update/revision** to reviews on:
  - The Top Quark
  - Dynamical Electroweak Symmetry Breaking
  - Astrophysical Constants
  - Dark Matter
  - Big-Bang Nucleosynthesis
  - Neutrino Cross Section Measurements
  - Accelerator Physics of Colliders
  - High-Energy Collider Parameters
  - Total Hadronic Cross Sections Plots

See **pdgLive.lbl.gov** for online access to PDG database.

See **pdg.lbl.gov/AtomicNuclearProperties** for Atomic Properties of Materials.

PARTICLE LISTINGS*

MAJOR REVIEWS IN THE PARTICLE LISTINGS

*The divider sheets give more detailed indices for each main section of the Particle Listings.

INTRODUCTION

ONLINE PARTICLE PHYSICS INFORMATION

INTRODUCTION

1. Overview

The *Review of Particle Physics* and the abbreviated version, the *Particle Physics Booklet,* are reviews of the field of Particle Physics. This complete *Review* includes a compilation/evaluation of data on particle properties, called the "Particle Listings." These Listings include 3,283 new measurements from 899 papers, in addition to the 32,153 measurements from 8,944 papers that first appeared in previous editions [1].

Both books include Summary Tables with our best values and limits for particle properties such as masses, widths or lifetimes, and branching fractions, as well as an extensive summary of searches for hypothetical particles. In addition, we give a long section of "Reviews, Tables, and Plots" on a wide variety of theoretical and experimental topics, a quick reference for the practicing particle physicist.

The *Review* and the *Booklet* are published in even-numbered years. This edition is an updating through January 2014 (and, in some areas, well into 2014). As described in the section "Online Particle Physics Information" following this introduction, the content of this *Review* is available on the World-Wide Web, and is updated between printed editions (`http://pdg.lbl.gov/`).

The Summary Tables give our best values of the properties of the particles we consider to be well established, a summary of search limits for hypothetical particles, and a summary of experimental tests of conservation laws.

The Particle Listings contain all the data used to get the values given in the Summary Tables. Other measurements considered recent enough or important enough to mention, but which for one reason or another are not used to get the best values, appear separately just beneath the data we do use for the Summary Tables. The Particle Listings also give information on unconfirmed particles and on particle searches, as well as short "reviews" on subjects of particular interest or controversy.

The Particle Listings were once an archive of all published data on particle properties. This is no longer possible because of the large quantity of data. We refer interested readers to earlier editions for data now considered to be obsolete.

We organize the particles into six categories:

Gauge and Higgs bosons
Leptons
Quarks
Mesons
Baryons
Searches for monopoles, supersymmetry, compositeness, extra dimensions, *etc.*

The last category only includes searches for particles that do not belong to the previous groups; searches for heavy charged leptons and massive neutrinos, by contrast, are with the leptons.

In Sec. 2 of this Introduction, we list the main areas of responsibility of the authors, and also list our large number of consultants, without whom we would not have been able to produce this *Review.* In Sec. 4, we mention briefly the naming scheme for hadrons. In Sec. 5, we discuss our procedures for choosing among measurements of particle properties and for obtaining best values of the properties from the measurements.

The accuracy and usefulness of this *Review* depend in large part on interaction between its users and the authors. We appreciate comments, criticisms, and suggestions for improvements of any kind. Please send them to the appropriate author, according to the list of responsibilities in Sec. 2 below, or to the LBNL addresses below.

To order a copy of the *Review* or the *Particle Physics Booklet* from North and South America, Australia, and the Far East, send email to `PDG@LBL.GOV`

2. Particle Listings responsibilities

* Asterisk indicates the people to contact with questions or comments about Particle Listings sections.

Gauge and Higgs bosons

γ	C. Grab, D.E. Groom*
Gluons	R.M. Barnett,* A.V. Manohar
Graviton	D.E. Groom*
W, Z	A. Gurtu,* M. Grünewald*
Higgs bosons	K. Hikasa, G. Weiglein*
Heavy bosons	H.E. Haber,* M. Tanabashi
Axions	K.A. Olive, F. Takahashi, G. Raffelt*

Leptons

Neutrinos	M. Goodman, C.-J. Lin,* K. Nakamura, K.A. Olive, A. Piepke, P. Vogel
e, μ	C. Grab, C.-J. Lin*
τ	K.G. Hayes, K. Mönig*

Quarks

Quarks	R.M. Barnett,* A.V. Manohar
Top quark	K. Hagiwara, W.-M. Yao*
b', t'	K. Hagiwara, W.-M. Yao*
Free quark	J. Beringer*

Mesons

π, η	J. Beringer,* C. Grab
Unstable mesons	C. Amsler, M. Doser,* S. Eidelman,* T. Gutsche, C. Hanhart, B. Heltsley, J.J. Hernández-Rey, A. Masoni, S. Navas, C. Patrignani, S. Spanier, N.A. Törnqvist, G. Venanzoni
K (stable)	G. D'Ambrosio, C.-J. Lin*
D (stable, no mix.)	J. Rademacker, C.G. Wohl*
D^0 mixing	D.M. Asner, W.-M. Yao*

Baryons

B (stable)	M. Kreps, Y. Kwon, J.G. Smith, W.-M. Yao*
Stable baryons	C. Grab, C.G. Wohl*
Unstable baryons	V. Burkert, E. Klempt, M. Pennington, L. Tiator, R.L. Workman*
Charmed baryons	J. Rademacker, C.G. Wohl*
Bottom baryons	M. Kreps, Y. Kwon, J.G. Smith, W.-M. Yao*

Miscellaneous searches

Monopole	D. Milstead*
Supersymmetry	H.K. Dreiner,* A. de Gouvêa, F. Moortgat, K.A. Olive
Technicolor	K. Agashe,* M. Tanabashi
Compositeness	M. Tanabashi, J. Terning*
Extra Dimensions	T. Gherghetta, H.E. Haber*,
WIMPs and Other	K. Hikasa,*

3. Consultants

The Particle Data Group benefits greatly from the assistance of some 700 physicists who are asked to verify every piece of data entered into this *Review*. Of special value is the advice of the PDG Advisory Committee which meets biennially and thoroughly reviews all aspects of our operation. The members of the 2014 committee are:

D. Harris (FNAL)
T. Carli (CERN)
L. Hall (UC Berkeley)
J. Olson (Princeton)
A. Slosar (BNL)
J. Tanaka (Tokyo)

We have especially relied on the expertise of the following people for advice on particular topics:

- S.I. Alekhin (COMPAS Group, IHEP, Protvino)
- B. Allanach (U. of Cambridge)
- C. Andreopoulos (STFC Rutherford Appleton Lab.)
- H. An (Perimeter Institute)
- F. Anulli (INFN, Rome)
- M. Artuso (Syracuse University)
- R. Barbieri (SNS and INFN, Pisa)
- M. Bardeen (FNAL)
- W. Barletta (MIT)
- J. Bernabeu (University of Valencia)
- F. Bernlochner (University of Victoria)
- W. Bertl (PSI)
- C. Bozzi(INFN, Ferrara)
- T. Browder (University of Hawaii)
- O. Bruening (CERN)
- G. Castelo-Branco (Techn. U. of Lisboa)
- F. Cavanna (Yale University)
- S. Centro (INFN, Padua)
- F. Cerutti (LBNL)
- G. Colangelo (University of Bern)
- J. Conway (UC Davis)
- K. Cranmer (NYU)
- C. Csaki (Cornell U.)
- D. Denisov (FNAL)
- D. d'Enterria (CERN)
- M. Dine (UCSC)
- J. Dingfelder (Bonn, Germany)
- M. D'Onofrio (U. of Liverpool)
- S. Dytman (University of Pittsburgh)
- G. Edda (University of Geneva)
- A. Falkowski (U. of Warsaw)
- W. Fischer (BNL)
- P. Gambino (Univ. degli Studi di Torino)
- I. Garcia Irastorza (U. of Zaragoza)
- R. Garisto (PRL)
- M. Gersabeck (Univ. of Manchester)
- C. Giunti (INFN Turin)
- S. Givannella (INFN, Frascati)
- C. Glasman (Madrid)
- B. Golob (Ljubljana, Slovenia)
- E. Goudzovski (U. of Birmingham)
- J. Guy (UPMC, Paris)
- F. Halzen (U. of Wisconsin)
- F. Harris (University of Hawaii)
- S. Heinemeyer (Karlsruhe Inst. of Techn.)
- W. Hollik (Karlsruhe Inst. of Techn.)
- G. Isidori (INFN, Frascati)
- M. Jose Costa (IFIC Valencia)
- J. Jowett (CERN)
- S.G. Karshenboim (MPQ, Pulkovo Obs., Russia)
- E. Kearns T (Boston University)
- M. Klein (University of Liverpool)
- T. Kobayashi (KEK)
- P. Koppenburg (CERN)
- A. Korytov (U. of Florida)
- T. Koseki (University of Tokyo)
- W. Kozanecki (Saclay)
- A. Kronfeld (FNAL)
- O. Leroy (CPPM, Marseille)
- E.B. Levichev (BINP, Novosibirsk)
- E. Linder (LBNL)
- D. London (University of Montreal)
- P. Lukens (FNAL)
- L. Malgeri (CERN)
- S. Martin (Northern Illinois U.)
- C. Milardi (INFN, Frascati)
- P.J. Mohr (NIST)
- S. Monteil (LPC Clermont)
- U. Mosel (University of Giessen)
- M. Mulders (CERN)
- B. Murray (U. of Warwick)
- T. Nakadaira (KEK)
- H. O'Connell (FNAL)

4. Naming scheme for hadrons

We introduced in the 1986 edition [2] a new naming scheme for the hadrons. Changes from older terminology affected mainly the heavier mesons made of u, d, and s quarks. Otherwise, the only important change to known hadrons was that the $F^{\pm}$ became the $D_s^{\pm}$. None of the lightest pseudoscalar or vector mesons changed names, nor did the $c\overline{c}$ or $b\overline{b}$ mesons (we do, however, now use χ_c for the $c\overline{c}$ χ states), nor did any of the established baryons. The Summary Tables give both the new and old names whenever a change has occurred.

The scheme is described in "Naming Scheme for Hadrons" (p. 120) of this *Review*.

We give here our conventions on type-setting style. Particle symbols are italic (or slanted) characters: e^-, p, Λ, π^0, K_L, D_s^+, b. Charge is indicated by a superscript: B^-, Δ^{++}. Charge is not normally indicated for p, n, or the quarks, and is optional for neutral isosinglets: η or η^0. Antiparticles and particles are distinguished by charge for charged leptons and mesons: τ^+, K^-. Otherwise, distinct antiparticles are indicated by a bar (overline): $\overline{\nu}_\mu$, $\overline{t}$, $\overline{p}$, $\overline{K}^0$, and $\overline{\Sigma}^+$ (the antiparticle of the Σ^-).

5. Procedures

5.1. ***Selection and treatment of data*** : The Particle Listings contain all relevant data known to us that are published in journals. With very few exceptions, we do not include results from preprints or conference reports. Nor do we include data that are of historical importance only (the Listings are not an archival record). We search every volume of 20 journals through our cutoff date for relevant data. We also include later published papers that are sent to us by the authors (or others).

In the Particle Listings, we clearly separate measurements that are used to calculate or estimate values given in the Summary Tables from measurements that are not used. We give explanatory comments in many such cases. Among the reasons a measurement might be excluded are the following:

- It is superseded by or included in later results.
- No error is given.
- It involves assumptions we question.
- It has a poor signal-to-noise ratio, low statistical significance, or is otherwise of poorer quality than other data available.
- It is clearly inconsistent with other results that appear to be more reliable. Usually we then state the criterion, which sometimes is quite subjective, for selecting "more reliable" data for averaging. See Sec. 5.4.
- It is not independent of other results.
- It is not the best limit (see below).
- It is quoted from a preprint or a conference report.

In some cases, *none* of the measurements is entirely reliable and no average is calculated. For example, the masses of many of the baryon resonances, obtained from partial-wave analyses, are quoted as estimated ranges thought to probably include the true values, rather than as averages with errors. This is discussed in the Baryon Particle Listings.

For upper limits, we normally quote in the Summary Tables the strongest limit. We do not average or combine upper limits except in a very few cases where they may be re-expressed as measured numbers with Gaussian errors.

As is customary, we assume that particle and antiparticle share the same spin, mass, and mean life. The Tests of Conservation Laws table, following the Summary Tables, lists tests of CPT as well as other conservation laws.

We use the following indicators in the Particle Listings to tell how we get values from the tabulated measurements:

- OUR AVERAGE—From a weighted average of selected data.
- OUR FIT—From a constrained or overdetermined multi-parameter fit of selected data.
- OUR EVALUATION—Not from a direct measurement, but evaluated from measurements of related quantities.
- OUR ESTIMATE—Based on the observed range of the data. Not from a formal statistical procedure.
- OUR LIMIT—For special cases where the limit is evaluated by us from measured ratios or other data. Not from a direct measurement.

An experimentalist who sees indications of a particle will of course want to know what has been seen in that region in the past. Hence we include in the Particle Listings all

reported states that, in our opinion, have sufficient statistical merit and that have not been disproved by more reliable data. However, we promote to the Summary Tables only those states that we feel are well established. This judgment is, of course, somewhat subjective and no precise criteria can be given. For more detailed discussions, see the minireviews in the Particle Listings.

5.2. ***Averages and fits*** : We divide this discussion on obtaining averages and errors into three sections: (1) treatment of errors; (2) unconstrained averaging; (3) constrained fits.

5.2.1. *Treatment of errors:* In what follows, the "error" δx means that the range $x \pm \delta x$ is intended to be a 68.3% confidence interval about the central value x. We treat this error as if it were Gaussian. Thus when the error *is* Gaussian, δx is the usual one standard deviation (1σ). Many experimenters now give statistical and systematic errors separately, in which case we usually quote both errors, with the statistical error first. For averages and fits, we then add the the two errors in quadrature and use this combined error for δx.

When experimenters quote asymmetric errors $(\delta x)^+$ and $(\delta x)^-$ for a measurement x, the error that we use for that measurement in making an average or a fit with other measurements is a continuous function of these three quantities. When the resultant average or fit $\overline{x}$ is less than $x-(\delta x)^-$, we use $(\delta x)^-$; when it is greater than $x+(\delta x)^+$, we use $(\delta x)^+$. In between, the error we use is a linear function of x. Since the errors we use are functions of the result, we iterate to get the final result. Asymmetric output errors are determined from the input errors assuming a linear relation between the input and output quantities.

In fitting or averaging, we usually do not include correlations between different measurements, but we try to select data in such a way as to reduce correlations. Correlated errors are, however, treated explicitly when there are a number of results of the form $A_i \pm \sigma_i \pm \Delta$ that have identical systematic errors Δ. In this case, one can first average the $A_i \pm \sigma_i$ and then combine the resulting statistical error with Δ. One obtains, however, the same result by averaging $A_i \pm (\sigma_i^2 + \Delta_i^2)^{1/2}$, where $\Delta_i = \sigma_i \Delta [\sum (1/\sigma_j^2)]^{1/2}$. This procedure has the advantage that, with the modified systematic errors Δ_i, each measurement may be treated as independent and averaged in the usual way with other data. Therefore, when appropriate, we adopt this procedure. We tabulate Δ and invoke an automated procedure that computes Δ_i before averaging and we include a note saying that there are common systematic errors.

Another common case of correlated errors occurs when experimenters measure two quantities and then quote the two and their difference, *e.g.*, m_1, m_2, and $\Delta = m_2 - m_1$. We cannot enter all of m_1, m_2 and Δ into a constrained fit because they are not independent. In some cases, it is a good approximation to ignore the quantity with the largest error and put the other two into the fit. However, in some cases correlations are such that the errors on m_1, m_2 and Δ are comparable and none of the three values can be ignored. In this case, we put all three values into the fit and invoke an automated procedure to increase the errors prior to fitting such that the three quantities can be treated as independent measurements in the constrained fit. We include a note saying that this has been done.

5.2.2. *Unconstrained averaging:* To average data, we use a standard weighted least-squares procedure and in some cases, discussed below, increase the errors with a "scale factor." We begin by assuming that measurements of a given quantity are uncorrelated, and calculate a weighted average and error as

$$\overline{x} \pm \delta\overline{x} = \frac{\sum_i w_i\, x_i}{\sum_i w_i} \pm \left(\sum_i w_i\right)^{-1/2} , \qquad (1)$$

where

$$w_i = 1/(\delta x_i)^2 .$$

Here x_i and δx_i are the value and error reported by the ith experiment, and the sums run over the N experiments. We then calculate $\chi^2 = \sum w_i(\overline{x} - x_i)^2$ and compare it with $N-1$, which is the expectation value of χ^2 if the measurements are from a Gaussian distribution.

If $\chi^2/(N-1)$ is less than or equal to 1, and there are no known problems with the data, we accept the results.

If $\chi^2/(N-1)$ is very large, we may choose not to use the average at all. Alternatively, we may quote the calculated average, but then make an educated guess of the error, a conservative estimate designed to take into account known problems with the data.

Finally, if $\chi^2/(N-1)$ is greater than 1, but not greatly so, we still average the data, but then also do the following:

(a) We increase our quoted error, $\delta\overline{x}$ in Eq. (1), by a scale factor S defined as

$$S = \left[\chi^2/(N-1)\right]^{1/2} . \qquad (2)$$

Our reasoning is as follows. The large value of the χ^2 is likely to be due to underestimation of errors in at least one of the experiments. Not knowing which of the errors are underestimated, we assume they are all underestimated by the same factor S. If we scale up all the input errors by this factor, the χ^2 becomes $N-1$, and of course the output error $\delta\overline{x}$ scales up by the same factor. See Ref. 3.

When combining data with widely varying errors, we modify this procedure slightly. We evaluate S using only the experiments with smaller errors. Our cutoff or ceiling on δx_i is arbitrarily chosen to be

$$\delta_0 = 3N^{1/2}\, \delta\overline{x} ,$$

where $\delta\overline{x}$ is the unscaled error of the mean of all the experiments. Our reasoning is that although the low-precision experiments have little influence on the values $\overline{x}$ and $\delta\overline{x}$, they can make significant contributions to the χ^2, and the contribution of the high-precision experiments thus tends to be obscured. Note that if each experiment has the same error δx_i, then $\delta\overline{x}$ is $\delta x_i/N^{1/2}$, so each δx_i is well below the cutoff. (More often, however, we simply exclude measurements with relatively large errors from averages and fits: new, precise data chase out old, imprecise data.)

Our scaling procedure has the property that if there are two values with comparable errors separated by much more than their stated errors (with or without a number of other values of lower accuracy), the scaled-up error $\delta\,\overline{x}$ is approximately half the interval between the two discrepant values.

We emphasize that our scaling procedure for *errors* in no way affects central values. And if you wish to recover the unscaled error $\delta\overline{x}$, simply divide the quoted error by S.

(b) If the number M of experiments with an error smaller than δ_0 is at least three, and if $\chi^2/(M-1)$ is greater than 1.25, we show in the Particle Listings an ideogram of the data. Figure 1 is an example. Sometimes one or two data points lie apart from the main body; other times the data split into two or more groups. We extract no numbers from these ideograms; they are simply visual aids, which the reader may use as he or she sees fit.

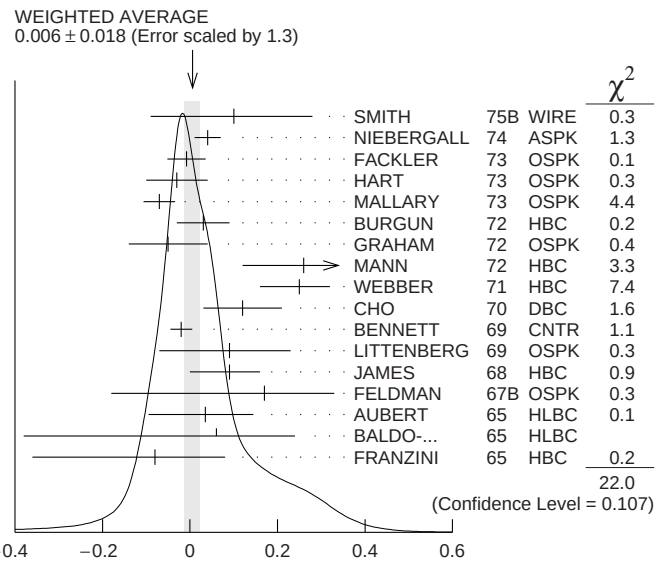

Figure 1: A typical ideogram. The arrow at the top shows the position of the weighted average, while the width of the shaded pattern shows the error in the average after scaling by the factor S. The column on the right gives the χ^2 contribution of each of the experiments. Note that the next-to-last experiment, denoted by the incomplete error flag ($\perp$), is not used in the calculation of S (see the text).

Each measurement in an ideogram is represented by a Gaussian with a central value x_i, error δx_i, and area proportional to $1/\delta x_i$. The choice of $1/\delta x_i$ for the area is somewhat arbitrary. With this choice, the center of gravity of the ideogram corresponds to an average that uses weights $1/\delta x_i$ rather than the $(1/\delta x_i)^2$ actually used in the averages. This may be appropriate when some of the experiments have seriously underestimated systematic errors. However, since for this choice of area the height of the Gaussian for each measurement is proportional to $(1/\delta\, x_i)^2$, the peak position of the ideogram will often favor the high-precision measurements at least as much as does the least-squares average. See our 1986 edition [2] for a detailed discussion of the use of ideograms.

5.2.3. *Constrained fits:* In some cases, such as branching ratios or masses and mass differences, a constrained fit may be needed to obtain the best values of a set of parameters. For example, most branching ratios and rate measurements are analyzed by making a simultaneous least-squares fit to all the data and extracting the partial decay fractions P_i, the partial widths Γ_i, the full width Γ (or mean life), and the associated error matrix.

Assume, for example, that a state has m partial decay fractions P_i, where $\sum P_i = 1$. These have been measured in N_r different ratios R_r, where, e.g., $R_1 = P_1/P_2$, $R_2 = P_1/P_3$, *etc.* [We can handle any ratio R of the form $\sum \alpha_i P_i / \sum \beta_i P_i$, where α_i and β_i are constants, usually 1 or 0. The forms $R = P_i P_j$ and $R = (P_i P_j)^{1/2}$ are also allowed.] Further assume that *each* ratio R has been measured by N_k experiments (we designate each experiment with a subscript k, e.g., R_{1k}). We then find the best values of the fractions P_i by minimizing the χ^2 as a function of the $m-1$ independent parameters:

$$\chi^2 = \sum_{r=1}^{N_r} \sum_{k=1}^{N_k} \left(\frac{R_{rk} - R_r}{\delta R_{rk}} \right)^2 , \qquad (3)$$

where the R_{rk} are the measured values and R_r are the fitted values of the branching ratios.

In addition to the fitted values $\overline{P}_i$, we calculate an error matrix $\langle \delta\overline{P}_i \ \delta\overline{P}_j \rangle$. We tabulate the diagonal elements of $\delta\,\overline{P}_i = \langle \delta\,\overline{P}_i \ \delta\,\overline{P}_i \rangle^{1/2}$ (except that some errors are scaled as discussed below). In the Particle Listings, we give the complete correlation matrix; we also calculate the fitted value of each ratio, for comparison with the input data, and list it above the relevant input, along with a simple unconstrained average of the same input.

Three comments on the example above:

(1) There was no connection assumed between measurements of the full width and the branching ratios. But often we also have information on partial widths Γ_i as well as the total width Γ. In this case we must introduce Γ as a parameter in the fit, along with the P_i, and we give correlation matrices for the widths in the Particle Listings.

(2) We try to pick those ratios and widths that are as independent and as close to the original data as possible. When one experiment measures all the branching fractions and constrains their sum to be one, we leave one of them (usually the least well-determined one) out of the fit to make the set of input data more nearly independent. We now do allow for correlations between input data.

(3) We calculate scale factors for both the R_r and P_i when the measurements for any R give a larger-than-expected contribution to the χ^2. According to Eq. (3), the double sum for χ^2 is first summed over experiments $k = 1$ to N_k, leaving a single sum over ratios $\chi^2 = \sum \chi^2_r$. One is tempted to define a scale factor for the ratio r as $S_r^2 = \chi^2_r / \langle \chi^2_r \rangle$. However, since $\langle \chi^2_r \rangle$ is not a fixed quantity (it is somewhere between N_k and N_{k-1}), we do not know how to evaluate this expression. Instead we define

$$S_r^2 = \frac{1}{N_k} \sum_{k=1}^{N_k} \frac{\left(R_{rk} - \overline{R}_r\right)^2}{\langle (R_{rk} - \overline{R}_r)^2 \rangle}. \qquad (4)$$

With this definition the expected value of S_r^2 is one. We can show that

$$\langle (R_{rk} - \overline{R}_r)^2 \rangle = \langle (\delta R_{rk})^2 \rangle - (\delta \overline{R}_r)^2 , \qquad (5)$$

where $\delta\overline{R}_r$ is the fitted error for ratio r.

The fit is redone using errors for the branching ratios that are scaled by the larger of S_r and unity, from which new and often larger errors $\delta\overline{P}_i{}'$ are obtained. The scale factors we finally list in such cases are defined by $S_i = \delta\overline{P}_i{}'/\delta\overline{P}_i$. However, in line with our policy of not letting S affect the central values, we give the values of $\overline{P}_i$ obtained from the original (unscaled) fit.

There is one special case in which the errors that are obtained by the preceding procedure may be changed. When a fitted branching ratio (or rate) $\overline{P}_i$ turns out to be less than three standard deviations ($\delta\overline{P}_i'$) from zero, a new smaller error $(\delta\overline{P}_i'')^-$ is calculated on the low side by requiring the area under the Gaussian between $\overline{P}_i - (\delta\overline{P}_i'')^-$ and $\overline{P}_i$ to be 68.3% of the area between zero and $\overline{P}_i$. A similar correction is made for branching fractions that are within three standard deviations of one. This keeps the quoted errors from overlapping the boundary of the physical region.

5.3. ***Rounding*** : While the results shown in the Particle Listings are usually exactly those published by the experiments, the numbers that appear in the Summary Tables (means, averages and limits) are subject to a set of rounding rules.

The basic rule states that if the three highest order digits of the error lie between 100 and 354, we round to two significant digits. If they lie between 355 and 949, we round to one significant digit. Finally, if they lie between 950 and 999, we round up to 1000 and keep two significant digits. In all cases, the central value is given with a precision that matches that of the error. So, for example, the result (coming from an average) 0.827 ± 0.119 would appear as 0.83 ± 0.12, while 0.827 ± 0.367 would turn into 0.8 ± 0.4.

Rounding is not performed if a result in a Summary Table comes from a single measurement, without any averaging. In that case, the number of digits published in the original paper is kept, unless we feel it inappropriate. Note that, even for a single measurement, when we combine statistical and systematic errors in quadrature, rounding rules apply to the result of the combination. It should be noted also that most of the limits in the Summary Tables come from a single source (the best limit) and, therefore, are not subject to rounding.

Finally, we should point out that in several instances, when a group of results come from a single fit to a set of data, we have chosen to keep two significant digits for all the results. This happens, for instance, for several properties of the W and Z bosons and the τ lepton.

5.4. ***Discussion*** : The problem of averaging data containing discrepant values is nicely discussed by Taylor in Ref. 4. He considers a number of algorithms that attempt to incorporate inconsistent data into a meaningful average. However, it is difficult to develop a procedure that handles simultaneously in a reasonable way two basic types of situations: (a) data that lie apart from the main body of the data are incorrect (contain unreported errors); and (b) the opposite—it is the main body of data that is incorrect. Unfortunately, as Taylor shows, case (b) is not infrequent. He concludes that the choice of procedure is less significant than the initial choice of data to include or exclude.

We place much emphasis on this choice of data. Often we solicit the help of outside experts (consultants). Sometimes, however, it is simply impossible to determine which of a set of discrepant measurements are correct. Our scale-factor technique is an attempt to address this ignorance by increasing the error. In effect, we are saying that present experiments do not allow a precise determination of this quantity because of unresolvable discrepancies, and one must await further measurements. The reader is warned of this situation by the size of the scale factor, and if he or she desires can go back to the literature (via the Particle Listings) and redo the average with a different choice of data.

Our situation is less severe than most of the cases Taylor considers, such as estimates of the fundamental constants like $\hbar$, *etc.* Most of the errors in his case are dominated by systematic effects. For our data, statistical errors are often at least as large as systematic errors, and statistical errors are usually easier to estimate. A notable exception occurs in partial-wave analyses, where different techniques applied to the same data yield different results. In this case, as stated earlier, we often do not make an average but just quote a range of values.

A brief history of early Particle Data Group averages is given in Ref. 3. Figure 2 shows some histories of our values of a few particle properties. Sometimes large changes occur. These usually reflect the introduction of significant new data or the discarding of older data. Older data are discarded in favor of newer data when it is felt that the newer data have smaller systematic errors, or have more checks on systematic errors, or have made corrections unknown at the time of the older experiments, or simply have much smaller errors. Sometimes, the scale factor becomes large near the time at which a large jump takes place, reflecting the uncertainty introduced by the new and inconsistent data. By and large, however, a full scan of our history plots shows a dull progression toward greater precision at central values quite consistent with the first data points shown.

We conclude that the reliability of the combination of experimental data and our averaging procedures is usually good, but it is important to be aware that fluctuations outside of the quoted errors can and do occur.

ACKNOWLEDGMENTS

The publication of the *Review of Particle Physics* is supported by the Director, Office of Science, Office of High Energy Physics of the U.S. Department of Energy under Contract No. DE–AC02–05CH11231; by the U.S. National Science Foundation under Agreement No. PHY-0652989; by the European Laboratory for Particle Physics (CERN); by an implementing arrangement between the governments of Japan (MEXT: Ministry of Education, Culture, Sports, Science and Technology) and the United States (DOE) on cooperative research and development; and by the Italian National Institute of Nuclear Physics (INFN).

We thank all those who have assisted in the many phases of preparing this *Review*. We particularly thank the many who have responded to our requests for verification of data entered in the Listings, and those who have made suggestions or pointed out errors.

ONLINE PARTICLE PHYSICS INFORMATION

Updated Nov. 2013 by T. Basaglia (CERN), A. Holtkamp (CERN).†

1. Introduction

The collection of online information resources in particle physics and related areas presented in this chapter is of necessity incomplete. An expanded and regularly updated online version can be found at:

`http://library.web.cern.ch/particle_physics_information`

Suggestions for additions and updates are very welcome.†

2. Particle Data Group (PDG) resources

- **Review of Particle Physics (RPP)** A comprehensive report on the fields of particle physics and related areas of cosmology and astrophysics, including both review articles and a compilation/evaluation of data on particle properties. The review section includes articles, tables and plots on a wide variety of theoretical and experimental topics of interest to particle physicists and astrophysicists. The particle properties section provides tables of published measurements as well as the Particle Data Groups best values and limits for particle properties such as masses, widths, lifetimes, and branching fractions, and an extensive summary of searches for hypothetical particles. RPP is published as a 1500-page book every two years, with partial updates made available once each year on the web.

  All the contents of the book version of RPP are available online:

  `http://pdg.lbl.gov`

  The printed book can be ordered:

  `http://pdg.lbl.gov/2013/html/receive_our_products.html`

  Of historical interest is the complete RPP collection which can be found online:

  `http://library.web.cern.ch/PDG_publications/review_particle_physics`

- **Particle Physics booklet:** An abridged version of the Review of Particle Physics available as a pocket-sized 300-page booklet. Although produced in print and available online only as a PDF file, the booklet is included in this guide because it is one of the most useful summaries of physics data. The booklet contains an abbreviated set of reviews and the summary tables from the most recent edition of the Review of Particle Physics.

  The PDF file of the booklet can be downloaded:

  `http://pdg.lbl.gov/current/booklet.pdf`

  The printed booklet can be ordered:

  `http://pdg.lbl.gov/2013/html/receive_our_products.html`

- **PDGLive:** A web application for browsing the contents of the PDG database that contains the information published in the Review of Particle Physics. It allows one to navigate to a particle of interest, see a summary of the information available, and then proceed to the detailed information published in the Review of Particle Physics. Data entries are directly linked to the corresponding bibliographic information in INSPIRE.

  `http://pdglive.lbl.gov`

- **Computer-readable files:** Data files that can be downloaded from PDG include tables of particle masses and widths, PDG Monte Carlo particle numbers, and cross-section data. The files are updated with each new edition of the Review of Particle Physics.

  `http://pdg.lbl.gov/current/html/computer_read.html`

3. Particle Physics Information Platforms

- **INSPIRE:** The time-honored SPIRES database suite has in November 2011 been replaced by INSPIRE, which combines the most successful aspects of SPIRES - like comprehensive content and high-quality metadata - with the modern technology of Invenio, the CERN open-source digital-library software, offering major improvements like increased speed and Google-like free-text search syntax. INSPIRE serves as one-stop information platform for the particle physics community, comprising 7 interlinked databases on literature, conferences, institutions, journals, researchers, experiments, jobs. INSPIRE is jointly developed and maintained by CERN, DESY, Fermilab and SLAC. Close interaction with the user community and with arXiv, ADS, HepData, PDG and publishers is the backbone of INSPIRE's evolution.

  `http://inspirehep.net/`

  More information on this project at:

  `http://inspirehep.net/info/general/project/index`

  `blog: http://blog.inspirehep.net/`

  `twitter: @inspirehep`

4. Literature Databases

- **ADS:** The SAO/NASA Astrophysics Data System is a Digital Library portal for researchers in Astronomy and Physics, operated by the Smithsonian Astrophysical Observatory (SAO) under a NASA grant. The ADS maintains three bibliographic databases containing more than 9.3 million records: Astronomy and Astrophysics, Physics, and arXiv e-prints. The main body of data in the ADS consists of bibliographic records, which are searchable through highly customizable query forms, and full-text scans of much of the astronomical literature which can be browsed or searched via a full-text search interface. Integrated in its databases, the ADS provides access and pointers to a wealth of external resources, including electronic articles, data catalogs and archives. In addition, ADS provides the myADS Update Service, a free custom notification service promoting current awareness of the recent literature in astronomy and physics based on each individual subscriber's queries.

  `http://adswww.harvard.edu/`

- **arXiv.org:** A repository of full text papers in physics, mathematics, computer science, statistics, nonlinear sciences, quantitative finance and quantitative biology interlinked with ADS and INSPIRE. Papers are usually sent by their authors to arXiv in advance of submission to a journal for publication. Primarily covers 1991 to the present but authors are encouraged to post older papers retroactively. Permits searching by author, title, and words in

† Please send comments and corrections to `Annette.Holtkamp@cern.ch`.

abstract and experimentally also in the fulltext. Allows limiting by subfield archive or by date.

`http://arXiv.org`

- **CDS:** The CERN Document Server contains records of more than 1,000,000 CERN and non-CERN articles, preprints, theses. It includes records for internal and technical notes, official CERN committee documents, and multimedia objects. CDS is going to focus on its role as institutional repository covering all CERN material from the early 50s and reflecting the holdings of the CERN library. Non-CERN particle and accelerator physics content is in the process of being exported to INSPIRE.

  `http://cds.cern.ch`

- **INSPIRE HEP:** The HEP collection, the flagship of the INSPIRE suite, serves more than 1 million bibliographic records with a growing number of fulltexts attached and metadata including author affiliations, abstracts, references, keywords as well as links to arXiv, ADS, PDG, HepData and publisher platforms. It provides fast metadata and fulltext searches, plots extracted from fulltext, author disambiguation, author profile pages and citation analysis and is expanding its content to, e.g., experimental notes.

  `http://inspirehep.net`

- **JACoW:** The Joint Accelerator Conference Website publishes the proceedings of APAC, EPAC, PAC, IPAC, ABDW, BIW, COOL, CYCLOTRONS, DIPAC, ECRIS, FEL, HIAT, ICALEPCS, IBIC, ICAP, LINAC, North American PAC, PCaPAC, RuPAC, SRF. A custom interface allows searching on keywords, titles, authors, and in the fulltext.

  `http://www.jacow.org/`

- **KISS (KEK Information Service System) for preprints:** The KEK Library preprint and technical report database contains bibliographic records of preprints and technical reports held in the KEK library with links to the full text images of more than 100,000 papers scanned from their worldwide collection of preprints. Particularly useful for older scanned preprints. KISS links are included in INSPIRE HEP.

  `http://www-lib.kek.jp/kiss/kiss_prepri.html`

- **MathSciNet:** This database of over 2.8 million items provides reviews, abstracts and bibliographic information for much of the mathematical sciences literature. Over 100,000 new items are added each year, most of them classified according to the Mathematics Subject Classification. Authors are uniquely identified, enabling a search for publications by individual author. Over 80,000 reviews on the current published literature are added each year. Citation data allows to track the history and influence of research publications.

  `http://www.ams.org/mathscinet`

- **OSTI SciTech Connect:** A portal to free, publicly available DOE-sponsored R&D results including technical reports, bibliographic citations, journal articles, conference papers, books, multimedia anid data information. SciTech Connect is a consolidation of two core DOE search engines, the Information Bridge and the Energy Citations Database. SciTech Connect incorporates all of the R&D information from these two products into one search interface. It includes over 2.5 million citations, including citations to 1.4 million journal articles, 364,000 of which have digital object identifiers (DOIs) linking to full-text articles on publishers' websites. SciTech Connect also has over 313,000 full-text DOE sponsored STI reports; most of these are post-1991, but close to 85,000 of the reports were published prior to 1990.

  `http://www.osti.gov/scitech/`

5. Particle Physics Journals and Conference Proceedings Series

- **CERN Journals List:** This list of journals and conference series publishing particle physics content provides information on Open Access, copyright policies and terms of use.

  `http://library.web.cern.ch/oa/where_publish`

- **INSPIRE Journals:** The database covers more than 3,300 journals publishing HEP-related articles.

  `http://inspirehep.net/collection/journals`

6. Conference Databases

- **INSPIRE Conferences:** The database of more than 19,500 past, present and future conferences, schools, and meetings of interest to high-energy physics and related fields is searchable by title, acronym, series, date, location. Included are information about published proceedings, links to conference contributions in the INSPIRE HEP database, and links to the conference Web site when available. New conferences can be submitted from the entry page.

  `http://inspirehep.net/conferences`

7. Research Institutions

- **INSPIRE Institutions:** The database of more than 10,500 institutes, laboratories, and university departments in which research on particle physics and astrophysics is performed covers six continents and over a hundred countries. Included are address and Web links where available as well as links to the papers from each institution in the HEP database, to scientists listed in HEPNames affiliated to this institution in the past or present and to experiments performed at this institution. Searches can be performed by name, acronym, location, etc. The site offers an alphabetical list by country as well as a list of the top 500 HEP and astrophysics institutions sorted by country.

  `http://inspirehep.net/institutions`

8. People

- **INSPIRE HEPNames:** Searchable worldwide database of over 100,000 people associated with particle physics and related fields. The affiliation history of these researchers, their e-mail addresses, web pages, experiments they participated in, PhD advisor, information on their graduate students and links to their papers in the INSPIRE HEP, arXiv and ADS databases are provided as well as a user interface to update these informations.

  `http://inspirehep.net/hepnames`

9. Experiments

- **INSPIRE Experiments:** Contains more than 2,500 past, present, and future experiments in particle physics. Lists both accelerator and non-accelerator experiments. Includes official experiment name and number, location, and collaboration lists. Simple searches by participant, title, experiment number, institution, date approved, accelerator, or detector, return a description of the experiment, including a complete list of authors, title, overview of the experiment's goals and methods, and a link to the experiment's web page if available. Publication lists distinguish articles in refereed journals, theses, technical or instrumentation papers and those which rank among Topcite at 50 or more citations.

  `http://inspirehep.net/Experiments`

- **Cosmic ray/Gamma ray/Neutrino and similar experiments:** This extensive collection of experimental Web sites is organized by focus of study and also by location. Additional sections link to educational materials, organizations, related Web sites, etc. The site is maintained at the Max Planck Institute for Nuclear Physics, Heidelberg.

  `http://www.mpi-hd.mpg.de/hfm/CosmicRay/CosmicRaySites.html`

10. Jobs

- **AAS Job Register:** The American Astronomical Society publishes once a month graduate, postgraduate, faculty and other positions mainly in astronomy and astrophysics.
  `http://jobregister.aas.org/`
- **APS Careers:** A gateway for physicists, students, and physics enthusiasts to information about physics jobs and careers. Physics job listings, career advice, upcoming workshops and meetings, and career and job related resources provided by the American Physical Society.
  `http://www.aps.org/jobs/`
- **brightrecruits.com:** A recruitment service run by IOP Publishing that connects employers from different industry sectors with jobseekers who have a background in physics and engineering.
  `http://brightrecruits.com/`
- **IOP Careers:** Careers information and resources primarily aimed at university students are provided by the UK Institute of Physics.
  `http://www.iop.org/careers/`
- **INSPIRE HEPJobs:** Lists academic and research jobs in high energy physics, nuclear physics, accelerator physics and astrophysics with the option to post a job or to receive email notices of new job listings. More than 900 jobs are currently listed.
  `http://inspirehep.net/jobs`
- **Physics Today Jobs:** Online recruitment advertising website for Physics Today magazine, published by the American Institute of Physics. Physics Today Jobs is the managing partner of the AIP Career Network, an online job board network for the physical science, engineering, and computing disciplines. 8,000 resumes are currently available, and more than 2,500 jobs were posted in 2012.
  `http://www.physicstoday.org/jobs`

11. Software Repositories

Particle Physics

- **CERNLib:** The CERN Program Library contains a large collection of general purpose libraries and modules offered in both source code and object code forms. It provides programs applicable to a wide range of physics research problems such as general mathematics, data analysis, detectors simulation, data-handling, etc. It also includes links to commercial, free, and other software. Development of this site has been discontinued.
  `http://wwwasd.web.cern.ch/wwwasd/index.html`
- **FastJet:** FastJet is a software package for jet finding in pp and e+e- collisions. It includes fast native implementations of many sequential recombination clustering algorithms, plugins for access to a range of cone jet finders and tools for advanced jet manipulation.
  `http://fastjet.fr/`
- **FermiTools:** Fermilab's software tools program provides a repository of Fermilab- developed software packages of value to the HEP community. Permits searching for packages by title or subject category.
  `http://www.fnal.gov/fermitools/`
- **FreeHEP:** A collection of software and information about software useful in high- energy physics and adjacent disciplines, focusing on open-source software for data analysis and visualization. Searching can be done by title, subject, date acquired, date updated, or by browsing an alphabetical list of all packages.
  `http://www.freehep.org/`
- **GenSer:** The Generator Services project collaborates with Monte Carlo (MC) generators authors and with LHC experiments in order to prepare validated LCG compliant code for both the theoretical and experimental communities at the LHC, sharing the user support duties, providing assistance for the development of the new object-oriented generators and guaranteeing the maintenance of the older packages on the LCG supported platforms. The project consists of the generators repository, validation, HepMC record and MCDB event databases.
  `http://sftweb.cern.ch/generators/`
- **Hepforge:** A development environment for high-energy physics software development projects, in particular housing many event-generator related projects, that offers a ready-made, easy-to-use set of Web based tools, including shell account with up to date development tools, web page hosting, subversion and CVS code management systems, mailing lists, bug tracker and wiki system.
  `http://www.hepforge.org/`
- **QUDA:** Library for performing calculations in lattice QCD on GPUs using NVIDIA's "C for CUDA" API. The current release includes optimized solvers for Wilson, Clover-improved Wilson,Twisted mass, Improved staggered (asqtad or HISQ) and Domain wall fermion actions.
  `http://lattice.github.com/quda/`
- **ROOT:** This framework for data processing in high-energy physics, born at CERN, offers applications to store, access, process, analyze and represent data or perform simulations.
  `http://root.cern.ch/drupal`
- **tmLQCD:** This freely available software suite provides a set of tools to be used in lattice QCD simulations, mainly a (P)HMC implementation for Wilson and Wilson twisted mass fermions and inverter for different versions of the Dirac operator.
  `https://github.com/etmc/tmLQCD`
- **USQCD:** The software suite enables lattice QCD computations to be performed with high performance across a variety of architectures. The page contains links to the project web pages of the individual software modules, as well as to complete lattice QCD application packages which use them.
  `http://usqcd.jlab.org/usqcd-software/`

Astrophysics

- **IRAF:** The Image Reduction and Analysis Facility is a general purpose software system for the reduction and analysis of astronomical data. IRAF is written and supported by the IRAF programming group at the National Optical Astronomy Observatories (NOAO) in Tucson, Arizona.
  `http://iraf.noao.edu/`
- **Starlink:** Starlink was a UK Project supporting astronomical data processing. It was shut down in 2005 but its open-source software continues to be developed at the Joint Astronomy Centre. The software products are a collection of applications and libraries, usually focused on a specific aspect of data reduction or analysis.
  `http://starlink.jach.hawaii.edu/starlink`
- Links to a large number of astronomy software archives are listed at:
  `http://heasarc.nasa.gov/docs/heasarc/astro-update/`

Apps

- **arXiv mobile:** Android app for browsing and searching arXiv.org, and for reading, saving and sharing articles.
  `https://play.google.com/store/apps/details?id=com.commonsware.android.arXiv`
- **arXiv scanner:** Scans downloads folder for pdf files from arXiv. Adds title, authors and summary and makes all this information easily searchable from inside the application.
  `https://play.google.com/store/apps/details?id=com.agio.arxiv.scaner`
- **aNarXiv:** arXiv viewer.
  `https://play.google.com/store/apps/details?id=`

com.nephoapp.anarxiv

- **Scholarley:** Android client for Mendeley. The helper arXiv feeder intercepts pdf downloads from arXiv and sends the pdf link and all metadata to Scholarley.

  https://play.google.com/store/apps/details?id=info.matthewwardrop.scholarley

  https://play.google.com/store/apps/details?id=info.matthewwardrop.scholarley.feeder.arxiv

- **Collider:** This mobile app allows to see data from the ATLAS experiment at the LHC.

  http://collider.physics.ox.ac.uk/

- **LHSee:** This smartphone app allows to see collisions from the Large Hadron Collider.

  http://www2.physics.ox.ac.uk/about-us/outreach/public/lhsee

- **The Particles:** App for Apple iPad, Windows 8 and Microsoft Surface. Allows to browse a wealth of real event images and videos, read popular biographies of each of the particles and explore the A-Z of particle physics with its details and definitions of key concepts, laboratories and physicists. Developed by Science Photo Library in partnership with Prof. Frank Close.

  http://www.sciencephoto.com/apps/particles.html

12. Data repositories

Particle Physics

- **HepData:** The HepData Project, funded by the STFC(UK) and based at the IPPP at Durham University, has for more than 30 years compiled a Reaction Data database, comprising total and differential cross sections, structure functions, fragmentation functions, distributions of jet measures, polarisations, etc from a wide range of particle physics scattering experiments worldwide. It is regularly updated to include the latest data including that from the LHC. HepData and the data therein can also be accessed through Inspire. HepData also provides a series of on-line data reviews on a wide variety of topics with links to the data in the Reaction Database. In addition, HepData hosts a Parton Distribution Function server with an on-line PDF calculator and plotter.

  http://hepdata.cedar.ac.uk/

- **ILDG:** The International Lattice Data Grid is an international organization which provides standards, services, methods and tools that facilitates the sharing and interchange of lattice QCD gauge configurations among scientific collaborations, by uniting their regional data grids. It offers semantic access with local tools to worldwide distributed data.

  http://www.usqcd.org/ildg/

- **MCDB - Monte Carlo Database:** This central database of MC events aims to facilitate communication between Monte-Carlo experts and users of event samples in LHC collaborations. Having these events stored in a public place along with the corresponding documentation allows for direct cross checks of the performances on reference samples.

  http://mcdb.cern.ch/

- **MCPLOTS:** mcplots is a repository of Monte Carlo plots comparing High Energy Physics event generators to a wide variety of available experimental data. The site is supported by the LHC Physics Centre at CERN.

  http://mcplots.cern.ch/

Astrophysics

- **NASA's HEASARC:** The High Energy Astrophysics Science Archive Research Center (HEASARC) is the primary archive for NASA's (and other space agencies') missions dealing with electromagnetic radiation from extremely energetic phenomena ranging from black holes to the Big Bang.

  http://heasarc.gsfc.nasa.gov/

- **LAMBDA @ HEASARC:** This data center for Cosmic Microwave Background research, a merger of the High Energy Astrophysics Science Archive Research Center (HEASARC) and the Legacy Archive for Microwave Background Data Analysis (LAMBDA), provides archive data from NASA missions, software tools, and links to other sites of interest.

  http://lambda.gsfc.nasa.gov/

- The NASA archives provide access to raw and processed datasets from numerous NASA missions.

  Hubble telescope, other missions (UV, optical):

  http://archive.stsci.edu/

  Spitzer telescope, other missions (Infrared):

  http://irsa.ipac.caltech.edu/

  Chandra, Fermi telescopes, other missions:

  http://heasarc.gsfc.nasa.gov/

- **NASA/IPAC Extragalactic Database (NED):** An astronomical database that collates and cross-correlates information on extragalactic objects. It contains their positions, basic data, and names as well as bibliographic references to published papers, and notes from catalogs and other publications. NED supports searches for objects and references, and offers browsing capabilities for abstracts of articles of extragalactic interest.

  http://ned.ipac.caltech.edu/

- **SIMBAD:** The SIMBAD astronomical database provides basic data, cross-identifications, bibliography and measurements for astronomical objects outside the solar system. It can be queried by object name, coordinates and various criteria. Lists of objects and scripts can be submitted.

  http://simbad.u-strasbg.fr/simbad/

- **Virtual Observatory:** The Virtual Observatory provides a suite of resources to query for original data from a large number of archives. Two main tools are provided. One runs queries across multiple databases (such as the SDSS database) and combines the results. The other queries hundreds of archives for all datasets that fall on a particular piece of sky.

  http://www.us-vo.org/

General Physics

- **NIST Physical Measurement Laboratory:** The National Institute of Standards and Technology provides access to physical reference data (physical constants, atomic spectroscopy data, x-ray and gamma-ray data, radiation dosimetry data, nuclear physics data and more) and measurements and calibrations data (dimensional measurements, electromagnetic measurements). The site points to a general interest page, linking to exhibits of the Physical Measurement Laboratory in the NIST Virtual Museum.

  http://physics.nist.gov/

- **Springer Materials - The Landolt-Börnstein Database:** Landolt-Börnstein is a high-quality data collection in all areas of physical sciences and engineering, among others particle physics, electronic structure and transport, magnetism, superconductivity. International experts scan the primary literature in more than 8,000 peer-reviewed journals and evaluate and select the most valid information to be included in the database. It includes more than 100,000 online documents, 1,2 million references, and covers 250,000 chemical substances. The search functionality is freely accessible and the search results are displayed in their context, whereas the full text is secured to subscribers.

  http://www.springermaterials.com/

13. Data preservation

Particle Physics

- **DPHEP:** The efforts to define and coordinate Data Preservation and Long Term Analysis in HEP are coordinated by a study group formed to investigate the issues associated with these activities. The group, DPHEP, was initiated during 2008-2009 and includes all HEP major experiments and labs.

  Details of the organizational structure, the objectives, workshops and publications can be found on the website.

  The group is endorsed by the International Committee for Future Accelerators (ICFA).

  The experiments at colliders: BaBar, Belle, BES-III, Cleo, CDF, D0, H1 and ZEUS and the associated computing centres at SLAC (USA), KEK (Japan), IHEP (China), Jlab (USA), BNL (USA), Fermilab (USA), DESY (Germany), and CERN are all represented in the group. The LHC collabaorations have also joined the initiative in 2011. The participating experiments are in various stages of studying, preparing, or operating long-term data preservation and analysis systems. Technological methods, such as virtualization, and information management tools such as INSPIRE are also helpful in this area of research. Data access policies and outreach in HEP using real data are among the investigative areas of the DPHEP Study Group.

  `http://dphep.org`

Astrophysics

More formal and advanced data preservation activity is ongoing in the field of Experimental Astrophysics, including:

- SDSS

  `http://sdss.org`
- Fermi

  `http://fermi.gsfc.nasa.gov/ssc/data`
- IVOA

  `http://www.ivoa.net/`

14. Particle Physics Education and Outreach Sites

Science Educators' Networks:

- **IPPOG:** The International Particle Physics Outreach Group is a network of particle physicists, researchers, informal science educators and science explainers aiming to raise awareness, understanding and standards of global outreach efforts in particle physics and general science by providing discussion forums and regular information exchange for science institutions, proposing and implementing strategies to share lessons learned and best practices and promoting current outreach efforts of network members.

  `http://ippog.web.cern.ch/ippog/`

- **Interactions.org:** Designed to serve as a central resource for communicators of particle physics. The daily updated site provides links to current particle physics news from the world's press, high-resolution photos and graphics from the particle physics laboratories of the world; links to education and outreach programs; information about science policy and funding; links to universities; a glossary; a conference calendar; and links to many educational sites.

  `http://www.interactions.org`

- **I2U2:** Interactions in Understanding the Universe is an educational virtual organization strengthening the education and outreach activities of scientific experiments at US universities and laboratories by providing an infrastructure for hands-on laboratory courses.

  `http://www.i2u2.org`

Master Classes

- **CMS physics masterclass:** Lectures from active scientists give insight into methods of basic research, enabling the students to perform measurements on real data from the CMS experiment at the LHC. Like in an international research collaboration, the participants then discuss their results and compare with expectations.

  `http://cms.web.cern.ch/content/cms-physics-masterclass`

- **International Masterclasses:** Each year about 6000 high school students in 28 countries come to one of about 130 nearby universities or research centres for one day in order to unravel the mysteries of particle physics. Lectures from active scientists give insight in topics and methods of basic research at the fundaments of matter and forces, enabling the students to perform measurements on real data from particle physics experiments themselves. At the end of each day, like in an international research collaboration, the participants join in a video conference for discussion and combination of their results.

  `http://physicsmasterclasses.org/`

- **MINERVA:** MINERVA (Masterclass INvolving Event recognition visualised with Atlantis) is a masterclass tool for students to learn more about the ATLAS experiment at CERN, based on a simplified setup of the ATLAS event display, Atlantis.

  `http://atlas-minerva.web.cern.ch/atlas-minerva/`

General Sites

- **Contemporary Physics Education Project (CPEP):** Provides charts, brochures, Web links, and classroom activities. Online interactive courses include: Fundamental Particles and Interactions; Plasma Physics and Fusion; History and Fate of the Universe; and Nuclear Science.

  `http://www.cpepweb.org/`

Particle Physics Lessons & Activities

- **Angels and Demons:** With the aim of looking at the myth versus the reality of science at CERN this site offers teacher resources, slide shows and videos of talks given to teachers visiting CERN.

  `http://angelsanddemons.web.cern.ch/`

- **Big Bang:** An exhibition of the UK Science Museum with an interactive game about the hunt for the Higgs.

  `http://www.sciencemuseum.org.uk/antenna/bigbang/`

- **Big Bang Science: Exploring the origins of matter:** This Web site, produced by the Particle Physics and Astronomy Research Council of the UK (PPARC), explains what physicists are looking for with their giant instruments. Big Bang Science focuses on CERN particle detectors and on United Kingdom scientists' contribution to the search for the fundamental building blocks of matter.

  `http://hepwww.rl.ac.uk/pub/bigbang/part1.html`

- **CAMELIA:** CAMELIA (Cross-platform Atlas Multimedia Educational Lab for Interactive Analysis) is a discovery tool for the general public, based on computer gaming technology.

  `http://www.atlas.ch/camelia.html`

- **CERNland:** With a range of games, multimedia applications and films CERNland is the virtual theme park developed to bring the excitement of CERN's research to a young audience aged between 7 and 12. CERNland is designed to show children what is being done at CERN and inspire them with some physics at the same time.

  `http://www.cernland.net/`

- **CollidingParticles:** A series of films following a team of physicists involved in research at the LHC.

  `http://www.collidingparticles.com/`

- **Hands-On Universe:** This educational program enables students to investigate the Universe while applying tools and cocncepts from science, math and technology.

  `http://handsonuniverse.org/`

- **HYPATIA:** HYPATIA (Hybrid Pupil's Analysis Tool for Interactions in Atlas) is a tool for high school students to inspect the

graphic visualizaton of products of particle collisions in the ATLAS detector at CERN.

`http://hypatia.phys.uoa.gr/`

- **Lancaster Particle Physics:** This site, suitable for 16+ students, offers a number of simulations and explanations of particle physics, including a section on the LHC.

  `http://www.lppp.lancs.ac.uk/`

- **LHC @ home:** Platform for volunteers to help physicists develop and exploit particle accelerators like CERN's Large Hadron Collider, and to compare theory with experiment in the search for new fundamental particles.

  `http://lhcathome.web.cern.ch/LHCathome/`

  The LHC @ home 2.0 project Test4Theory allows users to participate in running simulations of high-energy particle physics using their home computers. The results are submitted to a database which is used as a common resource by both experimental and theoretical scientists working on the Large Hadron Collider at CERN.

  `http://boinc01.cern.ch/about-test4theory`

  SIXTRACK is a LHC @ home research project that allows users with Internet-connected computers to participate in advancing Accelerator Physics.

  `http://lhcathomeclassic.cern.ch/sixtrack/`

- **Particle Adventure:** One of the most popular Web sites for learning the fundamentals of matter and force. An award-winning interactive tour of quarks, neutrinos, antimatter, extra dimensions, dark matter, accelerators and particle detectors from the Particle Data Group of Lawrence Berkeley National Laboratory. Simple elegant graphics and translations into 15 languages.

  `http://particleadventure.org/`

- **Particle Detectives:** This website, maintained by the Science and Technology Facilities Council (STFC), is for inquisitive 14-19 year olds, their teachers and for researchers who want to find out and talk about the world's biggest scientific adventure, the Large Hadron Collider, featuring e.g. an LHC experiment simulator.

  `http://www.lhc.ac.uk/The+Particle+Detectives/15273.aspx`

- **Quarked! - Adventures in the Subatomic Universe:** This project, targeted to kids aged 7-12 (and their families), brings subatomic physics to life through a multimedia project including an interactive website, a facilitated program for museums and schools, and an educational outreach program.

  `http://www.quarked.org/`

- **QuarkNet:** Brings the excitement of particle physics research to high school teachers and their students. Teachers join research groups at about 50 universities and labs across the country. These research groups are part of particle physics experiments at CERN or Fermilab. About 100,000 students from 500+ US high schools learn fundamental physics as they participate in inquiry-oriented investigations and analyze real data online. QuarkNet is supported in part by the National Science Foundation and the U.S. Department of Energy.

  `https://quarknet.i2u2.org/`

- **Rewarding Learning videos about CERN:** The three videos based on interviews with scientists and engineers at CERN introduce pupils to CERN and the type of research and work undertaken there and are accompanied by teachers' notes.

  `http://www.nicurriculum.org.uk/STEMWorks/resources/cern/index.asp`

Lab Education Offices

- **Brookhaven National Laboratory (BNL) Educational Programs:** The Office of Educational Programs mission is to design, develop, implement, and facilitate workforce development and education initiatives that support the scientific mission at Brookhaven National Laboratory and the Department of Energy.

  `http://www.bnl.gov/education/`

- **CERN:** The CERN education website offers informations about teacher programmes and educational resources for schools.

  `http://education.web.cern.ch/education/`

- **DESY:** Offers courses for pupils and teachers as well as information for the general public, mostly in German.

  `http://www.desy.de/information_services/education/`

- **FermiLab Education Office:** Provides education resources and information about activities for educators, physicists, students and visitors to the Lab. In addition to information on 25 programs, the site provides online data-based investigations for high school students, online versions of exhibits in the Lederman Science Center, links to particle physics discovery resources, web-based instructional resources, what works for education and outreach, and links to the Lederman Science Center and the Teacher Resource Center.

  `http://ed.fnal.gov/`

- **LBL Education:** Berkeley Lab's Center for Science & Engineering Education (CSEE) carries out the Department of Energys education mission to train the next generation of scientists, as well as helping them to gain an understanding of the relationships among frontier science, technology, and society.

  `http://www.lbl.gov/education/`

- **Exploring SLAC Science:** This Stanford Linear Accelerator Center Web site explains physics concepts related to experiments conducted at SLAC.

  `http://www6.slac.stanford.edu/ExploringSLACScience.aspx`

Educational Programs of Experiments

- **ATLAS Discovery Quest:** One of several access points to ATLAS education and outreach pages. This page gives access to explanations of physical concepts, blogs, ATLAS facts, news, and information for students and teachers.

  `http://www.atlas.ch/physics.html`

- **ATLAS eTours:** Give a description of the Large Hadron Collider, explain how the ATLAS detector at the LHC works and give an overview over the experiments and their physics goals.

  `http://www.atlas.ch/etours.html`

- **CMS Education:** Provides access to educational resources (Story of the Universe, The Size of Things, What is a Particle), and to multimedia material, such as interviews, movies and photos.

  `http://cms.web.cern.ch/tags/education`

- **Education and Outreach @ IceCube:** Educational pages of the IceCube (South Pole Neutrino Detector).

  `http://icecube.wisc.edu/outreach`

- **LIGO Science Education Center:** The LIGO (Laser Interferometer Gravitational-wave Observatory) Science Education Center has over 40 interactive, hands-on exhibits that relate to the science of LIGO. The site hosts field trips for students, teacher training programs, and tours for the general public. Visitors can explore science concepts such as light, gravity, waves, and interference; learn about LIGO's search for gravitational waves; and interact with scientists and engineers.

  `http://www.ligo-la.caltech.edu/SEC.html`

- **Pierre Auger Observatory's Educational Pages:** The site offers information about cosmic rays and their detection, and provides material for students and teachers.

  `http://www.auger.org/cosmic_rays/`

News

- **asimmetrie:** bimonthly magazine about particle physics published by INFN, the Istituto Nazionale di Fisica Nucleare

  `http://www.asimmetrie.it/`

- **CERN Courier:**

  twitter: @particlenews
- **physics.org news:** This IOP news site presents physics stories from around the world wide web.
  http://www.physics.org/news.asp
- **SLAC Signals:** This email newsletter reports about cutting-edge science, major SLAC milestones and other lab information. It has replaced SLAC Today in November 2013. Its signup page can be found at
  http://eepurl.com/IqPl1
- **symmetry:** This magazine about particle physics and its connections to other aspects of life and science, from interdisciplinary collaborations to policy to culture is published 6 times per year by Fermilab and SLAC.
  http://www.symmetrymagazine.org/
  twitter: @symmetrymag

Art in Physics

- **Arts@CERN:** A 3-year artists residency programme in Digital Arts and Dance/ Performance.
  http://arts.web.cern.ch/collide/
- **Superposition:** This artist-in-residence programme from the Institute of Physics invites visual artists and physicists to collaboratively explore and contribute to contemporary art.
  http://www.physics.org/superposition

Blogs

This is a very incomplete collection of particle physics related blogs:

- **ATLAS blog:**
  http://www.atlas.ch/blog
- **Physics arXiv blog:** Technology Review blog on new ideas at arXiv.org.
  http://www.technologyreview.com/blog/arxiv/
- **Life and Physics:** Jon Butterworth's blog in the Guardian.
  http://www.guardian.co.uk/science/life-and-physics
- **Not Even Wrong:** Peter Woit's blog on topics in physics and mathematics.
  http://www.math.columbia.edu/∼woit/wordpress/
- **Of Particular Significance:** Conversations about science, with a current focus on particle physics, with theoretical physicist Matt Strassler.
  http://profmattstrassler.com/
- **Preposterous Universe:** Theoretical physicist Sean Carroll's blog.
  http://www.preposterousuniverse.com/
- **Quantum diaries:** Thoughts on work and life from particle physicists from around the world.
  http://www.quantumdiaries.org/
  The US LHC blog gives a vivid account of the daily activity of US LHC researchers.
  http://www.quantumdiaries.org/lab-81/
- **Science blogs:** Launched in January 2006, ScienceBlogs features bloggers from a wide array of scientific disciplines, including physics.
  http://scienceblogs.com/channel/physical-science/

GAUGE AND HIGGS BOSONS

γ

$I(J^{PC}) = 0,1(1^{--})$

Mass $m < 1 \times 10^{-18}$ eV
Charge $q < 1 \times 10^{-35}$ e
Mean life τ = Stable

g or gluon

$I(J^{P}) = 0(1^{-})$

Mass $m = 0$ [a]
SU(3) color octet

graviton

$J = 2$

Mass $m < 6 \times 10^{-32}$ eV

W

$J = 1$

Charge = ± 1 e
Mass $m = 80.385 \pm 0.015$ GeV
$m_Z - m_W = 10.4 \pm 1.6$ GeV
$m_{W^+} - m_{W^-} = -0.2 \pm 0.6$ GeV
Full width $\Gamma = 2.085 \pm 0.042$ GeV
$\langle N_{\pi^\pm} \rangle = 15.70 \pm 0.35$
$\langle N_{K^\pm} \rangle = 2.20 \pm 0.19$
$\langle N_p \rangle = 0.92 \pm 0.14$
$\langle N_{\text{charged}} \rangle = 19.39 \pm 0.08$

W^- modes are charge conjugates of the modes below.

W^+ DECAY MODES		Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)
$\ell^+ \nu$	[b]	(10.86± 0.09) %		–
$e^+ \nu$		(10.71± 0.16) %		40192
$\mu^+ \nu$		(10.63± 0.15) %		40192
$\tau^+ \nu$		(11.38± 0.21) %		40173
hadrons		(67.41± 0.27) %		–
$\pi^+ \gamma$		$< 7 \times 10^{-5}$	95%	40192
$D_s^+ \gamma$		$< 1.3 \times 10^{-3}$	95%	40168
cX		(33.3 ± 2.6) %		–
$c\overline{s}$		(31 $^{+13}_{-11}$) %		–
invisible	[c]	(1.4 ± 2.9) %		–

Z

$J = 1$

Charge = 0
Mass $m = 91.1876 \pm 0.0021$ GeV [d]
Full width $\Gamma = 2.4952 \pm 0.0023$ GeV
$\Gamma(\ell^+\ell^-) = 83.984 \pm 0.086$ MeV [b]
$\Gamma(\text{invisible}) = 499.0 \pm 1.5$ MeV [e]
$\Gamma(\text{hadrons}) = 1744.4 \pm 2.0$ MeV
$\Gamma(\mu^+\mu^-)/\Gamma(e^+e^-) = 1.0009 \pm 0.0028$
$\Gamma(\tau^+\tau^-)/\Gamma(e^+e^-) = 1.0019 \pm 0.0032$ [f]

Average charged multiplicity

$\langle N_{charged} \rangle = 20.76 \pm 0.16$ (S = 2.1)

Couplings to quarks and leptons

$g_V^\ell = -0.03783 \pm 0.00041$
$g_V^u = 0.25^{+0.07}_{-0.06}$
$g_V^d = -0.33^{+0.05}_{-0.06}$
$g_A^\ell = -0.50123 \pm 0.00026$
$g_A^u = 0.50^{+0.04}_{-0.06}$
$g_A^d = -0.523^{+0.050}_{-0.029}$
$g^{\nu_\ell} = 0.5008 \pm 0.0008$
$g^{\nu_e} = 0.53 \pm 0.09$
$g^{\nu_\mu} = 0.502 \pm 0.017$

Asymmetry parameters [g]

$A_e = 0.1515 \pm 0.0019$
$A_\mu = 0.142 \pm 0.015$
$A_\tau = 0.143 \pm 0.004$
$A_s = 0.90 \pm 0.09$
$A_c = 0.670 \pm 0.027$
$A_b = 0.923 \pm 0.020$

Charge asymmetry (%) at Z pole

$A_{FB}^{(0\ell)} = 1.71 \pm 0.10$
$A_{FB}^{(0u)} = 4 \pm 7$
$A_{FB}^{(0s)} = 9.8 \pm 1.1$
$A_{FB}^{(0c)} = 7.07 \pm 0.35$
$A_{FB}^{(0b)} = 9.92 \pm 0.16$

Gauge & Higgs Boson Summary Table

Mass $m >$ 476 GeV, CL = 95% (electroweak fit)

Z_η of $E_6 \rightarrow SU(3) \times SU(2) \times U(1) \times U(1)_\eta$ (with $g_\eta = e/\cos\theta_W$)

Mass $m >$ 1.870×10^3 GeV, CL = 95% ($p\overline{p}$ direct search)

Mass $m >$ 619 GeV, CL = 95% (electroweak fit)

Scalar Leptoquarks

Mass $m >$ 830 GeV, CL = 95% (1st generation, pair prod.)

Mass $m >$ 304 GeV, CL = 95% (1st gener., single prod.)

Mass $m >$ 840 GeV, CL = 95% (2nd gener., pair prod.)

Mass $m >$ 73 GeV, CL = 95% (2nd gener., single prod.)

Mass $m >$ 525 GeV, CL = 95% (3rd gener., pair prod.)

(See the Particle Listings for assumptions on leptoquark quantum numbers and branching fractions.)

Diquarks

Mass $m >$ 3.750×10^3 GeV, CL = 95%

Axigluon

Mass $m >$ 3.360×10^3 GeV, CL = 95%

Axions (A^0) and Other Very Light Bosons, Searches for

The standard Peccei-Quinn axion is ruled out. Variants with reduced couplings or much smaller masses are constrained by various data. The Particle Listings in the full *Review* contain a Note discussing axion searches.

The best limit for the half-life of neutrinoless double beta decay with Majoron emission is $> 7.2 \times 10^{24}$ years (CL = 90%).

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] Theoretical value. A mass as large as a few MeV may not be precluded.

[b] ℓ indicates each type of lepton (e, μ, and τ), not sum over them.

[c] This represents the width for the decay of the W boson into a charged particle with momentum below detectability, p< 200 MeV.

[d] The Z-boson mass listed here corresponds to a Breit-Wigner resonance parameter. It lies approximately 34 MeV above the real part of the position of the pole (in the energy-squared plane) in the Z-boson propagator.

[e] This partial width takes into account Z decays into $\nu\overline{\nu}$ and any other possible undetected modes.

[f] This ratio has not been corrected for the τ mass.

[g] Here $A \equiv 2g_V g_A/(g_V^2+g_A^2)$.

[h] Here ℓ indicates e or μ.

[i] The value is for the sum of the charge states or particle/antiparticle states indicated.

[j] This value is updated using the product of (i) the $Z \to b\overline{b}$ fraction from this listing and (ii) the b-hadron fraction in an unbiased sample of weakly decaying b-hadrons produced in Z-decays provided by the Heavy Flavor Averaging Group (HFAG, http://www.slac.stanford.edu/xorg/hfag/osc/PDG_2009/#FRACZ).

[k] See the Z Particle Listings for the γ energy range used in this measurement.

[l] For $m_{\gamma\gamma} = (60 \pm 5)$ GeV.

[n] The limits assume no invisible decays.

Lepton Summary Table

LEPTONS

e

$J = \frac{1}{2}$

Mass $m = (548.57990946 \pm 0.00000022) \times 10^{-6}$ u
Mass $m = 0.510998928 \pm 0.000000011$ MeV

$\beta'/A = (2 \pm 7) \times 10^{-3}$
$\overline{\eta} = 0.02 \pm 0.08$

μ^+ modes are charge conjugates of the modes below.

μ^- DECAY MODES		Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)
$e^-\overline{\nu}_e\nu_\mu$		$\approx 100\%$		53
$e^-\overline{\nu}_e\nu_\mu\gamma$	[d]	(1.4 ± 0.4) %		53
$e^-\overline{\nu}_e\nu_\mu e^+e^-$	[e]	$(3.4 \pm 0.4) \times 10^{-5}$		53
Lepton Family number (LF) violating modes				
$e^-\nu_e\overline{\nu}_\mu$	LF	[f] < 1.2 %	90%	53
$e^-\gamma$	LF	$< 5.7 \times 10^{-13}$	90%	53
$e^-e^+e^-$	LF	$< 1.0 \times 10^{-12}$	90%	53
$e^-2\gamma$	LF	$< 7.2 \times 10^{-11}$	90%	53

τ

$J = \frac{1}{2}$

Mass $m = 1776.82 \pm 0.16$ MeV
$(m_{\tau^+} - m_{\tau^-})/m_{\text{average}} < 2.8 \times 10^{-4}$, CL = 90%
Mean life $\tau = (290.3 \pm 0.5) \times 10^{-15}$ s
$c\tau = 87.03$ μm
Magnetic moment anomaly > -0.052 and < 0.013, CL = 95%
$\text{Re}(d_\tau) = -0.220$ to 0.45×10^{-16} $e$cm, CL = 95%
$\text{Im}(d_\tau) = -0.250$ to 0.0080×10^{-16} $e$cm, CL = 95%

Weak dipole moment

$\text{Re}(d_\tau^w) < 0.50 \times 10^{-17}$ $e$cm, CL = 95%
$\text{Im}(d_\tau^w) < 1.1 \times 10^{-17}$ $e$cm, CL = 95%

Weak anomalous magnetic dipole moment

$\text{Re}(\alpha_\tau^w) < 1.1 \times 10^{-3}$, CL = 95%
$\text{Im}(\alpha_\tau^w) < 2.7 \times 10^{-3}$, CL = 95%
$\tau^\pm \to \pi^\pm K_S^0 \nu_\tau$ (RATE DIFFERENCE) / (RATE SUM) = (-0.36 ± 0.25)%

Decay parameters

See the τ Particle Listings for a note concerning τ-decay parameters.

$\rho(e \text{ or } \mu) = 0.745 \pm 0.008$
$\rho(e) = 0.747 \pm 0.010$
$\rho(\mu) = 0.763 \pm 0.020$
$\xi(e \text{ or } \mu) = 0.985 \pm 0.030$
$\xi(e) = 0.994 \pm 0.040$
$\xi(\mu) = 1.030 \pm 0.059$
$\eta(e \text{ or } \mu) = 0.013 \pm 0.020$
$\eta(\mu) = 0.094 \pm 0.073$
$(\delta\xi)(e \text{ or } \mu) = 0.746 \pm 0.021$
$(\delta\xi)(e) = 0.734 \pm 0.028$
$(\delta\xi)(\mu) = 0.778 \pm 0.037$
$\xi(\pi) = 0.993 \pm 0.022$
$\xi(\rho) = 0.994 \pm 0.008$
$\xi(a_1) = 1.001 \pm 0.027$
$\xi(\text{all hadronic modes}) = 0.995 \pm 0.007$

τ^+ modes are charge conjugates of the modes below. "$h^\pm$" stands for $\pi^\pm$ or $K^\pm$. "ℓ" stands for e or μ. "Neutrals" stands for γ's and/or π^0's.

τ^- DECAY MODES		Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)

Lepton Summary Table

Lepton Family number (LF), Lepton number (L), or Baryon number (B) violating modes

L means lepton number violation (*e.g.* $\tau^- \to e^+\pi^-\pi^-$). Following common usage, LF means lepton family violation *and not* lepton number violation (*e.g.* $\tau^- \to e^-\pi^+\pi^-$). B means baryon number violation.

$e^-\gamma$	LF	$<$	3.3	$\times 10^{-8}$	CL=90%	888
$\mu^-\gamma$	LF	$<$	4.4	$\times 10^{-8}$	CL=90%	885
$e^-\pi^0$	LF	$<$	8.0	$\times 10^{-8}$	CL=90%	883
$\mu^-\pi^0$	LF	$<$	1.1	$\times 10^{-7}$	CL=90%	880
$e^-K^0_S$	LF	$<$	2.6	$\times 10^{-8}$	CL=90%	819
$\mu^-K^0_S$	LF	$<$	2.3	$\times 10^{-8}$	CL=90%	815
$e^-\eta$	LF	$<$	9.2	$\times 10^{-8}$	CL=90%	804

Heavy Charged Lepton Searches

$L^\pm$ – charged lepton

Mass $m >$ 100.8 GeV, CL = 95% [h] Decay to νW.

$L^\pm$ – stable charged heavy lepton

Mass $m >$ 102.6 GeV, CL = 95%

Neutrino Properties

See the note on "Neutrino properties listings" in the Particle Listings.

Mass $m <$ 2 eV (tritium decay)
Mean life/mass, $\tau/m >$ 300 s/eV, CL = 90% (reactor)
Mean life/mass, $\tau/m > 7\times10^9$ s/eV (solar)
Mean life/mass, $\tau/m >$ 15.4 s/eV, CL = 90% (accelerator)
Magnetic moment $\mu < 0.29\times10^{-10}\ \mu_B$, CL = 90% (reactor)

Number of Neutrino Types

Number $N = 2.984 \pm 0.008$ (Standard Model fits to LEP data)
Number $N = 2.92 \pm 0.05$ (S = 1.2) (Direct measurement of invisible Z width)

Neutrino Mixing

The following values are obtained through data analyses based on the 3-neutrino mixing scheme described in the review "Neutrino Mass, Mixing, and Oscillations" by K. Nakamura and S.T. Petcov in this *Review*.

$\sin^2(2\theta_{12}) = 0.846 \pm 0.021$
$\Delta m^2_{21} = (7.53 \pm 0.18)\times10^{-5}$ eV^2
$\sin^2(2\theta_{23}) = 0.999^{+0.001}_{-0.018}$ (normal mass hierarchy)
$\sin^2(2\theta_{23}) = 1.000^{+0.000}_{-0.017}$ (inverted mass hierarchy)
$\Delta m^2_{32} = (2.44 \pm 0.06)\times10^{-3}$ eV^2 [i] (normal mass hierarchy)
$\Delta m^2_{32} = (2.52 \pm 0.07)\times10^{-3}$ eV^2 [i] (inverted mass hierarchy)
$\sin^2(2\theta_{13}) = (9.3 \pm 0.8)\times10^{-2}$

Stable Neutral Heavy Lepton Mass Limits

Mass $m >$ 45.0 GeV, CL = 95% (Dirac)
Mass $m >$ 39.5 GeV, CL = 95% (Majorana)

Neutral Heavy Lepton Mass Limits

Mass $m >$ 90.3 GeV, CL = 95%
(Dirac ν_L coupling to e, μ, τ; conservative case(τ))
Mass $m >$ 80.5 GeV, CL = 95%
(Majorana ν_L coupling to e, μ, τ; conservative case(τ))

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] This is the best limit for the mode $e^- \to \nu\gamma$. The best limit for "electron disappearance" is 6.4×10^{24} yr.

[b] See the "Note on Muon Decay Parameters" in the μ Particle Listings for definitions and details.

[c] P_μ is the longitudinal polarization of the muon from pion decay. In standard $V-A$ theory, $P_\mu = 1$ and $\rho = \delta = 3/4$.

[d] This only includes events with the γ energy > 10 MeV. Since the $e^-\overline{\nu}_e\nu_\mu$ and $e^-\overline{\nu}_e\nu_\mu\gamma$ modes cannot be clearly separated, we regard the latter mode as a subset of the former.

[e] See the relevant Particle Listings for the energy limits used in this measurement.

[f] A test of additive vs. multiplicative lepton family number conservation.

[g] Basis mode for the τ.

[h] $L^\pm$ mass limit depends on decay assumptions; see the Full Listings.

[i] The sign of Δm^2_{32} is not known at this time. The range quoted is for the absolute value.

QUARKS

The u-, d-, and s-quark masses are estimates of so-called "current-quark masses," in a mass-independent subtraction scheme such as $\overline{\text{MS}}$ at a scale $\mu \approx 2$ GeV. The c- and b-quark masses are the "running" masses in the $\overline{\text{MS}}$ scheme. For the b-quark we also quote the 1S mass. These can be different from the heavy quark masses obtained in potential models.

u

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

$m_u = 2.3^{+0.7}_{-0.5}$ MeV Charge $= \frac{2}{3}\,e$ $I_z = +\frac{1}{2}$
$m_u/m_d = 0.38$–0.58

d

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

$m_d = 4.8^{+0.5}_{-0.3}$ MeV Charge $= -\frac{1}{3}\,e$ $I_z = -\frac{1}{2}$
$m_s/m_d = 17$–22
$\overline{m} = (m_u + m_d)/2 = 3.5^{+0.7}_{-0.2}$ MeV

s

$I(J^P) = 0(\frac{1}{2}^+)$

$m_s = 95 \pm 5$ MeV Charge $= -\frac{1}{3}\,e$ Strangeness $= -1$
$m_s\ /\ ((m_u + m_d)/2) = 27.5 \pm 1.0$

c

$I(J^P) = 0(\frac{1}{2}^+)$

$m_c = 1.275 \pm 0.025$ GeV Charge $= \frac{2}{3}\,e$ Charm $= +1$

b

$I(J^P) = 0(\frac{1}{2}^+)$

Charge $= -\frac{1}{3}\,e$ Bottom $= -1$

$m_b(\overline{\text{MS}}) = 4.18 \pm 0.03$ GeV
$m_b(1\text{S}) = 4.66 \pm 0.03$ GeV

t

$I(J^P) = 0(\frac{1}{2}^+)$

Charge $= \frac{2}{3}\,e$ Top $= +1$

Mass (direct measurements) $m = 173.21 \pm 0.51 \pm 0.71$ GeV [a,b]
Mass ($\overline{\text{MS}}$ from cross-section measurements) $m = 160^{+5}_{-4}$ GeV [a]
Mass (Pole from cross-section measurements) $m = 176.7^{+4.0}_{-3.4}$ GeV
$m_t - m_{\overline{t}} = -0.2 \pm 0.5$ GeV (S = 1.1)
Full width $\Gamma = 2.0 \pm 0.5$ GeV
$\Gamma(Wb)/\Gamma(Wq(q = b, s, d)) = 0.91 \pm 0.04$

t-quark EW Couplings

$F_0 = 0.690 \pm 0.030$
$F_- = 0.314 \pm 0.025$
$F_+ = 0.008 \pm 0.016$
$F_{V+A} < 0.29$, CL = 95%

t DECAY MODES		Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)
$Wq(q = b, s, d)$				–
Wb				–
$\ell\nu_\ell$anything		[c,d] (9.4±2.4) %		–
$\gamma q(q{=}u,c)$		[e] $< 5.9 \times 10^{-3}$	95%	–
$\Delta T = 1$ weak neutral current ($T1$) modes				
$Zq(q{=}u,c)$	$T1$	[f] $< 2.1 \times 10^{-3}$	95%	–

b′ (4th Generation) Quark, Searches for

Mass $m >$ 190 GeV, CL = 95% ($p\overline{p}$, quasi-stable b')
Mass $m >$ 400 GeV, CL = 95% (pp, neutral-current decays)
Mass $m >$ 675 GeV, CL = 95% (pp, charged-current decays)
Mass $m >$ 46.0 GeV, CL = 95% (e^+e^-, all decays)

t′ (4th Generation) Quark, Searches for

Mass $m >$ 782 GeV, CL = 95% (pp, neutral-current decays)
Mass $m >$ 700 GeV, CL = 95% (pp, charged-current decays)

Free Quark Searches

All searches since 1977 have had negative results.

NOTES

[a] A discussion of the definition of the top quark mass in these measurements can be found in the review "The Top Quark."
[b] Based on published top mass measurements using data from Tevatron Run-I and Run-II and LHC at $\sqrt{s} = 7$ TeV. Including the most recent unpublished results from Tevatron Run-II, the Tevatron Electroweak Working Group reports a top mass of 173.2 ± 0.9 GeV. See the note "The Top Quark' in the Quark Particle Listings of this *Review*.
[c] ℓ means e or μ decay mode, not the sum over them.
[d] Assumes lepton universality and W-decay acceptance.
[e] This limit is for $\Gamma(t \to \gamma q)/\Gamma(t \to Wb)$.
[f] This limit is for $\Gamma(t \to Zq)/\Gamma(t \to Wb)$.

Meson Summary Table

LIGHT UNFLAVORED MESONS ($S = C = B = 0$)

For $I = 1$ (π, b, ρ, a): $u\overline{d}$, $(u\overline{u}-d\overline{d})/\sqrt{2}$, $d\overline{u}$;
for $I = 0$ (η, η', h, h', ω, ϕ, f, f'): $c_1(u\overline{u} + d\overline{d}) + c_2(s\overline{s})$

$\pi^\pm$

$I^G(J^P) = 1^-(0^-)$

Mass $m = 139.57018 \pm 0.00035$ MeV (S = 1.2)
Mean life $\tau = (2.6033 \pm 0.0005) \times 10^{-8}$ s (S = 1.2)
$c\tau = 7.8045$ m

$\pi^\pm \to \ell^\pm \nu\gamma$ form factors [a]

$F_V = 0.0254 \pm 0.0017$
$F_A = 0.0119 \pm 0.0001$
F_V slope parameter $a = 0.10 \pm 0.06$
$R = 0.059^{+0.009}_{-0.008}$

π^- modes are charge conjugates of the modes below.

For decay limits to particles which are not established, see the section on Searches for Axions and Other Very Light Bosons.

π^+ DECAY MODES		Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K_S^0 modes, not as $\overline{K}^0$ modes. Nearly always it is a K_S^0 that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\,\Gamma(K_S^0) = \Gamma(\overline{K}^0)$.

$r_2 \equiv a_1/a_0$ in $D^0 \to \pi^-\ell^+\nu_\ell = 6 \pm 3.0$

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K^0_S modes, not as $\overline{K}^0$ modes. Nearly always it is a K^0_S that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\,\Gamma(K^0_S) = \Gamma(\overline{K}^0)$.

BOTTOM MESONS ($B = \pm 1$)

$B^+ = u\overline{b}$, $B^0 = d\overline{b}$, $\overline{B}^0 = \overline{d}b$, $B^- = \overline{u}b$, similarly for B^*'s

B-particle organization

Many measurements of B decays involve admixtures of B hadrons. Previously we arbitrarily included such admixtures in the $B^\pm$ section, but because of their importance we have created two new sections: "$B^\pm/B^0$ Admixture" for $\Upsilon(4S)$ results and "$B^\pm/B^0/B_s^0/b$-baryon Admixture" for results at higher energies. Most inclusive decay branching fractions and χ_b at high energy are found in the Admixture sections. B^0-$\overline{B}^0$ mixing data are found in the B^0 section, while B_s^0-$\overline{B}_s^0$ mixing data and B-$\overline{B}$ mixing data for a B^0/B_s^0 admixture are found in the B_s^0 section. CP-violation data are found in the $B^\pm$, B^0, and $B^\pm$ B^0 Admixture sections. b-baryons are found near the end of the Baryon section.

The organization of the B sections is now as follows, where bullets indicate particle sections and brackets indicate reviews.

- $B^\pm$
  mass, mean life, CP violation, branching fractions
- B^0
  mass, mean life, B^0-$\overline{B}^0$ mixing, CP violation, branching fractions
- $B^\pm$ B^0 Admixtures
  CP violation, branching fractions
- $B^\pm/B^0/B_s^0/b$-baryon Admixtures
  mean life, production fractions, branching fractions
- B^*
  mass
- $B_1(5721)^0$
  mass
- $B_2^*(5747)^0$
  mass
- B_s^0
  mass, mean life, B_s^0-$\overline{B}_s^0$ mixing, CP violation, branching fractions
- B_s^*
  mass
- $B_{s1}(5830)^0$
  mass
- $B_{s2}^*(5840)^0$
  mass
- $B_c^\pm$
  mass, mean life, branching fractions

At the end of Baryon Listings:

- Λ_b
  mass, mean life, branching fractions
- $\Lambda_b(5912)^0$
  mass, mean life
- $\Lambda_b(5920)^0$
  mass, mean life
- Σ_b
  mass
- Σ_b^*
  mass
- Ξ_b^0, Ξ_b^-
  mass, mean life, branching fractions
- $\Xi_b(5945)^0$

mass, mean life

- Ω_b^-

mass, branching fractions

- b-baryon Admixture

mean life, branching fractions

$B^\pm$ $I(J^P) = \frac{1}{2}(0^-)$

I, J, P need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B^\pm} = 5279.26 \pm 0.17$ MeV
Mean life $\tau_{B^\pm} = (1.638 \pm 0.004) \times 10^{-12}$ s
$c\tau = 491.1\ \mu$m

Meson Summary Table

B^- modes are charge conjugates of the modes below. Modes which do not identify the charge state of the B are listed in the $B^\pm/B^0$ ADMIXTURE section.

The branching fractions listed below assume 50% $B^0\overline{B}{}^0$ and 50% B^+B^- production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^*, and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

B^+ DECAY MODES		Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)

$\overline{B}^0$ modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing. Modes which do not identify the charge state of the B are listed in the $B^\pm/B^0$ ADMIXTURE section.

The branching fractions listed below assume 50% $B^0\overline{B}^0$ and 50% B^+B^- production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^*, and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

$A_{CP}(B \to K^* e^+ e^-) = -0.18 \pm 0.15$
$A_{CP}(B \to K^*\mu^+\mu^-) = -0.03 \pm 0.13$
$A_{CP}(B \to K^*\ell^+\ell^-) = -0.04 \pm 0.07$
$A_{CP}(B \to \eta\text{anything}) = -0.13^{+0.04}_{-0.05}$

The branching fraction measurements are for an admixture of B mesons at the $\Upsilon(4S)$. The values quoted assume that $B(\Upsilon(4S) \to B\overline{B}) = 100\%$.

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ *anything*, the treatment of multiple D's in the final state must be defined. One possibility would be to count the number of events with one-or-more D's and divide by the total number of B's. Another possibility would be to count the total number of D's and divide by the total number of B's, which is the definition of average multiplicity. The two definitions are identical if only one D is allowed in the final state. Even though the "one-or-more" definition seems sensible, for practical reasons inclusive branching fractions are almost always measured using the multiplicity definition. For heavy final state particles, authors call their results inclusive branching fractions while for light particles some authors call their results multiplicities. In the B sections, we list all results as inclusive branching fractions, adopting a multiplicity definition. This means that inclusive branching fractions can exceed 100% and that inclusive partial widths can exceed total widths, just as inclusive cross sections can exceed total cross section.

$\overline{B}$ modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing.

$B^\pm/B^0/B_s^0/b$-baryon ADMIXTURE

These measurements are for an admixture of bottom particles at high energy (LHC, LEP, Tevatron, S$p\overline{p}$S).

Mean life $\tau = (1.568 \pm 0.009) \times 10^{-12}$ s

Mean life $\tau = (1.72 \pm 0.10) \times 10^{-12}$ s Charged b-hadron admixture

Mean life $\tau = (1.58 \pm 0.14) \times 10^{-12}$ s Neutral b-hadron admixture

$\tau_{\text{charged } b\text{-hadron}}/\tau_{\text{neutral } b\text{-hadron}} = 1.09 \pm 0.13$

$|\Delta\tau_b|/\tau_{b,\overline{b}} = -0.001 \pm 0.014$

$\text{Re}(\epsilon_b)\ /\ (1 + |\epsilon_b|^2) = (1.2 \pm 0.4) \times 10^{-3}$

The branching fraction measurements are for an admixture of B mesons and baryons at energies above the $\Upsilon(4S)$. Only the highest energy results (LHC, LEP, Tevatron, S$p\overline{p}$S) are used in the branching fraction averages. In the following, we assume that the production fractions are the same at the LHC, LEP, and at the Tevatron.

For inclusive branching fractions, *e.g.*, $B \to D^{\pm}$anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

The modes below are listed for a $\overline{b}$ initial state. b modes are their charge conjugates. Reactions indicate the weak decay vertex and do not include mixing.

$\overline{b}$ DECAY MODES	Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)

PRODUCTION FRACTIONS

The production fractions for weakly decaying b-hadrons at high energy have been calculated from the best values of mean lives, mixing parameters, and branching fractions in this edition by the Heavy Flavor Averaging Group (HFAG) as described in the note "B^0-$\overline{B}^0$ Mixing" in the B^0 Particle Listings. The production fractions in b-hadronic Z decay or $p\overline{p}$ collisions at the Tevatron are also listed at the end of the section. Values assume

$$\mathrm{B}(\overline{b} \to B^+) = \mathrm{B}(\overline{b} \to B^0)$$
$$\mathrm{B}(\overline{b} \to B^+) + \mathrm{B}(\overline{b} \to B^0) + \mathrm{B}(\overline{b} \to B_s^0) + \mathrm{B}(b \to b\text{-baryon}) = 100\ \%.$$

The correlation coefficients between production fractions are also reported:

$cor(B_s^0, b\text{-baryon}) = -0.291$
$cor(B_s^0, B^{\pm}{=}B^0) = -0.083$
$cor(b\text{-baryon}, B^{\pm}{=}B^0) = -0.929.$

The notation for production fractions varies in the literature (f_d, d_{B^0}, $f(b \to \overline{B}^0)$, Br($b \to \overline{B}^0$)). We use our own branching fraction notation here, B($\overline{b} \to B^0$).

Note these production fractions are b-hadronization fractions, not the conventional branching fractions of b-quark to a B-hadron, which may have considerable dependence on the initial and final state kinematic and production environment.

BOTTOM, STRANGE MESONS ($B = \pm 1, S = \mp 1$)

$B_s^0 = s\overline{b}$, $\overline{B}_s^0 = \overline{s}b$, similarly for B_s^*'s

B_s^0

$I(J^P) = 0(0^-)$

I, J, P need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B_s^0} = 5366.77 \pm 0.24$ MeV
$m_{B_s^0} - m_B = 87.35 \pm 0.23$ MeV
Mean life $\tau = (1.512 \pm 0.007) \times 10^{-12}$ s
$c\tau = 453.3\ \mu$m
$\Delta\Gamma_{B_s^0} = \Gamma_{B_{sL}^0} - \Gamma_{B_{sH}^0} = (0.091 \pm 0.008) \times 10^{12}\ s^{-1}$

B_s^0-$\overline{B}_s^0$ mixing parameters

$\Delta m_{B_s^0} = m_{B_{sH}^0} - m_{B_{sL}^0} = (17.761 \pm 0.022) \times 10^{12}\ \hbar\ s^{-1}$
$= (1.1691 \pm 0.0014) \times 10^{-8}$ MeV
$x_s = \Delta m_{B_s^0}/\Gamma_{B_s^0} = 26.85 \pm 0.13$
$\chi_s = 0.499311 \pm 0.000007$

CP violation parameters in B_s^0

$\mathrm{Re}(\epsilon_{B_s^0}) / (1 + |\epsilon_{B_s^0}|^2) = (-1.9 \pm 1.0) \times 10^{-3}$
$C_{KK}(B_s^0 \to K^+K^-) = 0.14 \pm 0.11$
$S_{KK}(B_s^0 \to K^+K^-) = 0.30 \pm 0.13$
CP Violation phase $\beta_s = (0.0 \pm 3.5) \times 10^{-2}$
$A_{CP}(B_s \to \pi^+K^-) = 0.28 \pm 0.04$
$A_{CP}(B_s^0 \to [K^+K^-]_D \overline{K}^*(892)^0) = 0.04 \pm 0.16$

These branching fractions all scale with $B(\overline{b} \to B_s^0)$.

The branching fraction $B(B_s^0 \to D_s^-\ell^+\nu_\ell \text{anything})$ is not a pure measurement since the measured product branching fraction $B(\overline{b} \to B_s^0) \times B(B_s^0 \to D_s^-\ell^+\nu_\ell \text{anything})$ was used to determine $B(\overline{b} \to B_s^0)$, as described in the note on "B^0-$\overline{B}^0$ Mixing"

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

Other decays

invisible	< 1.6	%	CL=90%	–

$\psi(3770)$

$I^G(J^{PC}) = 0^-(1^{--})$

Mass m = 3773.15 ± 0.33 MeV
Full width Γ = 27.2 ± 1.0 MeV
Γ_{ee} = 0.262 ± 0.018 keV (S = 1.4)

In addition to the dominant decay mode to $D\overline{D}$, $\psi(3770)$ was found to decay into the final states containing the J/ψ (BAI 05, ADAM 06). ADAMS 06 and HUANG 06A searched for various decay modes with light hadrons and found a statistically significant signal for the decay to $\phi\eta$ only (ADAMS 06).

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as S = $\sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] See the "Note on $\pi^\pm \to \ell^\pm\nu\gamma$ and $K^\pm \to \ell^\pm\nu\gamma$ Form Factors" in the $\pi^\pm$ Particle Listings for definitions and details.

[b] Measurements of $\Gamma(e^+\nu_e)/\Gamma(\mu^+\nu_\mu)$ always include decays with γ's, and measurements of $\Gamma(e^+\nu_e\gamma)$ and $\Gamma(\mu^+\nu_\mu\gamma)$ never include low-energy γ's. Therefore, since no clean separation is possible, we consider the modes with γ's to be subreactions of the modes without them, and let $[\Gamma(e^+\nu_e) + \Gamma(\mu^+\nu_\mu)]/\Gamma_{\rm total} = 100\%$.

[c] See the $\pi^\pm$ Particle Listings for the energy limits used in this measurement; low-energy γ's are not included.

[d] Derived from an analysis of neutrino-oscillation experiments.

[e] Astrophysical and cosmological arguments give limits of order 10^{-13}; see the π^0 Particle Listings.

[f] C parity forbids this to occur as a single-photon process.

[g] See the "Note on scalar mesons" in the $f_0(500)$ Particle Listings . The interpretation of this entry as a particle is controversial.

[h] See the "Note on $\rho(770)$" in the $\rho(770)$ Particle Listings .

[i] The $\omega\rho$ interference is then due to $\omega\rho$ mixing only, and is expected to be small. If $e\mu$ universality holds, $\Gamma(\rho^0 \to \mu^+\mu^-) = \Gamma(\rho^0 \to e^+e^-) \times 0.99785$.

[j] See the "Note on scalar mesons" in the $f_0(500)$ Particle Listings .

[k] See the "Note on $a_1(1260)$" in the $a_1(1260)$ Particle Listings in PDG 06, Journal of Physics (generic for all A,B,E,G) **G33** 1 (2006).

[l] This is only an educated guess; the error given is larger than the error on the average of the published values. See the Particle Listings for details.

[n] See the "Note on non-$q\overline{q}$ mesons" in the Particle Listings in PDG 06, Journal of Physics (generic for all A,B,E,G) **G33** 1 (2006).

[o] See the "Note on the $\eta(1405)$" in the $\eta(1405)$ Particle Listings.

[p] See the "Note on the $f_1(1420)$" in the $\eta(1405)$ Particle Listings.

[q] See also the $\omega(1650)$ Particle Listings.

[r] See the "Note on the $\rho(1450)$ and the $\rho(1700)$" in the $\rho(1700)$ Particle Listings.

[s] See also the $\omega(1420)$ Particle Listings.

[t] See the "Note on $f_0(1710)$" in the $f_0(1710)$ Particle Listings in 2004 edition of *Review of Particle Physics*.

[u] See the note in the $K^\pm$ Particle Listings.

[v] The definition of the slope parameter g of the $K \to 3\pi$ Dalitz plot is as follows (see also "Note on Dalitz Plot Parameters for $K \to 3\pi$ Decays" in the $K^\pm$ Particle Listings):

$$|M|^2 = 1 + g(s_3 - s_0)/m^2_{\pi^+} + \cdots .$$

[x] For more details and definitions of parameters see the Particle Listings.

[y] See the $K^\pm$ Particle Listings for the energy limits used in this measurement.

[z] Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ's.

[aa] Structure-dependent part.

[bb] Direct-emission branching fraction.

[cc] Violates angular-momentum conservation.

[dd] Derived from measured values of ϕ_{+-}, ϕ_{00}, $|\eta|$, $|m_{K^0_L} - m_{K^0_S}|$, and $\tau_{K^0_S}$, as described in the introduction to "Tests of Conservation Laws."

[ee] The CP-violation parameters are defined as follows (see also "Note on CP Violation in $K_S \to 3\pi$" and "Note on CP Violation in K^0_L Decay" in the Particle Listings):

$$\eta_{+-} = |\eta_{+-}|e^{i\phi_{+-}} = \frac{A(K^0_L \to \pi^+\pi^-)}{A(K^0_S \to \pi^+\pi^-)} = \epsilon + \epsilon'$$

$$\eta_{00} = |\eta_{00}|e^{i\phi_{00}} = \frac{A(K^0_L \to \pi^0\pi^0)}{A(K^0_S \to \pi^0\pi^0)} = \epsilon - 2\epsilon'$$

$$\delta = \frac{\Gamma(K^0_L \to \pi^-\ell^+\nu) - \Gamma(K^0_L \to \pi^+\ell^-\nu)}{\Gamma(K^0_L \to \pi^-\ell^+\nu) + \Gamma(K^0_L \to \pi^+\ell^-\nu)} ,$$

$$\mathrm{Im}(\eta_{+-0})^2 = \frac{\Gamma(K^0_S \to \pi^+\pi^-\pi^0)^{CP\ \mathrm{viol.}}}{\Gamma(K^0_L \to \pi^+\pi^-\pi^0)} ,$$

$$\mathrm{Im}(\eta_{000})^2 = \frac{\Gamma(K^0_S \to \pi^0\pi^0\pi^0)}{\Gamma(K^0_L \to \pi^0\pi^0\pi^0)} .$$

where for the last two relations CPT is assumed valid, *i.e.*, $\mathrm{Re}(\eta_{+-0}) \simeq 0$ and $\mathrm{Re}(\eta_{000}) \simeq 0$.

[ff] See the K^0_S Particle Listings for the energy limits used in this measurement.

[gg] The value is for the sum of the charge states or particle/antiparticle states indicated.

[hh] $\mathrm{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.

[ii] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K^0_L \to \pi^+\pi^-\gamma$(DE).

[jj] See the K^0_L Particle Listings for the energy limits used in this measurement.

[*kk*] Allowed by higher-order electroweak interactions.

[*ll*] Violates *CP* in leading order. Test of direct *CP* violation since the indirect *CP*-violating and *CP*-conserving contributions are expected to be suppressed.

[*nn*] See the "Note on $f_0(1370)$" in the $f_0(1370)$ Particle Listings and in the 1994 edition.

[*oo*] See the note in the $L(1770)$ Particle Listings in Reviews of Modern Physics **56** S1 (1984), p. S200. See also the "Note on $K_2(1770)$ and the $K_2(1820)$" in the $K_2(1770)$ Particle Listings .

[*pp*] See the "Note on $K_2(1770)$ and the $K_2(1820)$" in the $K_2(1770)$ Particle Listings .

[*qq*] This result applies to $Z^0 \to c\overline{c}$ decays only. Here ℓ^+ is an average (not a sum) of e^+ and μ^+ decays.

[*rr*] See the Particle Listings for the (complicated) definition of this quantity.

[*ss*] The branching fraction for this mode may differ from the sum of the submodes that contribute to it, due to interference effects. See the relevant papers in the Particle Listings.

[*tt*] These subfractions of the $K^-2\pi^+$ mode are uncertain: see the Particle Listings.

[*uu*] Submodes of the $D^+ \to K^-2\pi^+\pi^0$ and $K^0_S\,2\pi^+\pi^-$ modes were studied by ANJOS 92C and COFFMAN 92B, but with at most 142 events for the first mode and 229 for the second – not enough for precise results. With nothing new for 18 years, we refer to our 2008 edition, Physics Letters **B667** 1 (2008), for those results.

[*vv*] The unseen decay modes of the resonances are included.

[*xx*] This is *not* a test for the ΔC=1 weak neutral current, but leads to the $\pi^+\ell^+\ell^-$ final state.

[*yy*] This mode is not a useful test for a ΔC=1 weak neutral current because both quarks must change flavor in this decay.

[*zz*] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.

[*aaa*] This value is obtained by subtracting the branching fractions for 2-, 4- and 6-prongs from unity.

[*bbb*] This is the sum of our $K^-2\pi^+\pi^-$, $K^-2\pi^+\pi^-\pi^0$, $\overline{K}^0 2\pi^+2\pi^-$, $K^+2K^-\pi^+$, $2\pi^+2\pi^-$, $2\pi^+2\pi^-\pi^0$, $K^+K^-\pi^+\pi^-$, and $K^+K^-\pi^+\pi^-\pi^0$, branching fractions.

[*ccc*] This is the sum of our $K^-3\pi^+2\pi^-$ and $3\pi^+3\pi^-$ branching fractions.

[*ddd*] The branching fractions for the $K^-e^+\nu_e$, $K^*(892)^-e^+\nu_e$, $\pi^-e^+\nu_e$, and $\rho^-e^+\nu_e$ modes add up to 6.19 ± 0.17 %.

[*eee*] This is a doubly Cabibbo-suppressed mode.

[*fff*] The two experiments measuring this fraction are in serious disagreement. See the Particle Listings.

[*ggg*] Submodes of the $D^0 \to K^0_S\pi^+\pi^-\pi^0$ mode with a K^* and/or ρ were studied by COFFMAN 92B, but with only 140 events. With nothing new for 18 years, we refer to our 2008 edition, Physics Letters **B667** 1 (2008), for those results.

[*hhh*] This branching fraction includes all the decay modes of the resonance in the final state.

[*iii*] This limit is for either D^0 or $\overline{D}^0$ to pe^-.

[*jjj*] This limit is for either D^0 or $\overline{D}^0$ to $\overline{p}e^+$.

[*kkk*] This is the purely e^+ semileptonic branching fraction: the e^+ fraction from τ^+ decays has been subtracted off. The sum of our (non-τ) e^+ exclusive fractions — an $e^+\nu_e$ with an η, η', ϕ, K^0, K^{*0}, or $f_0(980)$ — is 7.0 ± 0.4 %

[*lll*] This fraction includes η from η' decays.

[*nnn*] Two times (to include μ decays) the $\eta' e^+\nu_e$ branching fraction, plus the $\eta'\pi^+$, $\eta'\rho^+$, and $\eta' K^+$ fractions, is (18.6 ± 2.3)%, which considerably exceeds the inclusive η' fraction of (11.7 ± 1.8)%. Our best guess is that the $\eta'\rho^+$ fraction, (12.5 ± 2.2)%, is too large.

[*ooo*] This branching fraction includes all the decay modes of the final-state resonance.

[*ppp*] A test for $u\overline{u}$ or $d\overline{d}$ content in the D_s^+. Neither Cabibbo-favored nor Cabibbo-suppressed decays can contribute, and ω–ϕ mixing is an unlikely explanation for any fraction above about 2×10^{-4}.

[*qqq*] We decouple the $D_s^+ \to \phi\pi^+$ branching fraction obtained from mass projections (and used to get some of the other branching fractions) from the $D_s^+ \to \phi\pi^+$, $\phi \to K^+K^-$ branching fraction obtained from the Dalitz-plot analysis of $D_s^+ \to K^+K^-\pi^+$. That is, the ratio of these two branching fractions is not exactly the $\phi \to K^+K^-$ branching fraction 0.491.

[*rrr*] This is the average of a model-independent and a K-matrix parametrization of the $\pi^+\pi^-$ S-wave and is a sum over several f_0 mesons.

[*sss*] An ℓ indicates an e or a μ mode, not a sum over these modes.

[*ttt*] An $CP(\pm1)$ indicates the CP=+1 and CP=−1 eigenstates of the D^0-$\overline{D}^0$ system.

[*uuu*] D denotes D^0 or $\overline{D}^0$.

[*vvv*] $D^{*0}_{CP_+}$ decays into $D^0\pi^0$ with the D^0 reconstructed in CP-even eigenstates K^+K^- and $\pi^+\pi^-$.

[*xxx*] $\overline{D}^{**}$ represents an excited state with mass $2.2 < M < 2.8$ GeV/c^2.

[*yyy*] $X(3872)^+$ is a hypothetical charged partner of the $X(3872)$.

[*zzz*] $\Theta(1710)^{++}$ is a possible narrow pentaquark state and $G(2220)$ is a possible glueball resonance.

[*aaaa*] $(\overline{\Lambda}_c^- p)_s$ denotes a low-mass enhancement near 3.35 GeV/c^2.

[*bbaa*] Stands for the possible candidates of $K^*(1410)$, $K^*_0(1430)$ and $K^*_2(1430)$.

[*ccaa*] B^0 and B^0_s contributions not separated. Limit is on weighted average of the two decay rates.

[*ddaa*] This decay refers to the coherent sum of resonant and nonresonant $J^P = 0^+$ $K\pi$ components with $1.60 < m_{K\pi} < 2.15$ GeV/c^2.

[*eeaa*] $X(214)$ is a hypothetical particle of mass 214 MeV/c^2 reported by the HyperCP experiment, Physical Review Letters **94** 021801 (2005)

[*ffaa*] $\Theta(1540)^+$ denotes a possible narrow pentaquark state.

[*ggaa*] Here S and P are the hypothetical scalar and pseudoscalar particles with masses of 2.5 GeV/c^2 and 214.3 MeV/c^2, respectively.

[*hhaa*] These values are model dependent.

[*iiaa*] Here "anything" means at least one particle observed.

[*jjaa*] This is a B($B^0 \to D^{*-}\ell^+\nu_\ell$) value.

[*kkaa*] D^{**} stands for the sum of the $D(1\,^1P_1)$, $D(1\,^3P_0)$, $D(1\,^3P_1)$, $D(1\,^3P_2)$, $D(2\,^1S_0)$, and $D(2\,^1S_1)$ resonances.

[*llaa*] $D^{(*)}\overline{D}^{(*)}$ stands for the sum of $D^*\overline{D}^*$, $D^*\overline{D}$, $D\overline{D}^*$, and $D\overline{D}$.

[*nnaa*] $X(3915)$ denotes a near-threshold enhancement in the $\omega J/\psi$ mass spectrum.

[*ooaa*] Inclusive branching fractions have a multiplicity definition and can be greater than 100%.

[*ppaa*] D_j represents an unresolved mixture of pseudoscalar and tensor D^{**} (P-wave) states.

[*qqaa*] Not a pure measurement. See note at head of B^0_s Decay Modes.

[*rraa*] For $E_\gamma > 100$ MeV.

[*ssaa*] Includes $p\overline{p}\pi^+\pi^-\gamma$ and excludes $p\overline{p}\eta$, $p\overline{p}\omega$, $p\overline{p}\eta'$.

[*ttaa*] For a narrow state A with mass less than 960 MeV.

[*uuaa*] For a narrow scalar or pseudoscalar A^0 with mass 0.21–3.0 GeV.

[*vvaa*] For a narrow resonance in the range $2.2 < M(X) < 2.8$ GeV.

[*xxaa*] BHARDWAJ 11 does not observe this decay and presents a stronger 90% CL limit than this value. See measurements listings for details.

[*yyaa*] J^{PC} known by production in e^+e^- via single photon annihilation. I^G is not known; interpretation of this state as a single resonance is unclear because of the expectation of substantial threshold effects in this energy region.

[*zzaa*] $2m_\tau < M(\tau^+\tau^-) < 9.2$ GeV

[*aabb*] 2 GeV $< m_{K^+K^-} <$ 3 GeV

[*bbbb*] X = scalar with $m < 8.0$ GeV

[*ccbb*] $X\overline{X}$ = vectors with $m < 3.1$ GeV

[*ddbb*] X and $\overline{X}$ = zero spin with $m < 4.5$ GeV

[*eebb*] 1.5 GeV $< m_X <$ 5.0 GeV

[*ffbb*] 201 MeV $< M(\mu^+\mu^-) <$ 3565 MeV

[*ggbb*] 0.5 GeV $< m_X <$ 9.0 GeV, where m_X is the invariant mass of the hadronic final state.

[*hhbb*] Spectroscopic labeling for these states is theoretical, pending experimental information.

[*iibb*] 1.5 GeV $< m_X <$ 5.0 GeV

[*jjbb*] 1.5 GeV $< m_X <$ 5.0 GeV

[*kkbb*] For $m_{\tau^+\tau^-}$ in the ranges 4.03–9.52 and 9.61–10.10 GeV.

Meson Summary Table

See also the table of suggested $q\overline{q}$ quark-model assignments in the Quark Model section.

• Indicates particles that appear in the preceding Meson Summary Table. We do not regard the other entries as being established.

Baryon Summary Table

This short table gives the name, the quantum numbers (where known), and the status of baryons in the Review. Only the baryons with 3- or 4-star status are included in the Baryon Summary Table. Due to insufficient data or uncertain interpretation, the other entries in the table are not established baryons. The names with masses are of baryons that decay strongly. The spin-parity J^P (when known) is given with each particle. For the strongly decaying particles, the J^P values are considered to be part of the names.

$|q_p + q_{\overline{p}}|/e < 7 \times 10^{-10}$, CL = 90% [b]
$|q_p + q_e|/e < 1 \times 10^{-21}$ [c]
Magnetic moment $\mu = 2.792847356 \pm 0.000000023\ \mu_N$
$(\mu_p + \mu_{\overline{p}}) / \mu_p = (0 \pm 5) \times 10^{-6}$
Electric dipole moment $d < 0.54 \times 10^{-23}$ $e$cm
Electric polarizability $\alpha = (11.2 \pm 0.4) \times 10^{-4}$ fm^3
Magnetic polarizability $\beta = (2.5 \pm 0.4) \times 10^{-4}$ fm^3 (S = 1.2)
Charge radius, μp Lamb shift = 0.84087 ± 0.00039 fm [d]
Charge radius, ep CODATA value = 0.8775 ± 0.0051 fm [d]
Magnetic radius = 0.777 ± 0.016 fm
Mean life $\tau > 2.1 \times 10^{29}$ years, CL = 90% [e] ($p \to$ invisible mode)
Mean life $\tau > 10^{31}$ to 10^{33} years [e] (mode dependent)

See the "Note on Nucleon Decay" in our 1994 edition (Phys. Rev. **D50**, 1173) for a short review.

The "partial mean life" limits tabulated here are the limits on τ/B_i, where τ is the total mean life and B_i is the branching fraction for the mode in question. For N decays, p and n indicate proton and neutron partial lifetimes.

p DECAY MODES	Partial mean life (10^{30} years)	Confidence level	p (MeV/c)
Antilepton + meson			
$N \to e^+\pi$	> 2000 (n), > 8200 (p)	90%	459

Ω⁻

$I(J^P) = 0(\frac{3}{2}^+)$

$J^P = \frac{3}{2}^+$ is the quark-model prediction; and $J = 3/2$ is fairly well established.

Mass $m = 1672.45 \pm 0.29$ MeV
$(m_{\Omega^-} - m_{\overline{\Omega}^+}) / m_{\Omega^-} = (-1 \pm 8) \times 10^{-5}$
Mean life $\tau = (0.821 \pm 0.011) \times 10^{-10}$ s
$c\tau = 2.461$ cm
$(\tau_{\Omega^-} - \tau_{\overline{\Omega}^+}) / \tau_{\Omega^-} = 0.00 \pm 0.05$
Magnetic moment $\mu = -2.02 \pm 0.05\ \mu_N$

Decay parameters

ΛK^-	$\alpha = 0.0180 \pm 0.0024$
$\Lambda K^-, \overline{\Lambda} K^+$	$(\alpha + \overline{\alpha})/(\alpha - \overline{\alpha}) = -0.02 \pm 0.13$
$\Xi^0\pi^-$	$\alpha = 0.09 \pm 0.14$
$\Xi^-\pi^0$	$\alpha = 0.05 \pm 0.21$

Ω⁻ DECAY MODES	Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)

CHARMED BARYONS ($C=+1$)

$\Lambda_c^+ = udc$, $\Sigma_c^{++} = uuc$, $\Sigma_c^+ = udc$, $\Sigma_c^0 = ddc$,
$\Xi_c^+ = usc$, $\Xi_c^0 = dsc$, $\Omega_c^0 = ssc$

Λ_c^+

$I(J^P) = 0(\frac{1}{2}^+)$

J is not well measured; $\frac{1}{2}$ is the quark-model prediction.

Mass $m = 2286.46 \pm 0.14$ MeV
Mean life $\tau = (200 \pm 6) \times 10^{-15}$ s (S = 1.6)
$c\tau = 59.9\ \mu$m

Decay asymmetry parameters

$\Lambda\pi^+$	$\alpha = -0.91 \pm 0.15$
$\Sigma^+\pi^0$	$\alpha = -0.45 \pm 0.32$
$\Lambda\ell^+\nu_\ell$	$\alpha = -0.86 \pm 0.04$
$(\alpha + \overline{\alpha})/(\alpha - \overline{\alpha})$ in $\Lambda_c^+ \to \Lambda\pi^+$, $\overline{\Lambda}_c^- \to \overline{\Lambda}\pi^-$	$= -0.07 \pm 0.31$
$(\alpha + \overline{\alpha})/(\alpha - \overline{\alpha})$ in $\Lambda_c^+ \to \Lambda e^+\nu_e$, $\overline{\Lambda}_c^- \to \overline{\Lambda} e^-\overline{\nu}_e$	$= 0.00 \pm 0.04$

Nearly all branching fractions of the Λ_c^+ are measured relative to the $pK^-\pi^+$ mode, but there are no model-independent measurements of this branching fraction. We explain how we arrive at our value of $B(\Lambda_c^+ \to pK^-\pi^+)$ in a Note at the beginning of the branching-ratio measurements in the Listings. When this branching fraction is eventually well determined, all the other branching fractions will slide up or down proportionally as the true value differs from the value we use here.

$\Lambda_c(2595)^+$ $I(J^P) = 0(\frac{1}{2}^-)$

The spin-parity follows from the fact that $\Sigma_c(2455)\pi$ decays, with little available phase space, are dominant. This assumes that $J^P = 1/2^+$ for the $\Sigma_c(2455)$.

Mass $m = 2592.25 \pm 0.28$ MeV
$m - m_{\Lambda_c^+} = 305.79 \pm 0.24$ MeV
Full width $\Gamma = 2.6 \pm 0.6$ MeV

$\Lambda_c^+\pi\pi$ and its submode $\Sigma_c(2455)\pi$ — the latter just barely — are the only strong decays allowed to an excited Λ_c^+ having this mass; and the submode seems to dominate.

$\Lambda_c(2595)^+$ DECAY MODES	Fraction (Γ_i/Γ)	p (MeV/c)
$\Lambda_c^+\pi^+\pi^-$	[u] ≈ 67 %	117
$\Sigma_c(2455)^{++}\pi^-$	24 ± 7 %	†
$\Sigma_c(2455)^0\pi^+$	24 ± 7 %	†
$\Lambda_c^+\pi^+\pi^-$ 3-body	18 ± 10 %	117
$\Lambda_c^+\pi^0$	[v] not seen	258
$\Lambda_c^+\gamma$	not seen	288

$\Lambda_c(2625)^+$ $I(J^P) = 0(\frac{3}{2}^-)$

J^P has not been measured; $\frac{3}{2}^-$ is the quark-model prediction.

Mass $m = 2628.11 \pm 0.19$ MeV (S = 1.1)
$m - m_{\Lambda_c^+} = 341.65 \pm 0.13$ MeV (S = 1.1)
Full width $\Gamma < 0.97$ MeV, CL = 90%

$\Lambda_c^+\pi\pi$ and its submode $\Sigma(2455)\pi$ are the only strong decays allowed to an excited Λ_c^+ having this mass.

$\Lambda_c(2625)^+$ DECAY MODES	Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)

$\Xi^-\ell^-\overline{\nu}_\ell$ anything	(6.0 ± 1.6) $\times 10^{-3}$	–

NOTES

This Summary Table only includes established baryons. The Particle Listings include evidence for other baryons. The masses, widths, and branching fractions for the resonances in this Table are Breit-Wigner parameters, but pole positions are also given for most of the N and Δ resonances.

For most of the resonances, the parameters come from various partial-wave analyses of more or less the same sets of data, and it is not appropriate to treat the results of the analyses as independent or to average them together. Furthermore, the systematic errors on the results are not well understood. Thus, we usually only give ranges for the parameters. We then also give a best guess for the mass (as part of the name of the resonance) and for the width. The *Note on N and Δ Resonances* and the *Note on Λ and Σ Resonances* in the Particle Listings review the partial-wave analyses.

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame. For any resonance, the *nominal* mass is used in calculating p. A dagger ("†") in this column indicates that the mode is forbidden when the nominal masses of resonances are used, but is in fact allowed due to the nonzero widths of the resonances.

[a] The masses of the p and n are most precisely known in u (unified atomic mass units). The conversion factor to MeV, 1 u = 931.494061(21) MeV, is less well known than are the masses in u.

[b] The $|m_p - m_{\overline{p}}|/m_p$ and $|q_p + q_{\overline{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\overline{p}}/m_{\overline{p}}|/(q_p/m_p)$.

[c] The limit is from neutrality-of-matter experiments; it assumes $q_n = q_p + q_e$. See also the charge of the neutron.

[d] The μp and ep values for the charge radius are much too different to average them. The disagreement is not yet understood.

[e] The first limit is for $p \rightarrow$ anything or "disappearance" modes of a bound proton. The second entry, a rough range of limits, assumes the dominant decay modes are among those investigated. For antiprotons the best limit, inferred from the observation of cosmic ray $\overline{p}$'s is $\tau_{\overline{p}} > 10^7$ yr, the cosmic-ray storage time, but this limit depends on a number of assumptions. The best direct observation of stored antiprotons gives $\tau_{\overline{p}}/\mathrm{B}(\overline{p} \rightarrow e^-\gamma) > 7 \times 10^5$ yr.

[f] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.

[g] Lee and Yang in 1956 proposed the existence of a mirror world in an attempt to restore global parity symmetry—thus a search for oscillations between the two worlds. Oscillations between the worlds would be maximal when the magnetic fields B and B' were equal. The limit for any B' in the range 0 to 12.5 μT is >12 s (95% CL).

[h] The parameters g_A, g_V, and g_{WM} for semileptonic modes are defined by $\overline{B}_f[\gamma_\lambda(g_V + g_A\gamma_5) + i(g_{WM}/m_{B_i})\ \sigma_{\lambda\nu}\ q^\nu]B_i$, and ϕ_{AV} is defined by $g_A/g_V = |g_A/g_V|e^{i\phi_{AV}}$. See the "Note on Baryon Decay Parameters" in the neutron Particle Listings.

[i] Time-reversal invariance requires this to be 0° or 180°.

[j] This coefficient is zero if time invariance is not violated.

[k] This limit is for γ energies between 15 and 340 keV.

[l] The decay parameters γ and Δ are calculated from α and ϕ using

$$\gamma = \sqrt{1-\alpha^2}\,\cos\phi\,, \qquad \tan\Delta = -\frac{1}{\alpha}\,\sqrt{1-\alpha^2}\,\sin\phi\,.$$

See the "Note on Baryon Decay Parameters" in the neutron Particle Listings.

[n] See the Listings for the pion momentum range used in this measurement.

[o] The error given here is only an educated guess. It is larger than the error on the weighted average of the published values.

[p] A theoretical value using QED.

[q] See the note on "Λ_c^+ Branching Fractions" in the Λ_c^+ Particle Listings.

[r] This branching fraction includes all the decay modes of the final-state resonance.

[s] An ℓ indicates an e or a μ mode, not a sum over these modes.

[t] The value is for the sum of the charge states or particle/antiparticle states indicated.

[u] Assuming isospin conservation, so that the other third is $\Lambda_c^+\pi^0\pi^0$.

[v] A test that the isospin is indeed 0, so that the particle is indeed a Λ_c^+.

[x] Not a pure measurement. See note at head of Λ_b^0 Decay Modes.

[y] Here h^- means π^- or K^-.

Searches Summary Table

SEARCHES FOR MONOPOLES, SUPERSYMMETRY, TECHNICOLOR, COMPOSITENESS, EXTRA DIMENSIONS, etc.

Magnetic Monopole Searches

Isolated supermassive monopole candidate events have not been confirmed. The most sensitive experiments obtain negative results.

Best cosmic-ray supermassive monopole flux limit:

$< 1.4 \times 10^{-16}$ cm^{-2}sr^{-1}s^{-1} for $1.1 \times 10^{-4} < \beta < 1$

Supersymmetric Particle Searches

Limits are based on the Minimal Supersymmetric Standard Model (MSSM) with additional assumptions as follows:

1) $\widetilde{\chi}^0_1$ (or $\widetilde{\gamma}$) is lightest supersymmetric particle; 2) R-parity is conserved; 3) With the exception of $\widetilde{t}$ and $\widetilde{b}$, all scalar quarks are assumed to be degenerate in mass and $m_{\widetilde{q}_R} = m_{\widetilde{q}_L}$. 4) Limits for charged sleptons refer to the $\widetilde{\ell}_R$ states. 5) Unless otherwise stated, gaugino mass unification at the GUT scale is assumed. For squarks and gluinos, the Constrained MSSM (CMSSM) limits and simplified model limits are presented.

See the Particle Listings for a Note giving details of supersymmetry.

$\widetilde{\chi}^0_i$ — neutralinos (mixtures of $\widetilde{\gamma}$, $\widetilde{Z}^0$, and $\widetilde{H}^0_i$)

Mass $m_{\widetilde{\chi}^0_1} > 46$ GeV, CL = 95%
[all tanβ, all m_0, all $m_{\widetilde{\chi}^0_2} - m_{\widetilde{\chi}^0_1}$]

Mass $m_{\widetilde{\chi}^0_2} > 62.4$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}^0_2} - m_{\widetilde{\chi}^0_1}$]

Mass $m_{\widetilde{\chi}^0_3} > 99.9$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}^0_3} - m_{\widetilde{\chi}^0_1}$]

Mass $m_{\widetilde{\chi}^0_4} > 116$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}^0_2} - m_{\widetilde{\chi}^0_1}$]

$\widetilde{\chi}^\pm_i$ — charginos (mixtures of $\widetilde{W}^\pm$ and $\widetilde{H}^\pm_i$)

Mass $m_{\widetilde{\chi}^\pm_1} > 94$ GeV, CL = 95%
[tan$\beta < 40$, $m_{\widetilde{\chi}^\pm_1} - m_{\widetilde{\chi}^0_1} > 3$ GeV, all m_0]

$\widetilde{\nu}$ — sneutrino

Mass $m > 94$ GeV, CL = 95%
[$1 \le$ tan$\beta \le 40$, $m_{\widetilde{e}_R} - m_{\widetilde{\chi}^0_1} > 10$ GeV]

$\widetilde{e}$ — scalar electron (selectron)

Mass $m > 107$ GeV, CL = 95% [all $m_{\widetilde{e}_R} - m_{\widetilde{\chi}^0_1}$]

$\widetilde{\mu}$ — scalar muon (smuon)

Mass $m > 94$ GeV, CL = 95%
[$1 \le$ tan$\beta \le 40$, $m_{\widetilde{\mu}_R} - m_{\widetilde{\chi}^0_1} > 10$ GeV]

$\widetilde{\tau}$ — scalar tau (stau)

Mass $m > 81.9$ GeV, CL = 95%
[$m_{\widetilde{\tau}_R} - m_{\widetilde{\chi}^0_1} > 15$ GeV, all θ_τ]

$\widetilde{q}$ – scalar quark partners (squarks) of the first two quark generations

The first of these limits is within CMSSM with cascade decays, evaluated assuming a fixed value of the parameters μ and tanβ. Limits assume two-generations of mass degenerate squarks ($\widetilde{q}_L$ and $\widetilde{q}_R$) and gaugino mass parameters that are constrained by the unification condition at the grand unification scale. The second limit assumes a simplified model with a 100% branching ratio for the prompt decay $\widetilde{q} \to q\widetilde{\chi}^0_1$.

Mass $m > 1110$ GeV, CL = 95% [tanβ=10, $\mu > 0$, A_0=0]
Mass $m > 750$ GeV, CL = 95%
[jets + $\not{E}_T$, $\widetilde{q} \to q\widetilde{\chi}^0_1$ simplified model, $m_{\widetilde{\chi}^0_1}$= 0 GeV]

$\widetilde{b}$ — scalar bottom (sbottom)

Mass $m > 89$ GeV, CL = 95%
[$\widetilde{b} \to b\widetilde{\chi}^0_1$, $m_{\widetilde{b}_1} - m_{\widetilde{\chi}^0_1} > 8$ GeV, all θ_b]
Mass $m > 600$ GeV, CL = 95%
[jets + $\not{E}_T$, $\widetilde{b} \to b\widetilde{\chi}^0_1$ simplified model, $m_{\widetilde{\chi}^0_1}$= 0 GeV]

$\widetilde{t}$ — scalar top (stop)

Mass $m > 95.7$ GeV, CL = 95%
[$\widetilde{t} \to c\widetilde{\chi}^0_1$, $m_{\widetilde{t}} - m_{\widetilde{\chi}^0_1} > 10$ GeV, all θ_t]
Mass $m > 650$ GeV, CL = 95%
[1 $\ell^\pm$ + jets + $\not{E}_T$, $\widetilde{t} \to t\widetilde{\chi}^0_1$ simplified model, $m_{\widetilde{\chi}^0_1}$=0 GeV]

$\widetilde{g}$ — gluino

The first of these limits is within the CMSSM for ($m_{\widetilde{g}} \gtrsim$ 5 GeV), and includes the effects of cascade decays, evaluated assuming a fixed value of the parameters μ and tanβ. Limit assumes GUT relations between gaugino masses and the gauge couplings. The second limit assumes a simplified model with a 100% branching ratio for the prompt 3 body decay $\widetilde{g} \to q\overline{q}\widetilde{\chi}^0_1$, independent of the squark mass.

Mass $m > 800$ GeV, CL = 95% [any $m_{\widetilde{q}}$]
Mass $m > 950$ GeV, CL = 95%
[jets + $\not{E}_T$, $\widetilde{g} \to q\overline{q}\widetilde{\chi}^0_1$ simplified model, $m_{\widetilde{\chi}^0_1} = 0$ GeV]

Technicolor

The limits for technicolor (and top-color) particles are quite varied depending on assumptions. See the Technicolor section of the full *Review* (the data listings).

Quark and Lepton Compositeness, Searches for

Scale Limits Λ for Contact Interactions
(the lowest dimensional interactions with four fermions)

If the Lagrangian has the form

$$\pm \frac{g^2}{2\Lambda^2}\, \overline{\psi}_L \gamma_\mu \psi_L\, \overline{\psi}_L \gamma^\mu \psi_L$$

(with $g^2/4\pi$ set equal to 1), then we define $\Lambda \equiv \Lambda^\pm_{LL}$. For the full definitions and for other forms, see the Note in the Listings on Searches for Quark and Lepton Compositeness in the full *Review* and the original literature.

$\Lambda^+_{LL}(eeee)$	>	8.3 TeV, CL = 95%
$\Lambda^-_{LL}(eeee)$	>	10.3 TeV, CL = 95%
$\Lambda^+_{LL}(ee\mu\mu)$	>	8.5 TeV, CL = 95%
$\Lambda^-_{LL}(ee\mu\mu)$	>	9.5 TeV, CL = 95%
$\Lambda^+_{LL}(ee\tau\tau)$	>	7.9 TeV, CL = 95%
$\Lambda^-_{LL}(ee\tau\tau)$	>	7.2 TeV, CL = 95%
$\Lambda^+_{LL}(\ell\ell\ell\ell)$	>	9.1 TeV, CL = 95%
$\Lambda^-_{LL}(\ell\ell\ell\ell)$	>	10.3 TeV, CL = 95%
$\Lambda^+_{LL}(eeuu)$	>	23.3 TeV, CL = 95%
$\Lambda^-_{LL}(eeuu)$	>	12.5 TeV, CL = 95%
$\Lambda^+_{LL}(eedd)$	>	11.1 TeV, CL = 95%
$\Lambda^-_{LL}(eedd)$	>	26.4 TeV, CL = 95%
$\Lambda^+_{LL}(eecc)$	>	9.4 TeV, CL = 95%
$\Lambda^-_{LL}(eecc)$	>	5.6 TeV, CL = 95%
$\Lambda^+_{LL}(eebb)$	>	9.4 TeV, CL = 95%
$\Lambda^-_{LL}(eebb)$	>	10.2 TeV, CL = 95%
$\Lambda^+_{LL}(\mu\mu qq)$	>	9.6 TeV, CL = 95%
$\Lambda^-_{LL}(\mu\mu qq)$	>	13.1 TeV, CL = 95%
$\Lambda(\ell\nu\ell\nu)$	>	3.10 TeV, CL = 90%
$\Lambda(e\nu qq)$	>	2.81 TeV, CL = 95%
$\Lambda^+_{LL}(qqqq)$	>	7.6 TeV, CL = 95%
$\Lambda^-_{LL}(qqqq)$	>	7.6 TeV, CL = 95%
$\Lambda^+_{LL}(\nu\nu qq)$	>	5.0 TeV, CL = 95%
$\Lambda^-_{LL}(\nu\nu qq)$	>	5.4 TeV, CL = 95%

Excited Leptons

The limits from $\ell^{*+}\ell^{*-}$ do not depend on λ (where λ is the $\ell\ell^*$ transition coupling). The λ-dependent limits assume chiral coupling.

$e^{*\pm}$ — excited electron

Mass $m >$ 103.2 GeV, CL = 95% (from $e^* e^*$)
Mass $m >$ 2.200×10^3 GeV, CL = 95% (from $e e^*$)
Mass $m >$ 356 GeV, CL = 95% (if $\lambda_\gamma = 1$)

$\mu^{*\pm}$ — excited muon

Mass $m >$ 103.2 GeV, CL = 95% (from $\mu^* \mu^*$)
Mass $m >$ 2.200×10^3 GeV, CL = 95% (from $\mu \mu^*$)

$\tau^{*\pm}$ — excited tau

Mass $m >$ 103.2 GeV, CL = 95% (from $\tau^* \tau^*$)
Mass $m >$ 185 GeV, CL = 95% (from $\tau \tau^*$)

ν^* — excited neutrino

Mass $m >$ 102.6 GeV, CL = 95% (from $\nu^* \nu^*$)
Mass $m >$ 213 GeV, CL = 95% (from $\nu \nu^*$)

q^* — excited quark

Mass $m >$ 338 GeV, CL = 95% (from $q^* q^*$)
Mass $m >$ 3.500×10^3 GeV, CL = 95% (from q^*X)

Color Sextet and Octet Particles

Color Sextet Quarks (q_6)

Mass $m >$ 84 GeV, CL = 95% (Stable q_6)

Color Octet Charged Leptons (ℓ_8)

Mass $m >$ 86 GeV, CL = 95% (Stable ℓ_8)

Color Octet Neutrinos (ν_8)

Mass $m >$ 110 GeV, CL = 90% ($\nu_8 \rightarrow \nu g$)

Extra Dimensions

Please refer to the Extra Dimensions section of the full *Review* for a discussion of the model-dependence of these bounds, and further constraints.

Constraints on the fundamental gravity scale

$M_{TT} >$ 3.2 TeV, CL = 95% ($pp \rightarrow e^+ e^-,\ \mu^+ \mu^-,\ \gamma\gamma$)
$M_C >$ 4.16 TeV, CL = 95% ($pp \rightarrow \ell\bar{\ell}$)
$M_D >$ 2.16 TeV, CL = 95% ($pp \rightarrow G \rightarrow \ell\bar{\ell}$)

Constraints on the radius of the extra dimensions, for the case of two-flat dimensions of equal radii

$R <$ 30 μm, CL = 95% (direct tests of Newton's law)
$R <$ 23 μm, CL = 95% ($pp \rightarrow j G$)
$R <$ 0.16–916 nm (astrophysics; limits depend on technique and assumptions)

TESTS OF CONSERVATION LAWS

Updated May 2014 by L. Wolfenstein (Carnegie-Mellon University) and C.-J. Lin (LBNL).

In keeping with the current interest in tests of conservation laws, we collect together a Table of experimental limits on all weak and electromagnetic decays, mass differences, and moments, and on a few reactions, whose observation would violate conservation laws. The Table is given only in the full *Review of Particle Physics*, not in the Particle Physics Booklet. For the benefit of Booklet readers, we include the best limits from the Table in the following text. Limits in this text are for CL=90% unless otherwise specified. The Table is in two parts: "Discrete Space-Time Symmetries," *i.e.*, C, P, T, CP, and CPT; and "Number Conservation Laws," *i.e.*, lepton, baryon, hadronic flavor, and charge conservation. The references for these data can be found in the the Particle Listings in the *Review*. A discussion of these tests follows.

CPT INVARIANCE

General principles of relativistic field theory require invariance under the combined transformation CPT. The simplest tests of CPT invariance are the equality of the masses and lifetimes of a particle and its antiparticle. The best test comes from the limit on the mass difference between K^0 and $\overline{K}^0$. Any such difference contributes to the CP-violating parameter ϵ. Assuming CPT invariance, ϕ_ϵ, the phase of ϵ should be very close to 44°. (See the review "CP Violation in K_L decay" in this edition.) In contrast, if the entire source of CP violation in K^0 decays were a $K^0 - \overline{K}^0$ mass difference, ϕ_ϵ would be $44° + 90°$.

Assuming that there is no other source of CPT violation than this mass difference, it is possible to deduce that[1]

$$m_{\overline{K}^0} - m_{K^0} \approx \frac{2(m_{K_L^0} - m_{K_S^0})\,|\eta|\,(\frac{2}{3}\phi_{+-} + \frac{1}{3}\phi_{00} - \phi_{\rm SW})}{\sin\phi_{\rm SW}}\ ,$$

where $\phi_{\rm SW} = (43.51 \pm 0.05)°$, the superweak angle. Using our best values of the CP-violation parameters, we get $|(m_{\overline{K}^0} - m_{K^0})/m_{K^0}| \leq 0.6 \times 10^{-18}$ at CL=90%. Limits can also be placed on specific CPT-violating decay amplitudes. Given the small value of $(1 - |\eta_{00}/\eta_{+-}|)$, the value of $\phi_{00} - \phi_{+-}$ provides a measure of CPT violation in $K_L^0 \to 2\pi$ decay. Results from CERN [1] and Fermilab [2] indicate no CPT-violating effect.

CP AND T INVARIANCE

Given CPT invariance, CP violation and T violation are equivalent. The original evidence for CP violation came from the measurement of $|\eta_{+-}| = |A(K_L^0 \to \pi^+\pi^-)/A(K_S^0 \to \pi^+\pi^-)| = (2.232 \pm 0.011) \times 10^{-3}$. This could be explained in terms of K^0–$\overline{K}^0$ mixing, which also leads to the asymmetry $[\Gamma(K_L^0 \to \pi^- e^+ \nu) - \Gamma(K_L^0 \to \pi^+ e^- \overline{\nu})]/[\text{sum}] = (0.334 \pm 0.007)\%$. Evidence for CP violation in the kaon decay amplitude comes from the measurement of $(1 - |\eta_{00}/\eta_{+-}|)/3 = Re(\epsilon'/\epsilon) = (1.66 \pm 0.23) \times 10^{-3}$. In the Standard Model much larger CP-violating effects are expected. The first of these, which is associated with B–$\overline{B}$ mixing, is the parameter $sin(2\beta)$ now measured quite accurately to be 0.682 ± 0.019. A number of other CP-violating observables are being measured in B decays; direct evidence for CP violation in the B decay amplitude comes from the asymmetry $[\Gamma(\overline{B}^0 \to K^-\pi^+) - \Gamma(B^0 \to K^+\pi^-)]/[\text{sum}] = -0.082 \pm 0.006$. Direct tests of T violation are much more difficult; a measurement by CPLEAR of the difference between the oscillation probabilities of K^0 to $\overline{K^0}$ and $\overline{K^0}$ to K^0 is related to T violation [3]. A nonzero value of the electric dipole moment of the neutron and electron requires both P and T violation. The current experimental results are $< 2.9 \times 10^{-26}$ e cm (neutron), and $< (10.5 \pm 0.07) \times 10^{-28}$ e cm (electron). The BABAR experiment has reported the first direct observation of T violation in the B system. The measured T-violating parameters in the time evolution of the neutral B mesons are $\Delta S_T^+ = -1.37 \pm 0.15$ and $\Delta S_T^- = 1.17 \pm 0.21$, with a significance of 14σ [4]. This observation of T violation, with exchange of initial and final states of the neutral B, was made possible in a B-factory using the Einstein-Podolsky-Rosen Entanglement of the two B's produced in the decay of the $\Upsilon(4S)$ and the two time-ordered decays of the B's as filtering measurements of the meson state [5].

CONSERVATION OF LEPTON NUMBERS

Present experimental evidence and the standard electroweak theory are consistent with the absolute conservation of three separate lepton numbers: electron number L_e, muon number L_μ, and tau number L_τ, except for the effect of neutrino mixing associated with neutrino masses. Searches for violations are of the following types:

a) $\Delta L = 2$ for one type of charged lepton. The best limit comes from the search for neutrinoless double beta decay $(Z, A) \to (Z + 2, A) + e^- + e^-$. The best laboratory limit is $t_{1/2} > 2.1 \times 10^{25}$ yr (CL=90%) for ^{76}Ge.

b) Conversion of one charged-lepton type to another. For purely leptonic processes, the best limits are on $\mu \to e\gamma$ and $\mu \to 3e$, measured as $\Gamma(\mu \to e\gamma)/\Gamma(\mu \to \text{all}) < 5.7 \times 10^{-13}$ and $\Gamma(\mu \to 3e)/\Gamma(\mu \to \text{all}) < 1.0 \times 10^{-12}$. For semileptonic processes, the best limit comes from the coherent conversion process in a muonic atom, $\mu^- + (Z, A) \to e^- + (Z, A)$, measured as $\Gamma(\mu^-\text{Ti} \to e^-\text{Ti})/\Gamma(\mu^-\text{Ti} \to \text{all}) < 4.3 \times 10^{-12}$. Of special interest is the case in which the hadronic flavor also changes, as in $K_L \to e\mu$ and $K^+ \to \pi^+ e^- \mu^+$, measured as $\Gamma(K_L \to e\mu)/\Gamma(K_L \to \text{all}) < 4.7 \times 10^{-12}$ and $\Gamma(K^+ \to \pi^+ e^- \mu^+)/\Gamma(K^+ \to \text{all}) < 1.3 \times 10^{-11}$. Limits on the conversion of τ into e or μ are found in τ decay and are much less stringent than those for $\mu \to e$ conversion, *e.g.*, $\Gamma(\tau \to \mu\gamma)/\Gamma(\tau \to \text{all}) < 4.4 \times 10^{-8}$ and $\Gamma(\tau \to e\gamma)/\Gamma(\tau \to \text{all}) < 3.3 \times 10^{-8}$.

c) Conversion of one type of charged lepton into another type of charged antilepton. The case most studied is $\mu^- + (Z, A) \to e^+ + (Z - 2, A)$, the strongest limit being $\Gamma(\mu^-\text{Ti} \to e^+\text{Ca})/\Gamma(\mu^-\text{Ti} \to \text{all}) < 3.6 \times 10^{-11}$.

d) Neutrino oscillations. It is expected even in the standard electroweak theory that the lepton numbers are not separately conserved, as a consequence of lepton mixing analogous

to Cabibbo-Kobayashi-Maskawa quark mixing. However, if the only source of lepton-number violation is the mixing of low-mass neutrinos then processes such as $\mu \to e\gamma$ are expected to have extremely small unobservable probabilities. For small neutrino masses, the lepton-number violation would be observed first in neutrino oscillations, which have been the subject of extensive experimental studies. Compelling evidence for neutrino mixing has come from atmospheric, solar, accelerator, and reactor neutrinos. Recently, the reactor neutrino experiments have measured the last neutrino mixing angle θ_{13} and found it to be relatively large. For a comprehensive review on neutrino mixing, including the latest results on θ_{13}, see the review *"Neutrino Mass, Mixing, and Oscillations"* by K. Nakamura and S.T. Petcov in this edition of RPP.

CONSERVATION OF HADRONIC FLAVORS

In strong and electromagnetic interactions, hadronic flavor is conserved, *i.e.* the conversion of a quark of one flavor (d, u, s, c, b, t) into a quark of another flavor is forbidden. In the Standard Model, the weak interactions violate these conservation laws in a manner described by the Cabibbo-Kobayashi-Maskawa mixing (see the section "Cabibbo-Kobayashi-Maskawa Mixing Matrix"). The way in which these conservation laws are violated is tested as follows:

(a) $\Delta S = \Delta Q$ rule. In the strangeness-changing semileptonic decay of strange particles, the strangeness change equals the change in charge of the hadrons. Tests come from limits on decay rates such as $\Gamma(\Sigma^+ \to ne^+\nu)/\Gamma(\Sigma^+ \to \text{all}) < 5 \times 10^{-6}$, and from a detailed analysis of $K_L \to \pi e\nu$, which yields the parameter x, measured to be $(\mathrm{Re}\, x,\ \mathrm{Im}\, x) = (-0.002 \pm 0.006,\ 0.0012 \pm 0.0021)$. Corresponding rules are $\Delta C = \Delta Q$ and $\Delta B = \Delta Q$.

(b) Change of flavor by two units. In the Standard Model this occurs only in second-order weak interactions. The classic example is $\Delta S = 2$ via $K^0 - \overline{K}^0$ mixing, which is directly measured by $m(K_L) - m(K_S) = (0.5293 \pm 0.0009) \times 10^{10}\ \hbar s^{-1}$. The $\Delta B = 2$ transitions in the B^0 and B_s^0 systems via mixing are also well established. The measured mass differences between the eigenstates are $(m_{B^0_{\rm H}} - m_{B^0_{\rm L}}) = (0.510 \pm 0.003) \times 10^{12}\ \hbar s^{-1}$ and $(m_{B^0_{\rm sH}} - m_{B^0_{\rm sL}}) = (17.761 \pm 0.022) \times 10^{12}\ \hbar s^{-1}$. There is now strong evidence of $\Delta C = 2$ transition in the charm sector with the mass difference $m_{D^0_H} - m_{D^0_L} = (0.95^{+0.41}_{-0.44}) \times 10^{10}\ \hbar s^{-1}$. All results are consistent with the second-order calculations in the Standard Model.

(c) Flavor-changing neutral currents. In the Standard Model the neutral-current interactions do not change flavor. The low rate $\Gamma(K_L \to \mu^+\mu^-)/\Gamma(K_L \to \text{all}) = (6.84 \pm 0.11) \times 10^{-9}$ puts limits on such interactions; the nonzero value for this rate is attributed to a combination of the weak and electromagnetic interactions. The best test should come from $K^+ \to \pi^+\nu\overline{\nu}$, which occurs in the Standard Model only as a second-order weak process with a branching fraction of (0.4 to 1.2)$\times 10^{-10}$. Combining results from BNL-E787 and BNL-E949 experiments yield $\Gamma(K^+ \to \pi^+\nu\overline{\nu})/\Gamma(K^+ \to \text{all}) = (1.7 \pm 1.1) \times 10^{-10}$[6]. Limits for charm-changing or bottom-changing neutral currents are less stringent: $\Gamma(D^0 \to \mu^+\mu^-)/\Gamma(D^0 \to \text{all}) < 6.2 \times 10^{-9}$ and $\Gamma(B^0 \to \mu^+\mu^-)/\Gamma(B^0 \to \text{all}) < 6.3 \times 10^{-10}$. One cannot isolate flavor-changing neutral current (FCNC) effects in non leptonic decays. For example, the FCNC transition $s \to d + (\overline{u} + u)$ is equivalent to the charged-current transition $s \to u + (\overline{u} + d)$. Tests for FCNC are therefore limited to hadron decays into lepton pairs. Such decays are expected only in second-order in the electroweak coupling in the Standard Model. The LHCb and CMS experiments have recently observed the FCNC decay of $B_s^0 \to \mu^+\mu^-$. The current world average value is $\Gamma(B_s^0 \to \mu^+\mu^-)/\Gamma(B_s^0 \to \text{all}) = (3.1 \pm 0.7) \times 10^{-9}$, which is consistent with the Standard Model expectation.

Unless otherwise stated, limits are given at the 90% confidence level, while errors are given as ±1 standard deviation.

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

[a] C parity forbids this to occur as a single-photon process.

[b] See the Particle Listings for the (complicated) definition of this quantity.

[c] Time-reversal invariance requires this to be 0° or 180°.

[d] This coefficient is zero if time invariance is not violated.

[e] Allowed by higher-order electroweak interactions.

[f] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

[g] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.

[h] $\text{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.

[i] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K_L^0 \to \pi^+\pi^-\gamma(\text{DE})$.

[j] Neglecting photon channels. See, *e.g.*, A. Pais and S.B. Treiman, Phys. Rev. **D12**, 2744 (1975).

[k] Derived from measured values of ϕ_{+-}, ϕ_{00}, $|\eta|$, $|m_{K_L^0} - m_{K_S^0}|$, and $\tau_{K_S^0}$, as described in the introduction to "Tests of Conservation Laws."

[l] The $|m_p - m_{\overline{p}}|/m_p$ and $|q_p + q_{\overline{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\overline{p}}/m_{\overline{p}}|/(q_p/m_p)$.

[n] The value is for the sum of the charge states or particle/antiparticle states indicated.

[o] A test of additive vs. multiplicative lepton family number conservation.

[p] The sign of Δm^2_{32} is not known at this time. The range quoted is for the absolute value.

[q] Derived from an analysis of neutrino-oscillation experiments.

[r] This limit is for either D^0 or $\overline{D}^0$ to $p e^-$.

[s] This limit is for either D^0 or $\overline{D}^0$ to $\overline{p} e^+$.

[t] The first limit is for $p \to$ anything or "disappearance" modes of a bound proton. The second entry, a rough range of limits, assumes the dominant decay modes are among those investigated. For antiprotons the best limit, inferred from the observation of cosmic ray $\overline{p}$'s is $\tau_{\overline{p}} > 10^7$ yr, the cosmic-ray storage time, but this limit depends on a number of assumptions. The best direct observation of stored antiprotons gives $\tau_{\overline{p}}/\text{B}(\overline{p} \to e^-\gamma) > 7 \times 10^5$ yr.

[u] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.

[v] This is the best limit for the mode $e^- \to \nu\gamma$. The best limit for "electron disappearance" is 6.4×10^{24} yr.

[x] See the K_S^0 Particle Listings for the energy limits used in this measurement.

[y] See the K_L^0 Particle Listings for the energy limits used in this measurement.

[z] An ℓ indicates an e or a μ mode, not a sum over these modes.

[aa] This limit is for $\Gamma(t \to Z q)/\Gamma(t \to W b)$.

Unless otherwise stated, limits are given at the 90% confidence level, while errors are given as ±1 standard deviation.

1. PHYSICAL CONSTANTS

Table 1.1. Reviewed 2013 by P.J. Mohr (NIST). Mainly from the "CODATA Recommended Values of the Fundamental Physical Constants: 2010" by P.J. Mohr, B.N. Taylor, and D.B. Newell in Rev. Mod. Phys. **84**, 1527 (2012). The last group of constants (beginning with the Fermi coupling constant) comes from the Particle Data Group. The figures in parentheses after the values give the 1-standard-deviation uncertainties in the last digits; the corresponding fractional uncertainties in parts per 10^9 (ppb) are given in the last column. This set of constants (aside from the last group) is recommended for international use by CODATA (the Committee on Data for Science and Technology). The full 2010 CODATA set of constants may be found at `http://physics.nist.gov/constants`. See also P.J. Mohr and D.B. Newell, "Resource Letter FC-1: The Physics of Fundamental Constants," Am. J. Phys. **78**, 338 (2010).

* The meter is the length of the path traveled by light in vacuum during a time interval of 1/299 792 458 of a second.
† At $Q^2 = 0$. At $Q^2 \approx m_W^2$ the value is $\sim 1/128$.
‡ Absolute lab measurements of G_N have been made only on scales of about 1 cm to 1 m.
** See the discussion in Sec. 10, "Electroweak model and constraints on new physics."
†† The corresponding $\sin^2\theta$ for the effective angle is 0.23155(5).

2. ASTROPHYSICAL CONSTANTS AND PARAMETERS

Table 2.1. Revised November 2013 by D.E. Groom (LBNL). The figures in parentheses after some values give the 1-σ uncertainties in the last digit(s). Physical constants are from Ref. 1. While every effort has been made to obtain the most accurate current values of the listed quantities, the table does not represent a critical review or adjustment of the constants, and is not intended as a primary reference.

The values and uncertainties for the cosmological parameters depend on the exact data sets, priors, and basis parameters used in the fit. Many of the derived parameters reported in this table have non-Gaussian likelihoods. Parameters may be highly correlated, so care must be taken in propagating errors. (But in multiplications by h^{-2} *etc.* in the table below, independent errors were assumed.) Unless otherwise specified, cosmological parameters are from six-parameter fits to a flat ΛCDM cosmology using CMB data alone: *Planck* temperature + WMAP polarization data + high-resolution data from ACT and SPT [2]. For more information see Ref. 3 and the original papers.

25. $n_\gamma = \frac{2\zeta(3)}{\pi^2}\left(\frac{kT}{\hbar c}\right)^3$; $\rho_\gamma = \frac{\pi^2 kT}{15\,c^2}\left(\frac{kT}{\hbar c}\right)^3$; $s/k = \frac{2\cdot 43\cdot\pi^2}{11\cdot 45}\left(\frac{kT}{\hbar c}\right)^3$; $kT_0/\hbar c = 11.902(4)/\text{cm}$.
26. B.D. Fields, P. Molarto, and S. Sarkar, "Big-Bang Nucleosynthesis," in this *Review*.
27. $n_{\rm b}$ depends only upon the measured $\Omega_{\rm b}h^2$, the average baryon mass at the present epoch [28], and G_N: $n_{\rm b} = (\Omega_{\rm b}h^2)h^{-2}\rho_{\rm crit}/(0.93711\,\text{GeV}/c^2\text{ per baryon})$.
28. G. Steigman, JCAP **0610**, 016, (2006).
29. Conversion using length of sidereal year.
30. $\Omega_\nu h^2 = \sum m_{\nu_j}/93.04\,\text{eV}$, where the sum is over all neutrino mass eigenstates. The lower limit follows from neutrino mixing results reported in this *Review* combined with the assumptions that there are three light neutrinos ($m_\nu < 45$ GeV/c^2) and that the lightest neutrino is substantially less massive than the others: $\Delta m^2_{32} = (2.32^{+0.12}_{-0.08}) \times 10^{-3}$ eV^2, so $\sum m_{\nu_j} \geq m_{\nu_3} \approx \sqrt{\Delta m^2_{32}} = 0.05$ eV. (This becomes 0.10 eV if the mass hierarchy is inverted, with $m_{\nu_1} \approx m_{\nu_2} \gg m_{\nu_3}$.) Alternatively, if the limit obtained from tritium decay experiments ($m_\nu < 2\,\text{eV}$) is used for the upper limit, then $\Omega_\nu < 0.04$.
31. Astrophysical determinations of $\sum m_{\nu_j}$, reported in the Full Listings of this *Review* under "Sum of the neutrino masses," range from $< 0.17\,\text{eV}$ to $< 2.3\,\text{eV}$ in papers published since 2003.

Table 4.1. Revised 2011 by D.E. Groom (LBNL), and E. Bergren. Atomic weights of stable elements are adapted from the Commission on Isotopic Abundances and Atomic Weights, "Atomic Weights of the Elements 2007," `http://www.chem.qmul.ac.uk/iupac/AtWt/`. The atomic number (top left) is the number of protons in the nucleus. The atomic mass (bottom) of a stable elements is weighted by isotopic abundances in the Earth's surface. If the element has no stable isotope, the atomic mass (in parentheses) of the most stable isotope currently known is given. In this case the mass is from `http://www.nndc.bnl.gov/amdc/masstables/Ame2003/mass.mas03` and the longest-lived isotope is from `www.nndc.bnl.gov/ensdf/za_form.jsp`. The exceptions are Th, Pa, and U, which do have characteristic terrestrial compositions. Atomic masses are relative to the mass of ^{12}C, defined to be exactly 12 unified atomic mass units (u) (approx. g/mole). Relative isotopic abundances often vary considerably, both in natural and commercial samples; this is reflected in the number of significant figures given for the atomic mass. IUPAC does not accept the claims for elements 113, 115, 117, and 118 as conclusive at this time.

5. ELECTRONIC STRUCTURE OF THE ELEMENTS

Table 5.1. Reviewed 2011 by J.E. Sansonetti (NIST). The electronic configurations and the ionization energies are from the NIST database, "Ground Levels and Ionization Energies for the Neutral Atoms," W.C. Martin, A. Musgrove, S. Kotochigova, and J.E. Sansonetti, `http://www.nist.gov/pml/data/ion_energy.cfm`. The electron configuration for, say, iron indicates an argon electronic core (see argon) plus six $3d$ electrons and two $4s$ electrons.

	Element		Electron configuration ($3d^5$ = five $3d$ electrons, *etc.*)						Ground state $^{2S+1}L_J$	Ionization energy (eV)
1	H	Hydrogen	$1s$						$^2S_{1/2}$	13.5984
2	He	Helium	$1s^2$						$^1S_0$	24.5874
3	Li	Lithium	(He) $2s$						$^2S_{1/2}$	5.3917
4	Be	Beryllium	(He) $2s^2$						$^1S_0$	9.3227
5	B	Boron	(He) $2s^2$	$2p$					$^2P_{1/2}$	8.2980
6	C	Carbon	(He) $2s^2$	$2p^2$					$^3P_0$	11.2603
7	N	Nitrogen	(He) $2s^2$	$2p^3$					$^4S_{3/2}$	14.5341
8	O	Oxygen	(He) $2s^2$	$2p^4$					$^3P_2$	13.6181
9	F	Fluorine	(He) $2s^2$	$2p^5$					$^2P_{3/2}$	17.4228
10	Ne	Neon	(He) $2s^2$	$2p^6$					$^1S_0$	21.5645
11	Na	Sodium	(Ne) $3s$						$^2S_{1/2}$	5.1391
12	Mg	Magnesium	(Ne) $3s^2$						$^1S_0$	7.6462

Lanthanides

Transition elements

Actinides

* The usual LS coupling scheme does not apply for these three elements. See the introductory note to the NIST table from which this table is taken.

6. ATOMIC AND NUCLEAR PROPERTIES OF MATERIALS

Table 6.1 Abridged from `pdg.lbl.gov/AtomicNuclearProperties` by D. E. Groom (2007). See web pages for more detail about entries in this table including chemical formulae, and for several hundred other entries. Quantities in parentheses are for gases at 20° C and 1 atm, and square brackets indicate evaluation at 0° C and 1 atm. Boiling points are at 1 atm. Refractive indices n are evaluated at the sodium D line blend (589.2 nm); values $\gg 1$ in brackets are for $(n-1)\times 10^6$ (gases).

Material	Z	A	$\langle Z/A\rangle$	Nucl.coll. length λ_T {g cm^{-2}}	Nucl.inter. length λ_I {g cm^{-2}}	Rad.len. X_0 {g cm^{-2}}	$dE/dx\|_{\rm min}$ { MeV g^{-1}cm^2}	Density {g cm^{-3}} ({gℓ^{-1}})	Melting point (K)	Boiling point (K)	Refract. index (@ Na D)

7.1. Impedances (SI units)

ρ = resistivity at room temperature in $10^{-8}\,\Omega$ m:

~ 1.7 for Cu	~ 5.5 for W
~ 2.4 for Au	~ 73 for SS 304
~ 2.8 for Al	~ 100 for Nichrome

(Al alloys may have double the Al value.)

For alternating currents, instantaneous current I, voltage V, angular frequency ω:

$$V = V_0\, e^{j\omega t} = ZI\ . \tag{7.1}$$

Impedance of self-inductance L: $Z = j\omega L$.

Impedance of capacitance C: $Z = 1/j\omega C$.

Impedance of free space: $Z = \sqrt{\mu_0/\epsilon_0} = 376.7\ \Omega$.

High-frequency surface impedance of a good conductor:

$$Z = \frac{(1+j)\,\rho}{\delta}\ , \quad \text{where } \delta = \text{skin depth}\ ; \tag{7.2}$$

$$\delta = \sqrt{\frac{\rho}{\pi\nu\mu}} \approx \frac{6.6\text{ cm}}{\sqrt{\nu\,(\text{Hz})}} \quad \text{for Cu}\ . \tag{7.3}$$

7.2. Capacitors, inductors, and transmission Lines

The capacitance between two parallel plates of area A spaced by the distance d and enclosing a medium with the dielectric constant ε is

$$C = K\varepsilon A/d\,, \tag{7.4}$$

where the correction factor K depends on the extent of the fringing field. If the dielectric fills the capacitor volume without extending beyond the electrodes. the correction factor $K \approx 0.8$ for capacitors of typical geometry.

The inductance at high frequencies of a straight wire whose length ℓ is much greater than the wire diameter d is

$$L \approx 2.0\left[\frac{\text{nH}}{\text{cm}}\right]\cdot\ell\left(\ln\left(\frac{4\ell}{d}\right)-1\right)\ . \tag{7.5}$$

For very short wires, representative of vias in a printed circuit board, the inductance is

$$L(\text{in nH}) \approx \ell/d\,. \tag{7.6}$$

A transmission line is a pair of conductors with inductance L and capacitance C. The characteristic impedance $Z = \sqrt{L/C}$ and the phase velocity $v_p = 1/\sqrt{LC} = 1/\sqrt{\mu\varepsilon}$, which decreases with the inverse square root of the dielectric constant of the medium. Typical coaxial and ribbon cables have a propagation delay of about 5 ns/cm.

The impedance of a coaxial cable with outer diameter D and inner diameter d is

$$Z = 60\,\Omega\cdot\frac{1}{\sqrt{\varepsilon_r}}\ln\frac{D}{d}\,, \tag{7.7}$$

where the relative dielectric constant $\varepsilon_r = \varepsilon/\varepsilon_0$. A pair of parallel wires of diameter d and spacing $a > 2.5\,d$ has the impedance

$$Z = 120\,\Omega\cdot\frac{1}{\sqrt{\varepsilon_r}}\ln\frac{2a}{d}\,. \tag{7.8}$$

This yields the impedance of a wire at a spacing h above a ground plane,

$$Z = 60\,\Omega\cdot\frac{1}{\sqrt{\varepsilon_r}}\ln\frac{4h}{d}\,. \tag{7.9}$$

A common configuration utilizes a thin rectangular conductor above a ground plane with an intermediate dielectric (microstrip). Detailed calculations for this and other transmission line configurations are given by Gunston.*

7.3. Synchrotron radiation (CGS units)

For a particle of charge e, velocity $v = \beta c$, and energy $E = \gamma mc^2$, traveling in a circular orbit of radius R, the classical energy loss per revolution δE is

$$\delta E = \frac{4\pi}{3}\,\frac{e^2}{R}\,\beta^3\,\gamma^4\ . \tag{7.10}$$

For high-energy electrons or positrons ($\beta \approx 1$), this becomes

$$\delta E\ (\text{in MeV}) \approx 0.0885\ [E(\text{in GeV})]^4/R(\text{in m})\ . \tag{7.11}$$

For $\gamma \gg 1$, the energy radiated per revolution into the photon energy interval $d(\hbar\omega)$ is

$$dI = \frac{8\pi}{9}\alpha\,\gamma\,F(\omega/\omega_c)\,d(\hbar\omega)\ , \tag{7.12}$$

where $\alpha = e^2/\hbar c$ is the fine-structure constant and

$$\omega_c = \frac{3\gamma^3 c}{2R} \tag{7.13}$$

is the critical frequency. The normalized function $F(y)$ is

$$F(y) = \frac{9}{8\pi}\sqrt{3}\,y\int_y^\infty K_{5/3}\,(x)\ dx\ , \tag{7.14}$$

where $K_{5/3}\,(x)$ is a modified Bessel function of the third kind. For electrons or positrons,

$$\hbar\omega_c\,(\text{in keV}) \approx 2.22\ [E(\text{in GeV})]^3/R(\text{in m})\ . \tag{7.15}$$

Fig. 7.1 shows $F(y)$ over the important range of y.

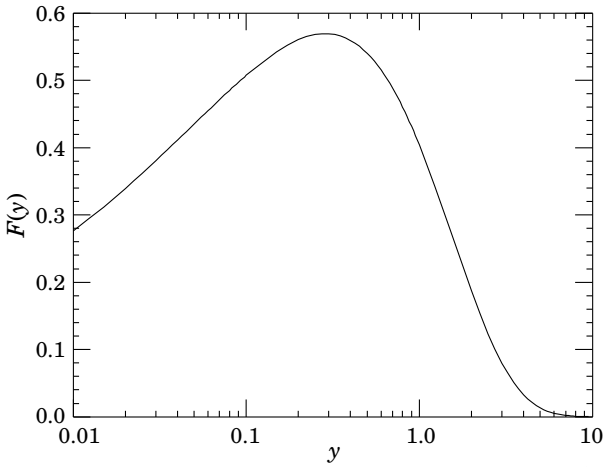

Figure 7.1: The normalized synchrotron radiation spectrum $F(y)$.

For $\gamma \gg 1$ and $\omega \ll \omega_c$,

$$\frac{dI}{d(\hbar\omega)} \approx 3.3\alpha\,(\omega R/c)^{1/3}\ , \tag{7.16}$$

whereas for

$$\gamma \gg 1 \text{ and } \omega \gtrsim 3\omega_c\ ,$$

$$\frac{dI}{d(\hbar\omega)} \approx \sqrt{\frac{3\pi}{2}}\,\alpha\,\gamma\left(\frac{\omega}{\omega_c}\right)^{1/2} e^{-\omega/\omega_c}\left[1+\frac{55}{72}\frac{\omega_c}{\omega}+\ldots\right]\ . \tag{7.17}$$

The radiation is confined to angles $\lesssim 1/\gamma$ relative to the instantaneous direction of motion. For $\gamma \gg 1$, where Eq. (7.12) applies, the mean number of photons emitted per revolution is

$$N_\gamma = \frac{5\pi}{\sqrt{3}}\alpha\gamma\ , \tag{7.18}$$

and the mean energy per photon is

$$\langle\hbar\omega\rangle = \frac{8}{15\sqrt{3}}\hbar\omega_c\ . \tag{7.19}$$

When $\langle\hbar\omega\rangle \gtrsim \mathrm{O}(E)$, quantum corrections are important.

See J.D. Jackson, *Classical Electrodynamics*, 3rd edition (John Wiley & Sons, New York, 1998) for more formulae and details. (Note that earlier editions had ω_c twice as large as Eq. (7.13).

8. NAMING SCHEME FOR HADRONS

Revised 2004 by M. Roos (University of Finland) and C.G. Wohl (LBNL).

8.1. Introduction

We introduced in the 1986 edition [1] a new naming scheme for the hadrons. Changes from older terminology affected mainly the heavier mesons made of the light (u, d, and s) quarks. Old and new names were listed alongside until 1994. Names also change from edition to edition because some characteristic like mass or spin changes. The Summary Tables give both the new and old names whenever a change occurred.

8.2. "Neutral-flavor" mesons ($S=C=B=T=0$)

Table 8.1 shows the names for mesons having the strangeness and all heavy-flavor quantum numbers equal to zero. The scheme is designed for all ordinary non-exotic mesons, but it will work for many exotic types too, if needed.

Table 8.1: Symbols for mesons with the strangeness and all heavy-flavor quantum numbers equal to zero.

	$J^{PC} =$	0^{-+}	1^{+-}	1^{--}	0^{++}
		2^{-+}	3^{+-}	2^{--}	1^{++}
		$\vdots$	$\vdots$	$\vdots$	$\vdots$
$q\overline{q}$ content	$^{2S+1}L_J =$	$^1(L\,\text{even})_J$	$^1(L\,\text{odd})_J$	$^3(L\,\text{even})_J$	$^3(L\,\text{odd})_J$
$u\overline{d}, u\overline{u}-d\overline{d}, d\overline{u}$	$(I=1)$	π	b	ρ	a
$d\overline{d}+u\overline{u}$ and/or $s\overline{s}$	$(I=0)$	η, η'	h, h'	ω, ϕ	f, f'
$c\overline{c}$		η_c	h_c	$\psi^\dagger$	χ_c
$b\overline{b}$		η_b	h_b	Υ	χ_b
$t\overline{t}$		η_t	h_t	θ	χ_t

†The J/ψ remains the J/ψ.

First, we assign names to those states with quantum numbers compatible with being $q\overline{q}$ states. The rows of the Table give the possible $q\overline{q}$ content. The columns give the possible parity/charge-conjugation states,

$$PC = -+,\ +-,\ --, \text{ and } ++\ ;$$

these combinations correspond one-to-one with the angular-momentum state $^{2S+1}L_J$ of the $q\overline{q}$ system being

$$^1(L\text{ even})_J,\ ^1(L\text{ odd})_J,\ ^3(L\text{ even})_J, \text{ or } ^3(L\text{ odd})_J\ .$$

Here S, L, and J are the spin, orbital, and total angular momenta of the $q\overline{q}$ system. The quantum numbers are related by $P=(-1)^{L+1}$, $C=(-1)^{L+S}$, and G parity $=(-1)^{L+S+I}$, where of course the C quantum number is only relevant to neutral mesons.

The entries in the Table give the meson names. The spin J is added as a subscript except for pseudoscalar and vector mesons, and the mass is added in parentheses for mesons that decay strongly. However, for the lightest meson resonances, we omit the mass.

Measurements of the mass, quark content (where relevant), and quantum numbers I, J, P, and C (or G) of a meson thus fix its symbol. Conversely, these properties may be inferred unambiguously from the symbol.

If the main symbol cannot be assigned because the quantum numbers are unknown, X is used. Sometimes it is not known whether a meson is mainly the isospin-0 mix of $u\overline{u}$ and $d\overline{d}$ or is mainly $s\overline{s}$. A prime (or pair ω, ϕ) may be used to distinguish two such mixing states.

We follow custom and use spectroscopic names such as $\Upsilon(1S)$ as the primary name for most of those ψ, Υ, and χ states whose spectroscopic identity is known. We use the form $\Upsilon(9460)$ as an alternative, and as the primary name when the spectroscopic identity is not known.

Names are assigned for $t\overline{t}$ mesons, although the top quark is evidently so heavy that it is expected to decay too rapidly for bound states to form.

Gluonium states or other mesons that are not $q\overline{q}$ states are, if the quantum numbers are *not* exotic, to be named just as are the $q\overline{q}$ mesons. Such states will probably be difficult to distinguish from $q\overline{q}$ states and will likely mix with them, and we make no attempt to distinguish those "mostly gluonium" from those "mostly $q\overline{q}$."

An "exotic" meson with J^{PC} quantum numbers that a $q\overline{q}$ system cannot have, namely $J^{PC}=0^{--}, 0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, \cdots$, would use the same symbol as does an ordinary meson with all the same quantum numbers as the exotic meson except for the C parity. But then the J subscript may still distinguish it; for example, an isospin-0 1^{-+} meson could be denoted ω_1.

8.3. Mesons with nonzero S, C, B, and/or T

Since the strangeness or a heavy flavor of these mesons is nonzero, none of them are eigenstates of charge conjugation, and in each of them one of the quarks is heavier than the other. The rules are:

1. The main symbol is an upper-case italic letter indicating the heavier quark as follows:
$$s \to \overline{K} \qquad c \to D \qquad b \to \overline{B} \qquad t \to T\ .$$
We use the convention that *the flavor and the charge of a quark have the same sign.* Thus the strangeness of the s quark is negative, the charm of the c quark is positive, and the bottom of the b quark is negative. In addition, I_3 of the u and d quarks are positive and negative, respectively. The effect of this convention is as follows: *Any flavor carried by a charged meson has the same sign as its charge.* Thus the K^+, D^+, and B^+ have positive strangeness, charm, and bottom, respectively, and all have positive I_3. The D_s^+ has positive charm *and* strangeness. Furthermore, the $\Delta(\text{flavor}) = \Delta Q$ rule, best known for the kaons, applies to every flavor.
2. If the lighter quark is not a u or a d quark, its identity is given by a subscript. The D_s^+ is an example.
3. If the spin-parity is in the "normal" series, $J^P = 0^+, 1^-, 2^+, \cdots$, a superscript "*" is added.
4. The spin is added as a subscript except for pseudoscalar or vector mesons.

8.4. Ordinary (3-quark) baryons

The symbols N, Δ, Λ, Σ, Ξ, and Ω used for more than 30 years for the baryons made of light quarks (u, d, and s quarks) tell the isospin and quark content, and the same information is conveyed by the symbols used for the baryons containing one or more heavy quarks (c and b quarks). The rules are:

1. Baryons with *three* u and/or d quarks are N's (isospin 1/2) or Δ's (isospin 3/2).
2. Baryons with *two* u and/or d quarks are Λ's (isospin 0) or Σ's (isospin 1). If the third quark is a c, b, or t quark, its identity is given by a subscript.
3. Baryons with *one* u or d quark are Ξ's (isospin 1/2). One or two subscripts are used if one or both of the remaining quarks are heavy: thus Ξ_c, Ξ_{cc}, Ξ_b, *etc.**
4. Baryons with *no* u or d quarks are Ω's (isospin 0), and subscripts indicate any heavy-quark content.
5. A baryon that decays strongly has its mass as part of its name. Thus p, Σ^-, Ω^-, Λ_c^+, *etc.*, but $\Delta(1232)^0$, $\Sigma(1385)^-$, $\Xi_c(2645)^+$, *etc.*

In short, the number of u plus d quarks together with the isospin determine the main symbol, and subscripts indicate any content of heavy quarks. A Σ always has isospin 1, an Ω always has isospin 0, *etc.*

8.5. Exotic baryons

In 2003, several experiments reported finding a strangeness $S = +1$, charge $Q = +1$ baryon, and one experiment reported finding an $S = -2$, $Q = -2$ baryon. Baryons with such quantum numbers cannot be made from three quarks, and thus they are exotic. The $S = +1$ baryon, which once would have been called a Z, was quickly dubbed the $\Theta(1540)^+$, and we proposed to name the $S = -2$ baryon the $\Phi(1860)$. However, these "discoveries" were then completely ruled out by many experiments with far larger statistics: See our 2008 *Review* [2].

Footnote and Reference:

* Sometimes a prime is necessary to distinguish two Ξ_c's in the same SU(n) multiplet. See the "Note on Charmed Baryons" in the Charmed Baryon Listings.

9. QUANTUM CHROMODYNAMICS

Revised October 2013 by S. Bethke (Max-Planck-Institute of Physics, Munich), G. Dissertori (ETH Zurich), and G.P. Salam (CERN and LPTHE, Paris).

9.1. Basics

Quantum Chromodynamics (QCD), the gauge field theory that describes the strong interactions of colored quarks and gluons, is the SU(3) component of the SU(3)×SU(2)×U(1) Standard Model of Particle Physics.

The Lagrangian of QCD is given by

$$\mathcal{L} = \sum_q \bar{\psi}_{q,a}(i\gamma^\mu \partial_\mu \delta_{ab} - g_s \gamma^\mu t^C_{ab} \mathcal{A}^C_\mu - m_q \delta_{ab})\psi_{q,b} - \frac{1}{4} F^A_{\mu\nu} F^{A\,\mu\nu} \,, \quad (9.1)$$

where repeated indices are summed over. The γ^μ are the Dirac γ-matrices. The $\psi_{q,a}$ are quark-field spinors for a quark of flavor q and mass m_q, with a color-index a that runs from $a = 1$ to $N_c = 3$, *i.e.* quarks come in three "colors." Quarks are said to be in the fundamental representation of the SU(3) color group.

The $\mathcal{A}^C_\mu$ correspond to the gluon fields, with C running from 1 to $N_c^2 - 1 = 8$, *i.e.* there are eight kinds of gluon. Gluons transform under the adjoint representation of the SU(3) color group. The t^C_{ab} correspond to eight 3×3 matrices and are the generators of the SU(3) group (cf. the section on "SU(3) isoscalar factors and representation matrices" in this *Review* with $t^C_{ab} \equiv \lambda^C_{ab}/2$). They encode the fact that a gluon's interaction with a quark rotates the quark's color in SU(3) space. The quantity g_s is the QCD coupling constant. Finally, the field tensor $F^A_{\mu\nu}$ is given by

$$F^A_{\mu\nu} = \partial_\mu \mathcal{A}^A_\nu - \partial_\nu \mathcal{A}^A_\mu - g_s\, f_{ABC} \mathcal{A}^B_\mu \mathcal{A}^C_\nu \qquad [t^A, t^B] = i f_{ABC} t^C \,, \quad (9.2)$$

where the f_{ABC} are the structure constants of the SU(3) group.

Neither quarks nor gluons are observed as free particles. Hadrons are color-singlet (*i.e.* color-neutral) combinations of quarks, anti-quarks, and gluons.

Ab-initio predictive methods for QCD include lattice gauge theory and perturbative expansions in the coupling. The Feynman rules of QCD involve a quark-antiquark-gluon ($q\bar{q}g$) vertex, a 3-gluon vertex (both proportional to g_s), and a 4-gluon vertex (proportional to g_s^2). A full set of Feynman rules is to be found for example in Ref. 1.

Useful color-algebra relations include: $t^A_{ab} t^A_{bc} = C_F \delta_{ac}$, where $C_F \equiv (N_c^2 - 1)/(2N_c) = 4/3$ is the color-factor ("Casimir") associated with gluon emission from a quark; $f_{ACD} f_{BCD} = C_A \delta_{AB}$ where $C_A \equiv N_c = 3$ is the color-factor associated with gluon emission from a gluon; $t^A_{ab} t^B_{ab} = T_R \delta_{AB}$, where $T_R = 1/2$ is the color-factor for a gluon to split to a $q\bar{q}$ pair.

The fundamental parameters of QCD are the coupling g_s (or $\alpha_s = \frac{g_s^2}{4\pi}$) and the quark masses m_q.

There is freedom for an additional CP-violating term to be present in the QCD Lagrangian, $\theta \frac{\alpha_s}{8\pi} F^A_{\mu\nu} \tilde{F}^{A\,\mu\nu}$, where $\tilde{F}^{A\,\mu\nu}$ is the dual of the gluon field tensor, $\frac{1}{2}\epsilon_{\mu\nu\sigma\rho} F^{A\,\sigma\rho}$. Experimental limits on the neutron electric dipole moment [2] constrain the coefficient of this contribution to satisfy $|\theta| \lesssim 10^{-10}$. Further discussion is to be found in Ref. 3 and in the Axions section in the Listings of this *Review*.

This section will concentrate mainly on perturbative aspects of QCD as they relate to collider physics. Related textbooks and reviews include Refs. 1,4–6. Aspects specific to Monte Carlo event generators are reviewed in a dedicated section Chap. 40. Lattice QCD is also reviewed in a section of its own Chap. 18, with additional discussion of non-perturbative aspects to be found in the sections on "Quark Masses", "The CKM quark-mixing matrix", "Structure Functions", "Fragmentation Functions" and "Event Generators" in this *Review*. For an overview of some of the QCD issues and recent results in heavy-ion physics, see for example Refs. [7–9].

9.1.1. *Running coupling* :

In the framework of perturbative QCD (pQCD), predictions for observables are expressed in terms of the renormalized coupling $\alpha_s(\mu_R^2)$, a function of an (unphysical) renormalization scale μ_R. When one takes μ_R close to the scale of the momentum transfer Q in a given process, then $\alpha_s(\mu_R^2 \simeq Q^2)$ is indicative of the effective strength of the strong interaction in that process.

The coupling satisfies the following renormalization group equation (RGE):

$$\mu_R^2 \frac{d\alpha_s}{d\mu_R^2} = \beta(\alpha_s) = -(b_0 \alpha_s^2 + b_1 \alpha_s^3 + b_2 \alpha_s^4 + \cdots) \quad (9.3)$$

where $b_0 = (11C_A - 4n_f T_R)/(12\pi) = (33 - 2n_f)/(12\pi)$ is referred to as the 1-loop beta-function coefficient, the 2-loop coefficient is $b_1 = (17C_A^2 - n_f T_R(10C_A + 6C_F))/(24\pi^2) = (153 - 19n_f)/(24\pi^2)$, and the 3-loop coefficient is $b_2 = (2857 - \frac{5033}{9} n_f + \frac{325}{27} n_f^2)/(128\pi^3)$ for the SU(3) values of C_A and C_F. The 4-loop coefficient, b_3, is to be found in Refs. 10, 11[†]. The minus sign in Eq. (9.3) is the origin of Asymptotic Freedom, *i.e.* the fact that the strong coupling becomes weak for processes involving large momentum transfers ("hard processes"), $\alpha_s \sim 0.1$ for momentum transfers in the 100 GeV – TeV range.

The β-function coefficients, the b_i, are given for the coupling of an *effective theory* in which n_f of the quark flavors are considered light ($m_q \ll \mu_R$), and in which the remaining heavier quark flavors decouple from the theory. One may relate the coupling for the theory with $n_f + 1$ light flavors to that with n_f flavors through an equation of the form

$$\alpha_s^{(n_f+1)}(\mu_R^2) = \alpha_s^{(n_f)}(\mu_R^2) \left(1 + \sum_{n=1}^{\infty} \sum_{\ell=0}^{n} c_{n\ell} \, [\alpha_s^{(n_f)}(\mu_R^2)]^n \ln^\ell \frac{\mu_R^2}{m_h^2} \right) , \quad (9.4)$$

where m_h is the mass of the $(n_f+1)^{\text{th}}$ flavor, and the first few $c_{n\ell}$ coefficients are $c_{11} = \frac{1}{6\pi}$, $c_{10} = 0$, $c_{22} = c_{11}^2$, $c_{21} = \frac{19}{24\pi^2}$, and $c_{20} = -\frac{11}{72\pi^2}$ when m_h is the $\overline{\text{MS}}$ mass at scale m_h ($c_{20} = \frac{7}{24\pi^2}$ when m_h is the pole mass — mass definitions are discussed below and in the review on "Quark Masses"). Terms up to $c_{4\ell}$ are to be found in Refs. 12, 13. Numerically, when one chooses $\mu_R = m_h$, the matching is a modest effect, owing to the zero value for the c_{10} coefficient. Relations between n_f and (n_f+2) flavors where the two heavy flavors are close in mass are given to three loops in Ref. 14.

Working in an energy range where the number of flavors is taken constant, a simple exact analytic solution exists for Eq. (9.3) only if one neglects all but the b_0 term, giving $\alpha_s(\mu_R^2) = (b_0 \ln(\mu_R^2/\Lambda^2))^{-1}$. Here Λ is a constant of integration, which corresponds to the scale where the perturbatively-defined coupling would diverge, *i.e.* it is the non-perturbative scale of QCD. A convenient approximate analytic solution to the RGE that includes also the b_1, b_2, and b_3 terms is given by (see for example Ref. 15),

$$\alpha_s(\mu_R^2) \simeq \frac{1}{b_0 t} \left(1 - \frac{b_1}{b_0^2} \frac{\ln t}{t} + \frac{b_1^2(\ln^2 t - \ln t - 1) + b_0 b_2}{b_0^4 t^2} - \frac{b_1^3(\ln^3 t - \frac{5}{2}\ln^2 t - 2\ln t + \frac{1}{2}) + 3 b_0 b_1 b_2 \ln t - \frac{1}{2} b_0^2 b_3}{b_0^6 t^3} \right) ,$$

$$t \equiv \ln \frac{\mu_R^2}{\Lambda^2} \,, \quad (9.5)$$

again parametrized in terms of a constant Λ. Note that Eq. (9.5) is one of several possible approximate 4-loop solutions for $\alpha_s(\mu_R^2)$, and that a value for Λ only defines $\alpha_s(\mu_R^2)$ once one knows which particular approximation is being used. An alternative to the use of formulas such as Eq. (9.5) is to solve the RGE exactly, numerically (including

[†] One should be aware that the b_2 and b_3 coefficients are renormalization-scheme-dependent, and given here in the $\overline{\text{MS}}$ scheme, as discussed below.

the discontinuities, Eq. (9.4), at flavor thresholds). In such cases the quantity Λ is not defined at all. For these reasons, in determinations of the coupling, it has become standard practice to quote the value of α_s at a given scale (typically the mass of the Z boson, M_Z) rather than to quote a value for Λ.

The value of the coupling, as well as the exact forms of the b_2, c_{10} (and higher-order) coefficients, depend on the renormalization scheme in which the coupling is defined, *i.e.* the convention used to subtract infinities in the context of renormalization. The coefficients given above hold for a coupling defined in the modified minimal subtraction ($\overline{\rm MS}$) scheme [16], by far the most widely used scheme.

A discussion of determinations of the coupling and a graph illustrating its scale dependence ("running") are to be found in Section 9.3.4. The RunDec package [17,18] is often used to calculate the evolution of the coupling.

9.1.2. ***Quark masses*** :

Free quarks have never been observed, which is understood as a result of a long-distance, confining property of the strong QCD force. Up, down, strange, charm, and bottom quarks all *hadronize*, *i.e.* become part of a meson or baryon, on a timescale $\sim 1/\Lambda$; the top quark instead decays before it has time to hadronize. This means that the question of what one means by the quark mass is a complex one, which requires that one adopts a specific prescription. A perturbatively defined prescription is the pole mass, m_q, which corresponds to the position of the divergence of the propagator. This is close to one's physical picture of mass. However, when relating it to observable quantities, it suffers from substantial non-perturbative ambiguities (see *e.g.* Ref. 19). An alternative is the $\overline{\rm MS}$ mass, $\overline{m}_q(\mu_R^2)$, which depends on the renormalization scale μ_R.

Results for the masses of heavier quarks are often quoted either as the pole mass or as the $\overline{\rm MS}$ mass evaluated at a scale equal to the mass, $\overline{m}_q(\overline{m}_q^2)$; light quark masses are often quoted in the $\overline{\rm MS}$ scheme at a scale $\mu_R \sim 2$ GeV . The pole and $\overline{\rm MS}$ masses are related by a slowly converging series that starts $m_q = \overline{m}_q(\overline{m}_q^2)(1 + \dfrac{4\alpha_s(\overline{m}_q^2)}{3\pi} + \mathcal{O}(\alpha_s^2))$, while the scale-dependence of $\overline{\rm MS}$ masses is given by

$$\mu_R^2 \frac{d\overline{m}_q(\mu_R^2)}{d\mu_R^2} = \left[-\frac{\alpha_s(\mu_R^2)}{\pi} + \mathcal{O}(\alpha_s^2)\right]\overline{m}_q(\mu_R^2)\,. \qquad (9.6)$$

More detailed discussion is to be found in a dedicated section of the *Review*, "Quark Masses."

9.2. Structure of QCD predictions

9.2.1. ***Fully inclusive cross sections*** :

The simplest observables in QCD are those that do not involve initial-state hadrons and that are fully inclusive with respect to details of the final state. One example is the total cross section for $e^+e^- \to$ hadrons at center-of-mass energy Q, for which one can write

$$\frac{\sigma(e^+e^- \to \text{hadrons}, Q)}{\sigma(e^+e^- \to \mu^+\mu^-, Q)} \equiv R(Q) = R_{\rm EW}(Q)(1 + \delta_{\rm QCD}(Q))\,, \qquad (9.7)$$

where $R_{\rm EW}(Q)$ is the purely electroweak prediction for the ratio and $\delta_{\rm QCD}(Q)$ is the correction due to QCD effects. To keep the discussion simple, we can restrict our attention to energies $Q \ll M_Z$, where the process is dominated by photon exchange ($R_{\rm EW} = 3\sum_q e_q^2$, neglecting finite-quark-mass corrections, where the e_q are the electric charges of the quarks),

$$\delta_{\rm QCD}(Q) = \sum_{n=1}^{\infty} c_n \cdot \left(\frac{\alpha_s(Q^2)}{\pi}\right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right)\,. \qquad (9.8)$$

The first four terms in the α_s series expansion are then to be found in Ref. 20

$$c_1 = 1\,, \qquad c_2 = 1.9857 - 0.1152 n_f\,, \qquad (9.9a)$$

$$c_3 = -6.63694 - 1.20013 n_f - 0.00518 n_f^2 - 1.240\eta \qquad (9.9b)$$

$$c_4 = -156.61 + 18.775 n_f - 0.7974 n_f^2 + 0.0215 n_f^3 + (17.828 - 0.575 n_f)\eta, \qquad (9.9c)$$

with $\eta = (\sum e_q)^2/(3\sum e_q^2)$. For corresponding expressions including also Z exchange and finite-quark-mass effects, see Refs. [21–23].

A related series holds also for the QCD corrections to the hadronic decay width of the τ lepton, which essentially involves an integral of $R(Q)$ over the allowed range of invariant masses of the hadronic part of the τ decay (see e.g. Ref. 24). The series expansions for QCD corrections to Higgs-boson (partial) decay widths are summarized in Refs. 25, 26.

One characteristic feature of Eqs. (9.8) and (9.9) is that the coefficients of α_s^n increase rapidly order by order: calculations in perturbative QCD tend to converge more slowly than would be expected based just on the size of α_s[††]. Another feature is the existence of an extra "power-correction" term $\mathcal{O}(\Lambda^4/Q^4)$ in Eq. (9.8), which accounts for contributions that are fundamentally non-perturbative. All high-energy QCD predictions involve such corrections, though the exact power of Λ/Q depends on the observable.

Scale dependence. In Eq. (9.8) the renormalization scale for α_s has been chosen equal to Q. The result can also be expressed in terms of the coupling at an arbitrary renormalization scale μ_R,

$$\delta_{\rm QCD}(Q) = \sum_{n=1}^{\infty} \overline{c}_n\left(\frac{\mu_R^2}{Q^2}\right) \cdot \left(\frac{\alpha_s(\mu_R^2)}{\pi}\right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right)\,, \qquad (9.10)$$

where $\overline{c}_1(\mu_R^2/Q^2) \equiv c_1$, $\overline{c}_2(\mu_R^2/Q^2) = c_2 + \pi b_0 c_1 \ln(\mu_R^2/Q^2)$, $\overline{c}_3(\mu_R^2/Q^2) = c_3 + (2b_0c_2\pi + b_1c_1\pi^2)\ln(\mu_R^2/Q^2) + b_0^2c_1\pi^2\ln^2(\mu_R^2/Q^2)$, *etc.* Given an infinite number of terms in the α_s expansion, the μ_R dependence of the $\overline{c}_n(\mu_R^2/Q^2)$ coefficients will exactly cancel that of $\alpha_s(\mu_R^2)$, and the final result will be independent of the choice of μ_R: physical observables do not depend on unphysical scales.

With just terms up to $n = N$, a residual μ_R dependence will remain, which implies an uncertainty on the prediction of $R(Q)$ due to the arbitrariness of the scale choice. This uncertainty will be $\mathcal{O}(\alpha_s^{N+1})$, *i.e.* of the same order as the neglected terms. For this reason it is standard to use QCD predictions' scale dependence as an estimate of the uncertainties due to neglected terms. One usually takes a central value for $\mu_R \sim Q$, in order to avoid the poor convergence of the perturbative series that results from the large $\ln^{n-1}(\mu_R^2/Q^2)$ terms in the $\overline{c}_n$ coefficients when $\mu_R \ll Q$ or $\mu_R \gg Q$.

9.2.1.1. *Processes with initial-state hadrons:*

Deep Inelastic Scattering. To illustrate the key features of QCD cross sections in processes with initial-state hadrons, let us consider deep-inelastic scattering (DIS), $ep \to e + X$, where an electron e with four-momentum k emits a highly off-shell photon (momentum q) that interacts with the proton (momentum p). For photon virtualities $Q^2 \equiv -q^2$ far above the squared proton mass (but far below the Z mass), the differential cross section in terms of the kinematic variables Q^2, $x = Q^2/(2p\cdot q)$ and $y = (q\cdot p)/(k\cdot p)$ is

$$\frac{d^2\sigma}{dxdQ^2} = \frac{4\pi\alpha}{2xQ^4}\left[(1 + (1-y)^2)F_2(x,Q^2) - y^2F_L(x,Q^2)\right]\,, \qquad (9.11)$$

where α is the electromagnetic coupling and $F_2(x,Q^2)$ and $F_L(x,Q^2)$ are proton structure functions, which encode the interaction between the photon (in given polarization states) and the proton. In the presence of parity-violating interactions (e.g. νp scattering) an additional F_3 structure function is present. For an extended review, including equations for the full electroweak and polarized cases, see Sec. 19 of this *Review*.

Structure functions are not calculable in perturbative QCD, nor is any other cross section that involves initial-state hadrons. To zeroth order in α_s, the structure functions are given directly in terms of non-perturbative parton (quark or gluon) distribution functions (PDFs),

$$F_2(x,Q^2) = x\sum_q e_q^2 f_{q/p}(x)\,, \qquad F_L(x,Q^2) = 0\,, \qquad (9.12)$$

[††] The situation is significantly worse near thresholds, e.g. the $t\bar{t}$ production threshold. An overview of some of the methods used in such cases is to be found for example in Ref. 27.

where $f_{q/p}(x)$ is the PDF for quarks of type q inside the proton, *i.e.* the number density of quarks of type q inside a fast-moving proton that carry a fraction x of its longitudinal momentum (the quark flavor index q, here, is not to be confused with the photon momentum q in the lines preceding Eq. (9.11)). Since PDFs are non-perturbative, and difficult to calculate accurately in lattice QCD [28], they must be extracted from data.

The above result, with PDFs $f_{q/p}(x)$ that are independent of the scale Q, corresponds to the "quark-parton model" picture in which the photon interacts with point-like free quarks, or equivalently, one has incoherent elastic scattering between the electron and individual constituents of the proton. As a consequence, in this picture also F_2 and F_L are independent of Q. When including higher orders in pQCD, Eq. (9.12) becomes

$$F_2(x,Q^2) = x\sum_{n=0}^{\infty}\frac{\alpha_s^n(\mu_R^2)}{(2\pi)^n}\sum_{i=q,g}\int_x^1\frac{dz}{z}C_{2,i}^{(n)}(z,Q^2,\mu_R^2,\mu_F^2)\,f_{i/p}\Big(\frac{x}{z},\mu_F^2\Big) + \mathcal{O}\Big(\frac{\Lambda^2}{Q^2}\Big)\,. \quad (9.13)$$

Just as in Eq. (9.10), we have a series in powers of $\alpha_s(\mu_R^2)$, each term involving a coefficient $C_{2,i}^{(n)}$ that can be calculated using Feynman graphs. An important difference relative to Eq. (9.10) stems from the fact that the quark's momentum, when it interacts with the photon, can differ from its momentum when it was extracted from the proton, because it may have radiated gluons in between. As a result, the $C_{2,i}^{(n)}$ coefficients are functions that depend on the ratio, z, of these two momenta, and one must integrate over z. For the electromagnetic component of DIS with light quarks and gluons, the zeroth order coefficient functions are $C_{2,q}^{(0)} = e_q^2\delta(1-z)$ and $C_{2,g}^{(0)} = 0$, and corrections are known up to $\mathcal{O}(\alpha_s^3)$ (N^{3}LO) [29]. For weak currents they are known fully to α_s^2 (NNLO) [30] with substantial results known also at N^{3}LO [31]. For heavy quark production they are known to $\mathcal{O}(\alpha_s^2)$ [32] (NLO insofar as the series starts at $\mathcal{O}(\alpha_s)$), with work ongoing towards NNLO [33,34,35].

The majority of the emissions that modify a parton's momentum are collinear (parallel) to that parton, and don't depend on the fact that the parton is destined to interact with a photon. It is natural to view these emissions as modifying the proton's structure rather than being part of the coefficient function for the parton's interaction with the photon. Technically, one uses a procedure known as *collinear factorization* to give a well-defined meaning to this distinction, most commonly through the $\overline{\rm MS}$ factorization scheme, defined in the context of dimensional regularization. The $\overline{\rm MS}$ factorization scheme involves an arbitrary choice of *factorization scale*, μ_F, whose meaning can be understood roughly as follows: emissions with transverse momenta above μ_F are included in the $C_{2,q}^{(n)}(z,Q^2,\mu_R^2,\mu_F^2)$; emissions with transverse momenta below μ_F are accounted for within the PDFs, $f_{i/p}(x,\mu_F^2)$. While collinear factorization is generally believed to be valid for suitable (sufficiently inclusive) observables in processes with hard scales, Ref. 36, which reviews the factorization proofs in detail, is cautious in the statements it makes about their exhaustivity, notably for the hadron-collider processes that we shall discuss below. Further discussion is to be found in Refs. 37,38.

The PDFs' resulting dependence on μ_F is described by the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) equations [39], which to leading order (LO) read

$$\mu_F^2\frac{\partial f_{i/p}(x,\mu_F^2)}{\partial\mu_F^2} = \sum_j\frac{\alpha_s(\mu_F^2)}{2\pi}\int_x^1\frac{dz}{z}P_{i\leftarrow j}^{(1)}(z)f_{j/p}\left(\frac{x}{z},\mu_F^2\right), \quad (9.14)$$

with, for example, $P_{q\leftarrow g}^{(1)}(z) = T_R(z^2+(1-z)^2)$. The other LO* splitting functions are listed in Chap. 19 of this *Review*, while results up to next-to-leading order (NLO), α_s^2, and next-to-next-to-leading order (NNLO), α_s^3, are given in Refs. 40 and 41 respectively. Beyond LO, the coefficient functions are also μ_F dependent, for example $C_{2,i}^{(1)}(x,Q^2,\mu_R^2,\mu_F^2) = C_{2,i}^{(1)}(x,Q^2,\mu_R^2,Q^2) - \ln\left(\frac{\mu_F^2}{Q^2}\right)\sum_j\int_x^1\frac{dz}{z}C_{2,j}^{(0)}(\frac{x}{z})P_{j\leftarrow i}^{(1)}(z)$.

As with the renormalization scale, the choice of factorization scale is arbitrary, but if one has an infinite number of terms in the perturbative series, the μ_F-dependences of the coefficient functions and PDFs will compensate each other fully. Given only N terms of the series, a residual $\mathcal{O}(\alpha_s^{N+1})$ uncertainty is associated with the ambiguity in the choice of μ_F. As with μ_R, varying μ_F provides an input in estimating uncertainties on predictions. In inclusive DIS predictions, the default choice for the scales is usually $\mu_R = \mu_F = Q$.

Hadron-hadron collisions. The extension to processes with two initial-state hadrons can be illustrated with the example of the total (inclusive) cross section for W boson production in collisions of hadrons h_1 and h_2, which can be written as

$$\sigma(h_1h_2\to W+X) = \sum_{n=0}^{\infty}\alpha_s^n(\mu_R^2)\sum_{i,j}\int dx_1dx_2\,f_{i/h_1}\Big(x_1,\mu_F^2\Big)f_{j/h_2}\Big(x_2,\mu_F^2\Big) \times\hat{\sigma}_{ij\to W+X}^{(n)}\Big(x_1x_2s,\mu_R^2,\mu_F^2\Big)\times\left(1+\mathcal{O}\left(\frac{\Lambda^2}{Q^2}\right)\right), \quad (9.15)$$

where s is the squared center-of-mass energy of the collision. At LO, $n=0$, the hard (partonic) cross section $\hat{\sigma}_{ij\to W+X}^{(0)}(x_1x_2s,\mu_R^2,\mu_F^2)$ is simply proportional to $\delta(x_1x_2s - M_W^2)$, in the narrow W-boson width approximation (see Sec. 48 of this *Review* for detailed expressions for this and other hard scattering cross sections). It is non-zero only for choices of i,j that can directly give a W, such as $i=u$, $j=\bar{d}$. At higher orders, $n\geq 1$, new partonic channels contribute, such as gq, and there is no restriction $x_1x_2s = M_W^2$.

Equation 9.15 involves a collinear factorization between hard cross section and PDFs, just like Eq. (9.13). As long as the same factorization scheme is used in DIS and pp or $p\bar{p}$ (usually the $\overline{\rm MS}$ scheme), then PDFs extracted in DIS can be directly used in pp and $p\bar{p}$ predictions [42,36] (with the anti-quark distributions in an anti-proton being the same as the quark distributions in a proton).

Fully inclusive hard cross sections are known to NNLO, i.e. corrections up to relative order α_s^2, for Drell-Yan (DY) lepton-pair and vector-boson production [43,44], Higgs-boson production via gluon fusion [44–46], Higgs-boson production in association with a vector boson [47], Higgs-boson production via vector-boson fusion [48] (in an approximation that factorizes the production of the two vector bosons), Higgs-pair production [49], and top-antitop production [50]. A review of fully inclusive Higgs-related results is to be found in Ref. 51.

Photoproduction. γp (and $\gamma\gamma$) collisions are similar to pp collisions, with the subtlety that the photon can behave in two ways: there is "direct" photoproduction, in which the photon behaves as a point-like particle and takes part directly in the hard collision, with hard subprocesses such as $\gamma g\to q\bar{q}$; there is also resolved photoproduction, in which the photon behaves like a hadron, with non-perturbative partonic substructure and a corresponding PDF for its quark and gluon content, $f_{i/\gamma}(x,Q^2)$.

While useful to understand the general structure of γp collisions, the distinction between direct and resolved photoproduction is not well defined beyond leading order, as discussed for example in Ref. 52.

The high-energy limit. In situations in which the total center-of-mass energy $\sqrt{s}$ is much larger than other scales in the problem (*e.g.*

* LO is generally taken to mean the lowest order at which a quantity is non-zero. This definition is nearly always unambiguous, the one major exception being for the case of the hadronic branching ratio of virtual photons, Z, τ, etc., for which two conventions exist: LO can either mean the lowest order that contributes to the hadronic branching fraction, *i.e.* the term "1" in Eq. (9.7); or it can mean the lowest order at which the hadronic branching ratio becomes sensitive to the coupling, $n=1$ in Eq. (9.8), as is relevant when extracting the value of the coupling from a measurement of the branching ratio. Because of this ambiguity, we avoided use of the term "LO" in that context.

Q in DIS, m_b for $b\bar{b}$ production in pp collisions, *etc.*), each power of α_s beyond LO can be accompanied by a power of $\ln(s/Q^2)$ (or $\ln(s/m_b^2)$, *etc.*). This is known as the high-energy or Balitsky-Fadin-Kuraev-Lipatov (BFKL) limit [53–55]. Currently it is possible to account for the dominant and first subdominant [56,57] power of $\ln s$ at each order of α_s, and also to estimate further subdominant contributions that are numerically large (see Refs. 58–60 and references therein).

Physically, the summation of all orders in α_s can be understood as leading to a growth with s of the gluon density in the proton. At sufficiently high energies this implies non-linear effects, whose treatment has been the subject of intense study (see for example Refs. 61, 62 and references thereto). Note that it is not straightforward to relate these results to the genuinely non-perturbative total, elastic and diffractive cross sections for hadron-hadron scattering (experimental results for which are summarized in section Chap. 50 of this *Review*).

9.2.2. ***Non fully inclusive cross-sections*** :

QCD final states always consist of hadrons, while perturbative QCD calculations deal with partons. Physically, an energetic parton fragments ("showers") into many further partons, which then, on later timescales, undergo a transition to hadrons ("hadronization"). Fixed-order perturbation theory captures only a small part of these dynamics.

This does not matter for the fully inclusive cross sections discussed above: the showering and hadronization stages are unitary, *i.e.* they do not change the overall probability of hard scattering, because they occur long after it has taken place.

Less inclusive measurements, in contrast, may be affected by the extra dynamics. For those sensitive just to the main directions of energy flow (jet rates, event shapes, cf. Sec. 9.3.1) fixed order perturbation theory is often still adequate, because showering and hadronization don't substantially change the overall energy flow. This means that one can make a prediction using just a small number of partons, which should correspond well to a measurement of the same observable carried out on hadrons. For observables that instead depend on distributions of individual hadrons (which, e.g., are the inputs to detector simulations), it is mandatory to account for showering and hadronization. The range of predictive techniques available for QCD final states reflects this diversity of needs of different measurements.

While illustrating the different methods, we shall for simplicity mainly use expressions that hold for e^+e^- scattering. The extension to cases with initial-state partons will be mostly straightforward (space constraints unfortunately prevent us from addressing diffraction and exclusive hadron-production processes; extensive discussion is to be found in Refs. 63, 64).

9.2.2.1. *Preliminaries: Soft and collinear limits:*

Before examining specific predictive methods, it is useful to be aware of a general property of QCD matrix elements in the soft and collinear limits. Consider a squared tree-level matrix element $|M_n^2(p_1,\ldots,p_n)|$ for the process $e^+e^- \to n$ partons with momenta $p_1,\ldots,p_n$, and a corresponding phase-space integration measure $d\Phi_n$. If particle n is a gluon, and additionally it becomes collinear (parallel) to another particle i and its momentum tends to zero (it becomes "soft"), the matrix element simplifies as follows,

$$\lim_{\theta_{in}\to 0,\, E_n\to 0} d\Phi_n |M_n^2(p_1,\ldots,p_n)| = d\Phi_{n-1}|M_{n-1}^2(p_1,\ldots,p_{n-1})| \frac{\alpha_s C_i}{\pi}\frac{d\theta_{in}^2}{\theta_{in}^2}\frac{dE_n}{E_n}\,, \qquad (9.16)$$

where $C_i = C_F$ (C_A) if i is a quark (gluon). This formula has non-integrable divergences both for the inter-parton angle $\theta_{in} \to 0$ and for the gluon energy $E_n \to 0$, which are mirrored also in the structure of divergences in loop diagrams. These divergences are important for at least two reasons: firstly, they govern the typical structure of events (inducing many emissions either with low energy or at small angle with respect to hard partons); secondly, they will determine which observables can be calculated within perturbative QCD.

9.2.2.2. *Fixed-order predictions:*

Let us consider an observable $\mathcal{O}$ that is a function $\mathcal{O}_n(p_1,\ldots,p_n)$ of the four-momenta of the n final-state particles in an event (whether partons or hadrons). In what follows, we shall consider the cross section for events weighted with the value of the observable, $\sigma_{\mathcal{O}}$. As examples, if $\mathcal{O}_n \equiv 1$ for all n, then $\sigma_{\mathcal{O}}$ is just the total cross section; if $\mathcal{O}_n \equiv \hat{\tau}(p_1,\ldots,p_n)$ where $\hat{\tau}$ is the value of the Thrust for that event (see Sec. 9.3.1.2), then the average value of the Thrust is $\langle\tau\rangle = \sigma_{\mathcal{O}}/\sigma_{\rm tot}$; if $\mathcal{O}_n \equiv \delta(\tau - \hat{\tau}(p_1,\ldots,p_n))$ then one gets the differential cross section as a function of the Thrust, $\sigma_{\mathcal{O}} \equiv d\sigma/d\tau$.

In the expressions below, we shall omit to write the non-perturbative power correction term, which for most common observables is proportional to a single power of Λ/Q.

LO. If the observable $\mathcal{O}$ is non-zero only for events with at least n final-state particles, then the LO QCD prediction for the weighted cross section in e^+e^- annihilation is

$$\sigma_{\mathcal{O},LO} = \alpha_s^{n-2}(\mu_R^2)\int d\Phi_n |M_n^2(p_1,\ldots,p_n)|\,\mathcal{O}_n(p_1,\ldots,p_n)\,, \qquad (9.17)$$

where the squared tree-level matrix element, $|M_n^2(p_1,\ldots,p_n)|$, includes relevant symmetry factors, has been summed over all subprocesses (e.g. $e^+e^- \to q\bar{q}q\bar{q}$, $e^+e^- \to q\bar{q}gg$) and has had all factors of α_s extracted in front. In processes other than e^+e^- collisions, the center-of-mass energy of the LO process is generally not fixed, and so the powers of the coupling are often brought inside the integrals, with the scale μ_R chosen event by event, as a function of the event kinematics.

Other than in the simplest cases (see the review on Cross Sections in this *Review*), the matrix elements in Eq. (9.17) are usually calculated automatically with programs such as CompHEP [65], MadGraph [66], Alpgen [67], Comix/Sherpa [68], and Helac/Phegas [69]. Some of these (CompHEP, MadGraph) use formulas obtained from direct evaluations of Feynman diagrams. Others (Alpgen, Helac/Phegas and Comix/Sherpa) use methods designed to be particularly efficient at high multiplicities, such as Berends-Giele recursion [70], which builds up amplitudes for complex processes from simpler ones (see also the reviews and discussion in Refs. [71–73]).

The phase-space integration is usually carried out by Monte Carlo sampling, in order to deal with the sometimes complicated cuts that are used in corresponding experimental measurements. Because of the divergences in the matrix element, Eq. (9.16), the integral converges only if the observable vanishes for kinematic configurations in which one of the n particles is arbitrarily soft or it is collinear to another particle. As an example, the cross section for producing any configuration of n partons will lead to an infinite integral, whereas a finite result will be obtained for the cross section for producing n deposits of energy (or jets, see Sec. 9.3.1.1), each above some energy threshold and well separated from each other in angle.

LO calculations can be carried out for $2 \to n$ processes with $n \lesssim 6-10$. The exact upper limit depends on the process, the method used to evaluate the matrix elements (recursive methods are more efficient), and the extent to which the phase-space integration can be optimized to work around the large variations in the values of the matrix elements.

NLO. Given an observable that is non-zero starting from n final-state particles, its prediction at NLO involves supplementing the LO result, Eq. (9.17), with the $2 \to (n+1)$-particle squared tree-level matrix element ($|M_{n+1}^2|$), and the interference of an $2 \to n$ tree-level and $2 \to n$ 1-loop amplitude ($2\mathrm{Re}(M_n M_{n,1-\mathrm{loop}}^*)$),

$$\sigma_{\mathcal{O}}^{NLO} = \sigma_{\mathcal{O}}^{LO} + \alpha_s^{n-1}(\mu_R^2)\int d\Phi_{n+1} |M_{n+1}^2(p_1,\ldots,p_{n+1})|\,\mathcal{O}_{n+1}(p_1,\ldots,p_{n+1}) + \alpha_s^{n-1}(\mu_R^2)\int d\Phi_n\, 2\mathrm{Re}\,[\, M_n(p_1,\ldots,p_n) M_{n,1-\mathrm{loop}}^*(p_1,\ldots,p_n)\,]\,\mathcal{O}_n(p_1,\ldots,p_n)\,. \qquad (9.18)$$

Relative to LO calculations, two important issues appear in the NLO calculations. Firstly, the extra complexity of loop-calculations

relative to tree-level calculations means that their automation is at a comparatively early stage (see below). Secondly, loop amplitudes are infinite in 4 dimensions, while tree-level amplitudes are finite, but their *integrals* are infinite, due to the divergences of Eq. (9.16). These two sources of infinities have the same soft and collinear origins and cancel after the integration only if the observable $\mathcal{O}$ satisfies the property of infrared and collinear safety,

$$\begin{aligned} \mathcal{O}_{n+1}(p_1,\ldots,p_s,\ldots,p_n) &\to \mathcal{O}_n(p_1,\ldots,p_n) \qquad \text{if } p_s \to 0 \\ \mathcal{O}_{n+1}(p_1,\ldots,p_a,p_b,\ldots,p_n) &\to \mathcal{O}_n(p_1,\ldots,p_a+p_b,\ldots,p_n) \\ &\qquad \text{if } p_a \,||\, p_b\,. \end{aligned} \tag{9.19}$$

Examples of infrared-safe quantities include event-shape distributions and jet cross sections (with appropriate jet algorithms, see below). Unsafe quantities include the distribution of the momentum of the hardest QCD particle (which is not conserved under collinear splitting), observables that require the complete absence of radiation in some region of phase-space (e.g. rapidity gaps or 100% isolation cuts, which are affected by soft emissions), or the particle multiplicity (affected by both soft and collinear emissions). The non-cancellation of divergences at NLO due to infrared or collinear unsafety compromises the usefulness not only of the NLO calculation, but also that of a LO calculation, since LO is only an acceptable approximation if one can prove that higher-order terms are smaller. Infrared and collinear unsafety usually also imply large non-perturbative effects.

As with LO calculations, the phase-space integrals in Eq. (9.18) are usually carried out by Monte Carlo integration, so as to facilitate the study of arbitrary observables. Various methods exist to obtain numerically efficient cancellation among the different infinities. These include notably dipole [74], FKS [75] and antenna [76] subtraction.

NLO calculations exist for a wide range of processes. Many calculations have been performed process by process and are available in dedicated packages, among them NLOJet++ [77] for e^+e^-, DIS, and hadron-hadron processes involving just light partons in the final state, MCFM [78] for hadron-hadron processes with vector bosons and/or heavy quarks in the final state, VBFNLO for vector-boson fusion, di- and tri-boson processes [79], and the Phox family [80] for processes with photons in the final state. Recent years have seen a move towards automated NLO calculations, with publicly available programs such as GoSam [81], Helac-NLO [82], the aMC@NLO framework [83] and NJet [84], as well as other codes such as BlackHat [85], Open Loops [86], Recola [87] and Rocket [88] that have also been used for a range of predictions. These tools rely in part on a wide array of developments reviewed in Refs. 72,89, as well as on external codes for the subtraction of divergences such as Helac-Dipoles [90], MadFKS [91] and Sherpa [92]. The most complex processes for which NLO QCD corrections have been obtained so far are $e^+e^- \to 7$ jets [93], $pp \to W + 5$ jets [94] and $pp \to 5$ jets [95].

NNLO. Conceptually, NNLO and NLO calculations are similar, except that one must add a further order in α_s, consisting of: the squared $(n+2)$-parton tree-level amplitude, the interference of the $(n+1)$-parton tree-level and 1-loop amplitudes, the interference of the n-parton tree-level and 2-loop amplitudes, and the squared n-parton 1-loop amplitude.

Each of these elements involves large numbers of soft and collinear divergences, satisfying relations analogous to Eq. (9.16) that now involve multiple collinear or soft particles and higher loop orders (see e.g. Refs. 96,97,98). Arranging for the cancellation of the divergences after numerical Monte Carlo integration is one of the significant challenges of NNLO calculations, as is the determination of the relevant 2-loop amplitudes. At the time of writing, the processes for which fully exclusive NNLO calculations exist include the 3-jet cross section in e^+e^- collisions [99,100] (for which NNLO means α_s^3), as well as vector-boson [101,102], Higgs-boson [103,104], WH [105], Higgs-pair [49] and di-photon [106] production in pp and $p\bar{p}$ collisions. Progress has also been reported recently on dijet [107] and Higgs+jet [108] production in pp collisions, while the methods used for the total $pp \to t\bar{t}$ cross section [50] lend themselves also to future more differential results.

9.2.2.3. *Resummation:*

Many experimental measurements place tight constraints on emissions in the final state. For example, in e^+e^- events, that one minus the Thrust should be less than some value $\tau \ll 1$, or in $pp \to Z$ events that the Z-boson transverse momentum should be much smaller than its mass, $p_{t,Z} \ll M_Z$. A further example is the production of heavy particles or jets near threshold (so that little energy is left over for real emissions) in DIS and pp collisions.

In such cases, the constraint vetoes a significant part of the integral over the soft and collinear divergence of Eq. (9.16). As a result, there is only a partial cancellation between real emission terms (subject to the constraint) and loop (virtual) contributions (not subject to the constraint), causing each order of α_s to be accompanied by a large coefficient $\sim L^2$, where *e.g.* $L = \ln\tau$ or $L = \ln(M_Z/p_{t,Z})$. One ends up with a perturbative series whose terms go as $\sim (\alpha_s L^2)^n$. It is not uncommon that $\alpha_s L^2 \gg 1$, so that the perturbative series converges very poorly if at all.** In such cases one may carry out a "resummation," which accounts for the dominant logarithmically enhanced terms to all orders in α_s, by making use of known properties of matrix elements for multiple soft and collinear emissions, and of the all-orders properties of the divergent parts of virtual corrections, following original works such as Refs. 109–118 and also through soft-collinear effective theory [119,120] (cf. also the review in Ref. 121).

For cases with double logarithmic enhancements (two powers of logarithm per power of α_s), there are two classification schemes for resummation accuracy. Writing the cross section including the constraint as $\sigma(L)$ and the unconstrained (total) cross section as $\sigma_{\rm tot}$, the series expansion takes the form

$$\sigma(L) \simeq \sigma_{\rm tot} \sum_{n=0}^{\infty} \sum_{k=0}^{2n} R_{nk} \alpha_s^n(\mu_R^2) L^k, \qquad L \gg 1 \tag{9.20}$$

and leading log (LL) resummation means that one accounts for all terms with $k = 2n$, next-to-leading-log (NLL) includes additionally all terms with $k = 2n-1$, *etc.* Often $\sigma(L)$ (or its Fourier or Mellin transform) *exponentiates* ‡,

$$\sigma(L) \simeq \sigma_{\rm tot} \exp\left[\sum_{n=1}^{\infty} \sum_{k=0}^{n+1} G_{nk} \alpha_s^n(\mu_R^2) L^k\right], \qquad L \gg 1\,, \tag{9.21}$$

where one notes the different upper limit on k ($\leq n+1$) compared to Eq. (9.20). This is a more powerful form of resummation: the G_{12} term alone reproduces the full LL series in Eq. (9.20). With the form Eq. (9.21) one still uses the nomenclature LL, but this now means that all terms with $k = n+1$ are included, and NLL implies all terms with $k = n$, *etc.*

For a large number of observables, NLL resummations are available in the sense of Eq. (9.21) (see Refs. 125–127 and references therein). NNLL has been achieved for the DY and Higgs-boson p_t distributions [128–131](also available in the CuTe [132], HRes [133] and ResBos [134] families of programs) and related variables [135], the back-to-back energy-energy correlation in e^+e^- [136], the jet broadening in e^+e^- collisions [137], the jet-veto survival probability in Higgs and Z production in pp collisions [138], an event-shape type observable known as the beam Thrust [139], hadron-collider jet masses in specific limits [140] (see also Ref. 141), the production of

** To be precise one should distinguish two causes of the divergence of perturbative series. That which interests us here is associated with the presence of a new large parameter (*e.g.* ratio of scales). Nearly all perturbative series also suffer from "renormalon" divergences $\alpha_s^n n!$ (reviewed in Ref. 19), which however have an impact only at very high perturbative orders and have a deep connection with non-perturbative contributions.

‡ Whether or not this happens depends on the quantity being resummed. A classic example involves jet rates in e^+e^- collisions as a function of a jet-resolution parameter $y_{\rm cut}$. The logarithms of $1/y_{\rm cut}$ exponentiate for the k_t (Durham) jet algorithm [122], but not [123] for the JADE algorithm [124] (both are discussed below in Sec. 9.3.1.1).

top anti-top pairs near threshold [142–144] (and references therein), and high-p_t W and Z production [145]. Finally, the parts believed to be dominant in the N^{3}LL resummation are available for the Thrust variable and heavy-jet mass in e^+e^- annihilations [146,147] (confirmed for Thrust at NNLL in Ref. 148), and for Higgs- and vector-boson production near threshold [149,150] in hadron collisions (NNLL in Refs. 151,152). The inputs and methods involved in these various calculations are somewhat too diverse to discuss in detail here, so we recommend that the interested reader consult the original references for further details.

9.2.2.4. *Fragmentation functions:*

Since the parton-hadron transition is non-perturbative, it is not possible to perturbatively calculate quantities such as the energy-spectra of specific hadrons in high-energy collisions. However, one can factorize perturbative and non-perturbative contributions via the concept of fragmentation functions. These are the final-state analogue of the parton distribution functions that are used for initial-state hadrons.

It should be added that if one ignores the non-perturbative difficulties and just calculates the energy and angular spectrum of partons in perturbative QCD with some low cutoff scale $\sim \Lambda$ (using resummation to sum large logarithms of $\sqrt{s}/\Lambda$), then this reproduces many features of the corresponding hadron spectra. This is often taken to suggest that hadronization is "local" in momentum space.

Section 20 of this *Review* provides further information (and references) on these topics, including also the question of heavy-quark fragmentation.

9.2.2.5. *Parton-shower Monte Carlo generators:*

Parton-shower Monte Carlo (MC) event generators like PYTHIA [153–155], HERWIG [156–158], SHERPA [92], and ARIADNE [159] provide fully exclusive simulations of QCD events. Because they provide access to "hadron-level" events they are a crucial tool for all applications that involve simulating the response of detectors to QCD events. Here we give only a brief outline of how they work and refer the reader to Chap. 40 and Ref. 160 for a full overview.

The MC generation of an event involves several stages. It starts with the random generation of the kinematics and partonic channels of whatever *hard scattering process* the user has requested at some high scale Q_0 (for complex processes, this may be carried out by an external program). This is followed by a *parton shower*, usually based on the successive random generation of gluon emissions (or $g \to q\bar{q}$ splittings). Each is generated at a scale lower than the previous emission, following a (soft and collinear resummed) perturbative QCD distribution that depends on the momenta of all previous emissions. Common choices of scale for the ordering of emissions are virtuality, transverse momentum or angle. Parton showering stops at a scale of order 1 GeV, at which point a *hadronization model* is used to convert the resulting partons into hadrons. One widely-used model involves stretching a color "string" across quarks and gluons, and breaking it up into hadrons [161,162]. Another breaks each gluon into a $q\bar{q}$ pair and then groups quarks and anti-quarks into colorless "clusters", which then give the hadrons [156]. For pp and γp processes, modeling is also needed to treat the collision between the two hadron remnants, which generates an *underlying event* (UE), usually implemented via additional $2 \to 2$ scatterings ("multiple parton interactions") at a scale of a few GeV, following Ref. 163.

A deficiency of the soft and collinear approximations that underlie parton showers is that they may fail to reproduce the full pattern of hard wide-angle emissions, important, for example, in many new physics searches. It is therefore common to use LO multi-parton matrix elements to generate hard high-multiplicity partonic configurations as additional starting points for the showering, supplemented with some prescription (CKKW [164], MLM [165]) for consistently merging samples with different initial multiplicities.

MCs, as described above, generate cross sections for the requested hard process that are correct at LO. A wide variety of processes are available in MC implementations that are correct to NLO, using the MC@NLO [166] or POWHEG [167] prescriptions, notably through the aMC@NLO [83] and POWHEGBox programs [168]. Techniques have also been developed recently to combine NLO plus shower accuracy for different multiplicities of final-state jets [169]. Building on some of that work, a first example of NNLO plus shower accuracy has been described in Ref. 170 for Higgs production.

9.2.3. ***Accuracy of predictions*** :

Estimating the accuracy of perturbative QCD predictions is not an exact science. It is often said that LO calculations are accurate to within a factor of two. This is based on experience with NLO corrections in the cases where these are available. In processes involving new partonic scattering channels at NLO and/or large ratios of scales (such as jet observables in processes with vector bosons, or the production of high-p_t jets containing B-hadrons), the NLO to LO K-factors can be substantially larger than 2.

For calculations beyond LO, a conservative approach to estimate the perturbative uncertainty is to take it to be the last known perturbative order; a more widely used method is to estimate it from the change in the prediction when varying the renormalization and factorization scales around a central value Q that is taken close to the physical scale of the process. A conventional range of variation is $Q/2 < \mu_R, \mu_F < 2Q$. This should not be assumed to always estimate the full uncertainty from missing higher orders, but it does indicate the size of one important known source of higher-order ambiguity.[‡‡]

There does not seem to be a broad consensus on whether μ_R and μ_F should be kept identical or varied independently. One common option is to vary them independently with the restriction $\frac{1}{2}\mu_R < \mu_F < 2\mu_R$ [177]. This limits the risk of misleadingly small uncertainties due to fortuitous cancellations between the μ_F and μ_R dependence when both are varied together, while avoiding the appearance of large logarithms of μ_R^2/μ_F^2 when both are varied completely independently.

Calculations that involve resummations usually have an additional source of uncertainty associated with the choice of argument of the logarithms being resummed, *e.g.* $\ln(2\frac{p_{t,Z}}{M_Z})$ as opposed to $\ln(\frac{1}{2}\frac{p_{t,Z}}{M_Z})$. In addition to varying renormalization and factorization scales, it is therefore also advisable to vary the argument of the logarithm by a factor of two in either direction with respect to the "natural" argument.

The accuracy of QCD predictions is limited also by non-perturbative corrections, which typically scale as a power of Λ/Q. For measurements that are directly sensitive to the structure of the hadronic final state the corrections are usually linear in Λ/Q. The non-perturbative corrections are further enhanced in processes with a significant underlying event (*i.e.* in pp and $p\bar{p}$ collisions) and in cases where the perturbative cross sections fall steeply as a function of p_t or some other kinematic variable.

Non-perturbative corrections are commonly estimated from the difference between Monte Carlo events at the parton level and after hadronization. An issue to be aware of with this procedure is that "parton level" is not a uniquely defined concept. For example, in an event generator it depends on a (somewhat arbitrary and tunable) internal cutoff scale that separates the parton showering from the hadronization. In contrast no such cutoff scale exists in a NLO or NNLO partonic calculation. For this reason there are widespread reservations as to the appropriateness of deriving hadronization corrections from a Monte Carlo program and then applying them to NLO or NNLO predictions. There exist alternative methods for estimating hadronization corrections, which attempt to analytically deduce non-perturbative effects in one observable based on measurements of other observables (see the reviews [19,178]). While they directly address the problem of different possible definitions of parton level, it should also be said that they are far less flexible than Monte Carlo programs and not always able to provide equally good descriptions of the data.

[‡‡] A number of prescriptions also exist for setting the scale automatically, e.g. Refs. 171–174, eliminating uncertainties from scale variation, though not from the truncation of the perturbative series itself. Recently, there have also been studies of how to estimate uncertainties from missing higher orders that go beyond scale variations [175,176].

9.3. Experimental QCD

Since we are not able to directly measure partons (quarks or gluons), but only hadrons and their decay products, a central issue for every experimental test of perturbative QCD is establishing a correspondence between observables obtained at the partonic and the hadronic level. The only theoretically sound correspondence is achieved by means of *infrared and collinear safe* quantities, which allow one to obtain finite predictions at any order of perturbative QCD.

As stated above, the simplest case of infrared- and collinear-safe observables are total cross sections. More generally, when measuring fully inclusive observables, the final state is not analyzed at all regarding its (topological, kinematical) structure or its composition. Basically the relevant information consists in the rate of a process ending up in a partonic or hadronic final state. In e^+e^- annihilation, widely used examples are the ratios of partial widths or branching ratios for the electroweak decay of particles into hadrons or leptons, such as Z or τ decays, (cf. Sec. 9.2.1). Such ratios are often favored over absolute cross sections or partial widths because of large cancellations of experimental and theoretical systematic uncertainties. The strong suppression of non-perturbative effects, $\mathcal{O}(\Lambda^4/Q^4)$, is one of the attractive features of such observables, however, at the same time the sensitivity to radiative QCD corrections is small, which for example affects the statistical uncertainty when using them for the determination of the strong coupling constant. In the case of τ decays not only the hadronic branching ratio is of interest, but also moments of the spectral functions of hadronic tau decays, which sample different parts of the decay spectrum and thus provide additional information. Other examples of fully inclusive observables are structure functions (and related sum rules) in DIS. These are extensively discussed in Sec. 19 of this *Review*.

On the other hand, often the structure or composition of the final state are analyzed and cross sections differential in one or more variables characterizing this structure are of interest. Examples are jet rates, jet substructure, event shapes or transverse momentum distributions of jets or vector bosons in hadron collisions. The case of fragmentation functions, *i.e.* the measurement of hadron production as a function of the hadron momentum relative to some hard scattering scale, is discussed in Sec. 20 of this *Review*.

It is worth mentioning that, besides the correspondence between the parton and hadron level, also a correspondence between the hadron level and the actually measured quantities in the detector has to be established. The simplest examples are corrections for finite experimental acceptance and efficiencies. Whereas acceptance corrections essentially are of theoretical nature, since they involve extrapolations from the measurable (partial) to the full phase space, other corrections such as for efficiency, resolution and response, are of experimental nature. For example, measurements of differential cross sections such as jet rates require corrections in order to relate, *e.g.* the energy deposits in a calorimeter to the jets at the hadron level. Typically detector simulations and/or data-driven methods are used in order to obtain these corrections. Care should be taken here in order to have a clear separation between the parton-to-hadron level and hadron-to-detector level corrections. Finally, for the sake of an easy comparison to the results of other experiments and/or theoretical calculations, it is suggested to provide, whenever possible, measurements corrected for detector effects and/or all necessary information related to the detector response (*e.g.* the detector response matrix).

9.3.1. *Hadronic final-state observables* :

9.3.1.1. *Jets:*

In hard interactions, final-state partons and hadrons appear predominantly in collimated bunches, which are generically called *jets*. To a first approximation, a jet can be thought of as a hard parton that has undergone soft and collinear showering and then hadronization. Jets are used both for testing our understanding and predictions of high-energy QCD processes, and also for identifying the hard partonic structure of decays of massive particles like top quarks.

In order to map observed hadrons onto a set of jets, one uses a *jet definition*. The mapping involves explicit choices: for example when a gluon is radiated from a quark, for what range of kinematics should the gluon be part of the quark jet, or instead form a separate jet? Good jet definitions are infrared and collinear safe, simple to use in theoretical and experimental contexts, applicable to any type of inputs (parton or hadron momenta, charged particle tracks, and/or energy deposits in the detectors) and lead to jets that are not too sensitive to non-perturbative effects. An extensive treatment of the topic of jet definitions is given in Ref. 179 (for e^+e^- collisions) and Refs. 180, 181 (for pp or $p\bar{p}$ collisions). Here we briefly review the two main classes: cone algorithms, extensively used at older hadron colliders, and sequential recombination algorithms, more widespread in e^+e^- and ep colliders and at the LHC.

Very generically, most (iterative) cone algorithms start with some seed particle i, sum the momenta of all particles j within a cone of opening-angle R, typically defined in terms of (pseudo-)rapidity and azimuthal angle. They then take the direction of this sum as a new seed and repeat until the cone is stable, and call the contents of the resulting stable cone a jet if its transverse momentum is above some threshold $p_{t,\min}$. The parameters R and $p_{t,\min}$ should be chosen according to the needs of a given analysis.

There are many variants of cone algorithm, and they differ in the set of seeds they use and the manner in which they ensure a one-to-one mapping of particles to jets, given that two stable cones may share particles ("overlap"). The use of seed particles is a problem w.r.t. infrared and collinear safety, and seeded algorithms are generally not compatible with higher-order (or sometimes even leading-order) QCD calculations, especially in multi-jet contexts, as well as potentially subject to large non-perturbative corrections and instabilities. Seeded algorithms (JetCLU, MidPoint, and various other experiment-specific iterative cone algorithms) are therefore to be deprecated. A modern alternative is to use a seedless variant, SISCone [182].

Sequential recombination algorithms at hadron colliders (and in DIS) are characterized by a distance $d_{ij} = \min(k_{t,i}^{2p}, k_{t,j}^{2p})\Delta_{ij}^2/R^2$ between all pairs of particles i, j, where Δ_{ij} is their distance in the rapidity-azimuthal plane, $k_{t,i}$ is the transverse momentum w.r.t. the incoming beams, and R is a free parameter. They also involve a "beam" distance $d_{iB} = k_{t,i}^{2p}$. One identifies the smallest of all the d_{ij} and d_{iB}, and if it is a d_{ij}, then i and j are merged into a new pseudo-particle (with some prescription, a recombination scheme, for the definition of the merged four-momentum). If the smallest distance is a d_{iB}, then i is removed from the list of particles and called a jet. As with cone algorithms, one usually considers only jets above some transverse-momentum threshold $p_{t,\min}$. The parameter p determines the kind of algorithm: $p = 1$ corresponds to the (*inclusive-*)k_t algorithm [122,183,184], $p = 0$ defines the *Cambridge-Aachen* algorithm [185,186], while for $p = -1$ we have the *anti-*k_t algorithm [187]. All these variants are infrared and collinear safe to all orders of perturbation theory. Whereas the former two lead to irregularly shaped jet boundaries, the latter results in cone-like boundaries. The *anti-*k_t algorithm has become the de-facto standard for the LHC experiments.

In e^+e^- annihilations the k_t algorithm [122] uses $y_{ij} = 2\min(E_i^2, E_j^2)(1-\cos\theta_{ij})/Q^2$ as distance measure and repeatedly merges the pair with smallest y_{ij}, until all y_{ij} distances are above some threshold $y_{\rm cut}$, the jet resolution parameter. The (pseudo)-particles that remain at this point are called the jets. Here it is $y_{\rm cut}$ (rather than R and $p_{t,\min}$) that should be chosen according to the needs of the analysis. As mentioned above, the k_t algorithm has the property that logarithms $\ln(1/y_{\rm cut})$ exponentiate in resummation calculations. This is one reason why it is preferred over the earlier JADE algorithm [124], which uses the distance measure $y_{ij} = 2\,E_i\,E_j\,(1-\cos\theta_{ij})/Q^2$.

Efficient implementations of the above algorithms are available through the *FastJet* package [188], which is also packaged within *SpartyJet* [189].

9.3.1.2. *Event Shapes:*

Event-shape variables are functions of the four momenta in the hadronic final state that characterize the topology of an event's energy flow. They are sensitive to QCD radiation (and correspondingly to the strong coupling) insofar as gluon emission changes the shape of the energy flow.

The classic example of an event shape is the *Thrust* [190,191] in e^+e^- annihilations, defined as

$$\hat{\tau} = \max_{\vec{n}_\tau} \frac{\sum_i |\vec{p}_i \cdot \vec{n}_\tau|}{\sum_i |\vec{p}_i|} \,, \tag{9.22}$$

where $\vec{p}_i$ are the momenta of the particles or the jets in the final-state and the maximum is obtained for the Thrust axis $\vec{n}_\tau$. In the Born limit of the production of a perfect back-to-back $q\bar{q}$ pair the limit $\hat{\tau} \to 1$ is obtained, whereas a perfectly symmetric many-particle configuration leads to $\hat{\tau} \to 1/2$. Further event shapes of similar nature have been defined and extensively measured at LEP and at HERA, and for their definitions and reviews we refer to Refs. 1,4,178,192,193. Phenomenological discussions of event shapes at hadron colliders can be found in Refs. 194–196. Measurements of hadronic event-shape distributions have been published by CDF [197], ATLAS [198,199] and CMS [200,201].

Event shapes are used for many purposes. These include measuring the strong coupling, tuning the parameters of Monte Carlo programs, investigating analytical models of hadronization and distinguishing QCD events from events that might involve decays of new particles (giving event-shape values closer to the spherical limit).

9.3.1.3. *Jet substructure, quark vs. gluon jets:*

Jet substructure, which can be resolved by finding subjets or by measuring jet shapes, is sensitive to the details of QCD radiation in the shower development inside a jet and has been extensively used to study differences in the properties of quark and gluon induced jets, strongly related to their different color charges. In general there is clear experimental evidence that gluon jets have a softer particle spectrum and are "broader" than (light-) quark jets, when looking at observables such as the jet shape $\Psi(r/R)$. This is the fractional transverse momentum contained within a sub-cone of cone-size r for jets of cone-size R. It is sensitive to the relative fractions of quark and gluon jets in an inclusive jet sample and receives contributions from soft-gluon initial-state radiation and beam remnant-remnant interactions. Therefore, it has been widely employed for validation and tuning of Monte Carlo models. CDF has measured the jet shape $\Psi(r/R)$ for an inclusive jet sample [202] as well as for b-jets [203]. Similar measurements in photo-production and DIS at HERA have been reported in Refs. 204–206. At the LHC, jet shape measurements have been presented in Refs. 207,208 for inclusive jet samples, as well as for top pair events [209]. Further discussions, references and recent summaries can be found in Refs. 193, 210 and Sec. 4 of Ref. 211.

The use of jet substructure has also been suggested in order to distinguish QCD jets from jets that originate from hadronic decays of boosted massive particles (high-p_t electroweak bosons, top quarks and hypothesized new particles). Recently, a number of experimental studies have been carried out with Tevatron and LHC data, in order to investigate on the performance of the proposed algorithms for resolving jet substructure in various event classes, such as inclusive jet [212], dijet and W/Z+jet production [213], as well as in events with high transverse momentum jets (boosted configurations) [214,215]. For reviews and detailed references, see Ref. 211, sec. 5.3 of Ref. 180 and Ref. 216.

9.3.2. ***State of the art QCD measurements at colliders*** :

There exists a wealth of data on QCD-related measurements in e^+e^-, ep, pp, and $p\bar{p}$ collisions, to which a short overview like this would not be able to do any justice. Extensive reviews of the subject have been published in Refs. 192, 193 for e^+e^- colliders and in Ref. 217 for ep scattering, whereas for hadron colliders comprehensive overviews are given in, e.g., Refs. 181, [218–220].

Below we concentrate our discussion on measurements that are most sensitive to hard QCD processes, in particular jet production.

9.3.2.1. e^+e^- *colliders:* Analyses of jet production in e^+e^- collisions are mostly based on JADE data at center-of-mass energies between 14 and 44 GeV, as well as on LEP data at the Z resonance and up to 209 GeV. They cover the measurements of (differential or exclusive) jet rates (with multiplicities typically up to 4, 5 or 6 jets), the study of 3-jet events and particle production between the jets as a tool for testing hadronization models, as well as 4-jet production and angular correlations in 4-jet events. The latter are useful for measurements of the strong coupling constant and putting constraints on the QCD color factors, thus probing the non-abelian nature of QCD. There have also been extensive measurements of event shapes. The tuning of parton shower MC models, typically matched to matrix elements for 3-jet production, has led to good descriptions of the available, highly precise data. Especially for the large LEP data sample at the Z peak, the statistical uncertainties are mostly negligible and the experimental systematic uncertainties are at the per-cent level or even below. These are usually dominated by the uncertainties related to the MC model dependence of the efficiency and acceptance corrections (often referred to as "detector corrections").

9.3.2.2. *DIS and photoproduction:* Multi-jet production in ep collisions at HERA, both in the DIS and photoproduction regime, allows for tests of QCD factorization (one initial-state proton and its associated PDF versus the hard scattering which leads to high-p_t jets) and NLO calculations which exist for 2- and 3-jet final states. Sensitivity is also obtained to the product of the coupling constant and the gluon PDF. Experimental uncertainties of the order of $5-10\%$ have been achieved, mostly dominated by jet energy scale, whereas statistical uncertainties are negligible to a large extent. For comparison to theoretical predictions, at large jet p_t the PDF uncertainty dominates the theoretical uncertainty (typically of order 5 - 10%, in some regions of phase-space up to 20%), therefore jet observables become useful inputs for PDF fits. In general, the data are well described by NLO matrix-element calculations, combined with DGLAP evolution equations, in particular at large Q^2 and central values of jet pseudo-rapidity. At low values of Q^2 and x, in particular for large jet pseudo-rapidities, there are indications for the need of BFKL-type evolution, though the predictions for such schemes are still limited. In the case of photoproduction, a wealth of measurements with low p_t jets were performed in order to constrain the photon PDFs. The uncertainties related to these photon PDFs play a minor role at high jet p_t, which has allowed for precise tests of pQCD calculations.

A few examples of recent measurements can be found in Refs. 221–228 for DIS and in Refs. 229–233 for photoproduction.

9.3.2.3. *Hadron colliders:* Jet measurements at the Tevatron and the LHC have been performed with data samples from a wide range of luminosities and center-of-mass energies. In particular, LHC results have been published for luminosities up to $5\,\mathrm{fb}^{-1}$ and center-of-mass energies of 2.76 and 7 TeV, with preliminary results also available from 8 TeV collisions. Among the most important cross sections measured is the inclusive jet production as a function of the jet transverse energy (E_t) or the jet transverse momentum (p_t), for several rapidity regions and for p_t up to 700 GeV at the Tevatron and ~ 2 TeV at the LHC. The Tevatron measurements are based on the infrared- and collinear-safe k_t algorithm in addition to the more widely used Midpoint and JetCLU algorithms of the past, whereas the LHC experiments focus on the *anti-k_t* algorithm. Results by the CDF and D0 collaborations can be found in Refs. 234–236, whereas measurements by ALICE, ATLAS and CMS have been published in Refs. 237–243. In general we observe a good description of the data by the NLO QCD predictions, over about 9 orders of magnitude in cross section. The experimental systematic uncertainties are dominated by the jet energy scale uncertainty, quoted to be in the range of 1 to 2%, leading to uncertainties of $\sim 5-30\%$ on the cross section, increasing with p_t and rapidity. The PDF uncertainties dominate the theoretical uncertainty at large p_t and rapidity. In fact, inclusive jet data are important inputs to global PDF fits, in particular for constraining the high-x gluon PDF. Constraints on the PDFs can also be obtained from ratios of inclusive cross sections at different center-of-mass energies, as for example shown in Ref. [240].

A rather comprehensive summary, comparing NLO QCD predictions to data for inclusive jet production in DIS, pp, and $p\bar{p}$ collisions, is given in Ref. 244 and reproduced here in Fig. 9.1.

Dijet events are analyzed in terms of their invariant mass and angular distributions, which allows for tests of NLO QCD predictions (see e.g. Refs. [239,242] for recent LHC results), as well as to put stringent limits on deviations from the Standard Model, such as quark compositeness (some examples can be found in Refs. 245–248). Furthermore, dijet azimuthal correlations between the two leading jets, normalized to the total dijet cross cross section, are an extremely valuable tool for studying the spectrum of gluon radiation in the event. For example, results from the Tevatron [249,250] and the LHC [251,252] show that the LO (non-trivial) prediction for this observable, with at most three partons in the final state, is not able to describe the data for an azimuthal separation below $2\pi/3$, where NLO contributions (with 4 partons) restore the agreement with data. In addition, this observable can be employed to tune Monte Carlo predictions of soft gluon radiation. Beyond dijet final states, measurements of the production of three or more jets, including cross section ratios, have been performed [253–259], as a means of testing perturbative QCD predictions, tuning MC models, constraining PDFs or determining the strong coupling constant.

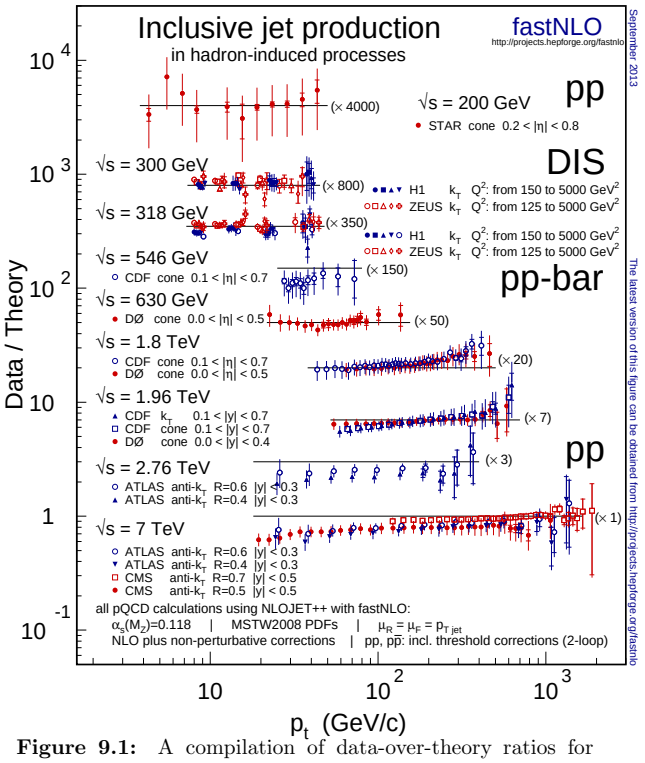

Figure 9.1: A compilation of data-over-theory ratios for inclusive jet cross sections as a function of jet transverse momentum (p_t), measured in different hadron-induced processes at different center-of-mass energies; from Ref. 244. The various ratios are scaled by arbitrary numbers (indicated between parentheses) for better readability of the plot. The theoretical predictions have been obtained at NLO accuracy, for parameter choices (coupling constant, PDFs, renormalization, and factorization scales) as indicated at the bottom of the figure.

Similarly important tests of QCD arise from measurements of vector boson (photon, W, Z) production together with jets, where the presence of the vector boson introduces an additional hard scale in the process. By now, many results have been obtained both at the Tevatron [260–268] and the LHC [201,269–275]. The measurements cover a large phase space, e.g. with jet transverse momenta between 30 GeV and $\sim$ 500 GeV and jet rapidities up to $|y| < 4.4$. Jet multiplicities as high as seven jets accompanying the vector boson have already been probed at the LHC, together with a substantial number of other kinematical observables. A general observation is that MC models, which implement a matching of matrix-element calculations with parton showers, provide a remarkably good description of the data. Also NLO calculations for up to four jets in addition to the vector boson are in good agreement with the data over that phase space, where such calculations are applicable. Altogether, this represents an impressive success of QCD at high jet multiplicities.

Instead of measuring the jets recoiling against the vector boson, where the precision is limited by the jet energy scale uncertainty, the vector boson's p_t distribution can also be directly probed [262,276–278]. For example, the Z p_t distribution, reconstructed using the Z decay to leptons, is sensitive to QCD radiation both at high and low scales and thus probes perturbative as well as non-perturbative effects. Similarly, photon production in special phase-space regions, such as di-photon production with small azimuthal separation between the two photons, allows for sensitive tests of QCD radiation without the need of direct jet reconstruction [279–282].

A substantial fraction of the jets produced at hadron colliders contain heavy quarks (b, c), whose mass introduces an additional scale in the event. Therefore, measurements of heavy quark production, either inclusive or in association with vector bosons, represent very important tests of multi-scale calculations in perturbative QCD. Results for b-jet production at the LHC [283,284] indicate that NLO and/or NLO plus parton shower QCD calculations describe the data well over most of the phase space. However, the observed discrepancies for small angular separation of the heavy quarks suggest that a better understanding of the $g \to b\bar{b}$ vertex may well be required [285]. Tevatron [286–297] and LHC [298–300] measurements for heavy quark production in association with a vector boson have been compared to NLO QCD and MC predictions. Typically, the experimental and theoretical uncertainties are still rather large. Nevertheless, it is worth noting that there are discrepancies between data and QCD predictions, in particular for γ plus (c, b)-jet, Z plus c-jet and W plus b-jet production.

Finally, top-quark production at the LHC starts to become an important tool for probing higher-order QCD calculations. Besides the precise determination of the inclusive cross section, used by CMS to measure the strong coupling constant for the first time at NNLO accuracy from hadron collider data [301], also measurements of differential cross sections and of jet production in association with top quarks start to probe QCD in this regime [302–304].

9.3.3. *Tests of the non-abelian nature of QCD* :

QCD is a gauge theory with SU(3) as underlying gauge group. For a general gauge theory with a simple Lie group, the couplings of the fermion fields to the gauge fields and the self-interactions in the non-abelian case are determined by the coupling constant and Casimir operators of the gauge group, as introduced in Sec. 9.1. Measuring the eigenvalues of these operators, called color factors, probes the underlying structure of the theory in a gauge invariant way and provides evidence of the gluon self-interactions. Typically, cross sections can be expressed as functions of the color factors, for example $\sigma = f(\alpha_s C_F, C_A/C_F, n_f T_R/C_F)$. Sensitivity at leading order in perturbation theory can be achieved by measuring angular correlations in 4-jet events in e^+e^- annihilation or 3-jet events in DIS. Some sensitivity, although only at NLO, is also obtained from event-shape distributions. Scaling violations of fragmentation functions and the different subjet structure in quark and gluon induced jets also give access to these color factors. In order to extract absolute values, *e.g.* for C_F and C_A, certain assumptions have to be made for other parameters, such as T_R, n_f or α_s, since typically only combinations (ratios, products) of all the relevant parameters appear in the perturbative predictions. A compilation of results [193] quotes world average values of $C_A = 2.89 \pm 0.03(\text{stat}) \pm 0.21(\text{syst})$ and $C_F = 1.30 \pm 0.01(\text{stat}) \pm 0.09(\text{syst})$, with a correlation coefficient of 82%. These results are in perfect agreement with the expectations from SU(3) of $C_A = 3$ and $C_F = 4/3$. An overview of the history and the current status of tests of Asymptotic Freedom, closely related to the non-abelian nature of QCD, can be found in Ref. 305.

9.3.4. ***Determinations of the strong coupling constant*** :

Beside the quark masses, the only free parameter in the QCD Lagrangian is the strong coupling constant α_s. The coupling constant in itself is not a physical observable, but rather a quantity defined in the context of perturbation theory, which enters predictions for experimentally measurable observables, such as R in Eq. (9.7).

Many experimental observables are used to determine α_s. Considerations in such determinations include:

- The observable's sensitivity to α_s as compared to the experimental precision. For example, for the e^+e^- cross section to hadrons (cf. R in Sec. 9.2.1), QCD effects are only a small correction, since the perturbative series starts at order α_s^0; 3-jet production or event shapes in e^+e^- annihilations are directly sensitive to α_s since they start at order α_s; the hadronic decay width of heavy quarkonia, $\Gamma(\Upsilon \to \text{hadrons})$, is very sensitive to α_s since its leading order term is $\propto \alpha_s^3$.
- The accuracy of the perturbative prediction, or equivalently of the relation between α_s and the value of the observable. The minimal requirement is generally considered to be an NLO prediction. Some observables are predicted to NNLO (many inclusive observables, 3-jet rates and event shapes in e^+e^- collisions) or even N^{3}LO (e^+e^- hadronic cross section and τ branching fraction to hadrons). In certain cases, fixed-order predictions are supplemented with resummation. The precise magnitude of theory uncertainties is usually estimated as discussed in Sec. 9.2.3.
- The size of uncontrolled non-perturbative effects. Sufficiently inclusive quantities, like the e^+e^- cross section to hadrons, have small non-perturbative uncertainties $\sim \Lambda^4/Q^4$. Others, such as event-shape distributions, have uncertainties $\sim \Lambda/Q$.
- The scale at which the measurement is performed. An uncertainty δ on a measurement of $\alpha_s(Q^2)$, at a scale Q, translates to an uncertainty $\delta' = (\alpha_s^2(M_Z^2)/\alpha_s^2(Q^2)) \cdot \delta$ on $\alpha_s(M_Z^2)$. For example, this enhances the already important impact of precise low-Q measurements, such as from τ decays, in combinations performed at the M_Z scale.

In this review, we update the measurements of α_s summarized in the 2012 edition, and we extract a new world average value of $\alpha_s(M_Z^2)$ from the most significant and complete results available today[♯].

We follow the same selection strategy and summary procedure as applied in the 2012 review, i.e. we restrict the selection of results from which to calculate the world average value of $\alpha_s(M_Z^2)$ to those which are

- published in a peer-reviewed journal
- based on the most complete perturbative QCD predictions, i.e. to those using NNLO or higher-order expansions.

While this excludes e.g. results from jet production in DIS at HERA and at hadron colliders, as well as those from heavy quarkonia decays for which calculations are available at NLO only, they will nevertheless be listed and cited in this review as they are important ingredients for the experimental evidence of the energy dependence of α_s, i.e. for Asymptotic Freedom, one of the key features of QCD.

In detail, we apply an intermediate step of pre-averaging results within certain sub-fields like e^+e^- annihilation, DIS and hadronic τ-decays, and calculate the overall world average from those pre-averages rather than from individual measurements. This is done because in a number of sub-fields one observes that different determinations of the strong coupling from substantially similar datasets lead to values of α_s that are only marginally compatible with each other, or with the final world average value, which presumably is a reflection of the challenges of evaluating systematic uncertainties. In such cases, a pre-average value will be determined, with a symmetric, overall uncertainty that encompasses the central values of all individual determinations ('*range averaging*').

Alternatively, in cases when results within a sub-field are largely independent of each other, we use the method of 'χ^2 *averaging*', as proposed, *e.g.*, in Ref. 308, in order to treat cases of possible (unknown) correlations as well as possibly underestimated systematic uncertainties in a meaningful and well defined manner: the central value is determined as the weighted average of the different input values. An initial uncertainty of the central value is determined treating the uncertainties of all individual measurements as being uncorrelated and being of Gaussian nature, and the overall χ^2 to the central value is determined. If this initial χ^2 is larger than the number of degrees of freedom, then all individual uncertainties are enlarged by a common factor such that χ^2/d.o.f. equals unity. If the initial value of χ^2 is smaller than the number of degrees of freedom, an overall, a-priori unknown correlation coefficient is introduced and determined by requiring that the total χ^2/d.o.f. of the combination equals unity. In both cases, the resulting overall uncertainty of α_s in this sub-field is larger than the initial estimate of the uncertainty.

9.3.5. ***Hadronic τ decays*** :

Several re-analyses of the hadronic τ decay width [24,309–314], based on N^{3}LO predictions [24], have been performed. They are based on different approaches to treat perturbative (fixed-order or contour-improved perturbative expansions) and non-perturbative contributions, the impact of which is a matter of intense discussions, see e.g. [315] and [316]. We also include the result from τ decay and lifetime measurements, obtained in Sec. *Electroweak Model and constraints on New Physics* of this *Review*, which amounts, if converted to the τ-mass scale, to $\alpha_s(M_\tau) = 0.327^{+0.019}_{-0.016}$. This result and the one from Baikov et al. [24] include both fixed-order and contour-improved perturbation theory, while the others adhere to either one or the other of the two. All these results are quoted for $n_f = 3$ quark flavors; they are summarized in Fig. 9.2(a).

We determine the pre-average result from τ-decays, to be used for calculating the final world average of $\alpha_s(M_Z^2)$, using the *range averaging* method defined above, as $\alpha_s(M_\tau^2) = 0.330 \pm 0.014$, unchanged from its value in the 2012 review[**]. This value of $\alpha_s(M_\tau^2)$ corresponds, when evolved to the scale of the Z-boson, using the QCD 4-loop beta-function plus 3-loop matching at the charm- and the bottom-quark masses (see Sec. *Quark Masses* in this *Review*), to $\alpha_s(M_Z^2) = 0.1197 \pm 0.0016$.

9.3.6. ***Lattice QCD*** :

There are several recent results on α_s from lattice QCD, see also Sec. *Lattice QCD* in this *Review*. The HPQCD collaboration [317] computes Wilson loops and similar short-distance quantities with lattice QCD and analyzes them with NNLO perturbative QCD. This yields a value for α_s, but the lattice scale must be related to a physical energy/momentum scale. This is achieved with the Υ'-Υ mass difference, however, many other quantities could be used as well [318]. HPQCD obtains $\alpha_s(M_Z^2) = 0.1184 \pm 0.0006$, where the uncertainty includes effects from truncating perturbation theory, finite lattice spacing and extrapolation of lattice data. An independent perturbative analysis of a subset of the same lattice-QCD data yields $\alpha_s(M_Z^2) = 0.1192 \pm 0.0011$ [319]. Using another, independent methodology, the current-current correlator method, HPQCD obtains $\alpha_s(M_Z^2) = 0.1183 \pm 0.0007$ [317]. The analysis of Ref. 320, which avoids the staggered fermion treatment of Ref. 317, finds $\alpha_s(M_Z^2) = 0.1205 \pm 0.0008 \pm 0.0005\,^{+0.0000}_{-0.0017}$, where the first uncertainty is statistical and the others are from systematics. Since this approach uses a different discretization of lattice fermions and a different general methodology, it provides an independent cross check of other lattice extractions of α_s. The JLQCD collaboration, in an analysis of Adler functions, obtains $\alpha_s(M_Z^2) = 0.1181 \pm 0.0003\,^{+0.0014}_{-0.0012}$ [321]. A study of the ETM collaboration [322] used lattice data with u, d, s and c quarks in the sea, obtaining results which are compatible with those quoted above. Finally, a determination of α_s from the QCD static energy [323] results in $\alpha_s(M_Z) = 0.1156^{+0.0021}_{-0.0022}$.

The published lattice results are summarized in Fig. 9.2(b). In contrast to the results from τ-decays, which were all based on the same (sub-)sets of data, the lattice evaluations are, at least in part, independent from each other, and so we use the χ^2 *averaging* method

[♯] The time evolution of α_s combinations can be followed by consulting Refs. [305–307] as well as earlier editions of this *Review*.

[**] The result from Boito *et al.* [314] is not regarded to extend the range due to its rather large - mainly statistical - uncertainty.

to determine $\alpha_s(M_Z^2) = 0.1185 \pm 0.0005$ which we take as result from the sub-field of lattice determinations†.

9.3.7. ***Deep inelastic lepton-nucleon scattering (DIS)*** :
Studies of DIS final states have led to a number of precise determinations of α_s: a combination [324] of precision measurements at HERA, based on NLO fits to inclusive jet cross sections in neutral current DIS at high Q^2, quotes a combined result of $\alpha_s(M_Z^2) = 0.1198 \pm 0.0032$, which includes a theoretical uncertainty of ± 0.0026. A combined analysis of non-singlet structure functions from DIS [325], based on QCD predictions up to N^{3}LO in some of its parts, gave $\alpha_s(M_Z^2) = 0.1142 \pm 0.0023$, including a theoretical uncertainty of ± 0.0008 (BBG). Further studies of singlet and non-singlet structure functions, based on NNLO predictions, resulted in $\alpha_s(M_Z^2) = 0.1134 \pm 0.0011$ [326] (ABM; only experimental uncertainties are included here) and in $\alpha_s(M_Z^2) = 0.1158 \pm 0.0035$ [327] (JR). The MSTW group [328], also including data on jet production at the Tevatron, obtains, at NNLO[♯♯], $\alpha_s(M_Z^2) = 0.1171 \pm 0.0024$. The NNPDF group [329] presented a result, $\alpha_s(M_Z^2) = 0.1173 \pm 0.0011$, which is in line with the one from the MSTW group.

Summarizing these results from world data on structure functions, applying the *range averaging* method as defined and motivated above, leads to a pre-average value of $\alpha_s(M_Z^2) = 0.1154 \pm 0.0020$ (see Fig. 9.2(c)).

We note that criticism has been expressed on some of the above extractions. Among the issues raised, we mention the neglect of singlet contributions at $x \geq 0.3$ in pure non-singlet fits [330], the impact and detailed treatment of particular classes of data in the fits [330,331], possible biases due to insufficiently flexible parametrizations of the PDFs [332] and the use of a fixed-flavor number scheme [333,334].

9.3.8. ***Heavy quarkonia decays*** :
The most recent extraction of the strong coupling constant from an analysis of radiative Υ decays [335] resulted in $\alpha_s(M_Z) = 0.119^{+0.006}_{-0.005}$. This determination is based on QCD at NLO only, so it will not be considered for the final extraction of the world average value of α_s; it is, however, an important ingredient for the demonstration of Asymptotic Freedom as given in Fig. 9.4.

9.3.9. ***Hadronic final states of e^+e^- annihilations*** :
Re-analyses of event shapes in e^+e^- annihilation, measured at the Z peak and LEP2 energies up to 209 GeV, using NNLO predictions matched to NLL resummation and Monte Carlo models to correct for hadronisation effects, resulted in $\alpha_s(M_Z^2) = 0.1224 \pm 0.0039$ (ALEPH) [336], with a dominant theoretical uncertainty of 0.0035, and in $\alpha_s(M_Z^2) = 0.1189 \pm 0.0043$ (OPAL) [337]. Similarly, an analysis of JADE data [338] at center-of-mass energies between 14 and 46 GeV gives $\alpha_s(M_Z^2) = 0.1172 \pm 0.0051$, with contributions from hadronization model and from perturbative QCD uncertainties of 0.0035 and 0.0030, respectively (JADE). A precise determination of α_s from 3-jet production alone, in NNLO, resulted in $\alpha_s(M_Z^2) = 0.1175 \pm 0.0025$ [339] from ALEPH data and in $\alpha_s(M_Z^2) = 0.1199 \pm 0.0059$ [340] from JADE. These results are summarized in the upper half of Fig. 9.2(d).

Computation of the NLO corrections to 5-jet production and comparison to the measured 5-jet rates at LEP [341] gave $\alpha_s(M_Z^2) = 0.1156^{+0.0041}_{-0.0034}$. A new computation of non-perturbative and perturbative QCD contributions to the scale evolution of quark and gluon jet multiplicities, including resummation and - in part - contributions beyond NLO, is reported [342] to result in $\alpha_s(M_Z^2) = 0.1199 \pm 0.0026$.

Another class of α_s determinations is based on analytic calculations of non-perturbative and hadronisation effects, rather than on Monte Carlo models [146,343–345], using methods like power corrections, factorisation of soft-collinear effective field theory, dispersive models and low scale QCD effective couplings. In these studies, the world data on Thrust distributions are analysed and fitted to perturbative QCD predictions in NNLO matched with resummation of leading logs up to N^{3}LL accuracy. The results range from $\alpha_s(M_Z^2) = 0.1131^{+0.0028}_{-0.0022}$ [345] to 0.1172 ± 0.0021 [146]; they are displayed in the lower half of Fig. 9.2(d).

We note that there is criticism on both classes of α_s extractions just described: those based on corrections of non-perturbative hadronisation effects using QCD-inspired Monte Carlo generators (since the parton level of a Monte Carlo is not defined in a manner equivalent to that of a fixed-order calculation), as well as the studies based on non-perturbative analytic calculations, as their systematics have not yet been verified e.g. by using observables other than Thrust.

Combining the results from e^+e^- annihilation data, using the *range averaging* method as many analyses are either based on similar datasets and/or are only marginally compatible with each other, results in $\alpha_s(M_Z^2) = 0.1177 \pm 0.0046$.

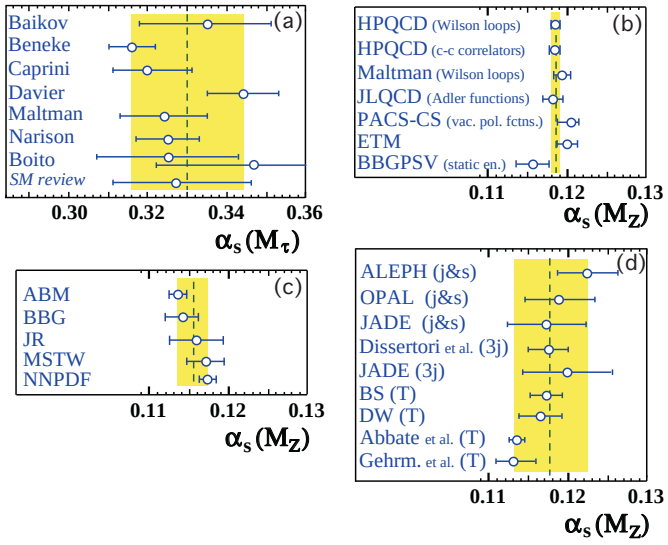

Figure 9.2: Summary of determinations of α_s from hadronic τ-decays (a), from lattice calculations (b), from DIS structure functions (c) and from e^+e^- annihilation (d). The shaded bands indicate the pre-average values explained in the text, to be included in the determination of the final world average of α_s.

9.3.10. ***Hadron collider jets*** :
Significant determinations of α_s from data at hadron colliders, i.e. the Tevatron and the LHC, are obtained, however mostly still limited to QCD at NLO. At $\sqrt{s} = 1.96$ TeV, $\alpha_s(M_Z^2) = 0.1161^{+0.0041}_{-0.0048}$ and $\alpha_s(M_Z^2) = 0.1191^{+0.0048}_{-0.0071}$ result from studies of inclusive jet cross sections [346] and from jet angular correlations [347], respectively. More recently, ATLAS data on inclusive jet production at $\sqrt{s} = 7$ TeV [239] became available, extending the verification of the running of α_s up to jet p_t of 600 GeV, and leading to $\alpha_s(M_Z^2) = 0.1151^{+0.0093}_{-0.0087}$ [348]. Here, experimental systematics, the choice of jet scale and the use of different PDFs dominate the large overall uncertainties. Preliminary determinations of α_s from CMS data on the ratio of inclusive 3-jet to 2-jet cross sections [259], at NLO, and from the top-quark cross section [301], in NNLO, quote values of $\alpha_s(M_Z^2) = 0.1148 \pm 0.0014(\text{exp.}) \pm 0.0018(\text{PDF})^{+0.0050}_{-0.0000}(\text{scale})$ and $\alpha_s(M_Z^2) = 0.1151^{+0.0033}_{-0.0032}$, respectively, indicating many new results to be expected for inclusion in upcoming reviews.

† The initial χ^2/d.o.f. was 4.7/6, requiring an overall correlation factor of 0.21 to bring χ^2/d.o.f. to unity, thereby increasing the initial overall uncertainty from 0.0004 to 0.0005.

♯♯ Note that for jet production at a hadron collider, only NLO predictions are available, while for the structure functions full NNLO was utilized.

9.3.11. ***Electroweak precision fits*** :
The N^{3}LO calculation of the hadronic Z decay width was used in a revision of the global fit to electroweak precision data [349], resulting in $\alpha_s(M_Z^2) = 0.1193 \pm 0.0028$, claiming a negligible theoretical uncertainty. For this *Review* the value obtained in Sec. *Electroweak model and constraints on new physics* from data at the Z-pole, $\alpha_s(M_Z^2) = 0.1197 \pm 0.0028$ will be used instead, as it is based on a more constrained data set where QCD corrections directly enter through the hadronic decay width of the Z. We note that all these results from electroweak precision data, however, strongly depend on the strict validity of Standard Model predictions and the existence of the minimal Higgs mechanism to implement electroweak symmetry breaking. Any - even small - deviation of nature from this model could strongly influence this extraction of α_s.

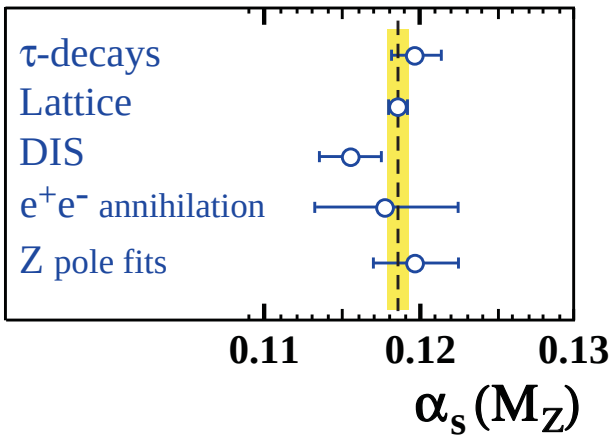

Figure 9.3: Summary of values of $\alpha_s(M_Z^2)$ obtained for various sub-classes of measurements (see Fig. 9.2 (a) to (d)). The new world average value of $\alpha_s(M_Z^2) = 0.1185 \pm 0.0006$ is indicated by the dashed line and the shaded band.

9.3.12. ***Determination of the world average value of $\alpha_s(M_Z^2)$*** :
Obtaining a world average value for $\alpha_s(M_Z^2)$ is a non-trivial exercise. A certain arbitrariness and subjective component is inevitable because of the choice of measurements to be included in the average, the treatment of (non-Gaussian) systematic uncertainties of mostly theoretical nature, as well as the treatment of correlations among the various inputs, of theoretical as well as experimental origin.

We have chosen to determine pre-averages for classes of measurements which are considered to exhibit a maximum of independence between each other, considering experimental as well as theoretical issues. These pre-averages are then combined to the final world average value of $\alpha_s(M_Z^2)$, using the χ^2 *averaging method* and error treatment as described above. The five pre-averages are summarized in Fig. 9.3; we recall that these are exclusively obtained from extractions which are based on (at least) full NNLO QCD predictions, and are published in peer-reviewed journals at the time of completing this *Review*.[◇◇] From these, we determine the new world average value of

$$\alpha_s(M_Z^2) = 0.1185 \pm 0.0006 \ , \tag{9.23}$$

with an uncertainty of well below 1 %.[***] This world average value is in excellent agreement with that from the 2009 [306] and the 2012 version of this review, although several new contributions have entered this determination. For convenience, we also provide corresponding values for $\Lambda_{\overline{MS}}$:

$$\Lambda_{\overline{MS}}^{(6)} = (90.6 \pm 3.4) \ \text{MeV} \ , \tag{9.24a}$$

$$\Lambda_{\overline{MS}}^{(5)} = (214 \pm 7) \ \text{MeV} \ , \tag{9.24b}$$

$$\Lambda_{\overline{MS}}^{(4)} = (297 \pm 8) \ \text{MeV} \ , \tag{9.24c}$$

$$\Lambda_{\overline{MS}}^{(3)} = (340 \pm 8) \ \text{MeV} \ , \tag{9.24d}$$

for $n_f = 6$, 5, 4 and 3 quark flavors, which are calculated using the 4-loop expression for the running of α_s according to Eq. (9.5) and 3-loop matching at the charm-, bottom- and top-quark pole masses of 1.5, 4.7 and 173 GeV/c^2, respectively.

In order to further test and verify the sensitivity of the new average value of $\alpha_s(M_Z^2)$ to the different pre-averages and classes of α_s determinations, we give each of the averages obtained when leaving out one of the five input values, as well as the respective, initial value of χ^2 :

$$\alpha_s(M_Z^2) = 0.1184 \pm 0.0006 \ \ (\text{w/o } \tau \text{ results; } \chi_0^2/\text{d.o.f.} = 2.3/3), \tag{9.25a}$$

$$\alpha_s(M_Z^2) = 0.1183 \pm 0.0012 \ \ (\text{w/o lattice results; } \chi_0^2/\text{d.o.f.} = 2.9/3), \tag{9.25b}$$

$$\alpha_s(M_Z^2) = 0.1187 \pm 0.0007 \ \ (\text{w/o DIS results; } \chi_0^2/\text{d.o.f.} = 0.6/3), \tag{9.25c}$$

$$\alpha_s(M_Z^2) = 0.1185 \pm 0.0005 \ \ (\text{w/o } e^+e^- \text{ results; } \chi_0^2/\text{d.o.f.} = 2.9/3), \text{ and} \tag{9.25d}$$

$$\alpha_s(M_Z^2) = 0.1185 \pm 0.0005 \ \ (\text{w/o e.w. precision fit; } \chi_0^2/\text{d.o.f.} = 2.7/3). \tag{9.25e}$$

They are well within the uncertainty of the overall world average quoted above. The lattice result, which has the smallest assigned uncertainty, agrees well - within 0.2 standard deviations - with the exclusive average of the other results. However, it largely determines the size of the overall uncertainty, which is a factor of 2 larger when disregarding lattice results at all.

Alternative procedures to calculate the world average using different methods of determining pre-average values and their uncertainties, were applied in order to estimate the impact on arbitrariness and subjective components mentioned above. For instance, when applying the *range averaging* throughout, for all pre-averages, then the world average emerges as $\alpha_s(M_Z^2) = 0.1182 \pm 0.0013$, probably constituting a rather conservative choice of error treatment. Using linear averages of α_s and its uncertainty for each of the pre-averages results in a world average of $\alpha_s(M_Z^2) = 0.1185 \pm 0.0011$, while applying the χ^2 averaging method throughout, for all pre-averages, gives $\alpha_s(M_Z^2) = 0.1179 \pm 0.0008$ as final result. The latter case, however, appears difficult to justify as it requires a rather large overall scaling factor for all input uncertainties, due to a very large, initial χ^2 value of 19.7 for 4 degrees of freedom, indicating a gross underestimate of the uncertainties of all pre-averages in this case.

There are apparent systematic differences between the various structure function results, and also between some of the results from Thrust and the other determinations in e^+e^- annihilation. Also, the size of uncertainties assigned for individual determinations largely differs within classes of results, such as from lattice calculations, but also from e^+e^- annihilations and from structure functions. We note that such and other differences have been extensively discussed at a specific workshop on measurements of α_s, however none of the explanations proposed so far have obtained enough of a consensus to definitely resolve the tensions between different extractions [351]. If the degree of consistency does not increase in the coming years, the method of averaging may have to be modified in the future, in order to de-emphasize the impact of results claiming overly optimistic (small) uncertainties.

◇◇ In addition to those mentioned above, one further result that was available only in unpublished form while this review was being prepared was Ref. 350, which quotes $\alpha_S(m_Z) = 0.1174^{+.0010}_{-.0005} \pm .001 \pm .0005_{\text{evol}}$, using an extraction from the pion decay constant. We leave its detailed consideration to future updates.

*** The weighted average, treating all inputs as uncorrelated measurements with Gaussian uncertainties, results in $\alpha_s(M_Z^2) = 0.11851 \pm 0.00048$ with $\chi^2/\text{d.o.f.} = 2.9/4$. Requiring $\chi^2/\text{d.o.f.}$ to reach unity calls for an overall correlation factor of 0.28, which increases the overall uncertainty to 0.00059.

The wealth of available results provides a rather precise and stable world average value of $\alpha_s(M_Z^2)$, as well as a clear signature and proof of the energy dependence of α_s, in full agreement with the QCD prediction of Asymptotic Freedom. This is demonstrated in Fig. 9.4, where results of $\alpha_s(Q^2)$ obtained at discrete energy scales Q, now also including those based just on NLO QCD, are summarized. Thanks to the results from the Tevatron [346,347] and from the LHC [259], the energy scales at which α_s is determined now extend to several hundred GeV up to 1 TeV$^\diamondsuit$.

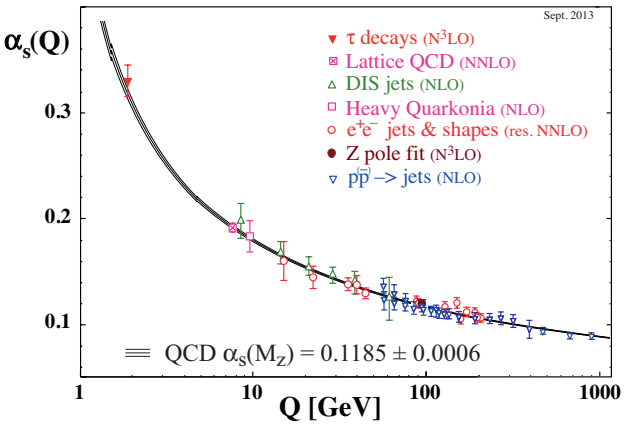

Figure 9.4: Summary of measurements of α_s as a function of the energy scale Q. The respective degree of QCD perturbation theory used in the extraction of α_s is indicated in brackets (NLO: next-to-leading order; NNLO: next-to-next-to leading order; res. NNLO: NNLO matched with resummed next-to-leading logs; N^{3}LO: next-to-NNLO).

$^\diamondsuit$ We note, however, that in many such studies, like those based on exclusive states of jet multiplicities, the relevant energy scale of the measurement is not uniquely defined. For instance, in studies of the ratio of 3- to 2-jet cross sections at the LHC, the relevant scale was taken to be the average of the transverse momenta of the two leading jets [259], but could alternatively have been chosen to be the transverse momentum of the 3^{rd} jet.

10. ELECTROWEAK MODEL AND CONSTRAINTS ON NEW PHYSICS

Revised November 2013 by J. Erler (U. Mexico) and A. Freitas (Pittsburgh U.).

10.1. Introduction

The standard model of the electroweak interactions (SM) [1] is based on the gauge group SU(2) × U(1), with gauge bosons W^i_μ, $i = 1, 2, 3$, and B_μ for the SU(2) and U(1) factors, respectively, and the corresponding gauge coupling constants g and g'. The left-handed fermion fields of the $i^{\rm th}$ fermion family transform as doublets $\Psi_i = \begin{pmatrix} \nu_i \\ \ell_i^- \end{pmatrix}$ and $\begin{pmatrix} u_i \\ d'_i \end{pmatrix}$ under SU(2), where $d'_i \equiv \sum_j V_{ij}\, d_j$, and V is the Cabibbo-Kobayashi-Maskawa mixing matrix. [Constraints on V and tests of universality are discussed in Ref. 2 and in the Section on "The CKM Quark-Mixing Matrix". The extension of the formalism to allow an analogous leptonic mixing matrix is discussed in the Section on "Neutrino Mass, Mixing, and Oscillations".] The right-handed fields are SU(2) singlets. In the minimal model there are three fermion families.

A complex scalar Higgs doublet, $\phi \equiv \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix}$, is added to the model for mass generation through spontaneous symmetry breaking with potential* given by,

$$V(\phi) = \mu^2 \phi^\dagger \phi + \frac{\lambda^2}{2} (\phi^\dagger \phi)^2. \tag{10.1}$$

For μ^2 negative, ϕ develops a vacuum expectation value, $v/\sqrt{2} = \mu/\lambda$, where $v \approx 246$ GeV, breaking part of the electroweak (EW) gauge symmetry, after which only one neutral Higgs scalar, H, remains in the physical particle spectrum. In non-minimal models there are additional charged and neutral scalar Higgs particles [3].

After the symmetry breaking the Lagrangian for the fermion fields, ψ_i, is

$$\begin{aligned} \mathscr{L}_F = & \sum_i \overline{\psi}_i \left(i\,\partial\!\!\!/ - m_i - \frac{m_i H}{v} \right) \psi_i \\ & - \frac{g}{2\sqrt{2}} \sum_i \overline{\Psi}_i\, \gamma^\mu\, (1-\gamma^5)(T^+\, W^+_\mu + T^-\, W^-_\mu)\, \Psi_i \\ & - e \sum_i Q_i\, \overline{\psi}_i\, \gamma^\mu\, \psi_i\, A_\mu \\ & - \frac{g}{2\cos\theta_W} \sum_i \overline{\psi}_i\, \gamma^\mu (g^i_V - g^i_A \gamma^5)\, \psi_i\, Z_\mu\ . \end{aligned} \tag{10.2}$$

Here $\theta_W \equiv \tan^{-1}(g'/g)$ is the weak angle; $e = g \sin\theta_W$ is the positron electric charge; and $A \equiv B\cos\theta_W + W^3 \sin\theta_W$ is the photon field (γ). $W^\pm \equiv (W^1 \mp i W^2)/\sqrt{2}$ and $Z \equiv -B \sin\theta_W + W^3 \cos\theta_W$ are the charged and neutral weak boson fields, respectively. The Yukawa coupling of H to ψ_i in the first term in $\mathscr{L}_F$, which is flavor diagonal in the minimal model, is $g m_i/2M_W$. The boson masses in the EW sector are given (at tree level, *i.e.*, to lowest order in perturbation theory) by,

$$M_H = \lambda\, v, \tag{10.3a}$$

$$M_W = \frac{1}{2}\, g\, v = \frac{e\, v}{2 \sin\theta_W}, \tag{10.3b}$$

$$M_Z = \frac{1}{2} \sqrt{g^2 + g'^2}\, v = \frac{e\, v}{2 \sin\theta_W \cos\theta_W} = \frac{M_W}{\cos\theta_W}, \tag{10.3c}$$

$$M_\gamma = 0. \tag{10.3d}$$

* There is no generally accepted convention to write the quartic term. Our numerical coefficient simplifies Eq. (10.3*a*) below and the squared coupling preserves the relation between the number of external legs and the power counting of couplings at a given loop order. This structure also naturally emerges from physics beyond the SM, such as supersymmetry.

The second term in $\mathscr{L}_F$ represents the charged-current weak interaction [4–7], where T^+ and T^- are the weak isospin raising and lowering operators. For example, the coupling of a W to an electron and a neutrino is

$$-\frac{e}{2\sqrt{2}\sin\theta_W} \left[W^-_\mu\, \overline{e}\, \gamma^\mu (1-\gamma^5) \nu + W^+_\mu\, \overline{\nu}\, \gamma^\mu\, (1-\gamma^5) e \right]. \tag{10.4}$$

For momenta small compared to M_W, this term gives rise to the effective four-fermion interaction with the Fermi constant given by $G_F/\sqrt{2} = 1/2v^2 = g^2/8M_W^2$. CP violation is incorporated into the EW model by a single observable phase in V_{ij}.

The third term in $\mathscr{L}_F$ describes electromagnetic interactions (QED) [8–10], and the last is the weak neutral-current interaction [5–7]. The vector and axial-vector couplings are

$$g^i_V \equiv t_{3L}(i) - 2 Q_i \sin^2\theta_W, \tag{10.5a}$$

$$g^i_A \equiv t_{3L}(i), \tag{10.5b}$$

where $t_{3L}(i)$ is the weak isospin of fermion i ($+1/2$ for u_i and ν_i; $-1/2$ for d_i and e_i) and Q_i is the charge of ψ_i in units of e.

The first term in Eq. (10.2) also gives rise to fermion masses, and in the presence of right-handed neutrinos to Dirac neutrino masses. The possibility of Majorana masses is discussed in the Section on "Neutrino Mass, Mixing, and Oscillations".

10.2. Renormalization and radiative corrections

In addition to the Higgs boson mass, M_H, the fermion masses and mixings, and the strong coupling constant, α_s, the SM has three parameters. The set with the smallest experimental errors contains the Z mass**, the Fermi constant, and the fine structure constant, which will be discussed in turn (if not stated otherwise, the numerical values quoted in Sec. 10.2–10.5 correspond to the main fit result in Table 10.6):

The Z boson mass, $M_Z = 91.1876 \pm 0.0021$ GeV, has been determined from the Z lineshape scan at LEP 1 [11].

The Fermi constant, $G_F = 1.1663787(6) \times 10^{-5}$ GeV^{-2}, is derived from the muon lifetime formula***,

$$\frac{\hbar}{\tau_\mu} = \frac{G_F^2 m_\mu^5}{192\pi^3}\, F(\rho) \left[1 + H_1(\rho) \frac{\widehat{\alpha}(m_\mu)}{\pi} + H_2(\rho) \frac{\widehat{\alpha}^2(m_\mu)}{\pi^2} \right], \tag{10.6}$$

where $\rho = m_e^2/m_\mu^2$, and where

$$F(\rho) = 1 - 8\rho + 8\rho^3 - \rho^4 - 12\rho^2 \ln\rho = 0.99981295, \tag{10.7a}$$

$$\begin{aligned} H_1(\rho) = & \frac{25}{8} - \frac{\pi^2}{2} - \left(9 + 4\pi^2 + 12 \ln\rho \right) \rho \\ & + 16\pi^2 \rho^{3/2} + \mathcal{O}(\rho^2) = -1.80793, \end{aligned} \tag{10.7b}$$

$$\begin{aligned} H_2(\rho) = & \frac{156815}{5184} - \frac{518}{81}\pi^2 - \frac{895}{36}\zeta(3) + \frac{67}{720}\pi^4 + \frac{53}{6}\pi^2 \ln 2 \\ & - (0.042 \pm 0.002)_{\rm had} - \frac{5}{4}\pi^2 \sqrt{\rho} + \mathcal{O}(\rho) = 6.64, \end{aligned} \tag{10.7c}$$

$$\widehat{\alpha}(m_\mu)^{-1} = \alpha^{-1} + \frac{1}{3\pi} \ln\rho + \mathcal{O}(\alpha) = 135.901 \tag{10.7d}$$

H_1 and H_2 capture the QED corrections within the Fermi model. The results for $\rho = 0$ have been obtained in Refs. 13 and 14, respectively, where the term in parentheses is from the hadronic

** We emphasize that in the fits described in Sec. 10.6 and Sec. 10.7 the values of the SM parameters are affected by all observables that depend on them. This is of no practical consequence for α and G_F, however, since they are very precisely known.

*** In the spirit of the Fermi theory, we incorporated the small propagator correction, $3/5\ m_\mu^2/M_W^2$, into Δr (see below). This is also the convention adopted by the MuLan collaboration [12]. While this breaks with historical consistency, the numerical difference was negligible in the past.

vacuum polarization [14]. The mass corrections to H_1 have been known for some time [15], while those to H_2 are more recent [16]. Notice the term linear in m_e whose appearance was unforeseen and can be traced to the use of the muon pole mass in the prefactor [16]. The remaining uncertainty in G_F is experimental and has recently been reduced by an order of magnitude by the MuLan collaboration [12] at the PSI.

The experimental determination of the fine structure constant, $\alpha = 1/137.035999074(44)$, is currently dominated by the $e^\pm$ anomalous magnetic moment [10]. In most EW renormalization schemes, it is convenient to define a running α dependent on the energy scale of the process, with $\alpha^{-1} \sim 137$ appropriate at very low energy, *i.e.* close to the Thomson limit. (The running has also been observed [17] directly.) For scales above a few hundred MeV this introduces an uncertainty due to the low energy hadronic contribution to vacuum polarization. In the modified minimal subtraction ($\overline{\rm MS}$) scheme [18] (used for this *Review*), and with $\alpha_s(M_Z) = 0.1193 \pm 0.0016$ we have $\widehat{\alpha}(m_\tau)^{-1} = 133.465 \pm 0.013$ and $\widehat{\alpha}(M_Z)^{-1} = 127.940 \pm 0.014$. (In this Section we denote quantities defined in the modified minimal subtraction ($\overline{\rm MS}$) scheme by a caret; the exception is the strong coupling constant, α_s, which will always correspond to the $\overline{\rm MS}$ definition and where the caret will be dropped.) The latter corresponds to a quark sector contribution (without the top) to the conventional (on-shell) QED coupling, $\alpha(M_Z) = \dfrac{\alpha}{1 - \Delta\alpha(M_Z)}$, of $\Delta\alpha^{(5)}_{\rm had}(M_Z) = 0.02771 \pm 0.00011$. These values are updated from Ref. 19 with $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ moved downwards and its uncertainty halved (partly due to a more precise charm quark mass). Its correlation with the $\mu^\pm$ anomalous magnetic moment (see Sec. 10.5), as well as the non-linear α_s dependence of $\widehat{\alpha}(M_Z)$ and the resulting correlation with the input variable α_s, are fully taken into account in the fits. This is done by using as actual input (fit constraint) instead of $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ the analogous low energy contribution by the three light quarks, $\Delta\alpha^{(3)}_{\rm had}(1.8\ {\rm GeV}) = (55.50 \pm 0.78) \times 10^{-4}$ [20], and by calculating the perturbative and heavy quark contributions to $\widehat{\alpha}(M_Z)$ in each call of the fits according to Ref. 19. Part of the uncertainty ($\pm 0.49 \times 10^{-4}$) is from e^+e^- annihilation data below 1.8 GeV and τ decay data (including uncertainties from isospin breaking effects), but uncalculated higher order perturbative ($\pm 0.41 \times 10^{-4}$) and non-perturbative ($\pm 0.44 \times 10^{-4}$) QCD corrections and the $\overline{\rm MS}$ quark mass values (see below) also contribute. Various evaluations of $\Delta\alpha^{(5)}_{\rm had}$ are summarized in Table 10.1 where the relation† between the $\overline{\rm MS}$ and on-shell definitions is given by [22]

$$\Delta\widehat{\alpha}(M_Z) - \Delta\alpha(M_Z) = \frac{\alpha}{\pi}\Big[\Big(\frac{100}{27} - \frac{1}{6} - \frac{7}{4}\ln\frac{M_Z^2}{M_W^2}\Big) + \frac{\alpha_s(M_Z)}{\pi}\Big(\frac{605}{108} - \frac{44}{9}\zeta(3)\Big) + \frac{\alpha_s^2(M_Z)}{\pi^2}\left(\frac{976481}{23328} - \frac{781}{18}\zeta(3) + \frac{275}{27}\zeta(5)\right)\Big] = 0.007165, \quad (10.8)$$

and where the first entry of the lowest order term is from fermions and the other two are from $W^\pm$ loops, which are usually excluded from the on-shell definition. The most recent results typically assume the validity of perturbative QCD (PQCD) at scales of 1.8 GeV and above, and are in reasonable agreement with each other. There is, however, some discrepancy between analyses based on $e^+e^- \to$ hadrons cross-section data and those based on τ decay spectral functions [20]. The latter utilize data from OPAL [34], CLEO [35], ALEPH [36], and Belle [37] and imply lower central values for the extracted M_H from a global fit to the indirect precision data of about 6%. This discrepancy is smaller than in the past and at least some of it appears to be experimental. The dominant $e^+e^- \to \pi^+\pi^-$ cross-section was measured with the CMD-2 [38] and SND [39] detectors at the VEPP-2M e^+e^- collider at Novosibirsk and the results are (after an initial discrepancy due to a flaw in the Monte Carlo event generator used by SND) in good agreement with each other. As an alternative to cross-section scans, one can use the high statistics radiative return events at e^+e^- accelerators operating at resonances such as the Φ or the $\Upsilon(4S)$. The method [40] is systematics limited but dominates over the Novosibirsk data throughout. The BaBar collaboration [41] studied multi-hadron events radiatively returned from the $\Upsilon(4S)$, reconstructing the radiated photon and normalizing to $\mu^\pm\gamma$ final states. Their result is higher compared to VEPP-2M and in fact agrees quite well with the τ analysis including the energy dependence (shape). In contrast, the shape and smaller overall cross-section from the $\pi^+\pi^-$ radiative return results from the Φ obtained by the KLOE collaboration [42] differs significantly from what is observed by BaBar. The discrepancy originates from the kinematic region $\sqrt{s} \gtrsim 0.6$ GeV, and is most pronounced for $\sqrt{s} \gtrsim 0.85$ GeV. All measurements including older data [43] and multi-hadron final states (there are also discrepancies in the $e^+e^- \to 2\pi^+2\pi^-$ channel [20]) are accounted for and corrections have been applied for missing channels [20]. Further improvement of this dominant theoretical uncertainty in the interpretation of precision data will require better measurements of the cross-section for $e^+e^- \to$ hadrons below the charmonium resonances including multi-pion and other final states. To improve the precisions in $\widehat{m}_c(\widehat{m}_c)$ and $\widehat{m}_b(\widehat{m}_b)$ it would help to remeasure the threshold regions of the heavy quarks as well as the electronic decay widths of the narrow $c\bar{c}$ and $b\bar{b}$ resonances.

Table 10.1: Evaluations of the on-shell $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ by different groups (for a more complete list of evaluations see the 2012 edition of this *Review*). For better comparison we adjusted central values and errors to correspond to a common and fixed value of $\alpha_s(M_Z) = 0.120$. References quoting results without the top quark decoupled are converted to the five flavor definition. Ref. [28] uses $\Lambda_{\rm QCD} = 380 \pm 60$ MeV; for the conversion we assumed $\alpha_s(M_Z) = 0.118 \pm 0.003$.

Further free parameters entering into Eq. (10.2) are the quark and lepton masses, where m_i is the mass of the $i^{\rm th}$ fermion ψ_i. For the light quarks, as described in the note on "Quark Masses" in the Quark Listings, $\widehat{m}_u = 2.3^{+0.7}_{-0.5}$ MeV, $\widehat{m}_d = 4.8^{+0.5}_{-0.3}$ MeV, and $\widehat{m}_s = 95 \pm 5$ MeV. These are running $\overline{\rm MS}$ masses evaluated at the scale $\mu = 2$ GeV. For the heavier quarks we use QCD sum rule [44] constraints [45] and recalculate their masses in each call of our fits to account for their direct α_s dependence. We find¶,

† In practice, $\alpha(M_Z)$ is directly evaluated in the $\overline{\rm MS}$ scheme using the FORTRAN package GAPP [21], including the QED contributions of both leptons and quarks. The leptonic three-loop contribution in the on-shell scheme has been obtained in Ref. 23.

¶ Other authors [46] advocate to evaluate and quote $\widehat{m}_c(\mu = 3\ {\rm GeV})$ instead. We use $\widehat{m}_c(\mu = \widehat{m}_c)$ because in the global analysis it is conve-

$\widehat{m}_c(\mu=\widehat{m}_c) = 1.274^{+0.030}_{-0.035}$ GeV and $\widehat{m}_b(\mu=\widehat{m}_b) = 4.199 \pm 0.024$ GeV, with a correlation of 33%.

The top quark "pole" mass (the quotation marks are a reminder that quarks do not form asymptotic states), $m_t = 173.24 \pm 0.81$ GeV, is an average based on the combination, $m_t = 173.20 \pm 0.51_{\,\rm stat.} \pm 0.71_{\,\rm syst.}$ GeV, of published and preliminary CDF and DØ results from the Tevatron [48], with the combination, $m_t = 173.29 \pm 0.23_{\,\rm stat.} \pm 0.92_{\,\rm syst.}$ GeV, obtained by the LHC Top Working Group [49]. Our average[$] differs slightly from the value, $m_t = 173.07 \pm 0.52_{\,\rm stat.} \pm 0.72_{\,\rm syst.}$ GeV, which appears in the top quark Listings in this *Review* and which is based exclusively on published Tevatron results. We are working, however, with $\overline{\rm MS}$ masses in all expressions to minimize theoretical uncertainties. Such a short distance mass definition (unlike the pole mass) is free from non-perturbative and renormalon [50] uncertainties. We therefore convert to the top quark $\overline{\rm MS}$ mass,

$$\widehat{m}_t(\mu=\widehat{m}_t) = m_t[1 - \frac{4}{3}\frac{\alpha_s}{\pi} + \mathcal{O}(\alpha_s^2)], \tag{10.9}$$

using the three-loop formula [51]. This introduces an additional uncertainty which we estimate to 0.5 GeV (the size of the three-loop term) and add in quadrature to the experimental pole mass error. This is convenient because we use the pole mass as an external constraint while fitting to the $\overline{\rm MS}$ mass. We are assuming that the kinematic mass extracted from the collider events corresponds within this uncertainty to the pole mass. In summary, we will use the fit constraint, $m_t = 173.24 \pm 0.81_{\,\rm exp.} \pm 0.5_{\,\rm QCD}$ GeV $= 173.24 \pm 0.95$ GeV.

$\sin^2\theta_W$ and M_W can be calculated from M_Z, $\widehat{\alpha}(M_Z)$, and G_F, when values for m_t and M_H are given, or conversely, M_H can be constrained by $\sin^2\theta_W$ and M_W. The value of $\sin^2\theta_W$ is extracted from neutral-current processes (see Sec. 10.3) and Z pole observables (see Sec. 10.4) and depends on the renormalization prescription. There are a number of popular schemes [52–58] leading to values which differ by small factors depending on m_t and M_H. The notation for these schemes is shown in Table 10.2.

Table 10.2: Notations used to indicate the various schemes discussed in the text. Each definition of $\sin^2\theta_W$ leads to values that differ by small factors depending on m_t and M_H. Numerical values are also given for illustration.

Scheme	Notation	Value
On-shell	s^2_W	0.22333
$\overline{\rm MS}$	$\widehat{s}^2_Z$	0.23126
$\overline{\rm MS}$ ND	$\widehat{s}^2_{\rm ND}$	0.23144
$\overline{\rm MS}$	$\widehat{s}^2_0$	0.23864
Effective angle	$\overline{s}^2_\ell$	0.23155

(*i*) The on-shell scheme [52] promotes the tree-level formula $\sin^2\theta_W = 1 - M^2_W/M^2_Z$ to a definition of the renormalized $\sin^2\theta_W$ to all orders in perturbation theory, *i.e.*, $\sin^2\theta_W \to s^2_W \equiv 1 - M^2_W/M^2_Z$:

$$M_W = \frac{A_0}{s_W(1-\Delta r)^{1/2}}\,, \qquad M_Z = \frac{M_W}{c_W}\,, \tag{10.10}$$

where $c_W \equiv \cos\theta_W$, $A_0 = (\pi\alpha/\sqrt{2}G_F)^{1/2} = 37.28039(1)$ GeV, and Δr includes the radiative corrections relating α, $\alpha(M_Z)$, G_F, M_W, and M_Z. One finds $\Delta r \sim \Delta r_0 - \rho_t/\tan^2\theta_W$, where $\Delta r_0 = 1 - \alpha/\widehat{\alpha}(M_Z) = 0.06637(11)$ is due to the running of α, and $\rho_t = 3G_F m_t^2/8\sqrt{2}\pi^2 = 0.00940\,(m_t/173.24\ {\rm GeV})^2$ represents the dominant (quadratic) m_t dependence. There are additional contributions to Δr from bosonic loops, including those which depend logarithmically on M_H and higher-order corrections[$$]. One has $\Delta r = 0.03639 \mp 0.00036 \pm 0.00011$, where the first uncertainty is from m_t and the second is from $\alpha(M_Z)$. Thus the value of s^2_W extracted from M_Z includes an uncertainty (∓ 0.00012) from the currently allowed range of m_t. This scheme is simple conceptually. However, the relatively large ($\sim 3\%$) correction from ρ_t causes large spurious contributions in higher orders.

s^2_W depends not only on the gauge couplings but also on the spontaneous-symmetry breaking, and it is awkward in the presence of any extension of the SM which perturbs the value of M_Z (or M_W). Other definitions are motivated by the tree-level coupling constant definition $\theta_W = \tan^{-1}(g'/g)$:

(*ii*) In particular, the modified minimal subtraction ($\overline{\rm MS}$) scheme introduces the quantity $\sin^2\widehat{\theta}_W(\mu) \equiv \widehat{g}'^2(\mu)/\big[\widehat{g}^{\,2}(\mu) + \widehat{g}'^2(\mu)\big]$, where the couplings $\widehat{g}$ and $\widehat{g}'$ are defined by modified minimal subtraction and the scale μ is conveniently chosen to be M_Z for many EW processes. The value of $\widehat{s}^2_Z = \sin^2\widehat{\theta}_W(M_Z)$ extracted from M_Z is less sensitive than s^2_W to m_t (by a factor of $\tan^2\theta_W$), and is less sensitive to most types of new physics. It is also very useful for comparing with the predictions of grand unification. There are actually several variant definitions of $\sin^2\widehat{\theta}_W(M_Z)$, differing according to whether or how finite $\alpha\ln(m_t/M_Z)$ terms are decoupled (subtracted from the couplings). One cannot entirely decouple the $\alpha\ln(m_t/M_Z)$ terms from all EW quantities because $m_t \gg m_b$ breaks SU(2) symmetry. The scheme that will be adopted here decouples the $\alpha\ln(m_t/M_Z)$ terms from the γ–Z mixing [18,53], essentially eliminating any $\ln(m_t/M_Z)$ dependence in the formulae for asymmetries at the Z pole when written in terms of $\widehat{s}^2_Z$. (A similar definition is used for $\widehat{\alpha}$.) The on-shell and $\overline{\rm MS}$ definitions are related by

$$\widehat{s}^2_Z = c\,(m_t, M_H)s^2_W = (1.0355 \pm 0.0004)s^2_W\,. \tag{10.11}$$

The quadratic m_t dependence is given by $c \sim 1 + \rho_t/\tan^2\theta_W$. The expressions for M_W and M_Z in the $\overline{\rm MS}$ scheme are

$$M_W = \frac{A_0}{\widehat{s}_Z(1-\Delta\widehat{r}_W)^{1/2}}\,, \qquad M_Z = \frac{M_W}{\widehat{\rho}^{\,1/2}\,\widehat{c}_Z}\,, \tag{10.12}$$

and one predicts $\Delta\widehat{r}_W = 0.06943 \pm 0.00011$. $\Delta\widehat{r}_W$ has no quadratic m_t dependence, because shifts in M_W are absorbed into the observed G_F, so that the error in $\Delta\widehat{r}_W$ is almost entirely due to $\Delta r_0 = 1 - \alpha/\widehat{\alpha}(M_Z)$. The quadratic m_t dependence has been shifted into $\widehat{\rho} \sim 1 + \rho_t$, where including bosonic loops, $\widehat{\rho} = 1.01031 \pm 0.00011$.

(*iii*) A variant $\overline{\rm MS}$ quantity $\widehat{s}^2_{\rm ND}$ (used in the 1992 edition of this *Review*) does not decouple the $\alpha\ln(m_t/M_Z)$ terms [54]. It is related to $\widehat{s}^2_Z$ by

$$\widehat{s}^2_Z = \widehat{s}^2_{\rm ND}/\Big(1 + \frac{\widehat{\alpha}}{\pi}d\Big), \tag{10.13a}$$

$$d = \frac{1}{3}\left(\frac{1}{\widehat{s}^2} - \frac{8}{3}\right)\left[(1+\frac{\alpha_s}{\pi})\,\ln\frac{m_t}{M_Z} - \frac{15\alpha_s}{8\pi}\right], \tag{10.13b}$$

Thus, $\widehat{s}^2_Z - \widehat{s}^2_{\rm ND} \approx -0.0002$.

nient to nullify any explicitly m_c dependent logarithms. Note also that our uncertainty for m_c (and to a lesser degree for m_b) is larger than in Refs. 46 and 47, for example. The reason is that we determine the continuum contribution for charm pair production using only resonance data and theoretical consistency across various sum rule moments, and then use any difference to the experimental continuum data as an additional uncertainty. We also include an uncertainty for the condensate terms which grows rapidly for higher moments in the sum rule analysis.

[$] At the time of writing this review, the efforts to establish a top quark averaging group involving both the Tevatron and the LHC were still in progress. Therefore we perform a simplified average ourselves, conservatively assuming that the entire Tevatron systematics is common to both colliders (ignoring correlations yields the same central value).

[$$] All explicit numbers quoted here and below include the two- and three-loop corrections described near the end of Sec. 10.2.

(*iv*) Some of the low-energy experiments discussed in the next section are sensitive to the weak mixing angle at almost vanishing momentum transfer (for a review, see Ref. 55). Thus, Table 10.2 also includes $\widehat{s}_0^2 \equiv \sin^2\widehat{\theta}_W(0)$.

(*v*) Yet another definition, the effective angle [56–58] $\overline{s}_f^2 = \sin\theta^f_{\rm eff}$ for the Z vector coupling to fermion f, is based on Z pole observables and described in Sec. 10.4.

Experiments are at such level of precision that complete one-loop, dominant two-loop, and partial three-loop radiative corrections must be applied. For neutral-current and Z pole processes, these corrections are conveniently divided into two classes:

1. QED diagrams involving the emission of real photons or the exchange of virtual photons in loops, but not including vacuum polarization diagrams. These graphs often yield finite and gauge-invariant contributions to observable processes. However, they are dependent on energies, experimental cuts, *etc.*, and must be calculated individually for each experiment.
2. EW corrections, including $\gamma\gamma$, γZ, ZZ, and WW vacuum polarization diagrams, as well as vertex corrections, box graphs, *etc.*, involving virtual W and Z bosons. The one-loop corrections are included for all processes, and many two-loop corrections are also important. In particular, two-loop corrections involving the top quark modify ρ_t in $\widehat{\rho}$, Δr, and elsewhere by

$$\rho_t \to \rho_t[1 + R(M_H, m_t)\rho_t/3]. \tag{10.14}$$

$R(M_H, m_t)$ can be described as an expansion in M_Z^2/m_t^2, for which the leading m_t^4/M_Z^4 [59] and next-to-leading m_t^2/M_Z^2 [60] terms are known. The complete two-loop calculation of Δr (without further approximation) has been performed in Refs. 61 and 62 for fermionic and purely bosonic diagrams, respectively. Similarly, the EW two-loop calculation for the relation between $\overline{s}_\ell^2$ and s_W^2 is complete [63,64].

Mixed QCD-EW contributions to gauge boson self-energies of order $\alpha\alpha_s m_t^2$ [65], $\alpha\alpha_s^2 m_t^2$ [66], and $\alpha\alpha_s^3 m_t^2$ [67] increase the predicted value of m_t by 6%. This is, however, almost entirely an artifact of using the pole mass definition for m_t. The equivalent corrections when using the $\overline{\rm MS}$ definition $\widehat{m}_t(\widehat{m}_t)$ increase m_t by less than 0.5%. The subleading $\alpha\alpha_s$ corrections [68] are also included. Further three-loop corrections of order $\alpha\alpha_s^2$ [69,70], $\alpha^3 m_t^6$, and $\alpha^2\alpha_s m_t^4$ [71], are rather small. The same is true for $\alpha^3 M_H^4$ [72] corrections unless M_H approaches 1 TeV.

The theoretical uncertainty from unknown higher-order corrections is estimated to amount to 4 MeV for the prediction of M_W [73] and 4.5×10^{-5} for $\overline{s}_\ell^2$ [74].

Throughout this *Review* we utilize EW radiative corrections from the program GAPP [21], which works entirely in the $\overline{\rm MS}$ scheme, and which is independent of the package ZFITTER [58]. Another resource is the recently developed modular fitting toolkit Gfitter [75].

10.3. Low energy electroweak observables

In the following we discuss EW precision observables obtained at low momentum transfers [6], *i.e.* $Q^2 \ll M_Z^2$. It is convenient to write the four-fermion interactions relevant to ν-hadron, ν-e, as well as parity violating e-hadron and e-e neutral-current processes in a form that is valid in an arbitrary gauge theory (assuming massless left-handed neutrinos). One has★

$$-\mathscr{L}^{\nu e} = \frac{G_F}{\sqrt{2}}\,\overline{\nu}\gamma_\mu(1-\gamma^5)\nu\;\overline{e}\,\gamma^\mu(g_{LV}^{\nu e} - g_{LA}^{\nu e}\,\gamma^5)e, \tag{10.15}$$

$$-\mathscr{L}^{\nu h} = \frac{G_F}{\sqrt{2}}\,\overline{\nu}\,\gamma_\mu(1-\gamma^5)\nu\sum_q[g_{LL}^{\nu q}\,\overline{q}\,\gamma^\mu(1-\gamma^5)q + g_{LR}^{\nu q}\,\overline{q}\,\gamma^\mu(1+\gamma^5)q], \tag{10.16}$$

$$-\mathscr{L}^{ee} = -\frac{G_F}{\sqrt{2}}\,g_{AV}^{ee}\,\overline{e}\,\gamma_\mu\gamma^5 e\,\overline{e}\,\gamma^\mu e, \tag{10.17}$$

$$-\mathscr{L}^{eh} = -\frac{G_F}{\sqrt{2}}\sum_q\left[g_{AV}^{eq}\,\overline{e}\,\gamma_\mu\gamma^5 e\,\overline{q}\,\gamma^\mu q + g_{VA}^{eq}\,\overline{e}\,\gamma_\mu e\,\overline{q}\;\gamma^\mu\gamma^5 q\right], \tag{10.18}$$

where one must include the charged-current contribution for ν_e-e and $\overline{\nu}_e$-e and the parity-conserving QED contribution for electron scattering.

Table 10.3: SM tree level expressions for the neutral-current parameters for ν-hadron, ν-e, and e^--scattering processes. To obtain the SM values in the last column, the tree level expressions have to be multiplied by the low-energy neutral-current ρ parameter, $\rho_{\rm NC} = 1.00066$, and further vertex and box corrections need to be added as detailed in Ref. 76. The dominant m_t dependence is again given by $\rho_{\rm NC} \sim 1 + \rho_t$.

Quantity	SM tree level	SM value
$g_{LV}^{\nu_\mu e}$	$-\frac{1}{2} + 2\,\widehat{s}_0^2$	-0.0396
$g_{LA}^{\nu_\mu e}$	$-\frac{1}{2}$	-0.5064
$g_{LL}^{\nu_\mu u}$	$\frac{1}{2} - \frac{2}{3}\,\widehat{s}_0^2$	0.3457
$g_{LL}^{\nu_\mu d}$	$-\frac{1}{2} + \frac{1}{3}\,\widehat{s}_0^2$	-0.4288
$g_{LR}^{\nu_\mu u}$	$-\frac{2}{3}\,\widehat{s}_0^2$	-0.1553
$g_{LR}^{\nu_\mu d}$	$\frac{1}{3}\,\widehat{s}_0^2$	0.0777
g_{AV}^{ee}	$\frac{1}{2} - 2\,\widehat{s}_0^2$	0.0225
g_{AV}^{eu}	$-\frac{1}{2} + \frac{4}{3}\,\widehat{s}_0^2$	-0.1887
g_{AV}^{ed}	$\frac{1}{2} - \frac{2}{3}\,\widehat{s}_0^2$	0.3419
g_{VA}^{eu}	$-\frac{1}{2} + 2\,\widehat{s}_0^2$	-0.0351
g_{VA}^{ed}	$\frac{1}{2} - 2\,\widehat{s}_0^2$	0.0248

The SM tree level expressions for the four-Fermi couplings are given in Table 10.3. Note that they differ from the respective products of the gauge couplings in Eq. (10.5) in the radiative corrections and in the presence of possible physics beyond the SM.

10.3.1. ***Neutrino scattering*** : For a general review on ν-scattering we refer to Ref. 77 (nonstandard neutrino scattering interactions are surveyed in Ref. 78).

The cross-section in the laboratory system for $\nu_\mu e \to \nu_\mu e$ or $\overline{\nu}_\mu e \to \overline{\nu}_\mu e$ elastic scattering [79] is (in this subsection we drop the redundant index L in the effective neutrino couplings)

$$\frac{d\sigma_{\nu,\bar\nu}}{dy} = \frac{G_F^2 m_e E_\nu}{2\pi}\left[(g_V^{\nu e}\pm g_A^{\nu e})^2 + (g_V^{\nu e}\mp g_A^{\nu e})^2(1-y)^2 - (g_V^{\nu e 2} - g_A^{\nu e 2})\frac{y\,m_e}{E_\nu}\right], \tag{10.19}$$

where the upper (lower) sign refers to $\nu_\mu(\overline{\nu}_\mu)$, and $y \equiv T_e/E_\nu$ (which runs from 0 to $(1 + m_e/2E_\nu)^{-1}$) is the ratio of the kinetic energy of the recoil electron to the incident ν or $\overline{\nu}$ energy. For $E_\nu \gg m_e$ this yields a total cross-section

$$\sigma = \frac{G_F^2 m_e E_\nu}{2\pi}\left[(g_V^{\nu e} \pm g_A^{\nu e})^2 + \frac{1}{3}(g_V^{\nu e} \mp g_A^{\nu e})^2\right]. \tag{10.20}$$

The most accurate measurements [79–84] of $\sin^2\theta_W$ from ν-lepton scattering (see Sec. 10.6) are from the ratio $R \equiv \sigma_{\nu_\mu e}/\sigma_{\bar\nu_\mu e}$, in which many of the systematic uncertainties cancel. Radiative corrections

★ We use here slightly different definitions (and to avoid confusion also a different notation) for the coefficients of these four-Fermi operators than we did in previous editions of this *Review*. The new couplings [76] are defined in the static limit, $Q^2 \to 0$, with specific radiative corrections included, while others (more experiment specific ones) are assumed to be removed by the experimentalist. They are convenient in that their determinations from very different types of processes can be straightforwardly combined.

(other than m_t effects) are small compared to the precision of present experiments and have negligible effect on the extracted $\sin^2\theta_W$. The most precise experiment (CHARM II) [82] determined not only $\sin^2\theta_W$ but $g_{V,A}^{\nu e}$ as well, which are shown in Fig. 10.1. The cross-sections for ν_e-e and $\overline{\nu}_e$-e may be obtained from Eq. (10.19) by replacing $g_{V,A}^{\nu e}$ by $g_{V,A}^{\nu e}+1$, where the 1 is due to the charged-current contribution.

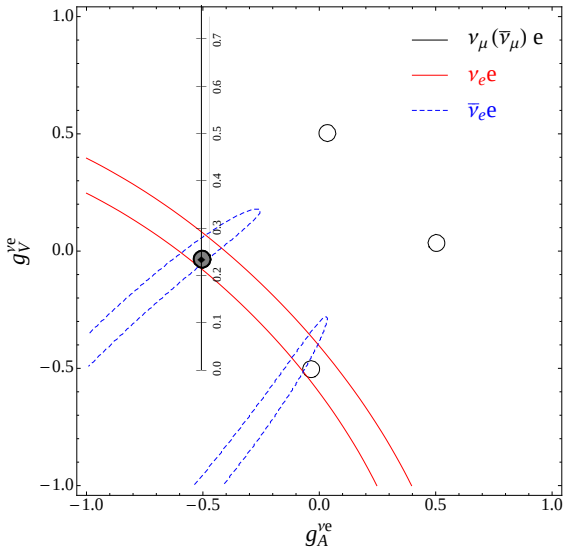

Figure 10.1: Allowed contours in $g_A^{\nu e}$ *vs.* $g_V^{\nu e}$ from neutrino-electron scattering and the SM prediction as a function of $\widehat{s}^2_Z$. (The SM best fit value $\widehat{s}^2_Z = 0.23126$ is also indicated.) The $\nu_e e$ [83] and $\bar{\nu}_e e$ [84] constraints are at 1 σ, while each of the four equivalent $\nu_\mu(\bar{\nu}_\mu)e$ [79–82] solutions ($g_{V,A} \to -g_{V,A}$ and $g_{V,A} \to g_{A,V}$) are at the 90% C.L. The global best fit region (shaded) almost exactly coincides with the corresponding $\nu_\mu(\bar{\nu}_\mu)e$ region. The solution near $g_A = 0, g_V = -0.5$ is eliminated by $e^+e^- \to \ell^+\ell^-$ data under the weak additional assumption that the neutral current is dominated by the exchange of a single Z boson.

A precise determination of the on-shell s^2_W, which depends only very weakly on m_t and M_H, is obtained from deep inelastic scattering (DIS) of neutrinos from (approximately) isoscalar targets [85]. The ratio $R_\nu \equiv \sigma^{NC}_{\nu N}/\sigma^{CC}_{\nu N}$ of neutral-to-charged-current cross-sections has been measured to 1% accuracy by CDHS [86] and CHARM [87] at CERN. CCFR [88] at Fermilab has obtained an even more precise result, so it is important to obtain theoretical expressions for R_ν and $R_{\bar{\nu}} \equiv \sigma^{NC}_{\bar{\nu}N}/\sigma^{CC}_{\bar{\nu}N}$ to comparable accuracy. Fortunately, many of the uncertainties from the strong interactions and neutrino spectra cancel in the ratio. A large theoretical uncertainty is associated with the c-threshold, which mainly affects σ^{CC}. Using the slow rescaling prescription [89] the central value of $\sin^2\theta_W$ from CCFR varies as $0.0111(m_c/\mathrm{GeV} - 1.31)$, where m_c is the effective mass which is numerically close to the $\overline{\rm MS}$ mass $\widehat{m}_c(\widehat{m}_c)$, but their exact relation is unknown at higher orders. For $m_c = 1.31 \pm 0.24$ GeV (determined from ν-induced dimuon production [90]) this contributes ± 0.003 to the total uncertainty $\Delta \sin^2\theta_W \sim \pm 0.004$. (The experimental uncertainty is also ± 0.003.) This uncertainty largely cancels, however, in the Paschos-Wolfenstein ratio [91],

$$R^- = \frac{\sigma^{NC}_{\nu N} - \sigma^{NC}_{\bar{\nu}N}}{\sigma^{CC}_{\nu N} - \sigma^{CC}_{\bar{\nu}N}} \,. \qquad (10.21)$$

It was measured by Fermilab's NuTeV collaboration [92] for the first time, and required a high-intensity and high-energy anti-neutrino beam.

A simple zero$^{\rm th}$-order approximation is

$$R_\nu = g_L^2 + g_R^2 r, \quad R_{\bar{\nu}} = g_L^2 + \frac{g_R^2}{r}, \quad R^- = g_L^2 - g_R^2, \quad (10.22)$$

where

$$g_L^2 \equiv (g_{LL}^{\nu_\mu u})^2 + (g_{LL}^{\nu_\mu d})^2 \approx \frac{1}{2} - \sin^2\theta_W + \frac{5}{9}\sin^4\theta_W, \quad (10.23a)$$

$$g_R^2 \equiv (g_{LR}^{\nu_\mu u})^2 + (g_{LR}^{\nu_\mu d})^2 \approx \frac{5}{9}\sin^4\theta_W, \qquad (10.23b)$$

and $r \equiv \sigma^{CC}_{\bar{\nu}N}/\sigma^{CC}_{\nu N}$ is the ratio of $\overline{\nu}$ to ν charged-current cross-sections, which can be measured directly. [In the simple parton model, ignoring hadron energy cuts, $r \approx (\frac{1}{3}+\epsilon)/(1+\frac{1}{3}\epsilon)$, where $\epsilon \sim 0.125$ is the ratio of the fraction of the nucleon's momentum carried by anti-quarks to that carried by quarks.] In practice, Eq. (10.22) must be corrected for quark mixing, quark sea effects, c-quark threshold effects, non-isoscalarity, W–Z propagator differences, the finite muon mass, QED and EW radiative corrections. Details of the neutrino spectra, experimental cuts, x and Q^2 dependence of structure functions, and longitudinal structure functions enter only at the level of these corrections and therefore lead to very small uncertainties. CCFR quotes $s^2_W = 0.2236 \pm 0.0041$ for $(m_t, M_H) = (175, 150)$ GeV with very little sensitivity to (m_t, M_H).

The NuTeV collaboration found $s^2_W = 0.2277 \pm 0.0016$ (for the same reference values), which was 3.0 σ higher than the SM prediction [92]. The deviation was in g_L^2 (initially 2.7 σ low) while g_R^2 was consistent with the SM. Since then a number of experimental and theoretical developments changed the interpretation of the measured cross section ratios, affecting the extracted $g^2_{L,R}$ (and thus s^2_W) including their uncertainties and correlation. In the following paragraph we give a semi-quantitative and preliminary discussion of these effects, but we stress that the precise impact of them needs to be evaluated carefully by the collaboration with a new and self-consistent set of PDFs, including new radiative corrections, while simultaneously allowing isospin breaking and asymmetric strange seas. This is an effort which is currently on its way and until it is completed we do not include the νDIS constraints in our default set of fits.

(i) In the original analysis NuTeV worked with a symmetric strange quark sea but subsequently measured [93] the difference between the strange and antistrange momentum distributions, $S^- \equiv \int_0^1 dx\, x[s(x) - \bar{s}(x)] = 0.00196 \pm 0.00143$, from dimuon events utilizing the first complete next-to-leading order QCD description [94] and parton distribution functions (PDFs) according to Ref. 95. The global PDF fits in Ref. 96 give somewhat smaller values, $S^- = 0.0013(9)$ [$S^- = 0.0010(13)$], where the semi-leptonic charmed-hadron branching ratio, $B_\mu = 8.8 \pm 0.5\%$, has [not] been used as an external constraint. The resulting S^- also depends on the PDF model used and on whether theoretical arguments (see Ref. 97 and references therein) are invoked favoring a zero crossing of $x[s(x) - \bar{s}(x)]$ at values much larger than seen by NuTeV and suggesting an effect of much smaller and perhaps negligible size. (ii) The measured branching ratio for K_{e3} decays enters crucially in the determination of the $\nu_e(\bar{\nu}_e)$ contamination of the $\nu_\mu(\bar{\nu}_\mu)$ beam. This branching ratio has moved from $4.82 \pm 0.06\%$ at the time of the original publication [92] to the current value of $5.07 \pm 0.04\%$, *i.e.* a change by more than $4\,\sigma$. This moves s^2_W about one standard deviation further away from the SM prediction while reducing the $\nu_e(\bar{\nu}_e)$ uncertainty. (iii) PDFs seem to violate isospin symmetry at levels much stronger than generally expected [98]. A minimum χ^2 set of PDFs [99] allowing charge symmetry violation for both valence quarks $[d_V^p(x) \neq u_V^n(x)]$ and sea quarks $[\bar{d}^p(x) \neq \bar{u}^n(x)]$ shows a reduction in the NuTeV discrepancy by about $1\,\sigma$. But isospin symmetry violating PDFs are currently not well constrained phenomenologically and within uncertainties the NuTeV anomaly could be accounted for in full or conversely made larger [99]. Still, the leading contribution from quark mass differences turns out to be largely model-independent [100] (at least in sign) and a shift, $\delta s^2_W = -0.0015 \pm 0.0003$ [97], has been estimated. (iv) QED splitting effects also violate isospin symmetry with an effect on s^2_W whose sign (reducing the discrepancy) is model-independent. The corresponding shift of $\delta s^2_W = -0.0011$ has been calculated in Ref. 101 but has a large uncertainty. (v) Nuclear shadowing effects [102] are likely to affect the interpretation of the NuTeV result at some level, but the NuTeV collaboration argues that their data are dominated by values of Q^2 at which nuclear shadowing is expected to be relatively

small. However, another nuclear effect, known as the isovector EMC effect [103], is much larger (because it affects all neutrons in the nucleus, not just the excess ones) and model-independently works to reduce the discrepancy. It is estimated to lead to a shift of $\delta s^2_W = -0.0019 \pm 0.0006$ [97]. It would be important to verify and quantify this kind of effect experimentally, *e.g.*, in polarized electron scattering. (vi) The extracted s^2_W may also shift at the level of the quoted uncertainty when analyzed using the most recent QED and EW radiative corrections [104,105], as well as QCD corrections to the structure functions [106]. However, these are scheme-dependent and in order to judge whether they are significant they need to be adapted to the experimental conditions and kinematics of NuTeV, and have to be obtained in terms of observable variables and for the differential cross-sections. In addition, there is the danger of double counting some of the QED splitting effects. (vii) New physics could also affect $g^2_{L,R}$ [107] but it is difficult to convincingly explain the entire effect that way.

10.3.2. *Parity violation* :

The SLAC polarized electron-deuteron DIS (eDIS) experiment [108] measured the right-left asymmetry,

$$A = \frac{\sigma_R - \sigma_L}{\sigma_R + \sigma_L} \,, \tag{10.24}$$

where $\sigma_{R,L}$ is the cross-section for the deep-inelastic scattering of a right- or left-handed electron: $e_{R,L}N \to e\mathrm{X}$. In the quark parton model,

$$\frac{A}{Q^2} = a_1 + a_2 \frac{1-(1-y)^2}{1+(1-y)^2} \,, \tag{10.25}$$

where $Q^2 > 0$ is the momentum transfer and y is the fractional energy transfer from the electron to the hadrons. For the deuteron or other isoscalar targets, one has, neglecting the s-quark and anti-quarks,

$$a_1 = \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(g^{eu}_{AV} - \frac{1}{2}g^{ed}_{AV}\right) \approx \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(-\frac{3}{4} + \frac{5}{3}\widehat{s}^2_0\right) \tag{10.26a}$$

$$a_2 = \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(g^{eu}_{VA} - \frac{1}{2}g^{ed}_{VA}\right) \approx \frac{9G_F}{5\sqrt{2}\pi\alpha}\left(\widehat{s}^2_0 - \frac{1}{4}\right). \tag{10.26b}$$

The Jefferson Lab Hall A Collaboration [109] improved on the SLAC result by determining A at $Q^2 = 1.085$ GeV and 1.901 GeV, and determined the weak mixing angle to 2% precision. In another polarized-electron scattering experiment on deuterons, but in the quasi-elastic kinematic regime, the SAMPLE experiment [110] at MIT-Bates extracted the combination $g^{eu}_{VA} - g^{ed}_{VA}$ at Q^2 values of 0.1 GeV^2 and 0.038 GeV^2. What was actually determined were nucleon form factors from which the quoted results were obtained by the removal of a multi-quark radiative correction [111]. Other linear combinations of the effective couplings have been determined in polarized-lepton scattering at CERN in μ-C DIS, at Mainz in e-Be (quasi-elastic), and at Bates in e-C (elastic). See the review articles in Refs. 112 and 113 for more details. Recent polarized electron asymmetry experiments, *i.e.*, SAMPLE, the PVA4 experiment at Mainz, and the HAPPEX and G0 experiments at Jefferson Lab, have focussed on the strange quark content of the nucleon. These are reviewed in Refs. 114 and 115.

The parity violating asymmetry, A_{PV}, in fixed target polarized Møller scattering, $e^-e^- \to e^-e^-$, is defined as in Eq. (10.24) and reads [116],

$$\frac{A_{PV}}{Q^2} = -2\, g^{ee}_{AV} \frac{G_F}{\sqrt{2}\pi\alpha} \frac{1-y}{1+y^4+(1-y)^4} \,, \tag{10.27}$$

where y is again the energy transfer. It has been measured at low $Q^2 = 0.026$ GeV^2 in the SLAC E158 experiment [117], with the result $A_{PV} = (-1.31 \pm 0.14_{\,\mathrm{stat.}} \pm 0.10_{\,\mathrm{syst.}}) \times 10^{-7}$. Expressed in terms of the weak mixing angle in the $\overline{\mathrm{MS}}$ scheme, this yields $\widehat{s}^2(Q^2) = 0.2403 \pm 0.0013$, and established the scale dependence of the weak mixing angle (see $Q_W(e)$ in Fig. 10.2) at the level of 6.4 σ. One can also extract the model-independent effective coupling, $g^{ee}_{AV} = 0.0190 \pm 0.0027$ [76] (the implications are discussed in Ref. 119).

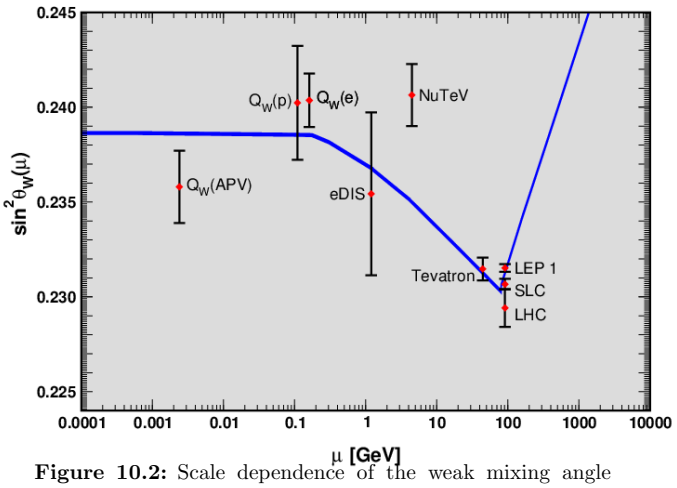

Figure 10.2: Scale dependence of the weak mixing angle defined in the $\overline{\mathrm{MS}}$ scheme [118] (for the scale dependence of the weak mixing angle defined in a mass-dependent renormalization scheme, see Ref. 119). The minimum of the curve corresponds to $\mu = M_W$, below which we switch to an effective theory with the $W^\pm$ bosons integrated out, and where the β-function for the weak mixing angle changes sign. At the location of the W boson mass and each fermion mass there are also discontinuities arising from scheme dependent matching terms which are necessary to ensure that the various effective field theories within a given loop order describe the same physics. However, in the $\overline{\mathrm{MS}}$ scheme these are very small numerically and barely visible in the figure provided one decouples quarks at $\mu = \widehat{m}_q(\widehat{m}_q)$. The width of the curve reflects the theory uncertainty from strong interaction effects which at low energies is at the level of $\pm 7 \times 10^{-5}$ [118]. Following the estimate [121] of the typical momentum transfer for parity violation experiments in Cs, the location of the APV data point is given by $\mu = 2.4$ MeV. For NuTeV we display the updated value from Ref. 120 and chose $\mu = \sqrt{20}$ GeV which is about half-way between the averages of $\sqrt{Q^2}$ for ν and $\overline{\nu}$ interactions at NuTeV. The Tevatron and LHC measurements are strongly dominated by invariant masses of the final state dilepton pair of $\mathcal{O}(M_Z)$ and can thus be considered as additional Z pole data points. For clarity we displayed the Tevatron point horizontally to the left.

In a similar experiment and at about the same $Q^2 = 0.025$ GeV^2, Qweak at Jefferson Lab [122] will be able to measure the weak charge of the proton (which is proportional to $2g^{eu}_{AV} + g^{ed}_{AV}$) and $\sin^2\theta_W$ in polarized ep scattering with relative precisions of 4% and 0.3%, respectively. The result based on the collaborations commissioning run [123] and about 4% of the data corresponds to the constraint $2g^{eu}_{AV} + g^{ed}_{AV} = 0.064 \pm 0.012$.

There are precise experiments measuring atomic parity violation (APV) [124] in cesium [125,126] (at the 0.4% level [125]), thallium [127], lead [128], and bismuth [129]. The EW physics is contained in the nuclear weak charges $Q^{Z,N}_W$, where Z and N are the numbers of protons and neutrons in the nucleus. In terms of the nucleon vector couplings,

$$g^{ep}_{AV} \equiv 2g^{eu}_{AV} + g^{ed}_{AV} \approx -\frac{1}{2} + 2\widehat{s}^2_0, \tag{10.28}$$

$$g^{en}_{AV} \equiv g^{eu}_{AV} + 2g^{ed}_{AV} \approx \frac{1}{2}, \tag{10.29}$$

one has,

$$Q^{Z,N}_W \equiv -2\left[Z(g^{ep}_{AV} + 0.00005) + N(g^{en}_{AV} + 0.00006)\right]\left(1 - \frac{\alpha}{2\pi}\right), \tag{10.30}$$

where the numerically small adjustments are discussed in Ref. 76 and include the result of the γZ-box correction from Ref. 130. *E.g.*, $Q_W(^{133}\mathrm{Cs})$ is extracted by measuring experimentally the ratio of the parity violating amplitude, E_{PNC}, to the Stark vector transition

polarizability, β, and by calculating theoretically $E_{\rm PNC}$ in terms of Q_W. One can then write,

$$Q_W = N \left(\frac{\mathrm{Im}\, E_{\rm PNC}}{\beta}\right)_{\rm exp.} \left(\frac{|e|\, a_B}{\mathrm{Im}\, E_{\rm PNC}} \frac{Q_W}{N}\right)_{\rm th.} \left(\frac{\beta}{a_B^3}\right)_{\rm exp.+th.} \left(\frac{a_B^2}{|e|}\right),$$

where a_B is the Bohr radius. The uncertainties associated with atomic wave functions are quite small for cesium [131]. The semi-empirical value of β used in early analyses added another source of theoretical uncertainty [132]. However, the ratio of the off-diagonal hyperfine amplitude to the polarizability was subsequently measured directly by the Boulder group [133]. Combined with the precisely known hyperfine amplitude [134] one finds $\beta = (26.991 \pm 0.046)\, a_B^3$, in excellent agreement with the earlier results, reducing the overall theory uncertainty (while slightly increasing the experimental error). Utilizing the state-of-the-art many-body calculation in Ref. 135 yields $\mathrm{Im}\, E_{\rm PNC} = (0.8906 \pm 0.0026) \times 10^{-11} |e|\, a_B\, Q_W/N$, while the two measurements [125,126] combine to give $\mathrm{Im}\, E_{\rm PNC}/\beta = -1.5924 \pm 0.0055$ mV/cm, and we would obtain $Q_W(^{133}_{78}\mathrm{Cs}) = -73.20 \pm 0.35$, or equivalently $55 g_{AV}^{ep} + 78 g_{AV}^{en} = 36.64 \pm 0.18$ which is in excellent agreement with the SM prediction of 36.66. However, a very recent atomic structure calculation [136] found significant corrections to two non-dominating terms, changing the result to $\mathrm{Im}\, E_{\rm PNC} = (0.8977 \pm 0.0040) \times 10^{-11} |e|\, a_B\, Q_W/N$, and yielding the constraint, $55 g_{AV}^{ep} + 78 g_{AV}^{en} = 36.35 \pm 0.21$ [$Q_W(^{133}_{78}\mathrm{Cs}) = -72.62 \pm 0.43$], *i.e.* a 1.5 σ SM deviation. Thus, the various theoretical efforts in [135–137] together with an update of the SM calculation [138] reduced an earlier 2.3 σ discrepancy from the SM (see the year 2000 edition of this *Review*), but there still appears to remain a small deviation. The theoretical uncertainties are 3% for thallium [139] but larger for the other atoms. The Boulder experiment in cesium also observed the parity-violating weak corrections to the nuclear electromagnetic vertex (the anapole moment [140]) .

In the future it could be possible to further reduce the theoretical wave function uncertainties by taking the ratios of parity violation in different isotopes [124,141]. There would still be some residual uncertainties from differences in the neutron charge radii, however [142]. Experiments in hydrogen and deuterium are another possibility for reducing the atomic theory uncertainties [143], while measurements of single trapped radium ions are promising [144] because of the much larger parity violating effect.

10.4. Physics of the massive electroweak bosons

If the CM energy $\sqrt{s}$ is large compared to the fermion mass m_f, the unpolarized Born cross-section for $e^+e^- \to f\bar{f}$ can be written as

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2(s)}{2s}\left[F_1(1+\cos^2\theta) + 2F_2\cos\theta\right] + B, \qquad (10.31a)$$

where

$$F_1 = Q_e^2 Q_f^2 - 2\chi\, Q_e Q_f \overline{g}_V^e \overline{g}_V^f \cos\delta_R + \chi^2 (\overline{g}_V^{e2} + \overline{g}_A^{e2})(\overline{g}_V^{f2} + \overline{g}_A^{f2}) \qquad (10.31b)$$

$$F_2 = -2\chi\, Q_e Q_f \overline{g}_A^e \overline{g}_A^f \cos\delta_R + 4\chi^2 \overline{g}_V^e \overline{g}_A^e \overline{g}_V^f \overline{g}_A^f \qquad (10.31c)$$

$$\tan\delta_R = \frac{M_Z\Gamma_Z}{M_Z^2 - s}\ ,\ \chi = \frac{G_F}{2\sqrt{2}\pi\alpha(s)} \frac{sM_Z^2}{\left[(M_Z^2 - s)^2 + M_Z^2\Gamma_Z^2\right]^{1/2}}\ , \qquad (10.32)$$

and B accounts for box graphs involving virtual Z and W bosons, and $\overline{g}_{V,A}^f$ are defined in Eq. (10.33) below. The differential cross-section receives important corrections from QED effects in the initial and final state, and interference between the two, see *e.g.* Ref. 145. For $q\bar{q}$ production, there are additional final-state QCD corrections, which are relatively large. Note also that the equations above are written in the CM frame of the incident e^+e^- system, which may be boosted due to the initial-state QED radiation.

Some of the leading virtual EW corrections are captured by the running QED coupling $\alpha(s)$ and the Fermi constant G_F. The remaining corrections to the $Zf\bar{f}$ interaction are absorbed by replacing the tree-level couplings Eq. (10.5) with the s-dependent *effective couplings* [146]

$$\overline{g}_V^f = \sqrt{\rho_f}\,(t_{3L}^{(f)} - 2Q_f\kappa_f \sin^2\theta_W), \qquad \overline{g}_A^f = \sqrt{\rho_f}\, t_{3L}^{(f)}. \qquad (10.33)$$

In these equations, the effective couplings are to be taken at the scale $\sqrt{s}$, but for notational simplicity we do not show this explicitly. At tree-level $\rho_f = \kappa_f = 1$, but inclusion of EW radiative corrections leads to non-zero $\rho_f - 1$ and $\kappa_f - 1$, which depend on the fermion f and on the renormalization scheme. In the on-shell scheme, the quadratic m_t dependence is given by $\rho_f \sim 1 + \rho_t$, $\kappa_f \sim 1 + \rho_t/\tan^2\theta_W$, while in $\overline{\rm MS}$, $\widehat{\rho}_f \sim \widehat{\kappa}_f \sim 1$, for $f \neq b$ ($\widehat{\rho}_b \sim 1 - \frac{4}{3}\rho_t$, $\widehat{\kappa}_b \sim 1 + \frac{2}{3}\rho_t$). In the $\overline{\rm MS}$ scheme the normalization is changed according to $G_F M_Z^2/2\sqrt{2}\pi \to \widehat{\alpha}/4\widehat{s}_Z^2\widehat{c}_Z^2$ in Eq. (10.32).

For the high-precision Z-pole observables discussed below, additional bosonic and fermionic loops, vertex corrections, and higher order contributions, *etc.*, must be included [60,63,64,147,148]. For example, in the $\overline{\rm MS}$ scheme one has $\widehat{\rho}_\ell = 0.9982$, $\widehat{\kappa}_\ell = 1.0013$, $\widehat{\rho}_b = 0.9870$, and $\widehat{\kappa}_b = 1.0068$.

To connect to measured quantities, it is convenient to define an effective angle $\overline{s}_f^2 \equiv \sin^2\overline{\theta}_{Wf} \equiv \widehat{\kappa}_f \widehat{s}_Z^2 = \kappa_f s_W^2$, in terms of which $\overline{g}_V^f$ and $\overline{g}_A^f$ are given by $\sqrt{\rho_f}$ times their tree-level formulae. One finds that the $\widehat{\kappa}_f$ ($f \neq b$) are almost independent of (m_t, M_H), and thus one can write

$$\overline{s}_\ell^2 = \widehat{s}_Z^2 + 0.00029, \qquad (10.34)$$

while the κ's for the other schemes are m_t dependent.

10.4.1. e^+e^- *scattering below the Z pole* :

Experiments at PEP, PETRA and TRISTAN have measured the unpolarized forward-backward asymmetry, A_{FB}, and the total cross-section relative to pure QED, R, for $e^+e^- \to \ell^+\ell^-$, $\ell = \mu$ or τ at CM energies $\sqrt{s} < M_Z$. They are defined as

$$A_{FB} \equiv \frac{\sigma_F - \sigma_B}{\sigma_F + \sigma_B}\ , \qquad R = \frac{\sigma}{\mathcal{R}_{\rm ini} 4\pi\alpha^2/3s}\ , \qquad (10.35)$$

where σ_F (σ_B) is the cross-section for ℓ^- to travel forward (backward) with respect to the e^- direction. Neglecting box graph contribution, they are given by

$$A_{FB} = \frac{3}{4}\frac{F_2}{F_1}\ , \qquad R = F_1\ . \qquad (10.36)$$

For the available data, it is sufficient to approximate the EW corrections through the leading running $\alpha(s)$ and quadratic m_t contributions [149,150] as described above. Reviews and formulae for $e^+e^- \to$ hadrons may be found in Ref. 151.

10.4.2. *Z pole physics* :

High-precision measurements of various Z pole ($\sqrt{s} \approx M_Z$) observables have been performed at LEP 1 and SLC [11,152–157], as summarized in Table 10.5. These include the Z mass and total width, Γ_Z, and partial widths $\Gamma(f\overline{f})$ for $Z \to f\overline{f}$, where $f = e$, μ, τ, light hadrons, b, or c. It is convenient to use the variables M_Z, Γ_Z, $R_\ell \equiv \Gamma(\mathrm{had})/\Gamma(\ell^+\ell^-)$ ($\ell = e, \mu, \tau$), $\sigma_{\rm had} \equiv 12\pi\,\Gamma(e^+e^-)\,\Gamma(\mathrm{had})/M_Z^2\,\Gamma_Z^2$[††], $R_b \equiv \Gamma(b\overline{b})/\Gamma(\mathrm{had})$, and $R_c \equiv \Gamma(c\overline{c})/\Gamma(\mathrm{had})$, most of which are weakly correlated experimentally. ($\Gamma(\mathrm{had})$ is the partial width into hadrons.) The three values for R_ℓ are consistent with lepton universality (although R_τ is somewhat low compared to R_e and R_μ), but we use the general analysis in which the three observables are treated as independent. Similar remarks apply to $A_{FB}^{0,\ell}$ defined through Eq. (10.39) with $P_e = 0$. ($A_{FB}^{0,\tau}$ is somewhat high). $\mathcal{O}(\alpha^3)$ QED corrections introduce a large anti-correlation (-30%) between Γ_Z and $\sigma_{\rm had}$. The anti-correlation between R_b and R_c is -18% [11]. The R_ℓ are insensitive to m_t except for the $Z \to b\overline{b}$ vertex and final state corrections and the implicit dependence through $\sin^2\theta_W$. Thus, they

[††] Note that in general $\sigma_{\rm had}$ receives additional EW corrections that are not captured in the partial widths [158], but they only become relevant in a full two-loop calculation.

are especially useful for constraining α_s. The invisible decay width [11], $\Gamma(\text{inv}) = \Gamma_Z - 3\,\Gamma(\ell^+\ell^-) - \Gamma(\text{had}) = 499.0 \pm 1.5$ MeV, can be used to determine the number of neutrino flavors, $N_\nu = \Gamma(\text{inv})/\Gamma^{\text{theory}}(\nu\overline{\nu})$, much lighter than $M_Z/2$. In practice, we determine N_ν by allowing it as an additional fit parameter and obtain,

$$N_\nu = 2.990 \pm 0.007\ . \tag{10.37}$$

Additional constraints follow from measurements of various Z-pole asymmetries. These include the forward-backward asymmetry A_{FB} and the polarization or left-right asymmetry,

$$A_{LR} \equiv \frac{\sigma_L - \sigma_R}{\sigma_L + \sigma_R}\ , \tag{10.38}$$

where $\sigma_L(\sigma_R)$ is the cross-section for a left-(right-)handed incident electron. A_{LR} was measured precisely by the SLD collaboration at the SLC [154], and has the advantages of being very sensitive to $\sin^2\theta_W$ and that systematic uncertainties largely cancel. After removing initial state QED corrections and contributions from photon exchange, γ–Z interference and EW boxes, see Eq. (10.31), one can use the effective tree-level expressions

$$A_{LR} = A_e P_e\ , \qquad A_{FB} = \frac{3}{4} A_f\, \frac{A_e + P_e}{1 + P_e A_e}\ , \tag{10.39}$$

where

$$A_f \equiv \frac{2\overline{g}_V^f\, \overline{g}_A^f}{\overline{g}_V^{f\,2} + \overline{g}_A^{f\,2}} = \frac{1 - 4|Q_f|\bar{s}_f^2}{1 - 4|Q_f|\bar{s}_f^2 + 8(|Q_f|\bar{s}_f^2)^2}\ . \tag{10.40}$$

P_e is the initial e^- polarization, so that the second equality in Eq. (10.41) is reproduced for $P_e = 1$, and the Z pole forward-backward asymmetries at LEP 1 ($P_e = 0$) are given by $A_{FB}^{(0,f)} = \frac{3}{4} A_e A_f$ where $f = e,\ \mu,\ \tau,\ b,\ c,\ s$ [11], and q, and where $A_{FB}^{(0,q)}$ refers to the hadronic charge asymmetry. Corrections for t-channel exchange and s/t-channel interference cause $A_{FB}^{(0,e)}$ to be strongly anti-correlated with R_e (-37%). The correlation between $A_{FB}^{(0,b)}$ and $A_{FB}^{(0,c)}$ amounts to 15%.

In addition, SLD extracted the final-state couplings A_b, A_c [11], A_s [155], A_τ, and A_μ [156], from left-right forward-backward asymmetries, using

$$A_{LR}^{FB}(f) = \frac{\sigma_{LF}^f - \sigma_{LB}^f - \sigma_{RF}^f + \sigma_{RB}^f}{\sigma_{LF}^f + \sigma_{LB}^f + \sigma_{RF}^f + \sigma_{RB}^f} = \frac{3}{4} A_f\ , \tag{10.41}$$

where, for example, σ_{LF}^f is the cross-section for a left-handed incident electron to produce a fermion f traveling in the forward hemisphere. Similarly, A_τ and A_e were measured at LEP 1 [11] through the negative total τ polarization, $\mathcal{P}_\tau$, as a function of the scattering angle θ, which can be writte as

$$\mathcal{P}_\tau = -\frac{A_\tau(1 + \cos^2\theta) + 2A_e\cos\theta}{(1 + \cos^2\theta) + 2A_\tau A_e\cos\theta} \tag{10.42}$$

The average polarization, $\langle\mathcal{P}_\tau\rangle$, obtained by integrating over $\cos\theta$ in the numerator and denominator of Eq. (10.42), yields $\langle\mathcal{P}_\tau\rangle = -A_\tau$, while A_e can be extracted from the angular distribution of $\mathcal{P}_\tau$.

The initial state coupling, A_e, was also determined through the left-right charge asymmetry [157] and in polarized Bhabba scattering [156] at SLC. Because $\overline{g}_V^\ell$ is very small, not only $A_{LR}^0 = A_e$, $A_{FB}^{(0,\ell)}$, and $\mathcal{P}_\tau$, but also $A_{FB}^{(0,b)}$, $A_{FB}^{(0,c)}$, $A_{FB}^{(0,s)}$, and the hadronic asymmetries are mainly sensitive to $\overline{s}_\ell^2$.

As mentioned in Sec. 10.2, radiative corrections to $\bar{s}_\ell^2$ have been computed with full two-loop and partial higher-order corrections. Moreover, fermionic two-loop EW corrections to $\bar{s}_q^2$ ($q = b,\ c,\ s$) have been obtained [74,148], but the purely bosonic contributions of this order are still missing. For the partial widths, $\Gamma(f\overline{f})$, and the hadronic peak cross-section, σ_{had}, currently only approximate EW two-loop corrections based on a large-m_t expansion [59,60,159,160] are known. Non-factorizable $\mathcal{O}(\alpha\alpha_s)$ corrections for the $Z \to q\bar{q}$ vertex are also available [147]. They add coherently, resulting in a sizable effect and shift $\alpha_s(M_Z)$ when extracted from Z lineshape observables by $\approx +0.0007$. Very recently, complete fermionic two-loop EW contributions to R_b [161] and to Γ_Z [162] have been calculated, but their numerical impact is relatively small, and they have not been included in the fits in this *Review*.

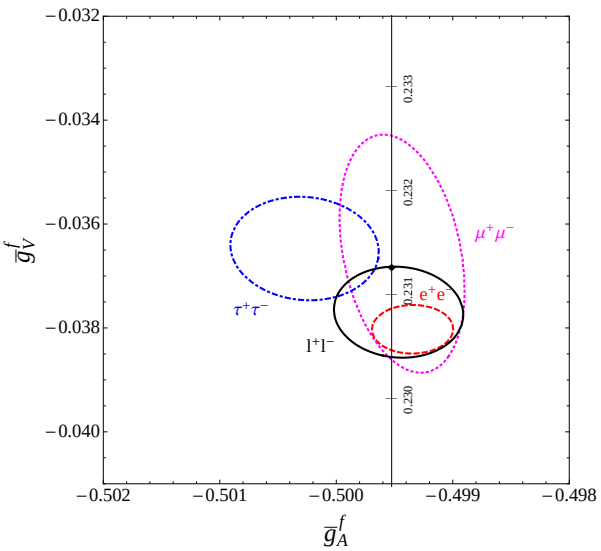

Figure 10.3: 1 σ (39.35% C.L.) contours for the Z-pole observables $\bar{g}_A^f$ and $\bar{g}_V^f$, $f = e, \mu, \tau$ obtained at LEP and SLC [11], compared to the SM expectation as a function of $\widehat{s}_Z^{\,2}$. (The SM best fit value $\widehat{s}_Z^{\,2} = 0.23126$ is also indicated.) Also shown is the 90% CL allowed region in $\bar{g}_{A,V}^\ell$ obtained assuming lepton universality.

As an example of the precision of the Z-pole observables, the values of $\bar{g}_A^f$ and $\bar{g}_V^f$, $f = e, \mu, \tau, \ell$, extracted from the LEP and SLC lineshape and asymmetry data, are shown in Fig. 10.3, which should be compared with Fig. 10.1. (The two sets of parameters coincide in the SM at tree-level.)

As for hadron colliders, the forward-backward asymmetry, A_{FB}, for e^+e^- and $\mu^+\mu^-$ final states (with invariant masses restricted to or dominated by values around M_Z) in $p\bar{p}$ collisions has been measured by the DØ [163] (only e^+e^-) and CDF [164,165] collaborations, and values for $\overline{s}_\ell^2$ were extracted. Assuming lepton universality and that the smallest systematic uncertainty (± 0.0003 from the e^+e^- analysis at CDF [164]) is common to both final states and experiments, these measurements combine to $\overline{s}_\ell^2 = 0.23176 \pm 0.00060$. By varying the invariant mass and the scattering angle (and assuming the electron couplings), information on the effective Z couplings to light quarks, $\overline{g}_{V,A}^{u,d}$, could also be obtained [163,166], but with large uncertainties and mutual correlations and not independently of $\overline{s}_\ell^2$ above. Similar analyses have also been reported by the H1 and ZEUS collaborations at HERA [167] and by the LEP collaborations [11]. This kind of measurement is harder in the pp environment due to the difficulty to assign the initial quark and antiquark in the underlying Drell-Yan process to the protons. Nevertheless, measurements of A_{FB} have been reported by the CMS [168] (only $\mu^+\mu^-$) and ATLAS [169] collaborations. Again assuming lepton universality and that the ± 0.0007 PDF uncertainty from ATLAS [169] is common to both experiments, these measurements combine to give the value, $\overline{s}_\ell^2 = 0.2297 \pm 0.0010$, which is driven by the more precise ATLAS results.

10.4.3. *LEP 2* :

LEP 2 [170,171] ran at several energies above the Z pole up to ~ 209 GeV. Measurements were made of a number of observables, including the cross-sections for $e^+e^- \to f\bar{f}$ for $f = q, \mu, \tau$; the differential cross-sections for $f = e, \mu, \tau$; R_q for $q = b, c$; $A_{FB}(f)$ for $f = \mu, \tau, b, c$; W branching ratios; and $\gamma\gamma$, WW, $WW\gamma$, ZZ, single W, and single Z cross-sections. They are in good agreement with the SM predictions, with the exceptions of R_b (2.1 σ low), $A_{FB}(b)$ (1.6 σ low), and the $W \to \tau\nu_\tau$ branching fraction (2.6 σ high).

The Z boson properties are extracted assuming the SM expressions for the γ–Z interference terms. These have also been tested experimentally by performing more general fits [170,172] to the

LEP 1 and LEP 2 data. Assuming family universality this approach introduces three additional parameters relative to the standard fit [11], describing the γ–Z interference contribution to the total hadronic and leptonic cross-sections, $j^{\rm tot}_{\rm had}$ and $j^{\rm tot}_{\ell}$, and to the leptonic forward-backward asymmetry, $j^{\rm fb}_{\ell}$. *E.g.*,

$$j^{\rm tot}_{\rm had} \sim g^{\ell}_V g^{\rm had}_V = 0.277 \pm 0.065, \tag{10.43}$$

which is in agreement with the SM expectation [11] of 0.21 ± 0.01. These are valuable tests of the SM; but it should be cautioned that new physics is not expected to be described by this set of parameters, since (i) they do not account for extra interactions beyond the standard weak neutral current, and (ii) the photonic amplitude remains fixed to its SM value.

Strong constraints on anomalous triple and quartic gauge couplings have been obtained at LEP 2 and the Tevatron as described in the Gauge & Higgs Bosons Particle Listings.

10.4.4. *W and Z decays* :

The partial decay widths for gauge bosons to decay into massless fermions $f_1\overline{f}_2$ (the numerical values include the small EW radiative corrections and final state mass effects) are given by

$$\Gamma(W^+ \to e^+\nu_e) = \frac{G_F M_W^3}{6\sqrt{2}\pi} \approx 226.32 \pm 0.05 \text{ MeV} , \tag{10.44a}$$

$$\Gamma(W^+ \to u_i\overline{d}_j) = \frac{\mathcal{R}^q_V G_F M_W^3}{6\sqrt{2}\pi} |V_{ij}|^2 \approx 705.5 \pm 0.4 \text{ MeV } |V_{ij}|^2, \tag{10.44b}$$

$$\Gamma(Z \to f\bar{f}) = \frac{G_F M_Z^3}{6\sqrt{2}\pi} \left[\mathcal{R}^f_V \bar{g}^{f2}_V + \mathcal{R}^f_A \bar{g}^{f2}_A\right] \approx \begin{cases} 167.22 \pm 0.02 \text{ MeV } (\nu\overline{\nu}), \\ 84.00 \pm 0.01 \text{ MeV } (e^+e^-), \\ 300.15 \pm 0.20 \text{ MeV } (u\overline{u}), \\ 382.96 \pm 0.14 \text{ MeV } (d\overline{d}), \\ 375.87 \mp 0.17 \text{ MeV } (b\overline{b}). \end{cases} \tag{10.44c}$$

Final-state QED and QCD corrections to the vector and axial-vector form factors are given by

$$\mathcal{R}^f_{V,A} = N_C[1 + \frac{3}{4}(Q_f^2 \frac{\alpha(s)}{\pi} + \frac{N_C^2 - 1}{2N_C}\frac{\alpha_s(s)}{\pi}) + \cdots], \tag{10.45}$$

where $N_C = 3$ (1) is the color factor for quarks (leptons) and the dots indicate finite fermion mass effects proportional to m_f^2/s which are different for $\mathcal{R}^f_V$ and $\mathcal{R}^f_A$, as well as higher-order QCD corrections, which are known to $\mathcal{O}(\alpha_s^4)$ [173–175]. These include singlet contributions starting from two-loop order which are large, strongly top quark mass dependent, family universal, and flavor non-universal [176]. Also the $\mathcal{O}(\alpha^2)$ self-energy corrections from Ref. 177 are taken into account.

For the W decay into quarks, Eq. (10.44*b*), only the universal massless part (non-singlet and $m_q = 0$) of the final-state QCD radiator function in $\mathcal{R}_V$ from Eq. (10.45) is used, and the QED corrections are modified. Expressing the widths in terms of $G_F M^3_{W,Z}$ incorporates the largest radiative corrections from the running QED coupling [52,178]. EW corrections to the Z widths are then taken into account through the effective couplings $\overline{g}^{i2}_{V,A}$. Hence, in the on-shell scheme the Z widths are proportional to $\rho_i \sim 1 + \rho_t$. There is additional (negative) quadratic m_t dependence in the $Z \to b\overline{b}$ vertex corrections [179] which causes $\Gamma(b\overline{b})$ to decrease with m_t. The dominant effect is to multiply $\Gamma(b\overline{b})$ by the vertex correction $1 + \delta\rho_{b\bar{b}}$, where $\delta\rho_{b\bar{b}} \sim 10^{-2}(-\frac{1}{2}m_t^2/M_Z^2 + \frac{1}{5})$. In practice, the corrections are included in ρ_b and κ_b, as discussed in Sec. 10.4.

For three fermion families the total widths are predicted to be

$$\Gamma_Z \approx 2.4955 \pm 0.0009 \text{ GeV} , \qquad \Gamma_W \approx 2.0897 \pm 0.0008 \text{ GeV} . \tag{10.46}$$

The uncertainties in these predictions are almost entirely induced from the fit error in $\alpha_s(M_Z) = 0.1193 \pm 0.0016$. These predictions are to be compared with the experimental results, $\Gamma_Z = 2.4952 \pm 0.0023$ GeV [11] and $\Gamma_W = 2.085 \pm 0.042$ GeV (see the Gauge & Higgs Boson Particle Listings for more details).

10.4.5. *H decays* :

The ATLAS and CMS collaborations at LHC observed a Higgs boson [180] with properties appearing well consistent with the SM Higgs (see the note on "The Higgs Boson H^0" in the Gauge & Higgs Boson Particle Listings). The kinematically reconstructed masses from ATLAS and CMS of the Higgs boson [181,182] average to

$$M_H = 125.6 \pm 0.4 \text{ GeV}. \tag{10.47}$$

In analogy to the W and Z decays discussed in the previous subsection, we can include some of the Higgs decay properties into the global analysis of Sec. 10.6. However, the total Higgs decay width, which in the SM amounts to

$$\Gamma_H = 4.20 \pm 0.08 \text{ MeV}, \tag{10.48}$$

is too small to be resolved at the LHC. Furthermore, it is difficult (and has not been attempted yet by the experimental collaborations) to form branching ratios when the Higgs production mechanisms differ strongly for different final states. On the other hand, Higgs decay rates into WW^* and ZZ^* (with at least one gauge boson off-shell), as well as $\gamma\gamma$ have been deduced predominantly from gluon-gluon fusion (ggF), so that theoretical production uncertainties mostly cancel in ratios of branching fractions. Thus, we can employ the results on the signal strength parameters, μ_{XX}, quantifying the yields of Higgs production and decay into XX, normalized to the SM expectation, to define

$$\rho_{XY} \equiv \ln \frac{\mu_{XX}}{\mu_{YY}} . \tag{10.49}$$

These quantities are constructed to have a SM expectation of zero (for $M_H = 125.5$ GeV for ATLAS and $M_H = 125.7$ GeV for CMS), and their physical range is over all real numbers, which allows one to straightforwardly use Gaussian error propagation (in view of the fairly large errors). Moreover, possible effects of new physics on Higgs production rates would also cancel and one may focus on the decay side of the processes. Presently, one often combines Higgs production in association with $t\bar{t}$-pairs (ttH) into one category with ggF since they are subject to similar theory uncertainties. Higgs production through vector boson fusion (VBF) and Higgs-strahlung (VH) are important for decays into $f\bar{f}$, but at the moment there is clear evidence for VH production only for the $b\bar{b}$ final state [182,183], while the measurement of $\tau\tau$ receives contributions from both ggF and VBF [184]. As a result, one cannot form a meaningful ratio where the dependence on the production mechanism drops out.

For each of the two LHC experiments, we consider the ratios with the smallest mutual correlations. Assuming that theory errors cancel in the ρ_{XY} while experimental systematics does not, we find for ATLAS [185],

$$\rho_{\gamma W} = 0.45 \pm 0.31 , \qquad \rho_{\gamma Z} = 0.08 \pm 0.28 ,$$

with a correlation of 25% (induced by the 15% uncertainty in the common $\mu_{\gamma\gamma}$), while for CMS [182] (using the same relative theory errors as ATLAS) we obtain,

$$\rho_{\gamma W} = 0.12 \pm 0.43 , \qquad \rho_{ZW} = 0.30 \pm 0.39 ,$$

with a correlation of 43% (due to the 27% uncertainty in μ_{WW}). We evaluate the decay rates with the package HDECAY [186].

10.5. Precision flavor physics

In addition to cross-sections, asymmetries, parity violation, W and Z decays, there is a large number of experiments and observables testing the flavor structure of the SM. These are addressed elsewhere in this *Review*, and are generally not included in this Section. However, we identify three precision observables with sensitivity to similar types of new physics as the other processes discussed here. The branching fraction of the flavor changing transition $b \to s\gamma$ is of comparatively low precision, but since it is a loop-level process (in the SM) its sensitivity to new physics (and SM parameters, such as heavy quark masses) is enhanced. A discussion can be found in the 2010

edition of this *Review*. The τ-lepton lifetime and leptonic branching ratios are primarily sensitive to α_s and not affected significantly by many types of new physics. However, having an independent and reliable low energy measurement of α_s in a global analysis allows the comparison with the Z lineshape determination of α_s which shifts easily in the presence of new physics contributions. By far the most precise observable discussed here is the anomalous magnetic moment of the muon (the electron magnetic moment is measured to even greater precision and can be used to determine α, but its new physics sensitivity is suppressed by an additional factor of m_e^2/m_μ^2, unless there is a new light degree of freedom such as a dark Z [187] boson). Its combined experimental and theoretical uncertainty is comparable to typical new physics contributions.

The extraction of α_s from the τ lifetime [188] is standing out from other determinations because of a variety of independent reasons: (i) the τ-scale is low, so that upon extrapolation to the Z scale (where it can be compared to the theoretically clean Z lineshape determinations) the α_s error shrinks by about an order of magnitude; (ii) yet, this scale is high enough that perturbation theory and the operator product expansion (OPE) can be applied; (iii) these observables are fully inclusive and thus free of fragmentation and hadronization effects that would have to be modeled or measured; (iv) duality violation (DV) effects are most problematic near the branch cut but there they are suppressed by a double zero at $s = m_\tau^2$; (v) there are data [34] to constrain non-perturbative effects both within ($\delta_{D=6,8}$) and breaking (δ_{DV}) the OPE; (vi) a complete four-loop order QCD calculation is available [175]; (vii) large effects associated with the QCD β-function can be re-summed [189] in what has become known as contour improved perturbation theory (CIPT). However, while there is no doubt that CIPT shows faster convergence in the lower (calculable) orders, doubts have been cast on the method by the observation that at least in a specific model [190], which includes the exactly known coefficients and theoretical constraints on the large-order behavior, ordinary fixed order perturbation theory (FOPT) may nevertheless give a better approximation to the full result. We therefore use the expressions [45,174,175,191],

$$\tau_\tau = \hbar \frac{1-\mathcal{B}_\tau^s}{\Gamma_\tau^e + \Gamma_\tau^\mu + \Gamma_\tau^{ud}} = 291.13 \pm 0.43 \text{ fs}, \qquad (10.50)$$

$$\Gamma_\tau^{ud} = \frac{G_F^2 m_\tau^5 |V_{ud}|^2}{64\pi^3} S(m_\tau, M_Z) \left(1 + \frac{3}{5}\frac{m_\tau^2 - m_\mu^2}{M_W^2}\right) \times$$
$$\left[1 + \frac{\alpha_s(m_\tau)}{\pi} + 5.202\,\frac{\alpha_s^2}{\pi^2} + 26.37\,\frac{\alpha_s^3}{\pi^3} + \right.$$
$$\left. 127.1\,\frac{\alpha_s^4}{\pi^4} + \frac{\widehat{\alpha}}{\pi}\left(\frac{85}{24} - \frac{\pi^2}{2}\right) + \delta_q\right], \qquad (10.51)$$

and Γ_τ^e and Γ_τ^μ can be taken from Eq. (10.6) with obvious replacements. The relative fraction of decays with $\Delta S = -1$, $\mathcal{B}_\tau^s = 0.0286 \pm 0.0007$, is based on experimental data since the value for the strange quark mass, $\widehat{m}_s(m_\tau)$, is not well known and the QCD expansion proportional to $\widehat{m}_s^2$ converges poorly and cannot be trusted. $S(m_\tau, M_Z) = 1.01907 \pm 0.0003$ is a logarithmically enhanced EW correction factor with higher orders re-summed [192]. δ_q contains the dimension six and eight terms in the OPE, as well as DV effects, $\delta_{D=6,8} + \delta_{DV} = -0.004 \pm 0.012$ [193]. Depending on how $\delta_{D=6}$, $\delta_{D=8}$, and δ_{DV} are extracted, there are strong correlations not only between them, but also with the gluon condensate ($D = 4$) and possibly $D > 8$ terms. These latter are suppressed in Eq. (10.51) by additional factors of α_s, but not so for more general weight functions. A simultaneous fit to all non-perturbative terms [193] (as is necessary if one wants to avoid *ad hoc* assumptions) indicates that the α_s errors may have been underestimated in the past. Higher statistics τ decay data [36] and spectral functions from e^+e^- annihilation (providing a larger fit window and thus more discriminatory power and smaller correlations) are likely to reduce the δ_q error in the future. Also included in δ_q are quark mass effects and the $D = 4$ condensate contributions. An uncertainty of similar size arises from the truncation of the FOPT series and is conservatively taken as the α_s^4 term (this is re-calculated in each call of the fits, leading to an α_s-dependent and thus asymmetric error) until a better understanding of the numerical differences between FOPT and CIPT has been gained. Our perturbative error covers almost the entire range from using CIPT to assuming that the nearly geometric series in Eq. (10.51) continues to higher orders. The experimental uncertainty in Eq. (10.50), is from the combination of the two leptonic branching ratios with the direct τ_τ. Included are also various smaller uncertainties (± 0.5 fs) from other sources which are dominated by the evolution from the Z scale. In total we obtain a $\sim 2\%$ determination of $\alpha_s(M_Z) = 0.1193^{+0.0022}_{-0.0020}$, which corresponds to $\alpha_s(m_\tau) = 0.327^{+0.019}_{-0.016}$, and updates the result of Refs. 45 and 194. For more details, see Refs. 193 and 195 where the τ spectral functions are used as additional input.

The world average of the muon anomalous magnetic moment[‡],

$$a_\mu^{\text{exp}} = \frac{g_\mu - 2}{2} = (1165920.80 \pm 0.63) \times 10^{-9}, \qquad (10.52)$$

is dominated by the final result of the E821 collaboration at BNL [196]. The QED contribution has been calculated to five loops [197] (fully analytic to three loops [198,199]). The estimated SM EW contribution [200–202], $a_\mu^{\text{EW}} = (1.52 \pm 0.03) \times 10^{-9}$, which includes leading two-loop [201] and three-loop [202] corrections, is at the level of twice the current uncertainty.

The limiting factor in the interpretation of the result are the uncertainties from the two- and three-loop hadronic contribution [203]. *E.g.,* Ref. 20 obtained the value $a_\mu^{\text{had}} = (69.23 \pm 0.42) \times 10^{-9}$ which combines CMD-2 [38] and SND [39] $e^+e^- \to$ hadrons cross-section data with radiative return results from BaBar [41] and KLOE [42]. This value suggests a 3.6 σ discrepancy between Eq. (10.52) and the SM prediction. An alternative analysis [20] using τ decay data and isospin symmetry (CVC) yields $a_\mu^{\text{had}} = (70.15 \pm 0.47) \times 10^{-9}$. This result implies a smaller conflict (2.4 σ) with Eq. (10.52). Thus, there is also a discrepancy between the spectral functions obtained from the two methods. For example, the channel that is relevant for the determination of a_μ^{had} from τ data, $\tau^- \to \nu_\tau \pi^- \pi^0$, has been measured to have a branching ratio of 25.51 ± 0.09 (global average), while if one uses the e^+e^- data and CVC to predict the branching ratio [20] we obtain an average of $\mathcal{B}_{\text{CVC}} = 24.93 \pm 0.13 \pm 0.22\,_{\text{CVC}}$, which is 2.3 σ lower. It is important to understand the origin of this difference, but two observations point to the conclusion that at least some of it is experimental: (i) There is also a direct discrepancy of 1.9 σ between $\mathcal{B}_{\text{CVC}}$ derived from BaBar (which is not inconsistent with τ decays) and KLOE. (ii) Isospin violating corrections have been studied in detail in Ref. 204 and found to be largely under control. The largest effect is due to higher-order EW corrections [205] but introduces a negligible uncertainty [192]. Nevertheless, a_μ^{had} is often evaluated excluding the τ decay data arguing [206] that CVC breaking effects (*e.g.*, through a relatively large mass difference between the $\rho^\pm$ and ρ^0 vector mesons) may be larger than expected. (This may also be relevant [206] in the context of the NuTeV result discussed above.) Experimentally [36], this mass difference is indeed larger than expected, but then one would also expect a significant width difference which is contrary to observation [36] [#]. Fortunately, due to the suppression at large s (from where the conflicts originate) these problems are less pronounced as far as a_μ^{had} is concerned. In the

[‡] In what follows, we summarize the most important aspects of $g_\mu - 2$, and give some details on the evaluation in our fits. For more details see the dedicated contribution on "The Muon Anomalous Magnetic Moment" in this *Review*. There are some small numerical differences (at the level of 0.1 standard deviations), which are well understood and mostly arise because internal consistency of the fits requires the calculation of all observables from analytical expressions and common inputs and fit parameters, so that an independent evaluation is necessary for this Section. Note, that in the spirit of a global analysis based on all available information we have chosen here to average in the τ decay data, as well.

[#] In the model of Ref. 207 an additional isospin correction due to γ–ρ mixing leads to a $\rho^\pm$–ρ^0 mass splitting that is large enough to reconcile the discrepancy between τ and e^+e^- data, but there is some debate about the magnitude of this effect [208].

following we view all differences in spectral functions as (systematic) fluctuations and average the results.

An additional uncertainty is induced by the hadronic three-loop light-by-light scattering contribution. Several recent independent model calculations yield compatible results: $a_\mu^{\rm LBLS} = (+1.36 \pm 0.25) \times 10^{-9}$ [209], $a_\mu^{\rm LBLS} = +1.37^{+0.15}_{-0.27} \times 10^{-9}$ [210], $a_\mu^{\rm LBLS} = (+1.16 \pm 0.40) \times 10^{-9}$ [211], and $a_\mu^{\rm LBLS} = (+1.05 \pm 0.26) \times 10^{-9}$ [212]. The sign of this effect is opposite [213] to the one quoted in the 2002 edition of this *Review*, and its magnitude is larger than previous evaluations [213,214]. There is also an upper bound $a_\mu^{\rm LBLS} < 1.59 \times 10^{-9}$ [210] but this requires an *ad hoc* assumption, too. Very recently, first results from lattice simulations have been obtained, finding agreement with the model calculations, although with large errors [215]. For the fits, we take the result from Ref. 212, shifted by 2×10^{-11} to account for the more accurate charm quark treatment of Ref. 210, and with increased error to cover all recent evaluations, resulting in $a_\mu^{\rm LBLS} = (+1.07 \pm 0.32) \times 10^{-9}$.

Other hadronic effects at three-loop order contribute [216] $a_\mu^{\rm had}(\alpha^3) = (-1.00 \pm 0.06) \times 10^{-9}$. Correlations with the two-loop hadronic contribution and with $\Delta\alpha(M_Z)$ (see Sec. 10.2) were considered in Ref. 199 which also contains analytic results for the perturbative QCD contribution.

Altogether, the SM prediction is

$$a_\mu^{\rm theory} = (1165918.41 \pm 0.48) \times 10^{-9} \,, \qquad (10.53)$$

where the error is from the hadronic uncertainties excluding parametric ones such as from α_s and the heavy quark masses. Using a correlation of about 84% from the data input to the vacuum polarization integrals [20], we estimate the correlation of the total (experimental plus theoretical) uncertainty in a_μ with $\Delta\alpha(M_Z)$ as 24%. The overall 3.0 σ discrepancy between the experimental and theoretical a_μ values could be due to fluctuations (the E821 result is statistics dominated) or underestimates of the theoretical uncertainties. On the other hand, the deviation could also arise from physics beyond the SM, such as supersymmetric models with large $\tan\beta$ and moderately light superparticle masses [217], or a dark Z boson [187].

10.6. Global fit results

In this section we present the results of global fits to the experimental data discussed in Sec. 10.3–Sec. 10.5. For earlier analyses see Refs. [11,113,218]

The values for m_t [48,49], M_W [170,219], Γ_W [170,220], M_H [181,182] and the ratios of Higgs branching fractions discussed in Sec. 10.4.5, ν-lepton scattering [79–84], the weak charges of the electron [117], the proton [122], cesium [125,126] and thallium [127], the weak mixing angle extracted from eDIS [109], the muon anomalous magnetic moment [196], and the τ lifetime are listed in Table 10.4. Likewise, the principal Z pole observables can be found in Table 10.5 where the LEP 1 averages of the ALEPH, DELPHI, L3, and OPAL results include common systematic errors and correlations [11]. The heavy flavor results of LEP 1 and SLD are based on common inputs and correlated, as well [11].

Note that the values of $\Gamma(\ell^+\ell^-)$, Γ(had), and Γ(inv) are not independent of Γ_Z, the R_ℓ, and $\sigma_{\rm had}$ and that the SM errors in those latter are largely dominated by the uncertainty in α_s. Also shown in both Tables are the SM predictions for the values of M_Z, M_H, $\alpha_s(M_Z)$, $\Delta\alpha^{(3)}_{\rm had}$ and the heavy quark masses shown in Table 10.6. The predictions result from a global least-square (χ^2) fit to all data using the minimization package MINUIT [221] and the EW library GAPP [21]. In most cases, we treat all input errors (the uncertainties of the values) as Gaussian. The reason is not that we assume that theoretical and systematic errors are intrinsically bell-shaped (which they are not) but because in most cases the input errors are either dominated by the statistical components or they are combinations of many different (including statistical) error sources, which should yield approximately Gaussian *combined* errors by the large number theorem. An exception is the theory dominated error on the τ lifetime, which we recalculate in each χ^2-function call since it depends itself on α_s. Sizes and shapes of the output errors (the uncertainties of the predictions and the SM fit parameters) are fully determined by the fit, and 1 σ errors are defined to correspond to $\Delta\chi^2 = \chi^2 - \chi^2_{\rm min} = 1$, and do not necessarily correspond to the 68.3% probability range or the 39.3% probability contour (for 2 parameters).

Table 10.4: Principal non-Z pole observables, compared with the SM best fit predictions. The first M_W and Γ_W values are from the Tevatron [219,220] and the second ones from LEP 2 [170]. The value of m_t differs from the one in the Particle Listings since it includes recent preliminary results. The world averages for $g^{\nu e}_{V,A}$ are dominated by the CHARM II [82] results, $g_V^{\nu e} = -0.035 \pm 0.017$ and $g_A^{\nu e} = -0.503 \pm 0.017$. The errors are the total (experimental plus theoretical) uncertainties. The τ_τ value is the τ lifetime world average computed by combining the direct measurements with values derived from the leptonic branching ratios [45]; in this case, the theory uncertainty is included in the SM prediction. In all other SM predictions, the uncertainty is from M_Z, M_H, m_t, m_b, m_c, $\widehat{\alpha}(M_Z)$, and α_s, and their correlations have been accounted for. The column denoted Pull gives the standard deviations.

Quantity	Value	Standard Model	Pull
m_t [GeV]	173.24 ± 0.95	173.87 ± 0.87	-0.7
M_W [GeV]	80.387 ± 0.016	80.363 ± 0.006	1.5

$\rho_{\gamma W}$	0.45 ± 0.31	0.01 ± 0.03	1.4
	0.12 ± 0.43	0.00 ± 0.03	0.3
$\rho_{\gamma Z}$	0.08 ± 0.28	0.01 ± 0.04	0.2
ρ_{ZW}	0.30 ± 0.39	0.00 ± 0.01	0.8
$g_V^{\nu e}$	-0.040 ± 0.015	-0.0397 ± 0.0001	0.0
$g_A^{\nu e}$	-0.507 ± 0.014	-0.5064	0.0
$Q_W(e)$	-0.0403 ± 0.0053	-0.0473 ± 0.0003	1.3
$Q_W(p)$	0.064 ± 0.012	0.0708 ± 0.0003	-0.6
Q_W(Cs)	-72.62 ± 0.43	-73.25 ± 0.01	1.5
Q_W(Tl)	-116.4 ± 3.6	-116.90 ± 0.02	0.1
$\widehat{s}^2_Z$(eDIS)	0.2299 ± 0.0043	0.23126 ± 0.00005	-0.3
τ_τ [fs]	291.13 ± 0.43	291.19 ± 2.41	0.0
$\frac{1}{2}(g_\mu - 2 - \frac{\alpha}{\pi})$	$(4511.07 \pm 0.79) \times 10^{-9}$	$(4508.68 \pm 0.08) \times 10^{-9}$	3.0

The agreement is generally very good. Despite the few discrepancies discussed in the following, the fit describes the data well, with a χ^2/d.o.f. = 48.3/44. The probability of a larger χ^2 is 30%. Only the final result for $g_\mu - 2$ from BNL is currently showing a large (3.0 σ) deviation. In addition, $A_{FB}^{(0,b)}$ from LEP 1 and A^0_{LR} (SLD) from hadronic final states differ by more than 2 σ. g_L^2 from NuTeV is nominally in conflict with the SM, as well, but the precise status is under investigation (see Sec. 10.3).

A_b can be extracted from $A_{FB}^{(0,b)}$ when $A_e = 0.1501 \pm 0.0016$ is taken from a fit to leptonic asymmetries (using lepton universality). The result, $A_b = 0.881 \pm 0.017$, is 3.2 σ below the SM prediction[§] and also 1.6 σ below $A_b = 0.923 \pm 0.020$ obtained from $A_{LR}^{FB}(b)$ at SLD. Thus, it appears that at least some of the problem in A_b is due to a statistical fluctuation or other experimental effect in one of the asymmetries. Note, however, that the uncertainty in $A_{FB}^{(0,b)}$ is strongly statistics dominated. The combined value, $A_b = 0.899 \pm 0.013$ deviates by 2.8 σ. It would be difficult to account for this 4.0% deviation by new physics that enters only at the level of radiative corrections

[§] Alternatively, one can use $A_\ell = 0.1481 \pm 0.0027$, which is from LEP 1 alone and in excellent agreement with the SM, and obtain $A_b = 0.893 \pm 0.022$ which is 1.9 σ low. This illustrates that some of the discrepancy is related to the one in A_{LR}.

Table 10.5: Principal Z pole observables and their SM predictions (*cf.* Table 10.4). The first $\bar{s}^2_\ell$ is the effective weak mixing angle extracted from the hadronic charge asymmetry, the second is the combined value from the Tevatron [163,164,165], and the third from the LHC [168,169]. The values of A_e are (i) from A_{LR} for hadronic final states [154]; (ii) from A_{LR} for leptonic final states and from polarized Bhabba scattering [156]; and (iii) from the angular distribution of the τ polarization at LEP 1. The A_τ values are from SLD and the total τ polarization, respectively.

Quantity	Value	Standard Model	Pull

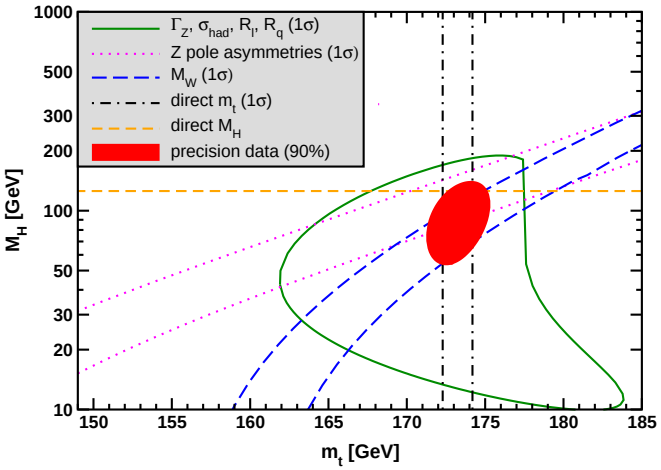

Figure 10.4: Fit result and one-standard-deviation (39.35% for the closed contours and 68% for the others) uncertainties in M_H as a function of m_t for various inputs, and the 90% CL region ($\Delta\chi^2 = 4.605$) allowed by all data. $\alpha_s(M_Z) = 0.1185$ is assumed except for the fits including the Z lineshape. The width of the horizontal dashed (yellow) band is not visible on the scale of the plot.

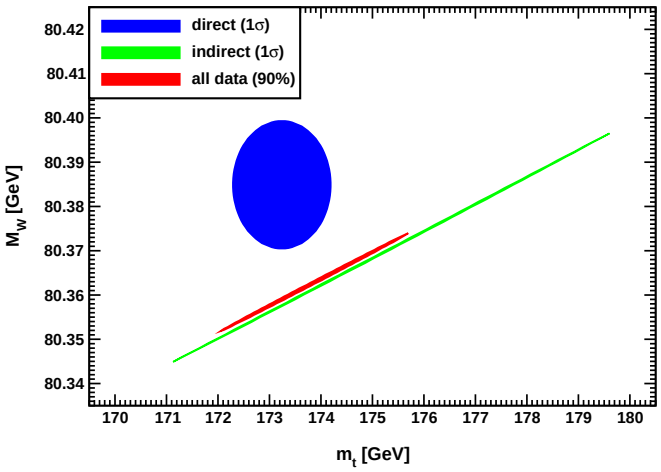

Figure 10.5: One-standard-deviation (39.35%) region in M_W as a function of m_t for the direct and indirect data, and the 90% CL region ($\Delta\chi^2 = 4.605$) allowed by all data.

since about a 20% correction to $\widehat{\kappa}_b$ would be necessary to account for the central value of A_b [222]. If this deviation is due to new physics, it is most likely of tree-level type affecting preferentially the third generation. Examples include the decay of a scalar neutrino resonance [223], mixing of the b quark with heavy exotics [224], and a heavy Z' with family non-universal couplings [225,226]. It is difficult, however, to simultaneously account for R_b, which has been measured on the Z peak and off-peak [227] at LEP 1. An average of R_b measurements at LEP 2 at energies between 133 and 207 GeV is 2.1 σ below the SM prediction, while $A_{FB}^{(b)}$ (LEP 2) is 1.6 σ low [171].

The left-right asymmetry, $A^0_{LR} = 0.15138 \pm 0.00216$ [154], based on all hadronic data from 1992–1998 differs 2.1 σ from the SM expectation of 0.1468 ± 0.0004. The combined value of $A_\ell = 0.1513 \pm 0.0021$ from SLD (using lepton-family universality and including correlations) is also 2.1 σ above the SM prediction; but there is experimental agreement between this SLD value and the LEP 1 value, $A_\ell = 0.1481 \pm 0.0027$, obtained from a fit to $A_{FB}^{(0,\ell)}$, $A_e(\mathcal{P}_\tau)$, and $A_\tau(\mathcal{P}_\tau)$, again assuming universality.

The observables in Table 10.4 and Table 10.5, as well as some other less precise observables, are used in the global fits described below. In all fits, the errors include full statistical, systematic, and theoretical uncertainties. The correlations on the LEP 1 lineshape and τ polarization, the LEP/SLD heavy flavor observables, the SLD lepton asymmetries, and the ν-e scattering observables, are included. The theoretical correlations between $\Delta\alpha^{(5)}_{\rm had}$ and $g_\mu - 2$, and between the charm and bottom quark masses, are also accounted for.

The data allow a simultaneous determination of M_Z, M_H, m_t, and the strong coupling $\alpha_s(M_Z)$. ($\widehat{m}_c$, $\widehat{m}_b$, and $\Delta\alpha^{(3)}_{\rm had}$ are also allowed to float in the fits, subject to the theoretical constraints [19,45] described in Sec. 10.2. These are correlated with α_s.) α_s is determined mainly from R_ℓ, Γ_Z, $\sigma_{\rm had}$, and τ_τ. The global fit to all data, including the hadron collider average $m_t = 173.24 \pm 0.95$ GeV, yields the result in Table 10.6 (the $\overline{\rm MS}$ top quark mass given there corresponds to $m_t = 173.87 \pm 0.87$ GeV). The weak mixing angle, see Table 10.2, is determined to

$$\widehat{s}^2_Z = 0.23126 \pm 0.00005, \qquad s^2_W = 0.22333 \pm 0.00011,$$

while the corresponding effective angle is $\bar{s}^2_\ell = 0.23155 \pm 0.00005$.

One can also perform a fit without the direct mass constraint, $M_H = 125.6 \pm 0.4$ GeV, in Eq. (10.47). In this case we obtain a 2% indirect mass determination,

$$M_H = 123.7 \pm 2.3 \text{ GeV}\,, \qquad (10.54)$$

Table 10.6: Principal SM fit result including mutual correlations (all masses in GeV). Note that $\widehat{m}_c(\widehat{m}_c)$ induces a significant uncertainty in the running of α beyond $\Delta\alpha^{(3)}_{\rm had}(1.8\ {\rm GeV})$ resulting in a relatively large correlation with M_H. Since this effect is proportional to the quark's electric charge squared it is much smaller for $\widehat{m}_b(\widehat{m}_b)$.

M_Z	91.1880 ± 0.0020	1.00	−0.08	0.01	−0.01	0.02	0.04	0.01
$\widehat{m}_t(\widehat{m}_t)$	164.09 ± 0.83	−0.08	1.00	0.00	−0.06	−0.16	0.08	0.06
$\widehat{m}_b(\widehat{m}_b)$	4.199 ± 0.024	0.01	0.00	1.00	0.26	−0.02	0.05	0.02

$M_{W,Z}$, $\Gamma_{W,Z}$, m_t	0.23105(14)	0.22292(29)	0.1173(43)	173.2 ± 0.9	$86^{+\ 27}_{-\ 23}$
low energy + $M_{H,Z}$	0.2327(14)	0.2289(54)	0.1195(21)	$123 \quad \pm 44$	125.6 ± 0.4

arising predominantly from the quantities in Eq. (10.49), since the branching ratio for $H \to ZZ^*$ varies very rapidly as a function of M_H for Higgs masses near 125 GeV. It is interesting to note that this value is closer to the ATLAS Higgs mass measurement in the ZZ^* channel, $M_H = 124.3^{+0.6}_{-0.5}({\rm stat.})^{+0.5}_{-0.3}({\rm syst.})$ GeV, which differs by more than 2 σ from their $\gamma\gamma$ result, $M_H = 126.8 \pm 0.2\,{\rm stat.} \pm 0.7\,{\rm syst.}$ GeV. Removing also the branching ratio constraints gives the loop-level determination from the precision data alone,

$$M_H = 89^{+22}_{-18}\ {\rm GeV}\ , \tag{10.55}$$

which is 1.5 σ below the kinematical constraint. This is mostly a reflection of the Tevatron determination of M_W, which is 1.5 σ higher than the SM best fit value in Table 10.4. Another consequence is that the 90% central confidence range determined from the precision data,

$$60\ {\rm GeV} < M_H < 127\ {\rm GeV}\ , \tag{10.56}$$

is only marginally consistent with Eq. (10.47). This is illustrated in Fig. 10.4 where one sees that the precision data together with M_H from the LHC prefer that m_t is closer to the upper end of its 1σ allowed range. Conversely, one can remove the direct M_W and Γ_W constraints from the fits and use Eq. (10.47) to obtain $M_W = 80.358 \pm 0.007$ GeV. This is 1.7 σ below the Tevatron/LEP 2 average, $M_W = 80.385 \pm 0.015$ GeV. Finally, one can carry out a fit without including the constraint, $m_t = 173.24 \pm 0.95$ GeV, from the hadron colliders. (The indirect prediction is for the $\overline{\rm MS}$ mass, $\widehat{m}_t(\widehat{m}_t) = 167.1 \pm 2.0$ GeV, which is in the end converted to the pole mass.) One obtains $m_t = 177.0 \pm 2.1$ GeV, which is 1.6 σ higher than the direct Tevatron/LHC average. The situation is summarized in Fig. 10.5 showing the 1 σ contours in the M_W-m_t plane from the direct and indirect determinations, as well as the combined 90% CL region.

As described in Sec. 10.2 and the paragraph following Eq. (10.52) in Sec. 10.5, there is considerable stress in the experimental e^+e^- spectral functions and also conflict when these are compared with τ decay spectral functions. These are below or above the 2σ level (depending on what is actually compared) but not larger than the deviations of some other quantities entering our analyses. The number and size or these deviations are not inconsistent with what one

would expect to happen as a result of random fluctuations. It is nevertheless instructive to study the effect of doubling the uncertainty in $\Delta\alpha^{(3)}_{\rm had}(1.8\ {\rm GeV}) = (55.50 \pm 0.78) \times 10^{-4}$ (see Sec. 10.2) on the loop-level determination. The result, $M_H = 86^{+22}_{-18}$ GeV, deviates even slightly *more* (1.6 σ) than Eq. (10.55), and demonstrates that the uncertainty in $\Delta\alpha_{\rm had}$ is currently of only secondary importance. Note also that a shift of $\pm 10^{-4}$ in $\Delta\alpha^{(3)}_{\rm had}(1.8\ {\rm GeV})$ corresponds to a shift of ∓ 4.3 GeV in M_H. The hadronic contribution to $\alpha(M_Z)$ is correlated with $g_\mu - 2$ (see Sec. 10.5). The measurement of the latter is higher than the SM prediction, and its inclusion in the fit favors a larger $\alpha(M_Z)$ and a lower M_H from the precision data (currently by 3.4 GeV).

The weak mixing angle can be determined from Z pole observables, M_W, and from a variety of neutral-current processes spanning a very wide Q^2 range. The results (for the older low energy neutral-current data see Refs. 113 and 218, as well as earlier editions of this *Review*) shown in Table 10.7 are in reasonable agreement with each other, indicating the quantitative success of the SM. The largest discrepancy is the value $\widehat{s}^2_Z = 0.23193 \pm 0.00029$ from the forward-backward asymmetries into bottom and charm quarks, which is 2.3 σ above the value 0.23126 ± 0.00005 from the global fit to all data, see Table 10.5. Similarly, $\widehat{s}^2_Z = 0.23067 \pm 0.00028$ from the SLD asymmetries (in both cases when combined with M_Z) is 2.1 σ low. The SLD result has the additional difficulty (within the SM) of implying very low and excluded [230] Higgs masses. This is also true for $\widehat{s}^2_Z = 0.23105 \pm 0.00014$ from M_W and M_Z and, as a consequence, for the global fit.

Table 10.8: Values of the model-independent neutral-current parameters, compared with the SM predictions. There is a second $g^{\nu e}_{LV,LA}$ solution, given approximately by $g^{\nu e}_{LV} \leftrightarrow g^{\nu e}_{LA}$, which is eliminated by e^+e^- data under the assumption that the neutral current is dominated by the exchange of a single Z boson. The $g^{\nu q}_{LL}$, as well as the $g^{\nu q}_{LR}$, are strongly correlated and non-Gaussian, so that for implementations we recommend the parametrization using g_i^2 and $\tan\theta_i = g^{\nu u}_{Li}/g^{\nu d}_{Li}$ where $i = L, R$. In the SM predictions, the parametric uncertainties from M_Z, M_H, m_t, m_b, m_c, $\widehat{\alpha}(M_Z)$, and α_s are negligible.

Quantity	Experimental Value	Standard Model	Correlation
$g^{\nu u}_{LL}$	0.328 ± 0.016	0.3457	
$g^{\nu d}_{LL}$	-0.440 ± 0.011	-0.4288	non-
$g^{\nu u}_{LR}$	-0.179 ± 0.013	-0.1553	Gaussian
$g^{\nu d}_{LR}$	$-0.027\ ^{+0.077}_{-0.048}$	0.0777	
g^2_L	0.3005 ± 0.0028	0.3034	
g^2_R	0.0329 ± 0.0030	0.0301	small
$\tan\theta_L$	$2.50 \quad \pm 0.035$	2.4630	
$\tan\theta_R$	$4.56 \quad ^{+0.42}_{-0.27}$	5.1765	
$g^{\nu e}_{LV}$	-0.040 ± 0.015	-0.0396	-0.05
$g^{\nu e}_{LA}$	-0.507 ± 0.014	-0.5064

$2\,g^{eu}_{AV} - g^{ed}_{AV}$	-0.708 ± 0.016	-0.7192	-0.45
$2\,g^{eu}_{VA} - g^{ed}_{VA}$	-0.144 ± 0.068	-0.0950	
g^{ee}_{VA}	0.0190 ± 0.0027	0.0225	

The extracted Z pole value of $\alpha_s(M_Z)$ is based on a formula with negligible theoretical uncertainty if one assumes the exact validity of the SM. One should keep in mind, however, that this value, $\alpha_s(M_Z) = 0.1197 \pm 0.0027$, is very sensitive to certain types of new physics such as non-universal vertex corrections. In contrast, the value derived from τ decays, $\alpha_s(M_Z) = 0.1193^{+0.0022}_{-0.0020}$, is theory dominated but less sensitive to new physics. The two values are in remarkable agreement with each other. They are also in perfect agreement with the averages from jet-event shapes in e^+e^- annihilation (0.1177 ± 0.0046) and lattice simulations (0.1185 ± 0.0005), whereas the DIS average (0.1154 ± 0.0020) is somewhat lower. For more details, other determinations, and references, see Section 9 on "Quantum Chromodynamics" in this *Review*.

Using $\alpha(M_Z)$ and $\widehat{s}^2_Z$ as inputs, one can predict $\alpha_s(M_Z)$ assuming grand unification. One finds [231] $\alpha_s(M_Z) = 0.130 \pm 0.001 \pm 0.01$ for the simplest theories based on the minimal supersymmetric extension of the SM, where the first (second) uncertainty is from the inputs (thresholds). This is slightly larger, but consistent with $\alpha_s(M_Z) = 0.1193 \pm 0.0016$ from our fit, as well as with most other determinations. Non-supersymmetric unified theories predict the low value $\alpha_s(M_Z) = 0.073 \pm 0.001 \pm 0.001$. See also the note on "Supersymmetry" in the Searches Particle Listings.

Most of the parameters relevant to ν-hadron, ν-e, e-hadron, and $e^-e^\pm$ processes are determined uniquely and precisely from the data in "model-independent" fits (*i.e.*, fits which allow for an arbitrary EW gauge theory). The values for the parameters defined in Eqs. (10.16)–(10.17) are given in Table 10.8 along with the predictions of the SM. The agreement is very good. (The ν-hadron results including the original NuTeV data can be found in the 2006 edition of this *Review*, and fits with modified NuTeV constraints in the 2008 and 2010 editions.) The off Z pole e^+e^- results are difficult to present in a model-independent way because Z propagator effects are non-negligible at TRISTAN, PETRA, PEP, and LEP 2 energies. However, assuming e-μ-τ universality, the low energy lepton asymmetries imply [151] $4\,(g^e_A)^2 = 0.99 \pm 0.05$, in good agreement with the SM prediction $\simeq 1$.

10.7. Constraints on new physics

The masses and decay properties of the electroweak bosons and low energy data can be used to search for and set limits on deviations from the SM. We will mainly discuss the effects of exotic particles (with heavy masses $M_{\rm new} \gg M_Z$ in an expansion in $M_Z/M_{\rm new}$) on the gauge boson self-energies. (Brief remarks are made on new physics which is not of this type.) Most of the effects on precision measurements can be described by three gauge self-energy parameters S, T, and U. We will define these, as well as the related parameters ρ_0, ϵ_i, and $\widehat{\epsilon}_i$, to arise from new physics only. In other words, they are equal to zero ($\rho_0 = 1$) exactly in the SM, and do not include any (loop induced) contributions that depend on m_t or M_H, which are treated separately. Our treatment differs from most of the original papers.

The dominant effect of many extensions of the SM can be described by the ρ_0 parameter,

$$\rho_0 \equiv \frac{M_W^2}{M_Z^2\,\widehat{c}^2_Z\,\widehat{\rho}}\ , \tag{10.57}$$

which describes new sources of SU(2) breaking that cannot be accounted for by the SM Higgs doublet or m_t effects. $\widehat{\rho}$ is calculated as in Eq. (10.12) assuming the validity of the SM. In the presence of $\rho_0 \neq 1$, Eq. (10.57) generalizes the second Eq. (10.12) while the first remains unchanged. Provided that the new physics which yields $\rho_0 \neq 1$ is a small perturbation which does not significantly affect other radiative corrections, ρ_0 can be regarded as a phenomenological parameter which multiplies G_F in Eqs. (10.16)–(10.17), (10.32), and Γ_Z in Eq. (10.44*c*). There are enough data to determine ρ_0, M_H, m_t, and α_s, simultaneously. From the global fit,

$$\rho_0 = 1.00040 \pm 0.00024\ , \tag{10.58}$$

$$\alpha_s(M_Z) = 0.1194 \pm 0.0017, \tag{10.59}$$

and M_H and m_t are as given in Table 10.6 and Table 10.5. The result in Eq. (10.58) is 1.7 σ above the SM expectation, $\rho_0 = 1$. It can be used to constrain higher-dimensional Higgs representations to have vacuum expectation values of less than a few percent of those of the doublets. Indeed, the relation between M_W and M_Z is modified if there are Higgs multiplets with weak isospin $> 1/2$ with significant vacuum expectation values. For a general (charge-conserving) Higgs structure,

$$\rho_0 = \frac{\sum_i [t(i)(t(i)+1) - t_3(i)^2]|v_i|^2}{2\sum_i t_3(i)^2|v_i|^2}, \tag{10.60}$$

where v_i is the expectation value of the neutral component of a Higgs multiplet with weak isospin $t(i)$ and third component $t_3(i)$. In order to calculate to higher orders in such theories one must define a set of four fundamental renormalized parameters which one may conveniently choose to be α, G_F, M_Z, and M_W, since M_W and M_Z are directly measurable. Then $\widehat{s}^2_Z$ and ρ_0 can be considered dependent parameters.

Eq. (10.58) can also be used to constrain other types of new physics. For example, non-degenerate multiplets of heavy fermions or scalars break the vector part of weak SU(2) and lead to a decrease in the value of M_Z/M_W. Each non-degenerate SU(2) doublet $\binom{f_1}{f_2}$ yields a positive contribution to ρ_0 [232] of

$$\frac{C\,G_F}{8\sqrt{2}\pi^2}\Delta m^2, \tag{10.61}$$

where

$$\Delta m^2 \equiv m_1^2 + m_2^2 - \frac{4m_1^2 m_2^2}{m_1^2 - m_2^2}\ln\frac{m_1}{m_2} \geq (m_1 - m_2)^2, \tag{10.62}$$

and $C = 1$ (3) for color singlets (triplets). Eq. (10.58) taken together with Eq. (10.61) implies the following constraint on the mass splitting at the 95% CL,

$$\sum_i \frac{C_i}{3}\,\Delta m_i^2 \leq (50\ \text{GeV})^2. \tag{10.63}$$

where the sum runs over all new-physics doublets, for example fourth-family quarks or leptons, $\binom{t'}{b'}$ or $\binom{\nu'}{\ell'-}$, vector-like fermion doublets (which contribute to the sum in Eq. (10.63) with an extra factor of 2), and scalar doublets such as $\binom{\tilde{t}}{\tilde{b}}$ in Supersymmetry (in the absence of L–R mixing).

Non-degenerate multiplets usually imply $\rho_0 > 1$. Similarly, heavy Z' bosons decrease the prediction for M_Z due to mixing and generally lead to $\rho_0 > 1$ [233]. On the other hand, additional Higgs doublets which participate in spontaneous symmetry breaking [234] or heavy lepton doublets involving Majorana neutrinos [235], both of which have more complicated expressions, as well as the vacuum expectation values of Higgs triplets or higher-dimensional representations can contribute to ρ_0 with either sign. Allowing for the presence of heavy degenerate chiral multiplets (the S parameter, to be discussed below) affects the determination of ρ_0 from the data, at present leading to a slightly larger value.

A number of authors [236–241] have considered the general effects on neutral-current and Z and W boson observables of various types of heavy (*i.e.*, $M_{\rm new} \gg M_Z$) physics which contribute to the W and Z self-energies but which do not have any direct coupling to the ordinary fermions. In addition to non-degenerate multiplets, which break the vector part of weak SU(2), these include heavy degenerate multiplets of chiral fermions which break the axial generators.

Such effects can be described by just three parameters, S, T, and U, at the (EW) one-loop level. (Three additional parameters are needed if the new physics scale is comparable to M_Z [242]. Further generalizations, including effects relevant to LEP 2, are described in Ref. 243.) T is proportional to the difference between the W and Z self-energies at $Q^2 = 0$ (*i.e.*, vector SU(2)-breaking), while S ($S+U$) is associated with the difference between the Z (W) self-energy at $Q^2 = M^2_{Z,W}$ and $Q^2 = 0$ (axial SU(2)-breaking). Denoting the contributions of new physics to the various self-energies by $\Pi^{\rm new}_{ij}$, we have

$$\widehat{\alpha}(M_Z)T \equiv \frac{\Pi^{\rm new}_{WW}(0)}{M_W^2} - \frac{\Pi^{\rm new}_{ZZ}(0)}{M_Z^2}\ , \tag{10.64a}$$

$$\frac{\widehat{\alpha}(M_Z)}{4\,\widehat{s}^2_Z\widehat{c}^2_Z}S \equiv \frac{\Pi^{\rm new}_{ZZ}(M_Z^2) - \Pi^{\rm new}_{ZZ}(0)}{M_Z^2} - \frac{\widehat{c}^2_Z - \widehat{s}^2_Z}{\widehat{c}_Z\widehat{s}_Z}\,\frac{\Pi^{\rm new}_{Z\gamma}(M_Z^2)}{M_Z^2} - \frac{\Pi^{\rm new}_{\gamma\gamma}(M_Z^2)}{M_Z^2}\ , \tag{10.64b}$$

$$\frac{\widehat{\alpha}(M_Z)}{4\,\widehat{s}^2_Z}(S+U) \equiv \frac{\Pi^{\rm new}_{WW}(M_W^2) - \Pi^{\rm new}_{WW}(0)}{M_W^2} - \frac{\widehat{c}_Z}{\widehat{s}_Z}\,\frac{\Pi^{\rm new}_{Z\gamma}(M_Z^2)}{M_Z^2} - \frac{\Pi^{\rm new}_{\gamma\gamma}(M_Z^2)}{M_Z^2}\ . \tag{10.64c}$$

S, T, and U are defined with a factor proportional to $\widehat{\alpha}$ removed, so that they are expected to be of order unity in the presence of new physics. In the $\overline{\rm MS}$ scheme as defined in Ref. 53, the last two terms in Eqs. (10.64*b*) and (10.64*c*) can be omitted (as was done in some earlier editions of this *Review*). These three parameters are related to other parameters (S_i, h_i, $\widehat{\epsilon}_i$) defined in Refs. [53,237,238] by

$$\begin{aligned} T &= h_V = \widehat{\epsilon}_1/\widehat{\alpha}(M_Z), \\ S &= h_{AZ} = S_Z = 4\,\widehat{s}^2_Z\,\widehat{\epsilon}_3/\widehat{\alpha}(M_Z), \\ U &= h_{AW} - h_{AZ} = S_W - S_Z \\ &= -4\,\widehat{s}^2_Z\,\widehat{\epsilon}_2/\widehat{\alpha}(M_Z). \end{aligned} \tag{10.65}$$

A heavy non-degenerate multiplet of fermions or scalars contributes positively to T as

$$\rho_0 - 1 = \frac{1}{1 - \widehat{\alpha}(M_Z)T} - 1 \simeq \widehat{\alpha}(M_Z)T, \tag{10.66}$$

where $\rho_0 - 1$ is given in Eq. (10.61). The effects of non-standard Higgs representations cannot be separated from heavy non-degenerate multiplets unless the new physics has other consequences, such as vertex corrections. Most of the original papers defined T to include the effects of loops only. However, we will redefine T to include all new sources of SU(2) breaking, including non-standard Higgs, so that T and ρ_0 are equivalent by Eq. (10.66).

A multiplet of heavy degenerate chiral fermions yields

$$S = \frac{C}{3\pi}\sum_i \Big(t_{3L}(i) - t_{3R}(i)\Big)^2, \tag{10.67}$$

where $t_{3L,R}(i)$ is the third component of weak isospin of the left- (right-)handed component of fermion i and C is the number of colors. For example, a heavy degenerate ordinary or mirror family would contribute $2/3\pi$ to S. In models with warped extra dimensions, sizeable correction to the S parameter are generated by mixing effects between the SM gauge bosons and their Kaluza-Klein (KK) excitations. One finds $S \approx 30v^2/M^2_{KK}$, where M_{KK} is the mass of the KK gauge bosons [244]. Large positive values $S > 0$ can also be generated in Technicolor models with QCD-like dynamics, where one expects [236] $S \sim 0.45$ for an iso-doublet of techni-fermions, assuming $N_{TC} = 4$ techni-colors, while $S \sim 1.62$ for a full techni-generation with $N_{TC} = 4$. However, the QCD-like models are excluded on other grounds (flavor changing neutral currents, too-light quarks and pseudo-Goldstone bosons [245], and absence of a Higgs-like scalar).

On the other hand, negative values $S < 0$ are possible, for example, for models of walking Technicolor [246] or loops involving scalars or Majorana particles [247]. The simplest origin of $S < 0$ would probably be an additional heavy Z' boson [233]. Supersymmetric extensions of the SM generally give very small effects. See Refs. 248 and 249 and the note on "Supersymmetry" in the Searches Particle Listings for a complete set of references.

Most simple types of new physics yield $U = 0$, although there are counter-examples, such as the effects of anomalous triple gauge vertices [238].

The SM expressions for observables are replaced by

$$\begin{aligned} M_Z^2 &= M_{Z0}^2\,\frac{1 - \widehat{\alpha}(M_Z)T}{1 - G_F M_{Z0}^2 S/2\sqrt{2}\pi}\ , \\ M_W^2 &= M_{W0}^2\,\frac{1}{1 - G_F M_{W0}^2(S+U)/2\sqrt{2}\pi}\ , \end{aligned} \tag{10.68}$$

where M_{Z0} and M_{W0} are the SM expressions (as functions of m_t and M_H) in the $\overline{\rm MS}$ scheme. Furthermore,

$$\Gamma_Z = \frac{M_Z^3\beta_Z}{1 - \widehat{\alpha}(M_Z)T}, \Gamma_W = M_W^3\beta_W, A_i = \frac{A_{i0}}{1 - \widehat{\alpha}(M_Z)T}\ , \tag{10.69}$$

where β_Z and β_W are the SM expressions for the reduced widths Γ_{Z0}/M^3_{Z0} and Γ_{W0}/M^3_{W0}, M_Z and M_W are the physical masses, and A_i (A_{i0}) is a neutral-current amplitude (in the SM).

The data allow a simultaneous determination of $\widehat{s}^2_Z$ (from the Z pole asymmetries), S (from M_Z), U (from M_W), T (mainly from Γ_Z), α_s (from R_ℓ, $\sigma_{\rm had}$, and τ_τ), M_H and m_t (from the hadron colliders), with little correlation among the SM parameters:

$$\begin{aligned} S &= -0.03 \pm 0.10, \\ T &= 0.01 \pm 0.12, \\ U &= 0.05 \pm 0.10, \end{aligned} \tag{10.70}$$

$\widehat{s}^2_Z = 0.23119 \pm 0.00016$, and $\alpha_s(M_Z) = 0.1196 \pm 0.0017$, where the uncertainties are from the inputs. The parameters in Eqs. (10.70), which by definition are due to new physics only, are in excellent agreement with the SM values of zero. Fixing $U = 0$ (as is also done in Fig. 10.6) moves S and T slightly upwards,

$$\begin{aligned} S &= 0.00 \pm 0.08, \\ T &= 0.05 \pm 0.07. \end{aligned} \tag{10.71}$$

Again, good agreement with the SM is observed. If only any one of the three parameters is allowed, then this parameter would deviate at the 1.5 to 1.7 σ level, reflecting the deviation in M_W. Using Eq. (10.66), the value of ρ_0 corresponding to T in Eq. (10.70) is 1.0000 ± 0.0009, while the one corresponding to Eq. (10.71) is 1.0004 ± 0.0005.

There is a strong correlation (90%) between the S and T parameters. The U parameter is -59% (-81%) anti-correlated with S (T). The allowed regions in S–T are shown in Fig. 10.6. From Eqs. (10.70) one obtains $S \leq 0.14$ and $T \leq 0.20$ at 95% CL, where the former puts the constraint $M_{KK} \gtrsim 3.5$ TeV on the masses of KK gauge bosons in warped extra dimensions.

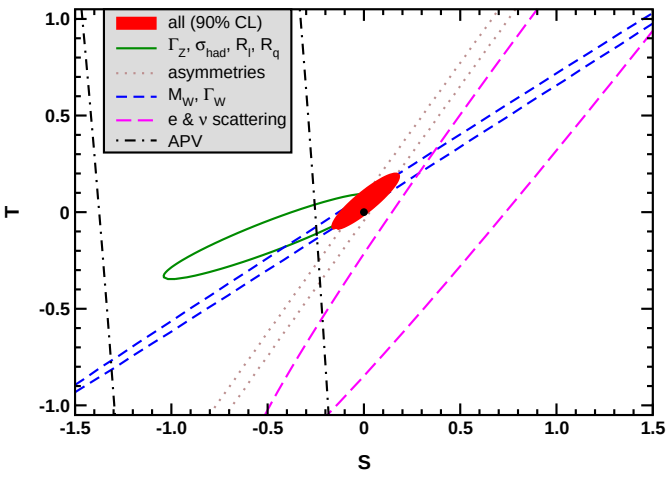

Figure 10.6: 1 σ constraints (39.35%) on S and T (for $U = 0$) from various inputs combined with M_Z. S and T represent the contributions of new physics only. Data sets not involving M_W or Γ_W are insensitive to U. With the exception of the fit to all data, we fix $\alpha_s = 0.1185$. The black dot indicates the Standard Model values $S = T = 0$.

The S parameter can also be used to constrain the number of fermion families, *under the assumption* that there are no new contributions to T or U and therefore that any new families are degenerate; then an extra generation of SM fermions is excluded at the 7 σ level corresponding to $N_F = 2.75 \pm 0.17$. This can be compared to the fit to the number of light neutrinos given in Eq. (10.37), $N_\nu = 2.990 \pm 0.007$. However, the S parameter fits are valid even for a very heavy fourth family neutrino. Allowing T to vary as well, the constraint on a fourth family is weaker [250]. However, a heavy fourth family would increase the Higgs production cross section through gluon fusion by a factor ~ 9, which is in considerable tension with the observed Higgs signal at LHC. Combining the limits from electroweak precision data with the measured Higgs production rate and limits from direct searches for heavy quarks [251], a fourth family of chiral fermions is now excluded by more than five standard deviations [252]. Similar remarks apply to a heavy mirror family [253] involving right-handed SU(2) doublets and left-handed singlets. In contrast, new doublets that receive most of their mass from a different source than the Higgs vacuum expectation value, such as vector-like fermion doublets or scalar doublets in Supersymmetry, give small or no contribution to S, T, U and the Higgs production cross section and thus are still allowed. Partial or complete vector-like fermion families are predicted in many grand unified theories [254].

There is no simple parametrization to describe the effects of every type of new physics on every possible observable. The S, T, and U formalism describes many types of heavy physics which affect only the gauge self-energies, and it can be applied to all precision observables. However, new physics which couples directly to ordinary fermions, such as heavy Z' bosons [233], mixing with exotic fermions [255], or leptoquark exchange [170,256] cannot be fully parametrized in the S, T, and U framework. It is convenient to treat these types of new physics by parameterizations that are specialized to that particular class of theories (*e.g.*, extra Z' bosons), or to consider specific models (which might contain, *e.g.,* Z' bosons and exotic fermions with correlated parameters). Fits to Supersymmetric models are described in Ref. 249. Models involving strong dynamics (such as (extended) Technicolor) for EW breaking are considered in Ref. 257. The effects of compactified extra spatial dimensions at the TeV scale are reviewed in Ref. 258, and constraints on Little Higgs models in Ref. 259. The implications of non-standard Higgs sectors, e.g., involving Higgs singlets or triplets, are discussed in Ref. 260, while additional Higgs doublets are considered in Refs. 234 and 261. Limits on new four-Fermi operators and on leptoquarks using LEP 2 and lower energy data are given in Refs. 170 and 262. Constraints on various types of new physics are reviewed in Refs. [7,75,113,138,153,263,264], and implications for the LHC in Ref. 265.

An alternate formalism [266] defines parameters, ϵ_1, ϵ_2, ϵ_3, and ϵ_b in terms of the specific observables M_W/M_Z, $\Gamma_{\ell\ell}$, $A_{FB}^{(0,\ell)}$, and R_b. The definitions coincide with those for $\widehat{\epsilon}_i$ in Eqs. (10.64) and (10.65) for physics which affects gauge self-energies only, but the ϵ's now parametrize arbitrary types of new physics. However, the ϵ's are not related to other observables unless additional model-dependent assumptions are made. Another approach [267] parametrizes new physics in terms of gauge-invariant sets of operators. It is especially powerful in studying the effects of new physics on non-Abelian gauge vertices. The most general approach introduces deviation vectors [263]. Each type of new physics defines a deviation vector, the components of which are the deviations of each observable from its SM prediction, normalized to the experimental uncertainty. The length (direction) of the vector represents the strength (type) of new physics.

One well explored type of physics beyond the SM are extra Z' bosons [268]. They do not spoil the observed approximate gauge coupling unification, and appear in many Grand Unified Theories (GUTs), models with extra dimensions [258], as well as in dynamical symmetry breaking [257] and Little Higgs models [259]. For example, the SO(10) GUT contains an extra U(1) as can be seen from its maximal subgroup, $\mathrm{SU}(5) \times \mathrm{U}(1)_\chi$. Similarly, the E_6 GUT contains the subgroup $\mathrm{SO}(10) \times \mathrm{U}(1)_\psi$. The Z_ψ possesses only axial-vector couplings to the ordinary fermions, and its mass is generally less constrained. The Z_η boson is the linear combination $\sqrt{3/8}\,Z_\chi - \sqrt{5/8}\,Z_\psi$. The Z_{LR} boson occurs in left-right models with gauge group $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{SU}(2)_R \times \mathrm{U}(1)_{B-L} \subset \mathrm{SO}(10)$, and the secluded Z_S emerges in a supersymmetric bottom-up scenario [269]. The sequential Z_{SM} boson is defined to have the same couplings to fermions as the SM Z boson. Such a boson is not expected in the context of gauge theories unless it has different couplings to exotic fermions than the ordinary Z boson. However, it serves as a useful reference case when comparing constraints from various sources. The physical Z' boson is in general a superposition of the SM Z and the new boson associated with the extra U(1). The mixing angle θ

Table 10.9: 95% CL lower mass limits (in GeV) on various extra Z' gauge bosons, appearing in models of unification. More general parametrizations are described in Refs. 268 and 271. The EW results [272] from low energy and W and Z boson data are for Higgs sectors consisting of doublets and singlets only ($\rho_0 = 1$) with unspecified $U(1)'$ charges. The next two columns show the limits from ATLAS [273] and CMS [274] from the combination of both lepton channels. The CDF [275] and DØ [276] bounds from searches in $\bar{p}p \to \mu^+\mu^-$ and e^+e^-, respectively, are listed in the next two columns, followed by the LEP 2 $e^+e^- \to f\bar{f}$ bounds [170] (assuming $\theta = 0$). The hadron collider bounds would be moderately weakened if there are open exotic decay channels [277]. The last column shows the 1 σ ranges for M_H when it is left unconstrained in the EW fits.

Z'	EW	ATLAS	CMS	CDF	DØ	LEP 2	M_H
Z_χ	1,141	2,540	–	930	903	785	$171^{+493}_{-\ 89}$
Z_ψ	147	2,380	2,600	917	891	500	$97^{+\ 31}_{-\ 25}$
Z_η	427	2,440	–	938	923	500	423^{+577}_{-350}
Z_{LR}	998	–	–	–	–	825	$804^{+174}_{-\ 35}$
Z_S	1,257	2,470	–	858	822	–	$149^{+353}_{-\ 68}$
Z_{SM}	1,403	2,860	2,960	1,071	1,023	1,760	331^{+669}_{-246}

satisfies,

$$\tan^2\theta = \frac{M^2_{Z^0_1} - M^2_Z}{M^2_{Z'} - M^2_{Z^0_1}} \ ,$$

where $M_{Z^0_1}$ is the SM value for M_Z in the absence of mixing. Note that $M_Z < M_{Z^0_1}$, and that the SM Z couplings are changed by the mixing. The couplings of the heavier Z' may also be modified by kinetic mixing [268,270]. If the Higgs U(1)$'$ quantum numbers are known, there will be an extra constraint,

$$\theta = C\,\frac{g_2}{g_1}\frac{M^2_Z}{M^2_{Z'}} \ ,$$

where $g_{1,2}$ are the U(1) and U(1)$'$ gauge couplings with $g_2 = \sqrt{\frac{5}{3}}\sin\theta_W\sqrt{\lambda}\,g_1$ and $g_1 = \sqrt{g^2 + g'^2}$. We assume that $\lambda \sim 1$, which happens if the GUT group breaks directly to SU(3) × SU(2) × U(1) × U(1)$'$. C is a function of vacuum expectation values. For minimal Higgs sectors it can be found in Ref. 233. Table 10.9 shows the 95% CL lower mass limits [272] for $\rho_0 = 1$ and 114.4 GeV $\leq M_H \leq$ 1 TeV. The last column shows the 1 σ ranges for M_H when it is left unconstrained. In cases of specific minimal Higgs sectors where C is known, the Z' mass limits from the EW precision data are generally pushed into the TeV region. The limits on $|\theta|$ are typically smaller than a few $\times 10^{-3}$. The mass bounds from direct searches at the LHC [273,274], however, exceed the EW precison constraints by a factor two or more for the models considered here. While the latter can be slightly improved by fixing M_H to the value measured at LHC, this general conclusion will not change. Also listed in Table 10.9 are the direct lower limits on Z' production from the Tevatron [275,276], as well as the LEP 2 bounds [170]. For more details see [268,272,278,279] and the note on "The Z' Searches" in the Gauge & Higgs Boson Particle Listings.

Acknowledgments:

We are indebted to M. Davier, B. Malaescu, and K. Maltman for providing us with additional information about their work in a form suitable to be included in our fits. We also thank R. H. Bernstein, K. S. McFarland, H. Schellman, and G. P. Zeller for discussions on the NuTeV analysis, and M. Spira for details about HDECAY. J.E. was supported by PAPIIT (DGAPA–UNAM) project IN106913 and CONACyT (México) project 151234, and grateful acknowledges the hospitality and support by the Mainz Institute for Theoretical Physics (MITP) where part of this work was completed. A.F. is supported in part by the National Science Foundation under grant no. PHY-1212635.

11. STATUS OF HIGGS BOSON PHYSICS

Written November 2013 by M. Carena (Fermi National Accelerator Laboratory and the University of Chicago), C. Grojean (ICREA at IFAE, Universitat Autònoma de Barcelona), M. Kado (Laboratoire de l'Accélérateur Linéaire, LAL and CERN), and V. Sharma (University of California San Diego).

I. Introduction

The observation by ATLAS [1] and CMS [2] of a new boson with a mass of approximately 125 GeV decaying into $\gamma\gamma$, WW and ZZ bosons and the subsequent studies of the properties of this particle is a milestone in the understanding of the mechanism that breaks electroweak symmetry and generates the masses of the known elementary particles[1], one of the most fundamental problems in particle physics.

In the Standard Model, the mechanism of electroweak symmetry breaking (EWSB) [3] provides a general framework to keep untouched the structure of the gauge interactions at high energy and still generate the observed masses of the W and Z gauge bosons by means of charged and neutral Goldstone bosons that manifest themselves as the longitudinal components of the gauge bosons. The discovery of ATLAS and CMS now strongly suggests that these three Goldstone bosons combine with an extra (elementary) scalar boson to form a weak doublet.

This picture matches very well with the Standard Model (SM) [4] which describes the electroweak interactions by a gauge field theory invariant under the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ symmetry group. In the SM, the EWSB mechanism posits a self-interacting complex doublet of scalar fields, and the renormalizable interactions are arranged such

[1] In the case of neutrinos, it is possible that the EWSB mechanism plays only a partial role in generating the observed neutrino masses, with additional contributions at a higher scale via the so called see-saw mechanism.

that the neutral component of the scalar doublet acquires a vacuum expectation value (VEV) $v \approx 246\,\text{GeV}$, which sets the scale of electroweak symmetry breaking.

Three massless Goldstone bosons are generated, which are absorbed to give masses to the W and Z gauge bosons. The remaining component of the complex doublet becomes the Higgs boson – a new fundamental scalar particle. The masses of all fermions are also a consequence of EWSB since the Higgs doublet is postulated to couple to the fermions through Yukawa interactions. However, the true structure behind the newly discovered boson, including the exact dynamics that triggers the Higgs VEV, and the corresponding ultraviolet completion is still unsolved.

Even if the discovered boson has weak couplings to all known SM degrees of freedom, it is not impossible that it is part of an extended symmetry structure or that it emerges from a light resonance of a strongly coupled sector. It needs to be established whether the Higgs boson is solitary or whether other states populate the EWSB sector.

Without the Higgs boson, the calculability of the SM would have been spoiled. In particular, perturbative unitarity [5,6] would be lost at high energies as the longitudinal W/Z boson scattering amplitude would grow as the centre-of-mass energy increases. Moreover, the radiative corrections to the self-energies of the gauge boson pertaining their longitudinal components would exhibit dangerous logarithmic divergences. With the discovery of the Higgs boson, it has been experimentally established that the SM is based on a gauge theory that could a priori be consistently extrapolated to the Planck scale. The Higgs boson must have couplings to W/Z gauge bosons and fermions precisely as those in the SM to maintain the consistency of the theory at high energies, hence, formally there is no need for new physics at the EW scale. However, the SM Higgs boson is a scalar particle, therefore without a symmetry to protect its mass, at the quantum level it has sensitivity to the physics in the ultraviolet. Quite generally, the Higgs mass parameter may be affected by the presence of heavy particles. Specifically, apart from terms proportional to m^2 itself, which are corrected by the Higgs field anomalous dimension, if there are fermion and boson particles with squared masses $m^2_{F,B} + \lambda^2_{F,B}\phi^2/2$,

$$m^2(Q) = m^2(\mu) + \delta m^2, \tag{11.1}$$

$$\delta m^2 = \sum_{B,F} g_{B,F}(-1)^{2S}\frac{\lambda^2_{B,F} m^2_{B,F}}{32\pi^2}\log(\frac{Q^2}{\mu^2}), \tag{11.2}$$

where $g_{B,F}$ and S correspond to the number of degrees of freedom and the spin of the boson and fermion particles, respectively. Therefore, particles that couple to the Higgs and have a large mass parameter $m^2_{B,F}$ would induce very large corrections to the Higgs mass parameter, demanding a large fine tuning to explain why m^2 remains small. Hence, in general, light scalars like the Higgs boson cannot naturally survive in the presence of heavy states at the grand-unification, string or Planck scales. This is known as the hierarchy or naturalness problem [7]. In the Standard Model where there are no other explicit mass parameter than the Higgs one, all corrections are proportional to the Higgs mass parameter itself.

There are two possible preferred solutions to the naturalness problem: one is based on a new fermion-boson symmetry in nature called supersymmetry (SUSY) [8–10]. This is a weakly coupled approach to EWSB, and in this case, the Higgs boson remains elementary and the corrections to its mass are cut at the scale at which SUSY is broken and remain insensitive to the details of the physics at higher scales. These theories predict at least one charged and three neutral Higgs particles[2] [12], and one of the neutral Higgs bosons, most often the lightest *CP*-even Higgs, has properties that resemble those of the SM Higgs boson. It will be referred to as a SM-like Higgs boson, meaning that its VEV is predominantly responsible for EWSB, and hence has SM-like couplings to the W and Z gauge bosons.

The other approach invokes the existence of strong interactions at a scale of the order of a TeV or above and induces strong breaking of the electroweak symmetry [13]. In the original incarnation of this second approach, dubbed technicolor, the strong interactions themselves trigger EWSB without the need of a Higgs boson. Another possibility, more compatible with the ATLAS and CMS discovery, is that the strong interactions produce 4 light resonances identified with the Higgs doublet and EWSB proceeds through vacuum misalignment [14].

Both approaches can have important effects on the phenomenology of the Higgs boson associated with EWSB. Also, in each case the Higgs role in unitarization is shared by other particles: additional Higgs bosons in supersymmetry, or new particles in the strong sector.

A third option has also been considered in the literature. It is also a variation of technicolor or Higgsless models [13,15]. In light of the Higgs boson discovery these models are ruled out. However, there still exists the possibility that the Higgs discovered at the LHC is in fact the Goldstone boson of the spontaneous breaking of scale invariance at a scale f [16,17]. Given the good agreement of the coupling measurements with the SM predictions, this scenario now requires rather involved model-building engineering.

The naturalness problem has been the prime argument for new physics at the TeV scale. But the absence of any direct signal of new dynamics and the apparent agreement of the Higgs couplings with the SM predictions, together with the strong bounds inherited from precision electroweak and flavor data leaves open the possibility that the Higgs boson may very well be elementary, weakly coupled and solitary till the Planck scale. Such a scenario, would force physicists to rethink the basic concepts of high energy physics.

In this review, some of the most interesting models proposed in the above two categories will be discussed in detail. Extensions of the SM Higgs sector without low-energy supersymmetry will also be discussed. These type of models do not address the naturalness problem in a specific manner, but provide grounds to explore new Higgs boson signals in a more model-independent way, with different types of coupling structure to fermions and gauge bosons. Extended Higgs sectors are usually quite restricted by experimental constraints from precision electroweak measurements as well as constraints from flavor changing neutral and charged current effects.

Section II is a review of the Higgs boson of the Standard Model, discussing its properties and the production mechanisms and decay rates. In Section III, the SM Higgs boson analysis channels are described. In Section IV, a general theoretical framework to describe the deviations of the Higgs couplings from the SM predictions is introduced and the experimental measurements of these Higgs couplings is reviewed together with the analysis establishing the spin and *CP*-properties of the Higgs boson. Section V presents, in detail, some of the most interesting models proposed for Higgs extensions of the SM and considers their experimental signatures. Section VI provides a brief outlook.

II. The Standard Model and the Mechanism of Electroweak Symmetry Breaking

As mentioned above, in the SM [4], the mechanism of electroweak symmetry breaking [3] is responsible for generating mass for the W and Z gauge bosons rendering the weak interactions short range. The SM scalar potential reads:

$$V(\Phi) = m^2\Phi^\dagger\Phi + \lambda(\Phi^\dagger\Phi)^2 \tag{11.3}$$

with the Higgs field Φ being a self-interacting SU(2) complex doublet (four real degrees of freedom) with weak hypercharge Y=1 (the hypercharge is normalized such that $Q = T_{3L} + Y/2$):

$$\Phi = \frac{1}{\sqrt{2}}\begin{pmatrix}\sqrt{2}\phi^+\\ \phi^0 + ia^0\end{pmatrix}. \tag{11.4}$$

$V(\Phi)$ is the most general renormalizable scalar potential and if the quadratic term is negative the neutral component of the scalar doublet

[2] Except in exotic SUSY scenarios where the Higgs boson is identified as a sneutrino, the scalar partner of a neutrino [11], in which case the gauge anomalies cancel without the need for a second Higgs doublet

acquires a non-zero vacuum expectation value (VEV)

$$\langle\Phi\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix}0\\ v\end{pmatrix}, \tag{11.5}$$

defining $\phi^0 = H + v$, inducing the spontaneous breaking of the SM gauge symmetry $\mathrm{SU(3)}_C \times \mathrm{SU(2)}_L \times \mathrm{U(1)}_Y$ into $\mathrm{SU(3)}_C \times \mathrm{U(1)}_{\rm em}$. The global minimum of the theory defines the ground state, and spontaneous symmetry breaking implies that there is a symmetry of the system (Lagrangian) that is not respected by the ground state. The Higgs field permeates the entire universe and through its self-interactions can cause spontaneous electroweak symmetry-breaking (EWSB) in the vacuum. From the 4 generators of the $\mathrm{SU(2)}_L \times \mathrm{U(1)}_Y$ gauge group, three are spontaneously broken, implying that they lead to non-trivial transformations of the ground state and indicate the existence of three massless Goldstone bosons identified with three of the four Higgs field degrees of freedom. The Higgs field couples to the W_μ and B_μ gauge fields associated with the $\mathrm{SU(2)}_L \times \mathrm{U(1)}_Y$ local symmetry, respectively, through the covariant derivative, $D_\mu\Phi = (\partial_\mu + ig\sigma^a W^a_\mu/2 + ig'YB_\mu/2)\Phi$ (g and g' are the SU(2) and U(1) gauge couplings and $\sigma^a, a = 1, 2, 3$ are the usual Pauli matrices) appearing in the kinetic term of the Higgs Lagrangian

$$\mathcal{L}_{\rm Higgs} = (D_\mu\Phi)^\dagger(D^\mu\Phi) - V(\Phi)\,. \tag{11.6}$$

As a result, the neutral and the two charged massless Goldstone degrees of freedom mix with the gauge fields corresponding to the broken generators of $\mathrm{SU(2)}_L \times \mathrm{U(1)}_Y$ and become the longitudinal components of the Z and W physical gauge bosons, respectively. The fourth generator remains unbroken since it is the one associated to the conserved $\mathrm{U(1)}_{\rm em}$ gauge symmetry, and its corresponding gauge field, the photon, remains massless. Similarly the eight color gauge bosons, the gluons, corresponding to the conserved $\mathrm{SU(3)}_C$ gauge symmetry with 8 unbroken generators, also remain massless. Hence, from the initial four degrees of freedom of the Higgs field, two are absorbed by the $W^\pm$ gauge bosons and one by the Z gauge boson that become massive:

$$M_W^2 = \frac{g^2v^2}{4} \quad M_Z^2 = \frac{(g'^2+g^2)v^2}{4}. \tag{11.7}$$

There is one remaining degree of freedom, H, that is the physical Higgs boson — a new scalar particle. The Higgs boson is neutral under the electromagnetic interactions and transforms as a singlet under $\mathrm{SU(3)}_C$ and hence does not couple at tree level to the massless photons and gluons.

The fermions of the SM acquire mass through a new type of renormalizable interactions between the Higgs field and the fermions: the Yukawa interactions,

$$\mathcal{L}_{\rm Yukawa} = -\hat{h}_{d_{ij}}\bar{q}_{L_i}\Phi\, d_{R_j} - \hat{h}_{u_{ij}}\bar{q}_{L_i}\tilde{\Phi}u_{R_j} - \hat{h}_{l_{ij}}\bar{l}_{L_i}\Phi\, e_{R_j} + h.c., \tag{11.8}$$

that respect the symmetries of the SM but generate fermion masses once EWSB occurs. In the above, $\tilde{\Phi} = i\sigma_2\Phi^*$ and q_L (l_L) and u_R, d_R (e_R) are the quark (lepton) $\mathrm{SU(2)}_L$ doublets and singlets, respectively, while each term is parametrized by a 3×3 matrix in family space. The mass term for neutrinos is omitted, but could be added in an analogous manner to the up type quarks when right-handed neutrinos are supplementing the SM particle content. Once the Higgs acquires a VEV, and after rotation to the fermion mass eigenstate basis that also diagonalize the Higgs-fermion interactions, $\hat{h}_{f_{ij}} \to h_f \mathbf{1_{3\times3}}$, all fermions acquire a mass given by $m_f = h_f v/\sqrt{2}$. It should be noted that the EWSB mechanism provides no additional insight on possible underlying reasons for the large variety of masses of the fermions, often referred to as the flavor hierarchy. The fermion masses, accounting for a large number of the free parameters of the SM are simply translated in terms of Yukawa couplings h_f.

II.1. The SM Higgs boson mass, couplings and quantum numbers

The SM Higgs boson is a *CP*-even scalar of spin 0. Its mass is given by $m_H = \sqrt{2\lambda}\,v$, where λ is the Higgs self-coupling parameter in $V(\Phi)$. The expectation value of the Higgs field, $v = (\sqrt{2}G_F)^{-1/2} \approx 246\,\mathrm{GeV}$, is fixed by the Fermi coupling G_F, which is determined with a precision of 0.6 ppm from muon decay measurements [18]. The quartic coupling λ, instead, is a free parameter in the SM, and hence there is, a priori, no prediction for the Higgs mass. Moreover the sign of the mass parameter $m^2 = -\lambda v^2$ is crucial for the EW symmetry breaking to take place, but it is not specified in the SM. Therefore, if the newly discovered particle is indeed the SM Higgs boson with $m_H \simeq 125\,\mathrm{GeV}$, it implies that $\lambda \simeq 0.13$ and $|m| \simeq 88.8\,\mathrm{GeV}$. It is interesting to observe that in the SM one needs to assume that the mass term in the potential is negative in order to trigger EWSB. In other theories beyond the SM (BSM), such as supersymmetry, the analogue of the Higgs mass parameter can be made negative dynamically.

The Higgs boson couplings to the fundamental particles are set by their masses. This is a new type of interaction, very weak for ordinary particles, such as up and down quarks, and electrons, but strong for heavy particles such as the W and Z bosons and the top quark. More precisely, the SM Higgs couplings to fundamental fermions are linearly proportional to the fermion masses, whereas the couplings to bosons are proportional to the square of the boson masses. The SM Higgs boson couplings to gauge bosons, Higgs bosons and fermions are summarized in the following Lagrangian:

$$\begin{aligned}\mathcal{L} = &- g_{Hff}\bar{f}fH + \frac{g_{HHH}}{6}H^3 + \frac{g_{HHHH}}{24}H^4 \\ &+ \delta_V V_\mu V^\mu\left(g_{HVV}H + \frac{g_{HHVV}}{2}H^2\right)\end{aligned} \tag{11.9}$$

with

$$g_{Hf\bar{f}} = \frac{m_f}{v}, \quad g_{HVV} = \frac{2m_V^2}{v}, \quad g_{HHVV} = \frac{2m_V^2}{v^2} \tag{11.10}$$

$$g_{HHH} = \frac{3m_H^2}{v}, \quad g_{HHHH} = \frac{3m_H^2}{v^2} \tag{11.11}$$

where $V = \mathrm{W}^\pm$ or Z and $\delta_W = 1, \delta_Z = 1/2$. As a result, the dominant mechanisms for Higgs boson production and decay involve the coupling of H to W, Z and/or the third generation quarks and leptons. The Higgs boson coupling to gluons [19,20], is induced at leading order by a one-loop graph in which H couples to a virtual $t\bar{t}$ pair. Likewise, the Higgs boson coupling to photons is also generated via loops, although in this case the one-loop graph with a virtual W^+W^- pair provides the dominant contribution [12] and the one involving a virtual $t\bar{t}$ pair is subdominant.

II.2. The SM custodial symmetry

The SM Higgs Lagrangian, $\mathcal{L}_{\rm Higgs}$ of Eq. (11.6), is, by construction, $\mathrm{SU(2)}_L \times \mathrm{U(1)}_Y$ gauge invariant, but it also has an approximate global symmetry. In the limit $g' \to 0$ and $h_f \to 0$, the Higgs sector has a global $\mathrm{SU(2)}_R$ symmetry, and hence in such limit it is invariant under a global $\mathrm{SU(2)}_L \times \mathrm{SU(2)}_R$ symmetry, with $\mathrm{SU(2)}_L$ just being the global variant of the SM chiral gauge symmetry. This symmetry is preserved for non-vanishing Yukawa couplings, provided $h_u = h_d$. Once the Higgs acquires a VEV, both the $\mathrm{SU(2)}_L$ and $\mathrm{SU(2)}_R$ symmetry groups are broken but the subgroup $\mathrm{SU(2)}_{L+R}$ remains unbroken and is the subgroup that defines the custodial symmetry of the SM [21].

In the limit $g' \to 0$ ($\sin^2\theta_W \to 0$), the W and Z gauge bosons have equal mass and form a triplet of the $\mathrm{SU(2)}_{L+R}$ unbroken global symmetry. The ρ parameter characterizes the breaking of the custodial symmetry, which manifest itself in the equality of the three tree-level SU(2)-gauge boson masses, even when $g' \neq 0$. Using the expressions for the W and Z gauge boson masses in term of the gauge couplings, one obtains

$$\frac{M_W^2}{M_Z^2} = \frac{g^2}{g'^2+g^2} = \cos^2\theta_W \quad \text{or} \quad \rho = \frac{M_W^2}{M_Z^2\cos^2\theta_W} = 1 \tag{11.12}$$

at tree level. The custodial symmetry protects the above relation between the W and Z masses under radiative corrections. All corrections to the ρ parameter are therefore proportional to terms that break the custodial symmetry. For instance, radiative corrections

involving the Higgs are proportional to g'^2. Since $m_t \neq m_b$, there are also relevant radiative corrections generated by massive fermions. They are proportional to $m_t^2 + m_b^2 - 2(m_t^2 m_b^2)\,\log(m_t^2/m_b^2)/(m_t^2 - m_b^2)$ [22].

One can conceive BSM theories in which the Higgs is a pseudo Nambu–Goldstone boson of a strongly interacting sector [23], and/or where there are additional degrees of freedom that may contribute to the W and Z mass via virtual loops, but in as much as the electroweak sector has a manifest custodial symmetry, the theory is protected from large radiative corrections. Precision measurement of the electroweak observables are powerful in constraining such large radiative corrections. The custodial isospin symmetry is a powerful probe of BSM physics. For a pedagogical discussion, see Ref. [24].

II.3. Stability of the Higgs potential

The discovery of a scalar particle with mass $m_H \approx 125\,\text{GeV}$ has far reaching consequences within the SM framework. Such a low value of the Higgs boson mass is in perfect agreement with the upper bound on the Higgs boson mass from perturbative unitarity constraints [5,6], thereby rendering the SM a consistent, calculable theory. Moreover, the precise value of m_H determines the value of the quartic coupling λ at the electroweak scale and makes it possible to investigate its behavior up to high energy scales. A larger value of m_H would have implied that the Higgs self-coupling would become non-perturbative at some scale Λ that could be well below the Planck scale. From the measured values of the Higgs mass, the top quark mass, the W and Z boson masses, and the strong gauge coupling, all within their experimental uncertainties, it follows that, similar to the SM gauge and Yukawa couplings, the Higgs quartic coupling remains perturbative all the way up to M_{Planck} [25].

The recently measured Higgs mass, however, generates an EW Higgs potential in which the vacuum state is at the edge between being stable and metastable. Indeed, for $m_H = 125.7 \pm 0.3\,\text{GeV}$ and allowing all relevant SM observables to fluctuate within their experimental and theoretical uncertainties, the metastability condition seems to be favored [26]. The high energy evolution of λ shows that it becomes negative at energies $\Lambda = \mathcal{O}(10^{10} - 10^{12})\,\text{GeV}$, with a broader range if a 3σ fluctuation in the top quark mass value is allowed, as shown in Fig. 11.1 [26]. When this occurs, the SM Higgs potential develops an instability and the long term existence of the EW vacuum is challenged. This behavior may call for new physics at an intermediate scale before the instability develops, i.e., below M_{Planck} or, otherwise, the electroweak vacuum remains metastable [27]. Therefore, within the SM framework, the relevant question is related to the lifetime of the EW metastable vacuum that is determined by the rate of quantum tunneling from this vacuum into the true vacuum of the theory. The running of the Higgs self coupling slows down at high energies with a cancellation of its β-function at energies just one to two orders of magnitude below the Planck scale [28,26]. This slow evolution of the quartic coupling is responsible for saving the EW vacuum from premature collapse allowing it to survive much longer times than those relevant from astrophysical considerations. It might help the Higgs boson to play the role of an inflaton [30] (see, however, Ref. [31] and references therein for potential issues with this Higgs-as-inflaton idea).

The peculiar behavior of the quartic coupling does not exclude the possibility that the SM might be all what is there up to the quantum gravity scale [29] or it could be the result of a special dynamics or a new symmetry at high energies, such as supersymmetry with possible flat directions. Still, physics at lower energies is desirable to solve other mysteries of the universe such as dark matter or the matter-antimatter asymmetry. The Higgs boson discovery at the LHC leaves all these options open.

II.4. Higgs production and decay mechanisms

Reviews of the SM Higgs boson's properties and phenomenology, with an emphasis on the impact of loop corrections to the Higgs boson decay rates and cross sections, can be found in Refs. [32–38].

II.4.1. Production mechanisms at hadron colliders

The main production mechanisms at the Tevatron and the LHC are gluon fusion, weak-boson fusion, associated production with a gauge boson and associated production with top quarks. Figure 11.2 depicts representative diagrams for these dominant Higgs production processes.

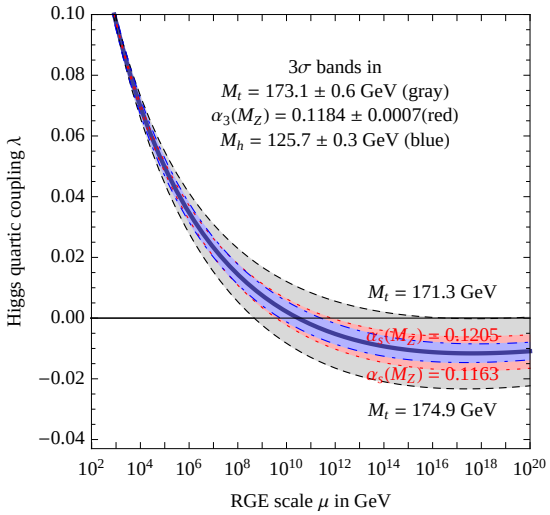

Figure 11.1: Renormalization group evolution of the Higgs self coupling λ, for the central values of $m_H = 125.7\,\text{GeV}$, $m_t = 173.4\,\text{GeV}$ and $\alpha_S(M_Z) = 0.1184$ (solid curve), and variation of these central values by $\pm$ 3 σ for the blue, gray and red, dashed curves, respectively. For negative values of λ, the lifetime of the SM vacuum due to quantum tunneling at zero temperature is longer than the age of the universe. From Ref. [26].

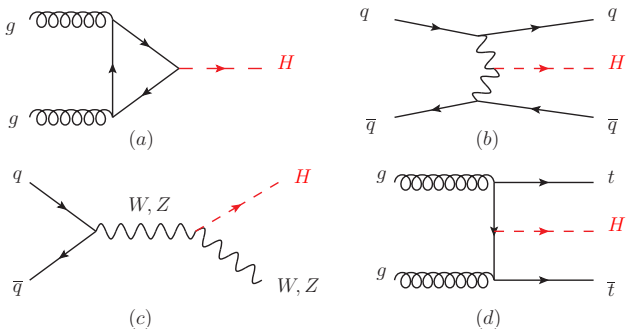

Figure 11.2: Generic Feynman diagrams contributing to the Higgs production in (a) gluon fusion, (b) weak-boson fusion, (c) Higgs-strahlung (or associated production with a gauge boson) and (d) associated production with top quarks.

The cross sections for the production of a SM Higgs boson as a function of $\sqrt{s}$, the center of mass energy, for pp collisions, including bands indicating the theoretical uncertainties, are summarized in Fig. 11.3 [39]. A detailed discussion, including uncertainties in the theoretical calculations due to missing higher order effects and experimental uncertainties on the determination of SM parameters involved in the calculations can be found in Refs. [36–38]. These references also contain state of the art discussions on the impact of PDF's uncertainties, QCD scale uncertainties and uncertainties due to different matching procedures when including higher order corrections matched to parton shower simulations as well as uncertainties due to hadronization and parton-shower events.

Table 11.1, from Refs. [36,38], summarizes the Higgs boson production cross sections and relative uncertainties for a Higgs mass of 125 GeV, for $\sqrt{s} = 7$, 8 and 14 TeV.

Table 11.1: The SM Higgs boson production cross sections or $m_H = 125\,\text{GeV}$ in pp collisions, as a function of the center of mass energy, $\sqrt{s}$. The predictions for the LHC energies are taken from Refs. [36,38], the ones for the Tevatron energy are from Ref. [40].

$\sqrt{s}$ (TeV)	Production cross section (in pb) for $m_H = 125\,\text{GeV}$					
	ggF	VBF	WH	ZH	$t\bar{t}H$	total
1.96	$0.95^{+17\%}_{-17\%}$	$0.065^{+8\%}_{-7\%}$	$0.13^{+8\%}_{-8\%}$	$0.079^{+8\%}_{-8\%}$	$0.004^{+10\%}_{-10\%}$	1.23
7	$15.1^{+15\%}_{-15\%}$	$1.22^{+3\%}_{-2\%}$	$0.58^{+4\%}_{-4\%}$	$0.33^{+6\%}_{-6\%}$	$0.09^{+12\%}_{-18\%}$	17.4
8	$19.3^{+15\%}_{-15\%}$	$1.58^{+3\%}_{-2\%}$	$0.70^{+4\%}_{-5\%}$	$0.41^{+6\%}_{-6\%}$	$0.13^{+12\%}_{-18\%}$	22.1
14	$49.8^{+20\%}_{-15\%}$	$4.18^{+3\%}_{-3\%}$	$1.50^{+4\%}_{-4\%}$	$0.88^{+6\%}_{-5\%}$	$0.61^{+15\%}_{-28\%}$	57.0

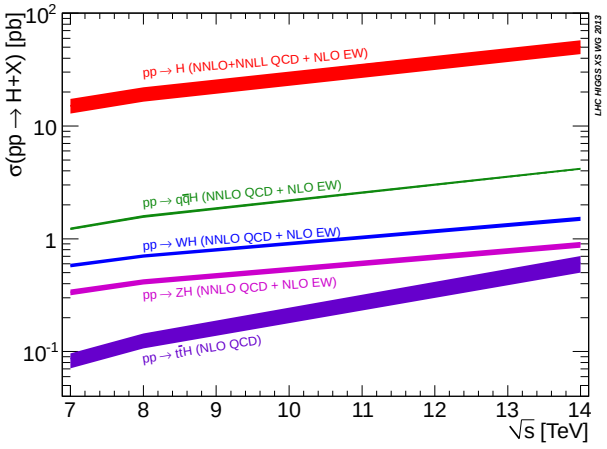

Figure 11.3: The SM Higgs boson production cross sections as a function of the center of mass energy, $\sqrt{s}$, for pp collisions. The theoretical uncertainties [39] are indicated as a band.

(i) Gluon fusion production mechanism

At high-energy hadron colliders, the Higgs boson production mechanism with the largest cross section is the gluon-fusion process, $gg \to H + X$, mediated by the exchange of a virtual, heavy top quark [41]. Contributions from lighter quarks propagating in the loop are suppressed proportional to m_q^2. QCD radiative corrections to the gluon-fusion process are very important and have been studied in detail. Including the full dependence on the quark and Higgs boson masses, the cross section has been calculated at the next-to-leading order (NLO) in α_s [42,43]. To a very good approximation, the leading top-quark contribution can be evaluated in the limit $m_t \to \infty$ by matching the Standard Model to an effective theory. The gluon-fusion amplitude is then evaluated from an effective Lagrangian containing a local $HG^a_{\mu\nu}G^{a\,\mu\nu}$ operator [19,20]. In this approximation the cross section is known at NLO [44] and at next-to-next-to-leading order (NNLO) [45], and a strong effort is under way to extend the calculations to NNNLO. The validity of the large top-quark mass approximation in NNLO calculations has been established at the percent level by means of approximate calculations of the m_t dependence based on asymptotic expansions [46].

The NLO QCD corrections increase the leading-order prediction for the cross section by about 80%, and the NNLO corrections further enhance the cross section by approximately 20% (at $\mu_f = \mu_r = m_H$). The convergence of the perturbation series can be improved by lowering the factorization and renormalization scales. Electroweak radiative corrections have been computed at NLO and increase the cross section by about 5% for $m_H \simeq 125\,\text{GeV}$ [47]. Mixed QCD-electroweak corrections of $O(\alpha\alpha_s)$ have been calculated in Ref. [48].

The NLO and NNLO fixed-order QCD predictions for the gluon-fusion cross section have been improved by resumming the soft-gluon contributions to the cross section at next-to-next-to-leading logarithmic (NNLL) and partial NNNLL accuracy [49]. The convergence of the perturbation series can be improved significantly by systematically resumming a subset of enhanced corrections contained in the time-like gluon form factor, using methods of soft-collinear effective theory [50]. Up-to-date predictions for the gluon-fusion cross section for different Higgs boson masses and LHC energies, and including detailed error budgets, have been obtained by combining the NNLO fixed-order QCD results with soft-gluon resummation at NNLL or NNNLL accuracy and two-loop electroweak corrections, and using the most recent sets of parton distribution functions [48,51].

Besides considering the inclusive Higgs boson production cross section at the LHC, it is important to study differential distributions in order to probe the properties of the Higgs boson in a detailed way. A more exclusive account of Higgs production is also required because experimental analyses often impose cuts on the final states in order to improve the signal-to-background ratio. To this end, it is useful to define benchmark cuts and compare the differential distributions obtained at various levels of theoretical accuracy (i.e., at NLO or NNLO) and with Monte Carlo generators. Many search modes for the Higgs boson are carried out by separating the events according to the number of jets or the transverse momentum and rapidity of the Higgs boson. For $p_T < 30\,\text{GeV}$, predictions for the transverse-momentum distribution can only be trusted after large logarithms of the form $\alpha_s^n \ln^{2n-1}(m_H/p_T)$ have been resummed to all orders in perturbation theory [52]. This has been accomplished with NNLL accuracy [53], and the results have been matched onto the fixed-order prediction at NNLO [54]. Electroweak corrections, and in particular the effect of the non-zero b-quark mass, on the p_T spectrum have been studied in Refs. [55,56]. Recently, there has been much activity in computing Higgs plus jet(s) production processes at NLO (see e.g. Refs. [57] and [58] for associated production with one and two jets, respectively), and even at NNLO [59]. In addition, efforts to improve the calculation of the Higgs production cross section with a jet veto (the "0-jet bin") by resumming large logarithms of the form $\alpha_s^n \ln^{2n-1}(m_H/p_T^{\text{veto}})$ at NNLL order and beyond [60] have been made. Accurate predictions for the jet-veto cross section are required, e.g., to suppress the background in the $H \to WW$ channel.

(ii) Vector boson fusion production mechanism

The SM Higgs production mode with the second-largest cross section at the LHC is the vector boson fusion (VBF). At the Tevatron, VBF also occurs, but for $m_H = 125\,\text{GeV}$ exhibits a smaller cross section than Higgs production in association with a W or Z boson. Higgs production via VBF, $qq \to qqH$, proceeds by the scattering of two (anti-)quarks, mediated by t- or u-channel exchange of a W or Z boson, with the Higgs boson radiated off the weak-boson propagator. The scattered quarks give rise to two hard jets in the forward and backward regions of the detector.[3] Because of the color-singlet nature of the weak-gauge boson exchange, gluon radiation from the central-rapidity regions is strongly suppressed [63]. These characteristic features of VBF processes can be exploited to distinguish them from a priori overwhelming QCD backgrounds, including gluon-fusion induced Higgs + 2 jet production, and from s-channel WH or ZH production with a hadronically decaying weak boson. After the application of specific selection cuts, the VBF channel provides a particularly clean environment not only for Higgs searches but also for the determination of Higgs boson couplings at the LHC [64].

Computations for total cross sections and differential distributions to Higgs production via VBF including NLO QCD and EW corrections have been presented in Refs. [33,65] and are available in the form of flexible parton-level Monte-Carlo generators. Parton-shower effects have been considered in Ref. [66]. Parts of the NNLO QCD corrections have been presented in Refs. [67,68]. The NNLO QCD corrections of Ref. [67] reduce the residual scale uncertainties on the inclusive cross section to approximately 2%. The uncertainties due to parton distributions are estimated to be at the same level.

[3] The production of a Higgs boson with two additional jets has been computed in Refs. [61] and [62].

(iii) WH and ZH associated production mechanism

The next most relevant Higgs boson production mechanisms after gluon fusion and VBF at the LHC, and the most relevant ones after gluon fusion at the Tevatron, are associated production with W and Z gauge bosons. The cross sections for the associated production processes, $pp \to VH + X$, with $V = W^{\pm}, Z$ receive contributions at NLO given by NLO QCD corrections to the Drell–Yan cross section [69,70,71] and from NLO EW corrections. The latter, unlike the QCD corrections, do not respect the factorization into Drell–Yan production since there are irreducible box contributions already at one loop [72]. At NNLO, the Drell-Yan-like corrections to WH production also give the bulk of the corrections to ZH production [73]. For ZH production there are, however, gluon-gluon induced contributions that do not involve a virtual Z gauge boson but are such that the Z gauge boson and H boson couple to gluons via top quark loops [74]. In addition, WH and ZH production receive non Drell–Yan-like corrections in the $q\bar{q}'$ and $q\overline{q}$ initiated channels, respectively, at the NNLO level, where the Higgs is radiated off top quark loops [75]. The full QCD corrections up to NNLO order, the NLO EW corrections and the NLO corrections to the gluon-gluon channel are available in a public program [76].

As neither the Higgs boson nor the weak gauge bosons are stable particles, their decays also have to be taken into account. Providing full kinematical information for the decay products can furthermore help in the suppression of large QCD backgrounds. Differential distributions for the processes $pp \to WH \to \nu_\ell \ell H$ and $pp \to ZH \to \ell^+\ell^- H \to \nu_\ell \bar{\nu}_\ell H$, including NLO QCD and EW corrections, have been presented in Ref. [77]. The NNLO QCD corrections to differential observables for WH production at the LHC, including the leptonic decays of the W boson and the decay of the Higgs boson into a $b\bar{b}$ pair, are presented in Ref. [78]. The WH and ZH production modes, together with Higgs production in association with a top quark pair, provide a relatively clean environment for studying the decay of the Higgs boson into bottom quarks.

(iv) Higgs production in association with $t\bar{t}$

Higgs radiation off top quarks, $pp \to Ht\bar{t}$, can provide important information on the the top-Higgs Yukawa coupling and gives access to the Higgs decay into bottom quarks. The LO cross section for this production process was computed in Ref. [79]. Later, the NLO QCD corrections [80] were evaluated yielding a moderate increase in the total cross section of at most 20%, but reducing significantly the scale dependence of the inclusive cross section. The total theoretical errors, estimated by combining the uncertainties from factorization and renormalization scales, strong gauge coupling, and parton distributions, amount to 10–15% of the corresponding inclusive cross section. Interfaces between NLO QCD calculations for $Ht\bar{t}$ production with parton-shower Monte Carlo programs have been provided in Ref. [81]. These programs provide the most flexible tools to date for the computation of differential distributions, including experimental selection cuts and vetoes on the final-state particles and their decay products.

(v) Subleading Higgs production mechanisms at the LHC

The Higgs boson production in association with bottom quarks is known at NNLO in the case of five quark flavors [82–84]. The coupling of the Higgs boson to a b quark is suppressed in the SM by the bottom quark mass over the Higgs VEV, m_b/v, implying that associated production of a SM Higgs boson with b quarks is very small at the LHC. In a two Higgs doublet model or a supersymmetric model, which will be discussed in Section V, this coupling is proportional to the ratio of neutral Higgs boson vacuum expectation values, $\tan\beta$, and can be significantly enhanced for large values of this ratio.

II.4.2. Production mechanisms at e^+e^- colliders

The main Higgs boson production cross sections at an e^+e^- collider are the Higgs-strahlung process $e^+e^- \to ZH$ [6,19,85], and the WW fusion process [86] $e^+e^- \to \bar{\nu}_e\nu_e W^*W^* \to \bar{\nu}_e\nu_e H$. As the center-of-mass energy $\sqrt{s}$ is increased, the cross-section for the Higgs-strahlung process decreases as s^{-1} and is dominant at low energies, while the cross-section for the WW fusion process grows as $\ln(s/m_H^2)$ and dominates at high energies [87–89]. The ZZ fusion mechanism, $e^+e^- \to e^+e^- Z^*Z^* \to e^+e^- H$, also contributes to Higgs boson production, with a cross-section suppressed by an order of magnitude with respect to that of WW fusion. The process $e^+e^- \to t\bar{t}H$ [90,91] becomes relevant for large $\sqrt{s} \geq 500\,\text{GeV}$. For a more detailed discussion of Higgs production properties at lepton colliders see for example Refs. [34,35,92,93] and references therein.

II.4.3. SM Higgs branching ratios and total width

For the understanding and interpretation of the experimental results, the computation of all relevant Higgs decay widths is essential, including an estimate of their uncertainties and, when appropriate, the effects of Higgs decays into off-shell particles with successive decays into lighter SM ones. A Higgs mass of about 125 GeV provides an excellent opportunity to explore the Higgs couplings to many SM particles. In particular the dominant decay modes are $H \to b\bar{b}$ and $H \to WW^*$, followed by $H \to gg$, $H \to \tau^+\tau^-$, $H \to c\bar{c}$ and $H \to ZZ^*$. With much smaller rates follow the Higgs decays into $H \to \gamma\gamma$, $H \to \gamma Z$ and $H \to \mu^+\mu^-$. Since the decays into gluons, diphotons and $Z\gamma$ are loop induced, they provide indirect information on the Higgs to WW, ZZ and $t\bar{t}$ couplings in different combinations. The Higgs decays into WW^* and ZZ^* effectively need to be studied considering the decays of the gauge bosons into four fermions, i.e., the leptonic, semi-leptonic and full hadronic final states. The uncertainties in the branching ratios include the missing higher order corrections in the theoretical calculations as well as the errors in the SM input parameters, in particular fermions masses and gauge couplings, involved in the calculations. In the following the state of the art of the theoretical calculations will be discussed and the reader is referred to Refs. [36,37,94] for further details.

The evaluation of radiative corrections of fermionic decays of the SM Higgs at different levels of accuracy are implemented in HDECAY [95]. The decays $H \to b\bar{b}$ and $H \to c\bar{c}$ are computed including the complete massless QCD corrections up to and including NNNNLO, with a corresponding scale dependence of about 0.1% [96]. Both the electroweak corrections to $H \to b\bar{b}$, $c\bar{c}$ as well as $H \to \tau^+\tau^-$ are known at NLO [97] providing predictions with an overall accuracy of about 1-2% for $m_H \simeq 125\,\text{GeV}$.

The loop induced decays of the SM Higgs are known at NLO and partially beyond that approximation. For $H \to gg$, the QCD corrections are known up to NNNLO in the limit of heavy top quarks [98,43] and the uncertainty from the scale dependence is about 3%. For the $H \to \gamma\gamma$, the full NLO QCD corrections are available [43,99]. The NLO electroweak corrections to $H \to gg$ and $H \to \gamma\gamma$ have been computed in Ref. [100]. Missing higher orders corrections are estimated to be below 1%. All these corrections are implemented in HDECAY. In addition the contribution of the $H \to \gamma e^+e^-$ decay via virtual photon conversion has been computed in Ref. [101]. The partial decay width $H \to Z\gamma$ is only implemented at LO in HDECAY, including the virtual W, top, bottom, and τ loop contributions. The QCD corrections have been calculated and are at the percent level [102], The theoretical uncertainty due to unknown electroweak corrections is estimated to be less than 5%, an accuracy that will be hard to achieve in measurements at the LHC.

The decays $H \to WW/ZZ \to 4f$ can be simulated with the Monte-Carlo generator of Ref. [103] that includes complete NLO QCD and EW corrections for Higgs decays into any possible four-fermion final state. All calculations are consistently performed with off-shell gauge bosons, without any on-shell approximation. For the SM Higgs boson the missing higher-order corrections are estimated to roughly 0.5%. Such uncertainties will have to be combined with the parametric uncertainties, in particular those associated to the bottom quark mass and the strong gauge coupling, to arrive at the full theory uncertainties. A detailed treatment of the differential distributions for a Higgs decay with four charged leptons in the final state is presented in Refs. [104,38].

The branching ratios for the most relevant decay modes of the SM Higgs boson as functions of m_H, including the most recent theoretical uncertainties, are shown in Fig. 11.4 and listed for $m_H = 125\,\text{GeV}$ in Table 11.2. The total width of a 125 GeV SM Higgs boson is

$\Gamma_H = 4.07 \times 10^{-3}$ GeV, with a relative uncertainty of $^{+4.0\%}_{-3.9\%}$. Further details of these calculations can be found in Refs. [94,105] and in the reviews [33–38].

Table 11.2: The branching ratios and the relative uncertainty [38] for a SM Higgs boson with $m_H = 125$ GeV.

Decay channel	Branching ratio	Rel. uncertainty
$H \to \gamma\gamma$	2.28×10^{-3}	$^{+5.0\%}_{-4.9\%}$
$H \to ZZ$	2.64×10^{-2}	$^{+4.3\%}_{-4.1\%}$
$H \to W^+W^-$	2.15×10^{-1}	$^{+4.3\%}_{-4.2\%}$
$H \to \tau^+\tau^-$	6.32×10^{-2}	$^{+5.7\%}_{-5.7\%}$
$H \to b\bar{b}$	5.77×10^{-1}	$^{+3.2\%}_{-3.3\%}$
$H \to Z\gamma$	1.54×10^{-3}	$^{+9.0\%}_{-8.9\%}$
$H \to \mu^+\mu^-$	2.19×10^{-4}	$^{+6.0\%}_{-5.9\%}$

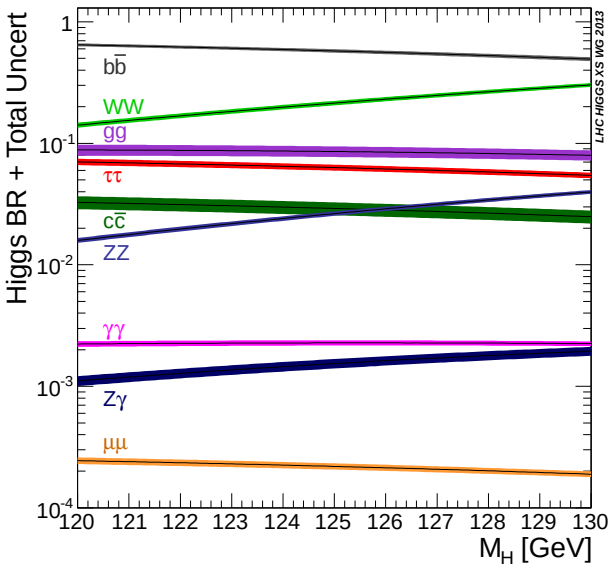

Figure 11.4: The branching ratios for the main decays of the SM Higgs boson near $m_H = 125$ GeV. The theoretical uncertainties [38] are indicated as a band.

III. The discovery of a Higgs boson

Indirect experimental bounds on the SM Higgs boson mass are obtained from a global fit of precision electroweak measurements of electroweak observables, by comparing them with theory predictions which account for M_H effects at higher orders (see the electroweak model and constraints on new physics in this review for more details). This global fit to the precision electroweak data accumulated in the last two decades at LEP, SLC, the Tevatron, and elsewhere, suggests $m_H = 89^{+22}_{-18}$ GeV, or $m_H < 127$ GeV at 90% confidence level [106].

Direct and model-independent searches for the Higgs boson were conducted by the ALEPH, DELPHI, L3, and OPAL experiments at the LEP e^+e^- collider. The combination of LEP data collected near the Z resonance and at centre-of-mass energies of up to 209 GeV yielded a 95% Confidence level (CL) lower bound [107] of 114.4 GeV for the mass of the SM Higgs boson.

Following the shutdown of the LEP collider in 2000, the direct search for the Higgs boson continued at Fermilab's Tevatron $p\overline{p}$ collider. The combined results [108] from approximately 10 fb^{-1} recorded by the CDF and D0 experiments excluded two ranges in m_H: between 90 GeV and 109 GeV, and between 149 GeV and 182 GeV. In addition, a broad excess in data was seen in the mass range 115 GeV $< m_H <$ 140 GeV with a local significance[4] of 3 standard deviations at $m_H = 125$ GeV. The commissioning in 2010 and the high intensity running of the LHC pp collider at CERN at $\sqrt{s}$ =7 TeV in 2011 followed by an energy boost to $\sqrt{s}$ =8 TeV in 2012 opened up a new landscape where the Higgs boson could be searched for, quickly and effectively, in the 110–1000 GeV mass range.

The announcement on July 4, 2012 of the observation [1,2] at the LHC of a narrow resonance with a mass of about 125 GeV has provided an important new direction in the decades-long search for the SM Higgs boson. The analyzed data corresponded to integrated luminosities of up to 4.8 (5.1) fb^{-1} at $\sqrt{s} = 7$ TeV in 2011 and 5.9 (5.3) at $\sqrt{s} = 8$ TeV in 2012 recorded by the ATLAS and CMS experiments, respectively. The observed decay channels indicated that the new particle is a boson. The evidence was strong that the new particle decays to $\gamma\gamma$ and ZZ with rates consistent with those predicted for the Standard Model (SM) Higgs boson. There were indications that the new particle also decays to W^+W^-. Although the experiments searched for decays to $b\bar{b}$ and $\tau^+\tau^-$, no statistically significant signal was found. The significance of these observations are quantified by a p-value [110], the probability for a background only experiment to give a result at least as signal-like as that observed in the data. For example, a p-value of 2.87×10^{-7} corresponds to a five-standard-deviation excess over the background-only prediction. ATLAS observed the largest excess with a local significance of 5.9σ at a mass $m_H = 126.5$ GeV, to be compared with an expected significance of 4.6σ if a SM Higgs boson were present at such a mass. CMS observed an excess with a local significance of 4.9σ at a mass of 125.5 GeV, to be compared with an expected significance of 5.9σ in this dataset.

Even as this discovery was being announced, ATLAS and CMS continued to accumulate pp collision data at $\sqrt{s} = 8$ TeV recording a total of about 20 fb^{-1} each at this energy. Figure 11.5 shows four snapshots of the evolution of the p-value and the signal significance near 125 GeV with increasing datasets analyzed by the two experiments.

In the remainder of this section the focus will be on the recent major results. Unless explicitly mentioned, all measurements are based on the full dataset of about 10 fb^{-1} recorded by the Tevatron experiments and about 25 fb^{-1} recorded by the LHC experiments. An extensive review of the searches for the Higgs boson from LEP to the LHC can be found in Ref [111].

III.1. The discovery channels

For a given m_H the sensitivity of a search channel depends on the production cross section of the Higgs bosons, its decay branching fraction, reconstructed mass resolution, selection efficiency and the level of background in the final state. For a low mass Higgs boson ($110 < m_H < 150$ GeV) where the natural width of the Higgs boson is only a few MeV, the five decay channels that play an important role at the LHC are listed in Table 11.3. In the $H \to \gamma\gamma$ and $H \to ZZ \to 4\ell$ channels, all final state particles can be very precisely measured and the reconstructed m_H resolution is excellent. While the $H \to W^+W^- \to \ell^+\nu_\ell\ell'^-\bar{\nu}_{\ell'}$ channel has relatively large branching fraction, the m_H resolution is poor due to the presence of neutrinos. The $H \to b\bar{b}$ and the $H \to \tau^+\tau^-$ channels suffer from large backgrounds and a poor mass resolution. For $m_H > 150$ GeV, the sensitive channels are $H \to WW$ and $H \to ZZ$ where the W or Z boson decays into a variety of leptonic and hadronic final states.

In order to distinguish between different production modes, the LHC experiments usually split the Higgs boson candidates into several mutually exclusive categories (or tags) based on the topological and/or kinematics features present in the event. These categories

[4] In this review, we use the phrase "local significance" to indicate a calculation of the significance not corrected for the look-elsewhere effect [109].

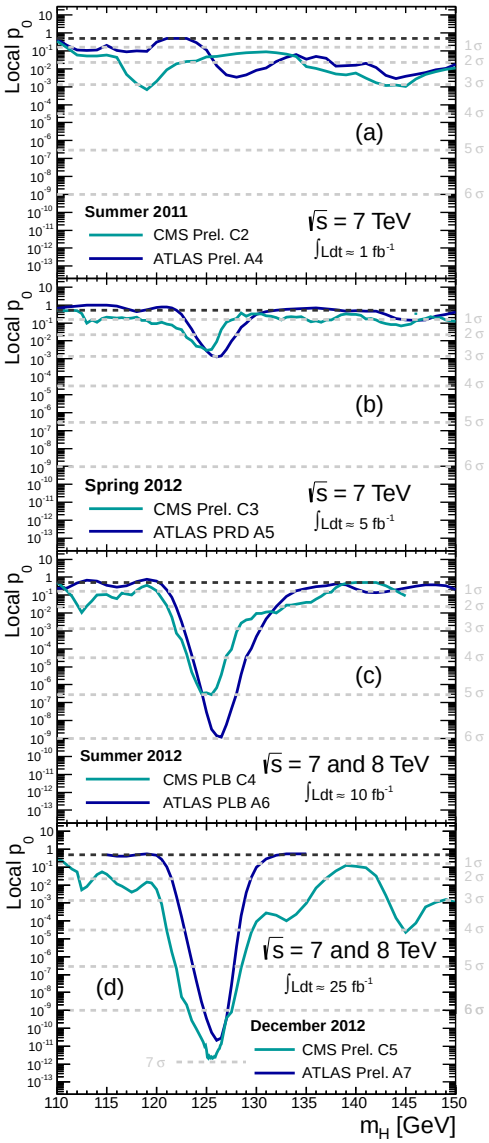

Figure 11.5: Evolution of the p-value and the signal significance observed by the ATLAS and CMS experiments with increasingly larger datasets: (a) Summer 2011 ($\approx 1\,\text{fb}^{-1}$/expt) for ATLAS A4 [112] and CMS C4 [113], (b) Spring 2012 ($\approx 5\,\text{fb}^{-1}$/expt) for ATLAS A5 [114] and CMS C3 [115], (c) Summer 2012 ($\approx 10\,\text{fb}^{-1}$/expt) for ATLAS A6 [1] and CMS C4 [2], and (d) December 2012 ($\approx 25\,\text{fb}^{-1}$/expt) for ATLAS A7 [116] and CMS C4 [117].

Table 11.3: The five sensitive channels for low mass SM Higgs boson searches at the LHC. The numbers reported are for $m_H = 125\,\text{GeV}$.

Decay channel	Mass resolution
$H \to \gamma\gamma$	1-2%
$H \to ZZ \to \ell^+\ell^-\ell'^+\ell'^-$	1-2%
$H \to W^+W^- \to \ell^+\nu_\ell\ell'^-\bar{\nu}_{\ell'}$	20%
$H \to b\bar{b}$	10%
$H \to \tau^+\tau^-$	15%

contain an admixture of various signal production modes. For example, a typical VBF category contains Higgs boson candidates accompanied by two energetic jets ($\geq 30\,\text{GeV}$) with a large dijet mass ($\geq 400\,\text{GeV}$) and separated by a large pseudorapidity ($\Delta\eta_{jj} \geq 3.5$).

While such a category is enriched in Higgs boson produced via VBF, the contamination from the dominant gluon fusion production mechanism can be significant. Hence a measurement of the Higgs boson production cross section in the VBF category does not imply a measurement of VBF production cross-section. Simulations are used to determine the relative contributions of the various Higgs production modes in a particular category.

III.1.1. $H \to \gamma\gamma$

In the $H \to \gamma\gamma$ channel a search is performed for a narrow peak over a smoothly falling background in the invariant mass distribution of two high p_T photons. The background in this channel is high and stems from prompt $\gamma\gamma$, γ+jet and dijet processes. In order to optimize search sensitivity and also to separate the various Higgs production modes, ATLAS and CMS experiments split events into several mutually exclusive categories. Diphoton events containing a high p_T muon, electron, dijets or missing energy (E_T^{miss}) consistent with the decay of a W or Z boson are tagged in the VH production category, those containing energetic dijets with a large mass and pseudorapidity difference are assigned to the VBF production category and the remaining events ($\approx 99\%$ of the total) are considered in the gluon fusion production category. While the VH category is relatively pure, the VBF category has significant contamination from the gluon fusion process. ATLAS uses the diphoton transverse momentum orthogonal to the diphoton thrust axis in the transverse plane (p_{Tt}) [118] to differentiate between Higgs boson produced via gluon fusion and the VBF/VH production modes.

Untagged events are further categorized according to their expected $m_{\gamma\gamma}$ resolution and signal-to-background ratio. Categories with good m_H resolution and larger signal-to-background ratio contribute most to the sensitivity of the search.

In each category, $Z \to e^+e^-$ and $Z \to \mu^+\mu^-\gamma$ events from data are used to construct a parametric signal model. The functional form of the background is determined by a fit to the full $m_{\gamma\gamma}$ distribution in each category. All categories are fitted simultaneously to determine the signal yield at a particular mass. In the full dataset, the $m_{\gamma\gamma}$ distribution after combining all categories are shown for the ATLAS experiment in Fig. 11.6 and for the CMS experiment in Fig. 11.7. ATLAS observes [119] its largest excess over background at $m_H = 126.8\,\text{GeV}$ with a significance of 7.4σ compared with 4.3σ expected for SM Higgs boson at that mass. CMS observes [120] its largest excess at $m_H = 125.4\,\text{GeV}$ with a significance of 3.2σ compared with 4.2σ expected for SM Higgs boson of that mass.

The signal strength $\mu = (\sigma \cdot \mathcal{B})_{\text{obs}}/(\sigma \cdot \mathcal{B})_{\text{SM}}$ which is the observed product of the Higgs boson production cross section (σ) and its branching ratio ($\mathcal{B}$) in units of the corresponding SM values, is $1.65^{+0.34}_{-0.30}$ for ATLAS and 0.78 ± 0.27 for CMS at $m_H = 125.5$ and $125\,\text{GeV}$ respectively.

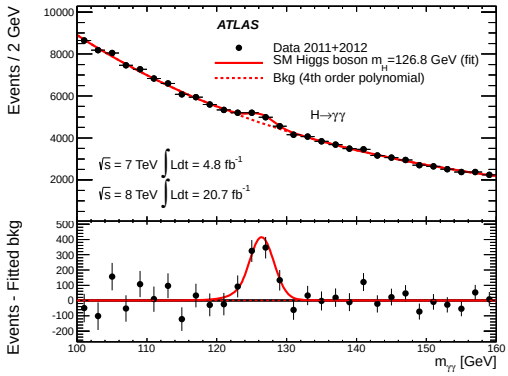

Figure 11.6: The combined invariant mass distribution of diphoton candidates observed by ATLAS [119]. The residuals of the data with respect to the fitted background are displayed in the lower panel.

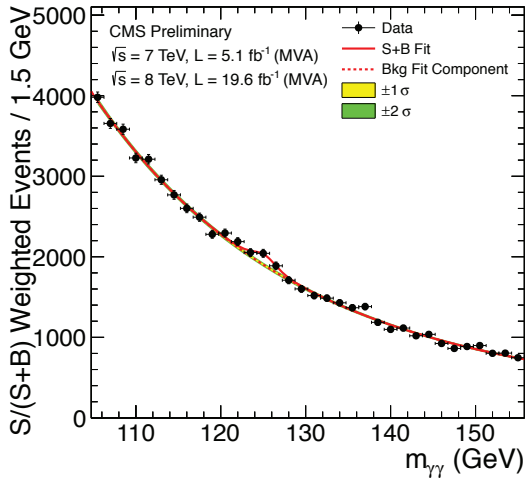

Figure 11.7: The combined CMS $M_{\gamma\gamma}$ distribution with each event weighted by the ratio of signal-to-background in each event category [120].

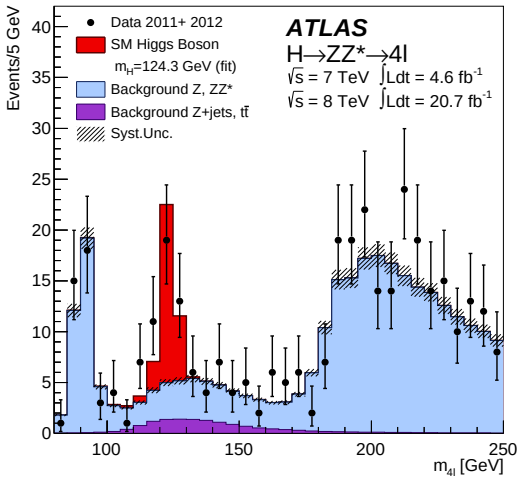

Figure 11.8: The combined $m_{4\ell}$ distribution from ATLAS [119].

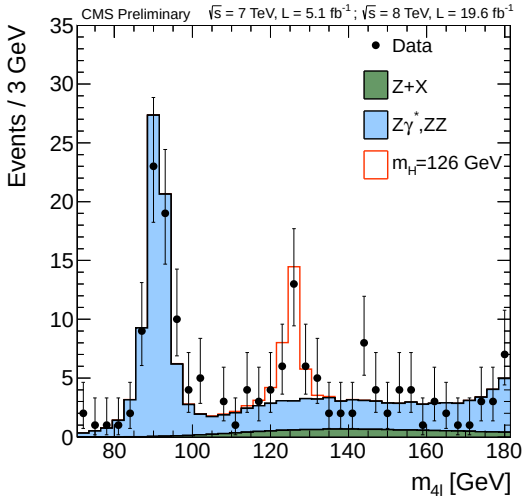

Figure 11.9: The combined $m_{4\ell}$ distribution from CMS [121].

III.1.2. $H \to ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$, $(\ell, \ell' = e, \mu)$

In the $H \to ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel a search is performed for a narrow mass peak over a small continuous background dominated by non-resonant $ZZ^{(*)}$ production from $q\overline{q}$ annihilation and gg fusion processes. The contribution and the shape of this background is taken from simulated events. The subdominant and reducible backgrounds stem from $Z + b\bar{b}$, $t\bar{t}$ and $Z +$ jets events. Their contribution is suppressed by requirements on lepton isolation and lepton impact parameter and their yield is estimated from control samples in data.

To help distinguish the Higgs signal from the dominant non-resonant $ZZ^{(*)}$ background, CMS uses a matrix element likelihood approach [2] to construct a kinematic discriminant built for each 4ℓ event based on the ratio of complete leading-order matrix elements $|\mathcal{M}_{sig}{}^2/\mathcal{M}_{bkg}{}^2|$ for the signal ($gg \to H \to 4\ell$) and background($q\overline{q} \to ZZ \to 4\ell$) hypotheses. The signal matrix element $\mathcal{M}_{sig}$ is computed assuming $m_H = m_{4\ell}$.

To enhance the sensitivity to VBF and VH production processes, the ATLAS and CMS experiment divide 4ℓ events into mutually exclusive categories. Events containing dijets with a large mass and pseudorapidity difference populate the VBF category. ATLAS requires presence of an additional lepton in the VH category. In events with less than two jets, CMS uses the $p_T^{4\ell}$ to distinguish between production via the gluon fusion and the VH/VBF processes.

Since the $m_{4\ell}$ resolutions and the reducible background levels are different in the 4μ, $4e$ and $2e2\mu$ sub-channels, they are analyzed separately and the results are then combined.

The combined ATLAS $m_{4\ell}$ distribution is shown in Fig. 11.8. The largest deviation from the SM background-only expectation is observed [119] at $m_H = 124.3\,\text{GeV}$ where the significance of the observed peak is 6.7σ in the full 7 and 8 TeV data. The expected significance for the SM Higgs boson at that mass is 4.4σ. As shown in Fig. 11.9, the CMS experiment observes [121] its largest excess at $m_H = 125.8\,\text{GeV}$ with a observed significance of 6.7σ to be compared with an expected significance of 7.2σ at that mass. Both experiments also observe a clear peak at $m_{4\ell} = 91\,\text{GeV}$ from Z/γ^* production at the expected SM rate [122].

The signal strength μ for the inclusive $H \to 4\ell$ production measured by the ATLAS and CMS experiments are $1.43^{+0.40}_{-0.35}$ at $m_H = 125.5\,\text{GeV}$ and $0.91^{+0.30}_{-0.24}$ at $m_H = 125.8\,\text{GeV}$ respectively.

III.2. Mass and width measurements

In order to measure the mass of the observed state, the ATLAS and CMS experiments combine the measurements from the $\gamma\gamma$ and ZZ channels which have excellent mass resolution and where excesses with large significance are observed. For a model-independent mass measurement, the signal strengths in the $\gamma\gamma$ and ZZ channels are assumed to be independent and not constrained to the expected rate ($\mu = 1$) for the SM Higgs boson. The combined mass measured by ATLAS [119] and CMS [124] are $125.5 \pm 0.2(\text{stat.})\,^{+0.5}_{-0.6}(\text{syst.})\,\text{GeV}$ and $125.7 \pm 0.3(\text{stat.}) \pm 0.3(\text{syst.})\,\text{GeV}$ respectively. In both experiments the systematic uncertainty is dominated by the imprecision in the knowledge of the photon energy and the lepton momentum scale. The significance of the difference between the measurements of the masses in the $\gamma\gamma$ and ZZ channels by the ATLAS experiment is 2.4σ [119]. Fig. 11.10 summarizes these measurements and our combination of the ATLAS and CMS results assuming uncorrelated systematic uncertainties between the two experiments.

The natural width of a SM Higgs boson with a mass of 125 GeV is about 4 MeV, much smaller than the instrumental mass resolution in the $\gamma\gamma$ and ZZ channels. CMS has placed 95% CL bound [123] on the natural width of the observed boson of $\Gamma_H < 3.4\,\text{GeV}$.

III.3. $H \to W^+W^- \to \ell^+\nu\ell^-\overline{\nu}$

While the production rate in the $H \to W^+W^- \to \ell^+\nu\ell^-\bar{\nu}$ channel is large, due to the presence of two neutrinos in the decay, the m_H

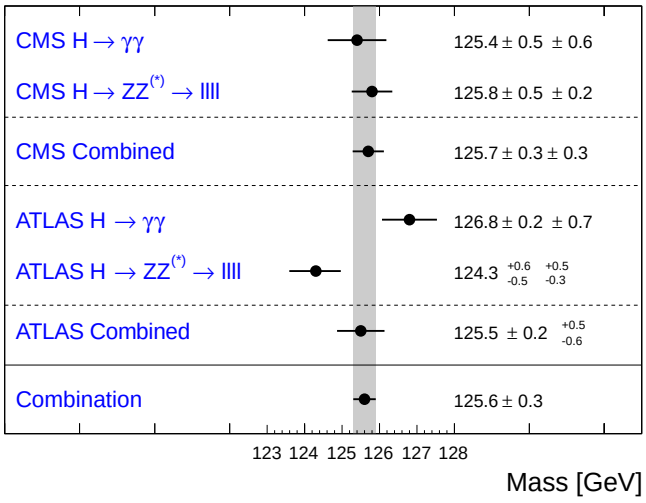

Figure 11.10: A compilation of the CMS and ATLAS mass measurements in the $\gamma\gamma$ and ZZ channels, the combined result from each experiment and our average of the combinations.

resolution is quite poor ($\approx 20\%\ m_H$) so the search is reduced to a counting experiment of the event yield in broad bins in m_H.

Experiments search for an excess of events with two leptons of opposite charge accompanied by missing energy and up to two jets. Events are divided into several categories depending on the lepton flavor combination (e^+e^-, $\mu^+\mu^-$and $e^\pm\mu^\mp$) and the number of accompanying jets ($N_{jet} = 0, 1, \geq 2$). The $N_{jet} \geq 2$ category is optimized for VBF production process by selecting two leading jets with a large pseudorapidity difference and with a large mass ($m_{jj} > 500\,\text{GeV}$). Backgrounds contributing to this channel are numerous and vary by the category of selected events. Reducing them and accurately estimating the remainder is major challenge in this analysis. For events with opposite flavor lepton and no accompanying high p_T jets, the dominant background stems from non-resonant WW production. Events with same-flavor leptons suffer from large Drell–Yan contamination. The $t\bar{t}$, Wt and W + jets (with the jet misidentified as a lepton) events contaminate all categories. Non-resonant WZ, ZZ and $W\gamma$ processes also contribute to the background at a sub-leading level.

A requirement of large missing transverse energy (E_T^{miss}) is used to reduce the Drell–Yan and multi-jet backgrounds. In the e^+e^- and $\mu^+\mu^-$ categories, events with $m_{\ell\ell}$ consistent with the Z mass are vetoed. The $t\bar{t}$ background is suppressed by a veto against identified b-jets or low p_T muons (assumed to be coming from semileptonic b-hadron decays within jets) and tight isolation requirements diminish the W+jets background. The scalarity of the Higgs boson and the $V-A$ nature of the W boson decay implies that the two charged leptons in the final state are emitted at small angles with respect to each other. Therefore the dilepton invariant mass ($m_{\ell\ell}$) and the azimuthal angle difference between the leptons ($\Delta\phi_{\ell\ell}$) are used to discriminate between the signal and non-resonant WW events. The transverse mass constructed from the dilepton p_T ($p_T^{\ell\ell}$) , E_T^{miss} and the azimuthal angle between E_T^{miss} and $p_T^{\ell\ell}$ and defined as $m_T = \sqrt{2p_T^{\ell\ell}E_T^{\text{miss}}(1-\cos\Delta\phi_{E_T^{\text{miss}}\ell\ell})}$ serves as an effective discriminant against backgrounds. The transverse mass variable also tracks the Higgs boson mass but with a poor mass resolution. All residual background rates except for the small contributions from non-resonant WZ, ZZ and $W\gamma$ are evaluated from control samples devised from data.

The m_T distributions of selected events is shown in Fig. 11.11 and Fig. 11.12 for the ATLAS and CMS experiments respectively. The 0-jet category is dominated by non-resonant WW background while $t\bar{t}$ dominates the 1 and 2 jet categories. Both experiments see a clear excess over background expectation in the 0 and 1 jet categories. ATLAS fits the m_T distributions and observes [119,126] the most significant excess for $m_H = 140\,\text{GeV}$. The significance of the observed excess for $m_H = 125.5\,\text{GeV}$ is 3.8σ, the same as expected. The measured inclusive signal strength $\mu = 1.01 \pm 0.31$ at $m_H = 125\,\text{GeV}$. In the VBF category an excess with a significance of 2.5σ corresponding to a signal strength of $\mu = 1.66 \pm 0.67 \pm 0.43$ is observed for $m_H = 125\,\text{GeV}$. The CMS analysis of 0 and 1 jet categories, using all lepton flavor combinations, shows [127] an excess with an observed significance of 4σ consistent with the expected significance of 5.1σ for a 125 GeV Higgs boson. A separate analysis optimized for the VBF production mode reports [128] no significant excess and sets a 95% CL upper limit of $\mu < 1.7$ for $m_H = 125\,\text{GeV}$.

The ATLAS and CMS experiments have also performed dedicated searches for the associated Higgs boson production (VH) in this channel. The signal consists of three (WH) or four (ZH) high p_T isolated leptons with missing transverse energy and low hadronic activity. The major backgrounds stem from triboson and diboson production where each boson decays leptonically. The 95% CL limits on μ of 7.2 [129] and 5.0 [130] have been set by ATLAS and CMS respectively for a $m_H = 125\,\text{GeV}$.

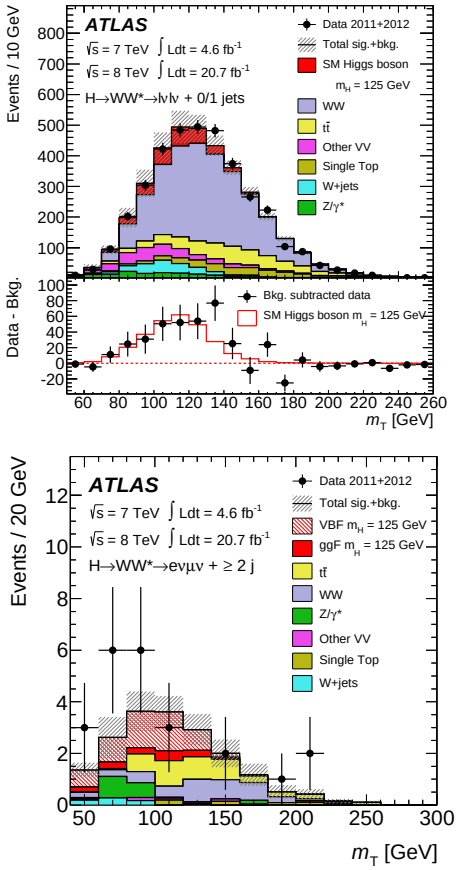

Figure 11.11: (Top) The m_T distribution for selected events summed over all lepton flavors and with ≤ 1 associated jets. The observed excess over the estimated SM background and the expectation from a SM Higgs boson with $m_H = 125\,\text{GeV}$ are shown in the lower panel. (Bottom) The m_T distribution for selected $e^\pm\mu^\mp$ events and with ≥ 2 associated jets [119].

III.4. Decays to fermions

As described in Section III.1, significant signals for the decay of the observed boson in the the $\gamma\gamma$, ZZ and W^+W^- channels have been measured by the ATLAS and CMS experiments. The measured signal strengths in these channels are consistent with this boson playing a role in electroweak symmetry breaking. However the nature of its interaction with fermions and whether this boson serves also

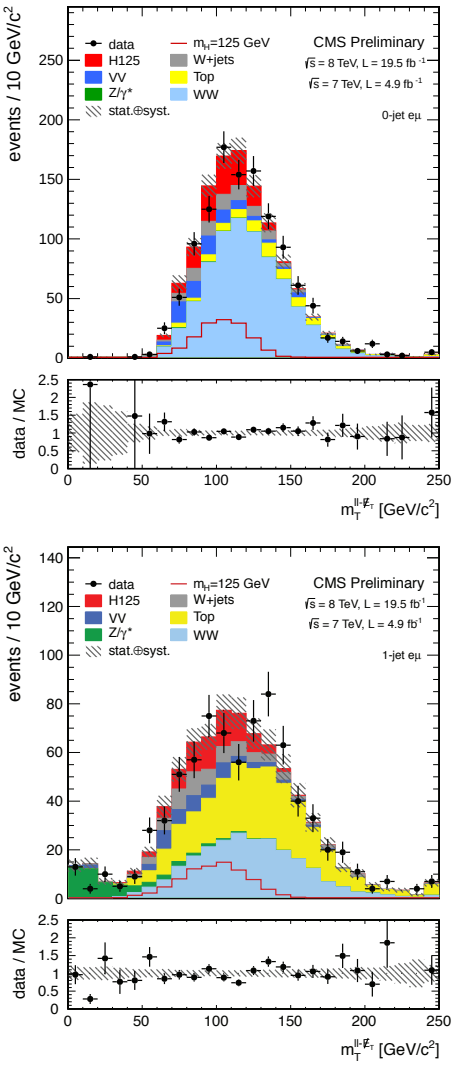

Figure 11.12: The m_T distribution for events, selected with a cut-based analysis, summed over all lepton flavors and with zero accompanying reconstructed jets (Top) and 1-jet (Bottom). The contributions of all SM background sources and a SM Higgs with m_H=125 GeV are stacked together [127].

as a source of mass generation for quarks and leptons via Yukawa interactions is a topic of active investigation[5].

At the hadron colliders, the most promising channel for probing the coupling of the Higgs field to the quarks and leptons are $H \to b\bar{b}$ and $H \to \tau^+\tau^-$ respectively. For a Higgs boson with $m_H \approx 125\,\text{GeV}$, the branching fraction to $b\bar{b}$ is about 57% and to $\tau^+\tau^-$ is about 6%. Nevertheless the presence of very large backgrounds makes the isolation of a Higgs boson signal in these channels quite challenging.

III.4.1. $H \to \tau^+\tau^-$

In the $H \to \tau\tau$ search, τ leptons decaying to electrons (τ_e), muons (τ_μ) and hadrons (τ_{had}) are considered. The $\tau^+\tau^-$ invariant mass ($m_{\tau\tau}$) is reconstructed from a kinematic fit of the visible products from the two τ leptons and the missing energy observed in the event. Due to the presence of missing neutrinos, the $m_{\tau^+\tau^-}$ resolution is poor ($\approx 15\%$). As a result, a broad excess over the expected background in the $m_{\tau\tau}$ distribution is searched for. The major sources of background stem from Drell–Yan $Z \to \tau^+\tau^-$ and $Z \to e^+e^-$, W+jets, $t\bar{t}$ and multijet production. Events in all sub-channels are divided into categories based on the number and kinematic properties of additional energetic jets in the event. The sensitivity of the search is generally higher for categories with one or more additional jets. The VBF category, consisting of a $\tau\tau$ pair with two energetic jets separated by a large pseudorapidity, has the best signal-to-background and search sensitivity followed by the $\tau^+\tau^-$+1 jet category. The signal to background discrimination relies in part on $m_{\tau\tau}$ resolution which improves with the boost of the Higgs boson, the non-VBF categories are further subdivided according to the observed boost of the $\tau^+\tau^-$ system. The 0-jet category which has the poorest signal/background ratio is used to constrain the background yields, the reconstruction efficiencies, and the energy scales. The CMS experiment uses the reconstructed mass as discriminating variable [131,132] while the ATLAS experiment combines various kinematic properties of each event categories with multivariate techniques to build a discriminant [133].

$H \to \tau^+\tau^-$ decays in the VH production mode are searched for in final states where the W or Z boson decays into leptons or into two jets (in [134] but currently not in the latest ATLAS results [133]) . While the decays to tau pairs are the dominant Higgs boson signal contribution, the final states used can additionally be produced by the decay of the Higgs boson into a pair of W bosons that both decay to leptons. The irreducible background in this search arises from non-resonant WZ and ZZ diboson production. The reducible backgrounds originate from W, Z, and $t\bar{t}$ events that contain at least one fake lepton in the final state due to a misidentified jet. The shape and yield of the major backgrounds in each category is estimated from control samples in data. Contributions from non-resonant WZ and ZZ diboson production is estimated from simulations but corrected for reconstruction efficiency using control samples formed from observed data.

Figure 11.13 shows the CMS [131] $m_{\tau\tau}$ distributions combining all non-VH categories, weighing the distributions in each category of each sub-channel by the ratio between the expected signal and background yields for that category. The inset plot shows the difference between the observed data and expected background distributions, together with the expected distribution for a SM Higgs boson signal with $m_H = 125\,\text{GeV}$. The significance of the observed excess at $m_H = 125\,\text{GeV}$ is 2.85 standard deviations and corresponds to a signal strength of $\mu = 1.10 \pm 0.41$. The result in this channel has been updated with an optimized analysis [132] yielding an observed excess of 3.4 standard deviations at $m_H = 125\,\text{GeV}$ corresponding to a signal strength of $\mu = 0.87 \pm 0.29$. It has not yet been included in the combination of all low mass Higgs boson searches.

The ATLAS results [133] are based on the full 8 TeV data sample of $20.3\,\text{fb}^{-1}$. At $m_H = 125\,\text{GeV}$, the observed (expected) deviation from the background-only hypothesis corresponds to a local significance of 4.1 (3.2) standard deviations and the best fit value of the signal strength $\mu = 1.4^{+0.5}_{-0.4}$. This result does not include the aforementioned leptonic VH modes. These results are summarized in Table 11.4.

Both ATLAS and CMS measurements provide substantial evidence of the coupling of the Higgs boson to leptons.

III.4.2. $H \to b\bar{b}$

The dominant production mode $gg \to H$ with $H \to b\bar{b}$ is overwhelmed by the background from the inclusive production of $p\bar{p} \to b\bar{b} + X$ via the strong interaction. The associated production modes WH and ZH (collectively termed VH modes) allow use of the leptonic W and Z decays to purify the signal and reject QCD backgrounds. The W bosons are reconstructed via their leptonic decay $W \to \ell\bar{\nu}_\ell$ where $\ell = e, \mu$ or τ. The Z boson is reconstructed via their decay into $e^+e^-, \mu^+\mu^-$or $\nu\bar{\nu}$. The Higgs boson candidate mass is reconstructed from two b-tagged jets in the event. Backgrounds arise from production of W and Z bosons in association with gluon, light and heavy-flavored jets (V+jets), $t\bar{t}$, non-resonant diboson (ZZ and WZ with $Z \to b\bar{b}$) and QCD multijet processes. Due to the limited $m_{b\bar{b}}$ mass resolution, a SM Higgs boson signal is expected to appear as a broad enhancement in the reconstructed dijet mass distribution. The crucial elements in this search are b-jet tagging

[5] We note here that the Higgs boson production via gluon fusion as observed in the $\gamma\gamma$, ZZ and W^+W^- channels provides indirect measurement of the Higgs boson coupling to the top quark at approximately the expected rate.

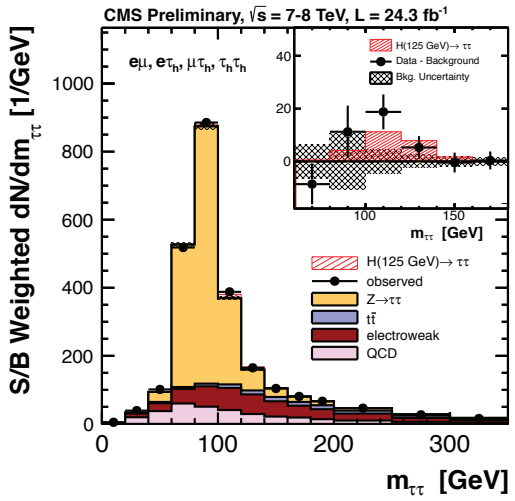

Figure 11.13: CMS results : The combined observed and expected $m_{\tau\tau}$ distributions for all sub-channels combined. The insert shows the difference between the observed data and the expected background distributions, together with the expected signal distribution for a SM Higgs signal at $m_H = 125\,\text{GeV}$ [131].

with high efficiency and low fake rate, accurate estimate of b-jet momentum and estimate of backgrounds from various signal depleted control samples constructed from data.

At the Tevatron, the $H \to b\bar{b}$ channel contributes the majority of the Higgs boson search sensitivity below $m_H = 130\,\text{GeV}$. The CDF and D0 experiments use multivariate analysis (MVA) techniques that combine several discriminating variables into a single final discriminant used to separate signal from background. Each channel is divided into exclusive sub-channels according to various lepton, jet multiplicity, and b-tagging characteristics in order to group events with similar signal-to-background ratio and thus optimize the overall search sensitivity. The combined CDF and D0 data show [135,108] an excess of events with respect to the predicted background in the 115-140 GeV mass range in the most sensitive bins of the discriminant distributions suggesting the presence of a signal. At $m_H = 125\,\text{GeV}$ the local significance of the excess is 3.0 standard deviations. At that mass, the observed signal strength $\mu = 1.59^{+0.69}_{-0.72}$. Figure 11.14 shows the best-fit cross section times branching ratio $(\sigma_{\text{WH}} + \sigma_{\text{ZH}}) \times \text{B}(H \to b\bar{b})$ as well as the SM prediction as a function of m_H.

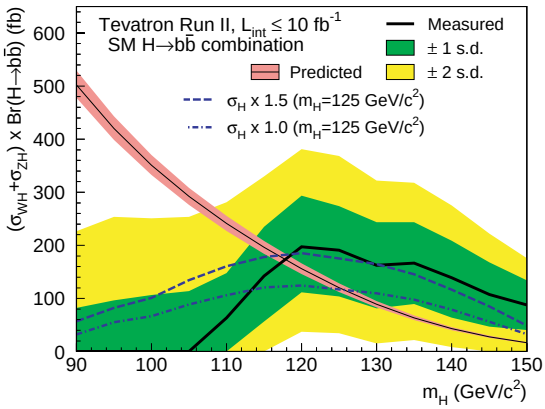

Figure 11.14: The combined CDF and D0 results on the best-fit cross section times branching ratio $(\sigma_{\text{WH}} + \sigma_{\text{ZH}}) \times \text{B}(H \to b\bar{b})$ as well as the SM prediction as a function of m_H [108].

To reduce the dominant V+jets background, following Ref. [136], the LHC experiments select a region in VH production phase space where the vector boson is significantly boosted and recoils from the $H \to b\bar{b}$ candidate with a large azimuthal angle $\Delta\phi_{\text{VH}}$. For each channel, events are categorized into different $p_T(\text{V})$ regions with varying signal/background ratios. Events with higher $p_T(\text{V})$ have smaller backgrounds and better $m_{b\bar{b}}$ resolution. CMS uses [137] MVA classifiers based on kinematic, topological and quality of b-jet tagging and trained on different values of m_H to separate Higgs boson signal in each category from backgrounds. The MVA outputs for all categories are then fit simultaneously. Figure 11.15 (Top) shows the combined MVA output of all channels where events are gathered in bins of similar expected signal-to-background ratios as predicted by the MVA discriminants. The excess of events observed in bins with the largest signal-to-background ratios is consistent with the production of a 125 GeV SM Higgs boson with a significance of 2.1 standard deviations. The observed signal strength at 125 GeV is $\mu = 1.0 \pm 0.5$. Figure 11.15 (Bottom) shows the $m_{b\bar{b}}$ distribution for all categories combined, weighted by the signal-to-background ratio in each category, with all backgrounds except dibosons subtracted. The data show the clear presence of a diboson ($W/Z + \text{Z} \to b\bar{b}$) signal, with a rate consistent with the Standard Model prediction, together with an excess that agrees with that expected from the production of a 125 GeV SM Higgs boson.

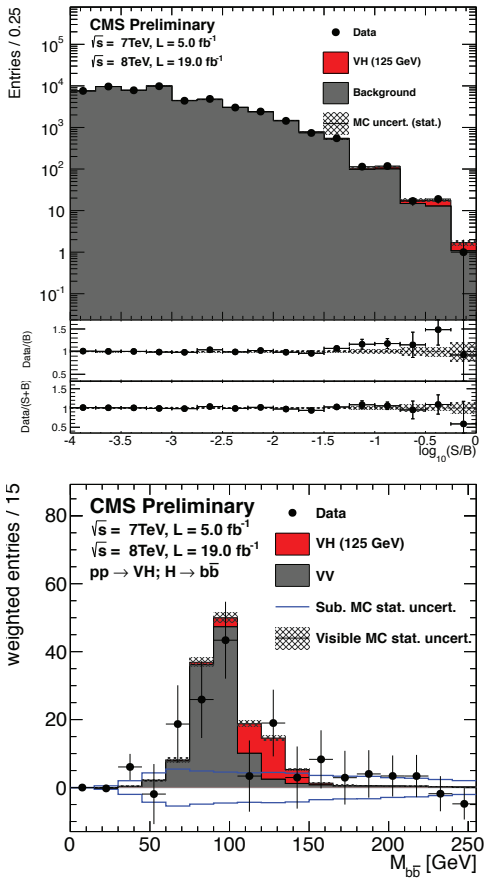

Figure 11.15: CMS results: (Top) The combination of all channels into a single distribution. The two bottom panels show the ratio of the data to the background-only prediction (above) and to the predicted sum of background and SM Higgs boson signal with a mass of 125 GeV (below). (Bottom) The $m_{b\bar{b}}$ distribution with all backgrounds, except dibosons, subtracted. The solid histograms for the backgrounds and the signal are summed cumulatively. The line histogram for signal and for VV backgrounds are also shown superimposed [137].

Table 11.4: Summary of the results in the five low mass Higgs channels measured at the LHC and the Tevatron. It should be noted that the ATLAS combined signal strength measurement only includes the bosonic $\gamma\gamma$, ZZ and WW channels. The latest result of the CMS experiment in the $H \to \tau^+\tau^-$ final state [132] is reported and denoted by (*).

ATLAS performs a cut based analysis [138], with selected events divided into a large number of categories in p_T(V). The discriminating variable used is $m_{b\bar{b}}$, and customized control samples devised from data are used to constrain the contributions of the dominant background processes. No significant excess is observed. The signal strength for $m_H = 125$ GeV is measured to be $\mu = 0.2 \pm 0.5(\text{stat.}) \pm 0.4(\text{syst.})$.

III.5. Observed signal strengths

The μ value obtained by ATLAS [119] and CMS [124] in the five channels and the combined best fit value are displayed in Fig. 11.16. The μ value for each channel and the combination is calculated for the best fit mass of 125.5 and 125.7 GeV by ATLAS and CMS respectively. The ATLAS combination used only the $\gamma\gamma$, WW and ZZ channels for which the full 7 and 8 TeV data were analyzed. Table 11.4 summarizes the measurements from the Tevatron and the LHC. All measurements are consistent with the expectation from the SM Higgs boson with a mass of 125 GeV.

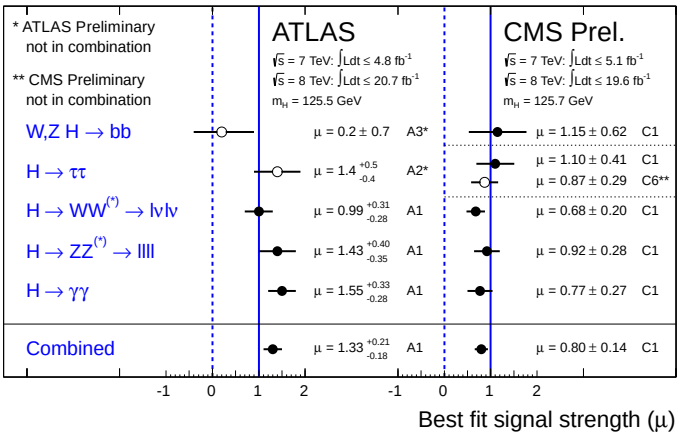

Figure 11.16: The signal strengths μ measured by the ATLAS experiment from Refs. A1 [119], A2 [133] and A3 [138], and CMS experiment from Ref. C1 [124] and C6 [132] in the five principal channels and their combination. It should be noted that the ATLAS combination only includes the bosonic $\gamma\gamma$, ZZ and WW channels.

III.6. Higgs Production in association with top quarks

As discussed in Section II, the coupling of the Higgs particle to top quarks plays a special role in the electroweak breaking mechanism and in its possible extensions. Substantial indirect evidence of this coupling is provided by the compatibility of observed rates of the Higgs boson in the main discovery channels as one of the main production processes, the gluon fusion, is dominated by a top quark loop. Direct evidence of this coupling at the LHC and the future e^+e^- colliders will be mainly available through the $t\bar{t}H$ final state. The analyses channels for such complex final states can be separated in four classes according to the decays of the Higgs boson. In each of these classes, most of the decay final states of the top quarks are considered. The topologies related to the decays of the top quarks are denoted 0L, 1L and 2L, for the fully hadronic, semi-leptonic and dilepton final states of the $t\bar{t}$ pair respectively.

The first in this set is the search for $t\bar{t}H$ production in the $H \to \gamma\gamma$ channel. This analysis relies on the search of a narrow mass peak in the $m_{\gamma\gamma}$ distribution. The background is estimated from the $m_{\gamma\gamma}$ sidebands. The sensitivity in this channel is mostly limited by the available statistics. This search was done in all three 0L and 1L final states by the ATLAS and CMS collaborations with the full 8 TeV datasets [139,140].

The second is the search in the $H \to b\bar{b}$ channel. This search is extremely intricate due to the large backgrounds, both physical and combinatorial in resolving the $b\bar{b}$ system related to the Higgs particle, in events with six jets and four b-tagged jets which are very hard to simulate. With the current dataset, the sensitivity of this analysis is already limited by the systematic uncertainties on the background predictions. The ATLAS search was done in the 1L channel with the 7 TeV dataset only [141]. The CMS collaboration after having published first results with the full 7 TeV dataset [142,143], has complemented this result with a full 8 TeV analysis [144] with the 1L and 2L channels.

The third channel is a specific search for $\tau^+\tau^-$ where the two taus decay to hadrons and in the 1L channel only performed by CMS with the full 8 TeV dataset [144].

Finally, both W^+W^- and $\tau^+\tau^-$ final states are searched for inclusively by CMS in the full 8 TeV dataset in multilepton topologies [145]. The corresponding $t\bar{t}H$ modes can be simply decomposed in terms of the decays of the Higgs boson and those of the top quarks as having four W bosons in the final state (or two W

Table 11.5: Summary of the results of searches for a Higgs boson in association with a top quark pair by the ATLAS and CMS collaborations. The results are given in terms of upper limits at the 95% CL on the signal strength, the expected limits are given in parentheses. For the results of the CMS searches, the measured signal strengths in each channel are also given. The ATLAS results indicated by ‡ are with the 7 TeV dataset only, and the results indicate by * are combining the full 7 TeV and 8 TeV datasets. The unmarked results are with the full 8 TeV dataset.

	ATLAS limits	CMS limits	CMS signal strengths
$t\bar{t}(H \to \gamma\gamma)$	<5.3 (6.4)	<5.4 (5.5)	$\mu = -0.2^{+2.4}_{-1.9}$
$t\bar{t}(H \to b\bar{b})$	<13.1 (10.5)‡	<4.5 (3.7)*	$\mu = 1.0^{+1.9}_{-2.0}$
$t\bar{t}(H \to 4\ell)$	–	<6.8 (8.8)	$\mu = -4.8^{+5.0}_{-1.2}$
$t\bar{t}(H \to 3\ell)$	–	<6.7 (3.8)	$\mu = 2.7^{+2.2}_{-1.8}$
$t\bar{t}(H \to SS2\ell)$	–	<9.1 (3.4)	$\mu = 5.3^{+2.2}_{-1.8}$
$t\bar{t}(H \to \tau^+\tau^-)$	–	<12.9 (14.2)	$\mu = -1.4^{+6.3}_{-5.5}$
Combination	–	<4.3 (1.8)	$\mu = 2.5\ ^{+1.1}_{-1.0}$

and two taus) and two b-quarks. Three resulting distinctive topologies with leptonic decays of the W bosons or the taus have been investigate by CMS [145] with the full 8 TeV dataset: (i) the same sign dileptons, (ii) the trileptons and (iii) the four leptons.

The results of all aforementioned analyses are reported in Table 11.5. CMS has performed a combination of all their channels [146] yielding an upper limit on the signal strength at the 95% CL of 4.3, while having an expected sensitivity of 1.8. This difference is due to an excess of events observed in various sensitive channels. The measured combined signal strength is $\mu = 2.5^{+1.1}_{-1.0}$, yielding first hints of the presence of a signal in this channel.

III.7. Searches for rare decays of the Higgs boson

III.7.1. $H \to Z\gamma$

The search for $H \to Z\gamma$ is performed in the final states where the Z boson decays into opposite sign and same flavor leptons ($\ell^+\ell^-$), ℓ here refers to e or μ. While the branching fraction for $H \to Z\gamma$ is comparable to $H \to \gamma\gamma$ (about 10^{-3}) at $m_H = 125\,\text{GeV}$, the observable signal yield is brought down by the small branching ratio of $Z \to (e^+e^- + \mu^+\mu^-) = 6.7 \times 10^{-2}$. In these channels, the $m_{\ell\ell\gamma}$ mass resolution is excellent (1-3%) so the analyses search for a narrow mass peak over a continuous background. The major backgrounds arise from the $Z + \gamma$, final state radiation in Drell–Yan decays and $Z +$ jets process where a jet is misidentified as a photon.

Events are divided into mutually exclusive categories on basis of the expected $m_{Z\gamma}$ resolution and the signal-to-background ratio. A VBF category is formed for $H \to Z\gamma$ candidates which are accompanied by two energetic jets separated by a large pseudorapidity. While this category contains only about 2% of the total event count, the signal-to-noise is about an order of magnitude higher. The search for a Higgs boson is conducted independently in each category and the results from all categories are then combined.

No excess of events is observed. The expected and observed 95% CL upper limits [147] on the signal strength μ are 10 and 9.5 respectively for $m_H = 125\,\text{GeV}$. The ATLAS expected and observed upper limits [148] on μ are 13.5 and 18.2 respectively at that mass.

III.7.2. $H \to \mu^+\mu^-$

$H \to \mu^+\mu^-$ is the only channel where the Higgs coupling to second generation fermions can be measured at the LHC. The branching fraction in this channel for a 125 GeV SM Higgs boson is 2.2×10^{-4}, about ten times smaller than that for $H \to \gamma\gamma$. The dominant and irreducible background arises from the $Z/\gamma^* \to \mu^+\mu^-$ process which has a rate several orders of magnitude larger than that from the SM Higgs boson signal. Due to the precise muon momentum measurement achieved by ATLAS and CMS, the $m_{\mu^+\mu^-}$ mass resolution is excellent ($\approx 2-3\%$) but rendered marginally asymmetric due to final state radiation from the muons. A search is performed for a narrow peak over a large but smoothly falling background. For optimal search sensitivity, events are divided into several categories. To take advantage of the superior muon momentum measurement in the central region, the two experiments subdivide events by the pseudorapidity of the muons. To suppress the Drell–Yan background, ATLAS requires $p_T^{\mu^+\mu^-} > 15\,\text{GeV}$ while CMS separates them into two $p_T^{\mu^+\mu^-}$ based categories. CMS further categorizes events by the number and the topology of additional energetic jets in the event.

No excess in the $m_{\mu^+\mu^-}$ spectrum is observed near 125 GeV. From an analysis of $21\,\text{fb}^{-1}$ data at 8 TeV, ATLAS sets [149] a 95% CL upper limit on the signal strength $\mu < 9.8$. The CMS analysis [150] of their 7 and 8 TeV data sets a limit of $\mu < 7.4$.

III.7.3. Rare modes outlook

Rare decays such as those described in the above sections are clearly limited by statistics. They however already deliver a remarkable message. If the coupling of the Higgs boson was as strong in the dimuon channel as it is for the top quark, this mode would have been observed already with large significance. Thus it leads to the conclusion that, contrary to gauge bosons, the observed Higgs boson couples in a non-universal way to the different families of the SM fermions.

These searches play an increasingly important role in the characterization of the couplings of the Higgs particle. New channels such as those related to charm decays [151] and exclusive quarkonia final states such as $J/\Psi\gamma$ [152] are also of great interest.

III.8. Non-standard decay channels

The main decay and production properties of H are consistent with a standard model Higgs boson. It may however have other decay channels beyond those predicted by the Standard Model. Among these and of great interest are those invisible decays into stable particles that do not interact with the detector. The other non-standard decay channels that have been investigated are the decays of the Higgs particle to hidden valley or dark particles.

III.8.1. Invisible Higgs boson decays

The discovery of the Higgs particle has immediately raised the question of its couplings to dark matter and how it could be used to further try to reveal its existence at colliders, using the Higgs boson as a portal to dark matter, see Ref. [153] and references therein. If kinematically accessible and with a sufficiently large coupling to the Higgs boson, dark matter particles, such as, e.g., neutralinos in SUSY models or heavy neutrinos in the context of fourth generation of fermions models, would manifest themselves as invisible decays of the Higgs boson, thus strongly motivating searches for invisible decays of the Higgs boson.

Searches for invisible decays of the Higgs particle have been carried out in the following channels, taking advantage of the VBF and associated production with a vector boson signatures: (i) the search for high transverse momentum mono-vector boson production by the ALTAS collaboration [154] using fat-jet substructure techniques; (ii) the associated production with a vector boson subsequently decaying either to a pair of leptons by the ATLAS [155] and the CMS [156] collaborations or a pair of b-quarks by CMS [157]; (iii) in the VBF production process by the CMS experiment [158]. An independent reinterpretation of the monojet search results by the ATLAS and CMS collaborations was also done in Ref. [153]. The results of these searches are reported in Table 11.6.

A combination of the VH and VBF channels by the CMS collaboration yields an upper limit on the invisible branching fraction of the Higgs boson, assuming SM production cross sections, of 54% at the 95% CL, while the expected sensitivity is 46% at 95% CL [156].

Table 11.6: Summary of the results of searches for invisible decays of the Higgs particle H. Results can be interpreted in terms of 95% CL limit on the invisible branching fraction for a Standard Model production cross section or as the ratio of the product of the ZH production cross section times the Higgs invisible branching fraction its SM expectation. The results in parentheses are the expected exclusions.

	ATLAS	CMS
$W, Z \to$ fatjet, $H \to$ inv.	1.6 (2.2)	–
$Z \to \ell^+\ell^-$, $H \to$ inv.	65% (84%)	75% (91%)
$Z \to b\bar{b}$, $H \to$ inv.	–	1.8 (2.0)
VBF $H \to$ inv.	–	69% (53%)

III.8.2. Exotic Higgs boson decays

The discovered Higgs particle not only serves as a probe for potential dark matter candidates, but also to search for other exotic particles arising from fields associated with a low-mass hidden sector. Such hidden sectors are composed of fields that are singlets under the SM group SU(3) × SU(2) × $U(1)$. These models are referred to as hidden valley models [159,160]. Since a light Higgs boson is a particle with a narrow width, even modest couplings to new states can give rise to a significant modification of Higgs phenomenology through exotic decays. Simple hidden valley models exist in which the Higgs boson decays to an invisible fundamental particle, which has a long lifetime to decay back to SM particles through small mixings with the SM Higgs boson; Ref. [160] describes an example. The Higgs boson may also decay to a pair of hidden valley "v-quarks," which subsequently hadronize in the hidden sector, forming "v-mesons." These mesons often prefer to decay to the heaviest state kinematically available, so that a possible signature is $h \to 4b$. Some of the v-mesons may be stable, implying a mixed missing energy plus heavy flavor final state. In other cases, the v-mesons may decay to leptons, implying the presence of low mass lepton resonances in high H_T events [161]. Other scenarios have been studied [162] in which Higgs bosons decay predominantly into light hidden sector particles, either directly, or through light SUSY states, and with subsequent cascades that increase the multiplicity of hidden sector particles. In such scenarios, the high multiplicity hidden sector particles, after decaying back into the Standard Model, appear in the detector as clusters of collimated leptons known as lepton jets.

A variety of models have been investigated searching for final states involving dark photons and hidden valley scalars. The resulting topologies searched for are prompt electron jets in the WH production process [163], displaced muonic jets [164], the four muons final state where and the search for long lived weakly interacting particles [165]. The latter occur not only in hidden valley scenarios, but also in gauge-mediated extensions of the Minimal Supersymmetric Standard Model (MSSM), the MSSM with R-parity violation, and inelastic dark matter [166]. Finally the CMS collaboration has performed a search for pair production of light bosons [167]. Such a scenario can occur in supersymmetric models with additional hidden (or dark) valleys.

IV. Properties and nature of the new bosonic resonance

As discussed in Section II, within the SM, all the Higgs couplings are fixed unambiguously once all the particle masses are known. Any deviation in the measurement of the couplings of the recently discovered Higgs boson could thus signal the presence of new physics beyond the Standard Model.

Measuring the Higgs couplings without relying on the SM assumption requires a general framework treating deviations from the SM coherently at the quantum level in order to provide theoretical predictions for relevant observables to be confronted with experimental data. The effective Lagrangian approach offers such a coherent framework. It assumes that the new physics degrees of freedom are sufficiently heavy to be integrated out and simply give rise to effective interactions among the light SM particles. By construction these effective Lagrangians cannot account for deviations in Higgs physics induced by light degrees of freedom, unless they are added themselves as extra fields in the effective Lagrangians. In Section V, several examples of models with light degrees of freedom affecting Higgs production and decay rates will be presented.

IV.1. Theoretical framework

IV.1.1. Effective Lagrangian formalism

The most general $\mathrm{SU(3)}_C \times \mathrm{SU(2)}_L \times \mathrm{U(1)}_Y$-invariant Lagrangian for a weak doublet Φ at the level of dimension-6 operators was first classified in a systematic way in Ref. [168]. Subsequent analyses pointed out the presence of redundant operators, and a minimal and complete list of operators was finally provided in Ref. [169]. For a single family of fermions, there are 59 independent ways to deform the SM. With the 3 families of fermions of the SM, a flavor index can be added to these 59 operators. Furthermore, new operator structures, that have been dismissed by means of Fierz transformations in the single family case, have to be considered. Of particular interest are the 18 CP-invariant[6] and the 4 CP-breaking[7] deformation-directions, in addition to 8 dipole operators, that affect, at tree-level, the Higgs production and decay rates [170,171,172].

A convenient basis of these operators relevant for Higgs physics, assuming that the Higgs is a CP-even weak doublet and the baryon and lepton numbers are conserved, is the following:

$$\mathcal{L} = \mathcal{L}_{SM} + \sum_i \bar{c}_i \mathcal{O}_i \,, \tag{11.13}$$

where the operators are listed in Table 11.7, Table 11.8 and Table 11.9. When the operator $\mathcal{O}_i$ is not hermitian, like $\mathcal{O}_{t,b,\tau,Htb}$ and the dipole operators, it is understood that the hermitian-conjugated operator is added to the Lagrangian. The factor multiplying each operator in the effective Lagrangian has been conveniently defined such that the new physics dependence is fully encoded in the dimensionless coefficients $\bar{c}_i$ which will all have to be smaller than 1 to ensure the consistency of the expansion in terms of higher dimensional operators. The SM gauge couplings are denoted by g', g, g_S while $y_{t,b,\tau}$ are the SM Yukawa couplings (in the mass eigenstate basis that diagonalizes the general Yukawa coupling matrices $Y_{u,d,l}$), λ is the SM Higgs quartic coupling and v denotes the weak scale defined through the Fermi constant at tree-level $v \equiv 1/(\sqrt{2}G_F)^{1/2} \approx 246.2\,\mathrm{GeV}$. $i\Phi^\dagger \overleftrightarrow{D}^\mu \Phi$ denotes the Hermitian derivative $i\Phi^\dagger(D^\mu\Phi) - i(D^\mu\Phi)^\dagger\Phi$, and $\sigma^{\mu\nu} \equiv i[\gamma^\mu, \gamma^\nu]/2$ and Φ^c is the Higgs charge-conjugate doublet: $\Phi^c = i\sigma^2\Phi^*$. Each operator $\mathcal{O}_{t,b,\tau}$ is further assumed to be flavor-aligned with the corresponding fermion mass term, as required in order to avoid large Flavor-Changing Neutral Currents (FCNC) mediated by the tree-level exchange of the Higgs boson. This implies one coefficient for the up-type quarks ($\bar{c}_t$), one for down-type quarks ($\bar{c}_b$), and one for the charged leptons ($\bar{c}_\tau$), i.e. the $\bar{c}_{t,b,\tau}$ matrices should be proportional to the identity matrix in flavor space. Requiring that the only source of flavor violation in the new physics sector are proportional to the SM Yukawa interactions, the so-called minimal flavor violation assumption, imposes the presence of the $y_u y_d$ factor in the $\mathcal{O}_{Hud}$ operator,and the Yukawa dependence in the 8 dipole operators, while all the other operators are flavor universal up to corrections like $Y_u Y_u^\dagger$ or $Y_d Y_d^\dagger$.

The choice of the basis of operators is not unique and using the equations of motion, i.e., performing field redefinitions, different dimension-6 operators can be obtained as linear combinations of the operators in the previous tables and of four-fermion operators. In

[6] When the 3 fermion families are considered, there is a nineteenth operator involving different families of leptons, $(\bar{L}^i\gamma^\mu\sigma^a L^i)(\bar{L}^j\gamma^\mu\sigma^a L^j)$, that alters the Fermi constant and hence indirectly affects the predictions of the Higgs rates. The coefficient of this operator is actually constrained by the fit of EW precision data and thus cannot give any observable deviation in Higgs physics.

[7] In this counting, non-hermitian operators with fermions that could have complex Wilson coefficients and would also break the CP-invariance are not included.

Table 11.7: List of 9 CP-even and 4 CP-odd bosonic operators affecting Higgs production and decay rates. The 4 CP-odd operators involve the dual field strengths defined as $\tilde{F}_{\mu\nu} = 1/2\,\epsilon_{\mu\nu\rho\sigma}F^{\rho\sigma}$ for $F = W, B, G$ (ϵ is the totally antisymmetric tensor normalized to $\epsilon_{0123} = 1$). See text for notations.

$\mathcal{O}_{dW} = (g\,y_d)/m_W^2\,(\bar{q}_L\sigma^i\Phi\sigma^{\mu\nu}d_R)\,W^i_{\mu\nu}$
$\mathcal{O}_{dG} = (g_S\,y_d)/m_W^2\,(\bar{q}_L\Phi\sigma^{\mu\nu}t^A d_R)\,G^A_{\mu\nu}$
$\mathcal{O}_{lB} = (g'\,y_l)/m_W^2\,(\bar{L}_L\Phi\sigma^{\mu\nu}l_R)\,B_{\mu\nu}$
$\mathcal{O}_{lW} = (g\,y_l)/m_W^2\,(\bar{L}_L\sigma^i\Phi\sigma^{\mu\nu}l_R)\,W^i_{\mu\nu}$

particular, two other standard bases [173,169] involve the two extra bosonic operators

$$\begin{aligned}\mathcal{O}_{WW} &\equiv \frac{g^2}{4m_W^2}\,\Phi^\dagger\Phi\,W^i_{\mu\nu}W^{i\,\mu\nu}\\ &= \mathcal{O}_W - \mathcal{O}_B + \mathcal{O}_{HB} - \mathcal{O}_{HW} + \frac{1}{4}\,\mathcal{O}_{BB} \qquad (11.14)\\ \mathcal{O}_{WB} &\equiv \frac{gg'}{4m_W^2}\,\Phi^\dagger\sigma^i\Phi\,W^i_{\mu\nu}B^{\mu\nu} = \mathcal{O}_B - \mathcal{O}_{HB} - \frac{1}{4}\,\mathcal{O}_{BB}\,.\end{aligned}$$

IV.1.2. Constraints on Higgs physics from other measurements

Among the 30 operators affecting Higgs physics, some of them were already severely constrained before the Higgs discovery and result in deviations of the Higgs couplings that remain below the LHC sensitivity. This is obviously the case of the operators giving rise to some oblique corrections

$$\Delta\epsilon_1 \equiv \Delta\rho \equiv \Delta\hat{T} = \bar{c}_T, \quad \Delta\epsilon_3 \equiv \Delta\hat{S} = \bar{c}_W + \bar{c}_B. \qquad (11.15)$$

Electroweak precision data from LEP-I physics at the Z-pole constrain these oblique parameters and restrict the deviations of the couplings of the Z to e_R, u_L, u_R, d_L and d_R, leaving the following intervals for the values of the Wilson coefficients with 95% probability [171,174]

$$\begin{aligned}-1.5\times10^{-3} < \bar{c}_T < 2.2\times10^{-3}\,,\\ -1.4\times10^{-3} < \bar{c}_W + \bar{c}_B < 1.9\times10^{-3}\,,\\ -5\times10^{-3} < \bar{c}_{Hl} < 0\times10^{-3}\,,\\ -1\times10^{-3} < \bar{c}_{Hq} < 2\times10^{-3}\,,\\ -8\times10^{-3} < \bar{c}_{Hu} < 0\times10^{-3}\,,\\ -53\times10^{-3} < \bar{c}_{Hd} < 1\times10^{-3}\,,\\ -7\times10^{-3} < \bar{c}^{(3)}_{Hq} < 4\times10^{-3}\,.\end{aligned} \qquad (11.16)$$

Two other linear combinations of the operators are constrained by the bounds on the anomalous triple gauge boson self-couplings [174]

$$\begin{aligned}-8.8\times10^{-2} < \bar{c}_W - \bar{c}_B + \bar{c}_{HW} - \bar{c}_{HB} < 13.2\times10^{-2}\,,\\ -2.2\times10^{-2} < \bar{c}_{HW} + \bar{c}_{HB} < 1.9\times10^{-2}\,.\end{aligned} \qquad (11.17)$$

Notice, that there is one linear combination of the four bosonic operators $\mathcal{O}_B, \mathcal{O}_W, \mathcal{O}_{HB}$ and $\mathcal{O}_{HW}$ that remains unconstrained. This direction, $\bar{c}_B = -\bar{c}_W = -\bar{c}_{HB} = \bar{c}_{HW}$, induces a deviation of the $H \to Z\gamma$ decay rate that can thus only be constrained directly from the Higgs data. This free direction is a simple linear combination of $\mathcal{O}_{WW}$ and $\mathcal{O}_{BB}$.

The minimal flavor violation assumption imposes Yukawa dependences in the 8 dipole operators and in the $\mathcal{O}_{Hud}$ operator. For the light generations of fermions, this dependence lowers the induced deviations in the Higgs rates below the experimental sensitivity reachable in any foreseeable future. The corresponding operators in the top sector are not suppressed but they are already constrained by the limit of the top dipole operators imposed by the bounds on the neutron electric dipole moment, on the $b \to s\gamma$ and $b \to s\ell^+\ell^-$ rates and on the $t\bar{t}$ cross section [175,171].

Finally, in the CP-even sector, only 8 operators can potentially induce sizable deviations of the Higgs rates and can only be constrained, at tree-level, by Higgs data. These 8 operators correspond to $\{\mathcal{O}_H, \mathcal{O}_6, \mathcal{O}_{BB}, \mathcal{O}_{GG}, \mathcal{O}_{WW}, \mathcal{O}_t, \mathcal{O}_b, \mathcal{O}_\tau\}$, where by $\mathcal{O}_{WW}$ is the linear combination defined in Eq. (11.14). Section IV.2 illustrates how the Higgs data accumulated at the LHC can (partially) constrain the Wilson coefficients of these 8 directions. Automatic tools [171,176] are being developed to analyze the experimental data within an effective field theory framework.

IV.2. Experimental results

IV.2.1. Introduction

As described in Section II, there are five main production modes of a Standard Model Higgs boson at the LHC. In the current dataset corresponding to an integrated luminosity of approximately 20 fb^{-1} of pp collisions at 8 TeV, and approximately 5 fb^{-1} of collisions at 7 TeV, the predicted numbers of SM Higgs bosons produced per experiment are 0.5 million, 40,000, 20,000 and 3,000 events produced in the gluon fusion, vector boson fusion, the associated WH or ZH, and the associated $t\bar{t}H$ production modes respectively. The typical number of events selected eventually in each decay channel is then much smaller ranging from O(10) to O(100) events per experiment. For

each main decay mode, exclusive categories according to production modes have been designed to maximize the sensitivity of the analyses to the presence of a signal and using known discriminating features of these modes. These categories can also be used to further separate production modes for each decay channel. Similarly at the Tevatron where the CDF and DØ experiments have gathered approximately 10 fb^{-1} of data at 1.96 TeV, the predicted numbers of SM Higgs boson events produced per experiment are approximately 10000 and 2000 events in the gluon fusion and VH associated production, respectively.

At the LHC or the Tevatron, in none of the production modes is the total cross section measurable. As a consequence, neither absolute branching fractions nor the total natural width of the Higgs boson can be directly measured. However a combined measurement of the large variety of categories described in Section III, with different sensitivities to various production and decay modes permits a wide variety of measurements of the production, decay or in general coupling properties. These measurements require in general a limited but nevertheless restrictive number of assumptions.

include the $b\bar{b}$ [178] and $\tau^+\tau^-$ channels [179]. The results of these two individual channels are nonetheless reported in Table 11.10. It should also be noted that the CMS combination includes the search for a Higgs boson in the $b\bar{b}$ decay channel and produced in association to a pair of top quarks [180].

From the categories individual signal strengths, an already quite coherent picture emerges with a good consistency of the observation in each of the channels categories with the expectation for a Standard Model Higgs boson. The errors on the measurements reported in Table 11.10 reflect both statistical and systematic uncertainties.

IV.2.3. Characterization of the main production modes

Coupling properties can be measured via a combined fit of all categories simultaneously with a parametrization of the number of signal events per categories defined as follows.

$$n^c_{signal} = (\sum_i \mu_i \sigma_{i,SM} \times A^c_{if} \times \varepsilon^c_{if}) \times \mu_f \times B_{f,SM} \times \mathcal{L}\,, \qquad (11.19)$$

Table 11.10: Summary of the individual categories signal strengths for the main analysis channels of ATLAS (A) and CMS (C). It should be noted that the expected number of SM signal events in each category is typically composed of various production modes. * denotes those results which are are not in the combination. ‡ denotes the $H \to \tau^+\tau^-$ ATLAS analysis which is the only measurement not based on the full dataset, but the full 2011 7 TeV dataset and a partial 2012 8 TeV set of pp collision events, corresponding to an integrated luminosity of approximately 13 fb^{-1}.

IV.2.2. Measuring the signal in categories

For each category of a given channel the number of signal events yield can be measured and be converted to signal strengths per categories μ_c. These categories signal strengths can be expressed as follows in terms of the number of signal events fitted in a given category c:

$$n^c_{signal} = \mu_c(\sum_i \sigma_{i,SM} \times A^c_{if} \times \varepsilon^c_{if}) \times B_{f,SM} \times \mathcal{L} \qquad (11.18)$$

where A represents the detector acceptance, ε the reconstruction efficiency and $\mathcal{L}$ the integrated luminosity. μ_c can be interpreted as the ratio of the number of signal events n^c_{signal} fitted in category c divided by the expected number of events in that category. The production index $i \in \{ggH, VBF, VH, ttH\}$ and the decay index $f \in \{\gamma\gamma, WW, ZZ, bb, \tau\tau\}$. Typically a given category covers mainly one decay mode, but possibly various production modes. Table 11.10 summarizes the individual categories signal strengths for the main categories considered by the two experiments ATLAS [119] and CMS [177] in their combined measurement of the coupling properties of the H. It should be noted that the ATLAS combination does not

where μ_i and μ_f are the main parameters of interest. It is manifest in the above equation that production mode (μ_i) and decay mode (μ_f) signal strengths cannot be determined simultaneously. However given that in the main channels the decay mode strength parameters factorize, for each decay mode individually, the products of the $\mu_i \times \mu_f$, where f is fixed can be measured simultaneously. The results of such fits in the $H \to \gamma\gamma$, $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ and $H \to Z^{(*)}Z^{(*)} \to 4\ell$ channels are shown in Fig. 11.17, illustrating a probe of the main production modes, where the small $t\bar{t}H$ mode component is assumed to scale as the gluon fusion mode ($\mu_{ggH+ttH} = \mu_{ggH} = \mu_{ttH}$). Similarly the VBF and VH production modes are scaled simultaneously ($\mu_{VBF+VH} = \mu_{VBF} = \mu_{VH}$). The SM expectation correspond to the (1,1) coordinates. The aspect ratio of the contours of Fig. 11.17 also shows the relative strength of the gluon fusion and the VBF+VH the observations for each individual channel.

IV.2.4. Evidence for VBF production

To cancel the dependence on the branching fractions, a measure of the presence of a VBF or VBF+VH signal is given by the ratio of the productions times decay signal strength parameters.

$$\rho_{VBF+VH,ggH+ttH} = \frac{\mu_{VBF+VH}\mu_f}{\mu_{ggF+ttH}\mu_f} = \frac{\mu_{VBF+VH}}{\mu_{ggF+ttH}} \qquad (11.20)$$

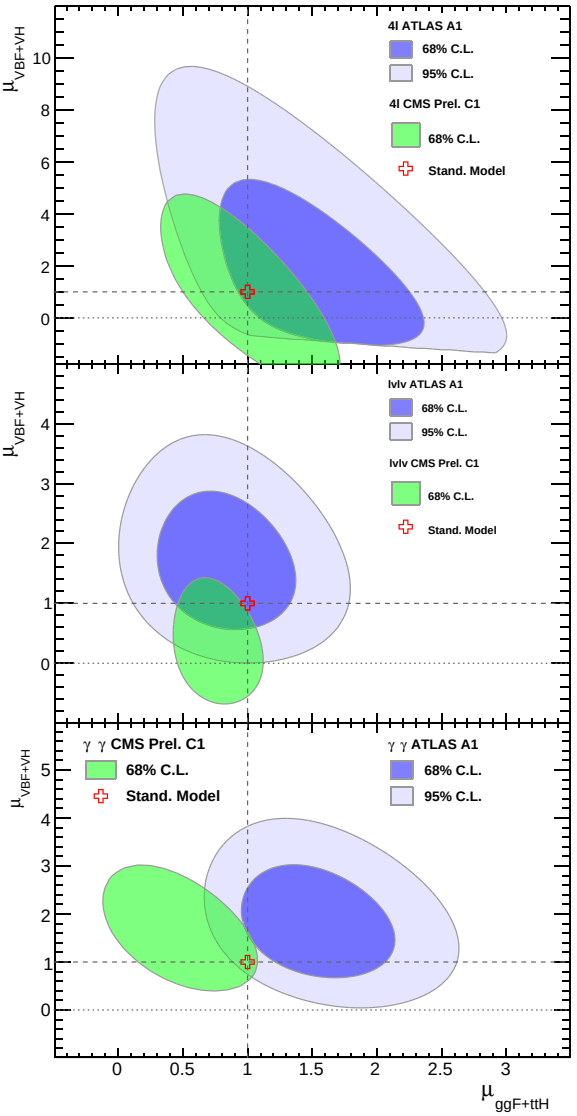

Figure 11.17: Likelihood contours for individual production mode signal strengths ($ggF+ttH$ versus $VBF+VH$) for various decay modes for the ATLAS experiment A1 [119] and the CMS experiment C1 [120] results.

For the VBF-only ratio $\rho_{VBF,ggH+ttH}$, the VH production mode is independently determined from the fit, thus needing at least one exclusive category to be sensitive enough to VH in order to remove the degeneracy with the VBF signal. The measured values of these parameters by the ATLAS (A) and CMS (C) experiments are the following:

$$\begin{aligned} \rho_{VBF,ggH+ttH} &= 1.1^{+0.4}_{-0.3} \ (A) \\ \rho_{VBF+VH,ggH+ttH} &= 1.1^{+0.4}_{-0.3} \ (A) \\ \rho_{VBF+VH,ggH+ttH} &= 1.7^{+0.7}_{-0.5} \ (C) \end{aligned} \tag{11.21}$$

The observation by ATLAS excludes a value of the $\rho_{VBF,ggH+ttH} = 0$ at more than 3σ, thus providing a quantitative evidence for VBF production. The observations by ATLAS and CMS exclude a value of $\rho_{VBF+VH,ggH+ttH} = 0$ at an even greater level of confidence.

IV.2.5. Measurement of the coupling properties of H

(i) From effective Lagrangians to Higgs observables

All 8 operators of the effective Lagrangian Eq. (11.13) that were unconstrained before the Higgs data induce, at tree-level, deviations in the Higgs couplings that respect the Lorentz structure of the SM interactions, or generate simple new interactions of the Higgs boson to the W and Z field strengths, or induce some contact interactions of the Higgs boson to photons (and to a photon and a Z boson) and gluons that take the form of the ones that are generated by integrating out the top quark. In other words, the Higgs couplings are described, in the unitary gauge, by the following effective Lagrangian [181,38]

Table 11.11: Correspondence between the κ's and the Wilson coefficients of the dimension-6 operators of the Higgs EFT Lagrangian constrained only by Higgs physics.

Coupling modifier	Wilson coefficient dependence
κ_3	$1 + \bar{c}_6 - 3\bar{c}_H/2$
κ_V	$1 - \bar{c}_H/2$
κ_f	$1 - \bar{c}_f - \bar{c}_H/2$
κ_γ	$(2\pi/\alpha)\,\sin^2\theta_W\,(4\bar{c}_{BB} + \bar{c}_{WW})$
$\kappa_{Z\gamma}$	$(\pi/\alpha)\,\sin 2\theta_W\,\bar{c}_{WW}$
κ_{VV}	$(\pi/\alpha)\,\bar{c}_{WW}$
κ_g	$(48\pi/\alpha)\,\sin^2\theta_W\,\bar{c}_{GG}$

$$\begin{aligned} \mathcal{L} = {} & \kappa_3 \frac{m_H^2}{2v} H^3 + \kappa_Z \frac{m_Z^2}{v} Z_\mu Z^\mu H + \kappa_W \frac{2m_W^2}{v} W^+_\mu W^{-\mu} H \\ & + \kappa_g \frac{\alpha_s}{12\pi v} G^a_{\mu\nu} G^{a\mu\nu} H + \kappa_\gamma \frac{\alpha}{2\pi v} A_{\mu\nu} A^{\mu\nu} H + \kappa_{Z\gamma} \frac{\alpha}{\pi v} A_{\mu\nu} Z^{\mu\nu} H \\ & + \kappa_{VV} \frac{\alpha}{2\pi v} \left(\cos^2\theta_W Z_{\mu\nu} Z^{\mu\nu} + 2\, W^+_{\mu\nu} W^{-\mu\nu} \right) H \\ & - \left(\kappa_t \sum_{f=u,c,t} \frac{m_f}{v} f\bar{f} + \kappa_b \sum_{f=d,s,b} \frac{m_f}{v} f\bar{f} + \kappa_\tau \sum_{f=e,\mu,\tau} \frac{m_f}{v} f\bar{f} \right) H. \end{aligned} \tag{11.22}$$

The correspondence between the Wilson coefficients of the dimension-6 operators and the κ's is given in Table 11.11. In the SM, the Higgs boson does not couple to massless gauge bosons at tree level, hence $\kappa_g = \kappa_\gamma = \kappa_{Z\gamma} = 0$. Nonetheless, the contact operators are generated radiatively by SM particles loops. In particular, the top quark gives a contribution to the 3 coefficients $\kappa_g, \kappa_\gamma, \kappa_{Z\gamma}$ that does not decouple in the infinite top mass limit. For instance, in that limit $\kappa_\gamma = \kappa_g = 1$ [19,20,182] (the contribution of the top quark to $\kappa_{Z\gamma}$ can be found in Ref. [182]).

The coefficient for the contact interactions of the Higgs boson to the W and Z field strengths is not independent but obeys the relation

$$(1 - \cos^4\theta_W)\kappa_{VV} = \sin 2\theta_W \kappa_{Z\gamma} + \sin^2\theta_W \kappa_{\gamma\gamma}. \tag{11.23}$$

This relation is a general consequence of the custodial symmetry [171]. When the Higgs boson is part of an $SU(2)_L$ doublet, the custodial symmetry could only be broken by the $\mathcal{O}_T$ operator at the level of dimension-6 operators and it is accidentally realized among the interactions with four derivatives, like the contact interactions considered.

The coefficient κ_3 can be accessed only through double Higgs production processes, hence it will remain largely unconstrained at the LHC. The LHC will also have a limited sensitivity on the coefficient κ_τ since the lepton contribution to the Higgs production cross section remains subdominant and the only way to access the Higgs coupling is via the $H \to \tau^+\tau^-$ and possibly $H \to \mu^+\mu^-$ channels. Until the associated production of a Higgs with a pair of top quarks is observed, the Higgs coupling to the top quark is only probed indirectly via the one-loop gluon fusion production or the radiative decay into two photons. However, these two processes are only sensitive to the two combinations $(\kappa_t + \kappa_g)$ and $(\kappa_t + \kappa_\gamma)$ and a deviation in the Higgs coupling to the top quark can in principle always be masked by new contact interactions to photons and gluons.

The operators already bounded by EW precision data and the limits on anomalous gauge couplings modify in general the Lorentz structure of the Higgs couplings and hence induce some modifications of the kinematical differential distributions [183,174]. A promising way to have a direct access to the Wilson coefficients of these operators in Higgs physics is to study the VH associated production with a W or

a Z at large invariant mass [183,184]. It has not been estimated yet whether the sensitivity on the determination of the Wilson coefficients in these measurements can compete with the one derived for the study of anomalous gauge couplings. In any case, these differential distributions could also be a way to directly test the hypothesis that the Higgs boson belongs to a $SU(2)_L$ doublet together with the longitudinal components of the massive electroweak gauge bosons.

(ii) Interpretations of the experimental data

To further interpret the observations in the analysis categories, a global approach can be adopted where the μ_i and μ_f categories signal strength parameters are further interpreted in terms of modifiers of the SM couplings κ_k where $k \in \{Z, W, f, g, \gamma, Z\gamma\}$ as in Eq. (11.22). These coupling modifiers κ are motivated as leading order coupling scale factors defined such that the cross sections σ_j and the partial decay widths Γ_j associated with the SM particle j scale with the factor κ_j^2 when compared to the corresponding SM prediction. The number of signal events per category for the various production modes are typically estimated at higher orders in the analyses but are scaled by these single LO-inspired factors, thus not taking into account possible intricacies and correlations of these parameters through the higher order corrections. This approximation is valid within the level of precision of current results and their compatibility with the SM expectation.

The κ_g, κ_γ and $\kappa_{Z\gamma}$, can be treated effectively as free parameters in the fit or in terms of the know SM field content and as a function of the SM coupling modifiers, in the following way:

$$\begin{aligned}
\kappa_g^2(\kappa_t, \kappa_b) &= 1.06 \cdot \kappa_t^2 - 0.07 \cdot \kappa_t\kappa_b + 0.01 \cdot \kappa_b^2 \\
\kappa_\gamma^2(\kappa_F, \kappa_V) &= 1.59 \cdot \kappa_V^2 - 0.66 \cdot \kappa_V\kappa_F + 0.07 \cdot \kappa_F^2 \\
\kappa_{Z\gamma}^2(\kappa_F, \kappa_V) &= 1.12 \cdot \kappa_V^2 - 0.15 \cdot \kappa_V\kappa_F + 0.03 \cdot \kappa_F^2
\end{aligned} \qquad (11.24)$$

These parametrizations are given for a Higgs boson mass hypothesis of 125 GeV. It can be noted from the expression of κ_γ that the coupling of the Higgs boson to photons is dominated by the loop of W bosons, and it is affected by the top quark loop mostly through its interference with the W loop. The sensitivity of the current measurements to the relative sign of the fermion and vector boson couplings to the Higgs boson is due to this large negative interference term. The κ_g parameter is expressed in terms of the scaling of production cross sections and therefore also depends on the pp collisions centre-of-mass energy. The parametrizations of κ_γ and $\kappa_{Z\gamma}$ are obtained from the scaling of partial widths and are only dependent on the Higgs boson mass hypothesis. Experiments use a more complete parametrization with the contributions from the b-quarks, τ-leptons in the loop [181,38].

The global fit is then performed expressing the μ_i and μ_f parameters in terms of a limited number of κ_k parameters or their ratios, under various assumptions. The parametrization for the production modes are: $\mu_{ggF} = \kappa_g^2$ for the gluon fusion; $\mu_{VBF,VH} = \kappa_V^2$ for the VBF and VH processes when the W and Z couplings are assumed to scale equally, and the following expression for the VBF production mode is used:

$$\kappa_{VBF}^2(\kappa_W, \kappa_Z) = \frac{\kappa_W^2\sigma_{WWH} + \kappa_Z^2\sigma_{ZZH}}{\sigma_{WWH} + \sigma_{ZZH}} \qquad (11.25)$$

when the couplings to the W and Z bosons are varied independently (σ_{WWH} and σ_{ZZH} denote the VBF cross sections via the fusion of a W and a Z boson respectively, the small interference term is neglected); $\mu_{ttH} = \kappa_t^2$ for the $t\bar{t}$H production mode. The decay mode signal strengths are parametrized as $\mu_k = \kappa_k^2/\kappa_H^2$ where $k \in \{Z, W, f, g, \gamma, Z\gamma\}$ denotes the decay mode and κ_H the overall modifier of the total width. Similarly to κ_g, κ_γ, and $\kappa_{Z\gamma}$, κ_H can be treated as an effective parameter or expressed in terms of the coupling modifiers to the SM field content.

Beyond this approximation two further assumptions are implicitly made: (i) the signals observed in the different search channels originate from a single narrow resonance with a mass of 125 GeV. The width of the assumed Higgs boson is neglected, both in the fitted signal model (for both approaches) and in the zero-width approximation (in the second case to allow the decomposition of signal yields); (ii) the tensor structure of the couplings is assumed to be the same as that of a SM Higgs boson. This means in particular that the observed state is assumed to be a CP-even scalar as in the SM.

A global fit to the data is then performed to specifically test three aspects of the coupling properties of the H under different assumptions: (i) the relative couplings of the Higgs boson to fermions and bosons; (ii) the relative couplings of the Higgs boson to the W and the Z, and (iii) the potential impact of the presence of new particles beyond the SM either in the loops or both in the loops and the decay of the H.

(iii) Relative couplings to bosons and fermions

In this benchmark only SM particles are assumed to contribute to the gluon fusion and the diphoton loops, all fermion couplings modifiers are required to scale simultaneously with a unique factor κ_F and all vector boson couplings modifiers must scale simultaneously with a unique factor κ_V. The global fit is then performed under both the assumption that no new particles affect the direct decays or the loops, and without assumptions on the total width.

In the first scenario it is a two parameters fit with κ_V and κ_F as parameters of interest. The contours from the two LHC experiments and the Tevatron combination are shown in Fig. 11.18.

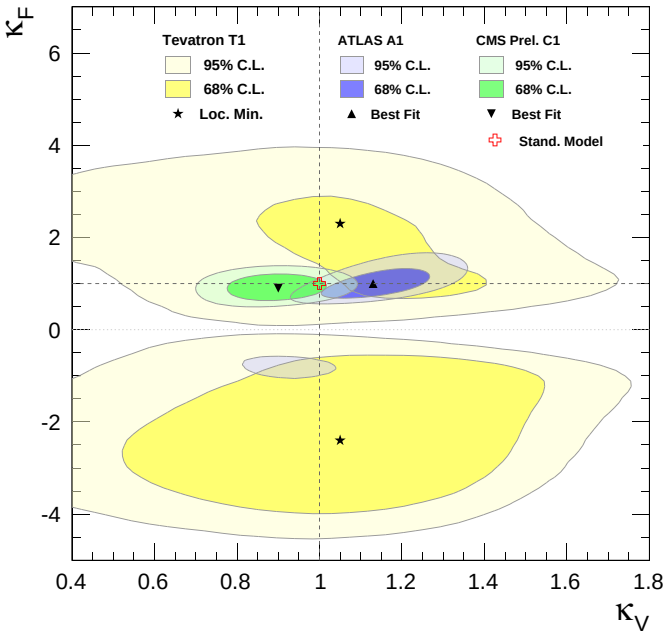

Figure 11.18: Likelihood contours of the global fit in the (κ_F, κ_V) plane for the ATLAS A1 [119], the CMS C1 [120] and the D0 and CDF combined T1 [108] results.

The global fit is only sensitive to the relative sign of κ_V and κ_F. By convention negative values of κ_F are considered. Such values are not excluded a priori, but would imply the existence of new physics at a light scale and would also raise questions about the stability of such a vacuum [185]. Among the five low mass Higgs channels, only the $\gamma\gamma$ is sensitive to the sign of κ_F through the interference of the W and t loops as shown in Eq. (11.24). The current global fit disfavors a negative value of κ_F at more than two standard deviations. A specific analysis for the Higgs boson production in association with a single top quark has been proposed [186,187] in order to more directly probe the sign of κ_F. All available experimental data show a fair agreement of the SM prediction of the couplings of the Higgs boson to fermions and gauge bosons. These results yield an indirect evidence for the coupling of the H to fermions.

In the second scenario the number of signal events per categories are parametrized using the two following parameters $\lambda_{FV} = \kappa_F/\kappa_V$

and $\lambda_{VV} = \kappa_V^2/\kappa_H$ where no assumption is made on the total width. It should be noted that this scenario corresponds to a model where the total width can vary but the field content that might modify the width should not sizably affect the loops.

The results for these two scenarios are reported in Table 11.12.

(iv) Probing the ratio of couplings to the W and Z bosons

The ratio of the couplings of the Higgs boson to W and Z bosons is an important probe of the EWSB mechanism as it is directly related to the tree level prediction $\rho = 1$ and the custodial symmetry. The W to Z couplings are probed in various production processes and decay modes of the Higgs boson. The ratio $\lambda_{WZ} = \kappa_W/\kappa_Z$ can therefore be probed under a large number of conditions.

The first requires that all fermion couplings scale with a single coupling modifier κ_F and the total width is allowed to vary, embedded in a single factor κ_{ZZ}. Both the ATLAS and CMS experiments have performed the a global fit using this model. Similarly to the λ_{FV} ratio, no assumption is made on the total width but the loops assume exclusively a SM content.

In order to be less dependent on loops, which in the case of the diphoton decay channel are dominated by the coupling to the W boson, and to the yet to be fully established coupling to fermions, since the main channels in the direct fermion decay channels rely on production processes dominated by gauge boson couplings (VH and VBF), additional models are used. In the first, performed by CMS only and denoted λ^*_{WZ} in Table 11.12, only the $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ and $H \to Z^{(*)}Z^{(*)} \to 4\ell$ channels are used in the fit. The second, similar to the latter and performed by the ATLAS collaboration only, consists in a fit of the ratio of categories signal strengths:

$$(\lambda^{\circ}_{WZ})^2 = \frac{\mu_{H\to WW^*}}{\mu_{H\to ZZ^*}} \qquad (11.26)$$

The other parameters of this model are the $\mu_{ggF+ttH} \times \mu_{H\to ZZ^*}$ and the ratio $\mu_{VBF+VH}/\mu_{ggF+ttH}$ which are fitted independently.

In the third, performed by ATLAS, the coupling to photons is taken as effective in the fit, thus decoupling the observation in the diphoton channel. The latter is denoted $\lambda^{\ddagger}_{WZ}$.

The results of all models are reported in Table 11.12. For all models probed the measured ratios λ_{WZ} are compatible with the SM expectation. Although these measurements are not the most precise tests of the custodial symmetry it is of fundamental check of the nature of the electroweak symmetry breaking mechanism to see that the ratio of the couplings of the H to the W and Z bosons are compatible with what is expected from the SM Higgs sector.

(v) Probing new physics in loops and in the decay

In the models described above the assumption is that no new fields sizably distort the loop contributions in the couplings of the H to gluons and photons and its couplings to known SM particles are probed. Assuming that the couplings of the H are equal to their SM expectation, the effective coupling of the H to photons and gluons can be used to probe new physics beyond the SM through the loops. These assumptions can be simply expressed as $\kappa_F = \kappa_V = 1$ and the κ_g and κ_γ couplings modifiers are free in the fit. A first approach is to probe for new physics beyond the SM in the loops and not in the decay. The total width is then defined as a function of the two effective coupling modifiers (for a Higgs boson mass hypothesis of $m_H = 125\,\text{GeV}$) as follows.

$$\kappa_H^2 = 0.085 \cdot \kappa_g^2 + 0.0023 \cdot \kappa_\gamma^2 + 0.91. \qquad (11.27)$$

The results of the combined fits performed by the ATLAS and CMS experiments are given in Table 11.12 and the contours of the combined likelihood in the $(\kappa_\gamma, \kappa_g)$ plane are shown in Fig. 11.19.

In the second approach, new physics is considered also in the decay thus affecting the total width of the H through decays to particles which are either "invisible" in that they escape detection in the experiments, or "undetected" in that they are not distinctive enough to be seen in the current analyses. This contribution is parametrized as an invisible and undetected branching fraction $Br_{inv,und}$ which is fitted in addition to the κ_γ and κ_g parameters. The ATLAS result on $Br_{inv,und}$ is from the preliminary combination including the fermion modes [116]. The results of this fit are also reported in Table 11.12. This indirect approach, can be combined with direct invisible decay searches.

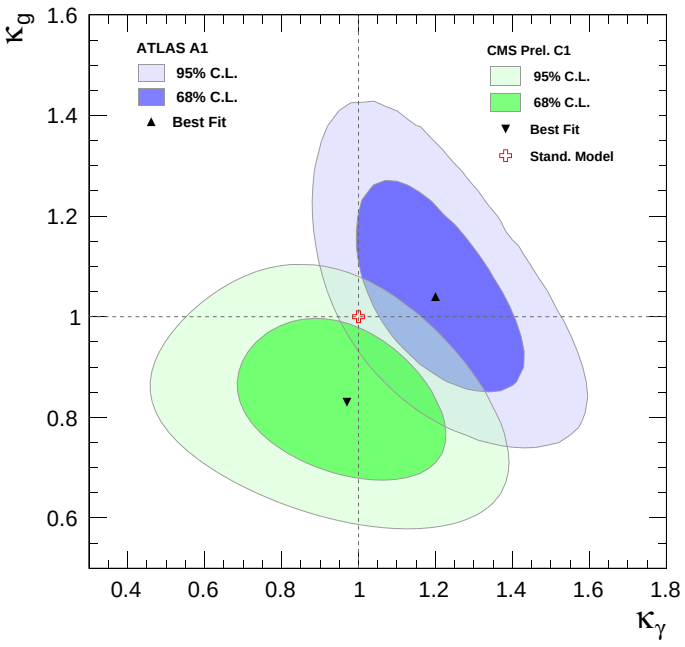

Figure 11.19: Likelihood contours of the global fit in the $(\kappa_g, \kappa_\gamma)$ plane for the ATLAS experiment A1 [119] and the CMS experiment C1 [120] results.

Table 11.12: Summary of the coupling properties measurements in terms of 68% confidence intervals. The ATLAS limit on the invisible or undetected branching fraction denoted by (*) is from the preliminary combination reported in Ref. [116].

(vi) Generic measurement of the H couplings to fermions and gauge bosons

A more generic model testing the couplings of the H to the W and Z bosons through a single coupling modifier parameter κ_V and the couplings to the third generation fermions are tested separatedly κ_b, κ_τ and κ_t. In this model the effective couplings to photons and gluons take into account possible loop induced contributions in the κ_γ and κ_g modifiers, respectively. The assumption is that no additional contribution affect the total width and that the couplings to the fermions of the first and second generation are equal to those of the third (separating charged leptons, and up and down type quarks).

The results of this global fit are reported in Table 11.12. It illustrates the good agreement of the measured coupling modifiers with the SM Higgs boson couplings, in particular with its dependence in mass as described in Section II.

IV.2.6. Differential cross sections

To further characterize the production and decay properties of H, first measurements of fiducial and differential cross sections have been carried out by the ATLAS collaboration [188], with the 8 TeV dataset of pp collision at LHC, corresponding to an integrated luminosity of 20.3 fb^{-1}, in the diphoton channel. The selection criteria to define the fiducial volume are the following: the two highest transverse momentum (E_T), isolated final state photons, within $|\eta| < 2.37$ and with $105\,\text{GeV} < M_{\gamma\gamma} < 160\,\text{GeV}$ are selected (the transition region between the barrel and endcap calorimeters is not removed); after the pair is selected, the same cut on $E_T/M_{\gamma\gamma}$ as in the event selection *i.e.* in excess of 0.35 (0.25) for the two photons is applied. Several observables have been studied: the transverse momentum rapidity of the diphoton system, the production angle in the Collins–Soper frame, the jet multiplicity, the jet veto fractions for a given jet multiplicity, and the transverse momentum distribution of the leading jet. The following additional observables: the difference in azimuthal angle between the leading and the subleading jets, and the transverse component of the vector sum of the momenta of the Higgs boson and dijet system, have also been measured in two jet events. To minimize the model dependence the differential cross sections are given within a specific fiducial region of the two photons. The observables were chosen to probe the production properties and the spin and parity of the H. The differential cross section in H transverse momentum is given in Fig. 11.20.

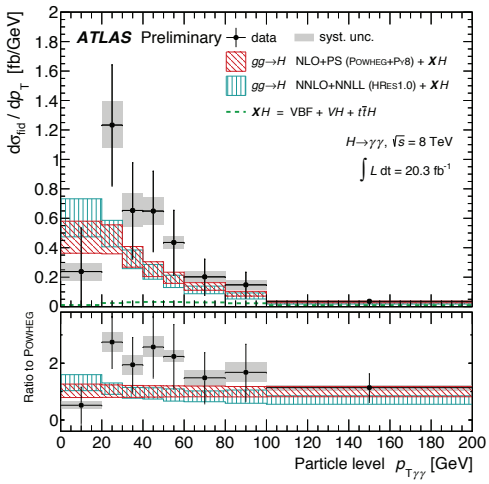

Figure 11.20: Observed differential cross sections in transverse momentum of the H in the diphoton channel, compared to the prediction of the ggH process [188].

IV.3. Main quantum numbers J^{PC}

The measurements of the signal event yields of the observed new state in all the channels discussed above and their compatibility with the Standard Model Higgs boson predictions, gives qualitative, but nonetheless compelling evidence of its nature. This qualitative picture is further complemented by the implications of the observation of the particle in the diphoton channel. According to the Landau–Yang theorem [189], the observation made in the diphoton channel excludes the spin 1 hypothesis and restricts possibilities for the spin of the observed particle to 0 or 2.

However, the Landau–Yang theorem does not apply if the observed state is not decaying to a pair of photons but to a pair of scalars subsequently decaying to two very collimated pairs of photons (as for example in the case of $H \to a_1 a_1 \to 4\gamma$). This possibility has not been rigorously tested but it is not experimentally favored as tight selection criteria are applied on the electromagnetic shower shapes of the reconstructed photons. A more systematic analysis of shower shapes and the fraction of conversions could be performed to further discriminate between the single prompt photon and the two overlapping photons hypotheses. There are also potential theoretical loopholes concerning the applicability of the Landau–Yang theorem, such as off-shell vector boson decays.

For the observed particle not to be of spin 0 and +1 parity would require an improbable conspiracy of effects. It is nevertheless very important that this hypothesis be independently tested.

IV.3.1. Charge conjugation C

The charge conjugation quantum number is multiplicative, therefore given that the Higgs-like particle is observed in the $H \to \gamma\gamma$ channel, and given that photons are C-odd eigenstates, assuming C conservation, the observed neutral particle should be C-even.

IV.3.2. General framework

To further assess the spin and parity quantum numbers of the discovered particle, a systematic analysis of its production and decay processes is performed. These analyses have been designed to be as independent as possible from the event yields measured in each exclusive categories, relying instead on the production and the decay angles, and on the threshold distributions, of the produced particle.

This leads to test hypotheses which are typically disfavored by the analysis of the rates, such as a pseudoscalar particle decaying to a pair of W or Z bosons which requires, decays through loops or to test spin 2 hypotheses for which no renormalizable model exist. The sizable interaction of the observed state with electroweak gauge bosons, if it were pseudoscalar, would imply low scale physics in the loops and therefore would be ruled out by the absence of direct observation of such states.

To define, generate and test the newly observed state without theoretical prejudice, the most general tensor structure is used for the three possible spin hypotheses of spin 0, spin 1 and spin 2. The most general spin-0 interaction amplitude with two gauge bosons can be written as follows [190,191]

$$\begin{aligned} A^{(0)} =& v^{-1}\left(g_1^{(0)} m_V^2 \varepsilon_1^* \varepsilon_2^* + g_2^{(0)} f_{\mu\nu}^{*(1)} f^{*(2),\mu\nu}\right. \\ &\left. + g_3^{(0)} f^{*(1),\mu\nu} f_{\mu\alpha}^{*(2)} \frac{q_\nu q_\alpha}{\Lambda^2} + g_4^{(0)} f_{\mu\nu}^{*(1)} \tilde{f}^{*(2),\mu\nu}\right), \end{aligned} \tag{11.28}$$

where the ε denotes the polarization vector of a spin 1 boson, q the momentum of the a vector boson, $f^{(i),\mu\nu} = \varepsilon_i^\mu q_i^\nu - \varepsilon_i^\nu q_i^\mu$ is the field strength tensor of a gauge boson with momentum q_i and polarization ε_i, and Λ is the new physics mass scale. The $g_j^{(0)}$ are dimensionless and momentum dependent complex form factors.

The first term corresponds to the Standard Model case 0^{++} where

$$\mathcal{L} \supset g_1^{(0)} H Z_\mu Z^\mu \tag{11.29}$$

The second (CP conserving if H^0 is 0^+) and fourth (CP violating) terms correspond to 5 dimensional operator couplings through loops of the type

$$\mathcal{L} \supset g_2^{(0)} H Z_{\mu\nu} Z^{\mu\nu} + g_4^{(0)} H Z_{\mu\nu} \tilde{Z}^{\mu\nu} \tag{11.30}$$

The third term corresponds to a dimension-7 operator involving new physics possibly appearing at a scale Λ.

Table 11.13: Benchmark scenarios for the analysis of the production and decay of the observed state with J^P quantum numbers. The subscripts refer to the specificities of the couplings of the observed state, where m denotes minimal couplings and h denotes couplings with higher dimension operators. For each scenarios only the non vanishing coupling constants are reported in this table. 0_h^+ denotes a scalar with higher orer (HO) couplings.

Scenario	Production	Decay	Scenario
0_m^+	$gg \to X$	$g_1^{(0)} = 2$	SM Higgs bosons
0_h^+	$gg \to X$	$g_2^{(0)} \neq 0$	HO scalar
0^-	$gg \to X$	$g_4^{(0)} \neq 0$	PSeudo scalar
1^+	$qq \to X$	$g_2^{(1)} \neq 0$	Pseudo vector
1^-	$qq \to X$	$g_a^{(1)} \neq 0$	Vector
2_m^+	$g_1^{(2)} \neq 0$	$g_1^{(2)} = g_5^{(2)} \neq 0$	Graviton tensor MC
2_h^+	$g_4^{(2)} \neq 0$	$g_4^{(2)} \neq 0$	Graviton tensor HD op.
2^-	$g_8^{(2)} \neq 0$	$g_8^{(2)} \neq 0$	Pseudo tensor

Analogously the most general spin 1 interaction amplitude with two gauge bosons can be expressed as follows

$$A^{(1)} = g_1^{(1)}\left[(\varepsilon_1^* q)(\varepsilon_2^* \varepsilon_X)\right] + g_2^{(1)} \epsilon_{\alpha\beta\mu\nu} \varepsilon_X^{\alpha} \varepsilon_1^{*,\mu} \varepsilon_2^{*,\nu} \tilde{q}^{\beta} \qquad (11.31)$$

Finally the general spin 2 case can be expressed as follows [190]

$$\begin{aligned} A^{(2)} = \frac{1}{\Lambda}\Bigg[& 2g_1^{(2)} t_{\mu\nu} f^{*1,\mu\alpha} f^{*2,\nu\alpha} + 2g_2^{(2)} t_{\mu\nu} \frac{q_\alpha q_\beta}{\Lambda^2} f^{*1,\mu\alpha} f^{*2,\nu\beta} \\ & + g_3^{(2)} \frac{\tilde{q}^\beta \tilde{q}^\alpha}{\Lambda^2} t_{\beta\nu} (f^{*1,\mu\nu} f^{*2}_{\nu\alpha} + f^{*2,\mu\nu} f^{*1}_{\nu\alpha}) \\ & + g_4^{(2)} \frac{\tilde{q}^\mu \tilde{q}^\nu}{\Lambda^2} t_{\mu\nu} f^{*1,\alpha\beta} f^{*2}_{\alpha\beta} + 2g_5^{(2)} m_V^2 t_{\mu\nu} \varepsilon_1^{*\mu} \varepsilon_2^{*\nu} \\ & + 2g_6^{(2)} m_V^2 \frac{\tilde{q}^\mu \tilde{q}^\nu}{\Lambda^2} t_{\mu\nu} (\varepsilon_1^{*\nu} \varepsilon_2^{*\alpha} - \varepsilon_1^{*\alpha} \varepsilon_2^{*\nu}) + g_7^{(2)} m_V^2 \frac{\tilde{q}^\mu \tilde{q}^\nu}{\Lambda^2} t_{\mu\nu} \varepsilon_1^* \varepsilon_2^* \\ & + g_8^{(2)} \frac{\tilde{q}^\mu \tilde{q}^\nu}{\Lambda^2} t_{\mu\nu} f^{*1,\alpha\beta} \tilde{f}^{*2}_{\alpha\beta} + g_9^{(2)} t_{\mu\alpha} \tilde{q}^\alpha \epsilon_{\mu\nu\rho\sigma} \varepsilon_1^{*\nu} \varepsilon_2^{*\rho} q^\sigma \\ & + g_{10}^{(2)} \frac{t_{\mu\alpha} \tilde{q}^\alpha}{\Lambda^2} \epsilon_{\mu\nu\rho\sigma} q^\rho \tilde{q}^\sigma (\varepsilon_1^{*\nu}(q\varepsilon_2^*) + \varepsilon_2^{*\nu}(q\varepsilon_1^*)) \Bigg] \end{aligned} \qquad (11.32)$$

where $t_{\mu\nu}$ is a symmetric traceless tensor, transverse to the momentum of the spin 2 state $t_{\mu\nu} q^\nu = 0$ [190]. As in the general spin 0 case $g_1^{(1),(2)}$ are dimensionless and momentum dependent complex form factors are effective and dimensionless. Similar amplitudes are derived in the case of fermion couplings, as reported in Ref. [36]. Studies of the spin and CP properties of the discovered state can either use an effective Lagrangian approach or generic scattering amplitudes. The two are equivalent at leading order. However the effective Lagrangian is typically used to generate specific hypotheses and the scattering amplitudes are used in analyses.

The JHU generator [190,192] has been used to define benchmark scenarios for exotic hypotheses of the nature of the observed state according to the general couplings of the observed new particle to gluons and quarks in production and to vector bosons in decay and includes all spin correlations and interferences of all contributing amplitudes. The models which have been investigated by experiments are reported in Table 11.13. It should be noted that while the 0_m^+ has a very detailed simulation at NLO in QCD, the alternative hypotheses do not.

The 2_m^+ scenario is investigated in different production modes according to the fraction of $q\overline{q}$ versus gg initiated processes. Results were derived by experiments for various fractions. These results will be reported for the two extreme cases where the observed state is fully produced in one or the other processes and will be denoted 2_{gg}^+ and 2_{qq}^+.

IV.3.3. Statistical procedure

Discriminant distributions are used to define the likelihood functions for a given J^P hypothesis and the background $\mathcal{L}_{J^P}$. The test statistic used to probe a given model is defined as $q = -2\ln \mathcal{L}_{J^P}/\mathcal{L}_{0^+}$. This test statistic is kept as independent as possible independent of the measured signal strength, which is left as a free parameter. To measure the compatibility of the observation with one or the other hypotheses, distributions of this test statistic are derived under a signal J^P and under the 0_m^+ hypotheses. It is important to note that to generate these distributions the number of signal events used is the number of signal events fitted on the data under the given hypothesis. Consequently the number of signal events generated under a given null hypothesis can be different from that of the alternative hypothesis. For the 0_m^+ hypothesis in some cases the SM signal normalization has been used. The two numbers characterizing the observation are: (i) the compatibility with the 0_m^+ hypothesis and (ii) the level of confidence of the exclusion of the hypothesis J^P. An example of distributions is illustrated in Fig. 11.22.

To quantify the compatibility of an observation with test statistic q_{obs} with the 0_m^+ hypothesis the cumulative probability $P_{0^+} = P(q > q_{obs}|0_m^+)$ is used. A perfect compatibility is obtained for a P_{0^+} value close to 50%. For a given analysis the observed P_{0^+} can change depending on which alternative hypothesis is tested.

To quantify the exclusion of an alternative hypothesis J^P, a probability $P_{J^P} = P(q > q_{obs}|J^P)$ is defined. The level of confidence at which the J^P is excluded is given by the CL_S criterion [193]

$$CL_S = \frac{P_{J^P}}{1 - P_{0^+}} \qquad (11.33)$$

IV.3.4. J^P determination

At the LHC, the determination of the spin and CP properties of the discovered state is done independently from the rates observed, from a global angular helicity analysis, derived from the general scattering amplitude expressed in Section IV.3.2 and when applicable in the threshold effects in the decay. The channels used for this analysis, the $H \to \gamma\gamma$, $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ and $H \to Z^{(*)}Z^{(*)} \to 4\ell$, are those where a the observation of a signal is established.

At the Tevatron, an analysis using the threshold distribution of the production of the discovered state [194] in the associated production mode VH with subsequent decay to a pair of b-quarks was performed by the D0 collaboration.

(i) The VH production at D0

The mass of the VH system is a very powerful discriminant to distinguish a $J^P = 0_m^+$, with a threshold behavior in $d\sigma/dM^2 \sim \beta$ from 0^- or 2^+ with threshold behaviors respectively in $\sim \beta^3$ and $\sim \beta^5$ (for a graviton like spin 2) [194]. The VH mass observable, is not only strongly discriminating signal hypotheses, but also have an increased separation of the 0^- and 2^+ hypotheses with respect to the backgrounds, thus allowing, with a small and not yet significant signal, to exclude that the observed state is 0^- at 98% CL [195] and 2^+ at the 99.9% CL [196].

(ii) The $\gamma\gamma$ channel at LHC

In the $H \to \gamma\gamma$ channel, the analysis is performed by ATLAS inclusively using the production angle $\cos\theta^*_{CS}$ as discriminant [197]. The definition chosen for the polar angle in the rest frame is the Collins–Soper frame, which is defined as the bisector axis of the momenta of the incoming protons in the diphoton rest frame. The 0_m^+ signal distribution is expected to be uniform with a cutoff due to the lower selection requirements on the photons transverse momentum. The $H \to \gamma\gamma$ channel is mostly sensitive to the gluon-initiated production scenario 2_{gg}^+, which yields a $\cos\theta^*_{CS}$ distribution peaking at values close to 1. It is much less so for the quark-initiated scenarios 2_{qq}^+. The results are derived from a fit of the signal in bins of $\cos\theta^*_{CS}$ and are summarized in Table 11.14. The data shows a good compatibility with the SM 0_m^+ hypothesis. ATLAS excludes the alternative hypotheses 2_{gg}^+ and 2_{qq}^+ at the 99% CL and 95% CL.

(iii) The $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ channel at LHC

The $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ the production and decay angles cannot be easily reconstructed due to the neutrinos in the final state, however an important feature is the V-A structure of the decay of the W bosons. A scalar state thus yields a clear spin correlation pattern that implies that the charged leptons e or μ from the decays of the W bosons are produced close to one another in the transverse plane. In the main analysis this feature is used to gain sensitivity, in this case the initial selection need to be reappraised in order not to discriminate specific J^P hypotheses. This feature, which immediately impacts observables such as the azimuthal angle between the two leptons $\Delta\Phi_{\ell\ell}$ or their invariant mass $M_{\ell\ell}$ in addition of the threshold behavior of the decay which is used in kinematic variables such as the transverse mass defined in Section III, can be used to discriminate spin and parity hypotheses. The approach adopted by ATLAS is a multivariate discriminant, whereas CMS uses a 2D-fit of the dilepton mass and the transverse mass. The results of the $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ analyses are summarized in Table 11.14. The hypotheses tested by this approach are the 1^+ and 1^- by the ATLAS experiment and the 2^+ by ATLAS and CMS. A good compatibility of the observation with the 0^+_m hypothesis is observed in the discrimination of all hypotheses. ATLAS excludes the 1^+ and 1^- hypotheses at the 98% CL and 99% CL respectively. When discriminating the 2^+ hypothesis, the $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ analysis is more sensitive to the quark-initiated production mode and is therefore complementary to the $H \to \gamma\gamma$ channel. ATLAS [197] and CMS [198] disfavor the 2^+_{gg} and 2^+_{qq} at different levels of confidence. The strongest observed exclusion is obtained by ATLAS excluding the 2^+_{gg} and 2^+_{qq} at the 98% CL and 99% CL respectively.

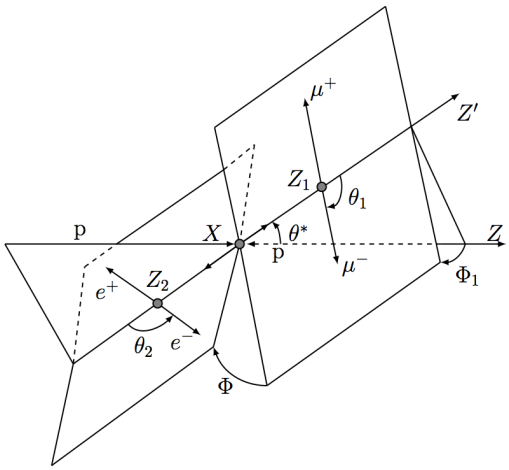

Figure 11.21: Definition of the production and decay angles defined for the $H \to Z^{(*)}Z^{(*)} \to 4\ell$ final state [199].

(iv) The $H \to Z^{(*)}Z^{(*)} \to 4\ell$ channel at LHC

The main $H \to Z^{(*)}Z^{(*)} \to 4\ell$ coupling analysis, as described in Section III, also uses a discriminant based on the 0^+_m nature of the Higgs boson to further discriminate the signal from the background. In this analysis this feature is used to discriminate between signal hypotheses. The observables sensitive to the spin and parity are the masses of the two Z bosons [191](due to the threshold dependence of the mass of the off-shell Z boson), two production angle θ^* and ϕ_1, and three decay angles, ϕ, θ_1 and θ_2. The production and decay angles defined as:

– θ_1 and θ_2, the angles between the negative final state lepton and the direction of flight of Z_1 and Z_2 in the rest frame.

– ϕ, the angle between the decay planes of the four final state leptons expressed in the four lepton rest frame.

– ϕ_1, the angle defined between the decay plane of the leading lepton pair and a plane defined by the vector of the Z_1 in the four lepton rest frame and the positive direction of the proton axis.

– θ^*, the production angle of the Z_1 defined in the four lepton rest frame with respect to the proton axis.

These angles are illustrated in Fig. 11.21. There are two approaches to this analysis. The first, used by CMS, is a matrix element likelihood approach where a kinematic discriminant is defined based on the ratio of the signal and background probabilities. These probabilities are defined using the leading-order matrix elements. A similar approach is also performed by ATLAS as a cross check of their main result. The main approach adopted by ATLAS is the combination of sensitive variables in a boosted decision tree. These analyses are sensitive to various J^P hypotheses and in particular to discriminate the 0^+_m hypothesis from the 0^-. In all scenarios investigated and for both the ATLAS and CMS experiments the data are compatible with the 0^+_m hypothesis. ATLAS [197] and CMS [199] exclude a pseudo scalar nature of the H^0 at CL_S levels of 98% and 99.8%. The distribution of the test statistic q defined in Section IV.3.3 is illustrated in Fig. 11.22 for the 0^+_m and 0^- hypotheses. All benchmark scenarios results are summarized in Table 11.14.

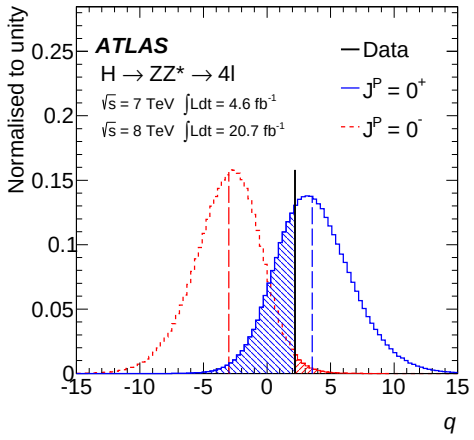

Figure 11.22: Expected distributions of q, for the Standard Model 0^+ (blue/solid line distribution) or 0^- (red/dashed line distribution) signals [197]. The observed value is indicated by the vertical solid line and the expected medians by the dashed lines. The colored areas correspond to the integrals of the expected distributions up to the observed value and are used to compute the p_0-values for the rejection of each hypothesis.

IV.3.5. Probing CP mixing

The most general decay amplitude for spin-0 state decaying to a pair of gauge bosons described in Section IV.3.2 can be expressed in a more compact form [190]

$$A^{(0)} = \frac{\varepsilon_1^{*\mu}\varepsilon_2^{*\nu}}{v}(a_1\, m_H^2\, g_{\mu\nu} + a_2\, q_\mu q_\nu + a_3\, \epsilon_{\mu\nu\alpha\beta}\, q_1^\alpha q_2^\beta) = A_1 + A_2 + A_3\,, \tag{11.34}$$

where q_i and ε_i are the momenta and polarization vectors of the two gauge bosons, and $q = q_1 + q_2$ is the four-momentum of the spin 0 boson.

The SM Higgs boson is dominated by the A_1 amplitude, while a 0^- state is dominated by A_3. The CMS collaboration has performed an analysis of the ratio $f_{a_3} = |A_3|^2/(|A_1|^2 + |A_3|^2)$ in the $H \to Z^{(*)}Z^{(*)} \to 4\ell$ channel [199], where the presence of the A_2 term is neglected. This second term corresponds to higher order couplings of the 0^+ state. The two extreme cases $f_{a_3} = 0, 1$ correspond

Table 11.14: Results in all benchmark scenarios for the analysis of the production and decay of the observed state with J^P quantum numbers, for the ATLAS (A) and CMS (C) experiments. The upper part of the table gives the compatibility of the observation with the SM 0_m^+ hypothesis. The lower part of the table gives the CL_S observed exclusion and in parenthesis the sensitivity of the given alternative model.

J^P	ZZ	WW	$\gamma\gamma$	Combined
0^-	31% A	–	–	–
	31% C	–	–	–
0_h^+	50% C	–	–	–
1^+	55% A	70% A	–	62% A
	4.5% C	–	–	–
1^-	15% A	66% A	–	33% A
	8.1% C	–	–	–
$2^+_{q\overline{q}}$	96% A	54% A	80% A	81% A
	3.6% C	–	–	–
2^+_{gg}	53% A	73% A	59% A	63% A
	82% C	33% C	–	63% C
0^-	2.2% (0.4%) A	–	–	–
	0.2% (0.5%) C	–	–	–
0_h^+	8.1% (4.5%) C	–	–	–
1^+	0.2% (0.2%) A	8.0% (8.0%) A	–	<0.1% (<0.1%) A
	<0.1% (1.1%) C	–	–	–
1^-	6.0% (0.4%) A	1.7% (2.0%) A	–	0.3% (<0.1%) A
	<0.1% (0.3%) C	–	–	–
$2^+_{q\overline{q}}$	2.6% (8.2%) A	<0.1% (<0.1%) A	12.4% A (13.5%)	<0.1% (<0.1%) A
	<0.1% (4.0%) C	–	–	–
2^+_{gg}	16.9% (9.2%) A	4.8% (5.4%) A	0.7% A (0.5%)	<0.1% (<0.1%) A
	1.4% (5.5%) C	14.0% (5.5%) C	–	0.6% (1.1%) C

approximately to the 0^+ and 0^- cases respectively. Other values of f_{a_3} would be an indication of *CP*-violation. The analysis uses a kinematic discriminant defined similarly to the cases discussed in Section IV.3.4 taking the dependence with f_{a_3} into account. Using the full dataset corresponding to an integrated luminosity of approximately 25 pb^{-1} of pp collisions at 7 TeV and 8 TeV, CMS measures $f_{a_3} = 0.00 \pm 0.23$ corresponding to a limit of $f_{a_3} < 0.58$ at 95% CL. It should be noted that an indication of *CP*-violation from f_{a_3} would not yield a measure of the mixing of opposite parity states.

V. New physics models of EWSB in the light of the Higgs boson discovery

A main theoretical motivation to add a Higgs boson to the Standard Model is that, without it, the longitudinal components of the massive EW gauge bosons would form a strongly coupled system as their scattering amplitude would have grown with their energy, destroying all the predictive power of the model above $4\pi v \sim 3$ TeV. The discovery of a light scalar with couplings to gauge bosons and fermions that are apparently consistent with SM predictions and the slow running of the Higgs self-coupling at high energies allows one to consider the SM as a valid perturbative description of nature all the way to the Planck scale. This picture is admittedly very attractive, but it posits that the Higgs boson is an elementary scalar field, which comes with an intrinsic instability of its mass under radiative corrections. This Higgs naturalness problem calls for new physics around the TeV scale. Supersymmetric models are the most elegant solution to maintain the perturbativity of the SM while alleviating the instability issue. Another possibility is that the Higgs boson itself has a finite size and is composite and thus never feels the UV degrees of freedom that would drag its mass to much higher scales. Both classes of models predict specific modifications from the SM Higgs properties. In this section, these possible deviations will be discussed in detail.

The realization of supersymmetry at low energies has many good qualities that render it attractive as a model of new physics. First of all since for every fermion there is a boson of equal mass and effective coupling to the SM-like Higgs, in the case of exact supersymmetry it yields an automatic cancellation of loop corrections to the Higgs mass parameter: (analogous to Eq. (11.2)) $\delta m^2 = 0$ [8,10]. In practice, it is known that SUSY must be broken in nature since no superpartners of the SM particles have been observed so far. Taking into account the fact that the fermion and boson couplings to the Higgs and the number of degrees of freedom of the SM particles and their superpartners are the same, the Higgs mass correction simply writes

$$\delta m^2 = \sum_F g_F \lambda_F^2 \frac{(m_B^2 - m_F^2)}{32\pi^2} \log \frac{Q^2}{\mu^2}, \qquad (11.35)$$

where the sum is over all fermion fields of mass m_F and includes implicitly their superpartners with a squared mass m_B^2. The mass difference between the boson and fermion degrees of freedom is governed by the soft supersymmetry breaking parameters. Therefore, independently of how large m_B^2 and m_F^2 are, all corrections are proportional to M_{SUSY}^2. Hence, provided that $M_{SUSY} \simeq \mathcal{O}(1$–few) TeV, the fine-tuning problem is solved, in the sense that the low energy mass parameters become insensitive to physics at the GUT or Planck scale. Another interesting feature of SUSY theories is related to the dynamical generation of EWSB [201]. In the SM a negative Higgs mass parameter, m^2, needs to be inserted by hand to induce EWSB. In SUSY, instead, even if the relevant Higgs mass parameter is positive in the ultraviolet, it may become negative and induce electroweak symmetry breaking radiatively through the strong effect of the top quark-Higgs coupling in its renormalization group evolution. Moreover, supersymmetry with a supersymmetry breaking scale of order 1 TeV allows for grand unification of the electroweak and strong gauge interactions in a consistent way, strongly supported by the prediction of the electroweak mixing angle at low energy scales, with an accuracy at the percent level [202,203]. In addition, supersymmetry theories can provide a suitable dark matter candidate [204] and even a low energy physics explanation of baryogenesis [205], all of this compatible with existing precision data.

In the following discussion, the Higgs sector will be explored in specific SUSY models. In all of them there is one neutral Higgs boson with properties that resemble those of the SM Higgs boson whereas additional neutral and charged Higgs bosons are also predicted and are intensively being sought for at the LHC (see Section V.9). In the simplest SUSY model the lightest Higgs boson mass, that usually plays the role of the SM-like Higgs, is predicted to be less than 135 GeV for stops in the TeV to few TeV range [206–220], whereas, larger values of the SM-like Higgs boson mass – up to about 250 GeV – can be obtained in non-minimal SUSY extensions of the SM [344,221–227]. In general, accommodating a SM-like Higgs boson with mass of 125 GeV results in constraints on the supersymmetric parameter space of specific SUSY models, as discussed below.

The more and more constraining bounds on the SUSY parameter space do not preclude a solution to the naturalness problem but they require either heavier SUSY partners or some specific engineering to hide any SUSY signal from the optimized searches conducted at the LHC. In their most commonly studied incarnations, SUSY models distinguish themselves from the background by a substantial amount of missing transverse energy (MET) taken away by the stable lightest supersymmetric particle (LSP), and by a large activity associated with the superpartners around the TeV scale. Nonetheless, light SUSY is still allowed by current LHC limits if these two characteristic features of the generic SUSY signals are softened. Compressing the SUSY spectrum [228] reduces the amount of available energy transferred to the visible particles at the end of the cascade decays of the heavy superpartners. Also the LSP's tend to be produced back-to-back, minimizing the amount of missing energy along the transverse direction. A compressed spectrum can be obtained if the gluino happens to be lighter than the other gauginos at the high scale in gravity mediated or gauge mediated SUSY breaking scenarios. Another approach, dubbed as stealth supersymmetry [229], is designed to reduce the SUSY signals by introducing a new light and approximately supersymmetric multiplet that is complementary to the

MSSM matter content. The heavy MSSM particles will chain-decay to the R-odd particle of this new multiplet but the small mass splitting within this multiplet kinematically limits the amount of MET finally taken away by the LSP. Dedicated experimental searches have already been designed to probe such scenarios.

A more radical solution to reduce the amount of MET in the final state is to revoke the R-parity assumption that is usually imposed to save the proton from a fast decay and also to guarantee the existence of a stable particle with a relic abundance compatible with what is expected to form the dark matter component of the Universe. R-parity is however not a necessity. For instance if the 96 new complex parameters of the R-parity violating MSSM [230] are arranged to follow a minimal flavor violation pattern [231], the proton lifetime will exceed the current bounds. Such scenarios predict either multilepton or multijet final states that are already the target of ongoing LHC searches.

While naturalness dictates relatively light stops and gluinos, the first and second generation of squarks and sleptons couple weakly to the Higgs sector and may be heavy. Moreover, small values of the μ parameter and therefore light Higgsinos would be a signature of a natural realization of electroweak symmetry breaking. Such SUSY spectra, consisting of light stops and light Higgsinos, have been under intense scrutiny by the experimental collaborations [232] in order to derive model-independent bounds on the stop masses and to understand if such natural SUSY scenarios endure [233] and can explain why the Higgs boson remains light.

In the context of weakly coupled models of EWSB one can also consider multiple Higgs $\mathrm{SU}(2)_L$ doublets as well as additional Higgs singlets, triplets or even more complicated multiplet structures, with or without low energy supersymmetry. In general for such models one needs to take into account experimental constraints from precision measurements and flavor changing neutral currents. The LHC signatures of such extended Higgs sectors are largely shaped by the role of the exotic scalar fields in EWSB.

The idea that the Higgs boson itself could be a composite bound state emerging from a new strongly-coupled sector has regained some interest. The composite Higgs idea is an interesting incarnation of EWSB via strong dynamics that smoothly interpolates between the standard Technicolor approach and the true SM limit. To avoid the usual conflict with EW data, it is sufficient if not necessary that a mass gap separates the Higgs resonance from the other resonances of the strong sector. Such a mass gap can naturally follow from dynamics if the strongly-interacting sector exhibits a global symmetry, G, broken dynamically to a subgroup H at the scale f, such that, in addition to the three Nambu–Goldstone bosons of SO(4)/SO(3) that describe the longitudinal components of the massive W and Z, the coset G/H contains, a fourth Nambu–Goldstone boson that can be identified with the physical Higgs boson. Simple examples of such a coset are SU(3)/SU(2) or SO(5)/SO(4), the latter being favored since it is invariant under the custodial symmetry (it is also possible to have non-minimal custodial cosets with extra Goldstone bosons, see for instance Ref. [234]). Attempts to construct composite Higgs models in 4D have been made by Georgi and Kaplan (see for instance Ref. [235]) and modern incarnations have been recently investigated in the framework of 5D warped models where, according to the principles of the AdS/CFT correspondence, the holographic composite Higgs boson then originates from a component of a gauge field along the 5th dimension with appropriate boundary conditions.

A last crucial ingredient in the construction of viable composite Higgs models is the concept of partial compositeness [236], i.e., the idea that there are only linear mass mixings between elementary fields and composite states[8]. After diagonalization of the mass matrices, the SM particles, fermions and gauge bosons, are admixtures of elementary and composite states and thus they interact with the strong sector, and in particular with the Higgs boson, through their composite component. This setup has important consequences on the flavor properties, chiefly the suppression of large flavor changing neutral currents involving light fermions. It also plays an important role in dynamically generating a potential for the would-be Goldstone bosons. Partial compositeness also links the properties of the Higgs boson to the spectrum of the fermionic resonances, i.e. the partners of the top quark. As in the MSSM, these top partners are really the agents that trigger the EWSB and also generate the mass of the Higgs boson that otherwise would remain an exact Goldstone boson and hence massless. The bounds from the direct searches for the top partners in addition to the usual constraints from EW precision data force the minimal composite Higgs models into some rather unnatural corners of their parameter spaces [238].

V.1. Higgs bosons in the Minimal Supersymmetric Standard Model (MSSM)

The particle masses and interactions in a supersymmetric theory are uniquely defined as a function of the superpotential and the Kähler potential [200]. A fundamental theory of supersymmetry breaking, however, is unknown at this time. Nevertheless, one can parameterize the low-energy theory in terms of the most general set of soft supersymmetry-breaking operators [239]. The simplest realistic model of low-energy supersymmetry is the Minimal Supersymmetric extension of the Standard Model (MSSM) [10,200], that associates a supersymmetric partner to each gauge boson and chiral fermion of the SM, and provides a realistic model of physics at the weak scale. However, even in this minimal model with the most general set of soft supersymmetry-breaking terms, more than 100 new parameters are introduced [240]. Fortunately, only a subset of these parameters impact the Higgs phenomenology through tree-level and quantum effects. Reviews of the properties and phenomenology of the Higgs bosons of the MSSM can be found for example in Refs. [34,200,241].

The MSSM contains the particle spectrum of a two-Higgs-doublet model (2HDM) extension of the SM and the corresponding supersymmetric partners. Two Higgs doublets,

$$\Phi_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} \phi_1^0 + i a_1^0 \\ \sqrt{2}\phi_1^- \end{pmatrix}, \tag{11.36}$$

$$\Phi_2 = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}\phi_2^+ \\ \phi_2^0 + i a_2^0 \end{pmatrix}, \tag{11.37}$$

with $Y = -1$ and $Y = 1$, respectively, are required to ensure an anomaly-free SUSY extension of the SM and to generate mass for both up-type and down-type quarks and charged leptons [12]. In our notation $\Phi_{1(2)}$ gives mass to the down(up) type fermions. The Higgs potential reads

$$\begin{aligned} V = {} & m_1^2 \Phi_1^\dagger \Phi_1 + m_2^2 \Phi_2^\dagger \Phi_2 - m_3^2 (\Phi_1^T i\sigma_2 \Phi_2 + \text{h.c.}) \\ & + \frac{1}{2}\lambda_1 (\Phi_1^\dagger \Phi_1)^2 + \frac{1}{2}\lambda_2 (\Phi_2^\dagger \Phi_2)^2 + \lambda_3 (\Phi_1^\dagger \Phi_1)(\Phi_2^\dagger \Phi_2) \\ & + \lambda_4 |\Phi_1^T i\sigma_2 \Phi_2|^2 + \frac{1}{2}\lambda_5 [(\Phi_1^T i\sigma_2 \Phi_2)^2 + \text{h.c.}] \\ & + [[\lambda_6 (\Phi_1^\dagger \Phi_1) + \lambda_7 (\Phi_2^\dagger \Phi_2)] \Phi_1^T i\sigma_2 \Phi_2 + \text{h.c.}] \end{aligned} \tag{11.38}$$

where $m_i^2 = \mu^2 + m_{H_i}^2$, with μ being the supersymmetric Higgsino mass parameter and m_{H_i} (for $i = 1, 2$) the Higgs doublet soft supersymmetric breaking mass parameters; $m_3^2 \equiv B\mu$ is associated to the B-term soft SUSY breaking parameter; and λ_i, for $i = 1$ to 7, are all the Higgs quartic couplings. After the spontaneous breaking of the electroweak symmetry, five physical Higgs particles are left in the spectrum: one charged Higgs pair, $H^\pm$, one CP-odd scalar, A, and two CP-even states, H and h.

$$\begin{aligned} H^\pm &= \sin\beta \phi_1^\pm + \cos\beta \phi_2^\pm , \\ A &= \sin\beta \, \mathrm{Im}\phi_1^0 + \cos\beta \, \mathrm{Im}\phi_2^0 , \\ H &= \cos\alpha (\mathrm{Re}(\phi_1^0) - v_1) + \sin\alpha (\mathrm{Re}(\phi_2^0) - v_2), \\ h &= -\sin\alpha (\mathrm{Re}(\phi_1^0) - v_1) + \cos\alpha (\mathrm{Re}(\phi_2^0) - v_2), \end{aligned} \tag{11.39}$$

where $\langle \phi_i^0 \rangle = v_i$ for i=1,2 and $v_1^2 + v_2^2 \approx (246\,\mathrm{GeV})^2$. The angle α diagonalizes the CP-even Higgs squared-mass matrix, while β

[8] For a pedagogical introduction to models of partial compositeness, see Ref. [237].

diagonalizes both the *CP*-odd and charged Higgs sectors with $\tan\beta = v_2/v_1$. The h and H denote the lightest and heaviest *CP*-even Higgs bosons, respectively.[9]

V.1.1. The MSSM Higgs boson masses

Quite generally for any two Higgs doublet model, including the MSSM, the phenomenology depends strongly on the size of the mixing angle α and therefore on the quartic couplings,

$$\sin\alpha = \frac{\mathcal{M}_{12}^2}{\sqrt{(\mathcal{M}_{12}^2)^2 + \left(\mathcal{M}_{11}^2 - m_h^2\right)^2}}, \tag{11.40}$$

where

$$\begin{aligned}\mathcal{M}_{12}^2 &= -\left(m_A^2 - (\lambda_3+\lambda_4)v^2\right)\sin\beta\cos\beta + \lambda_7 v^2\sin^2\beta \\ &\quad + \lambda_6 v^2\cos^2\beta, \\ \mathcal{M}_{11}^2 &= \left(m_A^2 + \lambda_5 v^2\right)\sin^2\beta + \lambda_1 v^2\cos^2\beta \\ &\quad + 2\lambda_6 v^2\cos\beta\sin\beta.\end{aligned} \tag{11.41}$$

The spectrum is given by

$$m_{h,H}^2 = \frac{\mathcal{M}_{11}^2 + \mathcal{M}_{22}^2 \mp \sqrt{\left(\mathcal{M}_{11}^2 - \mathcal{M}_{22}^2\right)^2 + 4(\mathcal{M}_{12}^2)^2}}{2}, \tag{11.42}$$

with

$$\mathcal{M}_{22}^2 = \left(m_A^2 + \lambda_5 v^2\right)\cos^2\beta + \lambda_2 v^2\sin^2\beta + 2\lambda_7 v^2\cos\beta\sin\beta\ . \tag{11.43}$$

The charged Higgs boson mass is given by

$$m_{H^\pm}^2 = m_A^2 + (\lambda_5 - \lambda_4)\frac{v^2}{2}. \tag{11.44}$$

The supersymmetric structure of the theory imposes constraints on the Higgs sector of the model. In particular, at tree level, the parameters of the Higgs self-interaction, $\lambda_{1,\ldots,4}$, are defined in terms of the electroweak gauge coupling constants,

$$\lambda_1 = \lambda_2 = g_2^2/4,\ \ \lambda_3 = -(g_1^2 - g_2^2)/4,\ \ \lambda_4 = -g_2^2/2, \tag{11.45}$$

and $\lambda_{5,6,7} = 0$. As a result, the Higgs sector at tree level is determined by only two free parameters: $\tan\beta$ and one Higgs boson mass, conventionally chosen to be the *CP*-odd Higgs boson mass, m_A. The other tree-level Higgs boson masses are then given in terms of these parameters. In the large $m_A \gg M_Z$ limit, also called the decoupling limit [242], $\sin\alpha \to -\cos\beta$, $\cos\alpha \to \sin\beta$, hence, $\cos(\beta-\alpha) \to 0$ and this implies that the lightest *CP*-even Higgs h behaves as the SM Higgs. The condition $\cos(\beta-\alpha) \to 0$ is also obtained if the quartic couplings are such that $\mathcal{M}_{12}^2\sin\beta = -(\mathcal{M}_{11}^2 - m_h^2)\cos\beta$ [243–245], independent of the value of m_A. The limit $\cos(\beta-\alpha) \to 0$ is called the alignment limit. As will be discussed below, in the MSSM the alignment limit can only occur once quantum corrections to the quartic couplings have been included.

The tree level value of m_h is maximized not only for $m_A \gg M_Z$ but also for $\tan\beta \gg 1$. In the large m_A limit, one finds $m_h^2 \simeq (M_Z\cos 2\beta)^2$ and $m_A \simeq m_H \simeq m_{H^\pm}$, up to corrections of $\mathcal{O}({M_Z}^2/m_A)$. Below the scale m_A, the Higgs sector of the effective low-energy theory consists only of h, which behaves as the SM Higgs boson. This scenario would have been excluded already by LEP and would not accommodate the recently discovered Higgs boson. However, radiative corrections have a significant impact on the values of Higgs boson masses and couplings in the MSSM. In particular, m_h can be lifted to agree with present LHC measurements.

[9] Observe that in the SM sections of this review, H denotes the SM Higgs, whereas in the sections about SUSY and more generally extensions of the SM with two Higgs doublets, H is used for the heaviest *CP*-even Higgs boson, since this is the standard notation in the literature.

The dominant radiative effects to the SM-like Higgs mass arise from the incomplete cancellation between top and scalar-top (stop) loops and at large $\tan\beta$ also from sbottom and stau loops. The loop contributions to the tree level quartic couplings depend on the SUSY spectrum, and render $\lambda_{5,6,7}$ non zero. The stop, sbottom and stau masses and mixing angles depend on the supersymmetric Higgsino mass parameter μ and on the soft-supersymmetry-breaking parameters [10,200]: M_Q, M_U, M_D, M_L, M_E, and A_t, A_b A_τ. The first three of these are the left-chiral and the two right-chiral top and bottom scalar quark mass parameters. The next two are the left-chiral stau/sneutrino and the right-chiral stau mass parameters, and the last three are the trilinear parameters that enter in the off-diagonal squark/slepton mixing elements: $X_t \equiv A_t - \mu\cot\beta$ and $X_{b,\tau} \equiv A_{b,\tau} - \mu\tan\beta$. The corrections affecting the Higgs boson masses, production, and decay properties depend on all of these parameters in various ways. At the two-loop level, the masses of the gluino and the electroweak gaugino also enter in the calculations. For simplicity, it is initially assumed that A_t, A_b, A_τ, μ, and the gluino and electroweak gaugino masses are real parameters. The impact of complex phases on MSSM parameters, which will induce *CP*-violation in the Higgs sector, is addressed below.

Radiative corrections to the Higgs boson masses have been computed using a number of techniques, with a variety of approximations; see Refs. [206–219,246]. The radiative corrections to m_h depend quartically on the top quark mass, quadratically and quartically on stop mixing parameter, and there is also a logarithmic dependence on the stop masses. For large $\tan\beta$, the stau/sbottom mixing parameters and masses are also relevant. In the large m_A (decoupling) limit and for $\tan\beta \gg 1$, which maximizes m_h at tree level, the m_h value can be maximized at loop level for $X_t \simeq \sqrt{6}M_{\rm SUSY}$ [10] where $M_{\rm SUSY} \simeq M_Q \simeq M_U \simeq M_D$ is an assumed common value of the soft SUSY-breaking squark mass parameters. This choice of X_t is called the "maximal-mixing scenario". For fixed X_t, the value of m_h can vary by several GeV by varying $M_{\rm SUSY}$ within a few TeV or by varying m_t within its experimental uncertainty, as well as by varying SUSY particle parameters that enter only beyond the one-loop order. Moreover, in the large $\tan\beta$ regime light staus and/or sbottoms with sizable mixing, governed by the μ parameter, yield negative radiative corrections to the mass of the lightest Higgs boson, and can lower it by several GeV [215,247]. Allowing for experimental and theoretical uncertainties, one finds that for $M_{\rm SUSY} \lesssim 2\,\text{TeV}$, large m_A, $\tan\beta \gg 1$ and for $X_t \simeq \sqrt{6}M_{\rm SUSY}$, the maximal value for the lightest Higgs mass is $m_h^{\rm max} = 135\,\text{GeV}$ [220,248–250]. Interestingly, the upper bound on the lightest neutral scalar boson is a prediction for both the *CP*-conserving (*CPC*) and *CP*-violating (*CPV*) MSSM scenarios [251,252].

The newly discovered SM-like Higgs boson, if interpreted as the lightest MSSM Higgs with a mass of about 125 GeV, provides information on the possible MSSM parameter space. In particular a sizable mixing in the stop sector is required ($|X_t/M_{\rm SUSY}| \geq 1.5$) for values of $M_{\rm SUSY} \simeq M_Q \simeq M_U \simeq M_D \simeq 1$ to a few TeV [247–258]. See for example Fig. 11.23 and Fig. 11.24. On the other hand, as shown in Fig. 11.25, considering the third generation soft SUSY breaking parameters as independent inputs, $M_Q \neq M_U \neq M_D$, one observes that $m_h \simeq$125 GeV can be obtained for one stop that is as light as can be experimentally allowed [259]- - i.e. in the few hundred GeV mass range- and the other one with a mass of the order of the stop mixing parameter. It is also possible to consider both stops significantly above a few TeV by varying/lowering the values of X_t and $\tan\beta$, in that case the impact of higher loops in the computation of the Higgs mass becomes relevant [246].

[10] The parameters X_t and $M_{\rm SUSY}$ depend on the renormalization scheme. The radiative corrections to the Higgs masses computed in the Feynman diagrammatic approach have been obtained in the on-shell (OS) renormalization scheme, whereas those based on the Renormalization Group approach have been calculated using the $\overline{MS}$ scheme. A detailed comparison of the results in the two schemes is presented in Refs. [218,214]. In particular, the lightest Higgs mass is maximized for $X_t^{\bar{M}S} \simeq \sqrt{6}M_{\rm SUSY}$ or equivalently $X_t^{OS} \simeq 2M_{\rm SUSY}$.

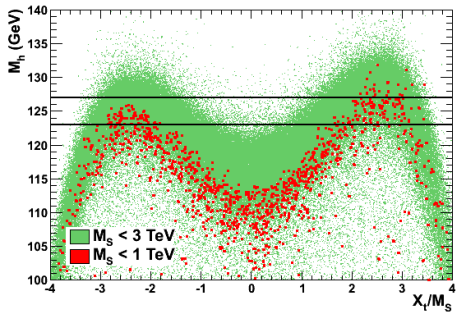

Figure 11.23: The maximal value of m_h as a function of $X_t/M_{\rm SUSY}$ ($M_{\rm SUSY} \equiv M_S$) in the pMSSM when all other soft SUSY-breaking parameters and $\tan\beta$ are scanned as defined in Ref. [253].

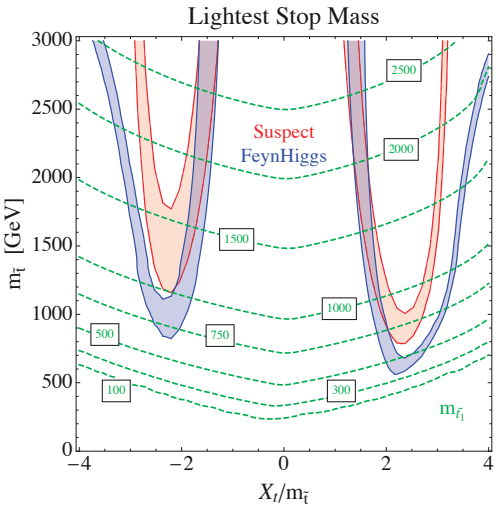

Figure 11.24: Contours of m_h in the MSSM as a function of $m_{\tilde{t}}$, a common stop mass $M_Q = M_U$, and the stop mixing parameter X_t for $\tan\beta = 20$. The red/blue bands show the result from Suspect/FeynHiggs for m_h in the range 124-126 GeV. The contours of constant lightest stop mass are shown in green Ref. [254].

For a given CP-odd Higgs mass m_A, the masses of the other two Higgs bosons, H and $H^\pm$, also receive radiative corrections (for a summary, see for instance Ref. [241]) , but in the absence of additional CP-violating phases, and for m_A larger than $m_h \simeq 125$ GeV, they are all similar, and at most about a few tens of GeV apart. Instead, for smaller values of m_A, the heavy Higgs is the SM one, $m_H \simeq 125$ GeV and $m_h \simeq m_A$, but this scenario is strongly challenged by present data [248]. For a more detailed discussion of the effect of radiative corrections on the heavy Higgs masses see for example Refs. [34] and [241].

V.1.2. MSSM Higgs boson couplings

The phenomenology of the Higgs sector depends on the couplings of the Higgs bosons to gauge bosons and fermions. The couplings of the two CP-even Higgs bosons to W and Z bosons are given in terms of the angles α and β

$$g_{hVV} = g_V m_V \sin(\beta-\alpha), \quad g_{HVV} = g_V m_V \cos(\beta-\alpha), \qquad (11.46)$$

where $g_V \equiv 2m_V/v$, for $V = \mathrm{W}^\pm$ or Z ($g_V m_V$ is the SM hVV coupling). There are no tree-level couplings of A or $H^\pm$ to VV. The couplings of the Z boson to two neutral Higgs bosons, which must have opposite CP-quantum numbers, are given by $g_{\phi AZ}(p_\phi - p_A)$,

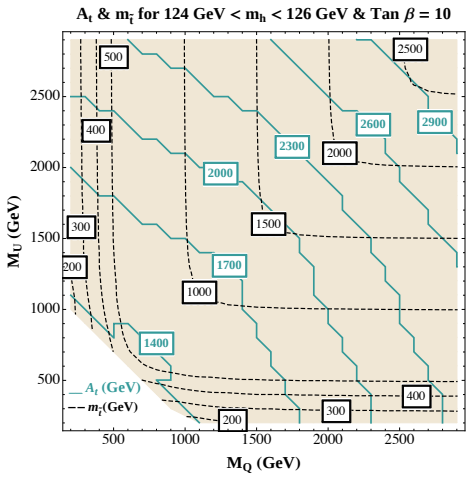

Figure 11.25: Contours of the stop mixing parameter, A_t, necessary for m_h to be in the 124–126 GeV range, given in the plane of the left- and right-handed stop soft supersymmetry-breaking mass parameters, M_Q and M_U, respectively. Other relevant parameters are fixed to be: $\mu = 650$ GeV, $m_A = 1500$ GeV, $A_\tau = 500$ GeV and $\tan\beta = 10$. From Ref. [247].

where $\phi = H$ or h, the momenta p_ϕ and p_A point into the vertex, and

$$g_{hAZ} = g_Z \cos(\beta-\alpha)/2, \quad g_{HAZ} = -g_Z \sin(\beta-\alpha)/2\,. \qquad (11.47)$$

Charged Higgs-W boson couplings to neutral Higgs bosons and four-point couplings of vector bosons and Higgs bosons can be found in Ref. [12].

The tree-level Higgs couplings to fermions obey the following property: the neutral components of one Higgs doublet, Φ_1, couple exclusively to down-type fermion pairs while the neutral components of the other doublet, Φ_2, couple exclusively to up-type fermion pairs [12]. This Higgs-fermion coupling structure defines the Type-II 2HDM [260]. In the MSSM, fermion masses are generated when both neutral Higgs components acquire vacuum expectation values, and the relations between Yukawa couplings and fermion masses are (in third-generation notation)

$$h_b = \sqrt{2}\, m_b/(v\cos\beta), \quad h_t = \sqrt{2}\, m_t/(v\sin\beta)\,. \qquad (11.48)$$

Similarly, one can define the Yukawa coupling of the Higgs boson to τ-leptons (the latter is a down-type fermion).

The couplings of the neutral Higgs bosons to $f\bar{f}$ relative to the SM value, $gm_f/2M_W$, are given by

$$\begin{aligned}
h b\bar{b}&: \; -\sin\alpha/\cos\beta = \sin(\beta-\alpha) - \tan\beta\cos(\beta-\alpha)\,,\\
h t\bar{t}&: \; \cos\alpha/\sin\beta = \sin(\beta-\alpha) + \cot\beta\cos(\beta-\alpha)\,,\\
H b\bar{b}&: \; \cos\alpha/\cos\beta = \cos(\beta-\alpha) + \tan\beta\sin(\beta-\alpha)\,,\\
H t\bar{t}&: \; \sin\alpha/\sin\beta = \cos(\beta-\alpha) - \cot\beta\sin(\beta-\alpha)\,,\\
A b\bar{b}&: \; \gamma_5\tan\beta\,,\\
A t\bar{t}&: \; \gamma_5\cot\beta\,,
\end{aligned} \qquad (11.49)$$

where the γ_5 indicates a pseudoscalar coupling. In each relation above, the factor listed for $b\bar{b}$ also pertains to $\tau^+\tau^-$. The charged Higgs boson couplings to fermion pairs are given by

$$\begin{aligned}
g_{H^- t\bar{b}} &= \frac{g}{\sqrt{2}M_W}\left[m_t\cot\beta\frac{1+\gamma_5}{2} + m_b\tan\beta\frac{1-\gamma_5}{2}\right],\\
g_{H^-\tau^+\nu} &= \frac{g}{\sqrt{2}M_W}\left[m_\tau\tan\beta\frac{1-\gamma_5}{2}\right].
\end{aligned} \qquad (11.50)$$

The non-standard neutral Higgs bosons have significantly enhanced couplings to down-type fermions at sizeable $\tan\beta$. From the above equations it is clear that this occurs near the alignment limit:

$\cos(\beta-\alpha) \ll 1$, where in the mass eigenbasis only one Higgs acquires a VEV [244,245]. In this case the lightest Higgs boson behaves like the SM one and H, A have $\tan\beta$ enhanced couplings to down type fermions, and analogous enhanced couplings are in place for the charged Higgs.

Quite in general, radiative corrections can modify significantly the values of the Higgs boson couplings to fermion pairs and to vector boson pairs. In a first approximation, when radiative corrections to the quartic couplings are computed, the diagonalizing angle α is shifted from its tree-level value, and hence one may compute a "radiatively-corrected" value for $\cos(\beta-\alpha)$. This shift provides an important source of the radiative corrections to the Higgs couplings [217,247]. The radiative corrections to the angle α can enable the alignment without decoupling for sizeable values of the Higgs mass parameter $\mu \geq M_{\rm SUSY}$ and sizeable $\tan\beta$. Additional contributions from the one-loop vertex corrections to tree-level Higgs couplings must also be considered [211,261–268]. These contributions alter significantly the Higgs-fermion Yukawa couplings at large $\tan\beta$, both in the neutral and charged Higgs sector. Moreover, these radiative corrections can modify the basic relationship $g_{h,H,A b\bar{b}}/g_{h,H,A\tau^+\tau^-} \propto m_b/m_\tau$, and change the main features of MSSM Higgs phenomenology.

V.1.3. Decay properties of MSSM Higgs bosons

In the MSSM, one must consider the decay properties of three neutral Higgs bosons and one charged Higgs pair. The mass, *CP* properties, decay and production properties of one of the neutral Higgs bosons should agree with Higgs data. Given that present data allows only for moderate departures from the SM predictions, it implies that some degree of alignment is necessary. In this subsection possible *CP*-violating effects are neglected, and will be commented upon later.

For heavy SUSY particles and sufficiently heavy non-SM-like Higgs bosons, the alignment is triggered by decoupling and departures of the lightest MSSM Higgs boson couplings to gauge bosons and fermions from those predicted in the SM would be minimal. If m_A is below a few hundred GeV, instead, departures from alignment depend on the radiative corrections to the mixing angle α that are proportional to ratios of mass parameters associated to the SUSY particles, and hence do not decouple for heavy SUSY spectra. The main effects occur in departures from the $h \to b\bar{b}$ decay rate, hence also in its total width and, thus, in all branching ratios. As mentioned before, additional effects induced through SUSY-QCD radiative corrections to the $hb\bar{b}$ coupling may also be relevant even in the presence of heavy SUSY particles.

The SM-like branching ratios of h can be modified if decays into supersymmetric particles are kinematically allowed, and, in particular, decays into a pair of the lightest supersymmetric particles - i.e. lightest neutralinos - can become dominant and would be invisible if R-parity is conserved [269–271], Moreover, if light superpartners exist that couple to photons and/or gluons, the h loop-induced coupling to gg and $\gamma\gamma$ could deviate sizeably from the corresponding SM predictions [247,272–275]. Light staus close to 100 GeV with large mixing can enhance the Higgs decay rate into diphotons by up to 40% with respect to the SM, without being in conflict with the stability of the Higgs potential [276]. Light charginos, close to the LEP limit, can also induce up to 10% variations in the Higgs to diphoton decay rate for small values of $\tan\beta \simeq 4$, and hence heavy stops with masses in the 10 TeV range [277]. Given the smallness of the Higgs to diphoton rate, and hence its negligible contribution to the total Higgs decay width, both light staus and charginos have the possibility of altering $BR(h \to \gamma\gamma)$ without altering any other decay rates. Light stops and light sbottoms could contribute to the Higgs-diphoton rate, but in practice they are strongly constrained by the fact that they would at the same time yield a much larger contribution to gluon fusion Higgs production. The Higgs to digluon decay rate and gluon fusion Higgs production can be suppressed due to sbottom effects at large $\tan\beta$ and large μ, but in practice such effects are very small for masses above 500 GeV as presently preferred by LHC searches [278]. Light stops, could give relevant contributions to the Higgs digluon rate and gluon fusion Higgs production, which depending on the value of the stop mixing and the stop masses could yield both suppression or enhancement with respect to the SM. In practice, due to the m_h constrains on the stop sector, light stops can only moderately vary the effective gluon-Higgs coupling and correspondingly the gluon fusion-Higgs production rate [56,38,279].

Given that some degree of alignment is necessary to agree with data, for the heavier Higgs states there are two possibilities to be considered: i) Alignment triggered by decoupling, hence $m_A \geq$ several hundred GeV: The HWW and HZZ couplings are very small. The dominant decay branching ratios strongly depend on $\tan\beta$. After incorporating the leading radiative corrections to Higgs couplings, the following decay features are relevant in the MSSM. The decay modes $H, A \to b\overline{b}$, $\tau^+\tau^-$ dominate when $\tan\beta$ is large (this holds even away from decoupling). For small $\tan\beta$, the $t\overline{t}$ decay mode dominates above its kinematic threshold. In contrast to the lightest SM-like Higgs boson, the vector boson decay modes of H are strongly suppressed due to the suppressed HVV couplings in the decoupling limit. For the charged Higgs boson, $H^+ \to t\bar{b}$ dominates. ii) Alignment without decoupling, hence $m_A \leq$ a few hundred GeV. The main difference with the previous case is that in the low $\tan\beta$ regime ($\tan\beta \leq 5$) additional decay channels may be allowed which involve decays into the lightest SM-like Higgs boson. For A and H, besides the $H, A \to b\overline{b}$, $\tau^+\tau^-$ decay modes, also $A \to Zh$, $H \to hh$ as well as $H \to WW/ZZ$ decay modes are available. For the charged Higgs boson, $H^+ \to \tau^+\nu_\tau$ dominates below the $t\bar{b}$ threshold, and also $H^\pm \to W^\pm h$ may be searched for. Both in i) and ii), the heavier Higgs states, H, A and $H^\pm$, are roughly mass degenerate (with masses $\pm$ 20 GeV or less apart).

In the case of sufficiently light SUSY particles, the heavy Higgs boson decays into charginos, neutralinos and third-generation squarks and sleptons can be important if they are kinematically allowed [269]. An interesting possibility is a significant branching ratio for the decay of a neutral Higgs boson to the invisible mode $\tilde{\chi}_1^0\tilde{\chi}_1^0$ (where the lightest neutralino $\tilde{\chi}_1^0$ is the lightest supersymmetric particle) [270], which poses a challenge at hadron colliders.

V.1.4. Production mechanisms of MSSM Higgs bosons

The production mechanisms for the SM Higgs boson at e^+e^- and hadron colliders can also be relevant for the production of the MSSM neutral Higgs bosons. However, one must take into account the possibility of enhanced or suppressed couplings with respect to those of the Standard Model, as previously discussed. The SUSY-QCD corrections due to the exchange of virtual squarks and gluinos may modify the cross sections depending on the values of these supersymmetric particle masses. At both lepton and hadron colliders there are new mechanisms that produce two neutral Higgs bosons, as well as processes that produce charged Higgs bosons singly or in pairs. In the following discussion, the main processes for MSSM Higgs boson production are summarized. For more detailed discussions see Refs. [34,241], and for the state-of-the-art calculations of higher order corrections as well as estimates of uncertainties at hadron colliders see Refs. [36–38] and references therein.

The main production mechanisms for the neutral MSSM Higgs bosons at e^+e^- colliders are Higgs-strahlung ($e^+e^- \to Zh, ZH$), vector boson fusion ($e^+e^- \to \nu\bar{\nu}h, \nu\bar{\nu}H$) – with W^+W^- fusion about an order of magnitude larger than ZZ fusion – and s-channel Z boson exchange ($e^+e^- \to Ah, AH$) [280]. For the Higgs-strahlung process [281], it is possible to reconstruct the mass and momentum of the Higgs boson recoiling against the particles from the Z boson decay, and hence sensitive searches for Higgs bosons decaying even to invisible final states are possible.

The main charged Higgs boson production process at e^+e^- colliders is via s-channel γ or Z boson exchange ($e^+e^- \to H^+H^-$). Charged Higgs bosons can also be produced in top quark decays via $t \to b + H^+$ if $m_H^\pm < m_t - m_b$ or via the one-loop process $e^+e^- \to W^\pm H^\mp$ [282,283], which allows the production of a charged Higgs boson with $m_H^\pm > \sqrt{s}/2$, even when H^+H^- production is kinematically forbidden. Other single charged Higgs production mechanisms include $t\bar{b}H^-/\bar{t}bH^+$ production [90], $\tau^+\nu H^-/\tau^-\bar{\nu}H^+$ production [284], and a variety of processes in which $H^\pm$ is produced in association with a one or two other gauge and/or Higgs bosons [285].

At hadron colliders, the dominant neutral Higgs production mechanism over the majority of the MSSM parameter space is gluon fusion, mediated by loops containing heavy top and bottom quarks and the corresponding supersymmetric partners [286]. The effect of light stops that may contribute to the gluon fusion production will be partially cancelled by the fact that they need to have sizeable mixing, while light sbottoms that could suppress gluon fusion through mixing effects are disfavored by data. Higgs boson radiation off bottom quarks becomes important for large $\tan\beta$, where at least two of the three neutral Higgs bosons have enhanced couplings to bottom-type fermions [287,288]. In the search for non-standard neutral Higgs bosons, A and H, the production can be via either of the above channels in the final inclusive ditau mode and via radiation off bottom quarks in the 4b's final mode. The total production rates of bottom quarks and τ pairs mediated by the production of a CP-odd Higgs boson in the large $\tan\beta$ regime are approximately given by

$$\begin{aligned}\sigma_{b\bar{b}A} \times \mathrm{BR}(A \to b\bar{b}) &\simeq \sigma^{\mathrm{SM}}_{b\bar{b}A}\ \frac{\tan^2\beta}{(1+\Delta_b)^2}\frac{9}{(1+\Delta_b)^2+9},\\ \sigma_{gg\to A,b\bar{b}A} \times \mathrm{BR}(A \to \tau^+\tau^-) &\simeq \sigma^{\mathrm{SM}}_{gg\to A,b\bar{b}A}\ \frac{\tan^2\beta}{(1+\Delta_b)^2+9},\end{aligned} \tag{11.51}$$

where $\sigma^{\mathrm{SM}}_{b\bar{b}A}$ and $\sigma^{\mathrm{SM}}_{gg\to A,b\bar{b}A}$ denote the values of the corresponding SM Higgs boson cross sections for a SM Higgs boson mass equal to m_A. For high $\tan\beta$, the function Δ_b includes the dominant effects of the SUSY radiative corrections affecting the relation between the bottom quark mass and the bottom Yukawa coupling [211,217,265–267,249], and it depends strongly on $\tan\beta$ and on the SUSY mass parameters. As a result of the Δ_b dependence shown in Eq. (11.51), it follows that the $b\bar{b}A$ channel is more sensitive to the specific SUSY scenario, while the inclusive $\tau^+\tau^-$ channel is rather robust under variations of the SUSY spectra. The production and decay rates of H, for m_A larger m_h^{max}, are governed by formulas similar to the ones presented above, and given that A and H are nearly degenerate in mass, the total signal cross section is increased by roughly a factor of two. Detailed discussions of the impact of radiative corrections in these search modes are presented in Refs. [249,289].

The vector boson fusion and Higgs-strahlung production of the CP-even Higgs bosons as well as the associated production of neutral Higgs bosons with top quark pairs have lower production cross sections by at least an order of magnitude with respect to the dominant ones, depending on the precise region of MSSM parameter space [36]. Higgs pair production of non-standard MSSM Higgs bosons has been studied in Ref. [290].

Charged Higgs bosons can be produced in several different modes at hadron colliders. If $m_{H^\pm} < m_t - m_b$, the charged Higgs boson can be produced in decays of the top quark via the decay $t \to bH^+$, which would compete with the SM process $t \to bW^+$. Relevant radiative corrections to $\mathrm{BR}(t \to H^+b)$ have been computed in Refs. [291–294]. For values of $m_{H^\pm}$ near m_t, width effects are important. In addition, the full $2 \to 3$ processes $pp/p\bar{p} \to H^+\bar{t}b + X$ and $pp/p\bar{p} \to H^-t\bar{b} + X$ must be considered. If $m_{H^\pm} > m_t - m_b$, then charged Higgs boson production occurs mainly through radiation from a third generation quark. Charged Higgs bosons may also be produced singly in association with a top quark via the $2 \to 3$ partonic processes gg, $q\bar{q} \to t\bar{b}H^-$ (and the charge conjugate final states). Charged Higgs bosons can also be produced via associated production with $W^\pm$ bosons through $b\bar{b}$ annihilation and gg-fusion [295]. They can also be produced in pairs via $q\bar{q}$ annihilation [296]. The inclusive H^+H^- cross section is less than the cross section for single charged Higgs associated production [296,297]. For a more extensive discussion of charged Higgs boson production at LHC see Refs. [10,298,36].

V.1.5. Benchmark scenarios in the MSSM for a 125 GeV light Higgs

The experimental uncertainties on the measurements of the production cross sections times branching ratios are at present rather large, and a Higgs sector that differs significantly from the SM case can still fit the data. Hence it is important to explore scenarios where the lightest Higgs agrees with present data but still allows for novel new physics features, and to consider the implications of such scenarios in the search for the remaining MSSM Higgs bosons. The additional Higgs bosons are sought for mainly via the channels

$$\begin{aligned}&pp \to A/H \to \tau^+\tau^- \ \text{(inclusive)},\\ &b\bar{b}A/H, A/H \to \tau^+\tau^- \ \text{(with } b\text{−tag)},\\ &b\bar{b}A/H, A/H \to b\bar{b} \ \text{(with } b\text{−tag)},\\ &pp \to t\bar{t} \to H^\pm W^\mp b\bar{b},\ H^\pm \to \tau\nu_\tau\ ,\\ &gb \to H^-t \quad \text{or} \quad g\bar{b} \to H^+\bar{t},\ H^\pm \to \tau\nu_\tau\ .\end{aligned} \tag{11.52}$$

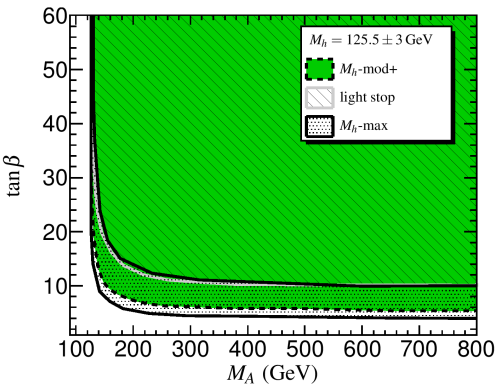

Figure 11.26: Allowed regions in the $(m_A, \tan\beta)$ plane, compatible with the lightest Higgs boson mass, $m_h = 125.5 \pm 3\,\mathrm{GeV}$, for the maximal mixing scenario (hatched black region), the moderate stop mixing benchmark scenario (green shaded region) and the light stop scenario (blue hatched region), as defined in Ref. [248].

The non-observation of any additional state in these production and decay modes puts by now stringent constraints on the MSSM parameter space, in particular on the values of the tree level parameters m_A and $\tan\beta$. Similarly, the non-observation of supersymmetric particles puts constraints on masses of stops and sbottoms as well as gluinos and electroweak gauginos that are relevant for the Higgs sector. Assuming $m_h \simeq 125$ GeV, it is possible to do a scan of the MSSM parameters considering a simplified structure of the Higgs radiative corrections [299], or varying a restricted number of the most relevant parameters [300], and obtain a best fit to the various, measured rates of cross sections and branching ratios. However, due to the large number of free parameters that are relevant for the Higgs sector, a complete scan of the MSSM parameter space is impractical in experimental analyses and phenomenological studies. In the past, for LEP, the Tevatron and the LHC it has been useful to define a set of benchmark scenarios to highlight interesting conditions for MSSM Higgs searches [248,249]. After the Higgs boson discovery, updated MSSM benchmarks scenarios have been defined, that over a wide range of parameter space are compatible with both the mass and the detected production and decay rates of the observed signal [248,38]. They include: i) an updated version of the maximal mixing scenario with a larger value of the gluino mass compatible with LHC bounds. This scenario was originally defined to consider values of the stop mixing to maximize the m_h value and, as a result, only a small region of parameter space is compatible with $m_h \approx 125\,\mathrm{GeV}$; ii) a moderate mixing scenario in which the light CP-even Higgs boson can be interpreted as the newly discovered state within almost the whole parameter space of the $m_A - \tan\beta$ plane that is un-excluded by limits from Higgs searches at LEP and the LHC; iii) a light stop scenario with stop masses in the few to several hundred GeV range that can give contributions to gluon fusion Higgs production; iv) a light stau scenario where the light stau can enhance the SM branching ratio into diphotons for large $\tan\beta$ and v) a tau-phobic scenario that exhibits variations of $BR(h \to b\bar{b})$ and $BR(h \to \tau^+\tau^-)$ with respect to their SM values.

The above benchmarks are just examples that interpret the LHC signal as the lightest *CP*-even MSSM Higgs boson. In Fig. 11.26 the regions in the $(m_A, \tan\beta)$ plane that are compatible with a light *CP* even Higgs mass, $m_h = (125.5 \pm 3)\,\text{GeV}$, are shown for the above benchmarks scenarios. The parameter space allowed by cases ii, iv and v is overlapping, hence only the moderate mixing scenario is shown in the figure. In the light stop and light stau scenarios the lightest Higgs properties would deviate from those of the SM Higgs in all of the allowed parameter space due to loop effects, irrespective of the precise value of m_A. In the maximal mixing and moderate mixing scenarios, h tends to behave as a SM-like Higgs as the theory approaches the decoupling limit. In the tau-phobic scenario, h behaves SM-like due to alignment for specific regions of $\tan\beta$ and large μ, irrespective of the value of m_A. The above benchmarks also have different behavior for the properties of the heavy Higgs bosons. In particular, in the light stau scenario, the decay of $A/H \to \tilde{\tau}_1^+\tilde{\tau}_1^-$ becomes relevant. In the above benchmarks it is also possible to have decays of $H \to hh$ in regions of moderate m_A and moderate $\tan\beta$ as far as one is away from alignment. Also for the previous benchmarks, under the assumption of gaugino mass unification: $M_1 \simeq M_2/2$, and considering the traditional $A/H \to \tau^+\tau^-$ search channel, one would observe variations in the LHC reach depending on the values of μ and M_2. If both parameters are small, as in the maximal and moderate mixing scenarios, then the decays of heavy neutral Higgs bosons into electroweakinos become competitive for small to moderate $\tan\beta$ and m_A. On the contrary, if at least one of the two parameters becomes larger, as in the rest of the benchmark scenarios, then the decay of heavy neutral Higgs bosons into electroweakinos closes up and the reach in $A/H \to \tau^+\tau^-$ is significantly enhanced for the same regions of $\tan\beta$ and m_A. Lastly, varying the parameter μ in both sign and magnitude induces relevant variations in the possible discovery reach through the 4*b*'s channel, and to a lesser extent through the inclusive ditau channel. Future precision measurements of the Higgs boson couplings to fermions and gauge bosons together with information on heavy Higgs searches will provide powerful information on the SUSY parameter space [245,299]. If no other new states beyond the current Higgs candidate are discovered at the LHC, it becomes mandatory to understand what would be the required precision of the Higgs rate measurements to distinguish the MSSM from the SM.

V.2. Indirect constraints on additional states

Interpreting the lightest Higgs as the observed Higgs with a mass of about 125 GeV, improvements in our understanding of *B*-physics observables put indirect constraints on additional Higgs bosons in mass ranges that would be accessible in direct LHC searches. In particular, $\text{BR}(B_s \to \mu^+\mu^-)$, $\text{BR}(b \to s\gamma)$, and $\text{BR}(B_u \to \tau\nu)$ play an important role within minimal flavor-violating (MFV) models [301], in which flavor effects proportional to the CKM matrix elements are induced, as in the SM. For example, see Refs. [302–309]. The supersymmetric contributions to these observables come both at the tree and loop level, and have a different parametric dependence, but share the property that they become significant for large values of $\tan\beta$, which is also the regime in which searches for non-standard MSSM Higgs bosons at hadron colliders are the most powerful.

In the SM, the relevant contributions to the rare decay $B_s \to \mu^+\mu^-$ come through the *Z*-penguin and the *W*-box diagrams [310]. In supersymmetry with large $\tan\beta$, there are also significant contributions from Higgs-mediated neutral currents [311–314], which depend on the SUSY spectra, and grow with the sixth power of $\tan\beta$ and decrease with the fourth power of the *CP*-odd Higgs boson mass m_A. Therefore, measurements at the LHC experiments [315] put strong restrictions on possible flavor-changing neutral currents (FCNC) in the MSSM at large $\tan\beta$ [302,309,316].

Further constraints are obtained from the rare decay $b \to s\gamma$. The SM rate is known up to NNLO corrections [317,318] and is in good agreement with measurements [319]. In the Type-II 2HDM and in the absence of other sources of new physics at the electroweak scale, a bound on $m_{H^\pm} > 380\,\text{GeV}$ can be derived [320]. Although this indirect bound appears much stronger than the results from direct charged Higgs searches, it can be invalidated by new physics contributions, such as those which can be present in the MSSM. In the minimal flavor-violating MSSM, there are new contributions from charged Higgs as well as chargino-stop and gluino-sbottom diagrams. The charged Higgs boson's contribution is enhanced for small values of its mass and can be partially canceled by the chargino and gluino contributions or by higher-order $\tan\beta$-enhanced loop effects.

The branching ratio $B_u \to \tau\nu$, measured by the Belle [321] and BaBar [322] collaborations is in good agreement with the SM prediction [323], but still leaves room for new physics In the MSSM, there is an extra tree-level contribution from the charged Higgs which interferes destructively with the SM contribution, and which increases for small values of the charged Higgs boson mass and large values of $\tan\beta$ [324]. Closely related decay modes that are also sensitive to charged Higgs effects are the $B \to D\tau\nu$ and $B \to D^*\tau\nu$ decays [325]. While predictions of the corresponding branching ratios suffer from large hadronic uncertainties coming from the $B \to D$ and $B \to D^*$ form factors, the ratios $\text{BR}(B \to D\tau\nu)/\text{BR}(B \to D\ell\nu)$ and $\text{BR}(B \to D^*\tau\nu)/\text{BR}(B \to D^*\ell\nu)$, where $\ell = e$ or μ, can be predicted with reasonable accuracy in the SM. Interestingly, recent results from BaBar [326] on these ratios are around 2σ above the SM predictions in both decay modes. Older results from Belle [327] give similar central values but with much larger uncertainties. The tensions in $B \to D\tau\nu$ and $B \to D^*\tau\nu$ cannot be addressed in the context of the MSSM with MFV [309] but would require more radical approaches. These observables constrain in an important way the parameter space for small values of the charged Higgs boson mass and sizeable values of $\tan\beta$ and are only mildly dependent on the SUSY spectra.

Several recent studies [307–309,302] show that, in extended regions of parameter space, the combined *B*-physics measurements impose strong constraints on minimally flavor-violating MSSM models to which Higgs boson searches at the LHC are sensitive. Consequently, the observation of a non-SM Higgs boson at the LHC would point to a rather narrow, well-defined region of MSSM parameter space or to something beyond the minimal flavor violation framework.

Another indirect constraint on the Higgs sector comes from the search for dark matter. Assuming a standard cosmological model, the proper thermal relic density is naturally obtained in particle physics models in which dark matter particles are weakly interacting and with masses of the order of the weak scale. In particular, the lightest supersymmetric particle, typically the lightest neutralino, is an excellent dark matter particle candidate [204]. Within the MSSM, the measured relic density places constraints in the parameter space, which in turn - for specific SUSY low energy spectra- have implications for Higgs searches at colliders, and also for experiments looking for direct evidence of dark matter particles in elastic scattering with atomic nuclei. Large values of $\tan\beta$ and small m_A are relevant for the $b\bar{b}A/H$ and $A/H \to \tau^+\tau^-$ searches at the LHC, and also provide a significant contribution from the *CP*-even Higgs *H* exchange to the spin-independent cross sections for direct detection experiments such as LUX, CDMS or Xenon, for example. Consequently, a signal at colliders would raise prospects for a signal in direct detection experiments and vice-versa, see for example Refs [302,307–309,328–334]. Theoretical uncertainties in the calculation of dark matter scattering cross sections, and in the precise value of the local dark matter density and velocity distributions, may dilute these model-dependent correlations.

V.3. Higgs Bosons in singlet extensions of the MSSM

In the MSSM, the Higgs mass parameter μ is a supersymmetric parameter, and as such, it should naturally be of order M_{GUT} or M_{Planck}. However, in order to enable electroweak symmetry breaking, μ should be of the order of the SUSY breaking scale, that for naturalness we argue should be reasonably close to the electroweak scale. The fact that phenomenologically it is required that μ be at the electroweak/TeV scale is known as the μ problem [335]. Supersymmetric models with additional singlets can provide a solution to the μ problem [335], by promoting the μ parameter to a dynamical singlet superfield *S* that only interacts with the MSSM Higgs doublets through a coupling λ_S at the level of the superpotential. An effective μ is generated when the real scalar component of *S* acquires a vacuum expectation value $\langle S \rangle$

$$\mu_{\mathit{eff}} = \lambda_S \langle S \rangle. \tag{11.53}$$

Table 11.15: Symmetries associated to various models with singlet extensions, the corresponding terms in the superpotential that only involve Higgs and singlet fields, and the number of neutral states in the Higgs sector for the case of CP conservation.

Model	MSSM	NMSSM	nMSSM	UMSSM
Symmetry	-	Z_3	Z_5^R, Z_7^R	$U(1)'$
Superpot.	$\mu\Phi_2\cdot\Phi_1$	$\lambda_S S\Phi_2\cdot\Phi_1+\frac{\kappa}{3}S^3$	$\lambda_S S\Phi_2\cdot\Phi_1+t_F S$	$\lambda_S S\Phi_2\cdot\Phi_1$
H_i^0	2	3	3	3
A_i^0	1	2	2	1

After the minimization of the Higgs potential the vacuum state relates the vacuum expectation values of the three *CP*-even neutral scalars, ϕ_1^0, ϕ_2^0 and S, to their soft supersymmetry breaking masses, hence, one expects that these VEVs should all be of order $M_{\rm SUSY}$ and therefore the μ problem is solved.

The solution of the μ problem through the addition of a singlet superfield to the MSSM comes along with the existence of an extra global U(1) symmetry, known as the Peccei–Quinn (PQ) symmetry [336]. Once the PQ symmetry is spontaneously broken by the Higgs VEVs, a pseudo-Nambu–Goldstone boson, the PQ axion appears in the theory. For values of λ_S of order one the lack of detection of such an axion rules out the theory. Making λ_S very small ($\leq 10^{-6}$) would decouple the axion and render things compatible with experimental results, but then one would be trading the μ problem by a λ_S problem, since there is no explanation to why λ_S should be so small. Promoting the PQ symmetry to a local symmetry involving additional gauge bosons and matter fields could be a viable option that has been explored in the literature. Alternatively there is the possibility to break the PQ symmetry explicitly. For that purpose one can consider a discrete Z_3 symmetry that allows the existence of a PQ odd S^3 term in the superpotential. This model extension has been called the Next-to-Minimal Supersymmetric SM (NMSSM) [337]. It is known however that discrete symmetries may come along with the existence of domain wall structures that imply that our universe would consist of disconnected domains with different ground states, creating unacceptably large anisotropies in the cosmic microwave background [338]. To avoid the problem of domain walls one can consider the existence of non-renormalizable operators that would lead to the preferred vacuum state. However, the same operators in turn may generate quadratically divergent tadpole contributions [339] that could shift the VEV of S to be much larger, order M_{GUT}, and ruin the singlet solution to the μ problem. To cure the problem of destabilizing tadpoles, discrete R-symmetries have been proposed that secure that tadpoles would only appear at very high order loops and be safely suppressed. Depending on the symmetries imposed on the theory, different models with singlet extensions of the MSSM (xMSSM) have been proposed. In Table 11.15 we show the most studied examples: the NMSSM, the Nearly-Minimal Supersymmetric SM (nMSSM) [340], and the U(1)′-extended MSSM (UMSSM) [341], specifying the new parameters appearing in the superpotential and the respective symmetries. A Secluded U(1)′-extended MSSM (sMSSM) [342] contains three singlets in addition to the standard UMSSM Higgs singlet; this model is equivalent to the nMSSM in the limit that the additional singlet VEV's are large, and the trilinear singlet coupling, λ_S, is small [343].

Based on the extended models defined in Table 11.15, we write the most generic supersymmetric and soft supersymmetry breaking scalar potentials for the three scalar fields: Φ_1, Φ_2 and S:

$$\begin{aligned} V_{xMSSM} = &\left|\lambda_S\Phi_2\cdot\Phi_1+t_F+\kappa S^2\right|^2+|\lambda_S S|^2\left(|\Phi_1|^2+|\Phi_2|^2\right)\\ &+\frac{g'^2+g^2}{8}\left(|\Phi_1|^2-|\Phi_2|^2\right)^2\\ &+\frac{g^2}{2}\left(|\Phi_1|^2|\Phi_2|^2-|\Phi_2\cdot\Phi_1|^2\right)\\ &+\frac{g_1'^2}{2}\left(Q_{\Phi_1}|\Phi_1|^2+Q_{\Phi_2}|\Phi_2|^2+Q_S|S|^2\right)^2 \end{aligned} \tag{11.54}$$

$$\begin{aligned} V_{\rm soft} = &\, m_{H_1}^2|\Phi_1|^2+m_{H_2}^2|\Phi_2|^2+m_s^2|S|^2\\ &+\left(A_s\lambda_S S H_u\cdot H_d+\frac{\kappa}{3}A_\kappa S^3+t_S S+h.c.\right). \end{aligned} \tag{11.55}$$

where $\Phi_2\cdot\Phi_1=\epsilon_{ij}\Phi_2^i\Phi_1^j$ and the couplings g', g, and g_1' are associated to the $U(1)_Y$, $SU(2)_L$, and $U(1)'$ gauge symmetries, respectively. t_F and t_S are supersymmetric and SUSY breaking tadpole terms, respectively, m_s is a SUSY breaking mass term for the scalar component of the field S, and A_s and A_κ are the trilinear soft SUSY breaking mass parameters associated with the new terms $\lambda_S S\Phi_2\cdot\Phi_1$ and $\kappa S^3/3$ in the superpotential, with the B-term of the MSSM expressed as $B\mu\equiv A_s\mu_{eff}$. In particular, κ and A_κ are the parameters for the NMSSM model, while t_F and t_S are those of the nMSSM. The UMSSM depends on the new coupling g_1' as well as on the U(1)′ charges of the Higgs fields, Q_{Φ_1}, Q_{Φ_2} and Q_S, that are free parameters with the restriction that they have to add to zero for the superpotential $\lambda_3 S\Phi_2\Phi_1$ to be gauge invariant. In a given U(1)′ construction the charges are specified. The addition of the singlet scalar field(s) imply that additional *CP*-even and *CP*-odd Higgs bosons will appear in the spectra, whereas the charged Higgs sector remains the same as in the MSSM given that the number of Higgs doublets remains unchanged. The mixing with the extra scalar S alters the masses and properties of the physical Higgs bosons, that in general can differ significantly from the SM or the MSSM. A detailed discussion of typical mass spectra and decay properties in these models can be found for example in Refs. [344,343]. Moreover, these models have extra neutralinos and in some cases extra neutral gauge bosons, Z'. The extra gauge boson sector is constrained by experimental data through direct Z' searches as well as the $Z-Z'$ mixing angle $\alpha_{ZZ'}$ constrained to be less that $\mathcal{O}(10^{-3})$ by precision electroweak data .

An interesting feature of models with a singlet extension of the MSSM is that they can easily lead to a strong first order phase transition that enables the possibility of baryogenesis at the electroweak scale [345]. In these models, the strong first order phase transition, necessary to preserve the baryon asymmetry created at the EW scale, is connected to the existence of the cubic soft SUSY breaking term A_S connecting the singlet scalar field with the two Higgs doublets, and does not require a too light SM like Higgs boson mass as it occurs in the MSSM. On the other hand, in SUSY models with extended singlets there is the possibility of additional *CP*-violating phases that may allow to generate the baryon asymmetry and are much less restricted by present electric dipole moments (EDM's) data than those in the MSSM.

V.3.1. The xMSSM Higgs boson masses and phenomenology

In singlet extensions of the MSSM the lightest *CP*-even Higgs mass at tree level, $m_{H_1}^{tree}$ receives a contribution from the singlet scalar that renders it larger than the MSSM value, in particular for small values of $\tan\beta$. The tree level upper bound reads[11]

$$m_{H_1}^{tree}\leq M_Z^2\cos^2 2\beta+\frac{1}{2}\lambda_S^2 v^2\sin^2 2\beta\,. \tag{11.56}$$

At the one-loop level, the top and stop loops (sbottom and stau loops for large $\tan\beta$) are the dominant contributions, that are common to the MSSM and to all the singlet extensions. Gauge couplings in the UMSSM are small compared to the top quark Yukawa coupling, hence the one-loop gauge contributions are negligible. Corrections exclusive to the NMSSM and the nMSSM enter only at the two loop level. Therefore, there are no significant model-dependent contributions at one loop order, and as a result, for large $\tan\beta$ the lightest *CP*-even Higgs mass does not differ in any significant way from the MSSM one. Fig. 11.27 shows the mass ranges for the lightest *CP*-even Higgs boson in the MSSM, NMSSM, nMSSM and UMSSM for a scan over parameters as defined in Ref. [343]. The value of $M_{\rm SUSY}$ is fixed to 1 TeV and the radiative corrections are computed only at one loop level. The upper bounds in Fig. 11.27 are indicative, since two loop corrections, as has been shown for the MSSM, can be rather relevant and have not been included. A value of the lightest SM Higgs mass of about 125 GeV is achievable in all these MSSM extensions, and this remains the case even after higher order corrections are implemented.

[11] Additional gauge interactions contribute to this increase with a term of $\mathcal{O}(g_1'^2v^2(Q_{\phi_2}^2\cos^2\beta+Q_{\phi_1}^2\sin^2\beta))$ in the UMSSM.

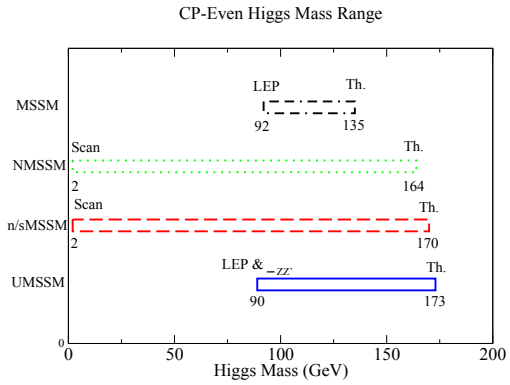

Figure 11.27: Mass ranges for the lightest *CP*-even Higgs boson in each extended MSSM scenario discussed in the text, and in the MSSM, for comparison. The value of $M_{\rm SUSY}$ is fixed to 1 TeV and the rest of parameters are scanned as defined in Ref. [343]. The radiative corrections are computed only at one loop level.

A singlet extended supersymmetric Higgs sector opens new avenues for discovery. Since the singlet pseudoscalar particle may be identified as the pseudo-Goldstone boson of a spontaneously broken Peccei–Quinn symmetry, it may become naturally light [346,347]. Generally, there is mixing of the singlet sector with the MSSM Higgs sector, and with a sufficiently light, singlet dominated scalar or pseudoscalar, H_1^0 or A_1^0, respectively, the SM-like Higgs boson H_2^0 may decay to pairs of H_1^0 or A_1^0. The light scalar and/or pseudoscalar may subsequently decay to $\tau\tau$ or $b\bar{b}$ pairs [348]. Such cascade decays are more difficult to detect than standard searches due to the potentially soft decay products. In addition, the light singlet scenario in the NMSSM or nMSSM is typically associated with a light singlino-dominated neutralino. The recently discovered SM-like Higgs boson can then decay to pairs of this neutralino [349,343], opening an invisible decay mode that is not excluded by present data. In the case of a heavy singlet dominated scalar, its detection would be more challenging than for a SM-like Higgs of similar mass due to the reduced couplings.

An indirect probe of an extended Higgs sector is through precision Higgs production and decay rate measurements of the recently discovered Higgs boson at the LHC. In models with extended singlets, at low $\tan\beta$ it is possible to trade the requirement of a large stop mixing by a sizeable trilinear Higgs-Higgs singlet coupling λ_S, rendering more freedom on the requirements for gluon fusion production. Similar to the MSSM, mixing in the Higgs sector -additionally triggered by the extra new parameter λ_S - can produce variations in the Higgs-$b\bar{b}$ and Higgs-$\tau^-\tau^+$ couplings that can alter the Higgs to ZZ/WW and diphoton rates. Light charginos at low $\tan\beta$ can independently contribute to enhance the di-photon rate, without altering any other of the Higgs decay rates [275,350]

V.4. Supersymmetry with extended gauge sectors

In the MSSM, the tree-level value of the lightest *CP*-even Higgs mass originates from the D-term dependence of the scalar potential that comes from the supersymmetric kinetic terms in the Kähler potential. The D-terms lead to tree-level quartic couplings which are governed by the squares of the gauge couplings of the weak interactions, under which the Higgs has non-trivial charges and hence the lightest Higgs mass is bounded to be smaller than M_Z. If new gauge interactions were present at the TeV scale, and the Higgs bosons would have non-trivial charges under them, there would be new D-term contributions that would lead to an enhancement of the tree-level Higgs mass value. Since the low energy gauge interactions reduce to the known $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ ones, in order for this mechanism to work, the extended gauge and Higgs sectors should be integrated out in a non-supersymmetric way. This means that there must be supersymmetry breaking terms that are of the order or larger than the new gauge boson masses. The tree-level quartic couplings would then be enhanced through their dependence on the square of the gauge couplings of the extended Higgs sector. This effect will be suppressed when the heavy gauge boson masses are larger than the supersymmetry breaking scale and will acquire its full potential only for large values of this scale.

One of the simplest possibilities is to extend the weak interactions to a $\mathrm{SU}(2)_1 \times \mathrm{SU}(2)_2$ sector, such that the known weak interactions are obtained after the spontaneous breaking of these groups to $\mathrm{SU}(2)_L$ [223]. This may be achieved by introducing a bi-doublet Σ under the two SU(2) gauge groups, which acquires a non-trivial vacuum expectation value u in the diagonal direction. The heavy gauge boson masses are therefore given by $M^2_{W'} = (g_1^2 + g_2^2)u^2/2$, and the weak coupling $g^2 = g_1^2 g_2^2/(g_1^2 + g_2^2)$. To obtain a new tree-level contribution to the Higgs potential, the Higgs bosons must be charged under the new gauge interactions. One possibility is to assume that the third generation quarks and leptons as well as the Higgs doublets have charges under the $\mathrm{SU}(2)_1$ group, while the second and third generations have charges under $\mathrm{SU}(2)_2$. This provides a natural explanation of the largeness of the third generation couplings compared to the first and second generation ones.

Under the above conditions, the D-term contributions to the neutral Higgs effective potential are given by

$$V_D = \frac{g^2\Delta + g'^2}{8}\left(|H_2^0|^2 - |H_1^0|^2\right)^2 \qquad (11.57)$$

with

$$\Delta = \left(1 + \frac{4m_\Sigma^2}{g_2^2 u^2}\right)\left(1 + \frac{4m_\Sigma^2}{(g_1^2 + g_2^2)u^2}\right)^{-1}, \qquad (11.58)$$

where m_Σ is the supersymmetry breaking term associated with the bi-doublet Σ. It is easy to see that while the MSSM D-term is recovered when $m_\Sigma \to 0$, it is replaced by the $\mathrm{SU}(2)_1 \times \mathrm{U}(1)_Y$ D-term when m_Σ becomes much larger than $M_{W'}$. The tree-level mass now reads

$$m_h^2|_{\rm tree} = \frac{g^2\Delta + g'^2}{4} v^2 \cos^2 2\beta, \qquad (11.59)$$

and reduces to the MSSM value, $M_Z^2 \cos^2 2\beta$, for $\Delta = 1$.

Assuming $g_1 \simeq g_2$, values of $g_{1,2}$ of order one are necessary to obtain the proper value of the weak gauge coupling. In addition, if values of m_Σ of order $M_{W'}$ are assumed, enhancements of order 50 percent of the MSSM D-term contribution to the Higgs mass may be obtained. Such enhancements are sufficient to obtain the measured Higgs mass value without the need of very heavy stops or large stop mixing parameters.

The gauge extension described above leads to new, heavy gauge and Higgs bosons, as well as new neutralinos and charginos. Constraints from precision measurements put bounds of the order of a few TeV on the mass of these gauge bosons, which may be probed at the higher energy run of the LHC collider. If the new gaugino supersymmetry breaking masses are smaller than the gauge boson masses, the new electroweakinos will have masses of the order of a few TeV and therefore the weak scale phenomenology reduces to the MSSM one.

Although a particular gauge extension of the MSSM was taken as an example, the results are rather general. Provided that the MSSM Higgs bosons are charged under the extended gauge group and that the supersymmetry breaking parameters associated with the new spontaneously broken gauge sector are large compared to the new gauge boson masses, non-decoupled D-terms for the Higgs fields are generated, leading to a modification of the tree-level Higgs mass prediction. Similar gauge extensions, including also new abelian gauge groups have been considered, for instance, in Ref. [351].

Gauge extensions of the MSSM can also lead to an enhancement of the Higgs mass value by modifying the renormalization group evolution of the Higgs quartic coupling to low energies. In the MSSM, the evolution of the quartic coupling is governed by the top-quark Yukawa interactions and depends on the fourth power of the top-quark Yukawa coupling. The neutralino and chargino contributions, which depend on the fourth power of the weak gauge couplings, are small due to the smallness of these couplings. Depending on the values of the soft supersymmetry breaking parameters in the gaugino and Higgsino

sectors, the $SU(2)_1$ gauginos may become light, with masses of the order of the weak scale. Since the $SU(2)_1$ coupling may be significantly larger than the $SU(2)_L$ one, for small values of the Higgsino mass parameter μ, the associated charginos and neutralinos may modify the evolution of the quartic coupling in a significant way [352]. This may lead to a significant increase of the lightest *CP*-even Higgs mass, even for small values of $\tan\beta \simeq 1$ for which the D-term contributions become small. In addition, under these conditions, light charginos may lead to a significant modification of the Higgs diphoton decay rate, which may be as large as 50% of the SM [352–356].

V.5. Effects of CP violation

In the Standard Model, *CP*-violation (*CPV*) is induced by phases in the Yukawa couplings of the quarks to the Higgs field, which results in one non-trivial phase in the CKM mixing matrix. SUSY scenarios with new *CPV* phases are theoretically appealing, since additional *CPV* beyond that observed in the K, D, and B meson systems is required to explain the observed cosmic matter-antimatter asymmetry [357]. In the MSSM *CP*-violation effects in the Higgs sector appear at the quantum level and are mostly determined by *CP* phases active in the third generation squark soft SUSY breaking trilinear mass parameters as well as in the gaugino/gluino masses. In extensions of the MSSM such as singlet extensions *CP* violation effects can be effective already at tree level and due to the larger number of new parameters there are many more sources of *CP* violation. In general *CP* violation effects in the Higgs sector are importantly constrained from electric dipole moments data [358].

V.5.1. Effects of CP violation on the MSSM Higgs spectrum

In the MSSM, there are additional sources of *CPV* from phases in the various mass parameters. In particular, the gaugino mass parameters ($M_{1,2,3}$), the Higgsino mass parameter, μ, the bilinear Higgs squared-mass parameter, m_{12}^2, and the trilinear couplings of the squark and slepton fields to the Higgs fields, A_f, may carry non-trivial phases. The two parameter combinations $\arg[\mu A_f (m_{12}^2)^*]$ and $\arg[\mu M_i (m_{12}^2)^*]$ are invariant under phase redefinitions of the MSSM fields [359,252]. Therefore, if one of these quantities is non-zero, there would be new sources of *CP*-violation, which affects the MSSM Higgs sector through radiative corrections [251,252,360–364]. The mixing of the neutral *CP*-odd and *CP*-even Higgs boson states is no longer forbidden. Hence, m_A is no longer a physical parameter. However, the charged Higgs boson mass $m_{H^\pm}$ is still physical and can be used as an input for the computation of the neutral Higgs spectrum of the theory.

For large values of $m_{H^\pm}$, corresponding to the decoupling limit, the properties of the lightest neutral Higgs boson state approach those of the SM Higgs boson. That is, for $m_{H^\pm} \gg M_W$, the lightest neutral Higgs boson is approximately a *CP*-even state, with *CPV* couplings that are suppressed by terms of $\mathcal{O}(m_W^2/m_{H^\pm}^2)$. In particular, the upper bound on the lightest neutral Higgs boson mass, takes the same value as in the *CP*-conserving case [252]. Nevertheless, there still can be significant mixing between the two heavier neutral mass eigenstates. For a detailed study of the Higgs boson mass spectrum and parametric dependence of the associated radiative corrections, see Refs. [360,363].

Major variations to the MSSM Higgs phenomenology occur in the presence of explicit *CPV* phases. In the *CPV* case, vector boson pairs couple to all three neutral Higgs boson mass eigenstates, H_i ($i = 1, 2, 3$), with couplings

$$g_{H_i VV} = \cos\beta \mathcal{O}_{1i} + \sin\beta \mathcal{O}_{2i}\,, \tag{11.60}$$

$$\begin{aligned} g_{H_i H_j Z} =& \mathcal{O}_{3i}\left(\cos\beta \mathcal{O}_{2j} - \sin\beta \mathcal{O}_{1j}\right) \\ & - \mathcal{O}_{3j}\left(\cos\beta \mathcal{O}_{2i} - \sin\beta \mathcal{O}_{1i}\right)\,, \end{aligned} \tag{11.61}$$

where the $g_{H_i VV}$ couplings are normalized to the analogous SM coupling and the $g_{H_i H_j Z}$ have been normalized to $g_Z^{\rm SM}/2$. The orthogoanl matrix $\mathcal{O}_{ij}$ is relating the weak eigenstates to the mass eigenstates. It has non-zero off-diagonal entries mixing the *CP*-even and *CP*-odd components of the weak eigenstates. The above couplings obey the relations

$$\sum_{i=1}^{3} g_{H_i ZZ}^2 = 1 \quad \text{and} \quad g_{H_k ZZ} = \varepsilon_{ijk}\, g_{H_i H_j Z}\,, \tag{11.62}$$

where ε_{ijk} is the Levi-Civita symbol.

Another consequence of *CPV* effects in the scalar sector is that all neutral Higgs bosons can couple to both scalar and pseudoscalar fermion bilinear densities. The couplings of the mass eigenstates H_i to fermions depend on the loop-corrected fermion Yukawa couplings (similarly to the *CPC* case), on $\tan\beta$ and on the $\mathcal{O}_{ji}$. The resulting expressions for the scalar and pseudoscalar components of the neutral Higgs boson mass eigenstates to fermions and the charged Higgs boson to fermions are given in Refs. [360,365].

The production processes of neutral MSSM Higgs bosons in the *CPV* scenario are similar to those in the *CPC* scenario, except for the fact that in any process, the *CP* eigenstates h, H, and A can be replaced by any of the three neutral Higgs mass eigenstates H_i. This is the case, since, in the presence of *CP* violation, the H_i's do not have well-defined *CP* quantum numbers. Regarding the decay properties, the lightest mass eigenstate, H_1, predominantly decays to $b\bar{b}$ if kinematically allowed, with a smaller fraction decaying to $\tau^+\tau^-$, similar to the *CPC* case. If kinematically allowed, a SM-like neutral Higgs boson, H_2 or H_3 can decay predominantly to $H_1 H_1$ leading to many new interesting signals both at lepton and hadron colliders; otherwise it will decay preferentially to $b\bar{b}$.

The discovery of a 125 GeV Higgs boson has put strong constraints on the realization of the *CPV* scenario within the MSSM. This is partly due to the fact that the observed Higgs rates are close to the SM values, and a large *CP*-violating component would necessary induce a large variation in the rate of the SM-like Higgs decay into the weak gauge bosons $W^\pm$ and Z. The measured Higgs mass imposes an additional constraint on the realization of this scenario. The *CP*-violating effects are enhanced for values of the modulus of X_t larger than the ones leading to maximal mixing, $|X_t| > \sqrt{6} M_S$. Such large values of $|X_t|$, however, lead to a decrease of the radiative corrections to the Higgs mass, and for sufficiently large $|X_t|$, the SM-like Higgs mass falls below the experimentally allowed range. This effect is increased by the fact that larger mixings in the Higgs sector lead to a reduction of the smaller mass eigenvalue. Once these effects are considered, the lightest Higgs component on the would be *CP*-odd Higgs A tends to be smaller than about 10 percent, and therefore difficult to test at the LHC. The Higgs mass constraints can be alleviated in more general two Higgs doublet models, or in the NMSSM, where the Higgs mass can be fixed in a way independent of the stop mass parameters.

CP-violating effects can still be significant in the heavy Higgs sector. For instance, the Higgs bosons H_2 and H_3 may be admixtures of *CP*-even and *CP*-odd scalars, and therefore both may be able to decay into pairs of weak gauge bosons. Although the observation of this effect would be a clear signal of *CP*-violation, the proximity of the masses of H_2 and H_3 within the MSSM makes the measurement of such effects quite challenging. In generic two Higgs doublet models, the mass splitting between the two heavy mass eigenstates may become larger, which could facilitate the detection of *CP*-violating effects at collider experiments.

V.6. Non-supersymmetric extensions of the Higgs sector

There are many ways to extend the minimal Higgs sector of the Standard Model. In the preceding sections the phenomenology of SUSY Higgs sectors is considered, which at tree level implies a constrained type-II 2HDM (with restrictions on the Higgs boson masses and couplings). In the following discussion, more generic 2HDM's [12,260,243,366] are presented. These models are theoretically less compelling since they do not provide an explanation for the SM Higgs naturalness problem, but can lead to different patterns of Higgs-fermion couplings, hence, to different phenomenology. It is also possible to consider models with a SM Higgs boson and one or more additional scalar SU(2) doublets that acquire no VEV and hence play

no role in the EWSB mechanism. These models are dubbed Inert Higgs Doublet Models (IHD) [367]. Due to the lack of a VEV, the inert Higgs bosons cannot decay into a pair of gauge bosons. And imposing a Z_2 symmetry that prevents them from coupling to the fermions, it follows that, if the lightest inert Higgs boson is neutral, it becomes a good dark matter candidate with interesting associated collider signals. Recent studies of IHD models in the light of a 125 GeV Higgs have been performed [368], showing that there can be non-negligible enhancement or suppression of Higgs to diphotons or Higgs to $Z\gamma$. This may be due to the presence of a light charged Higgs, as light as 100 GeV, that is not in conflict with collider or flavor constraints, because it has no couplings to fermions. It is interesting to study the interplay between collider and direct dark matter detection signals in these models.

Other extensions of the Higgs sector can include [344,369] multiple copies of $\mathrm{SU}(2)_L$ doublets, additional Higgs singlets [370], triplets or more complicated combinations of Higgs multiplets. It is also possible to enlarge the gauge symmetry beyond $\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$ along with the necessary Higgs structure to generate gauge boson and fermion masses. There are two main experimental constraints on these extensions: *(i)* precision measurements which constrain $\rho = m_W^2/(m_Z^2\cos^2\theta_W)$ to be very close to 1 and *(ii)* flavor changing neutral current (FCNC) effects. In electroweak models based on the SM gauge group, the tree-level value of ρ is determined by the Higgs multiplet structure. By suitable choices for the hypercharges, and in some cases the mass splitting between the charged and neutral Higgs sector or the vacuum expectation values of the Higgs fields, it is possible to obtain a richer combination of singlets, doublets, triplets and higher multiplets compatible with precision measurements [371]. Concerning the constraints coming from FCNC effects, the Glashow–Weinberg (GW) criterion [372] states that, in the presence of multiple Higgs doublets the tree-level FCNC's mediated by neutral Higgs bosons will be absent if all fermions of a given electric charge couple to no more than one Higgs doublet. An alternative way of suppressing FCNC in a two Higgs doublet model has been considered in Ref. [373], where it is shown that it is possible to have tree level FCNC completely fixed by the CKM matrix, as a result of an abelian symmetry.

V.6.1. Two-Higgs-doublet models

Supersymmetry demands the existence of two Higgs doublets such that one doublet couples to up-type quarks and the other to down-type quarks and charged leptons. This Higgs-fermion coupling structure is the one identified as type-II 2HDM [260] and assures that masses for both up and down-type quarks can be generated in a supersymmetric and gauge invariant way. Two Higgs doublet models [243], however, can have a more diverse Higgs-fermion coupling structure and can be viewed as a simple extension of the SM to realize the spontaneous breakdown of $\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$ to $\mathrm{U}(1)_{\mathrm{em}}$. Quite generally, if the two Higgs doublets contain opposite hypercharges, the scalar potential will contain mixing mass parameters of the kind $m_{12}^2\Phi_1^T i\sigma_2\Phi_2 + h.c.$. In the presence of such terms, both Higgs doublets will acquire vacuum expectation values, $v_1/\sqrt{2}$ and $v_2/\sqrt{2}$, respectively, and the gauge boson masses will keep their SM expressions with the Higgs vacuum expectation value v replaced by $v=\sqrt{v_1^2+v_2^2}$. Apart from the mass terms, the most generic renormalizable and gauge invariant scalar potential contains seven quartic couplings, which are defined in Eq. (11.38).

Considering two doublets with hypercharges, with $Y_{\Phi_1}=-1$ and $Y_{\Phi_2}=1$ as in Eqs. (11.36) and (11.37), and the most general, renormalizable Higgs potential will be given by Eq. (11.38). The same as in the MSSM case, after electroweak symmetry breaking and in the absence of *CP*-violation, the physical spectrum contains a pair of charged Higgs bosons $H^\pm$, a *CP*-odd Higgs boson A and two neutral *CP*-even Higgs bosons, h and H. The angles α and β diagonalize the *CP*-even, and the *CP*-odd and Charged Higgs sectors, respectively

The complete 2HDM is defined only after considering the interactions of the Higgs fields to fermions. Yukawa couplings of the generic from

$$-h_{ij}^a\bar{\Psi}_L^i H_a \Psi_R^j + h.c. \tag{11.63}$$

may be added to the renormalizable Lagrangian of the theory.

Table 11.16: Higgs boson couplings to up, down and charged lepton-type $SU(2)_L$ singlet fermions in the four discrete types of 2HDM models that satisfy the Glashow–Weinberg criterion, from Ref. [374].

Model	2HDM I	2HDM II	2HDM III	2HDM IV
u	Φ_2	Φ_2	Φ_2	Φ_2
d	Φ_2	Φ_1	Φ_2	Φ_1
e	Φ_2	Φ_1	Φ_1	Φ_2

Contrary to the SM, the two Higgs doublet structure does not ensure the alignment of the fermion mass terms $m_{ij}=h_{ij}^a v_a/\sqrt{2}$ with the Yukawa couplings h_{ij}^a. This implies that quite generally, the neutral Higgs boson will mediate flavor changing interactions between the different mass eigenstates of the fermion fields. Such flavor changing interactions should be suppressed in order to describe properly the Kaon, D and B meson phenomenology. Based on the Glashow–Weinberg criterion, it is clear that the simplest way of avoiding such transitions is to assume the existence of a symmetry that ensures the couplings of the fermions of each given quantum number (up-type and down-type quarks, charged and neutral leptons) to only one of the two Higgs doublets. Different models may be defined depending on which of these fermion fields couple to a given Higgs boson, see Table 11.16. Models of type-I [366] are those in which all SM fermions couple to a single Higgs field. In type-II models [260] down-type quarks and charged leptons couple to a common Higgs field, while the up-type quarks and neutral leptons couple to the other. In models of type-III (lepton-specific) quarks couple to one of the Higgs bosons, while leptons couple to the other. Finally, in models of type-IV (flipped), up-type quarks and charged leptons couple to one of the Higgs fields while down-quarks and neutral leptons couple to the other.

The two Higgs doublet model phenomenology depends strongly on the size of the mixing angle α and therefore on the quartic couplings. For large values of m_A, $\sin\alpha\to-\cos\beta$, $\cos\alpha\to\sin\beta$, $\cos(\beta-\alpha)\to 0$, and the lightest *CP*-even Higgs h behaves as the SM Higgs. The same behavior is obtained if the quartic couplings are such that $\mathcal{M}_{12}^2\sin\beta = -(\mathcal{M}_{11}^2 - m_h^2)\cos\beta$. The latter condition represents a situation in which the coupling of h to fermions and weak gauge bosons become the same as in the SM, without decoupling the rest of the non-standard scalars and it is of particular interest due to the fact that the recently discovered Higgs boson has SM-like properties. This situation will be referred to as alignment, as in the MSSM case.

In type-II Higgs doublet models, at large values of $\tan\beta$ and moderate values of m_A, the non-standard Higgs bosons H, A and $H^\pm$ couple strongly to bottom quarks and τ leptons. Hence the decay modes of the non-standard Higgs bosons tend to be dominated by b-quark and tau-lepton modes, including top quarks or neutrinos in the case of the charged Higgs. However, for large and negative values of λ_4, the charged Higgs boson mass may be sufficiently heavy to allow on-shell decays

$$\begin{aligned} &H^\pm\to W^\pm + (H,A),\\ &\qquad g_{H^\pm W^\mp H,A}\simeq\frac{M_W}{v}\sin(\beta-\alpha)(p_{H^+}-p_{H,A})\,, \end{aligned} \tag{11.64}$$

where p_{H^+} and $p_{H,A}$ are the charged and neutral scalar Higgs momenta pointing into the vertex. On the other hand, for large and positive values of λ_5, the above charged Higgs decay into a $W^\pm$ and the *CP*-odd Higgs boson may be allowed, but the heavy Higgs H may be sufficiently heavy to decay into a *CP*-odd Higgs boson and an on-shell Z.

$$H\to Z+A,\quad g_{HZA}\simeq\frac{M_Z}{v}\sin(\beta-\alpha)(p_H-p_A). \tag{11.65}$$

The decay $H^\pm\to W^\pm+H$, on the other hand may be allowed only if $\lambda_4<-\lambda_5$. The couplings controlling all the above decay modes are proportional to $\sin(\beta-\alpha)$ and therefore they are unsuppressed in the alignment limit. Moreover, these could still be the dominant decay modes at moderate values of $\tan\beta$, offering a way to evade the current bounds obtained assuming a dominant decay into bottom quarks or τ leptons.

The quartic couplings are restricted by the condition of stability of the effective potential as well as by the restriction of obtaining the proper value of the lightest *CP*-even Higgs mass. Close to the alignment limit, the lightest *CP*-even Higgs mass becomes, approximately independent of m_A and is given by

$$\begin{aligned} m_h^2 \simeq & v^2(\lambda_1 \cos^4\beta + \lambda_2 \sin^4\beta + 2\tilde{\lambda}_3 v^2 \cos^2\beta \sin^2\beta) \\ & + v^2(4\lambda_6 \cos^3\beta \sin\beta + 4\lambda_7 \sin^3\beta \cos\beta)\,, \end{aligned} \tag{11.66}$$

where $\tilde{\lambda}_3 = \lambda_3 + \lambda_4 + \lambda_5$.

The stability conditions imply the positiveness of all masses, as well as the avoidance of run-away solutions to large negative values of the fields in the scalar potential. These conditions imply

$$\begin{aligned} & \lambda_1 \geq 0, \quad \lambda_2 \geq 0, \quad \lambda_3 + \lambda_4 - |\lambda_5| \geq -\sqrt{\lambda_1 \lambda_2}, \\ & \lambda_3 \geq -\sqrt{\lambda_1 \lambda_2}, \quad 2|\lambda_6 + \lambda_7| < \frac{\lambda_1 + \lambda_2}{2} + \tilde{\lambda}_3, \end{aligned} \tag{11.67}$$

where the first four are necessary and sufficient conditions in the case of $\lambda_6 = \lambda_7 = 0$, while the last one is a necessary condition in the case all couplings are non-zero. Therefore, to obtain the conditions that allow the decays $H^\pm \to W^\pm H, A$ and $H \to ZA$, λ_3 should take large positive values in order to compensate for the effects of λ_4 and λ_5. For recent detailed discussions about 2HDM phenomenology see Refs. [369,375–378,245].

V.6.2. Higgs Triplets

Electroweak triplet scalars are the simplest non-doublet extension of the SM that can participate in the spontaneous breakdown of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ to $\mathrm{U}(1)_{\rm em}$. Two types of model have been developed in enough detail to make a meaningful comparison to LHC data: the Higgs triplet model (HTM) [379,380] and the Georgi–Machacek model (GM) [381–384].

The Higgs triplet model extends the SM by the addition of a complex $\mathrm{SU}(2)_L$ triplet scalar field Δ with hypercharge $Y = 2$, and a general gauge-invariant renormalizable potential $V(\Phi, \Delta)$ for Δ and the SM Higgs doublet Φ. The components of the triplet field can be parameterized as

$$\Delta = \frac{1}{\sqrt{2}} \begin{pmatrix} \Delta^+ & \sqrt{2}\Delta^{++} \\ v_\Delta + \delta + i\xi & -\Delta^+ \end{pmatrix}. \tag{11.68}$$

where Δ^+ is a singly-charged field, Δ^{++} is a doubly-charged field, δ is a neutral *CP*-even scalar, ξ is a neutral *CP*-odd scalar, and v_Δ is the triplet VEV. The general scalar potential mixes the doublet and triplet components. After electroweak symmetry breaking there are seven physical mass eigenstates, denoted $H^{\pm\pm}$, $H^\pm$, A, H, and h.

A distinguishing feature of the HTM is that it violates the custodial symmetry of the SM; thus the ρ parameter deviates from 1 even at tree level. Letting x denote the ratio of triplet and doublet VEVs, the tree level expression [385] is:

$$\rho = \frac{1 + 2x^2}{1 + 4x^2}\,. \tag{11.69}$$

The measured value of the ρ parameter then limits [386] the triplet VEV to be quite small, $x \lesssim 0.03$, or $v_\Delta < 8\,\mathrm{GeV}$. This constraint severely limits the role of the triplet scalar in the EWSB mechanism.

The small VEV of the Higgs triplet in the HTM is a virtue from the point of view of generating neutrino masses without the necessity for introducing right-handed neutrino fields. The gauge invariant dimension four interaction

$$h_{\nu_{ij}}\, \ell_i^T C^{-1} i\sigma_2\, \Delta\, \ell_j\,, \tag{11.70}$$

where ℓ_i are the lepton doublets, C is the charge conjugation matrix, and $h_{\nu_{ij}}$ is a complex symmetric coupling matrix, generates a Majorana mass matrix for the neutrinos:

$$m_{\nu_{ij}} = \sqrt{2} h_{\nu_{ij}} v_\Delta\,. \tag{11.71}$$

This can be combined with the usual neutrino seesaw to produce what is known as the type-II seesaw [387].

The HTM suggests the exciting possibility of measuring parameters of the neutrino mass matrix at the LHC. If the doubly-charged Higgs is light enough and/or its couplings to W^+W^+ are sufficiently suppressed, then its primary decay is into same-sign lepton pairs: $H^{++} \to \ell_i^+ \ell_j^+$; from Eq. (11.70) and Eq. (11.71) it is apparent that these decays are in general lepton-flavor violating with branchings proportional to elements of the neutrino mass matrix [388].

Precision electroweak data constrain the mass spectrum as well as the triplet VEV of the HTM [389,385,390]. As described in Ref. [390], these constraints favor a spectrum where H^{++} is the lightest of the exotic bosons, and where the mass difference between H^+ and H^{++} is a few hundred GeV. The favored triplet VEV is a few GeV, which also favors H^{++} decays into W^+W^+ over same-sign dileptons.

The Georgi–Machacek model addresses the ρ parameter constraint directly by building in custodial symmetry. Writing the complex doublet scalar of the SM as a $(2,2)$ under $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$, it is obvious that the next simplest construction respecting custodial symmetry is a scalar transforming like a $(3,3)$ [391]. These nine real degrees of freedom correspond to a complex electroweak triplet combined with a real triplet, with the scalar potential required to be invariant under $\mathrm{SU}(2)_R$. Under the custodial $\mathrm{SU}(2)_{L+R}$, they transform as $1 \oplus 3 \oplus 5$, with a *CP*-even neutral scalar as the custodial singlet (thus matching the SM Higgs boson), a *CP*-odd neutral scalar in the custodial triplet, and another *CP*-even neutral scalar in the custodial 5-plet.

The scalar components can be decomposed as [392]:

$$\Xi = \begin{pmatrix} \chi_3^* & \xi_1 & \chi_1 \\ -\chi_2^* & \xi_2 & \chi_2 \\ \chi_1^* & -\xi_1^* & \chi_3 \end{pmatrix}, \tag{11.72}$$

where ξ_2 is a real scalar and the others are complex scalars. Linear combinations of these account for the neutral custodial singlet, a neutral and singly-charged field making up the custodial triplet, and neutral, singly-charged, and doubly-charged fields making up the custodial 5-plet.

When combined with the usual SM doublet field Φ, the electroweak scale v is now related to the doublet and triplet VEVs by

$$v^2 = v_\Phi^2 + 8 v_\Xi^2\,. \tag{11.73}$$

Note that the GM triplets by themselves are sufficient to explain electroweak symmetry breaking and the existence of a 125 GeV neutral boson along with a custodial triplet of Goldstone bosons; the complex doublet field in the GM model is required to generate fermion masses via the usual dimension four Yukawa couplings. This raises the question of whether one can rule out the possibility that the 125 GeV boson is the neutral member of a custodial 5-plet rather than a custodial singlet, without invoking decays to fermions. A conclusive answer is given by observing that the ratio of the branching fractions to W versus Z bosons is completely determined by the custodial symmetry properties of the boson. For a custodial 5-plet, the ratio of the signal strength to WW over that to ZZ is predicted to be 1/4 that of a SM Higgs boson [391,393], and thus already ruled out by the experimental results shown in Table 11.12 of Section IV.2.5.

Another interesting general feature of Higgs triplet models is that, after mixing, the SM-like neutral boson can have stronger couplings to WW and ZZ than predicted by the SM [384,394]; this is in contrast to mixing with additional doublets and singlet, which can only reduce the WW and ZZ couplings versus the SM. This has interesting implications for trying to extract the total width of the 125 GeV boson without making theoretical assumptions [181,395].

Because of the built-in custodial symmetry, the triplet VEV in the GM model can be large compared to the doublet VEV. The custodial singlet neutral boson from the triplets mixes with the neutral boson from the doublet. Two interesting special cases are (i) the triplet VEV is small and the 125 GeV boson is SM-like except for small deviations, and (ii) the 125 GeV boson is mostly the custodial singlet

neutral boson from the electroweak triplets. The phenomenology of the doubly-charged and singly-charged bosons is similar to that of the HTM. The constraints on the GM model from precision electroweak data, LEP data, and current LHC data are described in Refs. [392,396–399].

V.7. Composite Higgs models

Within the SM, EWSB is posited but has no dynamical origin. Furthermore, the Higgs boson appears to be unnaturally light. A scenario that remedies these two catches is to consider the Higgs boson as a bound state of new dynamics becoming strong around the weak scale. The Higgs boson can be made significantly lighter than the other resonances of the strong sector if it appears as a pseudo-Nambu–Goldstone boson.

V.7.1. Little Higgs models

The idea behind the Little Higgs models [400,401] is to identify the Higgs doublet as a (pseudo) Nambu–Goldstone boson while keeping some sizable non-derivative interactions. By analogy with QCD where the pions $\pi^{\pm,0}$ appear as Nambu–Goldstone bosons associated to the breaking of the chiral symmetry $\mathrm{SU(2)_L \times SU(2)_R/SU(2)}$, switching on some interactions that break explicitly the global symmetry will generate masses for the would-be massless Nambu–Goldstone bosons of the order of $g\Lambda_{G/H}/(4\pi)$, where g is the coupling of the symmetry breaking interaction and $\Lambda_{G/H} = 4\pi f_{G/H}$ is the dynamical scale of the global symmetry breaking G/H. In the case of the Higgs boson, the top Yukawa interaction or the gauge interactions themselves will certainly break explicitly (part of) the global symmetry since they act non-linearly on the Higgs boson. Therefore, obtaining a Higgs mass around 100 GeV would demand a dynamical scale $\Lambda_{G/H}$ of the order of 1 TeV, which is known to lead to too large oblique corrections. Raising the strong dynamical scale by at least one order of magnitude requires an additional selection rule to ensure that a Higgs mass is generated at the 2-loop level only

$$m_H^2 = \frac{g^2}{16\pi^2}\Lambda_{G/H}^2 \rightarrow m_H^2 = \frac{g_1^2 g_2^2}{(16\pi^2)^2}\Lambda_{G/H}^2 \qquad (11.74)$$

The way to enforce this selection rule is through a "collective breaking" of the global symmetry:

$$\mathcal{L} = \mathcal{L}_{G/H} + g_1\mathcal{L}_1 + g_2\mathcal{L}_2. \qquad (11.75)$$

Each interaction $\mathcal{L}_1$ or $\mathcal{L}_2$ individually preserves a subset of the global symmetry such that the Higgs remains an exact Nambu–Goldstone boson whenever either g_1 or g_2 is vanishing. A mass term for the Higgs boson can be generated only by diagrams involving simultaneously both interactions. At one-loop, there is no such diagram that would be quadratically divergent. Explicitly, the cancellation of the SM quadratic divergences is achieved by a set of new particles around the Fermi scale: gauge bosons, vector-like quarks, and extra massive scalars, which are related, by the original global symmetry, to the SM particles with the same spin. Contrary to supersymmetry, the cancellation of the quadratic divergences is achieved by same-spin particles. These new particles, with definite couplings to SM particles as dictated by the global symmetries of the theory, are perfect goals for the LHC.

The simplest incarnation of the collective breaking idea, the so-called littlest Higgs model, is based on a non-linear σ-model describing the spontaneous breaking SU(5) down to SO(5). A subgroup $\mathrm{SU(2)_1 \times U(1)_1 \times SU(2)_2 \times U(1)_2}$ is weakly gauged. This model contains a weak doublet, that is identified with the Higgs doublet, and a complex weak triplet whose mass is not protected by collective breaking. Other popular little Higgs models are based on different coset spaces: minimal moose $(\mathrm{SU(3)^2/SU(3)})$ [402], the simplest little Higgs $(\mathrm{SU(3)^2/SU(2)^2})$ [403], the bestest little Higgs $(\mathrm{SO(6)^2/SO(6)})$ [404] *etc.* For comprehensive reviews, see Refs. [405,406].

Generically, oblique corrections in Little Higgs models are reduced either by increasing the coupling of one of the gauge groups (in the case of product group models) or by increasing the masses of the W and Z partners, leading ultimately to a fine-tuning of the order of a few percents, i.e., improving only marginally the situation of the MSSM (see for instance Ref. [407] and references therein). The compatibility of Little Higgs models with experimental data is significantly improved when the global symmetry involves a custodial symmetry as well as a T-parity [408] under which, in analogy with R-parity in SUSY models, the SM particles are even and their partners are odd. Such Little Higgs models would therefore appear in colliders as jet(s) with missing transverse energy [409] and the ATLAS and CMS searches for squarks and gluinos [410] can be recast to obtain limits on the masses of the heavy vector-like quarks. The T-even top partner, with an expected mass below 1 TeV to cancel the top loop quadratic divergence without too much fine-tuning, would decay dominantly into a $t + Z$ pair or into a $b + W$ pair or even into $t + H$. The latest CMS and ATLAS direct searches [411] for vector-like top partners put a lower bound around 700 GeV on their mass, excluding the most natural region of the parameter space of these models.

Table 11.17: Global symmetry breaking patterns and the corresponding Goldstone boson contents of the SM, the minimal composite Higgs model, the next to minimal composite Higgs model, and the minimal composite two Higgs doublet model. Note that the SU(3) model does not have a custodial invariance. a denotes a CP-odd scalar while h and H are CP-even scalars.

Model	Symmetry Pattern	Goldstone's
SM	SO(4)/SO(3)	W_L, Z_L
–	SU(3)/SU(2)×U(1)	W_L, Z_L, H
MCHM	SO(5)/SO(4)×U(1)	W_L, Z_L, H
NMCHM	SO(6)/SO(5)×U(1)	W_L, Z_L, H, a
MC2HM	SO(6)/SO(4)×SO(2) ×U(1)	$W_L, Z_L, h, H, H^\pm, a$

The motivation for Little Higgs models is to solve the little hierarchy problem, i.e., to push the need for new physics (responsible for the stability of the weak scale) up to around 10 TeV. Per se, Little Higgs models are effective theories valid up to their cutoff scale $\Lambda_{G/H}$. Their UV completions could either be weakly or strongly coupled.

V.7.2. Models of partial compositeness

The Higgs boson is a special object. Even in composite models, it cannot appear as a regular resonance of the strong sector without endangering the viability of the setup when confronted to data. The way out is that the Higgs appears as a pseudo Nambu–Goldstone boson: the new strongly coupled sector is supposed to be invariant under a global symmetry G spontaneously broken to a subgroup H at the scale f. To avoid conflict with EW precision measurements, it is better to avoid the strong interactions themselves to break the EW symmetry, hence the SM gauge symmetry itself should be contained in H. See Table 11.17 for a few examples of coset spaces.

The SM (light) fermions and gauge bosons cannot be part of the strong sector itself since LEP data have already put stringent bounds on the compositeness scale of these particles far above the TeV scale. The gauge bosons couple to the strong sector by a weak gauging of an SU(2)×U(1) subgroup of the global symmetry G. Inspiration for the construction of such models comes from the AdS/CFT correspondence: the components of a gauge field along extra warped space dimension can be interpreted as the Goldstone boson resulting from the breaking of global symmetry of the strong sector, see Fig. 11.28. The couplings of the SM fermions to the strong sector could a priori take two different forms: (i) a bilinear coupling of two SM fermions to a composite scalar operator, $\mathcal{O}$, of the form $\mathcal{L} = y\,\bar{q}_L u_R \mathcal{O} + \mathrm{hc}$ in simple analogy with the SM Yukawa interactions. This is the way fermion masses were introduced in Technicolor theories and it generically comes with severe flavor problems and calls for extended model building gymnastics [412] to circumvent them; (ii) a linear mass mixing with fermionic vector-like operators: $\mathcal{L} = \lambda_L\,\bar{q}_L \mathcal{Q}_R + \lambda_R \bar{\mathcal{U}}_L u_R$. $\mathcal{Q}$ and $\mathcal{U}$ are two fermionic composite operators of mass M_Q and M_U. Being part of the composite sector, they can have a direct coupling of generic order Y_* to the Higgs boson. In analogy with the photon-rho mixing in QCD, once the linear mixings are diagonalized, the physical states are a linear combination of elementary and composite fields. Effective

Yukawa couplings are generated and read for instance for the up-type quark

$$y = Y_* \sin\theta_L \sin\theta_R \tag{11.76}$$

where $\sin\theta_i = \lambda_i/\sqrt{M_U^2+\lambda_i^2}$, $i = L, R$, measure the amount of compositeness of the SM left- and right-handed up-type quark. If the strong sector is flavor-anarchic, i.e., if the couplings of the Higgs to the composite fermions does not exhibit any particular flavor structure, the relation Eq. (11.76) implies that the light fermions are mostly elementary states ($\sin\theta_i \ll 1$), while the third generation quarks need to have a sizable degree of compositeness. The partial compositeness paradigm offers an appealing dynamical explanation of the hierarchies in the fermion masses. In fact, assuming the strong sector to be almost conformal above the confinement scale, the low-energy values of the mass-mixing parameters $\lambda_{L,R}$ are determined by the (constant) anomalous dimension of the composite operator they mix with. If the UV scale at which the linear mixings are generated is large, then $\mathcal{O}(1)$ differences in the anomalous dimensions can generate naturally large hierarchies in the fermion masses via renormalization group running [413]. While the introduction of partial compositeness greatly ameliorated the flavor problem of the original composite Higgs models, nevertheless it did not solve the issue completely, at least in the case where the strong sector is assumed to be flavor-anarchic [414]. While the partial compositeness set-up naturally emerges in models built in space-times with extra dimensions, no fully realistic microscopic realization of partial compositeness has been proposed in the literature.

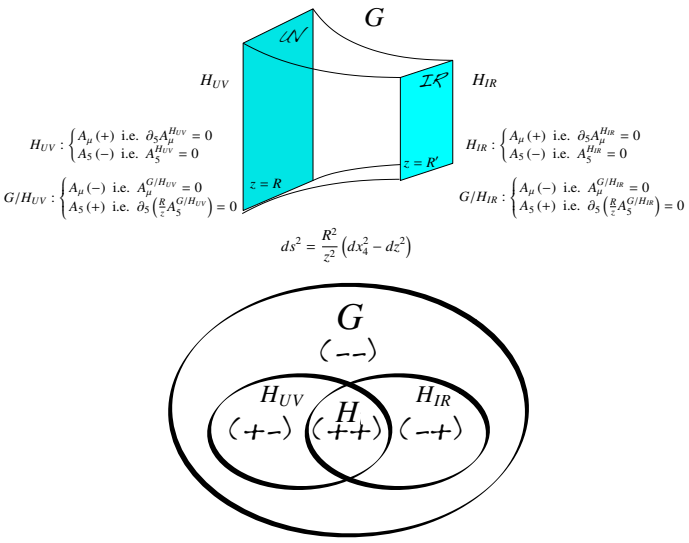

Figure 11.28: Composite models built in five dimensional Anti-de-Sitter space-time and their symmetry breaking pattern interpretation. In 5D, the gauge symmetry in the bulk, G, is broken by suitable boundary conditions to H_{UV} on the UV brane and to H_{IR} on the IR brane. The low energy theory mimics in 4D a strongly interacting sector invariant under a global symmetry G spontaneously broken to H_{IR} at the IR scale with a subgroup H_{UV} which is weakly gauged. The number of Goldstone bosons is equal to $\dim(G/H_{IR})$, $\dim(H_{UV}/H)$ being eaten to give a mass to some gauge bosons ($H = H_{UV} \cap H_{IR}$). The remaining $\dim(G/H_{IR}) - \dim(H_{UV}/H)$ massless Goldstone's are described on the 5D side by the massless modes of the gauge fields along the fifth dimension, A_5^H.

Another nice aspect of the partial compositeness structure is the dynamical generation of the Higgs potential. The Higgs being a pseudo-Nambu–Goldstone boson, its mass does not receive any contribution from the strong sector itself but it is generated at the one-loop level via the couplings of the SM particles to the strong sector since these interactions are breaking the global symmetries under which the Higgs doublet transforms non-linearly. The leading contribution to the potential arises from top loops and it takes the form

$$V(H) = m_\rho^4 \frac{\sin\theta_{tL}\sin\theta_{tR}}{16\pi^2}\left(\alpha\cos(H/f) + \beta\sin^2(H/f) + \gamma\sin^4(H/f)\right), \tag{11.77}$$

where α, β, γ are numbers of order 1 subject to selection rules following the transformation properties of the top quark under the global symmetries of the strong sector[12], and $m_\rho \approx g_\rho f$ is the typical mass scale of the strong sector resonances. The gauge contribution to the potential takes the form (g denotes the SU(2) gauge coupling)

$$m_\rho^4 \frac{g^2/g_\rho^2}{16\pi^2}\sin^2(H/f), \tag{11.78}$$

which is parametrically suppressed with respect to the top contribution by $g^2/(g_\rho y_t)$. The gauge term is always positive, and cannot trigger EWSB by itself. When $\alpha = 0$, the minimization condition of the potential simply reads

$$\sin^2\frac{\langle H\rangle}{f} = -\frac{\beta}{2\gamma}, \tag{11.79}$$

which implies that the natural expectation is that the scale f is generically of the order of the weak scale. Obtaining $v \ll f$, as required phenomenologically, requires some degree of tuning, which scales like $\xi \equiv v^2/f^2$. A mild tuning of the order of 10% ($\xi \approx 0.1$) is typically enough to comply with electroweak precision constraints. This is an important point: in partial compositeness models, the entire Higgs potential is generated at one loop, therefore the separation between v and f can only be obtained at a price of a tuning. This marks a difference with respect to the Little Higgs models, which realize a parametric hierarchy between the quartic and mass terms through the collective symmetry breaking mechanism. In fact in Little Higgs models, the quartic coupling is a tree-level effect, leading to a potential

$$V(H) \approx \frac{g_{\rm SM}^2}{16\pi^2} m_\rho^2 H^2 + g_{\rm SM}^2 H^4, \tag{11.80}$$

where $g_{\rm SM}$ generically denotes the SM couplings. The minimization condition now reads $v^2/f^2 \sim g_\rho^2/(16\pi^2)$, therefore v is formally loop suppressed with respect to f. This is the major achievement of the Little Higgs constructions, which however comes at the price of the presence of sub-TeV vectors carrying EW quantum numbers and therefore giving rise generically to large oblique corrections to the propagators of the W and the Z gauge bosons.

After minimization, the potential Eq. (11.77) leads to an estimate of the Higgs mass as

$$m_H^2 \approx g_\rho^3 y_t 2\pi^2 v^2. \tag{11.81}$$

It follows that the limit $f \to \infty$, i.e. $\xi \to 0$, is a true decoupling limit: all the resonances of the strong sector become heavy but the Higgs whose mass is protected by the symmetries of the coset G/H. When compared to the experimentally measured Higgs mass, this estimate puts an upper bound on the strength of the strong interactions: $1 \lesssim g_\rho \lesssim 2$. In this limit of not so large coupling, the Higgs potential receives additional contributions. In particular, the fermionic resonances in the top sector which follow from the global symmetry structure of the new physics sector can help raising the Higgs mass. For instance in the minimal SO(5)/SO(4) model, using some dispersion relation techniques, one obtains [416]

$$m_H^2 \approx \frac{6}{\pi^2}\frac{m_t^2}{f^2}\frac{m_{Q_4}^2 m_{Q_1}^2}{m_{Q_1}^2 - m_{Q_4}^2}\log\left(\frac{m_{Q_1}}{m_{Q_4}}\right) \tag{11.82}$$

[12] For instance in the SO(5)/SO(4) composite models, when the top quark is embedded into a spinorial representation of SO(5), then $\gamma = 0$ and when it is part of a **5**, **10** or **14** representation, $\alpha = 0$ as it can be inferred by looking at the structure of the H-dependent invariants built out of these representations [415]. The coefficient γ also generically comes with an extra power of the top compositeness fractions.

where Q_4 and Q_1 are fermionic color resonances transforming as a weak bi-doublet of hypercharge $Y = 1/6$ and $Y = 7/6$ and a weak singlet with hypercharge $Y = -1/3$. Therefore a 125 GeV mass is obtained if at least one of the fermionic resonances is lighter than $\sim 1.4\, f$. As in supersymmetric scenarios, the top sector is playing a crucial role in the dynamics of EWSB and can provide the first direct signs of new physics. The direct searches for these top partners, in particular the ones with exotic electric charges 5/3, are already exploring the natural parameter spaces of these models [417,418,411].

The main physics properties of a pseudo Nambu–Goldstone Higgs boson can be captured in a model-independent way by a few number of higher-dimensional operators. Indeed, the strong dynamics at the origin of the composite Higgs singles out a few operators among the complete list presented earlier in Section IV: these are the operators that involve extra powers of the Higgs doublets and they are therefore generically suppressed by a factor $1/f^2$ as opposed to the operators that involve extra derivatives or gauge bosons and are suppressed by a factor $1/(g_\rho^2 f^2)$. The relevant effective Lagrangian describing a strongly interacting light Higgs is:

$$\mathcal{L}_{\rm SILH} = \frac{c_H}{2f^2}\left(\partial_\mu\left(\Phi^\dagger\Phi\right)\right)^2 + \frac{c_T}{2f^2}\left(\Phi^\dagger \overleftrightarrow{D}^\mu \Phi\right)^2 - \frac{c_6\lambda}{f^2}\left(\Phi^\dagger\Phi\right)^3 + \left(\sum_f \frac{c_f\, y_f}{f^2}\Phi^\dagger\Phi\bar{f}_L\Phi f_R + \text{h.c.}\right). \tag{11.83}$$

Typically, these new interactions induce deviations in the Higgs couplings that scale like $\mathcal{O}(v^2/f^2)$, hence the measurements of the Higgs couplings can be translated into some constraints on the compositeness scale, $4\pi f$, of the Higgs boson. The peculiarity of these composite models is that, due to the Goldstone nature of the Higgs boson, the direct couplings to photons and gluons are further suppressed and generically the coupling modifiers defined in Section IV scale like

$$\begin{aligned}\kappa_{W,Z,f} &\sim 1 + \mathcal{O}\left(\frac{v^2}{f^2}\right),\\ \kappa_{Z\gamma} &\sim \mathcal{O}\left(\frac{v^2}{f^2}\right),\\ \kappa_{\gamma,g} &\sim \mathcal{O}\left(\frac{v^2}{f^2}\times\frac{y_t^2}{g_\rho^2}\right),\end{aligned} \tag{11.84}$$

where g_ρ denotes the typical coupling strength among the states of the strongly coupled sector and y_t is the top Yukawa coupling, the largest interaction that breaks the Goldstone symmetry. The $\kappa_{\rm Z\gamma,\gamma,g}$ coupling modifiers are not generated by the strong coupling operators of Eq. (11.83) but some subleading form-factor operator generated by loops of heavy resonances of the strong sector. The coupling modifiers also receive additional contributions from the other resonances of the strong sector, in particular the fermionic resonances of the top sector that are required to be light to generate a 125 GeV Higgs mass. Some indirect information on the resonance spectrum could thus be inferred by a precise measurement of the Higgs coupling deviations. However, it was realized [419] that the task is actually complicated by the fact that, in the minimal models, these top partners give a contribution to both κ_t (resulting from a modification of the top Yukawa coupling) and κ_γ and κ_g (resulting from new heavy particles running into the loops) and the structure of interactions are such that the net effect vanishes for inclusive quantities like $\sigma(gg \to H)$ or $\Gamma(H \to \gamma\gamma)$ as a consequence of the Higgs low energy theorem [19,20,182]. So one would need to rely on differential distribution, like the Higgs p_T distribution [420] (for a recent analysis and further references, see Ref. [421]), to *see* the top partner effects in Higgs data [422].

V.7.3. Minimal composite Higgs models

The minimal composite Higgs models (MCHM) are concrete examples of the partial compositeness paradigm. The Higgs doublet is described by the coset space SO(5)/SO(4) where a subgroup $\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$ is weakly gauged under which the four Goldstone bosons transform as a doublet of hypercharge 1. There is some freedom on how the global symmetry is acting on the SM fermions: in MCHM4 [415] the quarks and leptons are embedded into spinorial representations of SO(5), while in MHCM5 [423] they are part of fundamental representations (it might also be interesting phenomenologically to consider larger representations like MCHM14 [424] with the SM fermions inside a representation of dimension 14). The non-linearly realized symmetry acting on the Goldstone bosons leads to general predictions of the coupling of the Higgs boson to the EW gauge bosons. For instance, it can be shown that the quadratic terms in the W and Z bosons read

$$m_W^2(H)\left(W_\mu W^\mu + \frac{1}{2\cos^2\theta_W}Z_\mu Z^\mu\right)$$

with $m_W(H) = \dfrac{gf}{2}\sin\dfrac{H}{f}$. Expanding around the EW vacuum, the expression of the weak scale is:

$$v = f\sin(\langle H\rangle/f), \tag{11.85}$$

and the values of the modified Higgs couplings to the W and Z:

$$g_{HVV} = \frac{2m_V^2}{v}\sqrt{1-v^2/f^2}\,, \quad g_{HHVV} = \frac{2m_V^2}{v^2}(1-2v^2/f^2)\,. \tag{11.86}$$

Note that the Higgs couplings to gauge bosons is always suppressed compared to the SM prediction. This is a general result [425] that holds as long as the coset space is compact.

The Higgs couplings to the fermions depend on the representation which the SM fermions are embedded into. For the most commonly used embeddings, they take the following forms

$$\begin{aligned}&\text{MCHM4}: g_{Hff} = \frac{m_f}{v}\sqrt{1-v^2/f^2}\,,\\ &\text{MCHM5}: g_{Hff} = \frac{m_f}{v}\frac{1-2v^2/f^2}{\sqrt{1-v^2/f^2}}\,,\\ &\text{MCHM14}: g_{Hff} = \frac{m_f}{v}\left(1 + A(M_{1,4,9})\frac{v^2}{f^2} + O(v^4/f^4)\right),\\ &\qquad\text{with } A(M_{1,4,9}) = \frac{3M_1M_4 - 11M_1M_9 + 8M_4M_9}{2M_9(M_1-M_4)}\,.\end{aligned} \tag{11.87}$$

While in MHCM4 and MCHM5, the modifications of the couplings depend only on the Higgs compositeness scale, in MCHM14 the leading corrections do depend also on the mass spectrum of the resonances parametrized by M_1, M_4 and M_9 [424]. This is due to the fact that more than one SO(5) invariant give rise to SM fermion masses.

The (κ_V, κ_f) experimental fit of the Higgs couplings can thus be used to derive a lower bound on the Higgs compositeness scale $4\pi f \gtrsim 9$ TeV, which is less stringent than the indirect bound obtained from EW precision data, $4\pi f \gtrsim 15$ TeV [426], which is however subject to various assumptions [427].

V.8. The Higgs boson as a dilaton

The possibility that the new particle H^0 discovered at the LHC is in fact the Goldstone boson associated to the spontaneous breaking of scale invariance at a scale f attracted some attention [16,17] but is now challenged by the fact that all its properties are in good agreement with those predicted for the SM Higgs. And this scenario now requires rather involved model-building engineering. The first issue is the fact that the observed scalar couplings are close to their SM values. In a generic theory of spontaneously broken scale invariance, order one shifts are possible, and indeed expected in most models. Also, the apparent hierarchy between the light scalar and the cutoff of the dilaton effective theory is not reconcilable with the general walking technicolor (or Higgsless) type scenario unless a tuning is imposed.

The general couplings of a wide class of dilaton models are given (at leading order in a low-energy theorem limit for dilatons) by

$$\mathcal{L}_{dilaton} = \frac{\sigma}{f}\left[2M_W^2 W_\mu^\pm W^{\pm\mu} + M_Z^2 Z_\mu Z^\mu + \sum_{ij}\sqrt{m_f^i m_f^j}\Gamma^{ij}\bar{\psi}^i\psi^j\right] + \frac{\sigma}{f}\left[\frac{2}{e}\Delta\beta^{\rm em}F_{\mu\nu}^2 + \frac{2}{g_3}\Delta\beta^{\rm QCD}G_{\mu\nu}^{a\,2}\right] \tag{11.88}$$

where Γ^{ij} is a matrix that depends upon anomalous dimensions of operators in the conformal theory that give rise to fermion masses, and the terms $\Delta\beta$ are the differences in the beta functions of electromagnetism or QCD at scales above and below the scale at which conformal symmetry is spontaneously broken. The SM low energy theorem limit for the standard model Higgs is obtained from this expression by taking

$$f = v, \quad \Gamma^{ij} = I_{3\times 3}, \quad \Delta\beta^{em} = \beta^{em}_{top} + \beta^{em}_{W}, \quad \Delta\beta^{qcd} = \beta^{qcd}_{top}. \quad (11.89)$$

It is unclear why these relations might be approximately realized in a generic conformal field theory, as must be the case to be consistent with current data and allow for a scalar with mass of about 125 GeV . For example, in warped models of electroweak symmetry breaking (AdS/CFT duals to theories with strongly broken conformal invariance), the ratio v/f is a function of the geometry, and is suppressed when the 5D theory is perturbative, contrary to the experimental result that the v/f ratio should be close to 1.

An additional complication is that the mass of the dilaton is expected to appear, along with many other resonances, around the cutoff scale of the strongly interacting theory responsible for breaking the scale invariance spontaneously. Suppression of the dilation mass either requires a tuning of order $v^2/\Lambda^2 \sim$ percent, or a very special conformal dynamics where the beta function of the interaction leading to the scale invariance breaking remains small over a large region of couplings [428].

V.9. Searches for signatures of extended Higgs sectors

The measurements described in Section III and Section IV have established the existence of one state of the electroweak symmetry breaking sector, compatible within with a SM Higgs boson, but not that it is the only one.

Various classes of models beyond the Standard Model discussed above require extended Higgs sectors. These models, and in particular the MSSM and the NMSSM serve as guiding principle of the experimental searches for additional scalar states beyond the Standard Model. However these searches are made as model-independent as possible and can be summarized in the following classes: (i) the search for an additional *CP*-even state mostly in the high mass domain decaying to vector bosons, which would correspond to the heavy *CP*-even state in a generic 2HDM where the light state would be the discovered H or a generic additional singlet; (ii) the search for a state in the high mass domain decaying to pairs of fermions, which would correspond a *CP*-odd A and the heavy *CP*-even state H in a generic 2HDM; (iii) the search for charged Higgs bosons, which also appear in generic 2HDMs; (iv) the search for a *CP*-odd state a in the low mass region which appears in the NMSSM; and (v) doubly charged Higgs which are motivated in extensions of the Higgs sector with triplets.

(i) Searches for an additional CP-even state

(a) Exclusion limits from LEP

The negative result of LEP searches for the SM Higgs boson and the absolute lower limit on its mass of 114 GeV strongly disfavors the existence of a lower mass *CP*-even state, but does not exclude it if its couplings are reduced enough with respect to those of the SM Higgs boson. These searches were also interpreted as 95% CL upper bounds on the ratio of the coupling g_{HZZ} to its SM prediction as a function of the Higgs boson mass [107]. Among the MSSM new benchmarks, the low-m_H is one example which is disfavored by these function of the Higgs boson mass [107] searches, and nearly ruled out by current direct constraints and charged Higgs limits from LHC [429]. Another example is the light *CP*-even Higgs boson of the NMSSM, which is constrained to have a strong function of the Higgs boson mass [107] singlet component. An additional motivation for these scenarios is given by the slight excess observed at LEP [107] at a Higgs boson mass hypothesis of approximately 98 GeV. The light *CP*-even Higgs boson h was also searched for in association with the *CP*-odd A, these searches are described in Section III.

(b) Searches at Tevatron and at the LHC

The searches for the Standard Model Higgs boson before the discovery were covering a wide range of mass hypotheses. Until recently the range of investigation at LHC was from 100 GeV to 600 GeV. It has been extended to masses of up to 1 TeV. At the Tevatron this mass range was limited to up to 200 GeV. Since the discovery, the SM Higgs boson searches are reappraised to search for a heavy *CP*-even state. This state could be the heavy *CP*-even Higgs boson of a 2HDM, or a generic additional singlet. In both cases the natural width of the additional H state can be very different from that of the SM Higgs boson. To preserve unitarity of the longitudinal vector boson scattering and the longitudinal vector boson scattering into fermion pairs, the couplings of the additional *CP*-even Higgs boson to gauge bosons and fermions should not be too large and should constrain the natural width to be smaller than that of a unique Higgs boson at high mass with couplings to fermions and gauge bosons as predicted by the SM (and provided that trilinear and quartic couplings are not too large and that no new state affects the heavy state total width). It is therefore reasonable to consider total widths for the high mass *CP*-even state smaller than the equivalent SM width. For the sake of generality these searches should be done as a function of Higgs boson mass and total width. Until recently only two cases have been investigated: (i) the SM width using the complex pole scheme (CPS), and (ii) the narrow width approximation.

One example of searches for high mass *CP*-even Higgs bosons decaying to a pair of gauge bosons in the narrow width approximation in the $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ inclusive search channel by the ATLAS collaboration is given in Fig. 11.29. The searches for the Higgs boson in the $H \to \gamma\gamma$ and $H \to W^{(*)}W^{(*)}$ in the $\ell\nu\ell\nu$ and $\ell\nu q\overline{q}$ channels and the $H \to Z^{(*)}Z^{(*)}$ searches in the 4ℓ, $\ell\ell q\overline{q}$ and $\ell\ell\nu\nu$ channels have also been done, but in most cases are simple reinterpretations of the SM Higgs search in the CPS scheme. Recent references are summarized in Table 11.18.

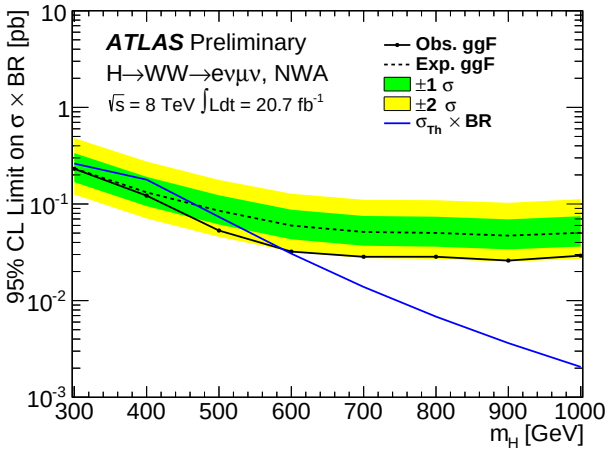

Figure 11.29: The 95% CL upper limits on the Higgs boson production cross section times branching ratio for $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ for the gluon-fusion process and a Higgs boson with a narrow lineshape (NWA). The green and yellow bands show the 1σ and 2σ uncertainties on the expected limit [478]. The expected cross section times branching ratio for the production of a SM Higgs boson is shown as a blue line.

(c) Searches for an additional state with the presence of H

In the post-discovery era, analyses in general need to take into account the presence of the newly discovered state. For searches with sufficiently high resolution of additional states non degenerate in mass, the strength of the observed state and limits on the signal strength of a

potential additional state can be set independently as discussed in the next section. However in some cases, such as when a channel does not have a sufficiently fine mass resolution or when the states are nearly degenerate in mass, specific analyses need to be designed. There are two examples of such analyses: (i) the search for an additional state in the $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ channel in ATLAS and (ii) the search for nearly degenerate states in the $H \to \gamma\gamma$ channel with the CMS detector.

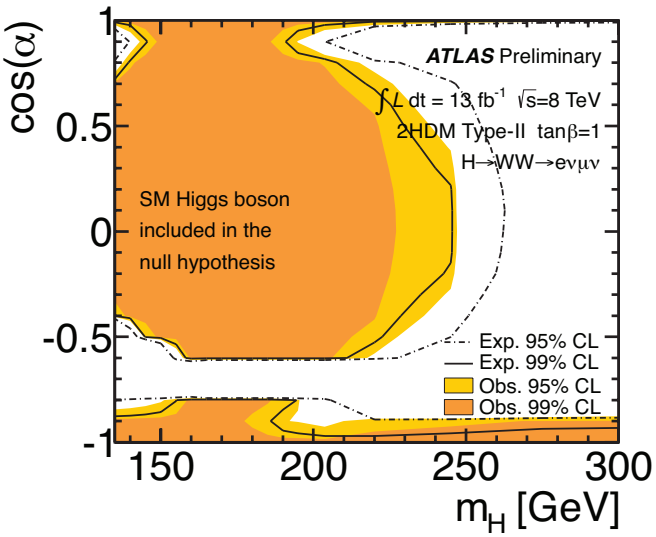

Figure 11.30: The ATLAS 95% CL exclusion contours in the $(\cos\alpha, m_H)$ plane for $\tan\beta = 1$ of the type-II 2HDM [430].

The search, in the $H \to W^{(*)}W^{(*)} \to \ell\nu\ell\nu$ channel, for an additional state is done using boosted decision tree combining several discriminating kinematic characteristics to optimally separate the signal from the background and a high mass signal H from the lower mass state h [430]. A simultaneous fit of the two states h and H is then made to test the presence of an additional state. In this case, the usual null hypothesis of background is generated including the SM signal. The results of this search are shown in Fig. 11.30.

The CMS search for nearly degenerate mass states decaying to a pair of photons [431] is more generic and could for instance apply to *CP*-odd Higgs bosons as well. It consists of a fit to the diphoton mass spectrum using two nearly degenerate mass templates.

(d) Type I 2HDM and Fermiophobia

The measurements of coupling properties of H indirectly excludes that the discovered state is fermiophobic. However, the presence of an additional fermiophobic state, as predicted by Type I 2HDMs, is not excluded. Prior to the discovery, ATLAS and CMS have performed searches for a fermiophobic Higgs boson, *i.e.* produced through couplings with vector bosons only (VBF and VH) and decaying in $h_f \to \gamma\gamma$, optimized for fermiophobic signatures in the diphoton channel [432,433]. CMS has further combined these results with searches for $h_f \to W^+W^-$ and $h_f \to ZZ$ assuming fermiophobic production and decay [434]. CMS excludes a fermiophobic Higgs boson in the range $110\,\text{GeV} < m_H < 188\,\text{GeV}$ at the 95% C.L.

(e) Interpretation benchmarks in the light of the discovered Higgs boson

Two specific benchmark scenarios driven by unitarity relations are proposed in Ref. [38], assuming the existence of an additional state h' with coupling scale factors, i.e, deviations from the couplings predicted for the SM Higgs at the same mass, denoted κ'_V and κ'_F for the couplings of h' to vector bosons and fermions respectively. The gauge boson scattering unitarity then yields the following sum rule

$$\kappa_V^2 + \kappa_V'^2 = 1 \tag{11.90}$$

and the unitarization of the gauge boson scattering to fermions yields

$$\kappa_V \cdot \kappa_F + \kappa'_V \cdot \kappa'_F = 1 \tag{11.91}$$

The two benchmark scenarios are then defined as follows: (i) a single coupling scale factor is assumed for the gauge bosons and the fermions, with an additional parameter to take into account decays to new states; (ii) two parameters are used to describe independently the couplings to fermions and the couplings to vector bosons. A direct application of the latter can be done in the *CP*-even sector of the type-I 2HDM.

(ii) Searches for additional states decaying to fermions

(a) Exclusion limits from LEP

In e^+e^- collisions at LEP centre-of-mass energies, the main production mechanisms of the neutral MSSM Higgs bosons were the Higgs-strahlung processes $e^+e^- \to hZ$, HZ and the pair production processes $e^+e^- \to hA$, HA, while the vector boson fusion processes played a marginal role. Higgs boson decays to $b\bar{b}$ and $\tau^+\tau^-$ were used in these searches.

The searches and limits from the four LEP experiments are described in Refs. [435,436]. The combined LEP data did not contain any excess of events which would imply the production of a Higgs boson, and combined limits were derived [437]. For $m_A \gg M_Z$ the limit on m_h is nearly that of the SM searches, as $\sin^2(\beta-\alpha) \approx 1$. For high values of $\tan\beta$ and low m_A ($m_A \leq m_h^{max}$), the $e^+e^- \to hA$ searches become the most important, and the lightest Higgs h is non SM-like. In this region, the 95% CL mass bounds are $m_h > 92.8\,\text{GeV}$ and $m_A > 93.4\,\text{GeV}$. In the m_h-max. scenario, values of $\tan\beta$ from 0.7 to 2.0 are excluded taking $m_t = 174.3\,\text{GeV}$, while a much larger $\tan\beta$ region is excluded for other benchmark scenarios such as the no-mixing one.

Neutral Higgs bosons may also be produced by Yukawa processes $e^+e^- \to f\bar{f}\phi$, where the Higgs particle $\phi \equiv h$, H, A, is radiated off a massive fermion ($f \equiv b$ or $\tau^\pm$). These processes can be dominant at low masses, and whenever the $e^+e^- \to hZ$ and hA processes are suppressed. The corresponding ratios of the $f\bar{f}h$ and $f\bar{f}A$ couplings to the SM coupling are $\sin\alpha/\cos\beta$ and $\tan\beta$, respectively. The LEP data have been used to search for $b\bar{b}b\bar{b}$, $b\bar{b}\tau^+\tau^-$, and $\tau^+\tau^-\tau^+\tau^-$ final states [438,439]. Regions of low mass and high enhancement factors are excluded by these searches.

A flavor-independent limit for Higgs bosons in the Higgs-strahlung process at LEP has also been set at 112 GeV [440].

In the case where the Higgs boson does not predominantly decay to a pair of b quarks, the searches for the SM Higgs boson have been performed at LEP. All four collaborations conducted dedicated searches for the Higgs boson with reduced model dependence, assuming it is produced via the Higgs-strahlung process, and not addressing its flavor of decay, a lower limit on the Higgs mass of 112.9 GeV is set by combining the data of all four experiments [440]. Using an effective Lagrangian approach and combining several results sensitive to the $h\gamma\gamma$, $hZ\gamma$ and hZZ couplings, an interpretation of several searches for the Higgs boson was made and set a lower limit of 106.7 GeV on the mass of a Higgs boson that can couple anomalously to photons [440].

(b) Searches at the Tevatron and LHC

The best sensitivity is in the regime with low to moderate m_A and with large $\tan\beta$ which enhances the couplings of the Higgs bosons to down-type fermions. The corresponding limits on the Higgs boson production cross section times the branching ratio of the Higgs boson into down-type fermions can be interpreted in MSSM benchmark scenarios [249]. If $\phi = A, H$ for $m_A > m_h^{\max}$, and $\phi = A, h$ for $m_A < m_h^{\max}$, the most promising channels at the Tevatron are the inclusive $p\bar{p} \to \phi \to \tau^+\tau^-$ process, with contributions from both

$gg \to \phi$ and $b\bar{b}\phi$ production, and $b\bar{b}\phi, \phi \to \tau^+\tau^-$ or $\phi \to b\bar{b}$, with $b\tau\tau$ or three tagged b-jets in the final state, respectively. Although Higgs boson production via gluon fusion has a higher cross section in general than via associated production, it cannot be used to study the $\phi \to b\bar{b}$ decay mode since the signal is overwhelmed by the QCD background.

The CDF and D0 collaborations have searched for neutral Higgs bosons produced in association with bottom quarks and which decay into $b\bar{b}$ [441,442], or into $\tau^+\tau^-$ [443,444]. The most recent searches in the $b\bar{b}\phi$ channel with $\phi \to b\bar{b}$ analyze approximately 2.6 fb^{-1} of data (CDF) and 5.2 fb^{-1} (D0), seeking events with at least three b-tagged jets. The cross section is defined such that at least one b quark not from ϕ decay is required to have $p_T > 20$ GeV and $|\eta| < 5$. The decay widths of the Higgs bosons are assumed to be much smaller than the experimental resolution. The invariant mass of the two leading jets as well as b-tagging variables are used to discriminate the signal from the backgrounds. The QCD background rates and shapes are inferred from data control samples, in particular, the sample with two b-tagged jets and a third, untagged jet. Separate-signal hypotheses are tested and limits are placed on $\sigma(p\overline{p} \to b\bar{b}\phi) \times \mathrm{BR}(\phi \to b\bar{b})$. A local excess of approximately 2.5σ significance has been observed in the mass range of 130–160 GeV, but D0's search is more sensitive and sets stronger limits. The D0 result had an $\mathcal{O}(2\sigma)$ local upward fluctuation in the 110 to 125 GeV mass range. These results have been superseded by the LHC searches and the excess seen in the D0 experiment has not been confirmed elsewhere.

ATLAS and CMS also search for $\phi \to \tau^+\tau^-$ in pp collisions at $\sqrt{s} = 7$ TeV. ATLAS seeks tau pairs in 4.7–4.8 fb^{-1} of data [445], and the search by CMS uses the full 4.9 fb^{-1} of 7 TeV data 4.9 fb^{-1} of 8 TeV data [446] and bb [448]. The searches are performed in categories of the decays of the two tau leptons: $e\tau_{\mathrm{had}}$, $\mu\tau_{\mathrm{had}}$, $e\mu$, and $\mu\mu$, where τ_{had} denotes a tau lepton which decays to one or more hadrons plus a tau neutrino, e denotes $\tau \to e\nu\nu$, and μ denotes $\tau \to \mu\nu\nu$. The dominant background comes from $Z \to \tau^+\tau^-$ decays, although $t\bar{t}$, W+jets and Z+jets events contribute as well. Separating events into categories based on the number of b-tagged jets improves the sensitivity in the MSSM. The $b\bar{b}$ annihilation process and radiation of a Higgs boson from a b quark gives rise to events in which the Higgs boson is accompanied by a $b\bar{b}$ pair in the final state. Requiring the presence of one or more b jets reduces the background from Z+jets. Data control samples are used to constrain background rates. The rates for jets to be identified as a hadronically decaying tau lepton are measured in dijet samples, and W+jets samples provide a measurement of the rate of events that, with a fake hadronic tau, can pass the signal selection requirements. Lepton fake rates are measured using samples of unisolated lepton candidates and same-sign lepton candidates. Constraints from the CMS searches for $h \to \tau^+\tau^-$ and $h \to b\bar{b}$ are shown in Fig. 11.31 in the m_h-max benchmark scenario, with $\mu = 200$ GeV and $\mu = -200$ GeV respectively. The neutral Higgs boson searches consider the contributions of both the CP-odd and CP-even neutral Higgs bosons with enhanced couplings to bottom quarks, as they were for the Tevatron results.

A search for $\phi \to \mu^+\mu^-$ has also been performed by the ATLAS collaboration [445]. The exclusion limits obtained are given in terms of cross section times branching fraction and combined with those of $\phi \to \tau^+\tau^-$ [445].

The LHC has the potential to explore a broad range of SUSY parameter space through the search for non-SM-like Higgs bosons. Nevertheless, Fig. 11.31 shows a broad region with intermediate $\tan\beta$ and large values of m_A that is not tested by present neutral or charged Higgs boson searches, and which cannot be covered completely via these searches, even with much larger data sets. In this region of parameter space it is possible that only the SM-like Higgs boson can be within the LHC's reach. If no other state of the EWSB sector than H is discovered, it may be challenging to determine only from the Higgs sector whether there is a supersymmetric extension of the SM in nature.

(iii) Searches for Charged Higgs bosons $H^\pm$

At e^+e^- colliders charged Higgs bosons can pair produced in the s-channel via γ or Z boson exchange. This process is dominant in the LEP centre-of-mass energies range *i.e.* up to 209 GeV. At higher

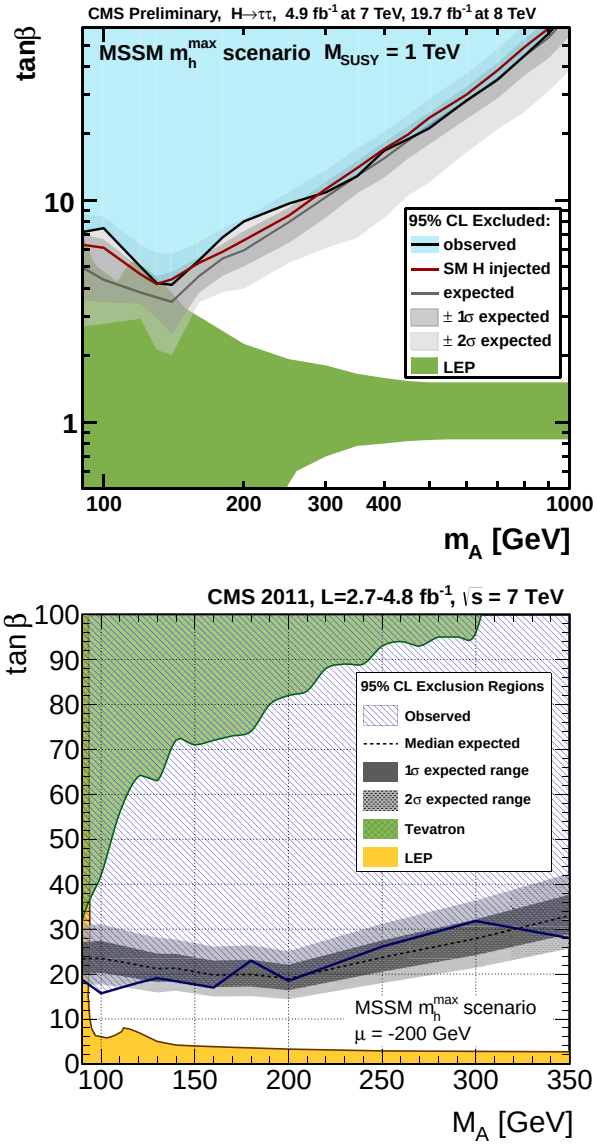

Figure 11.31: The 95% CL exclusion contours in the $(M_A, \tan\beta)$ parameter space for the MSSM mhmax scenario, for the $\tau^+\tau^-$ channel [446] (upper plot) and the $b\bar{b}$ channel [448](lower plot).

centre-of-mass energies, other processes can play an important role such as the production in top quark decays via $t \to b + H^+$ if $m_H^\pm < m_t - m_b$ or via the one-loop process $e^+e^- \to W^\pm H^\mp$ [282,283], which allows the production of a charged Higgs boson with $m_H^\pm > \sqrt{s}/2$, even when H^+H^- production is kinematically forbidden. Other single charged Higgs production mechanisms include $t\bar{b}H^-/\bar{t}bH^+$ production [90], $\tau^+\nu H^-/\tau^-\bar{\nu}H^+$ production [284], and a variety of processes in which $H^\pm$ is produced in association with a one or two other gauge and/or Higgs bosons [285].

At hadron colliders, Charged Higgs bosons can be produced in several different modes. If $m_{H^\pm} < m_t - m_b$, the charged Higgs boson can be produced in decays of the top quark via the decay $t \to bH^\pm$. Relevant QCD and SUSY-QCD corrections to $\mathrm{BR}(t \to H^\pm b)$ have been computed [291–294]. For values of $m_{H^\pm}$ near m_t, width effects are important. In addition, the full $2 \to 3$ processes $pp/p\bar{p} \to H^+\bar{t}b + X$ and $pp/p\bar{p} \to H^-t\bar{b} + X$ must be considered. If $m_{H^\pm} > m_t - m_b$, then charged Higgs boson production occurs mainly through radiation from a third generation quark. Charged Higgs bosons may also be

produced singly in association with a top quark via the $2 \to 3$ partonic processes gg, $q\bar{q} \to t\bar{b}H^-$. For charged Higgs boson production cross section predictions for the Tevatron and the LHC, see Refs. [38,10,37]. Charged Higgs bosons can also be produced via associated production with $W^\pm$ bosons through $b\bar{b}$ annihilation and gg-fusion [295] and in pairs via $q\bar{q}$ annihilation [296].

(a) Exclusion limits from LEP

Charged Higgs bosons have been searched for at LEP, where the combined data of the four experiments, ALEPH, DELPHI, L3, and OPAL, were sensitive to masses of up to about 90 GeV [437] in two decay channels, the $\tau\nu$ and $c\bar{s}$. The exclusion limit independent of the admixture of the two above mentioned branching fractions was 78.6 GeV.

(b) Exclusion limits from Tevatron

Compared to the LEP mass domain of searches, Tevatron covered a complementary range of charged Higgs mass hypotheses. The CDF and D0 collaborations have also searched for charged Higgs bosons in top quark decays with subsequent decays to $\tau\nu$ or to $c\bar{s}$ [449–451]. In the $H^+ \to c\bar{s}$, the limits on BR$(t \to H^+b)$ from CDF and D0 are $\approx 20\%$ in the mass range 90 GeV $< m_{H^+} <$ 160 GeV and assuming a branching fraction of 100% in this specific final state. $H^+ \to \tau^+\nu_\tau$ channel, D0's limits on BR$(t \to H^+b)$ are also $\approx 20\%$ in the same mass range and assuming a branching fraction of 100% in this final state. These limits are valid in general 2HDMs, and they have also been interpreted in terms of the MSSM [449–451].

(c) Exclusion limits from LHC

At the LHC the sensitive mass domain is much larger and the variety of search channels wider. Until recently, only the $\tau\nu$ and $c\bar{s}$ final states have been investigated.

The ATLAS and CMS collaborations have searched for charged Higgs bosons produced in the decay of top quarks in $t\bar{t}$ events. ATLAS has searched for the decay $H^+ \to \tau^+\nu_\tau$ in three final state topologies [452]: (i) lepton+jets: with $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(q\bar{q}')(\tau_{\rm lep}\nu)$, i.e., the W boson decays hadronically and the tau decays into an electron or a muon, with two neutrinos; (ii) τ +lepton: with $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(l\nu)(\tau_{\rm had}\nu)$ i.e., the W boson decays leptonically (with $\ell = e,\ \mu$) and the tau decays hadronically; (iii) τ+jets: $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(q\bar{q}')(\tau_{\rm had}\nu)$, i.e., both the W boson and the τ decay hadronically [453]. The latter channel has been recently updated with the full 8 TeV dataset of pp collisions, corresponding to an integrated luminosity of 19.5 fb^{-1} [453]. Assuming BR$(H^+ \to \tau^+\nu_\tau) = 100\%$, ATLAS sets upper limits on BR$(t \to H^+b)$ between 0.24% and 2.1% for charged Higgs boson masses between 90 GeV to 160 GeV. When interpreted in the context of the $m_h^{\rm max}$ scenario of the MSSM, these bounds exclude a large fraction of the ($m_{H^\pm}$,tan β) plane as illustrated in Fig. 11.32.

The CMS collaboration has searched for the charged Higgs boson in the decay products of top quark pairs: $t\bar{t} \to H^\pm W^\mp b\bar{b}$ and $t\bar{t} \to H^+H^-b\bar{b}$ [454,455] as well. Three types of final states with large missing transverse energy and jets originating from b-quark hadronization have been analyzed: the fully-hadronic channel with a hadronically decaying tau in association with jets, the dilepton channel with a hadronically decaying tau in association with an electron or muon and the dilepton channel with an electron-muon pair. Combining the results of these three analyses and assuming BR$(H^\pm \to \tau\nu)$=1, the upper limits on BR$(t \to H^+b)$ are less than 2% to 3% depending on the charged Higgs boson mass in the interval 80 GeV $< m_{H^+} <$160 GeV.

ATLAS has also searched for charged Higgs bosons in top quark decays assuming BR$(H^+ \to c\bar{s}) = 100\%$ [456], and sets limits of $\approx 20\%$ on BR$(t \to H^+b)$ in the 90 GeV $< m_{H^+} <$ 160 GeV mass range.

At the LHC various other channels can be investigated, in particular the challenging search for a heavy charged Higgs decaying to $t\bar{b}$, searches involving additional neutral scalars in particular in

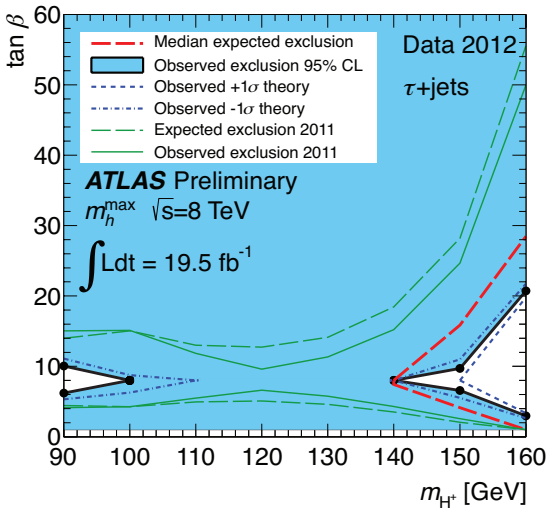

Figure 11.32: ATLAS exclusion limits of the searches of the light $H^\pm$, in the context of the MSSM m_h^{max} scenario with $\mu = 200$ GeV [453]. For comparison, the 2011 limits are also indicated.

WH, WA where A is the pseudo scalar MSSM Higgs boson, and Wa where a is the light CP-odd scalars of the NMSSM.

(iv) Searches for a light CP-odd Higgs boson a

A light pseudoscalar boson a from a two Higgs double model or a model, such as the NMSSM, enhanced with an additional singlet field. The theoretical motivations for singlet extensions of the MSSM are discussed in Section V.2. The main focus of searches for signatures of the NMSSM is on low mass pseudo-scalar boson a for several reasons: (i) in the NMSSM, the light pseudo-scalar a boson can, as a pseudo goldstone boson, be a natural candidate for an axion; (ii) scenarios where $m_a > 2m_b$ and a CP-even state h can decay to a pair of a ($m_h > 2m_a$) are excluded by direct searches at LEP in the $4b$ channel [437,457,458]. for Higgs boson decays to $4b$-quarks have been carried out at LEP; (iii) in the pre-discovery era, LEP limits on a CP-even higgs boson resulted in fine tuning MSSM constraints [459], these could be evaded through non standard decays of the Higgs to aa; (iv) an NMSSM CP-odd a boson with a mass in the range 9.2–12 GeV can also account for the difference observed between the measured anomalous muon magnetic moment and its prediction [460]. A scenario that has drawn particular attention was motivated by a small excess of events 2.3σ in the SM Higgs search at LEP at Higgs boson masse of around 98 GeV. Speculative interpretations of this excess as a signal of a Higgs boson with reduced couplings to b-quarks were given [459]. Complete reviews of the NMSSM phenomenology can be found in Refs. [461,458].

The potential benchmark scenarios have changed in the light of the H discovery. The discovered state could be the lightest or the next-to-lightest of the three CP-even states of the NMSSM. Light pseudoscalar scenarios are still very interesting in particular for the potential axion candidate. There are three main types of direct searches for the light a boson: (i) for masses below the Υ resonance, the search is for radiative decays $\Upsilon \to a\gamma$ at B-factories; (ii) the inclusive search for in high energy pp collisions at the LHC; (iii) the search for decays of a CP-even Higgs h boson to a pair of a bosons.

Radiative decays $\Upsilon \to a\gamma$, have been searched for in various colliders, the most recent results are searches for radiative decays of the $\Upsilon(1s)$ to $a\gamma$ with a subsequent decay of the a boson to a pair of taus at CLEO [462] and the radiative decays of the $\Upsilon(1s, 2s, 3s)$ to $a\gamma$ with subsequent decays to a pair of muons or taus by the Babar collaboration [463,464].

Direct inclusive searches for the light pseudo scalar a boson were performed in the $a \to \mu\mu$ channel at the Tevatron by the D0 experiment [465] and by the ATLAS [466] and CMS [467]

collaborations at the LHC.

Finally searches for the decays of a *CP*-even Higgs boson to a pair of a bosons where performed with subsequent decays to four photons by the ATLAS experiment [468], in the four muons final state by the CMS and D0 experiments [469,458], in the two muons and two taus final state by the D0 collaboration [458], and in the four taus final state by the ALEPH collaboration at LEP [470].

No significant excess in the searches for a light *CP*-odd a boson were found and limits on the production times branching fractions of the a boson have been set.

(v) Searches for doubly charged Higgs bosons $H^{\pm\pm}$

As discussed in Section V.6.2 the generation of small neutrino masses via the standard EWSB mechanism described in Section II, requires unnaturally small Yukawa couplings, provided that neutrinos are Dirac-type fermions. A Majorana mass term with a see-saw mechanism for neutrinos, would allow for naturally small masses and yield a framework for the appealing scenario of leptogenesis. However within the SM Majorana mass terms correspond to (non-renomalizable) dimension-5 operators. Such effective interactions can be generated via renormalizable interactions with an electroweak triplet of complex scalar fields (corresponding to a type-II see-saw mechanism). Other models such as the Zee–Babu model, with the introduction of two $SU(2)_L$ singlets, also generate Majorana mass terms. The signature of such models would be the presence of doubly charged Higgs bosons $H^{\pm\pm}$.

The main production mechanisms of $H^{\pm\pm}$ bosons at hadron colliders are the pair production in the s-channel through the exchange of a Z boson or a photon and the associated production with a Charged Higgs boson through the exchange of a W boson.

V.9.1. Standard decays for non-standard processes

The discovery of the H state has also allowed for searches of BSM (beyond the SM) processes involving standard decays of the Higgs boson. One example directly pertaining to the search for additional states of the EWSB sector is the search for Higgs bosons in the cascade decay of a heavy *CP*-even Higgs boson decaying to charged Higgs boson and a W boson, and the charged Higgs boson subsequently decaying to H and another W boson. This search has been performed by the ATLAS collaboration in $b\overline{b}$ decays of the H particle [485].

Another example of searches for non standard processes through the presence of the H particle is the search for large flavor changing neutral current decays of the top quark to H and a charm quark. This search has been performed with the ATLAS experiment in the $H \to \gamma\gamma$ channel [486].

V.9.2. Outlook of searches for additional states

Although the LHC program of searches for additional states covers a large variety of decay channels for additional states, various important topologies are still not covered. In particular when searching for additional states the decays of heavy additional particles such as those of the neutral states decaying to a pair of HH or to ZH are important. Similarly the search for charged Higgs bosons can be extended to include the search for HW and cover the high mass region with $t\overline{b}$ decays. The LHC program for searches of additional scalar states is also rich in other yet to be explored final states such as heavy neutral Higgs bosons decays to a top-quark pair or charged Higgs boson decays to a, AW.

VI. Summary and Outlook

The discovery of the Higgs boson is a milestone in particle physics and an extraordinary success of the LHC machine and the ATLAS and CMS collaborations. The emerging understanding of the nature of this new particle is confirmed by various measurements of its properties, all consistent with the EWSB mechanism and other properties of the Standard Model. The Higgs coupling to gauge bosons has been measured to a precision of nearly 10%. The combination of LHC and Tevatron experiments have accessed couplings to the heavier fermions, although this still needs further confirmation from the LHC experiments. The quantum numbers of the new particle have been probed and show an excellent consistency with $J^{PC} = 0^{++}$. Hints of the direct large Yukawa coupling to the top quark are emerging. Rare decay modes (e.g. $\mu\mu$ and $Z\gamma$) have been searched for, and the experiments will eventually have sensitivity to the expected SM rates. These measurements mark the start of a new era of precision Higgs boson measurements and the use of the Higgs boson as a portal to new physics. Positive or negative, searches for additional states belonging to the EWSB sector will bring invaluable insights on the needed extension(s) of the Standard Model at higher energies.

The Higgs boson couplings are not dictated by gauge symmetries. Thus, in addition to a new particle, the LHC has also discovered a new force, different in nature from the other fundamental interactions since it is non-universal and distinguishes between the three families of quarks and leptons.

Furthermore, the mere existence of the Higgs boson with a mass of approximately 125 GeV, embodies the problem of an unnatural cancellation among the quantum corrections to its mass. The non-observation of additional states which could stabilize the Higgs mass is a challenge for natural scenarios like supersymmetry or models with a new strong interaction in which the Higgs boson is not a fundamental particle. This increasingly pressing paradox starts questioning the principle of naturalness relying on the hypothesis that phenomena at different scales do not influence each others.

The unitarization of the vector boson scattering (VBS) amplitudes, dominated at high energies by their longitudinal polarizations, has been the basis of the *no lose* theorem at the LHC and was one of the main motivations to build the accelerator and the detectors. It motivated the existence of a Higgs boson or the observability of manifestations of strong dynamics at TeV scale. Now that a Higgs boson has been found and that its couplings to gauge bosons follow the SM predictions, perturbative unitarity is preserved to a large amount with the sole exchange of the Higgs boson and without the need for any additional states. It is, however, still an important channel to investigate further in order to better understand the nature of the Higgs sector and the possible completion of the SM at the TeV scale. In association with the double Higgs boson production channel by vector boson fusion, VBS could, for instance, confirm that the Higgs

boson is part of a weak doublet and also establish if it is a composite state and whether or not it emerges as a pseudo-Nambu–Goldstone boson from an underlying broken symmetry.

The search for the Higgs boson has occupied the Particle physics community for the last 50 years. Its discovery is now shaping and sharpening the physics programs of future accelerators.

12. THE CKM QUARK-MIXING MATRIX

Revised February 2014 by A. Ceccucci (CERN), Z. Ligeti (LBNL), and Y. Sakai (KEK).

12.1. Introduction

The masses and mixings of quarks have a common origin in the Standard Model (SM). They arise from the Yukawa interactions with the Higgs condensate,

$$\mathcal{L}_Y = -Y^d_{ij}\,\overline{Q^I_{Li}}\,\phi\,d^I_{Rj} - Y^u_{ij}\,\overline{Q^I_{Li}}\,\epsilon\,\phi^* u^I_{Rj} + \text{h.c.}, \tag{12.1}$$

where $Y^{u,d}$ are 3×3 complex matrices, ϕ is the Higgs field, i,j are generation labels, and ϵ is the 2×2 antisymmetric tensor. Q^I_L are left-handed quark doublets, and d^I_R and u^I_R are right-handed down- and up-type quark singlets, respectively, in the weak-eigenstate basis. When ϕ acquires a vacuum expectation value, $\langle\phi\rangle = (0, v/\sqrt{2})$, Eq. (12.1) yields mass terms for the quarks. The physical states are obtained by diagonalizing $Y^{u,d}$ by four unitary matrices, $V^{u,d}_{L,R}$, as $M^f_{\rm diag} = V^f_L\,Y^f\,V^{f\dagger}_R(v/\sqrt{2})$, $f = u, d$. As a result, the charged-current $W^\pm$ interactions couple to the physical u_{Lj} and d_{Lk} quarks with couplings given by

$$\frac{-g}{\sqrt{2}}(\overline{u_L},\,\overline{c_L},\,\overline{t_L})\gamma^\mu\,W^+_\mu\,V_{\rm CKM}\begin{pmatrix} d_L \\ s_L \\ b_L\end{pmatrix} + \text{h.c.},$$

$$V_{\rm CKM} \equiv V^u_L V^{d\dagger}_L = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb}\end{pmatrix}. \tag{12.2}$$

This Cabibbo-Kobayashi-Maskawa (CKM) matrix [1,2] is a 3×3 unitary matrix. It can be parameterized by three mixing angles and the CP-violating KM phase [2]. Of the many possible conventions, a standard choice has become [3]

$$V_{\rm CKM} = \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23}-c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23}-s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23}-c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23}-s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13}\end{pmatrix}, \tag{12.3}$$

where $s_{ij} = \sin\theta_{ij}$, $c_{ij} = \cos\theta_{ij}$, and δ is the phase responsible for all CP-violating phenomena in flavor-changing processes in the SM. The angles θ_{ij} can be chosen to lie in the first quadrant, so $s_{ij}, c_{ij} \geq 0$.

It is known experimentally that $s_{13} \ll s_{23} \ll s_{12} \ll 1$, and it is convenient to exhibit this hierarchy using the Wolfenstein parameterization. We define [4–6]

$$s_{12} = \lambda = \frac{|V_{us}|}{\sqrt{|V_{ud}|^2 + |V_{us}|^2}}\,, \qquad s_{23} = A\lambda^2 = \lambda\left|\frac{V_{cb}}{V_{us}}\right|,$$
$$s_{13}e^{i\delta} = V^*_{ub} = A\lambda^3(\rho + i\eta) = \frac{A\lambda^3(\bar\rho + i\bar\eta)\sqrt{1-A^2\lambda^4}}{\sqrt{1-\lambda^2}[1 - A^2\lambda^4(\bar\rho + i\bar\eta)]}\,, \tag{12.4}$$

These relations ensure that $\bar\rho + i\bar\eta = -(V_{ud}V^*_{ub})/(V_{cd}V^*_{cb})$ is phase-convention-independent, and the CKM matrix written in terms of λ, A, $\bar\rho$, and $\bar\eta$ is unitary to all orders in λ. The definitions of $\bar\rho, \bar\eta$ reproduce all approximate results in the literature. For example, $\bar\rho = \rho(1-\lambda^2/2+\ldots)$ and we can write $V_{\rm CKM}$ to $\mathcal{O}(\lambda^4)$ either in terms of $\bar\rho, \bar\eta$ or, traditionally,

$$V_{\rm CKM} = \begin{pmatrix} 1-\lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1-\lambda^2/2 & A\lambda^2 \\ A\lambda^3(1-\rho-i\eta) & -A\lambda^2 & 1\end{pmatrix} + \mathcal{O}(\lambda^4)\,. \tag{12.5}$$

The CKM matrix elements are fundamental parameters of the SM, so their precise determination is important. The unitarity of the CKM matrix imposes $\sum_i V_{ij}V^*_{ik} = \delta_{jk}$ and $\sum_j V_{ij}V^*_{kj} = \delta_{ik}$. The six vanishing combinations can be represented as triangles in a complex plane, of which the ones obtained by taking scalar products of neighboring rows or columns are nearly degenerate. The areas of all triangles are the same, half of the Jarlskog invariant, J [7], which is a phase-convention-independent measure of CP violation, defined by $\text{Im}\big[V_{ij}V_{kl}V^*_{il}V^*_{kj}\big] = J\sum_{m,n}\varepsilon_{ikm}\varepsilon_{jln}$.

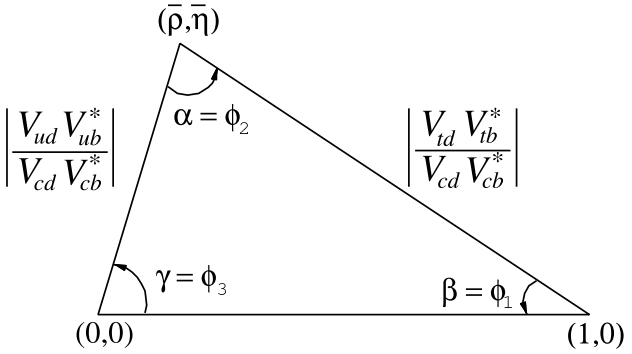

Figure 12.1: Sketch of the unitarity triangle.

The most commonly used unitarity triangle arises from

$$V_{ud}\,V^*_{ub} + V_{cd}\,V^*_{cb} + V_{td}\,V^*_{tb} = 0\,, \tag{12.6}$$

by dividing each side by the best-known one, $V_{cd}V^*_{cb}$ (see Fig. 1). Its vertices are exactly $(0,0)$, $(1,0)$, and, due to the definition in Eq. (12.4), $(\bar\rho, \bar\eta)$. An important goal of flavor physics is to overconstrain the CKM elements, and many measurements can be conveniently displayed and compared in the $\bar\rho, \bar\eta$ plane.

Processes dominated by loop contributions in the SM are sensitive to new physics, and can be used to extract CKM elements only if the SM is assumed. We describe such measurements assuming the SM in Sec. 12.2 and 12.3, give the global fit results for the CKM elements in Sec. 12.4, and discuss implications for new physics in Sec. 12.5.

12.2. Magnitudes of CKM elements

12.2.1. $|V_{ud}|$:

The most precise determination of $|V_{ud}|$ comes from the study of superallowed $0^+ \to 0^+$ nuclear beta decays, which are pure vector transitions. Taking the average of the twenty most precise determinations [8] yields

$$|V_{ud}| = 0.97425 \pm 0.00022. \tag{12.7}$$

The error is dominated by theoretical uncertainties stemming from nuclear Coulomb distortions and radiative corrections. A precise determination of $|V_{ud}|$ is also obtained from the measurement of the neutron lifetime. The theoretical uncertainties are very small, but the determination is limited by the knowledge of the ratio of the axial-vector and vector couplings, $g_A = G_A/G_V$ [9]. The PIBETA experiment [10] has improved the measurement of the $\pi^+ \to \pi^0 e^+\nu$ branching ratio to 0.6%, and quote $|V_{ud}| = 0.9728 \pm 0.0030$, in agreement with the more precise result listed above. The interest in this measurement is that the determination of $|V_{ud}|$ is very clean theoretically, because it is a pure vector transition and is free from nuclear-structure uncertainties.

12.2.2. $|V_{us}|$:

The product of $|V_{us}|$ and the form factor at $q^2 = 0$, $|V_{us}|\,f_+(0)$, has been extracted traditionally from $K^0_L \to \pi e\nu$ decays in order to avoid isospin-breaking corrections ($\pi^0 - \eta$ mixing) that affect $K^\pm$ semileptonic decay, and the complications induced by a second (scalar) form factor present in the muonic decays. The last round of measurements has lead to enough experimental constraints to justify the comparison between different decay modes. Systematic errors related to the experimental quantities, *e.g.*, the lifetime of neutral or charged kaons, and the form factor determinations for electron and muonic decays, differ among decay modes, and the consistency between different determinations enhances the confidence in the final result. For this reason, we follow the prescription [11] to average $K^0_L \to \pi e\nu$, $K^0_L \to \pi\mu\nu$, $K^\pm \to \pi^0 e^\pm\nu$, $K^\pm \to \pi^0\mu^\pm\nu$ and $K^0_S \to \pi e\nu$. The average of these five decay modes yields $|V_{us}|\,f_+(0) = 0.2163 \pm 0.0005$. Results obtained from each decay mode, and exhaustive references to

the experimental data, are listed for instance in Ref. [9]. The form factor value $f_+(0) = 0.960^{+0.005}_{-0.006}$ [12] from a three-flavor unquenched lattice QCD calculation gives [9] $|V_{us}| = 0.2253 \pm 0.0014$.[1] The broadly used classic calculation of $f_+(0)$ [15] is in good agreement with this value, while other calculations [16] differ by as much as 2%.

The calculation of the ratio of the kaon and pion decay constants enables one to extract $|V_{us}/V_{ud}|$ from $K \to \mu\nu(\gamma)$ and $\pi \to \mu\nu(\gamma)$, where (γ) indicates that radiative decays are included [17]. The KLOE measurement of the $K^+ \to \mu^+\nu(\gamma)$ branching ratio [18], combined with the lattice QCD calculation, $f_K/f_\pi = 1.1947 \pm 0.0045$ [19], leads to $|V_{us}| = 0.2253 \pm 0.0010$, where the accuracy is limited by the knowledge of the ratio of the decay constants. The average of these two determinations is quoted by Ref. 9 as

$$|V_{us}| = 0.2253 \pm 0.0008. \tag{12.8}$$

The latest determination from hyperon decays can be found in Ref. 21. The authors focus on the analysis of the vector form factor, protected from first order $SU(3)$ breaking effects by the Ademollo-Gatto theorem [22], and treat the ratio between the axial and vector form factors g_1/f_1 as experimental input, thus avoiding first order $SU(3)$ breaking effects in the axial-vector contribution. They find $|V_{us}| = 0.2250 \pm 0.0027$, although this does not include an estimate of the theoretical uncertainty due to second-order $SU(3)$ breaking, contrary to Eq. (12.8). Concerning hadronic τ decays to strange particles, the latest determinations based on LEP, *BABAR*, and Belle data yield $|V_{us}| = 0.2202 \pm 0.0015$ [23]. A measurement of the ratio of branching fractions $\mathcal{B}(\tau \to K\nu)/\mathcal{B}(\tau \to \pi\nu)$ by *BABAR* [24] combined with the above f_K/f_π value gives $|V_{us}| = 0.2244 \pm 0.0024$.

12.2.3. $|V_{cd}|$:

The magnitude of V_{cd} can be extracted from semileptonic charm decays, using theoretical knowledge of the form factors. In semileptonic D decays, unquenched lattice QCD calculations have predicted the normalization of the $D \to \pi\ell\nu$ and $D \to K\ell\nu$ form factors [13]. The dependence on the invariant mass of the lepton pair, q^2, is determined from lattice QCD and theoretical constraints from analyticity [14]. Using three-flavor unquenched lattice QCD calculations for $D \to \pi\ell\nu$, $f_+^{D\pi}(0) = 0.666 \pm 0.029$ [13], and the average of recent CLEO-c [25] and Belle [26] measurements of $D \to \pi\ell\nu$ decays, one obtains $|V_{cd}| = 0.220 \pm 0.006 \pm 0.010$, where the first uncertainty is experimental, and the second is from the theoretical uncertainty of the form factor.

Earlier determinations of $|V_{cd}|$ came from neutrino scattering data. The difference of the ratio of double-muon to single-muon production by neutrino and antineutrino beams is proportional to the charm cross section off valence d quarks, and therefore to $|V_{cd}|^2$ times the average semileptonic branching ratio of charm mesons, $\mathcal{B}_\mu$. The method was used first by CDHS [27] and then by CCFR [28,29] and CHARM II [30]. Averaging these results is complicated, because it requires assumptions about the scale of the QCD corrections, and because $\mathcal{B}_\mu$ is an effective quantity, which depends on the specific neutrino beam characteristics. Given that no recent experimental input is available, we quote the average from a past review, $\mathcal{B}_\mu |V_{cd}|^2 = (0.463 \pm 0.034) \times 10^{-2}$ [31]. Analysis cuts make these experiments insensitive to neutrino energies smaller than 30 GeV. Thus, $\mathcal{B}_\mu$ should be computed using only neutrino interactions with visible energy larger than 30 GeV. An appraisal [32] based on charm-production fractions measured in neutrino interactions [33,34] gives $\mathcal{B}_\mu = 0.088 \pm 0.006$. Data from the CHORUS experiment [35] are sufficiently precise to extract $\mathcal{B}_\mu$ directly, by comparing the number of charm decays with a muon to the total number of charmed hadrons found in the nuclear emulsions. Requiring the visible energy to be larger than 30 GeV, CHORUS finds $\mathcal{B}_\mu = 0.085 \pm 0.009 \pm 0.006$. We use the average of these two determinations, $\mathcal{B}_\mu = 0.087 \pm 0.005$, and obtain $|V_{cd}| = 0.230 \pm 0.011$. Averaging the two determinations above, we find

$$|V_{cd}| = 0.225 \pm 0.008. \tag{12.9}$$

[1] For lattice QCD inputs, we use the averages from Ref. 13 whenever possible, unless the minireviews [9,14] choose other values. Hereafter, the first error is statistical and the second is systematic, unless mentioned otherwise.

12.2.4. $|V_{cs}|$:

The direct determination of $|V_{cs}|$ is possible from semileptonic D or leptonic D_s decays, using unquenched lattice QCD calculations of the semileptonic D form factor or the D_s decay constant. For muonic decays, the average of Belle [36], CLEO-c [37] and *BABAR* [38] is $\mathcal{B}(D_s^+ \to \mu^+\nu) = (5.56 \pm 0.24) \times 10^{-3}$ [39]. For decays to τ leptons, the average of CLEO-c [37,40,41], *BABAR* [38] and Belle [36] gives $\mathcal{B}(D_s^+ \to \tau^+\nu) = (5.56 \pm 0.22) \times 10^{-2}$ [39]. From each of these values, determinations of $|V_{cs}|$ can be obtained using the PDG values for the mass and lifetime of the D_s, the masses of the leptons, and $f_{D_s} = (248.6 \pm 2.7)$ MeV [13]. The average of these determinations gives $|V_{cs}| = 1.008 \pm 0.021$, where the error is dominated by the lattice QCD determination of f_{D_s}. In semileptonic D decays, unquenched lattice QCD calculations of the $D \to K\ell\nu$ form factor is available [13]. Using $f_+^{DK}(0) = 0.747 \pm 0.019$ and the average of recent CLEO-c [25], Belle [26] and *BABAR* [42] measurements of $B \to K\ell\nu$ decays, one obtains $|V_{cs}| = 0.953 \pm 0.008 \pm 0.024$, where the first error is experimental and the second, which is dominant, is from the theoretical uncertainty of the form factor. Averaging the determinations from leptonic and semileptonic decays, we find

$$|V_{cs}| = 0.986 \pm 0.016. \tag{12.10}$$

Measurements of on-shell $W^\pm$ decays sensitive to $|V_{cs}|$ were made by LEP-2. The W branching ratios depend on the six CKM elements involving quarks lighter than m_W. The W branching ratio to each lepton flavor is $1/\mathcal{B}(W \to \ell\bar{\nu}_\ell) = 3\big[1 + \sum_{u,c,d,s,b} |V_{ij}|^2 \,(1 + \alpha_s(m_W)/\pi) + \ldots\big]$. Assuming lepton universality, the measurement $\mathcal{B}(W \to \ell\bar{\nu}_\ell) = (10.83 \pm 0.07 \pm 0.07)\,\%$ [43] implies $\sum_{u,c,d,s,b} |V_{ij}|^2 = 2.002 \pm 0.027$. This is a precise test of unitarity; however, only flavor-tagged W-decays determine $|V_{cs}|$ directly, such as DELPHI's tagged $W^+ \to c\bar{s}$ analysis, yielding $|V_{cs}| = 0.94^{+0.32}_{-0.26} \pm 0.13$ [44].

12.2.5. $|V_{cb}|$:

This matrix element can be determined from exclusive and inclusive semileptonic decays of B mesons to charm. The inclusive determinations use the semileptonic decay rate measurement, together with the leptonic energy and the hadronic invariant-mass spectra. The theoretical foundation of the calculation is the operator product expansion [45,46]. It expresses the total rate and moments of differential energy and invariant-mass spectra as expansions in α_s, and inverse powers of the heavy quark mass. The dependence on m_b, m_c, and the parameters that occur at subleading order is different for different moments, and a large number of measured moments overconstrains all the parameters, and tests the consistency of the determination. The precise extraction of $|V_{cb}|$ requires using a "threshold" quark mass definition [47,48]. Inclusive measurements have been performed using B mesons from Z^0 decays at LEP, and at e^+e^- machines operated at the $\Upsilon(4S)$. At LEP, the large boost of B mesons from the Z^0 allows the determination of the moments throughout phase space, which is not possible otherwise, but the large statistics available at the B factories lead to more precise determinations. An average of the measurements and a compilation of the references are provided by Ref. [14]: $|V_{cb}| = (42.2 \pm 0.7) \times 10^{-3}$.

Exclusive determinations are based on semileptonic B decays to D and D^*. In the $m_{b,c} \gg \Lambda_{\rm QCD}$ limit, all form factors are given by a single Isgur-Wise function [49], which depends on the product of the four-velocities of the B and $D^{(*)}$ mesons, $w = v \cdot v'$. Heavy quark symmetry determines the normalization of the rate at $w = 1$, the maximum momentum transfer to the leptons, and $|V_{cb}|$ is obtained from an extrapolation to $w = 1$. The exclusive determination, $|V_{cb}| = (39.5 \pm 0.8) \times 10^{-3}$ [14], has a comparable precision to the inclusive one, and the main theoretical uncertainty in the form factor and the experimental uncertainty in the rate near $w = 1$ are to a large extent independent of the inclusive determination. The V_{cb} and V_{ub} minireview [14] quotes a combination with a scaled error as

$$|V_{cb}| = (41.1 \pm 1.3) \times 10^{-3}. \tag{12.11}$$

Determinations of $|V_{cb}|$ with larger uncertainties, not included in this average, can be obtained from $\mathcal{B}(B \to D^{(*)}\tau\bar{\nu})$. The most precise

measurements involving the τ modes are those of the $|V_{cb}|$-independent ratios $\mathcal{B}(B \to D^{(*)}\tau\bar{\nu})/\mathcal{B}(B \to D^{(*)}\ell\bar{\nu})$ [50], which are 2–3 σ above the SM predictions.

12.2.6. $|V_{ub}|$:

The determination of $|V_{ub}|$ from inclusive $B \to X_u\ell\bar{\nu}$ decay is complicated due to large $B \to X_c\ell\bar{\nu}$ backgrounds. In most regions of phase space where the charm background is kinematically forbidden, the hadronic physics enters via unknown nonperturbative functions, so-called shape functions. (In contrast, the nonperturbative physics for $|V_{cb}|$ is encoded in a few parameters.) At leading order in $\Lambda_{\rm QCD}/m_b$, there is only one shape function, which can be extracted from the photon energy spectrum in $B \to X_s\gamma$ [51,52], and applied to several spectra in $B \to X_u\ell\bar{\nu}$. The subleading shape functions are modeled in the current determinations. Phase space cuts for which the rate has only subleading dependence on the shape function are also possible [53]. The measurements of both the hadronic and the leptonic systems are important for an optimal choice of phase space. A different approach is to make the measurements more inclusive by extending them deeper into the $B \to X_c\ell\bar{\nu}$ region, and thus reduce the theoretical uncertainties. Analyses of the electron-energy endpoint from CLEO [54], *BABAR* [55], and Belle [56] quote $B \to X_u e\bar{\nu}$ partial rates for $|\vec{p}_e| \geq 2.0\,\text{GeV}$ and 1.9 GeV, which are well below the charm endpoint. The large and pure $B\overline{B}$ samples at the B factories permit the selection of $B \to X_u\ell\bar{\nu}$ decays in events where the other B is fully reconstructed [57]. With this full-reconstruction tag method, the four-momenta of both the leptonic and the hadronic systems can be measured. It also gives access to a wider kinematic region because of improved signal purity. Ref. 14 quotes an inclusive average as $|V_{ub}| = (4.41 \pm 0.15\ ^{+0.15}_{-0.19}) \times 10^{-3}$.

To extract $|V_{ub}|$ from an exclusive channel, the form factors have to be known. Experimentally, better signal-to-background ratios are offset by smaller yields. The $B \to \pi\ell\bar{\nu}$ branching ratio is now known to 5%. Unquenched lattice QCD calculations of the $B \to \pi\ell\bar{\nu}$ form factor are available [58,59] for the high q^2 region ($q^2 > 16$ or $18\,\text{GeV}^2$). A fit to the experimental partial rates and lattice results versus q^2 yields $|V_{ub}| = (3.23 \pm 0.31) \times 10^{-3}$ [59]. Light-cone QCD sum rules are supposed to be applicable for $q^2 < 12\,\text{GeV}^2$ [60]. The minireview quotes a combination, $|V_{ub}| = (3.28 \pm 0.29) \times 10^{-3}$.

The uncertainties in extracting $|V_{ub}|$ from inclusive and exclusive decays are different to a large extent. A combination of the determinations is quoted by Ref. [14] as

$$|V_{ub}| = (4.13 \pm 0.49) \times 10^{-3}. \tag{12.12}$$

A determination of $|V_{ub}|$ not included in this average can be obtained from $\mathcal{B}(B \to \tau\bar{\nu}) = (1.14 \pm 0.22) \times 10^{-4}$ [65]. Using $f_B = (190.5 \pm 4.2)\,\text{MeV}$ [13] and $\tau_{B^\pm} = (1.641 \pm 0.008)\,\text{ps}$ [66], we find $|V_{ub}| = (4.22 \pm 0.42) \times 10^{-3}$. This decay is sensitive, for example, to tree-level charged Higgs contributions, and the measured rate is somewhat higher than the SM fit value.

12.2.7. $|V_{td}|$ *and* $|V_{ts}|$:

The CKM elements $|V_{td}|$ and $|V_{ts}|$ are not likely to be precisely measurable in tree-level processes involving top quarks, so one has to rely on determinations from B–$\overline{B}$ oscillations mediated by box diagrams with top quarks, or loop-mediated rare K and B decays. Theoretical uncertainties in hadronic effects limit the accuracy of the current determinations. These can be reduced by taking ratios of processes that are equal in the flavor $SU(3)$ limit to determine $|V_{td}/V_{ts}|$.

The mixing of the two B^0 mesons was discovered by ARGUS [61], and the mass difference is precisely measured by now, $\Delta m_d = (0.510 \pm 0.003)\,\text{ps}^{-1}$ [62]. In the B_s^0 system, Δm_s was first measured significantly by CDF [63] and the world average, dominated by a recent LHCb measurement [64], is $\Delta m_s = (17.761 \pm 0.022)\,\text{ps}^{-1}$ [62]. Assuming $|V_{tb}| = 1$, and using the unquenched lattice QCD calculations $f_{B_d}\sqrt{\widehat{B}_{B_d}} = (216 \pm 15)\,\text{MeV}$ and $f_{B_s}\sqrt{\widehat{B}_{B_s}} = (266 \pm 18)\,\text{MeV}$ [13],

$$|V_{td}| = (8.4 \pm 0.6) \times 10^{-3}, \qquad |V_{ts}| = (40.0 \pm 2.7) \times 10^{-3}. \tag{12.13}$$

The uncertainties are dominated by lattice QCD. Several uncertainties are reduced in the calculation of the ratio $\xi = (f_{B_s}\sqrt{\widehat{B}_{B_s}})/(f_{B_d}\sqrt{\widehat{B}_{B_d}}) = 1.268 \pm 0.063$ [13] and therefore the constraint on $|V_{td}/V_{ts}|$ from $\Delta m_d/\Delta m_s$ is more reliable theoretically. These provide a theoretically clean and significantly improved constraint

$$\left|V_{td}/V_{ts}\right| = 0.216 \pm 0.001 \pm 0.011. \tag{12.14}$$

The inclusive branching ratio $\mathcal{B}(B \to X_s\gamma) = (3.43 \pm 0.22) \times 10^{-4}$ extrapolated to $E_\gamma > E_0 = 1.6\,\text{GeV}$ [67] is also sensitive to $|V_{tb}V_{ts}|$. In addition to t-quark penguins, a large part of the sensitivity comes from charm contributions proportional to $V_{cb}V_{cs}^*$ via the application of 3×3 CKM unitarity (which is used here). With the NNLO calculation of $\mathcal{B}(B \to X_s\gamma)_{E_\gamma > E_0}/\mathcal{B}(B \to X_c e\bar{\nu})$ [68], we obtain $|V_{ts}/V_{cb}| = 1.02 \pm 0.05$. The $B_s \to \mu^+\mu^-$ rate [69] is also proportional to $|V_{tb}V_{ts}|^2$ in the SM, and the observed signal $\mathcal{B}(B_s \to \mu^+\mu^-) = (2.9 \pm 0.7) \times 10^{-9}$ is consistent with the SM, with sizable uncertainties.

A complementary determination of $|V_{td}/V_{ts}|$ is possible from the ratio of $B \to \rho\gamma$ and $K^*\gamma$ rates. The ratio of the neutral modes is theoretically cleaner than that of the charged ones, because the poorly known spectator-interaction contribution is expected to be smaller (W-exchange vs. weak annihilation). For now, because of low statistics we average the charged and neutral rates assuming the isospin symmetry and heavy quark limit motivated relation, $|V_{td}/V_{ts}|^2/\xi_\gamma^2 = [\Gamma(B^+ \to \rho^+\gamma) + 2\Gamma(B^0 \to \rho^0\gamma)]/[\Gamma(B^+ \to K^{*+}\gamma) + \Gamma(B^0 \to K^{*0}\gamma)] = (3.19 \pm 0.46)\%$ [67]. Here ξ_γ contains the poorly known hadronic physics. Using $\xi_\gamma = 1.2 \pm 0.2$ [70], and combining the experimental and theoretical errors in quadrature, gives $|V_{td}/V_{ts}| = 0.21 \pm 0.04$.

A theoretically clean determination of $|V_{td}V_{ts}^*|$ is possible from $K^+ \to \pi^+\nu\bar{\nu}$ decay [71]. Experimentally, only seven events have been observed [72] and the rate is consistent with the SM with large uncertainties. Much more data are needed for a precision measurement.

12.2.8. $|V_{tb}|$:

The determination of $|V_{tb}|$ from top decays uses the ratio of branching fractions $R = \mathcal{B}(t \to Wb)/\mathcal{B}(t \to Wq) = |V_{tb}|^2/(\sum_q |V_{tq}|^2) = |V_{tb}|^2$, where $q = b, s, d$. The CDF and DØ measurements performed on data collected during Run II of the Tevatron give $|V_{tb}| > 0.78$ [73] and $0.99 > |V_{tb}| > 0.90$ [74], respectively, at 95% CL. CMS recently measured the same quantity at 7 TeV and gives $|V_{tb}| > 0.92$ [75] at 95% CL.

The direct determination of $|V_{tb}|$, without assuming unitarity, is possible from the single top-quark-production cross section. The $(3.51^{+0.40}_{-0.37})$ pb average cross section measured by DØ [76] and CDF [77] implies $|V_{tb}| = 1.03 \pm 0.06$. The average t-channel single-top cross section at CMS [78] and ATLAS [79] at 7 TeV, $(68.5 \pm 5.8)\,\text{pb}$, implies $|V_{tb}| = 1.03 \pm 0.05$; the average cross section at 8 TeV from a subset of the data, $(85 \pm 12)\,\text{pb}$ [80], implies $|V_{tb}| = 0.99 \pm 0.07$. The average of these gives

$$|V_{tb}| = 1.021 \pm 0.032\,. \tag{12.15}$$

This does not include correlations between the 7 and 8 TeV measurements. The experimental uncertainties dominate, and a dedicated combination would be welcome.

A weak constraint on $|V_{tb}|$ can be obtained from precision electroweak data, where top quarks enter in loops. The sensitivity is best in $\Gamma(Z \to b\bar{b})$ and yields $|V_{tb}| = 0.77^{+0.18}_{-0.24}$ [81].

12.3. Phases of CKM elements

As can be seen from Fig. 12.1, the angles of the unitarity triangle are

$$\beta = \phi_1 = \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right),$$
$$\alpha = \phi_2 = \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right),$$
$$\gamma = \phi_3 = \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right). \tag{12.16}$$

Since CP violation involves phases of CKM elements, many measurements of CP-violating observables can be used to constrain these angles and the $\bar{\rho}, \bar{\eta}$ parameters.

12.3.1. ϵ and ϵ' :

The measurement of CP violation in K^0–$\overline{K}^0$ mixing, $|\epsilon| = (2.233 \pm 0.015) \times 10^{-3}$ [82], provides important information about the CKM matrix. In the SM, in the basis where $V_{ud}V_{us}^*$ is real [83]

$$|\epsilon| = \frac{G_F^2 f_K^2 m_K m_W^2}{12\sqrt{2}\,\pi^2 \Delta m_K} \widehat{B}_K \Big\{ \eta_1 S(x_c)\, \mathrm{Im}[(V_{cs}V_{cd}^*)^2] + \eta_2 S(x_t)\, \mathrm{Im}[(V_{ts}V_{td}^*)^2] + 2\eta_3 S(x_c, x_t)\, \mathrm{Im}(V_{cs}V_{cd}^* V_{ts}V_{td}^*) \Big\}, \quad (12.17)$$

where S is an Inami-Lim function [84], $x_q = m_q^2/m_W^2$, and η_i are perturbative QCD corrections. The constraint from ϵ in the $\bar{\rho}, \bar{\eta}$ plane is bounded by approximate hyperbolas. The dominant uncertainties are due to the bag parameter, for which we use $\widehat{B}_K = 0.766 \pm 0.010$ from lattice QCD [13], and the parametric uncertainty proportional to $\sigma(A^4)$ from $(V_{ts}V_{td}^*)^2$, which is approximately $\sigma(|V_{cb}|^4)$.

The measurement of $6\,\mathrm{Re}(\epsilon'/\epsilon) = 1 - |\eta_{00}/\eta_{+-}|^2$, where η_{00} and η_{+-} are the CP-violating amplitude ratios of K_S^0 and K_L^0 decays to two pions, provides a qualitative test of the CKM mechanism. Its nonzero experimental average, $\mathrm{Re}(\epsilon'/\epsilon) = (1.67 \pm 0.23) \times 10^{-3}$ [82], demonstrates the existence of direct CP violation, a prediction of the KM ansatz. While $\mathrm{Re}(\epsilon'/\epsilon) \propto \mathrm{Im}(V_{td}V_{ts}^*)$, this quantity cannot easily be used to extract CKM parameters, because the electromagnetic penguin contributions tend to cancel the gluonic penguins for large m_t [85], thereby significantly increasing the hadronic uncertainties. Most estimates [86–89] agree with the observed value, indicating that $\bar{\eta}$ is positive. Progress in lattice QCD, in particular finite-volume calculations [90,91], may eventually provide a determination of the $K \to \pi\pi$ matrix elements.

12.3.2. β / ϕ_1 :

12.3.2.1. *Charmonium modes:*

CP-violation measurements in B-meson decays provide direct information on the angles of the unitarity triangle, shown in Fig. 12.1. These overconstraining measurements serve to improve the determination of the CKM elements, or to reveal effects beyond the SM.

The time-dependent CP asymmetry of neutral B decays to a final state f common to B^0 and $\overline{B}^0$ is given by [92,93]

$$\mathcal{A}_f = \frac{\Gamma(\overline{B}^0(t) \to f) - \Gamma(B^0(t) \to f)}{\Gamma(\overline{B}^0(t) \to f) + \Gamma(B^0(t) \to f)} = S_f \sin(\Delta m_d\, t) - C_f \cos(\Delta m_d\, t), \quad (12.18)$$

where

$$S_f = \frac{2\,\mathrm{Im}\lambda_f}{1 + |\lambda_f|^2}, \qquad C_f = \frac{1 - |\lambda_f|^2}{1 + |\lambda_f|^2}, \qquad \lambda_f = \frac{q}{p}\frac{\bar{A}_f}{A_f}. \quad (12.19)$$

Here, q/p describes B^0–$\overline{B}^0$ mixing and, to a good approximation in the SM, $q/p = V_{tb}^* V_{td}/V_{tb}V_{td}^* = e^{-2i\beta + \mathcal{O}(\lambda^4)}$ in the usual phase convention. A_f ($\bar{A}_f$) is the amplitude of the $B^0 \to f$ ($\overline{B}^0 \to f$) decay. If f is a CP eigenstate, and amplitudes with one CKM phase dominate the decay, then $|A_f| = |\bar{A}_f|$, $C_f = 0$, and $S_f = \sin(\arg\lambda_f) = \eta_f \sin 2\phi$, where η_f is the CP eigenvalue of f and 2ϕ is the phase difference between the $B^0 \to f$ and $B^0 \to \overline{B}^0 \to f$ decay paths. A contribution of another amplitude to the decay with a different CKM phase makes the value of S_f sensitive to relative strong interaction phases between the decay amplitudes (it also makes $C_f \neq 0$ possible).

The $b \to c\bar{c}s$ decays to CP eigenstates ($B^0 \to$ charmonium $K_{S,L}^0$) are the theoretically cleanest examples, measuring $S_f = -\eta_f \sin 2\beta$. The $b \to sq\bar{q}$ penguin amplitudes have dominantly the same weak phase as the $b \to c\bar{c}s$ tree amplitude. Since only λ^2-suppressed penguin amplitudes introduce a new CP-violating phase, amplitudes with a single weak phase dominate, and we expect $\big||\bar{A}_{\psi K}/A_{\psi K}| - 1\big| < 0.01$. The e^+e^- asymmetric-energy B-factory experiments, *BABAR* [95] and Belle [96], provide precise measurements. The world average including LHCb [97] and other measurements is [98]

$$\sin 2\beta = 0.682 \pm 0.019\,. \quad (12.20)$$

This measurement has a four-fold ambiguity in β, which can be resolved by a global fit as mentioned in Sec. 12.4. Experimentally, the two-fold ambiguity $\beta \to \pi/2 - \beta$ (but not $\beta \to \pi + \beta$) can be resolved by a time-dependent angular analysis of $B^0 \to J/\psi K^{*0}$ [99,100], or a time-dependent Dalitz plot analysis of $B^0 \to \overline{D}^0 h^0$ ($h^0 = \pi^0, \eta, \omega$) with $\overline{D}^0 \to K_S^0\pi^+\pi^-$ [101,102]. These results indicate that negative $\cos 2\beta$ solutions are very unlikely, in agreement with the global CKM fit result.

The $b \to c\bar{c}d$ mediated transitions, such as $B^0 \to J/\psi\pi^0$ and $B^0 \to D^{(*)+}D^{(*)-}$, also measure approximately $\sin 2\beta$. However, the dominant component of the $b \to d$ penguin amplitude has a different CKM phase ($V_{tb}^*V_{td}$) than the tree amplitude ($V_{cb}^*V_{cd}$), and its magnitudes are of the same order in λ. Therefore, the effect of penguins could be large, resulting in $S_f \neq -\eta_f \sin 2\beta$ and $C_f \neq 0$. These decay modes have also been measured by *BABAR* and Belle. The world averages [98], $S_{J/\psi\pi^0} = -0.93 \pm 0.15$, $S_{D^+D^-} = -0.98 \pm 0.17$, and $S_{D^{*+}D^{*-}} = -0.71 \pm 0.09$ ($\eta_f = +1$ for these modes), are consistent with $\sin 2\beta$ obtained from $B^0 \to$ charmonium K^0 decays, and the C_f's are consistent with zero, although the uncertainties are sizable.

The $b \to c\bar{u}d$ decays, $B^0 \to \overline{D}^0 h^0$ with $\overline{D}^0 \to CP$ eigenstates, have no penguin contributions and provide theoretically clean $\sin 2\beta$ measurements. *BABAR* measured $S_{D^{(*)}h^0} = -0.56 \pm 0.25$ [94].

12.3.2.2. *Penguin-dominated modes:*

The $b \to s\bar{q}q$ penguin-dominated decays have the same CKM phase as the $b \to c\bar{c}s$ tree level decays, up to corrections suppressed by λ^2, since $V_{tb}^*V_{ts} = -V_{cb}^*V_{cs}[1 + \mathcal{O}(\lambda^2)]$. Therefore, decays such as $B^0 \to \phi K^0$ and $\eta' K^0$ provide $\sin 2\beta$ measurements in the SM. Any new physics contribution to the amplitude with a different weak phase would give rise to $S_f \neq -\eta_f \sin 2\beta$, and possibly $C_f \neq 0$. Therefore, the main interest in these modes is not simply to measure $\sin 2\beta$, but to search for new physics. Measurements of many other decay modes in this category, such as $B \to \pi^0 K_S^0$, $K_S^0 K_S^0 K_S^0$, *etc.*, have also been performed by *BABAR* and Belle. The results and their uncertainties are summarized in Fig. 12.3 and Table 12.1 of Ref. 93.

12.3.3. α / ϕ_2 :

Since α is the phase between $V_{tb}^*V_{td}$ and $V_{ub}^*V_{ud}$, only time-dependent CP asymmetries in $b \to u\bar{u}d$ decay dominated modes can directly measure $\sin 2\alpha$, in contrast to $\sin 2\beta$, where several different transitions can be used. Since $b \to d$ penguin amplitudes have a different CKM phase than $b \to u\bar{u}d$ tree amplitudes, and their magnitudes are of the same order in λ, the penguin contribution can be sizable, which makes the determination of α complicated. To date, α has been measured in $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ decay modes.

12.3.3.1. $B \to \pi\pi$*:*

It is now experimentally well established that there is a sizable contribution of $b \to d$ penguin amplitudes in $B \to \pi\pi$ decays. Thus, $S_{\pi^+\pi^-}$ in the time-dependent $B^0 \to \pi^+\pi^-$ analysis does not measure $\sin 2\alpha$, but

$$S_{\pi^+\pi^-} = \sqrt{1 - C_{\pi^+\pi^-}^2}\, \sin(2\alpha + 2\Delta\alpha), \quad (12.21)$$

where $2\Delta\alpha$ is the phase difference between $e^{2i\gamma}\bar{A}_{\pi^+\pi^-}$ and $A_{\pi^+\pi^-}$. The value of $\Delta\alpha$, hence α, can be extracted using the isospin relation among the amplitudes of $B^0 \to \pi^+\pi^-$, $B^0 \to \pi^0\pi^0$, and $B^+ \to \pi^+\pi^0$ decays [103],

$$\frac{1}{\sqrt{2}}\, A_{\pi^+\pi^-} + A_{\pi^0\pi^0} - A_{\pi^+\pi^0} = 0\,, \quad (12.22)$$

and a similar expression for the $\bar{A}_{\pi\pi}$'s. This method utilizes the fact that a pair of pions from $B \to \pi\pi$ decay must be in a zero angular momentum state, and, because of Bose statistics, they must have even isospin. Consequently, $\pi^0\pi^\pm$ is in a pure isospin-2 state, while the penguin amplitudes only contribute to the isospin-0 final state. The

latter does not hold for the electroweak penguin amplitudes, but their effect is expected to be small. The isospin analysis uses the world averages [98,104] $S_{\pi^+\pi^-} = -0.66 \pm 0.06$, $C_{\pi^+\pi^-} = -0.31 \pm 0.05$, the branching fractions of all three modes, and the direct CP asymmetry $C_{\pi^0\pi^0} = -0.43^{+0.25}_{-0.24}$. This analysis leads to 16 mirror solutions for $0 \le \alpha < 2\pi$. Because of this, and the sizable experimental error of the $B^0 \to \pi^0\pi^0$ rate and CP asymmetry, only a loose constraint on α can be obtained at present [105], $0° < \alpha < 10.1°$, $80.0° < \alpha < 104.0°$, $119.0° < \alpha < 151.0°$, and $165.2° < \alpha < 180°$ at 68% CL.

12.3.3.2. $B \to \rho\rho$:

The decay $B^0 \to \rho^+\rho^-$ contains two vector mesons in the final state, which in general is a mixture of CP-even and CP-odd components. Therefore, it was thought that extracting α from this mode would be complicated.

However, the longitudinal polarization fractions (f_L) in $B^+ \to \rho^+\rho^0$ and $B^0 \to \rho^+\rho^-$ decays were measured to be close to unity [106], which implies that the final states are almost purely CP-even. Furthermore, $\mathcal{B}(B^0 \to \rho^0\rho^0) = (0.97 \pm 0.24) \times 10^{-6}$ is much smaller than $\mathcal{B}(B^0 \to \rho^+\rho^-) = (24.2^{+3.1}_{-3.2}) \times 10^{-6}$ and $\mathcal{B}(B^+ \to \rho^+\rho^0) = (24.0^{+1.9}_{-2.0}) \times 10^{-6}$ [65], which implies that the effect of the penguin diagrams is small. The isospin analysis using the world averages, $S_{\rho^+\rho^-} = -0.05 \pm 0.17$ and $C_{\rho^+\rho^-} = -0.06 \pm 0.13$ [65], together with the time-dependent CP asymmetry, $S_{\rho^0\rho^0} = -0.3 \pm 0.7$ and $C_{\rho^0\rho^0} = -0.2 \pm 0.9$ [107], and the above-mentioned branching fractions, gives $0° < \alpha < 5.4°$, $84.6° < \alpha < 95.3°$ and $174.8° < \alpha < 180°$ at 68% CL [105], with mirror solutions at $3\pi/2 - \alpha$. A possible small violation of Eq. (12.22) due to the finite width of the ρ [108] is neglected.

12.3.3.3. $B \to \rho\pi$:

The final state in $B^0 \to \rho^+\pi^-$ decay is not a CP eigenstate, but this decay proceeds via the same quark-level diagrams as $B^0 \to \pi^+\pi^-$, and both B^0 and $\overline{B}{}^0$ can decay to $\rho^+\pi^-$. Consequently, mixing-induced CP violations can occur in four decay amplitudes, $B^0 \to \rho^\pm\pi^\mp$ and $\overline{B}{}^0 \to \rho^\pm\pi^\mp$. The time-dependent Dalitz plot analysis of $B^0 \to \pi^+\pi^-\pi^0$ decays permits the extraction of α with a single discrete ambiguity, $\alpha \to \alpha + \pi$, since one knows the variation of the strong phases in the interference regions of the $\rho^+\pi^-$, $\rho^-\pi^+$, and $\rho^0\pi^0$ amplitudes in the Dalitz plot [109]. The combination of Belle [110] and *BABAR* [111] measurements gives $\alpha = (54.1^{+7.7}_{-10.3})°$ and $(141.8^{+4.7}_{-5.4})°$ [105]. This constraint is still moderate.

Combining the $B \to \pi\pi$, $\rho\pi$, and $\rho\rho$ decay modes [105], α is constrained as

$$\alpha = (85.4^{+3.9}_{-3.8})°. \tag{12.23}$$

A different statistical approach [112] gives similar constraint from the combination of these measurements.

12.3.4. γ / ϕ_3 :

By virtue of Eq. (12.16), γ does not depend on CKM elements involving the top quark, so it can be measured in tree-level B decays. This is an important distinction from the measurements of α and β, and implies that the measurements of γ are unlikely to be affected by physics beyond the SM.

12.3.4.1. $B^\pm \to DK^\pm$:

The interference of $B^- \to D^0K^-$ ($b \to c\bar{u}s$) and $B^- \to \overline{D}{}^0K^-$ ($b \to u\bar{c}s$) transitions can be studied in final states accessible in both D^0 and $\overline{D}{}^0$ decays [92]. In principle, it is possible to extract the B and D decay amplitudes, the relative strong phases, and the weak phase γ from the data.

A practical complication is that the precision depends sensitively on the ratio of the interfering amplitudes

$$r_B = \left| A(B^- \to \overline{D}{}^0K^-)/A(B^- \to D^0K^-) \right|, \tag{12.24}$$

which is around 0.1−0.2. The original GLW method [113,114] considers D decays to CP eigenstates, such as $B^\pm \to D^{(*)}_{CP}(\to \pi^+\pi^-)K^{\pm(*)}$. To alleviate the smallness of r_B and make the interfering amplitudes (which are products of the B and D decay amplitudes) comparable in magnitude, the ADS method [115] considers final states where Cabibbo-allowed $\overline{D}{}^0$ and doubly-Cabibbo-suppressed D^0 decays interfere. Extensive measurements have been made by the B factories [116,117], CDF [118] and LHCb [119] using both methods.

It was realized that both D^0 and $\overline{D}{}^0$ have large branching fractions to certain three-body final states, such as $K_S\pi^+\pi^-$, and the analysis can be optimized by studying the Dalitz plot dependence of the interferences [120,121]. The best present determination of γ comes from this method. Belle [122] and *BABAR* [123] obtained $\gamma = (78^{+11}_{-12} \pm 4 \pm 9)°$ and $\gamma = (68 \pm 14 \pm 4 \pm 3)°$, respectively, where the last uncertainty is due to the D-decay modeling. (LHCb also measured $\gamma = (44^{+43}_{-38})°$ with the same method [124].) The error is sensitive to the central value of the amplitude ratio r_B (and r_B^* for the D^*K mode), for which Belle found somewhat larger central values than *BABAR*. The same values of $r_B^{(*)}$ enter the ADS analyses, and the data can be combined to fit for $r_B^{(*)}$ and γ. The D^0–$\overline{D}{}^0$ mixing has been neglected in all measurements, but its effect on γ is far below the present experimental accuracy [125], unless D^0–$\overline{D}{}^0$ mixing is due to CP-violating new physics, in which case it can be included in the analysis [126].

Combining the GLW, ADS, and Dalitz analyses [105], γ is constrained as

$$\gamma = (68.0^{+8.0}_{-8.5})°. \tag{12.25}$$

Similar results are found in Ref. [112].

12.3.4.2. $B^0 \to D^{(*)\pm}\pi^\mp$:

The interference of $b \to u$ and $b \to c$ transitions can be studied in $\overline{B}{}^0 \to D^{(*)+}\pi^-$ ($b \to c\bar{u}d$) and $\overline{B}{}^0 \to B^0 \to D^{(*)+}\pi^-$ ($\bar{b} \to \bar{u}c\bar{d}$) decays and their CP conjugates, since both B^0 and $\overline{B}{}^0$ decay to $D^{(*)\pm}\pi^\mp$ (or $D^\pm\rho^\mp$, *etc.*). Since there are only tree and no penguin contributions to these decays, in principle, it is possible to extract from the four time-dependent rates the magnitudes of the two hadronic amplitudes, their relative strong phase, and the weak phase between the two decay paths, which is $2\beta + \gamma$.

A complication is that the ratio of the interfering amplitudes is very small, $r_{D\pi} = A(B^0 \to D^+\pi^-)/A(\overline{B}{}^0 \to D^+\pi^-) = \mathcal{O}(0.01)$ (and similarly for $r_{D^*\pi}$ and $r_{D\rho}$), and therefore it has not been possible to measure it. To obtain $2\beta + \gamma$, $SU(3)$ flavor symmetry and dynamical assumptions have been used to relate $A(\overline{B}{}^0 \to D^-\pi^+)$ to $A(\overline{B}{}^0 \to D_s^-\pi^+)$, so this measurement is not model-independent at present. Combining the $D^\pm\pi^\mp$, $D^{*\pm}\pi^\mp$ and $D^\pm\rho^\mp$ measurements [127] gives $\sin(2\beta + \gamma) > 0.68$ at 68% CL [105], consistent with the previously discussed results for β and γ. The amplitude ratio is much larger in the analogous $B_s^0 \to D_s^\pm K^\mp$ decays, which will allow a model-independently extraction of $\gamma - 2\beta_s$ [128] at LHCb [129] (here $\beta_s = \arg(-V_{ts}V_{tb}^*/V_{cs}V_{cb}^*)$ is related to the phase of B_s mixing).

12.4. Global fit in the Standard Model

Using the independently measured CKM elements mentioned in the previous sections, the unitarity of the CKM matrix can be checked. We obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9999 \pm 0.0006$ (1st row), $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.024 \pm 0.032$ (2nd row), $|V_{ud}|^2 + |V_{cd}|^2 + |V_{td}|^2 = 1.000 \pm 0.004$ (1st column), and $|V_{us}|^2 + |V_{cs}|^2 + |V_{ts}|^2 = 1.025 \pm 0.032$ (2nd column), respectively. The uncertainties in the second row and column are dominated by that of $|V_{cs}|$. For the second row, a slightly better check is obtained from the measurement of $\sum_{u,c,d,s,b} |V_{ij}|^2$ in Sec. 12.2.4 minus the sum in the first row above: $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.002 \pm 0.027$. These provide strong tests of the unitarity of the CKM matrix. With the significantly improved direct determination of $|V_{tb}|$, the unitarity checks for the third row and column have also become fairly precise, leaving decreasing room for mixing with other states. The sum of the three angles of the unitarity triangle, $\alpha + \beta + \gamma = (175 \pm 9)°$, is also consistent with the SM expectation.

The CKM matrix elements can be most precisely determined using a global fit to all available measurements and imposing the SM constraints (*i.e.*, three generation unitarity). The fit must also use theory predictions for hadronic matrix elements, which

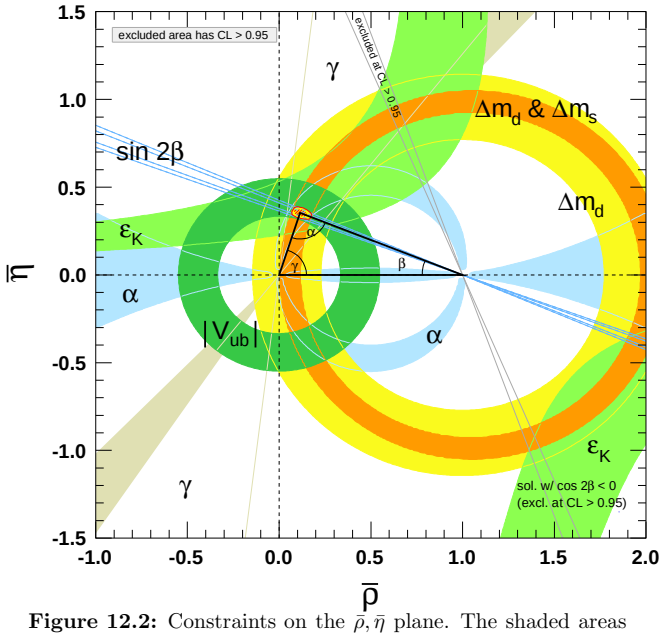

Figure 12.2: Constraints on the $\bar{\rho}, \bar{\eta}$ plane. The shaded areas have 95% CL.

sometimes have significant uncertainties. There are several approaches to combining the experimental data. CKMfitter [6,105] and Ref. 130 (which develops [131,132] further) use frequentist statistics, while UTfit [112,133] uses a Bayesian approach. These approaches provide similar results.

The constraints implied by the unitarity of the three generation CKM matrix significantly reduce the allowed range of some of the CKM elements. The fit for the Wolfenstein parameters defined in Eq. (12.4) gives

$$\lambda = 0.22537 \pm 0.00061\,, \qquad A = 0.814^{+0.023}_{-0.024}\,,$$
$$\bar{\rho} = 0.117 \pm 0.021\,, \qquad \bar{\eta} = 0.353 \pm 0.013\,. \qquad (12.26)$$

These values are obtained using the method of Refs. [6,105]. Using the prescription of Refs. [112,133] gives $\lambda = 0.2255 \pm 0.0006$, $A = 0.818 \pm 0.015$, $\bar{\rho} = 0.124 \pm 0.024$, $\bar{\eta} = 0.354 \pm 0.015$ [134]. The fit results for the magnitudes of all nine CKM elements are

$$V_{\rm CKM} = \begin{pmatrix} 0.97427 \pm 0.00014 & 0.22536 \pm 0.00061 & 0.00355 \pm 0.00015 \\ 0.22522 \pm 0.00061 & 0.97343 \pm 0.00015 & 0.0414 \pm 0.0012 \\ 0.00886^{+0.00033}_{-0.00032} & 0.0405^{+0.0011}_{-0.0012} & 0.99914 \pm 0.00005 \end{pmatrix}, \qquad (12.27)$$

and the Jarlskog invariant is $J = (3.06^{+0.21}_{-0.20}) \times 10^{-5}$.

Figure 12.2 illustrates the constraints on the $\bar{\rho}, \bar{\eta}$ plane from various measurements and the global fit result. The shaded 95% CL regions all overlap consistently around the global fit region.

12.5. Implications beyond the SM

The effects in B, B_s, K, and D decays and mixings due to high-scale physics (W, Z, t, H in the SM, and unknown heavier particles) can be parameterized by operators composed of SM fields, obeying the $SU(3) \times SU(2) \times U(1)$ gauge symmetry. Flavor-changing neutral currents, suppressed in the SM, are especially sensitive to beyond SM (BSM) contributions. Processes studied in great detail, both experimentally and theoretically, include neutral meson mixings, $B_{(s)} \to X\gamma$, $X\ell^+\ell^-$, $\ell^+\ell^-$, $K \to \pi\nu\bar{\nu}$, etc. The BSM contributions to these operators are suppressed by powers of the scale of new physics. Already at lowest order, there are many dimension-6 operators, and the observable effects of BSM interactions are encoded in their coefficients. In the SM, these coefficients are determined by just the four CKM parameters, and the W, Z, and quark masses. For example, Δm_d, $\Gamma(B \to \rho\gamma)$, $\Gamma(B \to \pi\ell^+\ell^-)$, and $\Gamma(B \to \ell^+\ell^-)$ are all proportional to $|V_{td}V_{tb}|^2$ in the SM, however, they may receive unrelated contributions from new physics. The new physics contributions may or may not obey the SM relations. (For example, the flavor sector of the MSSM contains 69 CP-conserving parameters and 41 CP-violating phases, *i.e.*, 40 new ones [135]). Thus, similar to the measurements of $\sin 2\beta$ in tree- and loop-dominated decay modes, overconstraining measurements of the magnitudes and phases of flavor-changing neutral-current amplitudes give good sensitivity to new physics.

To illustrate the level of suppression required for BSM contributions, consider a class of models in which the unitarity of the CKM matrix is maintained, and the dominant effect of new physics is to modify the neutral meson mixing amplitudes [136] by $(z_{ij}/\Lambda^2)(\overline{q}_i\gamma^\mu P_L q_j)^2$ (for recent reviews, see [137,138]). It is only known since the measurements of γ and α that the SM gives the leading contribution to $B^0 - \overline{B}^0$ mixing [6,139]. Nevertheless, new physics with a generic weak phase may still contribute to neutral meson mixings at a significant fraction of the SM [140,141,133]. The existing data imply that $\Lambda/|z_{ij}|^{1/2}$ has to exceed about 10^4 TeV for $K^0 - \overline{K}^0$ mixing, 10^3 TeV for $D^0 - \overline{D}^0$ mixing, 500 TeV for $B^0 - \overline{B}^0$ mixing, and 100 TeV for $B_s^0 - \overline{B}_s^0$ mixing [133,138]. (Some other operators are even better constrained [133].) The constraints are the strongest in the kaon sector, because the CKM suppression is the most severe. Thus, if there is new physics at the TeV scale, $|z_{ij}| \ll 1$ is required. Even if $|z_{ij}|$ are suppressed by a loop factor and $|V_{ti}^* V_{tj}|^2$ (in the down quark sector), similar to the SM, one expects percent-level effects, which may be observable in forthcoming flavor physics experiments. To constrain such extensions of the SM, many measurements irrelevant for the SM-CKM fit, such as the CP asymmetry in semileptonic $B_{d,s}^0$ decays, $A_{\rm SL}^{d,s}$, are important [142]. A DØ measurement sensitive to certain linear combinations of $A_{\rm SL}^d$ and $A_{\rm SL}^s$ shows a 3.6σ hint of a deviation from the SM [143].

Many key measurements which are sensitive to BSM flavor physics are not useful to think about in terms of constraining the unitarity triangle in Fig. 12.1. For example, besides the angles in Eq. (12.16), a key quantity in the B_s system is $\beta_s = \arg(-V_{ts}V_{tb}^*/V_{cs}V_{cb}^*)$, which is the small, λ^2-suppressed, angle of a "squashed" unitarity triangle, obtained by taking the scalar product of the second and third columns. This angle can be measured via time-dependent CP violation in $B_s^0 \to J/\psi\,\phi$, similar to β in $B^0 \to J/\psi K^0$. Since the $J/\psi\,\phi$ final state is not a CP eigenstate, an angular analysis of the decay products is needed to separate the CP-even and CP-odd components, which give opposite asymmetries. In the SM, the asymmetry for the CP-even part is $2\beta_s$ (sometimes the notation $\phi_s = -2\beta_s$ plus a possible BSM contribution to the B_s mixing phase is used). Testing if the data agree with the SM prediction, $2\beta_s = 0.0363 \pm 0.0018$ [105], is another sensitive test of the SM. After the first Tevatron CP-asymmetry measurements of $B_s^0 \to J/\psi\phi$ hinted at a possible tension with the SM, the current world average, dominated by LHCb [145] and including $B_s \to J/\psi\,K^+K^-$ and $J/\psi\,\pi^+\pi^-$ measurements, is $2\beta_s = 0.00 \pm 0.07$ [65]. This uncertainty is about 40 times the SM uncertainty; thus a lot will be learned from higher precision measurements in the future.

In the kaon sector, the two measured CP-violating observables ϵ and ϵ' are tiny, so models in which all sources of CP violation are small were viable before the B-factory measurements. Since the measurement of $\sin 2\beta$, we know that CP violation can be an $\mathcal{O}(1)$ effect, and only flavor mixing is suppressed between the three quark generations. Thus, many models with spontaneous CP violation are excluded. In the kaon sector, a very clean test of the SM will come from measurements of $K^+ \to \pi^+\nu\bar{\nu}$ and $K_L^0 \to \pi^0\nu\bar{\nu}$. These loop-induced rare decays are sensitive to new physics, and will allow a determination of β, independent of its value measured in B decays [146].

The CKM elements are fundamental parameters, so they should be measured as precisely as possible. The overconstraining measurements of CP asymmetries, mixing, semileptonic, and rare decays severely constrain the magnitudes and phases of possible new physics contributions to flavor-changing interactions. If new particles are observed at the LHC, it will be important to explore their flavor parameters as precisely as possible to understand the underlying physics.

13. *CP* VIOLATION IN THE QUARK SECTOR

Revised February 2014 by T. Gershon (University of Warwick) and Y. Nir (Weizmann Institute).

The CP transformation combines charge conjugation C with parity P. Under C, particles and antiparticles are interchanged, by conjugating all internal quantum numbers, *e.g.*, $Q \to -Q$ for electromagnetic charge. Under P, the handedness of space is reversed, $\vec{x} \to -\vec{x}$. Thus, for example, a left-handed electron e^-_L is transformed under CP into a right-handed positron, e^+_R.

If CP were an exact symmetry, the laws of Nature would be the same for matter and for antimatter. We observe that most phenomena are C- and P-symmetric, and therefore, also CP-symmetric. In particular, these symmetries are respected by the gravitational, electromagnetic, and strong interactions. The weak interactions, on the other hand, violate C and P in the strongest possible way. For example, the charged W bosons couple to left-handed electrons, e^-_L, and to their CP-conjugate right-handed positrons, e^+_R, but to neither their C-conjugate left-handed positrons, e^+_L, nor their P-conjugate right-handed electrons, e^-_R. While weak interactions violate C and P separately, CP is still preserved in most weak interaction processes. The CP symmetry is, however, violated in certain rare processes, as discovered in neutral K decays in 1964 [1], and observed in recent years in B decays. A K_L meson decays more often to $\pi^- e^+ \nu_e$ than to $\pi^+ e^- \overline{\nu}_e$, thus allowing electrons and positrons to be unambiguously distinguished, but the decay-rate asymmetry is only at the 0.003 level. The CP-violating effects observed in the B system are larger: the parameter describing the CP asymmetry in the decay time distribution of $B^0/\overline{B}^0$ meson transitions to CP eigenstates like $J/\psi K_S$ is about 0.7 [2,3]. These effects are related to $K^0 - \overline{K}^0$ and $B^0 - \overline{B}^0$ mixing, but CP violation arising solely from decay amplitudes has also been observed, first in $K \to \pi\pi$ decays [4–6], and more recently in B^0 [7,8], B^+ [9–11], and B^0_s [12] decays. CP violation is not yet experimentally established in the D system. Moreover, CP violation has not yet been observed in the decay of any baryon, nor in processes involving the top quark, nor in flavor-conserving processes such as electric dipole moments, nor in the lepton sector.

In addition to parity and to continuous Lorentz transformations, there is one other spacetime operation that could be a symmetry of the interactions: time reversal T, $t \to -t$. Violations of T symmetry have been observed in neutral K decays [13]. More recently, exploiting the fact that for neutral B mesons both flavor tagging and CP tagging can be used [14], T violation has been observed between states that are not CP-conjugate [15]. Moreover, T violation is expected as a corollary of CP violation if the combined CPT transformation is a fundamental symmetry of Nature [16]. All observations indicate that CPT is indeed a symmetry of Nature. Furthermore, one cannot build a locally Lorentz-invariant quantum field theory with a Hermitian Hamiltonian that violates CPT. (At several points in our discussion, we avoid assumptions about CPT, in order to identify cases where evidence for CP violation relies on assumptions about CPT.)

Within the Standard Model, CP symmetry is broken by complex phases in the Yukawa couplings (that is, the couplings of the Higgs scalar to quarks). When all manipulations to remove unphysical phases in this model are exhausted, one finds that there is a single CP-violating parameter [17]. In the basis of mass eigenstates, this single phase appears in the 3×3 unitary matrix that gives the W-boson couplings to an up-type antiquark and a down-type quark. (If the Standard Model is supplemented with Majorana mass terms for the neutrinos, the analogous mixing matrix for leptons has three CP-violating phases.) The beautifully consistent and economical Standard-Model description of CP violation in terms of Yukawa couplings, known as the Kobayashi-Maskawa (KM) mechanism [17], agrees with all measurements to date. (Some measurements are in tension with the predictions, and are discussed in more detail below. Pending verification, the results are not considered to change the overall picture of agreement with the Standard Model.) Furthermore, one can fit the data allowing new physics contributions to loop processes to compete with, or even dominate over, the Standard Model amplitudes [18,19]. Such an analysis provides model-independent proof that the KM phase is different from zero, and that the matrix of three-generation quark mixing is the dominant source of CP violation in meson decays.

The current level of experimental accuracy and the theoretical uncertainties involved in the interpretation of the various observations leave room, however, for additional subdominant sources of CP violation from new physics. Indeed, almost all extensions of the Standard Model imply that there are such additional sources. Moreover, CP violation is a necessary condition for baryogenesis, the process of dynamically generating the matter-antimatter asymmetry of the Universe [20]. Despite the phenomenological success of the KM mechanism, it fails (by several orders of magnitude) to accommodate the observed asymmetry [21]. This discrepancy strongly suggests that Nature provides additional sources of CP violation beyond the KM mechanism. (The evidence for neutrino masses implies that CP can be violated also in the lepton sector. This situation makes leptogenesis [22], a scenario where CP-violating phases in the Yukawa couplings of the neutrinos play a crucial role in the generation of the baryon asymmetry, a very attractive possibility.) The expectation of new sources motivates the large ongoing experimental effort to find deviations from the predictions of the KM mechanism.

CP violation can be experimentally searched for in a variety of processes, such as hadron decays, electric dipole moments of neutrons, electrons and nuclei, and neutrino oscillations. Hadron decays via the weak interaction probe flavor-changing CP violation. The search for electric dipole moments may find (or constrain) sources of CP violation that, unlike the KM phase, are not related to flavor-changing couplings. Following the discovery of the Higgs boson [23,24], searches for CP violation in the Higgs sector are becoming feasible. Future searches for CP violation in neutrino oscillations might provide further input on leptogenesis.

The present measurements of CP asymmetries provide some of the strongest constraints on the weak couplings of quarks. Future measurements of CP violation in K, D, B, and B^0_s meson decays will provide additional constraints on the flavor parameters of the Standard Model, and can probe new physics. In this review, we give the formalism and basic physics that are relevant to present and near future measurements of CP violation in the quark sector.

Before going into details, we list here the observables where CP violation has been observed at a level above 5σ [25–27]:

- Indirect CP violation in $K \to \pi\pi$ and $K \to \pi\ell\nu$ decays, and in the $K_L \to \pi^+\pi^- e^+ e^-$ decay, is given by

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}\,. \tag{13.1}$$

- Direct CP violation in $K \to \pi\pi$ decays is given by

$$\mathcal{R}e(\epsilon'/\epsilon) = (1.65 \pm 0.26) \times 10^{-3}\,. \tag{13.2}$$

- CP violation in the interference of mixing and decay in the tree-dominated $b \to c\bar{c}s$ transitions, such as $B^0 \to \psi K^0$, is given by (we use K^0 throughout to denote results that combine K_S and K_L modes, but use the sign appropriate to K_S):

$$S_{\psi K^0} = +0.682 \pm 0.019\,. \tag{13.3}$$

- CP violation in the interference of mixing and decay in various modes related to $b \to q\bar{q}s$ (penguin) transitions is given by

$$S_{\eta' K^0} = +0.63 \pm 0.06\,, \tag{13.4}$$

$$S_{\phi K^0} = +0.74\,^{+0.11}_{-0.13}\,, \tag{13.5}$$

$$S_{f_0 K^0} = +0.69\,^{+0.10}_{-0.12}\,, \tag{13.6}$$

$$S_{K^+K^-K_S} = +0.68\,^{+0.09}_{-0.10}\,, \tag{13.7}$$

- CP violation in the interference of mixing and decay in the $B^0 \to \pi^+\pi^-$ mode is given by

$$S_{\pi^+\pi^-} = -0.66 \pm 0.06\,. \tag{13.8}$$

- Direct CP violation in the $B^0 \to \pi^+\pi^-$ mode is given by

$$C_{\pi^+\pi^-} = -0.31 \pm 0.05\,. \tag{13.9}$$

- CP violation in the interference of mixing and decay in various modes related to $b \to c\bar{c}d$ transitions is given by

$$S_{\psi\pi^0} = -0.93 \pm 0.15\,, \tag{13.10}$$

$$S_{D^+D^-} = -0.98 \pm 0.17\,. \tag{13.11}$$

$$S_{D^{*+}D^{*-}} = -0.71 \pm 0.09\,. \tag{13.12}$$

- Direct CP violation in the $\overline{B}^0 \to K^-\pi^+$ mode is given by

$$\mathcal{A}_{\overline{B}^0 \to K^-\pi^+} = -0.082 \pm 0.006\,. \tag{13.13}$$

- Direct CP violation in $B^\pm \to D_+K^\pm$ decays (D_+ is the CP-even neutral D state) is given by

$$\mathcal{A}_{B^+ \to D_+K^+} = +0.19 \pm 0.03\,. \tag{13.14}$$

- Direct CP violation in the $\overline{B}{}^0_s \to K^+\pi^-$ mode is given by

$$\mathcal{A}_{\overline{B}{}^0_s \to K^+\pi^-} = +0.26 \pm 0.04\,. \tag{13.15}$$

In addition, large CP violation effects have recently been observed in certain regions of the phase space of $B^\pm \to K^+K^-K^\pm$, $\pi^+\pi^-K^\pm$, $\pi^+\pi^-\pi^\pm$ and $K^+K^-\pi^\pm$ decays [28,29].

13.1. Formalism

The phenomenology of CP violation for neutral flavored mesons is particularly interesting, since many of the observables can be cleanly interpreted. Although the phenomenology is superficially different for K^0, D^0, B^0, and B^0_s decays, this is primarily because each of these systems is governed by a different balance between decay rates, oscillations, and lifetime splitting. However, the general considerations presented in this section are identical for all flavored neutral pseudoscalar mesons. The phenomenology of CP violation for neutral mesons that do not carry flavor quantum numbers (such as the $\eta^{(\prime)}$ state) is quite different: such states are their own antiparticles and have definite CP eigenvalues, so the signature of CP violation is simply the decay to a final state with the opposite CP. Such decays are mediated by the electromagnetic or (OZI-suppressed) strong interaction, where CP violation is not expected and has not yet been observed. In the remainder of this review, we restrict ourselves to considerations of weakly decaying hadrons.

In this section, we present a general formalism for, and classification of, CP violation in the decay of a weakly decaying hadron, denoted M. We pay particular attention to the case that M is a K^0, D^0, B^0, or B^0_s meson. Subsequent sections describe the CP-violating phenomenology, approximations, and alternative formalisms that are specific to each system.

13.1.1. ***Charged- and neutral-hadron decays*** : We define decay amplitudes of M (which could be charged or neutral) and its CP conjugate $\overline{M}$ to a multi-particle final state f and its CP conjugate $\overline{f}$ as

$$A_f = \langle f\,|\mathcal{H}|\,M\rangle\,, \quad \overline{A}_f = \langle f\,|\mathcal{H}|\,\overline{M}\rangle\,,$$
$$A_{\overline{f}} = \langle \overline{f}\,|\mathcal{H}|\,M\rangle\,, \quad \overline{A}_{\overline{f}} = \langle \overline{f}\,|\mathcal{H}|\,\overline{M}\rangle\,, \tag{13.16}$$

where $\mathcal{H}$ is the Hamiltonian governing weak interactions. The action of CP on these states introduces phases ξ_M and ξ_f that depend on their flavor content, according to

$$CP|M\rangle = e^{+i\xi_M}\,|\overline{M}\rangle\,, \quad CP|f\rangle = e^{+i\xi_f}\,|\overline{f}\rangle\,, \tag{13.17}$$

with

$$CP|\overline{M}\rangle = e^{-i\xi_M}\,|M\rangle\,, \quad CP|\overline{f}\rangle = e^{-i\xi_f}\,|f\rangle \tag{13.18}$$

so that $(CP)^2 = 1$. The phases ξ_M and ξ_f are arbitrary and unobservable because of the flavor symmetry of the strong interaction. If CP is conserved by the dynamics, $[CP, \mathcal{H}] = 0$, then A_f and $\overline{A}_{\overline{f}}$ have the same magnitude and an arbitrary unphysical relative phase

$$\overline{A}_{\overline{f}} = e^{i(\xi_f - \xi_M)}\,A_f\,. \tag{13.19}$$

13.1.2. ***Neutral-meson mixing*** : A state that is initially a superposition of M^0 and $\overline{M}^0$, say

$$|\psi(0)\rangle = a(0)|M^0\rangle + b(0)|\overline{M}^0\rangle\,, \tag{13.20}$$

will evolve in time acquiring components that describe all possible decay final states $\{f_1, f_2, \ldots\}$, that is,

$$|\psi(t)\rangle = a(t)|M^0\rangle + b(t)|\overline{M}^0\rangle + c_1(t)|f_1\rangle + c_2(t)|f_2\rangle + \cdots\,. \tag{13.21}$$

If we are interested in computing only the values of $a(t)$ and $b(t)$ (and not the values of all $c_i(t)$), and if the times t in which we are interested are much larger than the typical strong interaction scale, then we can use a much simplified formalism [30]. The simplified time evolution is determined by a 2×2 effective Hamiltonian $\mathbf{H}$ that is not Hermitian, since otherwise the mesons would only oscillate and not decay. Any complex matrix, such as $\mathbf{H}$, can be written in terms of Hermitian matrices $\mathbf{M}$ and $\mathbf{\Gamma}$ as

$$\mathbf{H} = \mathbf{M} - \frac{i}{2}\mathbf{\Gamma}\,. \tag{13.22}$$

$\mathbf{M}$ and $\mathbf{\Gamma}$ are associated with $(M^0, \overline{M}^0) \leftrightarrow (M^0, \overline{M}^0)$ transitions via off-shell (dispersive), and on-shell (absorptive) intermediate states, respectively. Diagonal elements of $\mathbf{M}$ and $\mathbf{\Gamma}$ are associated with the flavor-conserving transitions $M^0 \to M^0$ and $\overline{M}^0 \to \overline{M}^0$, while off-diagonal elements are associated with flavor-changing transitions $M^0 \leftrightarrow \overline{M}^0$.

The eigenvectors of $\mathbf{H}$ have well-defined masses and decay widths. To specify the components of the strong interaction eigenstates, M^0 and $\overline{M}^0$, in the light (M_L) and heavy (M_H) mass eigenstates, we introduce three complex parameters: p, q, and, for the case that both CP and CPT are violated in mixing, z:

$$|M_L\rangle \propto p\sqrt{1-z}\,|M^0\rangle + q\sqrt{1+z}\,|\overline{M}^0\rangle$$
$$|M_H\rangle \propto p\sqrt{1+z}\,|M^0\rangle - q\sqrt{1-z}\,|\overline{M}^0\rangle\,, \tag{13.23}$$

with the normalization $|q|^2 + |p|^2 = 1$ when $z = 0$. (Another possible choice, which is in standard usage for K mesons, defines the mass eigenstates according to their lifetimes: K_S for the short-lived and K_L for the long-lived state. The K_L is experimentally found to be the heavier state. Yet another choice is often used for the D mesons: the eigenstates are labelled according to their dominant CP content [31].)

The real and imaginary parts of the eigenvalues $\omega_{L,H}$ corresponding to $|M_{L,H}\rangle$ represent their masses and decay widths, respectively. The mass and width splittings are

$$\Delta m \equiv m_H - m_L = \mathcal{R}e(\omega_H - \omega_L)\,,$$
$$\Delta\Gamma \equiv \Gamma_H - \Gamma_L = -2\,\mathcal{I}m(\omega_H - \omega_L)\,. \tag{13.24}$$

Note that here Δm is positive by definition, while the sign of $\Delta\Gamma$ is to be experimentally determined. The sign of $\Delta\Gamma$ has not yet been established for B^0 mesons, while $\Delta\Gamma < 0$ is established for K and B^0_s mesons. The Standard Model predicts $\Delta\Gamma < 0$ also for $B^0_{(s)}$ mesons (for this reason, $\Delta\Gamma = \Gamma_L - \Gamma_H$, which is still a signed quantity, is often used in the B^0 and B^0_s literature and is the convention used in the PDG experimental summaries).

Solving the eigenvalue problem for $\mathbf{H}$ yields

$$\left(\frac{q}{p}\right)^2 = \frac{\mathbf{M}^*_{12} - (i/2)\mathbf{\Gamma}^*_{12}}{\mathbf{M}_{12} - (i/2)\mathbf{\Gamma}_{12}} \tag{13.25}$$

and

$$z \equiv \frac{\delta m - (i/2)\delta\Gamma}{\Delta m - (i/2)\Delta\Gamma}\,, \tag{13.26}$$

where

$$\delta m \equiv \mathbf{M}_{11} - \mathbf{M}_{22}\,, \quad \delta\Gamma \equiv \mathbf{\Gamma}_{11} - \mathbf{\Gamma}_{22} \tag{13.27}$$

are the differences in effective mass and decay-rate expectation values for the strong interaction states M^0 and $\overline{M}^0$.

If either CP or CPT is a symmetry of $\mathbf{H}$ (independently of whether T is conserved or violated), then the values of δm and $\delta\Gamma$ are both zero, and hence $z = 0$. We also find that

$$\omega_H - \omega_L = 2\sqrt{\left(\mathbf{M}_{12} - \frac{i}{2}\mathbf{\Gamma}_{12}\right)\left(\mathbf{M}^*_{12} - \frac{i}{2}\mathbf{\Gamma}^*_{12}\right)}\,. \tag{13.28}$$

If either CP or T is a symmetry of $\mathbf{H}$ (independently of whether CPT is conserved or violated), then $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is real, leading to

$$\left(\frac{q}{p}\right)^2 = e^{2i\xi_M} \quad \Rightarrow \quad \left|\frac{q}{p}\right| = 1\,, \tag{13.29}$$

where ξ_M is the arbitrary unphysical phase introduced in Eq. (13.18). If, and only if, CP is a symmetry of $\mathbf{H}$ (independently of CPT and T), then both of the above conditions hold, with the result that the mass eigenstates are orthogonal

$$\langle M_H | M_L \rangle = |p|^2 - |q|^2 = 0\,. \tag{13.30}$$

13.1.3. ***CP-violating observables*** : All CP-violating observables in M and $\overline{M}$ decays to final states f and $\overline{f}$ can be expressed in terms of phase-convention-independent combinations of A_f, $\overline{A}_f$, $A_{\overline{f}}$, and $\overline{A}_{\overline{f}}$, together with, for neutral meson decays only, q/p. CP violation in charged meson and all baryon decays depends only on the combination $|\overline{A}_{\overline{f}}/A_f|$, while CP violation in flavored neutral meson decays is complicated by $M^0 \leftrightarrow \overline{M}^0$ oscillations, and depends, additionally, on $|q/p|$ and on $\lambda_f \equiv (q/p)(\overline{A}_f/A_f)$.

The decay rates of the two neutral kaon mass eigenstates, K_S and K_L, are different enough ($\Gamma_S/\Gamma_L \sim 500$) that one can, in most cases, actually study their decays independently. For D^0, B^0, and B^0_s mesons, however, values of $\Delta\Gamma/\Gamma$ (where $\Gamma \equiv (\Gamma_H + \Gamma_L)/2$) are relatively small, and so both mass eigenstates must be considered in their evolution. We denote the state of an initially pure $|M^0\rangle$ or $|\overline{M}^0\rangle$ after an elapsed proper time t as $|M^0_{\rm phys}(t)\rangle$ or $|\overline{M}^0_{\rm phys}(t)\rangle$, respectively. Using the effective Hamiltonian approximation, but not assuming CPT is a good symmetry, we obtain

$$\begin{aligned}
|M^0_{\rm phys}(t)\rangle &= \left(g_+(t) + z\,g_-(t)\right)|M^0\rangle - \sqrt{1-z^2}\,\frac{q}{p}\,g_-(t)|\overline{M}^0\rangle\,,\\
|\overline{M}^0_{\rm phys}(t)\rangle &= \left(g_+(t) - z\,g_-(t)\right)|\overline{M}^0\rangle - \sqrt{1-z^2}\,\frac{p}{q}\,g_-(t)|M^0\rangle\,,
\end{aligned} \tag{13.31}$$

where

$$g_\pm(t) \equiv \frac{1}{2}\left(e^{-im_H t - \frac{1}{2}\Gamma_H t} \pm e^{-im_L t - \frac{1}{2}\Gamma_L t}\right) \tag{13.32}$$

and $z = 0$ if either CPT or CP is conserved.

Defining $x \equiv \Delta m/\Gamma$ and $y \equiv \Delta\Gamma/(2\Gamma)$, and assuming $z = 0$, one obtains the following time-dependent decay rates:

$$\begin{aligned}
&\frac{d\Gamma\left[M^0_{\rm phys}(t) \to f\right]/dt}{e^{-\Gamma t}\mathcal{N}_f} =\\
&\quad\left(|A_f|^2 + |(q/p)\overline{A}_f|^2\right)\cosh(y\Gamma t) + \left(|A_f|^2 - |(q/p)\overline{A}_f|^2\right)\cos(x\Gamma t)\\
&\quad + 2\,\mathcal{R}e((q/p)A^*_f\overline{A}_f)\sinh(y\Gamma t) - 2\,\mathcal{I}m((q/p)A^*_f\overline{A}_f)\sin(x\Gamma t)\,,
\end{aligned} \tag{13.33}$$

$$\begin{aligned}
&\frac{d\Gamma\left[\overline{M}^0_{\rm phys}(t) \to f\right]/dt}{e^{-\Gamma t}\mathcal{N}_f} =\\
&\quad\left(|(p/q)A_f|^2 + |\overline{A}_f|^2\right)\cosh(y\Gamma t) - \left(|(p/q)A_f|^2 - |\overline{A}_f|^2\right)\cos(x\Gamma t)\\
&\quad + 2\,\mathcal{R}e((p/q)A_f\overline{A}^*_f)\sinh(y\Gamma t) - 2\,\mathcal{I}m((p/q)A_f\overline{A}^*_f)\sin(x\Gamma t)\,,
\end{aligned} \tag{13.34}$$

where $\mathcal{N}_f$ is a common, time-independent, normalization factor that can be determined bearing in mind that the range of t is $0 < t < \infty$. Decay rates to the CP-conjugate final state $\overline{f}$ are obtained analogously, with $\mathcal{N}_f = \mathcal{N}_{\overline{f}}$ and the substitutions $A_f \to A_{\overline{f}}$ and $\overline{A}_f \to \overline{A}_{\overline{f}}$ in Eqs. (13.33, 13.34). Terms proportional to $|A_f|^2$ or $|\overline{A}_f|^2$ are associated with decays that occur without any net $M^0 \leftrightarrow \overline{M}^0$ oscillation, while terms proportional to $|(q/p)\overline{A}_f|^2$ or $|(p/q)A_f|^2$ are associated with decays following a net oscillation. The $\sinh(y\Gamma t)$ and $\sin(x\Gamma t)$ terms of Eqs. (13.33, 13.34) are associated with the interference between these two cases. Note that, in multi-body decays, amplitudes are functions of phase-space variables. Interference may be present in some regions but not others, and is strongly influenced by resonant substructure.

When neutral pseudoscalar mesons are produced coherently in pairs from the decay of a vector resonance, $V \to M^0\overline{M}^0$ (for example, $\Upsilon(4S) \to B^0\overline{B}^0$ or $\phi \to K^0\overline{K}^0$), the time-dependence of their subsequent decays to final states f_1 and f_2 has a similar form to Eqs. (13.33, 13.34):

$$\begin{aligned}
&\frac{d\Gamma\left[V_{\rm phys}(t_1,t_2) \to f_1 f_2\right]/d(\Delta t)}{e^{-\Gamma|\Delta t|}\mathcal{N}_{f_1 f_2}} =\\
&\quad\left(|a_+|^2 + |a_-|^2\right)\cosh(y\Gamma\Delta t) + \left(|a_+|^2 - |a_-|^2\right)\cos(x\Gamma\Delta t)\\
&\quad - 2\,\mathcal{R}e(a^*_+ a_-)\sinh(y\Gamma\Delta t) + 2\,\mathcal{I}m(a^*_+ a_-)\sin(x\Gamma\Delta t)\,,
\end{aligned} \tag{13.35}$$

where $\Delta t \equiv t_2 - t_1$ is the difference in the production times, t_1 and t_2, of f_1 and f_2, respectively, and the dependence on the average decay time and on decay angles has been integrated out. The normalisation factor $\mathcal{N}_{f_1 f_2}$ can be evaluated, noting that the range of Δt is $-\infty < \Delta t < \infty$. The coefficients in Eq. (13.35) are determined by the amplitudes for no net oscillation from $t_1 \to t_2$, $\overline{A}_{f_1}A_{f_2}$, and $A_{f_1}\overline{A}_{f_2}$, and for a net oscillation, $(q/p)\overline{A}_{f_1}\overline{A}_{f_2}$ and $(p/q)A_{f_1}A_{f_2}$, via

$$a_+ \equiv \overline{A}_{f_1}A_{f_2} - A_{f_1}\overline{A}_{f_2}\,, \tag{13.36}$$

$$a_- \equiv -\sqrt{1-z^2}\left(\frac{q}{p}\overline{A}_{f_1}\overline{A}_{f_2} - \frac{p}{q}A_{f_1}A_{f_2}\right) + z\left(\overline{A}_{f_1}A_{f_2} + A_{f_1}\overline{A}_{f_2}\right)\,.$$

Assuming CPT conservation, $z = 0$, and identifying $\Delta t \to t$ and $f_2 \to f$, we find that Eqs. (13.35, 13.36) reduce essentially to Eq. (13.33) with $A_{f_1} = 0$, $\overline{A}_{f_1} = 1$, or to Eq. (13.34) with $\overline{A}_{f_1} = 0$, $A_{f_1} = 1$. Indeed, such a situation plays an important role in experiments that exploit the coherence of $V \to M^0\overline{M}^0$ (for example $\psi(3770) \to D^0\overline{D}^0$ or $\Upsilon(4S) \to B^0\overline{B}^0$) production. Final states f_1 with $A_{f_1} = 0$ or $\overline{A}_{f_1} = 0$ are called tagging states, because they identify the decaying pseudoscalar meson as, respectively, $\overline{M}^0$ or M^0. Before one of M^0 or $\overline{M}^0$ decays, they evolve in phase, so that there is always one M^0 and one $\overline{M}^0$ present. A tagging decay of one meson sets the clock for the time evolution of the other: it starts at t_1 as purely M^0 or $\overline{M}^0$, with time evolution that depends only on $t_2 - t_1$.

When f_1 is a state that both M^0 and $\overline{M}^0$ can decay into, then Eq. (13.35) contains interference terms proportional to $A_{f_1}\overline{A}_{f_1} \neq 0$ that are not present in Eqs. (13.33, 13.34). Even when f_1 is dominantly produced by M^0 decays rather than $\overline{M}^0$ decays, or vice versa, $A_{f_1}\overline{A}_{f_1}$ can be non-zero owing to doubly-CKM-suppressed decays (with amplitudes suppressed by at least two powers of λ relative to the dominant amplitude, in the language of Section 13.3), and these terms should be considered for precision studies of CP violation in coherent $V \to M^0\overline{M}^0$ decays [32]. The correlations in $V \to M^0\overline{M}^0$ decays can also be exploited to determine strong phase differences between favored and suppressed decay amplitudes [33,34].

13.1.4. ***Classification of CP-violating effects*** : We distinguish three types of CP-violating effects that can occur in the quark sector:

I. CP violation in decay is defined by

$$|\overline{A}_{\overline{f}}/A_f| \neq 1\,. \tag{13.37}$$

In charged meson (and all baryon) decays, where mixing effects are absent, this is the only possible source of CP

asymmetries:

$$\mathcal{A}_{f^\pm} \equiv \frac{\Gamma(M^- \to f^-) - \Gamma(M^+ \to f^+)}{\Gamma(M^- \to f^-) + \Gamma(M^+ \to f^+)} = \frac{|\overline{A}_{f^-}/A_{f^+}|^2 - 1}{|\overline{A}_{f^-}/A_{f^+}|^2 + 1} \,. \quad (13.38)$$

Note that the usual sign convention for CP asymmetries of hadrons is for the difference between the rate involving the particle that contains a heavy quark and that which contains an antiquark. Hence Eq. (13.38) corresponds to the definition for $B^\pm$ mesons, but the opposite sign is used for $D^\pm_{(s)}$ decays.

II. CP (and T) violation in mixing is defined by

$$|q/p| \neq 1 \,. \quad (13.39)$$

In charged-current semileptonic neutral meson decays $M, \overline{M} \to \ell^\pm X$ (taking $|A_{\ell^+X}| = |\overline{A}_{\ell^-X}|$ and $A_{\ell^-X} = \overline{A}_{\ell^+X} = 0$, as is the case in the Standard Model, to lowest order in G_F, and in most of its reasonable extensions), this is the only source of CP violation, and can be measured via the asymmetry of "wrong-sign" decays induced by oscillations:

$$\mathcal{A}_{\rm SL}(t) \equiv \frac{d\Gamma/dt\big[\overline{M}^0_{\rm phys}(t) \to \ell^+ X\big] - d\Gamma/dt\big[M^0_{\rm phys}(t) \to \ell^- X\big]}{d\Gamma/dt\big[\overline{M}^0_{\rm phys}(t) \to \ell^+ X\big] + d\Gamma/dt\big[M^0_{\rm phys}(t) \to \ell^- X\big]}$$
$$= \frac{1 - |q/p|^4}{1 + |q/p|^4}. \quad (13.40)$$

Note that this asymmetry of time-dependent decay rates is actually time-independent.

III. CP violation in interference between a decay without mixing, $M^0 \to f$, and a decay with mixing, $M^0 \to \overline{M}^0 \to f$ (such an effect occurs only in decays to final states that are common to M^0 and $\overline{M}^0$, including all CP eigenstates), is defined by

$$\mathcal{I}m(\lambda_f) \neq 0 \,, \quad (13.41)$$

with

$$\lambda_f \equiv \frac{q}{p}\frac{\overline{A}_f}{A_f} \,. \quad (13.42)$$

This form of CP violation can be observed, for example, using the asymmetry of neutral meson decays into final CP eigenstates f_{CP}

$$\mathcal{A}_{f_{CP}}(t) \equiv \frac{d\Gamma/dt\big[\overline{M}^0_{\rm phys}(t) \to f_{CP}\big] - d\Gamma/dt\big[M^0_{\rm phys}(t) \to f_{CP}\big]}{d\Gamma/dt\big[\overline{M}^0_{\rm phys}(t) \to f_{CP}\big] + d\Gamma/dt\big[M^0_{\rm phys}(t) \to f_{CP}\big]} \,. \quad (13.43)$$

If $\Delta\Gamma = 0$, as expected to a good approximation for B^0 mesons, but not for K^0 and B^0_s mesons, and $|q/p| = 1$, then $\mathcal{A}_{f_{CP}}$ has a particularly simple form (see Eq. (13.88), below). If, in addition, the decay amplitudes fulfill $|\overline{A}_{f_{CP}}| = |A_{f_{CP}}|$, the interference between decays with and without mixing is the only source of the asymmetry and $\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_{f_{CP}})\sin(x\Gamma t)$.

Examples of these three types of CP violation will be given in Sections 13.4, 13.5, and 13.6.

13.2. Theoretical Interpretation: General Considerations

Consider the $M \to f$ decay amplitude A_f, and the CP conjugate process, $\overline{M} \to \overline{f}$, with decay amplitude $\overline{A}_{\overline{f}}$. There are two types of phases that may appear in these decay amplitudes. Complex parameters in any Lagrangian term that contributes to the amplitude will appear in complex conjugate form in the CP-conjugate amplitude. Thus, their phases appear in A_f and $\overline{A}_{\overline{f}}$ with opposite signs. In the Standard Model, these phases occur only in the couplings of the $W^\pm$ bosons, and hence, are often called "weak phases." The weak phase of any single term is convention-dependent. However, the difference between the weak phases in two different terms in A_f is convention-independent. A second type of phase can appear in scattering or decay amplitudes, even when the Lagrangian is real. This phase originates from the possible contribution from intermediate on-shell states in the decay process. Since these phases are generated by CP-invariant interactions, they are the same in A_f and $\overline{A}_{\overline{f}}$. Usually the dominant rescattering is due to strong interactions; hence the designation "strong phases" for the phase shifts so induced. Again, only the relative strong phases between different terms in the amplitude are physically meaningful.

The "weak" and "strong" phases discussed here appear in addition to the spurious CP-transformation phases of Eq. (13.19). Those spurious phases are due to an arbitrary choice of phase convention, and do not originate from any dynamics or induce any CP violation. For simplicity, we set them to zero from here on.

It is useful to write each contribution a_i to A_f in three parts: its magnitude $|a_i|$, its weak phase ϕ_i, and its strong phase δ_i. If, for example, there are two such contributions, $A_f = a_1 + a_2$, we have

$$A_f = |a_1|e^{i(\delta_1+\phi_1)} + |a_2|e^{i(\delta_2+\phi_2)},$$
$$\overline{A}_{\overline{f}} = |a_1|e^{i(\delta_1-\phi_1)} + |a_2|e^{i(\delta_2-\phi_2)}. \quad (13.44)$$

Similarly, for neutral mesons, it is useful to write

$$\mathbf{M}_{12} = |\mathbf{M}_{12}|e^{i\phi_M} \,, \quad \mathbf{\Gamma}_{12} = |\mathbf{\Gamma}_{12}|e^{i\phi_\Gamma} \,. \quad (13.45)$$

Each of the phases appearing in Eqs. (13.44, 13.45) is convention-dependent, but combinations such as $\delta_1 - \delta_2$, $\phi_1 - \phi_2$, $\phi_M - \phi_\Gamma$, and $\phi_M + \phi_1 - \overline{\phi}_1$ (where $\overline{\phi}_1$ is a weak phase contributing to $\overline{A}_f$) are physical.

It is now straightforward to evaluate the various asymmetries in terms of the theoretical parameters introduced here. We will do so with approximations that are often relevant to the most interesting measured asymmetries.

1. The CP asymmetry in charged meson and all baryon decays [Eq. (13.38)] is given by

$$\mathcal{A}_f = -\frac{2|a_1a_2|\sin(\delta_2-\delta_1)\sin(\phi_2-\phi_1)}{|a_1|^2 + |a_2|^2 + 2|a_1a_2|\cos(\delta_2-\delta_1)\cos(\phi_2-\phi_1)} \,. \quad (13.46)$$

The quantity of most interest to theory is the weak phase difference $\phi_2 - \phi_1$. Its extraction from the asymmetry requires, however, that the amplitude ratio $|a_2/a_1|$ and the strong phase difference $\delta_2 - \delta_1$ are known. Both quantities depend on non-perturbative hadronic parameters that are difficult to calculate, but in some cases can be obtained from experiment.

2. In the approximation that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| \ll 1$ (valid for B^0 and B^0_s mesons), the CP asymmetry in semileptonic neutral-meson decays [Eq. (13.40)] is given by

$$\mathcal{A}_{\rm SL} = -\left|\frac{\mathbf{\Gamma}_{12}}{\mathbf{M}_{12}}\right|\sin(\phi_M - \phi_\Gamma) \,. \quad (13.47)$$

The quantity of most interest to theory is the weak phase $\phi_M - \phi_\Gamma$. Its extraction from the asymmetry requires, however, that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}|$ is known. This quantity depends on long-distance physics that is difficult to calculate.

3. In the approximations that only a single weak phase contributes to decay, $A_f = |a_f|e^{i(\delta_f+\phi_f)}$, and that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| = 0$, we obtain $|\lambda_f| = 1$, and the CP asymmetries in decays to a final CP eigenstate f [Eq. (13.43)] with eigenvalue $\eta_f = \pm 1$ are given by

$$\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_f)\ \sin(\Delta m t)\ \text{ with }\ \mathcal{I}m(\lambda_f) = \eta_f \sin(\phi_M + 2\phi_f) \,. \quad (13.48)$$

Note that the phase so measured is purely a weak phase, and no hadronic parameters are involved in the extraction of its value from $\mathcal{I}m(\lambda_f)$.

The discussion above allows us to introduce another classification of CP-violating effects:

1. *Indirect CP violation* is consistent with taking $\phi_M \neq 0$ and setting all other CP violating phases to zero. CP violation in mixing (type II) belongs to this class.
2. *Direct CP violation* cannot be accounted for by just $\phi_M \neq 0$. CP violation in decay (type I) belongs to this class.

The historical significance of this classification is related to theory. In superweak models [35], CP violation appears only in diagrams that contribute to $\mathbf{M}_{12}$, hence they predict that there is no direct CP violation. In most models and, in particular, in the Standard Model, CP violation is both direct and indirect. As concerns type III CP violation, observing $\eta_{f_1}\mathcal{I}m(\lambda_{f_1}) \neq \eta_{f_2}\mathcal{I}m(\lambda_{f_2})$ (for the same decaying meson and two different final CP eigenstates f_1 and f_2) would establish direct CP violation. The experimental observation of $\epsilon' \neq 0$, which was achieved by establishing that $\mathcal{I}m(\lambda_{\pi^+\pi^-}) \neq \mathcal{I}m(\lambda_{\pi^0\pi^0})$ (see Section 13.4), excluded the superweak scenario.

13.3. Theoretical Interpretation: The KM Mechanism

Of all the Standard Model quark parameters, only the Kobayashi-Maskawa (KM) phase is CP-violating. Having a single source of CP violation, the Standard Model is very predictive for CP asymmetries: some vanish, and those that do not are correlated.

To be precise, CP could be violated also by strong interactions. The experimental upper bound on the electric-dipole moment of the neutron implies, however, that $\theta_{\rm QCD}$, the non-perturbative parameter that determines the strength of this type of CP violation, is tiny, if not zero. (The smallness of $\theta_{\rm QCD}$ constitutes a theoretical puzzle, known as "the strong CP problem.") In particular, it is irrelevant to our discussion of hadron decays.

The charged current interactions (that is, the $W^\pm$ interactions) for quarks are given by

$$-\mathcal{L}_{W^\pm} = \frac{g}{\sqrt{2}}\,\overline{u_{Li}}\,\gamma^\mu\,(V_{\rm CKM})_{ij}\,d_{Lj}\,W^+_\mu + \text{h.c.} \qquad (13.49)$$

Here $i,j = 1,2,3$ are generation numbers. The Cabibbo-Kobayashi-Maskawa (CKM) mixing matrix for quarks is a 3×3 unitary matrix [36]. Ordering the quarks by their masses, *i.e.*, $(u_1,u_2,u_3) \to (u,c,t)$ and $(d_1,d_2,d_3) \to (d,s,b)$, the elements of $V_{\rm CKM}$ are written as follows:

$$V_{\rm CKM} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} . \qquad (13.50)$$

While a general 3×3 unitary matrix depends on three real angles and six phases, the freedom to redefine the phases of the quark mass eigenstates can be used to remove five of the phases, leaving a single physical phase, the Kobayashi-Maskawa phase, that is responsible for all CP violation in the Standard Model.

The fact that one can parametrize $V_{\rm CKM}$ by three real and only one imaginary physical parameters can be made manifest by choosing an explicit parametrization. The Wolfenstein parametrization [37,38] is particularly useful:

$$V_{\rm CKM} = \begin{pmatrix} 1-\frac{1}{2}\lambda^2-\frac{1}{8}\lambda^4 & \lambda & A\lambda^3(\rho-i\eta) \\ -\lambda+\frac{1}{2}A^2\lambda^5[1-2(\rho+i\eta)] & 1-\frac{1}{2}\lambda^2-\frac{1}{8}\lambda^4(1+4A^2) & A\lambda^2 \\ A\lambda^3[1-(1-\frac{1}{2}\lambda^2)(\rho+i\eta)] & -A\lambda^2+\frac{1}{2}A\lambda^4[1-2(\rho+i\eta)] & 1-\frac{1}{2}A^2\lambda^4 \end{pmatrix} . \qquad (13.51)$$

Here $\lambda \approx 0.23$ (not to be confused with λ_f), the sine of the Cabibbo angle, plays the role of an expansion parameter, and η represents the CP-violating phase. Terms of $\mathcal{O}(\lambda^6)$ have been neglected.

The unitarity of the CKM matrix, $(VV^\dagger)_{ij} = (V^\dagger V)_{ij} = \delta_{ij}$, leads to twelve distinct complex relations among the matrix elements. The six relations with $i \neq j$ can be represented geometrically as triangles in the complex plane. Two of these,

$$V_{ud}V^*_{ub} + V_{cd}V^*_{cb} + V_{td}V^*_{tb} = 0$$
$$V_{td}V^*_{ud} + V_{ts}V^*_{us} + V_{tb}V^*_{ub} = 0\,,$$

have terms of equal order, $\mathcal{O}(A\lambda^3)$, and so have corresponding triangles whose interior angles are all $\mathcal{O}(1)$ physical quantities that can be independently measured. The angles of the first triangle (see Fig. 13.1) are given by

$$\alpha \equiv \varphi_2 \equiv \arg\left(-\frac{V_{td}V^*_{tb}}{V_{ud}V^*_{ub}}\right) \simeq \arg\left(-\frac{1-\rho-i\eta}{\rho+i\eta}\right),$$
$$\beta \equiv \varphi_1 \equiv \arg\left(-\frac{V_{cd}V^*_{cb}}{V_{td}V^*_{tb}}\right) \simeq \arg\left(\frac{1}{1-\rho-i\eta}\right),$$
$$\gamma \equiv \varphi_3 \equiv \arg\left(-\frac{V_{ud}V^*_{ub}}{V_{cd}V^*_{cb}}\right) \simeq \arg\left(\rho+i\eta\right). \qquad (13.52)$$

The angles of the second triangle are equal to (α,β,γ) up to corrections of $\mathcal{O}(\lambda^2)$. The notations (α,β,γ) and $(\varphi_1,\varphi_2,\varphi_3)$ are both in common usage but, for convenience, we only use the first convention in the following.

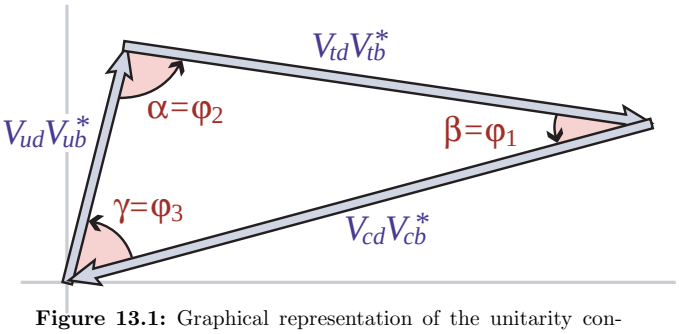

Figure 13.1: Graphical representation of the unitarity constraint $V_{ud}V^*_{ub} + V_{cd}V^*_{cb} + V_{td}V^*_{tb} = 0$ as a triangle in the complex plane.

Another relation that can be represented as a triangle,

$$V_{us}V^*_{ub} + V_{cs}V^*_{cb} + V_{ts}V^*_{tb} = 0\,, \qquad (13.53)$$

and, in particular, its small angle, of $\mathcal{O}(\lambda^2)$,

$$\beta_s \equiv \arg\left(-\frac{V_{ts}V^*_{tb}}{V_{cs}V^*_{cb}}\right), \qquad (13.54)$$

is convenient for analyzing CP violation in the B^0_s sector.

All unitarity triangles have the same area, commonly denoted by $J/2$ [39]. If CP is violated, J is different from zero and can be taken as the single CP-violating parameter. In the Wolfenstein parametrization of Eq. (13.51), $J \simeq \lambda^6 A^2 \eta$.

13.4. Kaons

CP violation was discovered in $K \to \pi\pi$ decays in 1964 [1]. The same mode provided the first observation of direct CP violation [4–6].

The decay amplitudes actually measured in neutral K decays refer to the mass eigenstates K_L and K_S, rather than to the K and $\overline{K}$ states referred to in Eq. (13.16). The final $\pi^+\pi^-$ and $\pi^0\pi^0$ states are CP-even. In the CP conservation limit, K_S (K_L) would be CP-even (odd), and therefore would (would not) decay to two pions. We define CP-violating amplitude ratios for two-pion final states,

$$\eta_{00} \equiv \frac{\langle\pi^0\pi^0|\mathcal{H}|K_L\rangle}{\langle\pi^0\pi^0|\mathcal{H}|K_S\rangle}\,, \quad \eta_{+-} \equiv \frac{\langle\pi^+\pi^-|\mathcal{H}|K_L\rangle}{\langle\pi^+\pi^-|\mathcal{H}|K_S\rangle}\,. \qquad (13.55)$$

Another important observable is the asymmetry of time-integrated semileptonic decay rates:

$$\delta_L \equiv \frac{\Gamma(K_L \to \ell^+\nu_\ell\pi^-) - \Gamma(K_L \to \ell^-\overline{\nu}_\ell\pi^+)}{\Gamma(K_L \to \ell^+\nu_\ell\pi^-) + \Gamma(K_L \to \ell^-\overline{\nu}_\ell\pi^+)}\,. \qquad (13.56)$$

CP violation has been observed as an appearance of K_L decays to two-pion final states [25],

$$|\eta_{00}| = (2.221 \pm 0.011)\times10^{-3} \qquad |\eta_{+-}| = (2.232 \pm 0.011)\times10^{-3} \qquad (13.57)$$

$$|\eta_{00}/\eta_{+-}| = 0.9951 \pm 0.0008\,, \tag{13.58}$$

where the phase ϕ_{ij} of the amplitude ratio η_{ij} has been determined both assuming CPT invariance:

$$\phi_{00} = (43.52 \pm 0.06)^\circ\,, \qquad \phi_{+-} = (43.51 \pm 0.05)^\circ\,, \tag{13.59}$$

and without assuming CPT invariance:

$$\phi_{00} = (43.7 \pm 0.8)^\circ\,, \qquad \phi_{+-} = (43.4 \pm 0.7)^\circ\,. \tag{13.60}$$

CP violation has also been observed in semileptonic K_L decays [25]

$$\delta_L = (3.32 \pm 0.06) \times 10^{-3}\,, \tag{13.61}$$

where δ_L is a weighted average of muon and electron measurements, as well as in K_L decays to $\pi^+\pi^-\gamma$ and $\pi^+\pi^-e^+e^-$ [25]. CP violation in $K \to 3\pi$ decays has not yet been observed [25,40].

Historically, CP violation in neutral K decays has been described in terms of the complex parameters ϵ and ϵ'. The observables η_{00}, η_{+-}, and δ_L are related to these parameters, and to those of Section 13.1, by

$$\begin{aligned}
\eta_{00} &= \frac{1-\lambda_{\pi^0\pi^0}}{1+\lambda_{\pi^0\pi^0}} &&= \epsilon - 2\epsilon'\,,\\
\eta_{+-} &= \frac{1-\lambda_{\pi^+\pi^-}}{1+\lambda_{\pi^+\pi^-}} &&= \epsilon + \epsilon'\,,\\
\delta_L &= \frac{1-|q/p|^2}{1+|q/p|^2} &&= \frac{2\mathcal{R}e(\epsilon)}{1+|\epsilon|^2}\,,
\end{aligned} \tag{13.62}$$

where, in the last line, we have assumed that $\left|A_{\ell^+\nu_\ell\pi^-}\right| = \left|\overline{A}_{\ell^-\overline{\nu}_\ell\pi^+}\right|$ and $\left|A_{\ell^-\overline{\nu}_\ell\pi^+}\right| = \left|\overline{A}_{\ell^+\nu_\ell\pi^-}\right| = 0$. (The convention-dependent parameter $\tilde{\epsilon} \equiv (1-q/p)/(1+q/p)$, sometimes used in the literature, is, in general, different from ϵ but yields a similar expression, $\delta_L = 2\mathcal{R}e(\tilde{\epsilon})/(1+|\tilde{\epsilon}|^2)$.) A fit to the $K \to \pi\pi$ data yields [25]

$$\begin{aligned}
|\epsilon| &= (2.228 \pm 0.011) \times 10^{-3}\,,\\
\mathcal{R}e(\epsilon'/\epsilon) &= (1.65 \pm 0.26) \times 10^{-3}\,.
\end{aligned} \tag{13.63}$$

In discussing two-pion final states, it is useful to express the amplitudes $A_{\pi^0\pi^0}$ and $A_{\pi^+\pi^-}$ in terms of their isospin components via

$$\begin{aligned}
A_{\pi^0\pi^0} &= \sqrt{\frac{1}{3}}\,|A_0|\,e^{i(\delta_0+\phi_0)} - \sqrt{\frac{2}{3}}\,|A_2|\,e^{i(\delta_2+\phi_2)},\\
A_{\pi^+\pi^-} &= \sqrt{\frac{2}{3}}\,|A_0|\,e^{i(\delta_0+\phi_0)} + \sqrt{\frac{1}{3}}\,|A_2|\,e^{i(\delta_2+\phi_2)}\,,
\end{aligned} \tag{13.64}$$

where we parameterize the amplitude $A_I(\overline{A}_I)$ for $K^0(\overline{K}^0)$ decay into two pions with total isospin $I = 0$ or 2 as

$$\begin{aligned}
A_I &\equiv \langle(\pi\pi)_I\,|\mathcal{H}|\,K^0\rangle = |A_I|\,e^{i(\delta_I+\phi_I)}\,,\\
\overline{A}_I &\equiv \langle(\pi\pi)_I\,|\mathcal{H}|\,\overline{K}^0\rangle = |A_I|\,e^{i(\delta_I-\phi_I)}\,.
\end{aligned} \tag{13.65}$$

The smallness of $|\eta_{00}|$ and $|\eta_{+-}|$ allows us to approximate

$$\epsilon \simeq \frac{1}{2}(1-\lambda_{(\pi\pi)_{I=0}})\,, \qquad \epsilon' \simeq \frac{1}{6}\left(\lambda_{\pi^0\pi^0} - \lambda_{\pi^+\pi^-}\right)\,. \tag{13.66}$$

The parameter ϵ represents indirect CP violation, while ϵ' parameterizes direct CP violation: $\mathcal{R}e(\epsilon')$ measures CP violation in decay (type I), $\mathcal{R}e(\epsilon)$ measures CP violation in mixing (type II), and $\mathcal{I}m(\epsilon)$ and $\mathcal{I}m(\epsilon')$ measure the interference between decays with and without mixing (type III).

The following expressions for ϵ and ϵ' are useful for theoretical evaluations:

$$\epsilon \simeq \frac{e^{i\pi/4}}{\sqrt{2}}\frac{\mathcal{I}m(\mathbf{M}_{12})}{\Delta m}\,, \qquad \epsilon' = \frac{i}{\sqrt{2}}\left|\frac{A_2}{A_0}\right| e^{i(\delta_2-\delta_0)}\sin(\phi_2-\phi_0)\,. \tag{13.67}$$

The expression for ϵ is only valid in a phase convention where $\phi_2 = 0$, corresponding to a real $V_{ud}V_{us}^*$, and in the approximation that also $\phi_0 = 0$. The phase of ϵ, $\arg(\epsilon) \approx \arctan(-2\Delta m/\Delta\Gamma)$, is independent of the electroweak model and is experimentally determined to be about $\pi/4$. The calculation of ϵ benefits from the fact that $\mathcal{I}m(\mathbf{M}_{12})$ is dominated by short distance physics. Consequently, the main sources of uncertainty in theoretical interpretations of ϵ are the values of matrix elements, such as $\langle K^0\,|(\overline{s}d)_{V-A}(\overline{s}d)_{V-A}|\,\overline{K}^0\rangle$. The expression for ϵ' is valid to first order in $|A_2/A_0| \sim 1/20$. The phase of ϵ' is experimentally determined, $\pi/2 + \delta_2 - \delta_0 \approx \pi/4$, and is independent of the electroweak model. Note that, accidentally, ϵ'/ϵ is real to a good approximation.

A future measurement of much interest is that of CP violation in the rare $K \to \pi\nu\overline{\nu}$ decays. The signal for CP violation is simply observing the $K_L \to \pi^0\nu\overline{\nu}$ decay. The effect here is that of interference between decays with and without mixing (type III) [41]:

$$\frac{\Gamma(K_L \to \pi^0\nu\overline{\nu})}{\Gamma(K^+ \to \pi^+\nu\overline{\nu})} = \frac{1}{2}\left[1 + |\lambda_{\pi\nu\overline{\nu}}|^2 - 2\,\mathcal{R}e(\lambda_{\pi\nu\overline{\nu}})\right] \simeq 1 - \mathcal{R}e(\lambda_{\pi\nu\overline{\nu}}), \tag{13.68}$$

where in the last equation we neglect CP violation in decay and in mixing (expected, model-independently, to be of order 10^{-5} and 10^{-3}, respectively). Such a measurement is experimentally very challenging but would be theoretically very rewarding [42]. Similar to the CP asymmetry in $B^0 \to J/\psi K_S$, the CP violation in $K \to \pi\nu\overline{\nu}$ decay is predicted to be large (that is, the ratio in Eq. (13.68) is neither CKM- nor loop-suppressed) and can be very cleanly interpreted.

Within the Standard Model, the $K_L \to \pi^0\nu\overline{\nu}$ decay is dominated by an intermediate top quark contribution and, consequently, can be interpreted in terms of CKM parameters [43]. (For the charged mode, $K^+ \to \pi^+\nu\overline{\nu}$, the contribution from an intermediate charm quark is not negligible, and constitutes a source of hadronic uncertainty.) In particular, $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu})$ provides a theoretically clean way to determine the Wolfenstein parameter η [44]:

$$\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) = \kappa_L[X(m_t^2/m_W^2)]^2A^4\eta^2\,, \tag{13.69}$$

where the hadronic parameter $\kappa_L \sim 2 \times 10^{-10}$ incorporates the value of the four-fermion matrix element which is deduced, using isospin relations, from $\mathcal{B}(K^+ \to \pi^0e^+\nu_e)$, and $X(m_t^2/m_W^2)$ is a known function of the top mass. An explicit calculation gives $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) = (2.4 \pm 0.4) \times 10^{-11}$ [45]. The currently tightest experimental limit is $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) < 2.6 \times 10^{-8}$ [46], which does not yet reach the bound $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) < 4.4 \times \mathcal{B}(K^+ \to \pi^+\nu\overline{\nu})$ [41]. Significant further progress is anticipated from experiments searching for $K \to \pi\nu\overline{\nu}$ decays in the next few years.

13.5. Charm

The existence of D^0–$\overline{D}^0$ mixing has been established in recent years [48–51]. The experimental constraints read [27,52] $x \equiv \Delta m/\Gamma = (0.48 \pm 0.18) \times 10^{-2}$ and $y \equiv \Delta\Gamma/(2\Gamma) = (0.66 \pm 0.09) \times 10^{-2}$. Thus, the data clearly show that $y \neq 0$, but improved measurements are needed to be sure of the size of x. Long-distance contributions make it difficult to calculate Standard Model predictions for the D^0–$\overline{D}^0$ mixing parameters. Therefore, the goal of the search for D^0–$\overline{D}^0$ mixing is not to constrain the CKM parameters, but rather to probe new physics. Here CP violation plays an important role. Within the Standard Model, the CP-violating effects are predicted to be small, since the mixing and the relevant decays are described, to an excellent approximation, by the physics of the first two generations only. The expectation is that the Standard Model size of CP violation in D decays is $\mathcal{O}(10^{-3})$ or less, but theoretical work is ongoing to understand whether QCD effects can significantly enhance it. At present, the most sensitive searches involve the $D^0 \to K^+K^-$, $D^0 \to \pi^+\pi^-$ and $D^0 \to K^\pm\pi^\mp$ modes.

The neutral D mesons decay via a singly-Cabibbo-suppressed transition to the CP eigenstates K^+K^- and $\pi^+\pi^-$. These decays are dominated by Standard-Model tree diagrams. Thus, we can write, for $f = K^+K^-$ or $\pi^+\pi^-$,

$$\begin{aligned}
A_f &= A_f^T e^{+i\phi_f^T}\left[1 + r_f e^{i(\delta_f+\phi_f)}\right]\,,\\
\bar{A}_f &= A_f^T e^{-i\phi_f^T}\left[1 + r_f e^{i(\delta_f-\phi_f)}\right]\,,
\end{aligned} \tag{13.70}$$

where $A_f^T e^{\pm i\phi_f^T}$ is the Standard Model tree-level contribution, ϕ_f^T and ϕ_f are weak, CP violating phases, δ_f is a strong phase difference, and r_f is the ratio between a subleading ($r_f \ll 1$) contribution with a weak phase different from ϕ_f^T and the Standard Model tree-level contribution. Neglecting r_f, λ_f is universal, and we can define an observable phase ϕ_D via

$$\lambda_f \equiv -|q/p|e^{i\phi_D} \,. \tag{13.71}$$

(In the limit of CP conservation, choosing $\phi_D = 0$ is equivalent to defining the mass eigenstates by their CP eigenvalue: $|D_\mp\rangle = p|D^0\rangle \pm q|\overline{D}^0\rangle$, with $D_-(D_+)$ being the CP-odd (CP-even) state; that is, the state that does not (does) decay into K^+K^-.)

We define the time integrated CP asymmetry for a final CP eigenstate f as follows:

$$a_f \equiv \frac{\int_0^\infty \Gamma(D^0_{\rm phys}(t) \to f)dt - \int_0^\infty \Gamma(\overline{D}^0_{\rm phys}(t) \to f)dt}{\int_0^\infty \Gamma(D^0_{\rm phys}(t) \to f)dt + \int_0^\infty \Gamma(\overline{D}^0_{\rm phys}(t) \to f)dt} \,. \tag{13.72}$$

(This expression corresponds to the D meson being tagged at production, hence the integration goes from 0 to $+\infty$; measurements are also possible with $\psi(3770) \to D^0\overline{D}^0$, in which case the integration goes from $-\infty$ to $+\infty$ giving slightly different results.) We take $x, y, r_f \ll 1$ and expand to leading order in these parameters. We can then separate the contribution to a_f into three parts [53],

$$a_f = a_f^d + a_f^m + a_f^i \,, \tag{13.73}$$

with the following underlying mechanisms:

1. a_f^d signals CP violation in decay (similar to Eq. (13.38)):

$$a_f^d = 2r_f \sin\phi_f \sin\delta_f \,. \tag{13.74}$$

2. a_f^m signals CP violation in mixing (similar to Eq. (13.47)). With our approximations, it is universal:

$$a^m = -\frac{y}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right)\cos\phi_D \,. \tag{13.75}$$

3. a_f^i signals CP violation in the interference of mixing and decay (similar to Eq. (13.48)). With our approximations, it is universal:

$$a^i = \frac{x}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right)\sin\phi_D \,. \tag{13.76}$$

One can isolate the effects of direct CP violation by taking the difference between the CP asymmetries in the K^+K^- and $\pi^+\pi^-$ modes:

$$\Delta a_{CP} \equiv a_{K^+K^-} - a_{\pi^+\pi^-} = a^d_{K^+K^-} - a^d_{\pi^+\pi^-} \,, \tag{13.77}$$

where we neglected a residual, experiment-dependent, contribution from indirect CP violation due to the fact that there may be a decay time dependent acceptance function that can be different for the K^+K^- and $\pi^+\pi^-$ channels. Recent evidence for such direct CP violation [54] has become less significant when including more data, with the current average giving [27]:

$$a^d_{K^+K^-} - a^d_{\pi^+\pi^-} = (-3.3 \pm 1.2) \times 10^{-3} \,. \tag{13.78}$$

One can also isolate the effects of indirect CP violation in the following way. Consider the time dependent decay rates in Eq. (13.33) and Eq. (13.34). The mixing processes modify the time dependence from a pure exponential. However, given the small values of x and y, the time dependences can be recast, to a good approximation, into purely exponential form, but with modified decay-rate parameters [55,56](given here for the K^+K^- final state):

$$\begin{aligned} \Gamma_{D^0\to K^+K^-} &= \Gamma \times [1 + |q/p|\,(y\cos\phi_D - x\sin\phi_D)] \;, \\ \Gamma_{\overline{D}^0\to K^+K^-} &= \Gamma \times [1 + |p/q|\,(y\cos\phi_D + x\sin\phi_D)] \;. \end{aligned} \tag{13.79}$$

One can define CP-conserving and CP-violating combinations of these two observables (normalized to the true width Γ):

$$\begin{aligned} y_{CP} &\equiv \frac{\Gamma_{\overline{D}^0\to K^+K^-} + \Gamma_{D^0\to K^+K^-}}{2\Gamma} - 1 \\ &= (y/2)\,(|q/p| + |p/q|)\cos\phi_D - (x/2)\,(|q/p| - |p/q|)\sin\phi_D \;, \\ A_\Gamma &\equiv \frac{\Gamma_{D^0\to K^+K^-} - \Gamma_{\overline{D}^0\to K^+K^-}}{2\Gamma} \\ &= -(a^m + a^i) \;. \end{aligned} \tag{13.80}$$

In the limit of CP conservation (and, in particular, within the Standard Model), $y_{CP} = (\Gamma_+ - \Gamma_-)/2\Gamma = y$ (where $\Gamma_+(\Gamma_-)$ is the decay width of the CP-even (-odd) mass eigenstate) and $A_\Gamma = 0$. Indeed, present measurements imply that CP violation is small [27],

$$\begin{aligned} y_{CP} &= (+0.87 \pm 0.16) \times 10^{-2} \;, \\ A_\Gamma &= (-0.01 \pm 0.05) \times 10^{-2} \;. \end{aligned}$$

The $K^\pm\pi^\mp$ states are not CP eigenstates, but they are still common final states for D^0 and $\overline{D}^0$ decays. Since $D^0(\overline{D}^0) \to K^-\pi^+$ is a Cabibbo-favored (doubly-Cabibbo-suppressed) process, these processes are particularly sensitive to x and/or $y = \mathcal{O}(\lambda^2)$. Taking into account that $\left|\lambda_{K^-\pi^+}\right|, \left|\lambda^{-1}_{K^+\pi^-}\right| \ll 1$ and $x, y \ll 1$, assuming that there is no direct CP violation (these are Standard Model tree-level decays dominated by a single weak phase, and there is no contribution from penguin-like and chromomagnetic operators), and expanding the time-dependent rates for $xt, yt \lesssim \Gamma^{-1}$, one obtains

$$\begin{aligned} \Gamma[D^0_{\rm phys}(t) \to K^+\pi^-] = \;& e^{-\Gamma t}|\overline{A}_{K^-\pi^+}|^2 \\ &\times \left[r_d^2 + r_d\left|\frac{q}{p}\right|(y'\cos\phi_D - x'\sin\phi_D)\Gamma t + \left|\frac{q}{p}\right|^2 \frac{y^2+x^2}{4}(\Gamma t)^2\right] \;, \\ \Gamma[\overline{D}^0_{\rm phys}(t) \to K^-\pi^+] = \;& e^{-\Gamma t}|\overline{A}_{K^-\pi^+}|^2 \\ &\times \left[r_d^2 + r_d\left|\frac{p}{q}\right|(y'\cos\phi_D + x'\sin\phi_D)\Gamma t + \left|\frac{p}{q}\right|^2 \frac{y^2+x^2}{4}(\Gamma t)^2\right] \;, \end{aligned} \tag{13.81}$$

where

$$\begin{aligned} y' &\equiv y\cos\delta - x\sin\delta \;, \\ x' &\equiv x\cos\delta + y\sin\delta \;. \end{aligned} \tag{13.82}$$

The weak phase ϕ_D is the same as that of Eq. (13.71) (a consequence of neglecting direct CP violation) and $r_d = \mathcal{O}(\tan^2\theta_c)$ is the amplitude ratio, $r_d = \left|\overline{A}_{K^-\pi^+}/A_{K^-\pi^+}\right| = \left|A_{K^+\pi^-}/\overline{A}_{K^+\pi^-}\right|$, that is, $\lambda_{K^-\pi^+} = r_d|q/p|e^{-i(\delta-\phi_D)}$ and $\lambda^{-1}_{K^+\pi^-} = r_d|p/q|e^{-i(\delta+\phi_D)}$. The parameter δ is a strong-phase difference for these processes, that can be obtained from measurements of quantum correlated $\psi(3770) \to D^0\overline{D}^0$ decays [34]. By fitting to the six coefficients of the various time-dependences, one can determine r_d, $|q/p|$, (x^2+y^2), $y'\cos\phi_D$, and $x'\sin\phi_D$. In particular, finding CP violation ($|q/p| \neq 1$ and/or $\sin\phi_D \neq 0$) at a level much higher than 10^{-3} would constitute evidence for new physics. The most stringent constraints to date on CP violation in charm mixing have been obtained with this method [57].

A fit to all data [27], including also results from time dependent analyses of $D^0 \to K_S\pi^+\pi^-$ decays, from which x, y, $|q/p|$ and ϕ_D can be determined directly, yields no evidence for indirect CP violation:

$$\begin{aligned} 1 - |q/p| &= +0.09\,^{+0.09}_{-0.11} \;, \\ \phi_D &= \left(-11\,^{+11}_{-12}\right)^\circ \;. \end{aligned}$$

More details on various theoretical and experimental aspects of $D^0 - \overline{D}^0$ mixing can be found in Ref. [31].

Searches for CP violation in charged $D_{(s)}$ decays have been performed in many modes. Searches in decays to Cabibbo-suppressed final states are particularly interesting, since in other channels effects are likely to be too small to be observable in current experiments.

Examples of relevant two-body modes are $D^+ \to \pi^+\pi^0$, $K_S K^+$, $\phi\pi^+$ and $D_s^+ \to K^+\pi^0$, $K_S\pi^+$, ϕK^+. The most precise results are $\mathcal{A}_{D^+\to K_S K^+} = -0.0011 \pm 0.0025$ and $\mathcal{A}_{D_s^+\to K_S\pi^+} = +0.031 \pm 0.015$ [27]. The precision of experiments is now sufficient that the effect from CP violation in the neutral kaon system can be seen in $D^+ \to K_S\pi^+$ decays [58,59].

Three-body final states provide additional possibilities to search for CP violation, since effects may vary over the phase-space. A number of methods have been proposed to exploit this feature and search for CP violation in ways that do not require modelling of the decay distribution [60–62]. Such methods are useful for analysis of charm decays since they are less sensitive to biases from production asymmetries, and are well suited to address the issue of whether or not CP violation effects are present. The results of all searches to date have been null – no significant CP violation effect has yet been observed in $D^+_{(s)}$ decays.

13.6. Beauty

13.6.1. ***CP violation in mixing of B^0 and B_s^0 mesons*** : The upper bound on the CP asymmetry in semileptonic B decays [26] implies that CP violation in $B^0 - \overline{B}^0$ mixing is a small effect (we use $\mathcal{A}_{\rm SL}/2 \approx 1 - |q/p|$, see Eq. (13.40)):

$$\mathcal{A}^d_{\rm SL} = (+0.7 \pm 2.7) \times 10^{-3} \implies |q/p| = 0.9997 \pm 0.0013 \,. \quad (13.83)$$

The Standard Model prediction is

$$\mathcal{A}^d_{\rm SL} = \mathcal{O}\left[(m_c^2/m_t^2)\sin\beta\right] \lesssim 0.001 \,. \quad (13.84)$$

An explicit calculation gives $(-4.1 \pm 0.6) \times 10^{-4}$ [63].

The experimental constraint on CP violation in $B_s^0 - \overline{B}_s^0$ mixing is somewhat weaker than that in the $B^0 - \overline{B}^0$ system [26]

$$\mathcal{A}^s_{\rm SL} = (-17.1 \pm 5.5) \times 10^{-3} \implies |q/p| = 1.0086 \pm 0.0028 \,. \quad (13.85)$$

The Standard Model prediction is $\mathcal{A}^s_{\rm SL} = \mathcal{O}\left[(m_c^2/m_t^2)\sin\beta_s\right] \lesssim 10^{-4}$, with an explicit calculation giving $(1.9 \pm 0.3) \times 10^{-5}$ [63]. The tension between the measurement and the prediction originates from a result from D0 for the inclusive same-sign dimuon asymmetry that deviates from the Standard Model prediction by 3.6σ [64]. As yet, this has not been confirmed by independent studies.

In models where $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is approximately real, such as the Standard Model, an upper bound on $\Delta\Gamma/\Delta m \approx \mathcal{R}e(\mathbf{\Gamma}_{12}/\mathbf{M}_{12})$ provides yet another upper bound on the deviation of $|q/p|$ from one. This constraint does not hold if $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is approximately imaginary. (An alternative parameterization uses $q/p = (1-\tilde{\epsilon}_B)/(1+\tilde{\epsilon}_B)$, leading to $\mathcal{A}_{\rm SL} \simeq 4\mathcal{R}e(\tilde{\epsilon}_B)$.)

13.6.2. ***CP violation in interference of B^0 decays with and without mixing*** : The small deviation (less than one percent) of $|q/p|$ from 1 implies that, at the present level of experimental precision, CP violation in B^0 mixing is a negligible effect. Thus, for the purpose of analyzing CP asymmetries in hadronic B^0 decays, we can use

$$\lambda_f = e^{-i\phi_{M(B^0)}}(\overline{A}_f/A_f) \,, \quad (13.86)$$

where $\phi_{M(B^0)}$ refers to the phase of $\mathbf{M}_{12}$ appearing in Eq. (13.45) that is appropriate for $B^0 - \overline{B}^0$ oscillations. Within the Standard Model, the corresponding phase factor is given by

$$e^{-i\phi_{M(B^0)}} = (V_{tb}^* V_{td})/(V_{tb} V_{td}^*) \,. \quad (13.87)$$

The class of CP violation effects in interference between mixing and decay is studied with final states that are common to B^0 and $\overline{B}^0$ decays [65,66]. It is convenient to rewrite Eq. (13.43) for B^0 decays as [67–69]

$$\mathcal{A}_f(t) = S_f \sin(\Delta m t) - C_f \cos(\Delta m t) \,,$$

$$S_f \equiv \frac{2\,\mathcal{I}m(\lambda_f)}{1+|\lambda_f|^2} \,, \quad C_f \equiv \frac{1-|\lambda_f|^2}{1+|\lambda_f|^2} \,, \quad (13.88)$$

where we assume that $\Delta\Gamma = 0$ and $|q/p| = 1$. An alternative notation in use is $A_f \equiv -C_f$ – this A_f should not be confused with the A_f of Eq. (13.16), but in the limit that $|q/p| = 1$ is equivalent with the $\mathcal{A}_f$ of Eq. (13.38).

A large class of interesting processes proceed via quark transitions of the form $\overline{b} \to \overline{q}q\overline{q}'$ with $q' = s$ or d. For $q = c$ or u, there are contributions from both tree (t) and penguin (p^{q_u}, where $q_u = u, c, t$ is the quark in the loop) diagrams (see Fig. 13.2) which carry different weak phases:

$$A_f = \left(V_{qb}^* V_{qq'}\right) t_f + \sum_{q_u=u,c,t} \left(V_{q_u b}^* V_{q_u q'}\right) p_f^{q_u} \,. \quad (13.89)$$

(The distinction between tree and penguin contributions is a heuristic one; the separation by the operator that enters is more precise. For a detailed discussion of the more complete operator product approach, which also includes higher order QCD corrections, see, for example, Ref. [70].) Using CKM unitarity, these decay amplitudes can always be written in terms of just two CKM combinations. For example, for $f = \pi\pi$, which proceeds via a $\overline{b} \to \overline{u}u\overline{d}$ transition, we can write

$$A_{\pi\pi} = (V_{ub}^* V_{ud})\, T_{\pi\pi} + (V_{tb}^* V_{td})\, P^t_{\pi\pi} \,, \quad (13.90)$$

where $T_{\pi\pi} = t_{\pi\pi} + p^u_{\pi\pi} - p^c_{\pi\pi}$ and $P^t_{\pi\pi} = p^t_{\pi\pi} - p^c_{\pi\pi}$. CP-violating phases in Eq. (13.90) appear only in the CKM elements, so that

$$\frac{\overline{A}_{\pi\pi}}{A_{\pi\pi}} = \frac{(V_{ub}V_{ud}^*)\, T_{\pi\pi} + (V_{tb}V_{td}^*)\, P^t_{\pi\pi}}{(V_{ub}^* V_{ud})\, T_{\pi\pi} + (V_{tb}^* V_{td})\, P^t_{\pi\pi}} \,. \quad (13.91)$$

For $f = J/\psi K$, which proceeds via a $\overline{b} \to \overline{c}c\overline{s}$ transition, we can write

$$A_{\psi K} = (V_{cb}^* V_{cs})\, T_{\psi K} + (V_{ub}^* V_{us})\, P^u_{\psi K} \,, \quad (13.92)$$

where $T_{\psi K} = t_{\psi K} + p^c_{\psi K} - p^t_{\psi K}$ and $P^u_{\psi K} = p^u_{\psi K} - p^t_{\psi K}$. A subtlety arises in this decay that is related to the fact that B^0 decays into a final $J/\psi K^0$ state while $\overline{B}^0$ decays into a final $J/\psi\overline{K}^0$ state. A common final state, *e.g.*, $J/\psi K_S$, is reached only via $K^0 - \overline{K}^0$ mixing. Consequently, the phase factor (defined in Eq. (13.45)) corresponding to neutral K mixing, $e^{-i\phi_{M(K)}} = (V_{cd}^* V_{cs})/(V_{cd} V_{cs}^*)$, plays a role:

$$\frac{\overline{A}_{\psi K_S}}{A_{\psi K_S}} = -\frac{(V_{cb}V_{cs}^*)\, T_{\psi K} + (V_{ub}V_{us}^*)\, P^u_{\psi K}}{(V_{cb}^* V_{cs})\, T_{\psi K} + (V_{ub}^* V_{us})\, P^u_{\psi K}} \times \frac{V_{cd}^* V_{cs}}{V_{cd} V_{cs}^*} \,. \quad (13.93)$$

For $q = s$ or d, there are only penguin contributions to A_f, that is, $t_f = 0$ in Eq. (13.89). (The tree $\overline{b} \to \overline{u}u\overline{q}'$ transition followed by $\overline{u}u \to \overline{q}q$ rescattering is included below in the P^u terms.) Again, CKM unitarity allows us to write A_f in terms of two CKM combinations. For example, for $f = \phi K_S$, which proceeds via a $\overline{b} \to \overline{s}s\overline{s}$ transition, we can write

$$\frac{\overline{A}_{\phi K_S}}{A_{\phi K_S}} = -\frac{(V_{cb}V_{cs}^*)\, P^c_{\phi K} + (V_{ub}V_{us}^*)\, P^u_{\phi K}}{(V_{cb}^* V_{cs})\, P^c_{\phi K} + (V_{ub}^* V_{us})\, P^u_{\phi K}} \times \frac{V_{cd}^* V_{cs}}{V_{cd} V_{cs}^*} \,, \quad (13.94)$$

where $P^c_{\phi K} = p^c_{\phi K} - p^t_{\phi K}$ and $P^u_{\phi K} = p^u_{\phi K} - p^t_{\phi K}$.

Since in general the amplitude A_f involves two different weak phases, the corresponding decays can exhibit both CP violation in the interference of decays with and without mixing, $S_f \neq 0$, and CP violation in decays, $C_f \neq 0$. (At the present level of experimental precision, the contribution to C_f from CP violation in mixing is negligible, see Eq. (13.83).) If the contribution from a second weak phase is suppressed, then the interpretation of S_f in terms of Lagrangian CP-violating parameters is clean, while C_f is small. If such a second contribution is not suppressed, S_f depends on hadronic parameters and, if the relevant strong phase difference is large, C_f is large.

A summary of $\overline{b} \to \overline{q}\overline{q}q'$ modes with $q' = s$ or d is given in Table 13.1. The $\overline{b} \to \overline{d}d\overline{q}$ transitions lead to final states that are similar to those from $\overline{b} \to \overline{u}u\overline{q}$ transitions and have similar phase dependence. Final states that consist of two vector mesons ($\psi\phi$ and $\phi\phi$) are not CP eigenstates, and angular analysis is needed to separate the CP-even from the CP-odd contributions.

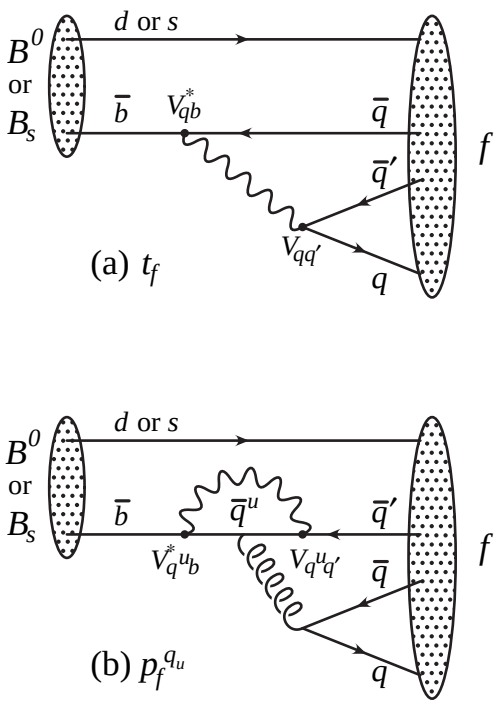

Figure 13.2: Feynman diagrams for (a) tree and (b) penguin amplitudes contributing to $B^0 \to f$ or $B_s^0 \to f$ via a $\overline{b} \to \overline{q}q\overline{q}'$ quark-level process.

Table 13.1: Summary of $\overline{b} \to \overline{q}q\overline{q}'$ modes with $q' = s$ or d. The second and third columns give examples of final hadronic states (usually those which are experimentally most convenient to study). The fourth column gives the CKM dependence of the amplitude A_f, using the notation of Eqs. (13.90, 13.92, 13.94), with the dominant term first and the subdominant second. The suppression factor of the second term compared to the first is given in the last column. "Loop" refers to a penguin versus tree-suppression factor (it is mode-dependent and roughly $\mathcal{O}(0.2-0.3)$) and $\lambda \simeq 0.23$ is the expansion parameter of Eq. (13.51).

$\overline{b} \to \overline{q}q\overline{q}'$	$B^0 \to f$	$B_s^0 \to f$	CKM dependence of A_f	Suppression
$\bar{b} \to \bar{c}c\bar{s}$	ψK_S	$\psi\phi$	$(V_{cb}^* V_{cs})T + (V_{ub}^* V_{us})P^u$	loop $\times\, \lambda^2$
$\bar{b} \to \bar{s}s\bar{s}$	ϕK_S	$\phi\phi$	$(V_{cb}^* V_{cs})P^c + (V_{ub}^* V_{us})P^u$	λ^2
$\bar{b} \to \bar{u}u\bar{s}$	$\pi^0 K_S$	K^+K^-	$(V_{cb}^* V_{cs})P^c + (V_{ub}^* V_{us})T$	λ^2/loop
$\bar{b} \to \bar{c}c\bar{d}$	D^+D^-	ψK_S	$(V_{cb}^* V_{cd})T + (V_{tb}^* V_{td})P^t$	loop
$\bar{b} \to \bar{s}s\bar{d}$	$K_S K_S$	ϕK_S	$(V_{tb}^* V_{td})P^t + (V_{cb}^* V_{cd})P^c$	$\lesssim 1$
$\bar{b} \to \bar{u}u\bar{d}$	$\pi^+\pi^-$	$\rho^0 K_S$	$(V_{ub}^* V_{ud})T + (V_{tb}^* V_{td})P^t$	loop
$\bar{b} \to \bar{c}u\bar{d}$	$D_{CP}\pi^0$	$D_{CP}K_S$	$(V_{cb}^* V_{ud})T + (V_{ub}^* V_{cd})T'$	λ^2
$\bar{b} \to \bar{c}u\bar{s}$	$D_{CP}K_S$	$D_{CP}\phi$	$(V_{cb}^* V_{us})T + (V_{ub}^* V_{cs})T'$	$\lesssim 1$

The cleanliness of the theoretical interpretation of S_f can be assessed from the information in the last column of Table 13.1. In case of small uncertainties, the expression for S_f in terms of CKM phases can be deduced from the fourth column of Table 13.1 in combination with Eq. (13.87) (and, for $b \to q\overline{q}s$ decays, the example in Eq. (13.93)). Here we consider several interesting examples.

For $B^0 \to J/\psi K_S$ and other $\overline{b} \to \overline{c}c\overline{s}$ processes, we can neglect the P^u contribution to A_f, in the Standard Model, to an approximation that is better than one percent, giving:

$$\lambda_{\psi K_S} = -e^{-2i\beta} \;\Rightarrow\; S_{\psi K_S} = \sin 2\beta\,, \quad C_{\psi K_S} = 0\,. \tag{13.95}$$

It is important to verify experimentally the level of suppression of the penguin contribution. Methods based on flavor symmetries [71–74] allow limits to be obtained. All are currently consistent with the P^u term being negligible.

In the presence of new physics, A_f is still likely to be dominated by the T term, but the mixing amplitude might be modified. We learn that, model-independently, $C_f \approx 0$ while S_f cleanly determines the mixing phase $(\phi_M - 2\arg(V_{cb}V_{cd}^*))$. The experimental measurement [27], $S_{\psi K} = +0.682 \pm 0.019$, gave the first precision test of the Kobayashi-Maskawa mechanism, and its consistency with the predictions for $\sin 2\beta$ makes it very likely that this mechanism is indeed the dominant source of CP violation in the quark sector.

For $B^0 \to \phi K_S$ and other $\overline{b} \to \overline{s}s\overline{s}$ processes (as well as some $\overline{b} \to \overline{u}u\overline{s}$ processes), we can neglect the subdominant contributions, in the Standard Model, to an approximation that is good to the order of a few percent:

$$\lambda_{\phi K_S} = -e^{-2i\beta} \;\Rightarrow\; S_{\phi K_S} = \sin 2\beta\,, \quad C_{\phi K_S} = 0\,. \tag{13.96}$$

A review of explicit calculations of the effects of subleading amplitudes can be found in Ref. [75]. In the presence of new physics, both A_f and $\mathbf{M}_{12}$ can have contributions that are comparable in size to those of the Standard Model and carry new weak phases. Such a situation gives several interesting consequences for penguin-dominated $b \to q\overline{q}s$ decays ($q = u, d, s$) to a final state f:

1. The value of $-\eta_f S_f$ may be different from $S_{\psi K_S}$ by more than a few percent, where η_f is the CP eigenvalue of the final state.
2. The values of $\eta_f S_f$ for different final states f may be different from each other by more than a few percent (for example, $S_{\phi K_S} \neq S_{\eta' K_S}$).
3. The value of C_f may be different from zero by more than a few percent.

While a clear interpretation of such signals in terms of Lagrangian parameters will be difficult because, under these circumstances, hadronic parameters play a role, any of the above three options will clearly signal new physics. Fig. 13.3 summarizes the present experimental results: none of the possible signatures listed above is unambiguously established, but there is definitely still room for new physics.

For the $\overline{b} \to \overline{u}u\overline{d}$ process $B \to \pi\pi$ and other related channels, the penguin-to-tree ratio can be estimated using SU(3) relations and experimental data on related $B \to K\pi$ decays. The result (for $\pi\pi$) is that the suppression is at the level of $0.2 - 0.3$ and so cannot be neglected. The expressions for $S_{\pi\pi}$ and $C_{\pi\pi}$ to leading order in $R_{PT} \equiv (|V_{tb}V_{td}|\, P_{\pi\pi}^t)/(|V_{ub}V_{ud}|\, T_{\pi\pi})$ are:

$$\lambda_{\pi\pi} = e^{2i\alpha}\left[(1 - R_{PT}e^{-i\alpha})/(1 - R_{PT}e^{+i\alpha})\right] \;\Rightarrow$$

$$S_{\pi\pi} \approx \sin 2\alpha + 2\,\mathcal{R}e(R_{PT})\cos 2\alpha \sin\alpha\,, \quad C_{\pi\pi} \approx 2\,\mathcal{I}m(R_{PT})\sin\alpha\,. \tag{13.97}$$

Note that R_{PT} is mode-dependent and, in particular, could be different for $\pi^+\pi^-$ and $\pi^0\pi^0$. If strong phases can be neglected, then R_{PT} is real, resulting in $C_{\pi\pi} = 0$. The size of $C_{\pi\pi}$ is an indicator of how large the strong phase is. The present experimental average is $C_{\pi^+\pi^-} = -0.31 \pm 0.05$ [27]. As concerns $S_{\pi\pi}$, it is clear from Eq. (13.97) that the relative size or strong phase of the penguin contribution must be known to extract α. This is the problem of penguin pollution.

The cleanest solution involves isospin relations among the $B \to \pi\pi$ amplitudes [76]:

$$\frac{1}{\sqrt{2}}A_{\pi^+\pi^-} + A_{\pi^0\pi^0} = A_{\pi^+\pi^0}\,. \tag{13.98}$$

The method exploits the fact that the penguin contribution to $P_{\pi\pi}^t$ is pure $\Delta I = 1/2$ (this is not true for the electroweak penguins which,

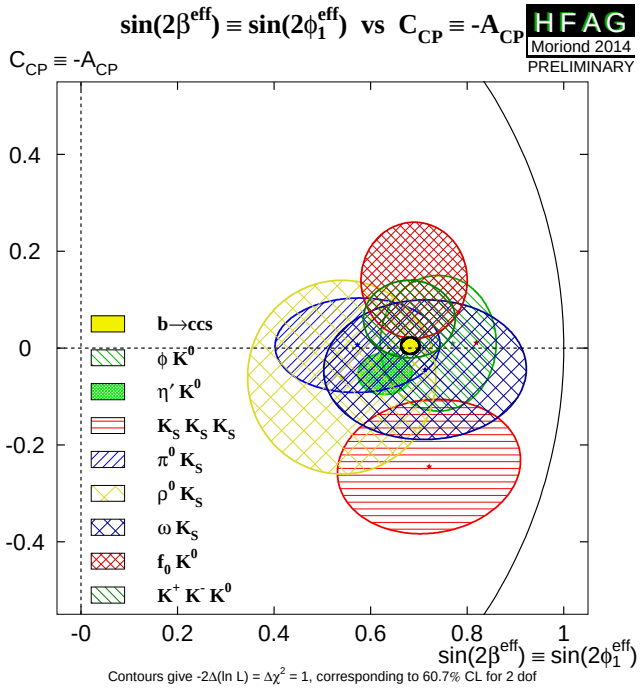

Figure 13.3: Summary of the results [27] of time-dependent analyses of $b \to q\overline{q}s$ decays, which are potentially sensitive to new physics.

however, are expected to be small), while the tree contribution to $T_{\pi\pi}$ contains pieces that are both $\Delta I = 1/2$ and $\Delta I = 3/2$. A simple geometric construction then allows one to find R_{PT} and extract α cleanly from $S_{\pi^+\pi^-}$. The key experimental difficulty is that one must measure accurately the separate rates for $B^0, \overline{B}^0 \to \pi^0\pi^0$.

CP asymmetries in $B \to \rho\pi$ and $B \to \rho\rho$ can also be used to determine α. In particular, the $B \to \rho\rho$ measurements are presently very significant in constraining α. The extraction proceeds via isospin analysis similar to that of $B \to \pi\pi$. There are, however, several important differences. First, due to the finite width of the ρ mesons, a final $(\rho\rho)_{I=1}$ state is possible [77]. The effect is, however, small, of the order of $(\Gamma_\rho/m_\rho)^2 \sim 0.04$. Second, due to the presence of three helicity states for the two vector mesons, angular analysis is needed to separate the CP-even and CP-odd components. The theoretical expectation is that the CP-odd component is small, which is supported by experiments which find that the $\rho^+\rho^-$ and $\rho^\pm\rho^0$ modes are dominantly longitudinally polarized. Third, an important advantage of the $\rho\rho$ modes is that the penguin contribution is expected to be small due to different hadronic dynamics. This expectation is confirmed by the smallness of $\mathcal{B}(B^0 \to \rho^0\rho^0) = (0.97 \pm 0.24) \times 10^{-6}$ [78,79] compared to $\mathcal{B}(B^0 \to \rho^+\rho^-) = (24.2 \pm 3.1) \times 10^{-6}$ [27]. Thus, $S_{\rho^+\rho^-}$ is not far from $\sin 2\alpha$. Finally, both $S_{\rho^0\rho^0}$ and $C_{\rho^0\rho^0}$ are experimentally accessible, which may allow a precision determination of α. However, a full isospin analysis should allow that the fractions of longitudinal polarisation in B and $\overline{B}$ decays may differ, which has not yet been done by the experiments. The consistency between the range of α determined by the $B \to \pi\pi, \rho\pi, \rho\rho$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism.

All modes discussed in this Section so far have possible contributions from penguin amplitudes. As shown in Table 13.1, CP violation can also be studied with final states, typically containing charmed mesons, where no such contribution is possible. The neutral charmed meson must be reconstructed in a final state, such as a CP eigenstate, common to D^0 and $\overline{D}^0$ so that the amplitudes for the B and $\overline{B}$ meson decays interfere. Although there is a second tree amplitude with a different weak phase, the contributions of the different diagrams can in many cases be separated experimentally (for example by exploiting different decays of the $\overline{D}^0$ mesons) making these channels very clean theoretically. Moreover, the interference between the two tree diagrams gives sensitivity to γ, as will be discussed in Section 13.6.4.

13.6.3. ***CP violation in interference of B_s^0 decays with and without mixing*** : As discussed in Section 13.6.1, the world average for $|q/p|$ in the B_s^0 system currently deviates from the Standard Model expectation due to an anomalous value of the dimuon asymmetry. Attributing the dimuon asymmetry result to a fluctuation, we again neglect the deviation of $|q/p|$ from 1, and use

$$\lambda_f = e^{-i\phi_M(B_s^0)}(\overline{A}_f/A_f) \,. \tag{13.99}$$

Within the Standard Model,

$$e^{-i\phi_{M(B_s^0)}} = (V_{tb}^* V_{ts})/(V_{tb} V_{ts}^*) \,. \tag{13.100}$$

Note that $\Delta\Gamma/\Gamma = 0.116 \pm 0.020$ [27] and therefore y should not be put to zero in Eqs. (13.33, 13.34). However, $|q/p| = 1$ is expected to hold to an even better approximation than for B^0 mesons. One therefore obtains

$$\mathcal{A}_f(t) = \frac{S_f \sin(\Delta m t) - C_f \cos(\Delta m t)}{\cosh(\Delta\Gamma t/2) - A_f^{\Delta\Gamma} \sinh(\Delta\Gamma t/2)} \,,$$

$$A_f^{\Delta\Gamma} \equiv \frac{-2\,\mathcal{R}e(\lambda_f)}{1 + |\lambda_f|^2} \,. \tag{13.101}$$

The presence of the $A_f^{\Delta\Gamma}$ term implies that information on λ_f can be obtained from analyses that do not use tagging of the initial flavor, through so-called effective lifetime measurements [80].

The $B_s^0 \to J/\psi\phi$ decay proceeds via the $\overline{b} \to \overline{c}c\overline{s}$ transition. The CP asymmetry in this mode thus determines (with angular analysis to disentangle the CP-even and CP-odd components of the final state) $\sin 2\beta_s$, where β_s is defined in Eq. (13.54) [81]. The $B_s^0 \to J/\psi\pi^+\pi^-$ decay, which has a large contributions from $J/\psi f_0(980)$ and is assumed to also proceed dominantly via the $\overline{b} \to \overline{c}c\overline{s}$ transition, has also been used to determine β_s. In this case no angular analysis is necessary, since the final state has been shown to be dominated by the CP-even component [82]. The combination of ATLAS, CDF, D0 and LHCb measurements yields [27]

$$-2\beta_s = +0.04\,^{+0.10}_{-0.13}, \tag{13.102}$$

consistent with the Standard Model prediction, $\beta_s = 0.018 \pm 0.001$ [18].

The experimental investigation of CP violation in the B_s^0 sector is still at a relatively early stage, and far fewer modes have been studied than in the B^0 system. First results on the $\overline{b} \to \overline{q}q\overline{s}$ decays $B_s^0 \to \phi\phi$ [83] and K^+K^- [84] have been reported recently. More channels are expected to be studied in the near future.

13.6.4. ***Direct CP violation in the B system*** :

An interesting class of decay modes is that of the tree-level decays $B^\pm \to D^{(*)}K^\pm$. These decays provide golden methods for a clean determination of the angle γ [86–90]. The method uses the decays $B^+ \to D^0K^+$, which proceeds via the quark transition $\overline{b} \to \overline{u}c\overline{s}$, and $B^+ \to \overline{D}^0K^+$, which proceeds via the quark transition $\overline{b} \to \overline{c}u\overline{s}$, with the D^0 and $\overline{D}^0$ decaying into a common final state. The decays into common final states, such $(\pi^0K_S)_DK^+$, involve interference effects between the two amplitudes, with sensitivity to the relative phase, $\delta + \gamma$ (δ is the relevant strong phase). The CP-conjugate processes are sensitive to $\delta - \gamma$. Measurements of branching ratios and CP asymmetries allow the determination of γ and δ from amplitude triangle relations. The method suffers from discrete ambiguities but, since all hadronic parameters can be determined from the data, has negligible theoretical uncertainty [85].

Unfortunately, the smallness of the CKM-suppressed $b \to u$ transitions makes it difficult at present to use the simplest methods [86–88] to determine γ. These difficulties are overcome (and the discrete ambiguities are removed) by performing a Dalitz plot analysis for multi-body D decays [89,90]. The consistency between the range of γ determined by the $B \to DK$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides

further support to the Kobayashi-Maskawa mechanism. As more data becomes available, determinations of γ from $B_s^0 \to D_s^{\mp} K^{\pm}$ [91,92] and $B^0 \to DK^{*0}$ [93–96] are expected to also give competitive measurements.

Decays to the final state $K^{\mp}\pi^{\pm}$ provided the first observations of direct CP violation in both B^0 and B_s^0 systems. The asymmetry arises due to interference between tree and penguin diagrams [97], similar to the effect discussed in Section 13.6.2. In principle, measurements of $\mathcal{A}_{\overline{B}^0 \to K^-\pi^+}$ and $\mathcal{A}_{\overline{B}_s^0 \to K^+\pi^-}$ could be used to determine the weak phase difference γ, but lack of knowledge of the relative magnitude and strong phase of the contributing amplitudes limits the achievable precision. The uncertainties on these hadronic parameters can be reduced by exploiting flavor symmetries, which predict a number of relations between asymmetries in different modes. One such relation is that the partial rate differences for B^0 and B_s^0 decays to $K^{\mp}\pi^{\pm}$ are expected to be approximately equal and opposite [98], which is consistent with current data. It is also expected that the partial rate asymmetries for $\overline{B}^0 \to K^-\pi^+$ and $B^- \to K^-\pi^0$ should be approximately equal; however, the experimental results currently show a significant discrepancy [27]:

$$\mathcal{A}_{\overline{B}^0 \to K^-\pi^+} = -0.082 \pm 0.006 \ , \qquad \mathcal{A}_{B^- \to K^-\pi^0} = 0.040 \pm 0.021 \ .$$

It is therefore of great interest to understand whether this originates from Standard Model QCD corrections, or whether it is a signature of new dynamics. Improved tests of a more precise relation between the partial rate differences of all four $K\pi$ final states [99–102], currently limited by knowledge of the CP asymmetry in $\overline{B}^0 \to K_S\pi^0$ decays, may help to resolve the situation.

13.7. Summary and Outlook

CP violation has been experimentally established in K and B meson decays. A full list of CP asymmetries that have been measured at a level higher than 5σ is given in the introduction to this review. In Section 13.1.4 we introduced three types of CP-violating effects. Examples of these three types include the following:

1. All three types of CP violation have been observed in $K \to \pi\pi$ decays:

$$\begin{aligned}
\mathcal{R}e(\epsilon') &= \frac{1}{6}\left(\left|\frac{\overline{A}_{\pi^0\pi^0}}{A_{\pi^0\pi^0}}\right| - \left|\frac{\overline{A}_{\pi^+\pi^-}}{A_{\pi^+\pi^-}}\right|\right) = (2.5 \pm 0.4) \times 10^{-6} \quad \text{(I)} \\
\mathcal{R}e(\epsilon) &= \frac{1}{2}\left(1 - \left|\frac{q}{p}\right|\right) = (1.66 \pm 0.02) \times 10^{-3} \quad \text{(II)} \\
\mathcal{I}m(\epsilon) &= -\frac{1}{2}\mathcal{I}m(\lambda_{(\pi\pi)_{I=0}}) = (1.57 \pm 0.02) \times 10^{-3} \ . \quad \text{(III)}
\end{aligned} \tag{13.103}$$

2. Direct CP violation has been observed in, for example, the $B^0 \to K^+\pi^-$ decays, while CP violation in interference of decays with and without mixing has been observed in, for example, the $B^0 \to J/\psi K_S$ decay:

$$\begin{aligned}
\mathcal{A}_{K^+\pi^-} &= \frac{|\overline{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 - 1}{|\overline{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 + 1} = -0.082 \pm 0.006 \quad \text{(I)} \\
S_{\psi K} &= \mathcal{I}m(\lambda_{\psi K}) = +0.682 \pm 0.019 \ . \quad \text{(III)}
\end{aligned} \tag{13.104}$$

Based on Standard Model predictions, further observations of CP violation in B^0, B^+ and B_s^0 decays seem likely in the near future, at both LHCb and its upgrade [103,104] as well as the Belle II experiment [105]. The first observation of CP violation in b baryons is also likely to be within reach of LHCb. The same experiments have great potential to improve the sensitivity to CP violation effects in the charm sector, though uncertainty in the Standard Model predictions makes it difficult to forecast whether or not discoveries will be forthcoming. A number of upcoming experiments have potential to make significant progress on rare kaon decays. Observables that are subject to clean theoretical interpretation, such as β from $S_{\psi K_S}$, β_s from $B_s^0 \to J/\psi\phi$, $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu})$ and γ from CP violation in $B \to DK$ decays, are of particular value for constraining the values of the CKM parameters and probing the flavor sector of extensions to the Standard Model. Progress in lattice QCD calculations is also needed to complement the anticipated experimental results. Other probes of CP violation now being pursued experimentally include the electric dipole moments of the neutron and electron, and the decays of tau leptons. Additional processes that are likely to play an important role in future CP studies include top-quark production and decay, Higgs boson decays and neutrino oscillations.

All measurements of CP violation to date are consistent with the predictions of the Kobayashi-Maskawa mechanism of the Standard Model. In fact, it is now established that the KM mechanism plays a major role in the CP violation measured in the quark sector. However, a dynamically-generated matter-antimatter asymmetry of the universe requires additional sources of CP violation, and such sources are naturally generated by extensions to the Standard Model. New sources might eventually reveal themselves as small deviations from the predictions of the KM mechanism, or else might not be observable in the quark sector at all, but observable with future probes such as neutrino oscillations or electric dipole moments. We cannot guarantee that new sources of CP violation will ever be found experimentally, but the fundamental nature of CP violation demands a vigorous effort.

A number of excellent reviews of CP violation are available [106–112], where the interested reader may find a detailed discussion of the various topics that are briefly reviewed here.

We thank David Kirkby for significant contributions to earlier version of this review.

14. NEUTRINO MASS, MIXING, AND OSCILLATIONS

Updated May 2014 by K. Nakamura (Kavli IPMU (WPI), U. Tokyo, KEK), and S.T. Petcov (SISSA/INFN Trieste, Kavli IPMU (WPI), U. Tokyo, Bulgarian Academy of Sciences).

The experiments with solar, atmospheric, reactor and accelerator neutrinos have provided compelling evidences for oscillations of neutrinos caused by nonzero neutrino masses and neutrino mixing. The data imply the existence of 3-neutrino mixing in vacuum. We review the theory of neutrino oscillations, the phenomenology of neutrino mixing, the problem of the nature - Dirac or Majorana, of massive neutrinos, the issue of CP violation in the lepton sector, and the current data on the neutrino masses and mixing parameters. The open questions and the main goals of future research in the field of neutrino mixing and oscillations are outlined.

14.1. Introduction: Massive neutrinos and neutrino mixing

It is a well-established experimental fact that the neutrinos and antineutrinos which take part in the standard charged current (CC) and neutral current (NC) weak interaction are of three varieties (types) or flavours: electron, ν_e and $\bar{\nu}_e$, muon, ν_μ and $\bar{\nu}_\mu$, and tauon, ν_τ and $\bar{\nu}_\tau$. The notion of neutrino type or flavour is dynamical: ν_e is the neutrino which is produced with e^+, or produces an e^- in CC weak interaction processes; ν_μ is the neutrino which is produced with μ^+, or produces μ^-, *etc.* The flavour of a given neutrino is Lorentz invariant. Among the three different flavour neutrinos and antineutrinos, no two are identical. Correspondingly, the states which describe different flavour neutrinos must be orthogonal (within the precision of the current data): $\langle\nu_{l'}|\nu_l\rangle = \delta_{l'l}$, $\langle\bar{\nu}_{l'}|\bar{\nu}_l\rangle = \delta_{l'l}$, $\langle\bar{\nu}_{l'}|\nu_l\rangle = 0$.

It is also well-known from the existing data (all neutrino experiments were done so far with relativistic neutrinos or antineutrinos), that the flavour neutrinos ν_l (antineutrinos $\bar{\nu}_l$), are always produced in weak interaction processes in a state that is predominantly left-handed (LH) (right-handed (RH)). To account for this fact, ν_l and $\bar{\nu}_l$ are described in the Standard Model (SM) by a chiral LH flavour neutrino field $\nu_{lL}(x)$, $l = e, \mu, \tau$. For massless ν_l, the state of ν_l ($\bar{\nu}_l$) which the field $\nu_{lL}(x)$ annihilates (creates) is with helicity (-1/2) (helicity +1/2). If ν_l has a non-zero mass $m(\nu_l)$, the state of ν_l ($\bar{\nu}_l$) is a linear superposition of the helicity (-1/2) and (+1/2) states, but the helicity +1/2 state (helicity (-1/2) state) enters into the superposition with a coefficient $\propto m(\nu_l)/E$, E being the neutrino energy, and thus is strongly suppressed. Together with the LH charged lepton field $l_L(x)$, $\nu_{lL}(x)$ forms an $SU(2)_L$ doublet. In the absence of neutrino mixing and zero neutrino masses, $\nu_{lL}(x)$ and $l_L(x)$ can be assigned one unit of the additive lepton charge L_l and the three charges L_l, $l = e, \mu, \tau$, are conserved by the weak interaction.

At present there is no compelling evidence for the existence of states of relativistic neutrinos (antineutrinos), which are predominantly right-handed, ν_R (left-handed, $\bar{\nu}_L$). If RH neutrinos and LH antineutrinos exist, their interaction with matter should be much weaker than the weak interaction of the flavour LH neutrinos ν_l and RH antineutrinos $\bar{\nu}_l$, *i.e.*, ν_R ($\bar{\nu}_L$) should be "sterile" or "inert" neutrinos (antineutrinos) [1]. In the formalism of the Standard Model, the sterile ν_R and $\bar{\nu}_L$ can be described by $SU(2)_L$ singlet RH neutrino fields $\nu_R(x)$. In this case, ν_R and $\bar{\nu}_L$ will have no gauge interactions, *i.e.*, will not couple to the weak $W^\pm$ and Z^0 bosons. If present in an extension of the Standard Model, the RH neutrinos can play a crucial role i) in the generation of neutrino masses and mixing, ii) in understanding the remarkable disparity between the magnitudes of neutrino masses and the masses of the charged leptons and quarks, and iii) in the generation of the observed matter-antimatter asymmetry of the Universe (via the leptogenesis mechanism [2]) . In this scenario which is based on the see-saw theory [3], there is a link between the generation of neutrino masses and the generation of the baryon asymmetry of the Universe. The simplest hypothesis (based on symmetry considerations) is that to each LH flavour neutrino field $\nu_{lL}(x)$ there corresponds a RH neutrino field $\nu_{lR}(x)$, $l = e, \mu, \tau$, although schemes with less (more) than three RH neutrinos are also being considered.

The experiments with solar, atmospheric, reactor and accelerator neutrinos have provided compelling evidences for the existence of neutrino oscillations [4,5], transitions in flight between the different flavour neutrinos ν_e, ν_μ, ν_τ (antineutrinos $\bar{\nu}_e$, $\bar{\nu}_\mu$, $\bar{\nu}_\tau$), caused by nonzero neutrino masses and neutrino mixing.

The existence of flavour neutrino oscillations implies that if a neutrino of a given flavour, say ν_μ, with energy E is produced in some weak interaction process, at a sufficiently large distance L from the ν_μ source the probability to find a neutrino of a different flavour, say ν_τ, $P(\nu_\mu \to \nu_\tau; E, L)$, is different from zero. $P(\nu_\mu \to \nu_\tau; E, L)$ is called the $\nu_\mu \to \nu_\tau$ oscillation or transition probability. If $P(\nu_\mu \to \nu_\tau; E, L) \neq 0$, the probability that ν_μ will not change into a neutrino of a different flavour, *i.e.*, the "ν_μ survival probability" $P(\nu_\mu \to \nu_\mu; E, L)$, will be smaller than one. If only muon neutrinos ν_μ are detected in a given experiment and they take part in oscillations, one would observe a "disappearance" of muon neutrinos on the way from the ν_μ source to the detector. Disappearance of the solar ν_e, reactor $\bar{\nu}_e$ and of atmospheric ν_μ and $\bar{\nu}_\mu$ due to the oscillations have been observed respectively, in the solar neutrino [6–14], KamLAND [15,16] and Super-Kamokande [17,18] experiments. Strong evidences for ν_μ disappearance due to oscillations were obtained also in the long-baseline accelerator neutrino experiments K2K [19]. Subsequently, the MINOS [20,21] and T2K [22,23] long baseline experiments reported compelling evidence for ν_μ disappearance due to oscillations, while evidences for ν_τ appearance due to $\nu_\mu \to \nu_\tau$ oscillations were published by the Super-Kamiokande [24] and OPERA [25] collaborations. As a consequence of the results of the experiments quoted above the existence of oscillations or transitions of the solar ν_e, atmospheric ν_μ and $\bar{\nu}_\mu$, accelerator ν_μ (at $L \sim 250$ km, $L \sim 295$ km and $L \sim 730$ km) and reactor $\bar{\nu}_e$ (at $L \sim 180$ km), driven by nonzero neutrino masses and neutrino mixing, was firmly established. There are strong indications that the solar ν_e transitions are affected by the solar matter [26,27].

Further important developments took place more recently in the period starting from June 2011. First, the T2K Collaboration reported [28] indications for $\nu_\mu \to \nu_e$ oscillations, *i.e.*, of "appearance" of ν_e in a beam of ν_μ, which had a statistical significance of 2.5σ. The MINOS [29] Collaboration also obtained data consistent with $\nu_\mu \to \nu_e$ oscillations. Subsequently, the Double Chooz Collaboration reported [30] indications for disappearance of reactor $\bar{\nu}_e$ at $L \sim 1.1$ km. Strong evidences for reactor $\bar{\nu}_e$ disappearance at $L \sim 1.65$ km and $L \sim 1.38$ km and (with statistical significance of 5.2σ and 4.9σ) were obtained respectively in the Daya Bay [31] and RENO [32] experiments. Further evidences for reactor $\bar{\nu}_e$ disappearance (at 2.9σ) and for $\nu_\mu \to \nu_e$ oscillations (at 3.1σ) were reported by the Double Chooz [33] and T2K [34] experiments, while the Daya Bay and RENO Collaborations presented updated, more precise results on reactor $\bar{\nu}_e$ disappearance [35,36,37](for the latest results of the Daya Bay, RENO, Double Chooz, MINOS and T2K experiments, see Section 14.6).

Oscillations of neutrinos are a consequence of the presence of flavour neutrino mixing, or lepton mixing, in vacuum. In the formalism of local quantum field theory, used to construct the Standard Model, this means that the LH flavour neutrino fields $\nu_{lL}(x)$, which enter into the expression for the lepton current in the CC weak interaction Lagrangian, are linear combinations of the fields of three (or more) neutrinos ν_j, having masses $m_j \neq 0$:

$$\nu_{lL}(x) = \sum_j U_{lj}\, \nu_{jL}(x), \quad l = e, \mu, \tau, \tag{14.1}$$

where $\nu_{jL}(x)$ is the LH component of the field of ν_j possessing a mass m_j and U is a unitary matrix - the neutrino mixing matrix [1,4,5]. The matrix U is often called the Pontecorvo-Maki-Nakagawa-Sakata (PMNS) or Maki-Nakagawa-Sakata (MNS) mixing matrix. Obviously, Eq. (14.1) implies that the individual lepton charges L_l, $l = e, \mu, \tau$, are not conserved.

All compelling neutrino oscillation data can be described assuming 3-flavour neutrino mixing in vacuum. The data on the invisible decay width of the Z-boson is compatible with only 3 light flavour neutrinos coupled to Z [38]. The number of massive neutrinos ν_j, n, can,

in general, be bigger than 3, $n > 3$, if, for instance, there exist sterile neutrinos and they mix with the flavour neutrinos. It is firmly established on the basis of the current data that at least 3 of the neutrinos ν_j, say ν_1, ν_2, ν_3, must be light, $m_{1,2,3} \lesssim 1$ eV (Section 14.6), and must have different masses, $m_1 \neq m_2 \neq m_3$. At present there are several experimental hints for existence of one or two light sterile neutrinos at the eV scale, which mix with the flavour neutrinos, implying the presence in the neutrino mixing of additional one or two neutrinos, ν_4 or $\nu_{4,5}$, with masses m_4 ($m_{4,5}$) ~ 1 eV. These hints will be briefly discusssed in Section 14.7 of the present review.

Being electrically neutral, the neutrinos with definite mass ν_j can be Dirac fermions or Majorana particles [39,40]. The first possibility is realised when there exists a lepton charge carried by the neutrinos ν_j, which is conserved by the particle interactions. This could be, *e.g.*, the total lepton charge $L = L_e + L_\mu + L_\tau$: $L(\nu_j) = 1$, $j = 1, 2, 3$. In this case the neutrino ν_j has a distinctive antiparticle $\bar{\nu}_j$: $\bar{\nu}_j$ differs from ν_j by the value of the lepton charge L it carries, $L(\bar{\nu}_j) = -1$. The massive neutrinos ν_j can be Majorana particles if no lepton charge is conserved (see, *e.g.*, Refs. [41,42]) . A massive Majorana particle χ_j is identical with its antiparticle $\bar{\chi}_j$: $\chi_j \equiv \bar{\chi}_j$. On the basis of the existing neutrino data it is impossible to determine whether the massive neutrinos are Dirac or Majorana fermions.

In the case of n neutrino flavours and n massive neutrinos, the $n \times n$ unitary neutrino mixing matrix U can be parametrised by $n(n-1)/2$ Euler angles and $n(n+1)/2$ phases. If the massive neutrinos ν_j are Dirac particles, only $(n-1)(n-2)/2$ phases are physical and can be responsible for CP violation in the lepton sector. In this respect the neutrino (lepton) mixing with Dirac massive neutrinos is similar to the quark mixing. For $n = 3$ there is just one CP violating phase in U, which is usually called "the Dirac CP violating phase." CP invariance holds if (in a certain standard convention) U is real, $U^* = U$.

If, however, the massive neutrinos are Majorana fermions, $\nu_j \equiv \chi_j$, the neutrino mixing matrix U contains $n(n-1)/2$ CP violation phases [43,44], *i.e.*, by $(n-1)$ phases more than in the Dirac neutrino case: in contrast to Dirac fields, the massive Majorana neutrino fields cannot "absorb" phases. In this case U can be cast in the form [43]

$$U = V\,P \tag{14.2}$$

where the matrix V contains the $(n-1)(n-2)/2$ Dirac CP violation phases, while P is a diagonal matrix with the additional $(n-1)$ Majorana CP violation phases α_{21}, α_{31},..., α_{n1},

$$P = diag\left(1, e^{i\frac{\alpha_{21}}{2}}, e^{i\frac{\alpha_{31}}{2}}, ..., e^{i\frac{\alpha_{n1}}{2}}\right) . \tag{14.3}$$

The Majorana phases will conserve CP if [45] $\alpha_{j1} = \pi q_j$, $q_j = 0, 1, 2$, $j = 2, 3, ..., n$. In this case $\exp[i(\alpha_{j1} - \alpha_{k1})] = \pm 1$ has a simple physical interpretation: this is the relative CP-parity of Majorana neutrinos χ_j and χ_k. The condition of CP invariance of the leptonic CC weak interaction in the case of mixing and massive Majorana neutrinos reads [41]:

$$U^*_{lj} = U_{lj}\,\rho_j\,, \quad \rho_j = \frac{1}{i}\eta_{CP}(\chi_j) = \pm 1\,, \tag{14.4}$$

where $\eta_{CP}(\chi_j) = i\rho_j = \pm i$ is the CP parity of the Majorana neutrino χ_j [45]. Thus, if CP invariance holds, the elements of U are either real or purely imaginary.

In the case of $n = 3$ there are altogether 3 CP violation phases - one Dirac and two Majorana. Even in the mixing involving only 2 massive Majorana neutrinos there is one physical CP violation Majorana phase. In contrast, the CC weak interaction is automatically CP-invariant in the case of mixing of two massive Dirac neutrinos or of two quarks.

14.2. Neutrino oscillations in vacuum

Neutrino oscillations are a quantum mechanical consequence of the existence of nonzero neutrino masses and neutrino (lepton) mixing, Eq. (14.1), and of the relatively small splitting between the neutrino masses. The neutrino mixing and oscillation phenomena are analogous to the $K^0 - \bar{K}^0$ and $B^0 - \bar{B}^0$ mixing and oscillations.

In what follows we will present a simplified version of the derivation of the expressions for the neutrino and antineutrino oscillation probabilities. The complete derivation would require the use of the wave packet formalism for the evolution of the massive neutrino states, or, alternatively, of the field-theoretical approach, in which one takes into account the processes of production, propagation and detection of neutrinos [46].

Suppose the flavour neutrino ν_l is produced in a CC weak interaction process and after a time T it is observed by a neutrino detector, located at a distance L from the neutrino source and capable of detecting also neutrinos $\nu_{l'}$, $l' \neq l$. We will consider the evolution of the neutrino state $|\nu_l\rangle$ in the frame in which the detector is at rest (laboratory frame). The oscillation probability, as we will see, is a Lorentz invariant quantity. If lepton mixing, Eq. (14.1), takes place and the masses m_j of all neutrinos ν_j are sufficiently small, the state of the neutrino ν_l, $|\nu_l\rangle$, will be a coherent superposition of the states $|\nu_j\rangle$ of neutrinos ν_j:

$$|\nu_l\rangle = \sum_j U^*_{lj}\,|\nu_j; \tilde{p}_j\rangle, \quad l = e, \mu, \tau\,, \tag{14.5}$$

where U is the neutrino mixing matrix and $\tilde{p}_j$ is the 4-momentum of ν_j [47].

We will consider the case of relativistic neutrinos ν_j, which corresponds to the conditions in both past and currently planned future neutrino oscillation experiments [49]. In this case the state $|\nu_j; \tilde{p}_j\rangle$ practically coincides with the helicity (-1) state $|\nu_j, L; \tilde{p}_j\rangle$ of the neutrino ν_j, the admixture of the helicity (+1) state $|\nu_j, R; \tilde{p}_j\rangle$ in $|\nu_j; \tilde{p}_j\rangle$ being suppressed due to the factor $\sim m_j/E_j$, where E_j is the energy of ν_j. If ν_j are Majorana particles, $\nu_j \equiv \chi_j$, due to the presence of the helicity (+1) state $|\chi_j, R; \tilde{p}_j\rangle$ in $|\chi_j; \tilde{p}_j\rangle$, the neutrino ν_l can produce an l^+ (instead of l^-) when it interacts, e.g., with nucleons. The cross section of such a $|\Delta L_l| = 2$ process is suppressed by the factor $(m_j/E_j)^2$, which renders the process unobservable at present.

If the number n of massive neutrinos ν_j is bigger than 3 due to a mixing between the active flavour and sterile neutrinos, one will have additional relations similar to that in Eq. (14.5) for the state vectors of the (predominantly LH) sterile antineutrinos. In the case of just one RH sterile neutrino field $\nu_{sR}(x)$, for instance, we will have in addition to Eq. (14.5):

$$|\bar{\nu}_{sL}\rangle = \sum_{j=1}^{4} U^*_{sj}\,|\nu_j; \tilde{p}_j\rangle \cong \sum_{j=1}^{4} U^*_{sj}\,|\nu_j, L; \tilde{p}_j\rangle\,, \tag{14.6}$$

where the neutrino mixing matrix U is now a 4×4 unitary matrix.

For the state vector of RH flavour antineutrino $\bar{\nu}_l$, produced in a CC weak interaction process we similarly get:

$$|\bar{\nu}_l\rangle = \sum_j U_{lj}\,|\bar{\nu}_j; \tilde{p}_j\rangle \cong \sum_{j=1} U_{lj}\,|\bar{\nu}_j, R; \tilde{p}_j\rangle, \quad l = e, \mu, \tau\,, \tag{14.7}$$

where $|\bar{\nu}_j, R; \tilde{p}_j\rangle$ is the helicity (+1) state of the antineutrino $\bar{\nu}_j$ if ν_j are Dirac fermions, or the helicity (+1) state of the neutrino $\nu_j \equiv \bar{\nu}_j \equiv \chi_j$ if the massive neutrinos are Majorana particles. Thus, in the latter case we have in Eq. (14.7): $|\bar{\nu}_j; \tilde{p}_j\rangle \cong |\nu_j, R; \tilde{p}_j\rangle \equiv |\chi_j, R; \tilde{p}_j\rangle$. The presence of the matrix U in Eq. (14.7) (and not of U^*) follows directly from Eq. (14.1).

We will assume in what follows that the spectrum of masses of neutrinos is not degenerate: $m_j \neq m_k$, $j \neq k$. Then the states $|\nu_j; \tilde{p}_j\rangle$ in the linear superposition in the r.h.s. of Eq. (14.5) will have, in general, different energies and different momenta, independently of whether they are produced in a decay or interaction process: $\tilde{p}_j \neq \tilde{p}_k$,

or $E_j \neq E_k$, $\mathbf{p}_j \neq \mathbf{p}_k$, $j \neq k$, where $E_j = \sqrt{p_j^2 + m_j^2}$, $p_j \equiv |\mathbf{p}_j|$. The deviations of E_j and p_j from the values for a massless neutrino E and $p = E$ are proportional to m_j^2/E_0, E_0 being a characteristic energy of the process, and are extremely small. In the case of $\pi^+ \to \mu^+ + \nu_\mu$ decay at rest, for instance, we have: $E_j = E + m_j^2/(2m_\pi)$, $p_j = E - \xi m_j^2/(2E)$, where $E = (m_\pi/2)(1 - m_\mu^2/m_\pi^2) \cong 30$ MeV, $\xi = (1 + m_\mu^2/m_\pi^2)/2 \cong 0.8$, and m_μ and m_π are the μ^+ and π^+ masses. Taking $m_j = 1$ eV we find: $E_j \cong E\,(1 + 1.2 \times 10^{-16})$ and $p_j \cong E\,(1 - 4.4 \times 10^{-16})$.

Suppose that the neutrinos are observed via a CC weak interaction process and that in the detector's rest frame they are detected after time T after emission, after traveling a distance L. Then the amplitude of the probability that neutrino $\nu_{l'}$ will be observed if neutrino ν_l was produced by the neutrino source can be written as [46,48,50]:

$$A(\nu_l \to \nu_{l'}) = \sum_j U_{l'j}\, D_j\, U_{jl}^\dagger, \qquad l, l' = e, \mu, \tau\,, \tag{14.8}$$

where $D_j = D_j(p_j; L, T)$ describes the propagation of ν_j between the source and the detector, $U_{jl}^\dagger$ and $U_{l'j}$ are the amplitudes to find ν_j in the initial and in the final flavour neutrino state, respectively. It follows from relativistic Quantum Mechanics considerations that [46,48]

$$D_j \equiv D_j(\tilde{p}_j; L, T) = e^{-i\tilde{p}_j\,(x_f - x_0)} = e^{-i(E_j T - p_j L)}\,, \qquad p_j \equiv |\mathbf{p}_j|\,, \tag{14.9}$$

where [51] x_0 and x_f are the space-time coordinates of the points of neutrino production and detection, $T = (t_f - t_0)$ and $L = \mathbf{k}(\mathbf{x}_f - \mathbf{x}_0)$, $\mathbf{k}$ being the unit vector in the direction of neutrino momentum, $\mathbf{p}_j = \mathbf{k}\mathrm{p_j}$. What is relevant for the calculation of the probability $P(\nu_l \to \nu_{l'}) = |A(\nu_l \to \nu_{l'})|^2$ is the interference factor $D_j D_k^*$ which depends on the phase

$$\delta\varphi_{jk} = (E_j - E_k)T - (p_j - p_k)L = (E_j - E_k)\left[T - \frac{E_j + E_k}{p_j + p_k}\,L\right] + \frac{m_j^2 - m_k^2}{p_j + p_k}\,L\,. \tag{14.10}$$

Some authors [52] have suggested that the distance traveled by the neutrinos L and the time interval T are related by $T = (E_j + E_k)\,L/(p_j + p_k) = L/\bar{v}$, $\bar{v} = (E_j/(E_j + E_k))v_j + (E_k/(E_j + E_k))v_k$ being the "average" velocity of ν_j and ν_k, where $v_{j,k} = p_{j,k}/E_{j,k}$. In this case the first term in the r.h.s. of Eq. (14.10) vanishes. The indicated relation has not emerged so far from any dynamical wave packet calculations. We arrive at the same conclusion concerning the term under discussion in Eq. (14.10) if one assumes [53] that $E_j = E_k = E_0$. Finally, it was proposed in Ref. 50 and Ref. 54 that the states of ν_j and $\bar{\nu}_j$ in Eq. (14.5) and Eq. (14.7) have the same 3-momentum, $p_j = p_k = p$. Under this condition the first term in the r.h.s. of Eq. (14.10) is negligible, being suppressed by the additional factor $(m_j^2 + m_k^2)/p^2$ since for relativistic neutrinos $L = T$ up to terms $\sim m_{j,k}^2/p^2$. We arrive at the same conclusion if $E_j \neq E_k$, $p_j \neq p_k$, $j \neq k$, and we take into account that neutrinos are relativistic and therefore, up to corrections $\sim m_{j,k}^2/E_{j,k}^2$, we have $L \cong T$ (see, *e.g.*, C. Giunti quoted in Ref. 46).

Although the cases considered above are physically quite different, they lead to the same result for the phase difference $\delta\varphi_{jk}$. Thus, we have:

$$\delta\varphi_{jk} \cong \frac{m_j^2 - m_k^2}{2p}\,L = 2\pi\,\frac{L}{L_{jk}^v}\,\mathrm{sgn}(m_j^2 - m_k^2)\,, \tag{14.11}$$

where $p = (p_j + p_k)/2$ and

$$L_{jk}^v = 4\pi\frac{p}{|\Delta m_{jk}^2|} \cong 2.48\ \mathrm{m}\ \frac{p[MeV]}{|\Delta m_{jk}^2|[eV^2]} \tag{14.12}$$

is the neutrino oscillation length associated with Δm_{jk}^2. We can safely neglect the dependence of p_j and p_k on the masses m_j and m_k and consider p to be the zero neutrino mass momentum, $p = E$. The phase difference $\delta\varphi_{jk}$, Eq. (14.11), is Lorentz-invariant.

Eq. (14.9) corresponds to a plane-wave description of the propagation of neutrinos ν_j. It accounts only for the movement of the center of the wave packet describing ν_j. In the wave packet treatment of the problem, the interference between the states of ν_j and ν_k is subject to a number of conditions [46], the localisation condition and the condition of overlapping of the wave packets of ν_j and ν_k at the detection point being the most important. For relativistic neutrinos, the localisation condition in space, for instance, reads: $\sigma_{xP}, \sigma_{xD} < L_{jk}^v/(2\pi)$, $\sigma_{xP(D)}$ being the spatial width of the production (detection) wave packet. Thus, the interference will not be suppressed if the spatial width of the neutrino wave packets determined by the neutrino production and detection processes is smaller than the corresponding oscillation length in vacuum. In order for the interference to be nonzero, the wave packets describing ν_j and ν_k should also overlap in the point of neutrino detection. This requires that the spatial separation between the two wave packets at the point of neutrinos detection, caused by the two wave packets having different group velocities $v_j \neq v_k$, satisfies $|(v_j - v_k)T| \ll \max(\sigma_{xP}, \sigma_{xD})$. If the interval of time T is not measured, T in the preceding condition must be replaced by the distance L between the neutrino source and the detector (for further discussion see, *e.g.*, Refs. [46,48,50]) .

For the $\nu_l \to \nu_{l'}$ and $\bar{\nu}_l \to \bar{\nu}_{l'}$ oscillation probabilities we get from Eq. (14.8), Eq. (14.9), and Eq. (14.11):

$$P(\nu_l \to \nu_{l'}) = \sum_j |U_{l'j}|^2\,|U_{lj}|^2 + 2\sum_{j>k} |U_{l'j}\,U_{lj}^*\,U_{lk}\,U_{l'k}^*| \cos(\frac{\Delta m_{jk}^2}{2p}\,L - \phi_{l'l;jk})\,, \tag{14.13}$$

$$P(\bar{\nu}_l \to \bar{\nu}_{l'}) = \sum_j |U_{l'j}|^2\,|U_{lj}|^2 + 2\sum_{j>k} |U_{l'j}\,U_{lj}^*\,U_{lk}\,U_{l'k}^*| \cos(\frac{\Delta m_{jk}^2}{2p}\,L + \phi_{l'l;jk})\,, \tag{14.14}$$

where $l, l' = e, \mu, \tau$ and $\phi_{l'l;jk} = \arg\left(U_{l'j}\,U_{lj}^*\,U_{lk}\,U_{l'k}^*\right)$. It follows from Eq. (14.8) - Eq. (14.10) that in order for neutrino oscillations to occur, at least two neutrinos ν_j should not be degenerate in mass and lepton mixing should take place, $U \neq \mathbf{1}$. The neutrino oscillations effects can be large if we have

$$\frac{|\Delta m_{jk}^2|}{2p}\,L = 2\pi\,\frac{L}{L_{jk}^v} \gtrsim 1\,,\ \ j \neq k\,. \tag{14.15}$$

at least for one Δm_{jk}^2. This condition has a simple physical interpretation: the neutrino oscillation length L_{jk}^v should be of the order of, or smaller, than source-detector distance L, otherwise the oscillations will not have time to develop before neutrinos reach the detector.

We see from Eq. (14.13) and Eq. (14.14) that $P(\nu_l \to \nu_{l'}) = P(\bar{\nu}_{l'} \to \bar{\nu}_l)$, $l, l' = e, \mu, \tau$. This is a consequence of CPT invariance. The conditions of CP and T invariance read [43,55,56]: $P(\nu_l \to \nu_{l'}) = P(\bar{\nu}_l \to \bar{\nu}_{l'})$, $l, l' = e, \mu, \tau$ (CP), $P(\nu_l \to \nu_{l'}) = P(\nu_{l'} \to \nu_l)$, $P(\bar{\nu}_l \to \bar{\nu}_{l'}) = P(\bar{\nu}_{l'} \to \bar{\nu}_l)$, $l, l' = e, \mu, \tau$ (T). In the case of CPT invariance, which we will assume to hold throughout this article, we get for the survival probabilities: $P(\nu_l \to \nu_l) = P(\bar{\nu}_l \to \bar{\nu}_l)$, $l, l' = e, \mu, \tau$. Thus, the study of the "disappearance" of ν_l and $\bar{\nu}_l$, caused by oscillations in vacuum, cannot be used to test whether CP invariance holds in the lepton sector. It follows from Eq. (14.13) and Eq. (14.14) that we can have CP violation effects in neutrino oscillations only if $\phi_{l'l;jk} \neq \pi q$, $q = 0, 1, 2$, *i.e.*, if $U_{l'j}\,U_{lj}^*\,U_{lk}\,U_{l'k}^*$, and therefore U itself, is not real. As a measure of CP and T violation in neutrino oscillations we can consider the asymmetries:

$$A_{\mathrm{CP}}^{(l'l)} \equiv P(\nu_l \to \nu_{l'}) - P(\bar{\nu}_l \to \bar{\nu}_{l'})\,, \quad A_{\mathrm{T}}^{(l'l)} \equiv P(\nu_l \to \nu_{l'}) - P(\nu_{l'} \to \nu_l)\,. \tag{14.16}$$

CPT invariance implies: $A_{\rm CP}^{(l'l)} = -A_{\rm CP}^{(ll')}$, $A_{\rm T}^{(l'l)} = P(\bar\nu_{l'} \to \bar\nu_l) - P(\bar\nu_l \to \bar\nu_{l'}) = A_{\rm CP}^{(l'l)}$. It follows further directly from Eq. (14.13) and Eq. (14.14) that

$$A_{\rm CP}^{(l'l)} = 4 \sum_{j>k} {\rm Im}\left(U_{l'j}\, U_{lj}^*\, U_{lk}\, U_{l'k}^*\right) \sin\frac{\Delta m^2_{jk}}{2p}\, L\,,\ \ l, l' = e, \mu, \tau\,. \tag{14.17}$$

Eq. (14.2) and Eq. (14.13) - Eq. (14.14) imply that $P(\nu_l \to \nu_{l'})$ and $P(\bar\nu_l \to \bar\nu_{l'})$ do not depend on the Majorana CP violation phases in the neutrino mixing matrix U [43]. Thus, the experiments investigating the $\nu_l \to \nu_{l'}$ and $\bar\nu_l \to \bar\nu_{l'}$ oscillations, $l, l' = e, \mu, \tau$, cannot provide information on the nature - Dirac or Majorana, of massive neutrinos. The same conclusions hold also when the $\nu_l \to \nu_{l'}$ and $\bar\nu_l \to \bar\nu_{l'}$ oscillations take place in matter [57]. In the case of $\nu_l \leftrightarrow \nu_{l'}$ and $\bar\nu_l \leftrightarrow \bar\nu_{l'}$ oscillations in vacuum, only the Dirac phase(s) in U can cause CP violating effects leading to $P(\nu_l \to \nu_{l'}) \neq P(\bar\nu_l \to \bar\nu_{l'})$, $l \neq l'$.

In the case of 3-neutrino mixing all different ${\rm Im}(U_{l'j} U_{lj}^* U_{lk} U_{l'k}^*) \neq 0$, $l' \neq l = e, \mu, \tau$, $j \neq k = 1, 2, 3$, coincide up to a sign as a consequence of the unitarity of U. Therefore one has [58]:

$$A_{\rm CP}^{(\mu e)} = -\,A_{\rm CP}^{(\tau e)} = A_{\rm CP}^{(\tau\mu)} = 4\, J_{\rm CP}\, \left(\sin\frac{\Delta m^2_{32}}{2p}\, L + \sin\frac{\Delta m^2_{21}}{2p}\, L + \sin\frac{\Delta m^2_{13}}{2p}\, L\right) \tag{14.18}$$

where

$$J_{\rm CP} = {\rm Im}\left(U_{\mu 3}\, U_{e3}^*\, U_{e2}\, U_{\mu 2}^*\right)\,, \tag{14.19}$$

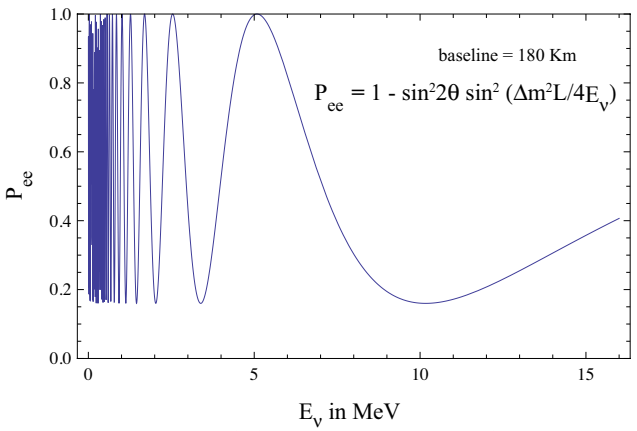

Figure 14.1: The ν_e ($\bar\nu_e$) survival probability $P(\nu_e \to \nu_e) = P(\bar\nu_e \to \bar\nu_e)$, Eq. (14.30), as a function of the neutrino energy for $L = 180$ km, $\Delta m^2 = 7.0 \times 10^{-5}$ eV^2 and $\sin^2 2\theta = 0.84$ (from Ref. 64).

is the "rephasing invariant" associated with the Dirac CP violation phase in U. It is analogous to the rephasing invariant associated with the Dirac CP violating phase in the CKM quark mixing matrix [59]. It is clear from Eq. (14.18) that $J_{\rm CP}$ controls the magnitude of CP violation effects in neutrino oscillations in the case of 3-neutrino mixing. If $\sin(\Delta m^2_{ij}/(2p)L) \cong 0$ for $(ij) = (32)$, or (21), or (13), we get $A_{\rm CP}^{(l'l)} \cong 0$. Thus, if as a consequence of the production, propagation and/or detection of neutrinos, effectively oscillations due only to one non-zero neutrino mass squared difference take place, the CP violating effects will be strongly suppressed. In particular, we get $A_{\rm CP}^{(l'l)} = 0$, unless all three $\Delta m^2_{ij} \neq 0$, $(ij) = (32), (21), (13)$.

If the number of massive neutrinos n is equal to the number of neutrino flavours, $n = 3$, one has as a consequence of the unitarity of the neutrino mixing matrix: $\sum_{l'=e,\mu,\tau} P(\nu_l \to \nu_{l'}) = 1$, $l = e, \mu, \tau$, $\sum_{l=e,\mu,\tau} P(\nu_l \to \nu_{l'}) = 1$, $l' = e, \mu, \tau$. Similar "probability conservation" equations hold for $P(\bar\nu_l \to \bar\nu_{l'})$. If, however, the number of light massive neutrinos is bigger than the number of flavour neutrinos as a consequence, *e.g.*, of a flavour neutrino - sterile neutrino mixing, we would have $\sum_{l'=e,\mu,\tau} P(\nu_l \to \nu_{l'}) = 1 - P(\nu_l \to \bar\nu_{sL})$, $l = e, \mu, \tau$, where we have assumed the existence of just one sterile neutrino. Obviously, in this case $\sum_{l'=e,\mu,\tau} P(\nu_l \to \nu_{l'}) < 1$ if $P(\nu_l \to \bar\nu_{sL}) \neq 0$. The former inequality is used in the searches for oscillations between active and sterile neutrinos.

Consider next neutrino oscillations in the case of one neutrino mass squared difference "dominance": suppose that $|\Delta m^2_{j1}| \ll |\Delta m^2_{n1}|$, $j = 2, ..., (n-1)$, $|\Delta m^2_{n1}|\, L/(2p) \gtrsim 1$ and $|\Delta m^2_{j1}|\, L/(2p) \ll 1$, so that $\exp[i(\Delta m^2_{j1}\, L/(2p)] \cong 1$, $j = 2, ..., (n-1)$. Under these conditions we obtain from Eq. (14.13) and Eq. (14.14), keeping only the oscillating terms involving Δm^2_{n1}:

$$P(\nu_{l(l')} \to \nu_{l'(l)}) \cong P(\bar\nu_{l(l')} \to \bar\nu_{l'(l)}) \cong \delta_{ll'} - 2|U_{ln}|^2 \left[\delta_{ll'} - |U_{l'n}|^2\right] (1 - \cos\frac{\Delta m^2_{n1}}{2p}\, L)\,. \tag{14.20}$$

It follows from the neutrino oscillation data (Sections 14.4 and 14.5) that in the case of 3-neutrino mixing, one of the two independent neutrino mass squared differences, say Δm^2_{21}, is much smaller in absolute value than the second one, Δm^2_{31}: $|\Delta m^2_{21}| \ll |\Delta m^2_{31}|$. The data imply:

$$\begin{aligned} |\Delta m^2_{21}| &\cong 7.5 \times 10^{-5}\ {\rm eV}^2\,, \\ |\Delta m^2_{31}| &\cong 2.5 \times 10^{-3}\ {\rm eV}^2\,, \\ |\Delta m^2_{21}|/|\Delta m^2_{31}| &\cong 0.03\,. \end{aligned} \tag{14.21}$$

Neglecting the effects due to Δm^2_{21} we get from Eq. (14.20) by setting $n = 3$ and choosing, *e.g.*, i) $l = l' = e$ and ii) $l = e(\mu)$, $l' = \mu(e)$ [60]:

$$P(\nu_e \to \nu_e) = P(\bar\nu_e \to \bar\nu_e) \cong 1 - 2|U_{e3}|^2 \left(1 - |U_{e3}|^2\right) \left(1 - \cos\frac{\Delta m^2_{31}}{2p}\, L\right)\,, \tag{14.22}$$

$$P(\nu_{\mu(e)} \to \nu_{e(\mu)}) \cong 2\,|U_{\mu 3}|^2\,|U_{e3}|^2 \left(1 - \cos\frac{\Delta m^2_{31}}{2p}\, L\right) = \frac{|U_{\mu 3}|^2}{1 - |U_{e3}|^2}\, P^{2\nu}\left(|U_{e3}|^2, m^2_{31}\right)\,, \tag{14.23}$$

Table 14.1: Sensitivity of different oscillation experiments.

Source	Type of ν	$\overline{E}$[MeV]	L[km]	min(Δm^2)[eV^2]
Reactor	$\overline{\nu}_e$	~ 1	1	$\sim 10^{-3}$
Reactor	$\overline{\nu}_e$	~ 1	100	$\sim 10^{-5}$
Accelerator	$\nu_\mu, \overline{\nu}_\mu$	$\sim 10^3$	1	~ 1
Accelerator	$\nu_\mu, \overline{\nu}_\mu$	$\sim 10^3$	1000	$\sim 10^{-3}$
Atmospheric ν's	$\nu_{\mu,e}, \overline{\nu}_{\mu,e}$	$\sim 10^3$	10^4	$\sim 10^{-4}$
Sun	ν_e	~ 1	1.5×10^8	$\sim 10^{-11}$

and $P(\bar\nu_{\mu(e)} \to \bar\nu_{e(\mu)}) = P(\nu_{\mu(e)} \to \nu_{e(\mu)})$. Here $P^{2\nu}\left(|U_{e3}|^2, m^2_{31}\right)$ is the probability of the 2-neutrino transition $\nu_e \to (s_{23}\nu_\mu + c_{23}\nu_\tau)$ due to Δm^2_{31} and a mixing with angle θ_{13}, where

$$\sin^2\theta_{13} = |U_{e3}|^2,\ \ s^2_{23} \equiv \sin^2\theta_{23} = \frac{|U_{\mu 3}|^2}{1 - |U_{e3}|^2},$$
$$c^2_{23} \equiv \cos^2\theta_{23} = \frac{|U_{\tau 3}|^2}{1 - |U_{e3}|^2}. \tag{14.24}$$

Eq. (14.22) describes with a relatively high precision the oscillations of reactor $\bar\nu_e$ on a distance $L \sim 1$ km in the case of 3-neutrino mixing. It was used in the analysis of the data of the Chooz [61], Double Chooz [30], Daya Bay [31] and RENO [32] experiments. Eq. (14.20) with $n = 3$ and $l = l' = \mu$ describes with a relatively good precision the effects of "disappearance" due to oscillations of the accelerator ν_μ,

seen in the K2K [19] MINOS [20,21] and T2K [22,23] experiments. The $\nu_\mu \to \nu_\tau$ transitions due to the oscillations, which the OPERA experiment [62,63] is observing, can be described by Eq. (14.20) with $n = 3$ and $l = \mu$, $l' = \tau$. Finally, the probability Eq. (14.23) describes with a good precision the $\nu_\mu \to \nu_e$ and $\bar\nu_\mu \to \bar\nu_e$ oscillations under the conditions of the K2K experiment.

In certain cases the dimensions of the neutrino source, ΔL, are not negligible in comparison with the oscillation length. Similarly, when analyzing neutrino oscillation data one has to include the energy resolution of the detector, ΔE, *etc.* in the analysis. As can be shown [41], if $2\pi\Delta L/L^v_{jk} \gg 1$, and/or $2\pi(L/L^v_{jk})(\Delta E/E) \gg 1$, the oscillating terms in the neutrino oscillation probabilities will be strongly suppressed. In this case (as well as in the case of sufficiently large separation of the ν_j and ν_k wave packets at the detection point) the interference terms in $P(\nu_l \to \nu_{l'})$ and $P(\bar\nu_{l'} \to \bar\nu_l)$ will be negligibly small and the neutrino flavour conversion will be determined by the average probabilities:

$$\bar P(\nu_l \to \nu_{l'}) = \bar P(\bar\nu_l \to \bar\nu_{l'}) \cong \sum_j |U_{l'j}|^2\, |U_{lj}|^2\,. \tag{14.25}$$

Suppose next that in the case of 3-neutrino mixing, $|\Delta m^2_{21}|\, L/(2p) \sim 1$, while at the same time $|\Delta m^2_{31(32)}|\, L/(2p) \gg 1$, and the oscillations due to Δm^2_{31} and Δm^2_{32} are strongly suppressed (averaged out) due to integration over the region of neutrino production, the energy resolution function, *etc.* In this case we get for the ν_e and $\bar\nu_e$ survival probabilities:

$$P(\nu_e \to \nu_e) = P(\bar\nu_e \to \bar\nu_e) \cong |U_{e3}|^4 + \left(1 - |U_{e3}|^2\right)^2\, P^{2\nu}(\nu_e \to \nu_e)\,, \tag{14.26}$$

$$\begin{aligned} P^{2\nu}(\nu_e \to \nu_e) &= P^{2\nu}(\bar\nu_e \to \bar\nu_e) \equiv P^{2\nu}_{ee}(\theta_{12}, \Delta m^2_{21}) \\ &= 1 - \frac{1}{2}\,\sin^2 2\theta_{12}\,\left(1 - \cos\frac{\Delta m^2_{21}}{2p}\,L\right) \\ &= 1 - \sin^2 2\theta_{12}\,\sin^2\left(\frac{\Delta m^2_{21}}{4E}\,L\right) \end{aligned} \tag{14.27}$$

being the ν_e and $\bar\nu_e$ survival probability in the case of 2-neutrino oscillations "driven" by the angle θ_{12} and Δm^2_{21}, with θ_{12} determined by

$$\cos^2\theta_{12} = \frac{|U_{e1}|^2}{1 - |U_{e3}|^2}\,, \quad \sin^2\theta_{12} = \frac{|U_{e2}|^2}{1 - |U_{e3}|^2}\,. \tag{14.28}$$

Eq. (14.26) with $P^{2\nu}(\bar\nu_e \to \bar\nu_e)$ given by Eq. (14.27) describes the effects of neutrino oscillations of reactor $\bar\nu_e$ observed by the KamLAND experiment.

In the case of 3-neutrino mixing with $0 < \Delta m^2_{21} < |\Delta m^2_{31(32)}|$ and $|U_{e3}|^2 = |\sin\theta_{13}|^2 \ll 1$ (see Section 14.8), one can identify Δm^2_{21} and θ_{12} as the neutrino mass squared difference and mixing angle responsible for the solar ν_e oscillations, and Δm^2_{31} and θ_{23} as those associated with the dominant atmospheric ν_μ and $\bar\nu_\mu$ oscillations. Thus, θ_{12} and θ_{23} are often called "solar" and "atmospheric" neutrino mixing angles and denoted as $\theta_{12} = \theta_\odot$ and $\theta_{23} = \theta_{\rm A}$ (or $\theta_{\rm atm}$), while Δm^2_{21} and Δm^2_{31} are often referred to as the "solar" and "atmospheric" neutrino mass squared differences and denoted as $\Delta m^2_{21} \equiv \Delta m^2_\odot$ and $\Delta m^2_{31} \equiv \Delta m^2_{\rm A}$ (or $\Delta m^2_{\rm atm}$).

The data of ν-oscillations experiments is often analyzed assuming 2-neutrino mixing:

$$|\nu_l\rangle \;= |\nu_1\rangle\cos\theta + |\nu_2\rangle\sin\theta\,, \quad |\nu_x\rangle \;= -|\nu_1\rangle\sin\theta + |\nu_2\rangle\cos\theta\;, \tag{14.29}$$

where θ is the neutrino mixing angle in vacuum and ν_x is another flavour neutrino or sterile (anti-) neutrino, $x = l' \neq l$ or $\nu_x \equiv \bar\nu_{sL}$. In this case we have [54]:

$$\begin{aligned} P^{2\nu}(\nu_l \to \nu_l) &= 1 - \frac{1}{2}\sin^2 2\theta\left(1 - \cos 2\pi\frac{L}{L^v}\right) = 1 - \sin^2 2\theta\left(\sin^2\frac{\Delta m^2}{4E}L\right), \\ P^{2\nu}(\nu_l \to \nu_x) &= 1 - P^{2\nu}(\nu_l \to \nu_l)\,, \end{aligned} \tag{14.30}$$

where $L^v = 4\pi\, E/\Delta m^2$ ($p = E$), $\Delta m^2 = m^2_2 - m^2_1 > 0$. Combining the CPT invariance constraints with the probability conservation one obtains: $P(\nu_l \to \nu_x) = P(\bar\nu_l \to \bar\nu_x) = P(\nu_x \to \nu_l) = P(\bar\nu_x \to \bar\nu_l)$. These equalities and Eq. (14.30) with $l = \mu$ and $x = \tau$ were used, for instance, in the analysis of the Super-K atmospheric neutrino data [17], in which the first compelling evidence for oscillations of neutrinos was obtained. The probability $P^{2\nu}(\nu_l \to \nu_x)$, Eq. (14.30), depends on two factors: on $(1 - \cos 2\pi L/L^v)$, which exhibits oscillatory dependence on the distance L and on the neutrino energy $p = E$ (hence the name "neutrino oscillations"), and on $\sin^2 2\theta$, which determines the amplitude of the oscillations. In order to have $P^{2\nu}(\nu_l \to \nu_x) \cong 1$, two conditions have to be fulfilled: one should have $\sin^2 2\theta \cong 1$ and $L^v \lesssim 2\pi L$ with $\cos 2\pi L/L^v \cong -1$. If $L^v \gg 2\pi L$, the oscillations do not have enough time to develop on the way to the neutrino detector and $P(\nu_l \to \nu_x) \cong 0$, while $P(\nu_l \to \nu_l) \cong 1$. The preceding comments are illustrated in Fig. 14.1 showing the dependence of the probability $P^{2\nu}(\nu_e \to \nu_e) = P^{2\nu}(\bar\nu_e \to \bar\nu_e)$ on the neutrino energy.

A given experiment searching for neutrino oscillations is specified, in particular, by the average energy of the neutrinos being studied, $\bar E$, and by the source-detector distance L. The requirement $L^v_{jk} \lesssim 2\pi L$ determines the minimal value of a generic neutrino mass squared difference $\Delta m^2 > 0$, to which the experiment is sensitive (figure of merit of the experiment): $\min(\Delta m^2) \sim 2\bar E/L$. Because of the interference nature of neutrino oscillations, experiments can probe, in general, rather small values of Δm^2 (see, *e.g.*, Ref. 50). Values of $\min(\Delta m^2)$, characterizing qualitatively the sensitivity of different experiments are given in Table 14.1. They correspond to the reactor experiments Chooz, Daya Bay, RENO, Double Chooz ($L \sim 1$ km) and KamLAND ($L \sim 100$ km), to accelerator experiments - past ($L \sim 1$ km), recent, current and future (K2K, MINOS, OPERA, T2K, NOνA [65]) , $L \sim (300 \div 1000)$ km), to the Super-Kamiokande experiment studying atmospheric neutrino oscillations, and to the solar neutrino experiments.

14.3. Matter effects in neutrino oscillations

The presence of matter can change drastically the pattern of neutrino oscillations: neutrinos can interact with the particles forming the matter. Accordingly, the Hamiltonian of the neutrino system in matter H_m, differs from the Hamiltonian in vacuum H_0, $H_m = H_0 + H_{int}$, where H_{int} describes the interaction of neutrinos with the particles of matter. When, for instance, ν_e and ν_μ propagate in matter, they can scatter (due to H_{int}) on the electrons ($\rm e^-$), protons (p) and neutrons (n) present in matter. The incoherent elastic and the quasi-elastic scattering, in which the states of the initial particles change in the process (destroying the coherence between the neutrino states), are not of interest - they have a negligible effect on the solar neutrino propagation in the Sun and on the solar, atmospheric and reactor neutrino propagation in the Earth [66]: even in the center of the Sun, where the matter density is relatively high (~ 150 g/cm^3), a ν_e with energy of 1 MeV has a mean free path with respect to the indicated scattering processes $\sim 10^{10}$ km. We recall that the solar radius is much smaller: $\rm R_\odot = 6.96 \times 10^5$ km. The oscillating ν_e and ν_μ can scatter also elastically in the forward direction on the $\rm e^-$, p and n, with the momenta and the spin states of the particles remaining unchanged. In such a process the coherence of the neutrino states is preserved.

The ν_e and ν_μ coherent elastic scattering on the particles of matter generates nontrivial indices of refraction of the ν_e and ν_μ in matter [26]: $\kappa(\nu_e) \neq 1$, $\kappa(\nu_\mu) \neq 1$. Most importantly, we have $\kappa(\nu_e) \neq \kappa(\nu_\mu)$. The difference $\kappa(\nu_e) - \kappa(\nu_\mu)$ is determined essentially by the difference of the real parts of the forward $\nu_e - e^-$ and $\nu_\mu - e^-$ elastic scattering amplitudes [26] Re $[\rm F_{\nu_e - e^-}(0)]$ − Re $[\rm F_{\nu_\mu - e^-}(0)]$: due to the flavour symmetry of the neutrino – quark (neutrino – nucleon) neutral current interaction, the forward $\nu_e - p, n$ and $\nu_\mu - p, n$ elastic scattering amplitudes are equal and therefore do not contribute to the difference of interest [67]. The imaginary parts of the forward scattering amplitudes (responsible, in particular, for decoherence effects) are proportional to the corresponding total scattering cross-sections and in the case of interest are negligible in comparison with the real parts. The real parts of the amplitudes

$\mathrm{F}_{\nu_e-e^-}(0)$ and $\mathrm{F}_{\nu_\mu-e^-}(0)$ can be calculated in the Standard Model. To leading order in the Fermi constant G_F, only the term in $\mathrm{F}_{\nu_e-e^-}(0)$ due to the diagram with exchange of a virtual $W^{\pm}$-boson contributes to $\mathrm{F}_{\nu_e-e^-}(0) - \mathrm{F}_{\nu_\mu-e^-}(0)$. One finds the following result for $\kappa(\nu_e) - \kappa(\nu_\mu)$ in the rest frame of the scatters [26,69,70]:

$$\kappa(\nu_e) - \kappa(\nu_\mu) = \frac{2\pi}{p^2}\ \left(\mathrm{Re}\ [\mathrm{F}_{\nu_e-e^-}(0)] - \mathrm{Re}\ [\mathrm{F}_{\nu_\mu-e^-}(0)]\right) = -\ \frac{1}{p}\sqrt{2}G_F N_e\ , \tag{14.31}$$

where N_e is the electron number density in matter. Given $\kappa(\nu_e) - \kappa(\nu_\mu)$, the system of evolution equations describing the $\nu_e \leftrightarrow \nu_\mu$ oscillations in matter reads [26]:

$$i\frac{d}{dt}\begin{pmatrix} A_e(t,t_0) \\ A_\mu(t,t_0)\end{pmatrix} = \begin{pmatrix} -\epsilon(t) & \epsilon' \\ \epsilon' & \epsilon(t)\end{pmatrix}\begin{pmatrix} A_e(t,t_0) \\ A_\mu(t,t_0)\end{pmatrix} \tag{14.32}$$

where $A_e(t,t_0)$ ($A_\mu(t,t_0)$) is the amplitude of the probability to find ν_e (ν_μ) at time t of the evolution of the system if at time $t_0 \leq t$ the neutrino ν_e or ν_μ has been produced and

$$\epsilon(t) = \frac{1}{2}\ [\frac{\Delta m^2}{2E}\cos 2\theta - \sqrt{2}G_F N_e(t)],\ \ \epsilon' = \frac{\Delta m^2}{4E}\sin 2\theta. \tag{14.33}$$

The term $\sqrt{2}G_F N_e(t)$ in $\epsilon(t)$ accounts for the effects of matter on neutrino oscillations. The system of evolution equations describing the oscillations of antineutrinos $\bar\nu_e \leftrightarrow \bar\nu_\mu$ in matter has exactly the same form except for the matter term in $\epsilon(t)$ which changes sign. The effect of matter in neutrino oscillations is usually called the Mikheyev, Smirnov, Wolfenstein (or MSW) effect.

Consider first the case of $\nu_e \leftrightarrow \nu_\mu$ oscillations in matter with constant density: $N_e(t) = N_e = const.$ Due to the interaction term H_{int} in H_m, the eigenstates of the Hamiltonian of the neutrino system in vacuum, $|\nu_{1,2}\rangle$ are not eigenstates of H_m. For the eigenstates $|\nu^m_{1,2}\rangle$ of H_m, which diagonalize the evolution matrix in the r.h.s. of the system Eq. (14.32) we have:

$$|\nu_e\rangle = |\nu^m_1\rangle\cos\theta_m + |\nu^m_2\rangle\sin\theta_m\,, \qquad |\nu_\mu\rangle = -|\nu^m_1\rangle\sin\theta_m\ + |\nu^m_2\rangle\cos\theta_m\ . \tag{14.34}$$

Here θ_m is the neutrino mixing angle in matter [26],

$$\sin 2\theta_m = \frac{\tan 2\theta}{\sqrt{(1-\frac{N_e}{N_e^{res}})^2 + \tan^2 2\theta}},\ \cos 2\theta_m = \frac{1 - N_e/N_e^{res}}{\sqrt{(1-\frac{N_e}{N_e^{res}})^2 + \tan^2 2\theta}}, \tag{14.35}$$

where the quantity

$$N_e^{res} = \frac{\Delta m^2\cos 2\theta}{2E\sqrt{2}G_F} \cong 6.56\times 10^6\ \frac{\Delta m^2[\mathrm{eV}^2]}{E[\mathrm{MeV}]}\cos 2\theta\,\mathrm{cm}^{-3}\ \mathrm{N_A}\,, \tag{14.36}$$

is called (for $\Delta m^2\cos 2\theta > 0$) "resonance density" [27,69], $\mathrm{N_A}$ being Avogadro's number. The "adiabatic" states $|\nu^m_{1,2}\rangle$ have energies $E^m_{1,2}$ whose difference is given by

$$E^m_2 - E^m_1 = \frac{\Delta m^2}{2E}\ \left((1-\frac{N_e}{N_e^{res}})^2\cos^2 2\theta + \sin^2 2\theta\right)^{\frac{1}{2}} \equiv \frac{\Delta M^2}{2E}\,. \tag{14.37}$$

The probability of $\nu_e \to \nu_\mu$ transition in matter with $N_e = const.$ has the form [26,69]

$$P^{2\nu}_m(\nu_e \to \nu_\mu) = |A_\mu(t)|^2 = \frac{1}{2}\sin^2 2\theta_m\ [1 - \cos 2\pi\frac{L}{L_m}\ ] \qquad L_m = 2\pi/(E^m_2 - E^m_1)\,, \tag{14.38}$$

where L_m is the oscillation length in matter. As Eq. (14.35) indicates, the dependence of $\sin^2 2\theta_m$ on N_e has a resonance character [27]. Indeed, if $\Delta m^2\cos 2\theta > 0$, for any $\sin^2 2\theta \neq 0$ there exists a value of N_e given by N_e^{res}, such that when $N_e = N_e^{res}$ we have $\sin^2 2\theta_m = 1$ independently of the value of $\sin^2 2\theta < 1$. This implies that the presence of matter can lead to a strong enhancement of the oscillation probability $P^{2\nu}_m(\nu_e \to \nu_\mu)$ even when the $\nu_e \leftrightarrow \nu_\mu$ oscillations in vacuum are suppressed due to a small value of $\sin^2 2\theta$. For obvious reasons

$$N_e = N_e^{res} \equiv \frac{\Delta m^2\cos 2\theta}{2E\sqrt{2}G_F}\,, \tag{14.39}$$

is called the "resonance condition" [27,69], while the energy at which Eq. (14.39) holds for given N_e and $\Delta m^2\cos 2\theta$, is referred to as the "resonance energy", E^{res}. The oscillation length at resonance is given by [27] $L^{res}_m = L^v/\sin 2\theta$, while the width in N_e of the resonance at half height reads $\Delta N_e^{res} = 2N_e^{res}\tan 2\theta$. Thus, if the mixing angle in vacuum is small, the resonance is narrow, $\Delta N_e^{res} \ll N_e^{res}$, and $L^{res}_m \gg L^v$. The energy difference $E^m_2 - E^m_1$ has a minimum at the resonance: $(E^m_2 - E^m_1)^{res} = \min\ (E^m_2 - E^m_1) = (\Delta m^2/(2E))\sin 2\theta$.

It is instructive to consider two limiting cases. If $N_e \ll N_e^{res}$, we have from Eq. (14.35) and Eq. (14.37), $\theta_m \cong \theta$, $\mathrm{L_m} \cong \mathrm{L^v}$ and neutrinos oscillate practically as in vacuum. In the limit $N_e \gg N_e^{res}$, $N_e^{res}\tan^2 2\theta$, one finds $\theta_m \cong \pi/2$ ($\cos 2\theta_m \cong -1$) and the presence of matter suppresses the $\nu_e \leftrightarrow \nu_\mu$ oscillations. In this case $|\nu_e\rangle \cong |\nu^m_2\rangle$, $|\nu_\mu\rangle = -|\nu^m_1\rangle$, *i.e.*, ν_e practically coincides with the heavier matter-eigenstate, while ν_μ coincides with the lighter one.

Since the neutral current weak interaction of neutrinos in the Standard Model is flavour symmetric, the formulae and results we have obtained are valid for the case of $\nu_e - \nu_\tau$ mixing and $\nu_e \leftrightarrow \nu_\tau$ oscillations in matter as well. The case of $\nu_\mu - \nu_\tau$ mixing, however, is different: to a relatively good precision we have [71] $\kappa(\nu_\mu) \cong \kappa(\nu_\tau)$ and the $\nu_\mu \leftrightarrow \nu_\tau$ oscillations in the matter of the Earth and the Sun proceed practically as in vacuum [72].

The analogs of Eq. (14.35) to Eq. (14.38) for oscillations of antineutrinos, $\bar\nu_e \leftrightarrow \bar\nu_\mu$, in matter can formally be obtained by replacing N_e with $(-N_e)$ in the indicated equations. It should be clear that depending on the sign of $\Delta m^2\cos 2\theta$, the presence of matter can lead to resonance enhancement either of the $\nu_e \leftrightarrow \nu_\mu$ or of the $\bar\nu_e \leftrightarrow \bar\nu_\mu$ oscillations, but not of both types of oscillations [69]. For $\Delta m^2\cos 2\theta < 0$, for instance, the matter can only suppress the $\nu_e \to \nu_\mu$ oscillations, while it can enhance the $\bar\nu_e \to \bar\nu_\mu$ transitions. This disparity between the behavior of neutrinos and that of antineutrinos is a consequence of the fact that the matter in the Sun or in the Earth we are interested in is not charge-symmetric (it contains e^-, p and n, but does not contain their antiparticles) and therefore the oscillations in matter are neither CP- nor CPT- invariant [57]. Thus, even in the case of 2-neutrino mixing and oscillations we have, *e.g.*, $P^{2\nu}_m(\nu_e \to \nu_{\mu(\tau)}) \neq P^{2\nu}_m(\bar\nu_e \to \bar\nu_{\mu(\tau)})$.

The matter effects in the $\nu_e \leftrightarrow \nu_{\mu(\tau)}$ ($\bar\nu_e \leftrightarrow \bar\nu_{\mu(\tau)}$) oscillations will be invariant with respect to the operation of time reversal if the N_e distribution along the neutrino path is symmetric with respect to this operation [58,73]. The latter condition is fulfilled (to a good approximation) for the N_e distribution along a path of a neutrino crossing the Earth [74].

14.3.1. *Effects of Earth matter on oscillations of neutrinos* :

The formalism we have developed can be applied, *e.g.*, to the study of matter effects in the $\nu_e \leftrightarrow \nu_{\mu(\tau)}$ ($\nu_{\mu(\tau)} \leftrightarrow \nu_e$) and $\bar\nu_e \leftrightarrow \bar\nu_{\mu(\tau)}$ ($\bar\nu_{\mu(\tau)} \leftrightarrow \bar\nu_e$) oscillations of neutrinos which traverse the Earth [75]. Indeed, the Earth density distribution in the existing Earth models [74] is assumed to be spherically symmetric and there are two major density structures - the core and the mantle, and a certain number of substructures (shells or layers). The Earth radius is $R_\oplus = 6371$ km; the Earth core has a radius of $R_c = 3486$ km, so the Earth mantle depth is 2885 km. For a spherically symmetric Earth density distribution, the neutrino trajectory in the Earth is specified by the value of the nadir angle θ_n of the trajectory. For $\theta_n \leq 33.17^o$, or path lengths $L \geq 10660$ km, neutrinos cross the Earth core. The path length for neutrinos which cross only the Earth mantle is given by $L = 2R_\oplus\cos\theta_n$. If neutrinos cross the Earth core, the lengths of the paths in the mantle, $2L^{\mathrm{man}}$, and in the core, L^{core}, are determined by: $L^{\mathrm{man}} = R_\oplus\cos\theta_n - (R_c^2 - R_\oplus^2\sin^2\theta_n)^{\frac{1}{2}}$, $L^{\mathrm{core}} = 2(R_c^2 - R_\oplus^2\sin^2\theta_n)^{\frac{1}{2}}$. The mean electron number densities in the mantle and in the core according to the PREM model read [74]: $\bar N_e^{man} \cong 2.2$ cm^{-3} $\mathrm{N_A}$, $\bar N_e^c \cong 5.4$ cm^{-3} $\mathrm{N_A}$. Thus, we have $\bar N_e^c \cong 2.5\ \bar N_e^{man}$. The change of N_e from the mantle to the core can well be approximated by a step function [74]. The electron number density N_e changes

relatively little around the indicated mean values along the trajectories of neutrinos which cross a substantial part of the Earth mantle, or the mantle and the core, and the two-layer constant density approximation, $N_e^{man} = const. = \bar{N}_e^{man}$, $N_e^c = const. = \bar{N}_e^c$, $\bar{N}_e^{man}$ and $\bar{N}_e^c$ being the mean densities along the given neutrino path in the Earth, was shown to be sufficiently accurate in what concerns the calculation of neutrino oscillation probabilities [58,77,78] (and references quoted in [77,78]) in a large number of specific cases. This is related to the fact that the relatively small changes of density along the path of the neutrinos in the mantle (or in the core) take place over path lengths which are typically considerably smaller than the corresponding oscillation length in matter.

In the case of 3-neutrino mixing and for neutrino energies of $E \gtrsim 2$ GeV, the effects due to Δm^2_{21} ($|\Delta m^2_{21}| \ll |\Delta m^2_{31}|$, see Eq. (14.21)) in the neutrino oscillation probabilities are sub-dominant and to leading order can be neglected: the corresponding resonance density $|N^{res}_{e21}| \lesssim 0.25\ cm^{-3}\ N_A \ll \bar{N}_e^{man,c}$ and the Earth matter strongly suppresses the oscillations due to Δm^2_{21}. For oscillations in vacuum this approximation is valid as long as the leading order contribution due to Δm^2_{31} in the relevant probabilities is bigger than approximately 10^{-3}. In this case the 3-neutrino $\nu_e \to \nu_{\mu(\tau)}$ ($\bar{\nu}_e \to \bar{\nu}_{\mu(\tau)}$) and $\nu_{\mu(\tau)} \to \nu_e$ ($\bar{\nu}_{\mu(\tau)} \to \bar{\nu}_e$) transition probabilities for neutrinos traversing the Earth, reduce effectively to a 2-neutrino transition probability (see, *e.g.*, Refs. [78–80]) , with Δm^2_{31} and θ_{13} playing the role of the relevant 2-neutrino vacuum oscillation parameters. As will be discussed in Sections 14.6 and 14.8, the value of $\sin^2 2\theta_{13}$ has been determined with a rather high precision in the Daya Bay [31] and RENO [32] experiments. The best fit values found in the two experiments read, respectively, $\sin^2 2\theta_{13} = 0.090$ [36] and 0.100 [37]. The 3-neutrino oscillation probabilities of the atmospheric and accelerator $\nu_{e,\mu}$ having energy E and crossing the Earth along a trajectory characterized by a nadir angle θ_n, for instance, have the following form:

$$P^{3\nu}_m(\nu_e \to \nu_e) \cong 1 - P^{2\nu}_m, \tag{14.40}$$

$$P^{3\nu}_m(\nu_e \to \nu_\mu) \cong P^{3\nu}_m(\nu_\mu \to \nu_e) \cong s^2_{23}\ P^{2\nu}_m, \qquad P^{3\nu}_m(\nu_e \to \nu_\tau) \cong c^2_{23}\ P^{2\nu}_m, \tag{14.41}$$

$$P^{3\nu}_m(\nu_\mu \to \nu_\mu) \cong 1 - s^4_{23}\ P^{2\nu}_m - 2c^2_{23}s^2_{23}\ \left[1 - Re\ (e^{-i\kappa} A^{2\nu}_m(\nu' \to \nu'))\right], \tag{14.42}$$

$$P^{3\nu}_m(\nu_\mu \to \nu_\tau) = 1 - P^{3\nu}_m(\nu_\mu \to \nu_\mu) - P^{3\nu}_m(\nu_\mu \to \nu_e). \tag{14.43}$$

Here $P^{2\nu}_m \equiv P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}; E, \theta_n)$ is the probability of the 2-neutrino $\nu_e \to \nu' \equiv (s_{23}\nu_\mu + c_{23}\nu_\tau)$ oscillations in the Earth, and κ and $A^{2\nu}_m(\nu' \to \nu') \equiv A^{2\nu}_m$ are known phase and 2-neutrino transition probability amplitude (see, *e.g.*, Refs. [78,79]). We note that Eq. (14.40) to Eq. (14.42) are based only on the assumptions that $|N^{res}_{e21}|$ is much smaller than the densities in the Earth mantle and core and that $|\Delta m^2_{21}| \ll |\Delta m^2_{31}|$, and does not rely on the constant density approximation. Similar results are valid for the corresponding antineutrino oscillation probabilities: one has just to replace $P^{2\nu}_m$, κ and $A^{2\nu}_m$ in the expressions given above with the corresponding quantities for antineutrinos (the latter are obtained from those for neutrinos by changing the sign in front of N_e). Obviously, we have: $P(\nu_{e(\mu)} \to \nu_{\mu(e)}), P(\bar{\nu}_{e(\mu)} \to \bar{\nu}_{\mu(e)}) \leq \sin^2\theta_{23}$, and $P(\nu_e \to \nu_\tau), P(\bar{\nu}_e \to \bar{\nu}_\tau) \leq \cos^2\theta_{23}$. The one Δm^2 dominance approximation and correspondingly Eq. (14.40) to Eq. (14.43) were used by the Super-Kamiokande Collaboration in their 2006 neutrino oscillation analysis of the multi-GeV atmospheric neutrino data [81].

In the case of neutrinos crossing only the Earth mantle and in the constant density approximation, $P^{2\nu}_m$ is given by the r.h.s. of Eq. (14.38) with θ and Δm^2 replaced by θ_{13} and Δm^2_{31}, while for κ and $A^{2\nu}_m$ we have (see, *e.g.*, Ref. 78):

$$\kappa \cong \frac{1}{2}[\frac{\Delta m^2_{31}}{2E}\ L + \sqrt{2}G_F \bar{N}_e^{man} L - \frac{\Delta M^2 L}{2E}],$$
$$A^{2\nu}_m = 1 + (e^{-i\frac{\Delta M^2 L}{2E}} - 1)\cos^2\theta'_m\ , \tag{14.44}$$

where ΔM^2 is defined in Eq. (14.37) (with $\theta = \theta_{13}$ and $\Delta m^2 = \Delta m^2_{31}$), θ'_m is the mixing angle in the mantle which coincides in vacuum with θ_{13} (Eq. (14.35) with $N_e = \bar{N}_e^{man}$ and $\theta = \theta_{13}$), and $L = 2R_\oplus \cos\theta_n$ is the distance the neutrino travels in the mantle.

It follows from Eq. (14.40) and Eq. (14.41) that for $\Delta m^2_{31}\cos 2\theta_{13} > 0$, the oscillation effects of interest, *e.g.*, in the $\nu_{e(\mu)} \to \nu_{\mu(e)}$ and $\nu_e \to \nu_\tau$ transitions will be maximal if $P^{2\nu}_m \cong 1$, *i.e.*, if Eq. (14.39) leading to $\sin^2 2\theta_m \cong 1$ is fulfilled, and ii) $\cos(\Delta M^2 L/(2E)) \cong -1$. Given the value of $\bar{N}_e^{man}$, the first condition determines the neutrino's energy, while the second determines the path length L, for which one can have $P^{2\nu}_m \cong 1$. For $\Delta m^2_{31} \cong 2.5 \times 10^{-3}$ eV^2, $\sin^2 2\theta_{13} \cong 0.090$ and $\bar{\mathrm{N}}_\mathrm{e}^{\mathrm{man}} \cong 2.2\ \mathrm{N_A cm^{-3}}$, one finds that $E_{res} \cong 7.1$ GeV and $L \cong 3522/\sin 2\theta_{13}$ km $\cong 11739$ km. Since for neutrinos crossing only the mantle $L \lesssim 10660$ km, the second condition can be satisfied only if $\sin^2 2\theta_{13} \gtrsim 0.11$, which falls in the 3σ range of the experimentally allowed values of $\sin^2 2\theta_{13}$. We still get a significant amplification of the probability $P^{2\nu}_m$, and therefore of $P(\nu_{e(\mu)} \to \nu_{\mu(e)})$ and $P(\nu_e \to \nu_\tau)$, even when $\cos(\Delta M^2 L/(2E)) = -0.5(-0.2)$: in this case $P^{2\nu}_m \cong 0.75$ (0.60). For $\sin^2 2\theta_{13} \cong 0.090$ we have $\cos(\Delta M^2 L/(2E)) = -0.5(-0.2)$ if $L \cong 7826$ (6622) km. Thus, for $\Delta m^2_{31} > 0$, the Earth matter effects can amplify $P^{2\nu}_m$, and therefore $P(\nu_{e(\mu)} \to \nu_{\mu(e)})$ and $P(\nu_e \to \nu_\tau)$, significantly when the neutrinos cross only the mantle, for $E \sim 7$ GeV and sufficiently large path lengths L. If $\Delta m^2_{31} < 0$ the same considerations apply for the corresponding antineutrino oscillation probabilities $\bar{P}^{2\nu}_m = \bar{P}^{2\nu}_m(\bar{\nu}_e \to (s_{23}\bar{\nu}_\mu + c_{23}\bar{\nu}_\tau))$ and correspondingly for $P(\bar{\nu}_{e(\mu)} \to \bar{\nu}_{\mu(e)})$ and $P(\bar{\nu}_e \to \bar{\nu}_\tau)$. For $\Delta m^2_{31} > 0$, the $\bar{\nu}_{e(\mu)} \to \bar{\nu}_{\mu(e)}$ and $\bar{\nu}_e \to \bar{\nu}_\tau$ oscillations are suppressed by the Earth matter, while if $\Delta m^2_{31} < 0$, the same conclusion holds for the $\nu_{e(\mu)} \to \nu_{\mu(e)}$ and $\nu_e \to \nu_\tau$, oscillations.

In the case of neutrinos crossing the Earth core, new resonance-like effects become possible in the $\nu_\mu \to \nu_e$ and $\nu_e \to \nu_{\mu(\tau)}$ (or $\bar{\nu}_\mu \to \bar{\nu}_e$ and $\bar{\nu}_e \to \bar{\nu}_{\mu(\tau)}$) transitions [77–79,82–84]. For $\Delta m^2_{31} > 0$ and certain values of $\sin^2\theta_{13} \lesssim 0.05$ we can have [83] $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}) \cong 1$, and correspondingly maximal $P^{3\nu}_m(\nu_e \to \nu_\mu) = P^{3\nu}_m(\nu_\mu \to \nu_e) \cong s^2_{23}$, only due to the effect of maximal constructive interference between the amplitudes of the $\nu_e \to \nu'$ transitions in the Earth mantle and in the Earth core. The effect differs from the MSW one and the enhancement happens in the case of interest at a value of the energy between the MSW resonance energies corresponding to the density in the mantle and that of the core, or at a value of the resonance density N^{res}_e which lies between the values of N_e in the mantle and in the core [77]. In Refs. [77,78] the enhancement was called "neutrino oscillation length resonance", while in Refs. [79,82] the term "parametric resonance" for the same effect was used [85]. The *mantle-core enhancement effect* is caused by the existence (for a given neutrino trajectory through the Earth core) of points of resonance-like maximal neutrino conversion, $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}) = 1$, in the corresponding space of neutrino oscillation parameters [83]. For $\Delta m^2_{31} < 0$ the mantle-core enhancement can take place for the antineutrino transitions, $\bar{\nu}_\mu \to \bar{\nu}_e$ and $\bar{\nu}_e \to \bar{\nu}_{\mu(\tau)}$.

A rather complete set of values of $\Delta m^2_{31}/E > 0$ and $\sin^2 2\theta_{13}$ for which $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}) = 1$ was found in Ref. 83. The location of these points in the $\Delta m^2_{31}/E - \sin^2 2\theta_{13}$ plane determines the regions in the plane where $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13})$ is large, $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}) \gtrsim 0.5$. These regions vary slowly with the nadir angle, being remarkably wide in the nadir angle and rather wide in the neutrino energy [83], so that the transitions of interest can produce noticeable effects in the measured observables. For $\sin^2\theta_{13} \lesssim 0.05$, there are two sets of values of $(\Delta m^2_{31}/E, \sin^2\theta_{13})$ for which $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}) = 1$, and thus two regions in $\Delta m^2_{31}/E - \sin^2 2\theta_{13}$ plane where $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}) \gtrsim 0.5$. For $\Delta m^2_{31} = 2.5 \times 10^{-3}$ eV^2 and nadir angle, *e.g.*, θ_n=0 (Earth center crossing neutrinos), we have $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}) = 1$ at $(E, \sin^2 2\theta_{13})$ =(3.4 GeV,0.034) and (5.2 GeV,0.15). At the same time for E =3.4 GeV (5.2 Gev), the probability $P^{2\nu}_m(\Delta m^2_{31}, \theta_{13}) \gtrsim 0.5$ for the values of $\sin^2 2\theta_{13}$ from the interval $0.02 \lesssim \sin^2 2\theta_{13} \lesssim 0.10$ ($0.04 \lesssim \sin^2 2\theta_{13} \lesssim 0.26$). Similar results hold for neutrinos crossing the Earth core along the trajectories with $\theta_n \neq 0$ (for further details see the last article in Ref. 83; see also the last article in Ref. 84).

The mantle-core enhancement of $P^{2\nu}_m$ (or $\bar{P}^{2\nu}_m$) is relevant, in particular, for the searches of sub-dominant $\nu_{e(\mu)} \to \nu_{\mu(e)}$ (or $\bar{\nu}_{e(\mu)} \to \bar{\nu}_{\mu(e)}$) oscillations of atmospheric neutrinos having energies $E \gtrsim 2$ GeV and crossing the Earth core on the way to the detector (see Ref. 77 to Ref. 84 and the references quoted therein). The effects

of Earth matter on the oscillations of atmospheric and accelerator neutrinos have not been observed so far. At present there are no compelling evidences for oscillations of the atmospheric ν_e and/or $\bar{\nu}_e$.

The expression for the probability of the $\nu_\mu \to \nu_e$ oscillations taking place in the Earth mantle in the case of 3-neutrino mixing, in which both neutrino mass squared differences Δm^2_{21} and Δm^2_{31} contribute and the CP violation effects due to the Dirac phase in the neutrino mixing matrix are taken into account, has the following form in the constant density approximation and keeping terms up to second order in the two small parameters $|\alpha| \equiv |\Delta m^2_{21}|/|\Delta m^2_{31}| \ll 1$ and $\sin^2\theta_{13} \ll 1$ [86]:

$$P^{3\nu\ man}_m(\nu_\mu \to \nu_e) \cong P_0 + P_{\sin\delta} + P_{\cos\delta} + P_3\,. \tag{14.45}$$

Here

$$P_0 = \sin^2\theta_{23}\,\frac{\sin^2 2\theta_{13}}{(A-1)^2}\,\sin^2[(A-1)\Delta]$$

$$P_3 = \alpha^2\,\cos^2\theta_{23}\,\frac{\sin^2 2\theta_{12}}{A^2}\,\sin^2(A\Delta)\,, \tag{14.46}$$

$$P_{\sin\delta} = -\,\alpha\,\frac{8\,J_{CP}}{A(1-A)}\,(\sin\Delta)\,(\sin A\Delta)\,(\sin[(1-A)\Delta])\,, \tag{14.47}$$

$$P_{\cos\delta} = \alpha\,\frac{8\,J_{CP}\,\cot\delta}{A(1-A)}\,(\cos\Delta)\,(\sin A\Delta)\,(\sin[(1-A)\Delta])\,, \tag{14.48}$$

where

$$\alpha = \frac{\Delta m^2_{21}}{\Delta m^2_{31}}\,,\ \Delta = \frac{\Delta m^2_{31}\,L}{4E}\,,\ A = \sqrt{2}G_{\rm F}N_e^{man}\frac{2E}{\Delta m^2_{31}}\,, \tag{14.49}$$

and $\cot\delta = J^{-1}_{CP}{\rm Re}(U_{\mu 3}U^*_{e3}U_{e2}U^*_{\mu 2})$, $J_{CP} = {\rm Im}(U_{\mu 3}U^*_{e3}U_{e2}U^*_{\mu 2})$. The analytic expression for $P^{3\nu\ man}_m(\nu_\mu \to \nu_e)$ given above is valid for [86] neutrino path lengths in the mantle ($L \leq 10660$ km) satisfying $L \lesssim 10560$ km $E[{\rm GeV}]\,(7.6\times10^{-5}\ {\rm eV}^2/\Delta m^2_{21})$, and energies $E \gtrsim 0.34$ GeV$(\Delta m^2_{21}/7.6\times10^{-5}\ {\rm eV}^2)\,(1.4\ {\rm cm}^{-3}N_A/N_e^{man})$. The expression for the $\bar{\nu}_\mu \to \bar{\nu}_e$ oscillation probability can be obtained formally from that for $P^{3\nu\ man}_m(\nu_\mu \to \nu_e)$ by making the changes $A \to -A$ and $J_{CP} \to -J_{CP}$, with $J_{CP}\cot\delta \equiv {\rm Re}(U_{\mu 3}U^*_{e3}U_{e2}U^*_{\mu 2})$ remaining unchanged. The term $P_{\sin\delta}$ in $P^{3\nu\ man}_m(\nu_\mu \to \nu_e)$ would be equal to zero if the Dirac phase in the neutrino mixing matrix U possesses a CP-conserving value. Even in this case, however, we have $A^{(e\mu)\ man}_{CP} \equiv (P^{3\nu\ man}_m(\nu_\mu \to \nu_e) - P^{3\nu\ man}_m(\bar{\nu}_\mu \to \bar{\nu}_e)) \neq 0$ due to the effects of the Earth matter. It will be important to experimentally disentangle the effects of the Earth matter and of J_{CP} in $A^{(e\mu)\ man}_{CP}$: this will allow to get information about the Dirac CP violation phase in U. This can be done, in principle, by studying the energy dependence of $P^{3\nu\ man}_m(\nu_\mu \to \nu_e)$ and $P^{3\nu\ man}_m(\bar{\nu}_\mu \to \bar{\nu}_e)$. Since the sign of $\Delta m^2_{31(32)}$ determines for given L whether the probability $P^{3\nu\ man}_m(\nu_\mu \to \nu_e)$ or $P^{3\nu\ man}_m(\bar{\nu}_\mu \to \bar{\nu}_e)$, as a function of energy, can be resonantly enhanced or suppressed by the matter effects, the study of the energy dependence of $P^{3\nu\ man}_m(\nu_\mu \to \nu_e)$ and/or of $P^{3\nu\ man}_m(\bar{\nu}_\mu \to \bar{\nu}_e)$ can provide also information on ${\rm sgn}(\Delta m^2_{31(32)})$. In the vacuum limit of $N_e^{man} = 0$ ($A = 0$) we have $A^{(e\mu)\ man}_{CP} = A^{(e\mu)}_{CP}$ (see Eq. (14.18)) and only the term $P_{\sin\delta}$ contributes to the asymmetry $A^{(e\mu)}_{CP}$.

The preceding remarks apply also to the probabilities $P^{3\nu\ man}_m(\nu_e \to \nu_\mu)$ and $P^{3\nu\ man}_m(\bar{\nu}_e \to \bar{\nu}_\mu)$). The probability $P^{3\nu\ man}_m(\nu_e \to \nu_\mu)$, for example, can formally be obtained from the expression for the probability $P^{3\nu\ man}_m(\nu_\mu \to \nu_e)$ by changing the sign of the term $P_{\sin\delta}$.

14.3.2. *Oscillations of solar neutrinos* :

Consider next the oscillations of solar ν_e while they propagate from the central part of the Sun, where they are produced, to the surface of the Sun [27,76](see also Ref. 26 and, *e.g.*, Ref. 87) Details concerning the production, spectrum, magnitude and particularities of the solar neutrino flux, the methods of detection of solar neutrinos, description of solar neutrino experiments and of the data they provided will be discussed in the next section (see also Ref. 88). The electron number density N_e changes considerably along the neutrino path in the Sun: it decreases monotonically from the value of ~ 100 cm^{-3} N_A in the center of the Sun to 0 at the surface of the Sun. According to the contemporary solar models (see, *e.g.*, Ref. [88,89]), N_e decreases approximately exponentially in the radial direction towards the surface of the Sun:

$$N_e(t) = N_e(t_0)\exp\left\{-\frac{t-t_0}{r_0}\right\}\,, \tag{14.50}$$

where $(t - t_0) \cong d$ is the distance traveled by the neutrino in the Sun, $N_e(t_0)$ is the electron number density at the point of ν_e production in the Sun, r_0 is the scale-height of the change of $N_e(t)$ and one has [88,89] $r_0 \sim 0.1R_\odot$.

Consider the case of 2-neutrino mixing, Eq. (14.34). Obviously, if N_e changes with t (or equivalently with the distance) along the neutrino trajectory, the matter-eigenstates, their energies, the mixing angle and the oscillation length in matter, become, through their dependence on N_e, also functions of t: $|\nu^m_{1,2}\rangle = |\nu^m_{1,2}(t)\rangle$, $E^m_{1,2} = E^m_{1,2}(t)$, $\theta_m = \theta_m(t)$ and $L_m = L_m(t)$. It is not difficult to understand qualitatively the possible behavior of the neutrino system when solar neutrinos propagate from the center to the surface of the Sun if one realizes that one is dealing effectively with a two-level system whose Hamiltonian depends on time and admits "jumps" from one level to the other (see Eq. (14.32)). Consider the case of $\Delta m^2\cos 2\theta > 0$. Let us assume first for simplicity that the electron number density at the point of a solar ν_e production in the Sun is much bigger than the resonance density, $N_e(t_0) \gg N_e^{res}$. Actually, this is one of the cases relevant to the solar neutrinos. In this case we have $\theta_m(t_0) \cong \pi/2$ and the state of the electron neutrino in the initial moment of the evolution of the system practically coincides with the heavier of the two matter-eigenstates:

$$|\nu_e\rangle \ \cong\ |\nu^m_2(t_0)\rangle\,. \tag{14.51}$$

Thus, at t_0 the neutrino system is in a state corresponding to the "level" with energy $E^m_2(t_0)$. When neutrinos propagate to the surface of the Sun they cross a layer of matter in which $N_e = N_e^{res}$: in this layer the difference between the energies of the two "levels" $(E^m_2(t) - E^m_1(t))$ has a minimal value on the neutrino trajectory (Eq. (14.37) and Eq. (14.39)). Correspondingly, the evolution of the neutrino system can proceed basically in two ways. First, the system can stay on the "level" with energy $E^m_2(t)$, *i.e.*, can continue to be in the state $|\nu^m_2(t)\rangle$ up to the final moment t_s, when the neutrino reaches the surface of the Sun. At the surface of the Sun $N_e(t_s) = 0$ and therefore $\theta_m(t_s) = \theta$, $|\nu^m_{1,2}(t_s)\rangle \equiv |\nu_{1,2}\rangle$ and $E^m_{1,2}(t_s) = E_{1,2}$. Thus, in this case the state describing the neutrino system at t_0 will evolve continuously into the state $|\nu_2\rangle$ at the surface of the Sun. Using Eq. (14.29) with $l = e$ and $x = \mu$, it is easy to obtain the probabilities to find ν_e and ν_μ at the surface of the Sun:

$$P(\nu_e \to \nu_e; t_s, t_0) \cong |\langle\nu_e|\nu_2\rangle|^2 = \sin^2\theta$$
$$P(\nu_e \to \nu_\mu; t_s, t_0) \cong |\langle\nu_\mu|\nu_2\rangle|^2 = \cos^2\theta\,. \tag{14.52}$$

It is clear that under the assumption made and if $\sin^2\theta \ll 1$, practically a total $\nu_e \to \nu_\mu$ conversion is possible. This type of evolution of the neutrino system and the $\nu_e \to \nu_\mu$ transitions taking place during the evolution, are called [27] "adiabatic." They are characterized by the fact that the probability of the "jump" from the upper "level" (having energy $E^m_2(t)$) to the lower "level" (with energy $E^m_1(t)$), P', or equivalently the probability of the $\nu^m_2(t_0) \to \nu^m_1(t_s)$ transition, $P' \equiv P'(\nu^m_2(t_0) \to \nu^m_1(t_s))$, on the whole neutrino trajectory is negligible:

$$P' \equiv P'(\nu^m_2(t_0) \to \nu^m_1(t_s)) \cong 0\ :\ \textit{adiabatic transitions}\,. \tag{14.53}$$

The second possibility is realized if in the resonance region, where the two "levels" approach each other closest the system "jumps" from the upper "level" to the lower "level" and after that continues to be in the state $|\nu^m_1(t)\rangle$ until the neutrino reaches the surface of the Sun. Evidently, now we have $P' \equiv P'(\nu^m_2(t_0) \to \nu^m_1(t_s)) \sim 1$. In this case

the neutrino system ends up in the state $|\nu_1^m(t_s)\rangle \equiv |\nu_1\rangle$ at the surface of the Sun and

$$P(\nu_e \to \nu_e; t_s, t_0) \cong |\langle \nu_e | \nu_1 \rangle|^2 = \cos^2\theta$$
$$P(\nu_e \to \nu_\mu; t_s, t_0) \cong |\langle \nu_\mu | \nu_1 \rangle|^2 = \sin^2\theta\,. \qquad (14.54)$$

Obviously, if $\sin^2\theta \ll 1$, practically no transitions of the solar ν_e into ν_μ will occur. The considered regime of evolution of the neutrino system and the corresponding $\nu_e \to \nu_\mu$ transitions are usually referred to as "extremely nonadiabatic."

Clearly, the value of the "jump" probability P' plays a crucial role in the the $\nu_e \to \nu_\mu$ transitions: it fixes the type of the transition and determines to a large extent the $\nu_e \to \nu_\mu$ transition probability [76,90,91]. We have considered above two limiting cases. Obviously, there exists a whole spectrum of possibilities since P' can have any value from 0 to $\cos^2\theta$ [92,93]. In general, the transitions are called "nonadiabatic" if P' is non-negligible.

Numerical studies have shown [27] that solar neutrinos can undergo both adiabatic and nonadiabatic $\nu_e \to \nu_\mu$ transitions in the Sun and the matter effects can be substantial in the solar neutrino oscillations for 10^{-8} eV$^2 \lesssim \Delta m^2 \lesssim 10^{-4}$ eV^2, $10^{-4} \lesssim \sin^2 2\theta < 1.0$.

The condition of adiabaticity of the solar ν_e transitions in Sun can be written as [76,90]

$$\gamma(t) \equiv \sqrt{2} G_F \frac{(N_e^{res})^2}{|\dot{N}_e(t)|} \tan^2 2\theta \left(1 + \tan^{-2} 2\theta_m(t)\right)^{\frac{3}{2}} \gg 1$$
$$\text{adiabatic transitions}\,, \qquad (14.55)$$

while if $\gamma(t) \lesssim 1$ the transitions are nonadiabatic (see also Ref. 93), where $\dot{N}_e(t) \equiv \frac{d}{dt} N_e(t)$. Condition in Eq. (14.55) implies that the $\nu_e \to \nu_{\mu(\tau)}$ transitions in the Sun will be adiabatic if $N_e(t)$ changes sufficiently slowly along the neutrino path. In order for the transitions to be adiabatic, condition in Eq. (14.55) has to be fulfilled at any point of the neutrino's path in the Sun.

Actually, the system of evolution equations Eq. (14.32) can be solved exactly for N_e changing exponentially, Eq. (14.50), along the neutrino path in the Sun [92,94]. More specifically, the system in Eq. (14.32) is equivalent to one second order differential equation (with appropriate initial conditions). The latter can be shown [95] to coincide in form, in the case of N_e given by Eq. (14.50), with the Schroedinger equation for the radial part of the nonrelativistic wave function of the Hydrogen atom [96]. On the basis of the exact solution, which is expressed in terms of confluent hypergeometric functions, it was possible to derive a complete, simple and very accurate analytic description of the matter-enhanced transitions of solar neutrinos in the Sun for any values of Δm^2 and θ [26,92,93,97,98] (see also Refs. [27,76,91,99,100]) .

The probability that a ν_e, produced at time t_0 in the central part of the Sun, will not transform into $\nu_{\mu(\tau)}$ on its way to the surface of the Sun (reached at time t_s) is given by

$$P_\odot^{2\nu}(\nu_e \to \nu_e; t_s, t_0) = \bar{P}_\odot^{2\nu}(\nu_e \to \nu_e; t_s, t_0) + \ \textit{Oscillating terms}. \qquad (14.56)$$

Here

$$\bar{P}_\odot^{2\nu}(\nu_e \to \nu_e; t_s, t_0) \equiv \bar{P}_\odot = \frac{1}{2} + \left(\frac{1}{2} - \mathrm{P}'\right) \cos 2\theta_m(t_0) \cos 2\theta\ , \qquad (14.57)$$

is the average survival probability for ν_e having energy $\mathrm{E} \cong \mathrm{p}$ [91], where

$$P' = \frac{\exp\left[-2\pi \mathrm{r}_0 \frac{\Delta m^2}{2E} \sin^2\theta\right] - \exp\left[-2\pi \mathrm{r}_0 \frac{\Delta m^2}{2E}\right]}{1 - \exp\left[-2\pi \mathrm{r}_0 \frac{\Delta m^2}{2E}\right]}\,, \qquad (14.58)$$

is [92] the "jump" probability for exponentially varying N_e, and $\theta_m(t_0)$ is the mixing angle in matter at the point of ν_e production [99]. The expression for $\bar{P}_\odot^{2\nu}(\nu_e \to \nu_e; t_s, t_0)$ with P' given by Eq. (14.58) is valid for $\Delta m^2 > 0$, but for both signs of $\cos 2\theta \neq 0$ [92,100]; it is valid for any given value of the distance along the neutrino trajectory and does not take into account the finite dimensions of the region of ν_e production in the Sun. This can be done by integrating over the different neutrino paths, *i.e.*, over the region of ν_e production.

The oscillating terms in the probability $P_\odot^{2\nu}(\nu_e \to \nu_e; t_s, t_0)$ [97,95] were shown [98] to be strongly suppressed for $\Delta m^2 \gtrsim 10^{-7}$ eV^2 by the various averagings one has to perform when analyzing the solar neutrino data. The current solar neutrino and KamLAND data suggest that $\Delta m^2 \cong 7.6 \times 10^{-5}$ eV^2. For $\Delta m^2 \gtrsim 10^{-7}$ eV^2, the averaging over the region of neutrino production in the Sun *etc.* renders negligible all interference terms which appear in the probability of ν_e survival due to the $\nu_e \leftrightarrow \nu_{\mu(\tau)}$ oscillations in vacuum taking place on the way of the neutrinos from the surface of the Sun to the surface of the Earth. Thus, the probability that ν_e will remain ν_e while it travels from the central part of the Sun to the surface of the Earth is effectively equal to the probability of survival of the ν_e while it propagates from the central part to the surface of the Sun and is given by the average probability $\bar{P}_\odot(\nu_e \to \nu_e; t_s, t_0)$ (determined by Eq. (14.57) and Eq. (14.58)).

If the solar ν_e transitions are adiabatic ($P' \cong 0$) and $\cos 2\theta_m(t_0) \cong -1$ (*i.e.*, $N_e(t_0)/|N_e^{res}| \gg 1, |\tan 2\theta|$, the ν_e are born "above" (in N_e) the resonance region), one has [27]

$$\bar{P}^{2\nu}(\nu_e \to \nu_e; t_s, t_0) \cong \frac{1}{2} - \frac{1}{2}\cos 2\theta. \qquad (14.59)$$

The regime under discussion is realised for $\sin^2 2\theta \cong 0.8$ (suggested by the data, Section 14.4), if $E/\Delta m^2$ lies approximately in the range $(2 \times 10^4 - 3 \times 10^7)$ MeV/eV^2 (see Ref. 93). This result is relevant for the interpretation of the Super-Kamiokande and SNO solar neutrino data. We see that depending on the sign of $\cos 2\theta \neq 0$, $\bar{P}^{2\nu}(\nu_e \to \nu_e)$ is either bigger or smaller than 1/2. It follows from the solar neutrino data that in the range of validity (in $E/\Delta m^2$) of Eq. (14.59) we have $\bar{P}^{2\nu}(\nu_e \to \nu_e) \cong 0.3$. Thus, the possibility of $\cos 2\theta \leq 0$ is ruled out by the data. Given the choice $\Delta m^2 > 0$ we made, the data imply that $\Delta m^2 \cos 2\theta > 0$.

If $E/\Delta m^2$ is sufficiently small so that $N_e(t_0)/|N_e^{res}| \ll 1$, we have $P' \cong 0$, $\theta_m(t_0) \cong \theta$ and the oscillations take place in the Sun as in vacuum [27]:

$$\bar{P}^{2\nu}(\nu_e \to \nu_e; t_s, t_0) \cong 1 - \frac{1}{2}\sin^2 2\theta\,, \qquad (14.60)$$

which is the average two-neutrino vacuum oscillation probability. This expression describes with good precision the transitions of the solar *pp* neutrinos (Section 14.4). The extremely nonadiabatic ν_e transitions in the Sun, characterised by $\gamma(t) \ll 1$, are also described by the average vacuum oscillation probability (Eq. (14.60)) (for $\Delta m^2 \cos 2\theta > 0$ in this case we have (see *e.g.*, Refs. [92,93]) $\cos 2\theta_m(t_0) \cong -1$ and $P' \cong \cos^2\theta$).

The probability of ν_e survival in the case 3-neutrino mixing takes a simple form for $|\Delta m^2_{31}| \cong 2.4 \times 10^{-3}$ eV$^2 \gg |\Delta m^2_{21}|$. Indeed, for the energies of solar neutrinos $E \lesssim 10$ MeV, N^{res} corresponding to $|\Delta m^2_{31}|$ satisfies $N^{res}_{e31} \gtrsim 10^3$ cm^{-3} $\mathrm{N_A}$ and is by a factor of 10 bigger than N_e in the center of the Sun. As a consequence, the oscillations due to Δm^2_{31} proceed as in vacuum. The oscillation length associated with $|\Delta m^2_{31}|$ satisfies $L^v_{31} \lesssim 10$ km $\ll \Delta R$, ΔR being the dimension of the region of ν_e production in the Sun. We have for the different components of the solar ν_e flux [88] $\Delta R \cong (0.04 - 0.20) R_\odot$. Therefore the averaging over ΔR strongly suppresses the oscillations due to Δm^2_{31} and we get [80,101]:

$$P_\odot^{3\nu} \cong \sin^4\theta_{13} + \cos^4\theta_{13}\ P_\odot^{2\nu}(\Delta m^2_{21}, \theta_{12}; N_e \cos^2\theta_{13})\,, \qquad (14.61)$$

where $P_\odot^{2\nu}(\Delta m^2_{21}, \theta_{12}; N_e \cos^2\theta_{13})$ is given by Eq. (14.56) to Eq. (14.58) in which $\Delta m^2 = \Delta m^2_{21}$, $\theta = \theta_{12}$ and the solar e^- number density N_e is replaced by $N_e \cos^2\theta_{13}$. Thus, the solar ν_e transitions observed by the Super-Kamiokande and SNO experiments are described approximately by:

$$P_\odot^{3\nu} \cong \sin^4\theta_{13} + \cos^4\theta_{13}\ \sin^2\theta_{12}\,. \qquad (14.62)$$

The data show that $P_{\odot}^{3\nu} \cong 0.3$, which is a strong evidence for matter effects in the solar ν_e transitions [102] since in the case of oscillations in vacuum $P_{\odot}^{3\nu} \cong \sin^4\theta_{13} + (1 - 0.5\sin^2 2\theta_{12})\cos^4\theta_{13} \gtrsim 0.51$, where we have used $\sin^2\theta_{13} \lesssim 0.0315$ and where we have used $\sin^2\theta_{13} \lesssim 0.0297$ and $\sin^2 2\theta_{12} \lesssim 0.92$ (see Section 14.8).

14.4. Measurements of $\Delta m^2_{\odot}$ and $\theta_{\odot}$

14.4.1. *Solar neutrino observations* :

Observation of solar neutrinos directly addresses the theory of stellar structure and evolution, which is the basis of the standard solar model (SSM). The Sun as a well-defined neutrino source also provides extremely important opportunities to investigate nontrivial neutrino properties such as nonzero mass and mixing, because of the wide range of matter density and the great distance from the Sun to the Earth.

The solar neutrinos are produced by some of the fusion reactions in the pp chain or CNO cycle. The combined effect of these reactions is written as

$$4p \rightarrow {}^4\mathrm{He} + 2e^+ + 2\nu_e. \qquad (14.63)$$

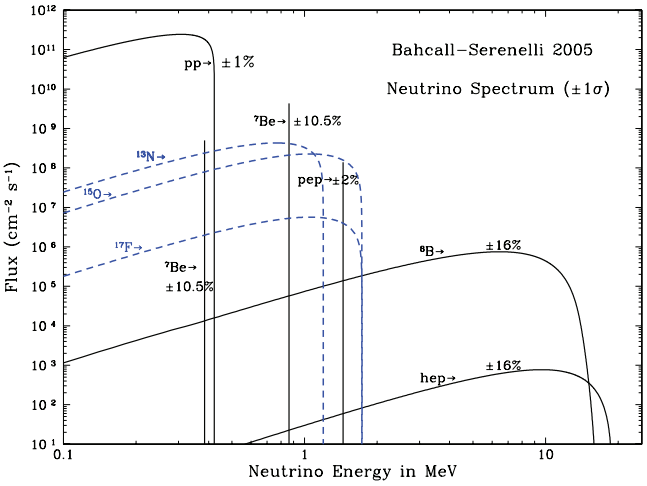

Figure 14.2: The solar neutrino spectrum predicted by the BS05(OP) standard solar model [103]. The neutrino fluxes are given in units of $\mathrm{cm}^{-2}\mathrm{s}^{-1}\mathrm{MeV}^{-1}$ for continuous spectra and $\mathrm{cm}^{-2}\mathrm{s}^{-1}$ for line spectra. The numbers associated with the neutrino sources show theoretical errors of the fluxes. This figure is taken from the late John Bahcall's web site, `http://www.sns.ias.edu/~jnb/`.

Positrons annihilate with electrons. Therefore, when considering the solar thermal energy generation, a relevant expression is

$$4p + 2e^- \rightarrow {}^4\mathrm{He} + 2\nu_e + 26.73\ \mathrm{MeV} - E_\nu\ , \qquad (14.64)$$

where E_ν represents the energy taken away by neutrinos, with an average value being $\langle E_\nu \rangle \sim 0.6$ MeV. There have been efforts to calculate solar neutrino fluxes from these reactions on the basis of SSM. A variety of input information is needed in the evolutionary calculations. The most elaborate SSM calculations have been developed by Bahcall and his collaborators, who define their SSM as the solar model which is constructed with the best available physics and input data. Therefore, their SSM calculations have been rather frequently updated. SSM's labelled as BS05(OP) [103], BSB06(GS) and BSB06(AGS) [89], and BPS08(GS) and BPS08(AGS) [104] represent some of recent model calculations. Here, "OP" means that newly calculated radiative opacities from the "Opacity Project" are used. The later models are also calculated with OP opacities. "GS" and "AGS" refer to old and new determinations of solar abundances of heavy elements. There are significant differences between the old, higher heavy element abundances (GS) and the new, lower heavy element abundances (AGS). The models with GS are consistent with helioseismological data, but the models with AGS are not.

The prediction of the BPS08(GS) model for the fluxes from neutrino-producing reactions is given in Table 14.2. Fig. 14.2 shows the solar-neutrino spectra calculated with the BS05(OP) model which is similar to the BPS08(GS) model. Here we note that in Ref. 105 the authors point out that electron capture on ^{13}N, ^{15}O, and ^{17}F produces line spectra of neutrinos, which have not been considered in the SSM calculations quoted above.

In 2011, a new SSM calculations [106] have been presented by A.M. Serenelli, W.C. Haxton, and C. Peña-Garay, by adopting the newly analyzed nuclear fusion cross sections. Their high metalicity SSM is labelled as SHP11(GS). For the same solar abundances as used in Ref. 103 and Ref. 89, the most significant change is a decrease of ^{8}B flux by $\sim 5\%$.

Table 14.2: Neutrino-producing reactions in the Sun (first column) and their abbreviations (second column). The neutrino fluxes predicted by the BPS08(GS) model [104] are listed in the third column.

Reaction	Abbr.	Flux ($\mathrm{cm}^{-2}\ \mathrm{s}^{-1}$)
$pp \rightarrow d\,e^+\,\nu$	pp	$5.97(1 \pm 0.006) \times 10^{10}$
$pe^-p \rightarrow d\,\nu$	pep	$1.41(1 \pm 0.011) \times 10^{8}$
$^3\mathrm{He}\ p \rightarrow {}^4\mathrm{He}\ e^+\nu$	hep	$7.90(1 \pm 0.15) \times 10^{3}$
$^7\mathrm{Be}\ e^- \rightarrow {}^7\mathrm{Li}\ \nu + (\gamma)$	^{7}Be	$5.07(1 \pm 0.06) \times 10^{9}$
$^8\mathrm{B} \rightarrow {}^8\mathrm{Be}^*\ e^+\nu$	^{8}B	$5.94(1 \pm 0.11) \times 10^{6}$
$^{13}\mathrm{N} \rightarrow {}^{13}\mathrm{C}\ e^+\nu$	^{13}N	$2.88(1 \pm 0.15) \times 10^{8}$
$^{15}\mathrm{O} \rightarrow {}^{15}\mathrm{N}\ e^+\nu$	^{15}O	$2.15(1^{+0.17}_{-0.16}) \times 10^{8}$
$^{17}\mathrm{F} \rightarrow {}^{17}\mathrm{O}\ e^+\nu$	^{17}F	$5.82(1^{+0.19}_{-0.17}) \times 10^{6}$

So far, solar neutrinos have been observed by chlorine (Homestake) and gallium (SAGE, GALLEX, and GNO) radiochemical detectors and water Cherenkov detectors using light water (Kamiokande and Super-Kamiokande) and heavy water (SNO). Recently, a liquid scintillation detector (Borexino) successfully observed low energy solar neutrinos.

A pioneering solar neutrino experiment by Davis and collaborators at Homestake using the ^{37}Cl - ^{37}Ar method proposed by Pontecorvo [107] started in the late 1960's. This experiment exploited ν_e absorption on ^{37}Cl nuclei followed by the produced ^{37}Ar decay through orbital e^- capture,

$$\nu_e + {}^{37}\mathrm{Cl} \rightarrow {}^{37}\mathrm{Ar} + e^- \ \ (\text{threshold } 814 \text{ keV}). \qquad (14.65)$$

The ^{37}Ar atoms produced are radioactive, with a half life ($\tau_{1/2}$) of 34.8 days. After an exposure of the detector for two to three times $\tau_{1/2}$, the reaction products were chemically extracted and introduced into a low-background proportional counter, where they were counted for a sufficiently long period to determine the exponentially decaying signal and a constant background. Solar-model calculations predict that the dominant contribution in the chlorine experiment came from ^{8}B neutrinos, but ^{7}Be, *pep*, ^{13}N, and ^{15}O neutrinos also contributed (for notations, refer to Table 14.2).

From the very beginning of the solar-neutrino observation [108], it was recognized that the observed flux was significantly smaller than the SSM prediction, provided nothing happens to the electron neutrinos after they are created in the solar interior. This deficit has been called "the solar-neutrino problem."

Gallium experiments (GALLEX and GNO at Gran Sasso in Italy and SAGE at Baksan in Russia) utilize the reaction

$$\nu_e + {}^{71}\mathrm{Ga} \rightarrow {}^{71}\mathrm{Ge} + e^- \ \ (\text{threshold } 233 \text{ keV}). \qquad (14.66)$$

They are sensitive to the most abundant *pp* solar neutrinos. The solar-model calculations predict that more than 80% of the capture rate in gallium is due to low energy *pp* and ^{7}Be solar neutrinos with

Table 14.3: Results from radiochemical solar-neutrino experiments. The predictions of a recent standard solar model BPS08(GS) are also shown. The first and the second errors in the experimental results are the statistical and systematic errors, respectively. SNU (Solar Neutrino Unit) is defined as 10^{-36} neutrino captures per atom per second.

	^{37}Cl→^{37}Ar (SNU)	^{71}Ga→^{71}Ge (SNU)
Homestake [6]	$2.56 \pm 0.16 \pm 0.16$	–
GALLEX [10]	–	$77.5 \pm 6.2^{+4.3}_{-4.7}$
GALLEX-Reanalysis [109]	–	$73.4^{+6.1+3.7}_{-6.0-4.1}$
GNO [11]	–	$62.9^{+5.5}_{-5.3} \pm 2.5$
GNO+GALLEX [11]	–	$69.3 \pm 4.1 \pm 3.6$
GNO+GALLEX-Reanalysis [109]	–	$67.6^{+4.0+3.2}_{-4.0-3.2}$
SAGE [8]	–	$65.4^{+3.1+2.6}_{-3.0-2.8}$
SSM [BPS08(GS)] [104]	$8.46^{+0.87}_{-0.88}$	$127.9^{+8.1}_{-8.2}$

the *pp* rate being about twice the ^{7}Be rate. SAGE reported the first results in 1991 [110]. They observed the capture rate to be $20^{+15}_{-20} \pm 32$ SNU, or a 90% confidence-level upper limit of 79 SNU. In 1992, GALLEX reported the observed capture rate of $83 \pm 19 \pm 8$ SNU [9]. It was the first evidence for low-energy solar-neutrino observation. Later, SAGE observed similar flux [111] to GALLEX. The latest SAGE results are published in Ref. 8. The GALLEX Collaboration finished observations in early 1997 [10,109]. Since April, 1998, a newly defined collaboration, GNO (Gallium Neutrino Observatory) continued the observations until April 2003. The GNO results are published in Ref. 11. The GNO + GALLEX joint analysis results are also presented in Ref. 11 and Ref. 109. The results from radiochemical solar neutrino experiments are shown in Table 14.3.

In 1987, the Kamiokande experiment in Japan succeeded in real-time solar neutrino observation, utilizing νe scattering,

$$\nu_x + e^- \to \nu_x + e^- \,, \tag{14.67}$$

in a large water-Cherenkov detector. This experiment takes advantage of the directional correlation between the incoming neutrino and the recoil electron. This feature greatly helps the clear separation of the solar-neutrino signal from the background. The Kamiokande result gave the first direct evidence that neutrinos come from the direction of the Sun [112]. Later, the high-statistics Super-Kamiokande experiment [113–116] with a 50-kton water Cherenkov detector replaced the Kamiokande experiment. Due to the high thresholds (recoil-electron total energy of 7 MeV in Kamiokande and 5 MeV at present in Super-Kamiokande) the experiments observe pure ^{8}B solar neutrinos. It should be noted that the reaction (Eq. (14.67)) is sensitive to all active neutrinos, $x = e$, μ, and τ. However, the sensitivity to ν_μ and ν_τ is much smaller than the sensitivity to ν_e, $\sigma(\nu_{\mu,\tau} e) \approx 0.16\, \sigma(\nu_e e)$.

Recently, the Super-Kamiokande experiment has reported [117] a $2.7\,\sigma$ indication of non-zero day-night asymmetry of ^{8}B solar neutrinos, $A_{DN} = 2(R_D - R_N)/(R_D + R_N) = -0.032 \pm 0.011 \pm 0.005$, where R_D and R_N are the average day and average night νe elastic-scattering rates of ^{8}B solar neutrinos. A non-zero day-night asymmetry implies the Earth matter effects on flavour oscillations of solar neutrinos (see, Subsections 14.4.2 and 14.4.3).

In 1999, a new real time solar-neutrino experiment, SNO (Sudbury Neutrino Observatory), in Canada started observation. This experiment used 1000 tons of ultra-pure heavy water (D_2O) contained in a spherical acrylic vessel, surrounded by an ultra-pure H_2O shield. SNO measured ^{8}B solar neutrinos via the charged-current (CC) and neutral-current (NC) reactions

$$\nu_e + d \to e^- + p + p \qquad \text{(CC)}\,, \tag{14.68}$$

and

$$\nu_x + d \to \nu_x + p + n \qquad \text{(NC)}\,, \tag{14.69}$$

as well as νe scattering, (Eq. (14.67)). The CC reaction, (Eq. (14.68)), is sensitive only to ν_e, while the NC reaction, (Eq. (14.69)), is sensitive to all active neutrinos. This is a key feature to solve the solar neutrino problem. If it is caused by flavour transitions such as neutrino oscillations, the solar neutrino fluxes measured by CC and NC reactions would show a significant difference.

The Q-value of the CC reaction is -1.4 MeV and the e^- energy is strongly correlated with the ν_e energy. Thus, the CC reaction provides an accurate measure of the shape of the ^{8}B neutrino spectrum. The contributions from the CC reaction and νe scattering can be distinguished by using different $\cos\,\theta$ distributions, where θ is the angle of the e^- momentum with respect to the Sun-Earth axis. While the νe scattering events have a strong forward peak, CC events have an approximate angular distribution of $1 - 1/3\,\cos\theta$.

The neutrino energy threshold of the NC reaction is 2.2 MeV. In the pure D_2O [13,14], the signal of the NC reaction was neutron capture in deuterium, producing a 6.25-MeV γ-ray. In this case, the capture efficiency was low and the deposited energy was close to the detection threshold of 5 MeV. In order to enhance both the capture efficiency and the total γ-ray energy (8.6 MeV), 2 tons of NaCl were added to the heavy water in the second phase of the experiment [118]. Subsequently NaCl was removed and an array of ^{3}He neutron counters were installed for the third phase measurement [119]. These neutron counters provided independent NC measurement with different systematics from that of the second phase, and thus strengthened the reliability of the NC measurement. After completion of data acquisition in 2006, the SNO group presented the results of Phase I and Phase II joint analysis [120] as well as the results of a combined analysis of all three phases [121].

Table 14.4 shows the ^{8}B solar neutrino results from real time experiments. The standard solar model predictions are also shown. Table 14.4 includes the results from the SNO group's joint analysis of the SNO Phase I and Phase II data with the analysis threshold as low as 3.5 MeV (effective electron kinetic energy) and significantly improved systematic uncertainties [120]. Also, the recent result from a combined analysis of all three phases [121] is included. It is seen from these tables that the results from all the solar-neutrino experiments, except SNO's NC result, indicate significantly less flux than expected from the solar-model predictions.

Another real time solar neutrino experiment, Borexino at Gran Sasso in Italy, started solar neutrino observation in 2007. This experiment measures solar neutrinos via νe scattering in 300 tons of ultra-pure liquid scintillator. With a detection threshold as low as 250 keV, the flux of monochromatic 0.862 MeV ^{7}Be solar neutrinos has been directly observed for the first time (see Table 14.5). The observed energy spectrum shows the characteristic Compton-edge over the background [122,123]. Borexino also reported an observation of null day-night asymmetry of the ^{7}Be neutrino flux, $A_{DN} = 2(R_D - R_N)/(R_D + R_N) = -0.001 \pm 0.012 \pm 0.007$ [124], where R_D and R_N are the day and night count rates of ^{7}Be neutrinos.

Further, Borexino measured the flux of monochromatic 1.44 MeV *pep* solar neutrinos [125]. The absence of the *pep* solar neutrino signal is disfavored at 98% CL. The *pep* solar neutrino flux measured *via* νe scattering (calculated from the measured interaction rate and the expected one with the assumption of no neutrino oscillations and the SHP11(GS) SSM [106], both given in [125]) is shown in Table 14.6 and compared with the SSM predictions. Also, an upper limit of the "unoscillated" CNO solar neutrino flux is determined [125] as $< 7.7 \times 10^8$ cm^{-2}s^{-1} (95% CL) by assuming the MSW large mixing angle solution with $\Delta m^2_\odot = (7.6 \pm 0.2) \times 10^{-5}$ eV^2 and $\tan^2\theta_\odot = 0.47^{+0.05}_{-0.04}$ and the SHP11(GS) SSM prediction [106] for the *pep* ν flux.

Borexino also measured ^{8}B solar neutrinos with an energy threshold of 3 MeV [126]. Measurements of low energy solar neutrinos are important not only to test the SSM further, but also to study the MSW effect over the energy region spanning from sub-MeV to 10 MeV.

Table 14.4: ^{8}B solar neutrino results from real time experiments. The predictions of BPS08(GS) and SHP11(GS) standard solar models are also shown. The first and the second errors in the experimental results are the statistical and systematic errors, respectively.

	Reaction	^{8}B ν flux (10^6cm^{-2}s^{-1})
Kamiokande [7]	νe	$2.80 \pm 0.19 \pm 0.33$
Super-K I [114,116]	νe	$2.38 \pm 0.02 \pm 0.08$
Super-K II [115,116]	νe	$2.41 \pm 0.05^{+0.16}_{-0.15}$

SSM [BPS08(GS)] [104]	–	$1.41(1 \pm 0.011)$
SSM [SHP11(GS)] [106]	–	$1.44(1 \pm 0.012)$

14.4.2. *Evidence for solar neutrino flavour conversion* :

Solar neutrino experiments achieved remarkable progress in the past ten years, and the solar-neutrino problem, which had remained unsolved for more than 30 years, has been understood as due to neutrino flavour conversion. In 2001, the initial SNO CC result combined with the Super-Kamiokande's high-statistics νe elastic scattering result [127] provided direct evidence for flavour conversion of solar neutrinos [13]. Later, SNO's NC measurements further strengthened this conclusion [14,118,119]. From the salt-phase measurement [118], the fluxes measured with CC, ES, and NC events were obtained as

$$\phi^{CC}_{SNO} = (1.68 \pm 0.06^{+0.08}_{-0.09}) \times 10^6 \text{cm}^{-2}\text{s}^{-1} , \quad (14.70)$$

$$\phi^{ES}_{SNO} = (2.35 \pm 0.22 \pm 0.15) \times 10^6 \text{cm}^{-2}\text{s}^{-1} , \quad (14.71)$$

$$\phi^{NC}_{SNO} = (4.94 \pm 0.21^{+0.38}_{-0.34}) \times 10^6 \text{cm}^{-2}\text{s}^{-1} , \quad (14.72)$$

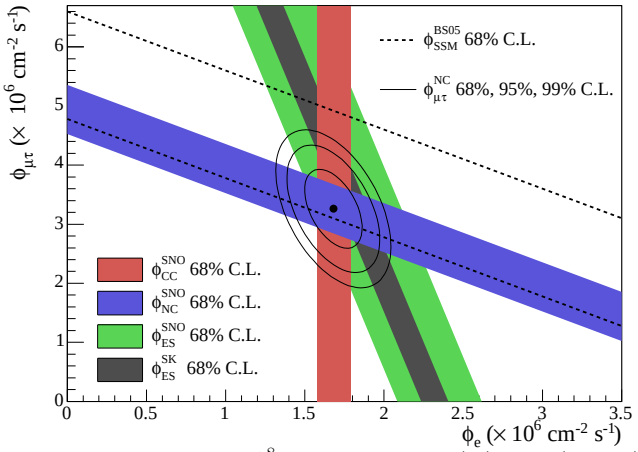

Figure 14.3: Fluxes of ^{8}B solar neutrinos, $\phi(\nu_e)$, and $\phi(\nu_{\mu \text{ or } \tau})$, deduced from the SNO's CC, ES, and NC results of the salt phase measurement [118]. The Super-Kamiokande ES flux is from Ref. 128. The BS05(OP) standard solar model prediction [103] is also shown. The bands represent the 1σ error. The contours show the 68%, 95%, and 99% joint probability for $\phi(\nu_e)$ and $\phi(\nu_{\mu \text{ or } \tau})$. The figure is from Ref. 118.

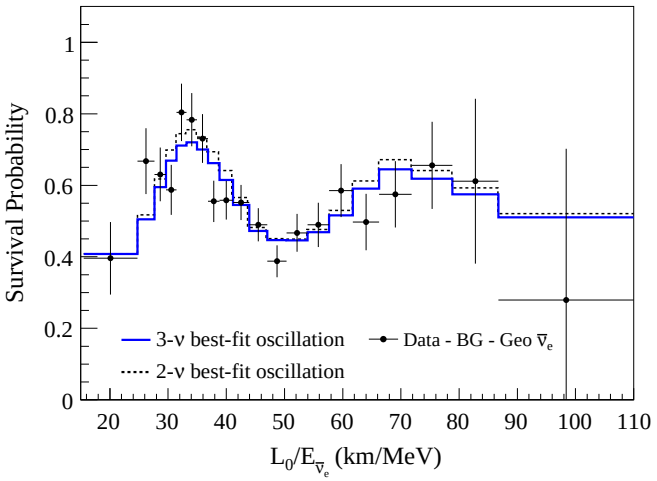

Figure 14.4: The ratio of the background and geoneutrino-subtracted $\bar{\nu}_e$ spectrum, observed in the KamLAND experiment, to the predicted one without oscillations (survival probability) as a function of L_0/E, where L_0=180 km. The histograms show the expected distributions based on the best-fit parameter values from the two- and three-flavor neutrino oscillation analyses. The figure is from Ref. 131.

where the first errors are statistical and the second errors are systematic. In the case of $\nu_e \to \nu_{\mu,\tau}$ transitions, Eq. (14.72) is a mixing-independent result and therefore tests solar models. It shows

good agreement with the ^{8}B solar-neutrino flux predicted by the solar model [103]. Fig. 14.3 shows the salt phase result of $\phi(\nu_\mu \text{ or } \tau)$ versus the flux of electron neutrinos $\phi(\nu_e)$ with the 68%, 95%, and 99% joint probability contours. The flux of non-ν_e active neutrinos, $\phi(\nu_\mu \text{ or } \tau)$, can be deduced from these results. It is

$$\phi(\nu_\mu \text{ or } \tau) = \left(3.26 \pm 0.25^{+0.40}_{-0.35}\right) \times 10^6 \text{cm}^{-2}\text{s}^{-1}. \quad (14.73)$$

The non-zero $\phi(\nu_\mu \text{ or } \tau)$ is strong evidence for neutrino flavor conversion. These results are consistent with those expected from the LMA (large mixing angle) solution of solar neutrino oscillation in matter [26,27] with $\Delta m^2_\odot \sim 7.5 \times 10^{-5}$ eV^2 and $\tan^2\theta_\odot \sim 0.45$. However, with the SNO data alone, the possibility of other solutions cannot be excluded with sufficient statistical significance.

14.4.3. *KamLAND experiment* :

KamLAND is a 1-kton ultra-pure liquid scintillator detector located at the old Kamiokande's site in Japan. The primary goal of the KamLAND experiment was a long-baseline (flux-weighted average distance of $\sim$ 180 km) neutrino oscillation studies using $\bar{\nu}_e$'s emitted from nuclear power reactors. The reaction $\bar{\nu}_e + p \to e^+ + n$ is used to detect reactor $\bar{\nu}_e$'s and a delayed coincidence of the positron with a 2.2 MeV γ-ray from neutron capture on a proton is used to reduce the backgrounds. With the reactor $\bar{\nu}_e$'s energy spectrum (< 8 MeV) and a prompt-energy analysis threshold of 2.6 MeV, this experiment has a sensitive Δm^2 range down to $\sim 10^{-5}$ eV^2. Therefore, if the LMA solution is the real solution of the solar neutrino problem, KamLAND should observe reactor $\bar{\nu}_e$ disappearance, assuming CPT invariance.

The first KamLAND results [15] with 162 ton·yr exposure were reported in December 2002. The ratio of observed to expected (assuming no $\bar{\nu}_e$ oscillations) number of events was

$$\frac{N_{\text{obs}} - N_{\text{BG}}}{N_{\text{NoOsc}}} = 0.611 \pm 0.085 \pm 0.041 \quad (14.74)$$

with obvious notation. This result showed clear evidence of an event deficit expected from neutrino oscillations. The 95% CL allowed regions are obtained from the oscillation analysis with the observed event rates and positron spectrum shape. A combined global solar + KamLAND analysis showed that the LMA is a unique solution to the solar neutrino problem with $> 5\sigma$ CL [129]. With increased statistics [16,130,131], KamLAND observed not only the distortion of the $\bar{\nu}_e$ spectrum, but also for the first time the periodic feature of the $\bar{\nu}_e$ survival probability expected from neutrino oscillations (see Fig. 14.4).

In the latest neutrino oscillation analysis in Ref. 132, parameters are better determined because of the reduction of uncertainties in the geo $\bar{\nu}_e$ flux and other backgrounds, resulted from the recent long-term shutdown of nuclear reactors in Japan. Including the data on θ_{13} from accelerator and short-baseline reactor experiments (see Section 14.6), a combined 3-neutrino oscillation analysis of solar and KamLAND data gives $\tan^2\theta_{12} = 0.436^{+0.029}_{-0.025}$, $\Delta m^2_{21} = (7.53 \pm 0.18) \times 10^{-5}$ eV^2, and $\sin^2\theta_{13} = 0.023 \pm 0.002$.

14.5. Measurements of $|\Delta m^2_{\text{A}}|$ and θ_{A}

14.5.1. *Atmospheric neutrino results* :

The interactions in massive underground detectors of atmospheric neutrinos provide a means of studying neutrino oscillations, because of the large range of distances traveled by these neutrinos ($\sim$10 to 1.3$\times$10^4 km) to reach a detector on Earth and relatively well-understood fluxes which are up-down symmetric (except for geomagnetic effects). Atmospheric neutrinos are produced by the decay of π and K mesons produced in the nuclear interactions of the primary component of cosmic rays in the atmosphere. Since pions are dominant and they decay according to $\pi^\pm \to \mu^\pm + \nu_\mu\,(\bar{\nu}_\mu)$, $\mu^\pm \to e^\pm + \nu_e\,(\bar{\nu}_e) + \bar{\nu}_\mu\,(\nu_\mu)$, we have for the ratio of the fluxes of $(\nu_\mu + \bar{\nu}_\mu)$ and $(\nu_e + \bar{\nu}_e)$ at low energies ($\lesssim$ 1 GeV) approximately $\Phi(\nu_\mu + \bar{\nu}_\mu) : \Phi(\nu_e + \bar{\nu}_e) \approx 2 : 1$. More elaborate calculations of the atmospheric neutrino fluxes are found in Refs. [133,134] (Honda *et al.*), [135] (Bartol), and [136] (FLUKA) with a typical uncertainty of 10 $\sim$ 20%.

The first compelling evidence for the neutrino oscillation was presented by the Super-Kamiokande Collaboration (SK-I) in 1998 [17] from the observation of atmospheric neutrinos. The zenith-angle distributions of the μ-like events which are mostly muon-neutrino and muon antineutrino initiated charged-current interactions, showed a clear deficit compared to the no-oscillation expectation. Note that a water Cherenkov detector cannot measure the charge of the final-state leptons, and therefore neutrino and antineutrino induced events cannot be discriminated. Neutrino events having their vertex in the 22.5 kton fiducial volume in Super-Kamiokande are classified into fully contained (FC) events and partially contained (PC) events. The FC events are required to have no activity in the anti-counter. Single-ring events have only one charged lepton which radiates Cherenkov light in the final state, and particle identification is particularly clean for single-ring FC events. A ring produced by an e-like ($e^\pm$, γ) particle exhibits a more diffuse pattern than that produced by a μ-like ($\mu^\pm$, $\pi^\pm$) particle, since an e-like particle produces an electromagnetic shower and low-energy electrons suffer considerable multiple Coulomb scattering in water. All the PC events were assumed to be μ-like since the PC events comprise a 98% pure charged-current ν_μ sample.

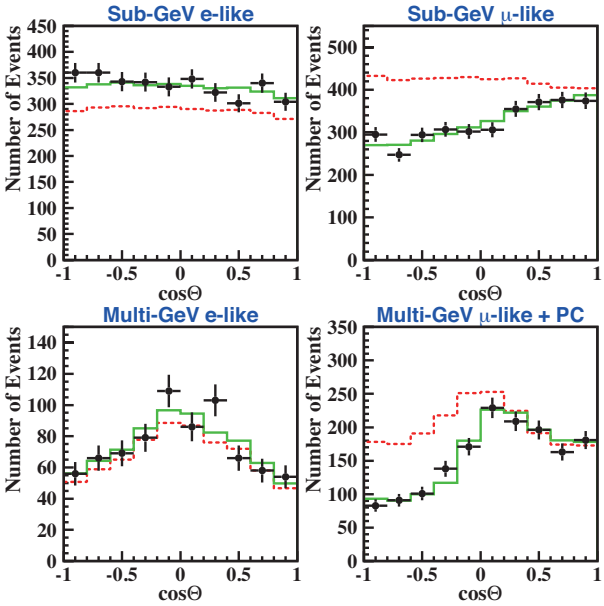

Figure 14.5: The zenith angle distributions for fully contained 1-ring e-like and μ-like events with visible energy < 1.33 GeV (sub-GeV) and > 1.33 GeV (multi-GeV). For multi-GeV μ-like events, a combined distribution with partially contained (PC) events is shown. The dotted histograms show the non-oscillated Monte Carlo events, and the solid histograms show the best-fit expectations for $\nu_\mu \leftrightarrow \nu_\tau$ oscillations. (This figure is provided by the Super-Kamiokande Collab.)

Fig. 14.5 shows the zenith-angle distributions of e-like and μ-like events from the SK-I measurement [137]. $\cos\theta = 1$ corresponds to the downward direction, while $\cos\theta = -1$ corresponds to the upward direction. Events included in these plots are single-ring FC events subdivided into sub-GeV (visible energy < 1.33 GeV) events and multi-GeV (visible energy > 1.33 GeV) events. The zenith-angle distribution of the multi-GeV μ-like events is shown combined with that of the PC events. The final-state leptons in these events have good directional correlation with the parent neutrinos. The dotted histograms show the Monte Carlo expectation for neutrino events. If the produced flux of atmospheric neutrinos of a given flavour remains unchanged at the detector, the data should have similar distributions to the expectation. However, the zenith-angle distribution of the μ-like events shows a strong deviation from the expectation. On the other hand, the zenith-angle distribution of the e-like events is consistent with the expectation. This characteristic feature may be interpreted that muon neutrinos coming from the opposite side of the

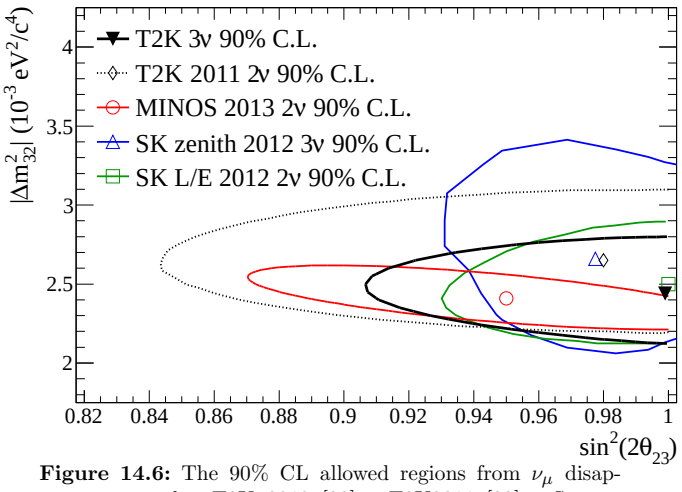

Figure 14.6: The 90% CL allowed regions from ν_μ disappearance results: T2K 2013 [23], T2K2011 [22], Super-Kamiokande [138], and MINOS [143]. The MINOS contour was obtained by assuming identical neutrino and antineutrino oscillation parameters. This figure is taken from Ref. 23.

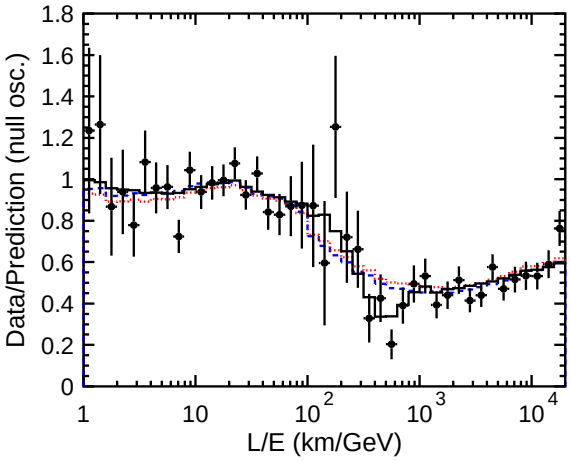

Figure 14.7: Results of the L/E analysis of SK-I atmospheric neutrino data. The points show the ratio of the data to the Monte Carlo prediction without oscillations, as a function of the reconstructed L/E. The error bars are statistical only. The solid line shows the best fit with 2-flavour $\nu_\mu \leftrightarrow \nu_\tau$ oscillations. The dashed and dotted lines show the best fit expectations for neutrino decay and neutrino decoherence hypotheses, respectively. (From Ref. 18.)

Earth's atmosphere, having travelled $\sim 10,000$ km, oscillate into other neutrinos and disappeared, while oscillations still do not take place for muon neutrinos coming from above the detector, having travelled from a few to a few tens km. Disappeared muon neutrinos may have oscillated into tau neutrinos because there is no indication of electron neutrino appearance. The atmospheric neutrinos corresponding to the events shown in Fig. 14.5 have $E = 1 \sim 10$ GeV. With $L = 10000$ km, the hypothesis of neutrino oscillations suggests $\Delta m^2 \sim 10^{-3} - 10^{-4}$ eV^2. The solid histograms show the best-fit results of a two-neutrino oscillation analysis with the hypothesis of $\nu_\mu \leftrightarrow \nu_\tau$. For the allowed parameter region from the recent results [138], see Fig. 14.6.

Although the SK-I atmospheric neutrino observations gave compelling evidence for muon neutrino disappearance which is consistent with two-neutrino oscillation $\nu_\mu \leftrightarrow \nu_\tau$ [139], the question may be asked whether the observed muon neutrino disappearance is really due to neutrino oscillations. First, other exotic explanations such as neutrino decay [140] and quantum decoherence [141] cannot be completely ruled out from the zenith-angle distributions alone. To confirm neutrino oscillation, characteristic sinusoidal behavior of the conversion probability as a function of neutrino energy E for a fixed distance L in the case of long-baseline neutrino oscillation experiments, or as a function of L/E in the case of atmospheric neutrino experiments, should be observed. By selecting events with high L/E resolution, evidence for the dip in the L/E distribution was observed at the right place expected from the interpretation of the SK-I data in terms of $\nu_\mu \leftrightarrow \nu_\tau$ oscillations [18], see Fig. 14.7. This dip cannot be explained by alternative hypotheses of neutrino decay and neutrino decoherence, and they are excluded at more than 3σ in comparison with the neutrino oscillation interpretation. For the constraints obtained from the L/E analysis, see Fig. 14.6.

Second, a search for ν_τ appearance signal was performed by using the SK-I, -II, -III, and -IV atmospheric neutrino data. Though the Super-Kamiokande detector cannot identify a CC ν_τ interaction on event by event basis, the Super-Kamiokande Collaboration demonstrated ν_τ appearance at the 3.8σ level through a neural network analysis on the zenith-angle distribution of multi-GeV contained events [24].

A more direct search for ν_τ appearance with identified CC ν_τ interaction has been performed by an accelerator long baseline experiment OPERA; see the next subsection.

14.5.2. *Results from accelerator experiments* :

The $\Delta m^2 \geq 2 \times 10^{-3}$ eV^2 region can be explored by accelerator-based long-baseline experiments with typically $E \sim 1$ GeV and $L \sim$ several hundred km. With a fixed baseline distance and a narrower, well understood neutrino spectrum, the value of $|\Delta m^2_{\rm A}|$ and, with higher statistics, also the mixing angle, are potentially better constrained in accelerator experiments than from atmospheric neutrino observations.

The K2K (KEK-to-Kamioka) long-baseline neutrino oscillation experiment [19] is the first accelerator-based experiment with a neutrino path length extending hundreds of kilometers. K2K aimed at confirmation of the neutrino oscillation in ν_μ disappearance in the $|\Delta m^2_{\rm A}| \geq 2 \times 10^{-3}$ eV^2 region. A horn-focused wide-band muon neutrino beam having an average $L/E_\nu \sim 200$ ($L = 250$ km, $\langle E_\nu \rangle \sim 1.3$ GeV), was produced by 12-GeV protons from the KEK-PS and directed to the Super-Kamiokande detector. The spectrum and profile of the neutrino beam were measured by a near neutrino detector system located 300 m downstream from the production target.

The construction of the K2K neutrino beam line and the near detector began before Super-Kamiokande's discovery of atmospheric neutrino oscillations. K2K experiment started data-taking in 1999 and was completed in 2004. The total number of protons on target (POT) for physics analysis amounted to 0.92×10^{20}. The observed number of beam-originated FC events in the 22.5 kton fiducial volume of Super-Kamiokande was 112, compared with an expectation of $158.1^{+9.2}_{-8.6}$ events without oscillation. For 58 1-ring μ-like subset of the data, the neutrino energy was reconstructed from measured muon momentum and angle, assuming CC quasi-elastic kinematics. The measured energy spectrum showed the distortion expected from neutrino oscillations. The probability that the observations are due to a statistical fluctuation instead of neutrino oscillation is 0.0015% or 4.3 σ [19].

MINOS is the second long-baseline neutrino oscillation experiment with near and far detectors. Neutrinos are produced by the NuMI (Neutrinos at the Main Injector) facility using 120 GeV protons from the Fermilab Main Injector. The far detector is a 5.4 kton (total mass) iron-scintillator tracking calorimeter with toroidal magnetic field, located underground in the Soudan mine. The baseline distance is 735 km. The near detector is also an iron-scintillator tracking calorimeter with toroidal magnetic field, with a total mass of 0.98 kton. The neutrino beam is a horn-focused wide-band beam. Its energy spectrum can be varied by moving the target position relative to the first horn and changing the horn current.

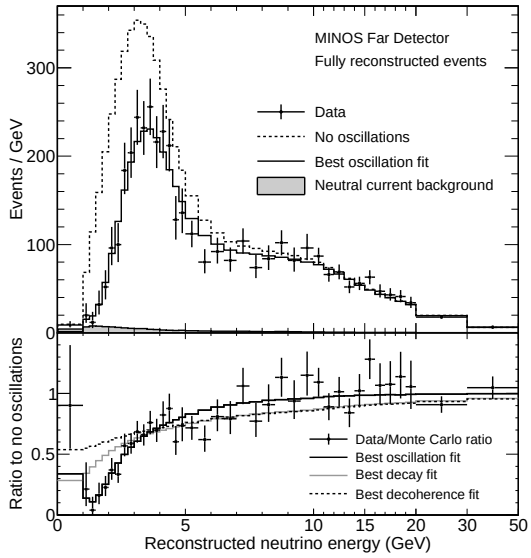

Figure 14.8: The top panel shows the energy spectra of fully reconstructed events in the MINOS far detector classified as CC interactions. The bottom panel shows the background subtracted ratios of data to the no-oscillation hypothesis. The best fit with the hypothesis of $\nu_\mu \to \nu_\tau$ oscillations as well as the best fit to alternative models (neutrino decay and decoherence) is also shown. This figure is taken from Ref. 21.

MINOS started the neutrino-beam run in 2005. Earlier ν_μ disappearance results were reported in Refs. [20,21]. Most of the data were taken with a "low-energy" option for the spectrum of the neutrino beam (the flux was enhanced in the 1-5 GeV energy range, peaking at 3 GeV). Fig. 14.8 shows the ratio of observed energy spectra and the expected spectra with no oscillation [21]. The MINOS data clearly favor the ν_μ disappearance. The alternative models to explain the ν_μ disappearance, neutrino decay and quantum decoherence of neutrinos, are disfavored at the 7σ and 9σ, respectively, by these MINOS data (see Fig. 14.8).

In addition to ν_μ disappearance, MINOS first observed muon antineutrino disappearance [142] with the NUMI beam line optimized for $\bar{\nu}_\mu$ production. Actually, MINOS produced a "ν_μ-dominated" or "$\bar{\nu}_\mu$-enhanced" beam by selectively focusing positive or negative pions and kaons. MINOS recently reported [143] the results of the neutrino oscillation analysis based on the data obtained with 10.71×10^{20} POT of the ν_μ-dominated beam and 3.36×10^{20} POT of the $\bar{\nu}_\mu$-enhanced beam. In addition, they used the atmospheric neutrino data based on the MINOS far detector exposure of 37.88 kt·yr [144]. Because the MINOS detector has a capability to separate neutrinos and antineutrinos on the event-by-event basis, it can use both ν_μ and $\bar{\nu}_\mu$ contained events from the ν_μ-dominated beam. From the $\bar{\nu}_\mu$-enhanced beam, $\bar{\nu}_\mu$ contained events are used. For the complete data sets used, refer to Ref. 143. Assuming the identical oscillation parameters for neutrinos and antineutrinos, the results of the fit within the two-neutrino oscillation framework using the full MINOS data sample yielded $|\Delta m^2_{\rm A}| = (2.41^{+0.09}_{-0.10}) \times 10^{-3}$ eV^2 and $\sin^2 2\theta_{\rm A} = 0.950^{+0.035}_{-0.036}$, or $\sin^2 2\theta_{\rm A} > 0.890$ at 90% CL. This result disfavors maximal mixing at the 86% CL. The 90% CL allowed region obtained from this analysis is shown in Fig. 14.6. Allowing independent oscillations for neutrinos and antineutrinos, characterised respectively by $|\Delta m^2_{\rm A}|$, $\theta_{\rm A}$ and $|\Delta \bar{m}^2_{\rm A}|$, $\bar{\theta}_{\rm A}$, the results of the fit are $|\Delta \bar{m}^2_{\rm A}| = (2.50^{+0.23}_{-0.25}) \times 10^{-3}$ eV^2 and $\sin^2 2\bar{\theta}_{\rm A} = 0.97^{+0.03}_{-0.08}$, or $\sin^2 2\theta_{\rm A} > 0.83$ at 90% CL, and $|\Delta m^2_{\rm A}|$ - $|\Delta \bar{m}^2_{\rm A}| = (0.12^{+0.24}_{-0.26}) \times 10^{-3}$ eV^2.

The T2K experiment is the first off-axis long-baseline neutrino oscillation experiment. The baseline distance is 295 km between the J-PARC in Tokai, Japan and Super-Kamiokande. A narrow-band ν_μ beam with a peak energy of 0.6 GeV, produced by 30 GeV protons from the J-PARC Main Ring, is directed 2.5° off-axis to SK. With this configuration, the ν_μ beam is tuned to the first oscillation maximum. T2K started the first physics run in 2010. The first ν_μ disappearance results with an off-axis beam were published in Ref. 22. In the recently updated ν_μ disappearance results [23] with 3.01×10^{20} POT, 58 1-ring μ-like events are observed, while 205 ± 17 events are expected for no neutrino oscillation. From three-neutrino oscillation analysis assuming $\Delta m^2_{32} > 0$ (normal mass ordering/hierarchy; see Section 14.8) and using $\sin^2 2\theta_{13} = 0.098$, $\Delta m^2_{21} = 7.5 \times 10^{-5}$ eV^2, $\sin^2 2\theta_{12} = 0.857$, and $\delta = 0$, the best-fit values of $\sin^2 \theta_{23} = 0.514 \pm 0.082$ and $|\Delta m^2_{32}| = 2.44^{+0.17}_{-0.15} \times 10^{-3}$ eV^2 are obtained. At the best-fit point, $\sin^2 2\theta_{23} = 0.999$. The T2K result is, therefore, consistent with maximal mixing. Fig. 14.6 shows the 90% CL allowed region of $\sin^2 2\theta_{23}$ and $|\Delta m^2_{32}|$, which is compared with the 90% CL allowed regions from the SK atmospheric neutrino observations [138], the MINOS experiment [143], and the earlier T2K result [22].

As of May 2014, both the T2K [145] and the MINOS [146] experiments have published more precise measurements of $\sin^2 \theta_{23}$ and $|\Delta m^2_{32}|$, using the three-neutrino oscillation formalism. Based on the data corresponding to 6.57×10^{20} POT, T2K [145] has estimated these parameters by fitting the reconstructed neutrino energy spectrum of 120 1-ring μ-like events. The 1D 68% CL intervals obtained are $\sin^2 \theta_{23} = 0.514^{+0.055}_{-0.056}$ and $\Delta m^2_{32} = (2.51 \pm 0.10) \times 10^{-3}$ eV^2 for normal mass ordering/hierarchy and $\sin^2 \theta_{23} = 0.511 \pm 0.055$ and $\Delta m^2_{13} = (2.48 \pm 0.10) \times 10^{-3}$ eV^2 for inverted mass ordering/hierarchy. The T2K results for $\sin^2 \theta_{23}$ is consistent with maximal mixing, $\theta_{23} = \pi/4$. MINOS [146] has made a combined analysis of the ν_μ disappearance [143] and $\nu_\mu \to \nu_e$ appearance [147] data using the complete set of accelerator and atmospheric neutrino data. The results obtained are $|\Delta m^2_{32}| = (2.28 - 2.46) \times 10^{-3}$ eV^2 (68% CL) and $\sin^2 \theta_{23} = 0.35 - 0.65$ (90% CL) for normal mass ordering/hierarchy and $|\Delta m^2_{32}| = (2.32 - 2.53) \times 10^{-3}$ eV^2 (68% CL) and $\sin^2 \theta_{23} = 0.34 - 0.67$ (90% CL) for inverted mass ordering/hierarchy. From this analysis, the best-fit value of $\sin^2 \theta_{23} < 0.5$ ($\theta_{23} < \pi/4$) is obtained for inverted hierarchy.

The regions of neutrino parameter space favored or excluded by various neutrino oscillation experiments are shown in Fig. 14.9.

Although the atmospheric neutrino oscillations and accelerator long-baseline ν_μ disappearance data are fully consistent with $\nu_\mu \to \nu_\tau$ oscillations, detection of identified CC ν_τ interaction on event-by-event basis remained to be demonstrated. For this purpose, a promising method is an accelerator long-baseline experiment using emulsion technique to identify short-lived τ leptons event-by-event. The only experiment of this kind is OPERA with a target mass of 1290 tons, a neutrino source at CERN and a detector at Gran Sasso with the baseline distance of 730 km. The detector is a combination of the "Emulsion Cloud Chamber" and magnetized spectrometer. The CNGS (CERN Neutrinos to Gran Sasso) neutrino beam with $\langle E_\nu \rangle = 17$ GeV is produced by high-energy protons from the CERN SPS, and the data were collected during 2008 and 2012, corresponding to a live exposure of 17.97×10^{19} POT in total. OPERA reported observation of the first ν_τ candidate in the hadronic decay channel of τ, $\tau \to 1h$ [62], in 2008 and 2009 data, and the second ν_τ candidate satisfying the criteria for the $\tau \to 3h$ decay kinematics [63] in a sub-sample of 2010 and 2011 data. As of July 2013, OPERA found the third ν_τ candidate in the $\tau \to \mu$ channel. With a simple counting method (likelihood approach), the observation of these three ν_τ candidates correspond to 3.2σ (3.5σ) significance of non-null observation [25]. OPERA's analysis is still on-going.

14.6. Measurements of θ_{13}

Reactor $\bar{\nu}_e$ disappearance experiments with $L \sim 1$ km, $\langle E \rangle \sim 3$ MeV are sensitive to $\sim E/L \sim 3 \times 10^{-3}$ eV^2 $\sim |\Delta m^2_{\rm A}|$. At this baseline distance, the reactor $\bar{\nu}_e$ oscillations driven by $\Delta m^2_\odot$ are negligible. Therefore, as can be seen from Eq. (14.22) and Eq. (14.24), θ_{13} can be directly measured. A reactor neutrino oscillation experiment at the Chooz nuclear power station in France [61] was the first experiment of this kind. The detector was located in an underground laboratory with 300 mwe (meter water equivalent) rock overburden, at about 1 km from the neutrino source. It consisted of a central 5-ton target filled with 0.09% gadolinium loaded liquid scintillator, surrounded by an intermediate 17-ton and outer 90-ton regions filled

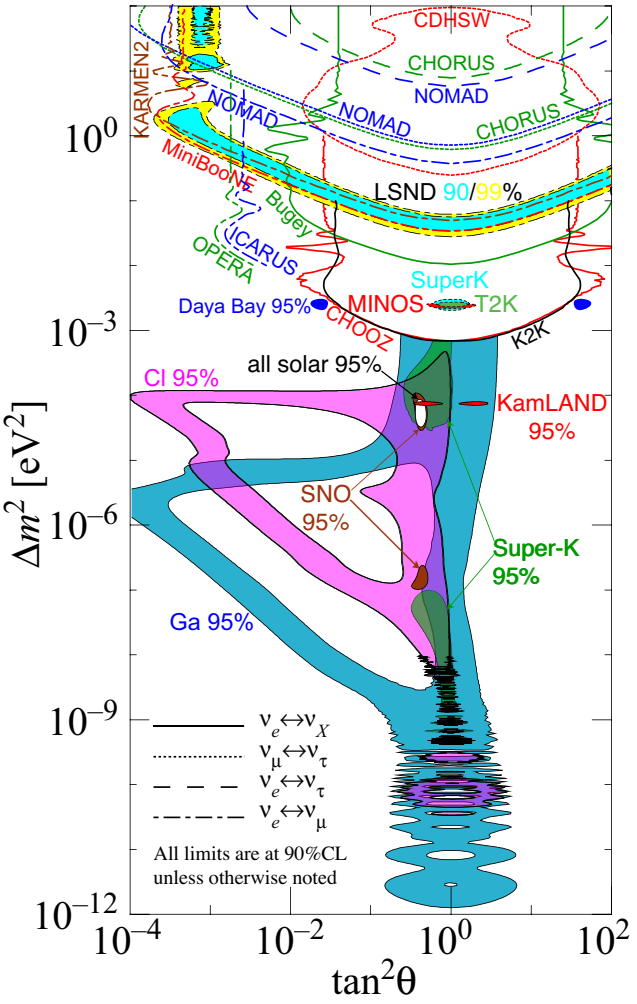

Figure 14.9: The regions of squared-mass splitting and mixing angle favored or excluded by various experiments based on two-flavor neutrino oscillation analyses. The figure was contributed by H. Murayama (University of California, Berkeley, and IPMU, University of Tokyo). References to the data used in the figure can be found at `http://hitoshi.berkeley.edu/neutrino`.

with undoped liquid scintillator. Reactor $\bar{\nu}_e$'s were detected via the reaction $\bar{\nu}_e + p \to e^+ + n$. Gd-doping was chosen to maximize the neutron capture efficiency. The Chooz experiment [61] found no evidence for $\bar{\nu}_e$ disappearance.

In 2012, the three reactor neutrino experiments Double Chooz [30], Daya Bay [31], and RENO [32] reported their first results on reactor $\bar{\nu}_e$ disappearance. Daya Bay and RENO measured reactor $\bar{\nu}_e$s with near and far detectors, and they obtained evidence for non-zero θ_{13} with a significance around 5σ. These three experiments have been accumulating statistics and improved results have been frequently reported (see below).

The $\bar{\nu}_e$ detectors of all the three experiments have similar structures; an antineutrino detector consisting of three layers and an optically independent outer veto detector. The innermost layer of the antineutrino detector is filled with Gd-doped liquid scintillator (LS), which is surrounded by a "γ-catcher" layer filled with Gd-free LS, and outside the γ-catcher is a buffer layer filled with mineral oil. An outer veto detector is filled with purified water (Daya Bay and RENO) or LS (Double Chooz). Double Chooz is planning to have a near detector in 2014.

The Daya Bay experiment [31,35] measured $\bar{\nu}_e$s from the Daya Bay nuclear power complex (six 2.9 GW_{th} reactors) in China with six functionally identical detectors deployed in two near (470 m and 576 m of flux-weighted baselines) and one far (1648 m) underground halls. Initially, Daya Bay reported [31] 5.2σ evidence for non-zero θ_{13} with live time of 55 days. More recent Daya Bay results [35] with live time of 139 days showed that the ratio of the observed to expected number of $\bar{\nu}_e$s at the far hall is $R = 0.944 \pm 0.007 \pm 0.003$ and the rate-only analysis in a three neutrino framework yielded $\sin^2 2\theta_{13} = 0.089 \pm 0.010 \pm 0.005$. This result excludes the no-oscillation hypothesis with a significance of 7.7σ [35]. In Ref. 36 the Day Bay collaboration reported their latest results based on live time of 217 days. In particular, from the rate+spectra oscillation analysis, $\sin^2 2\theta_{13} = 0.090^{+0.008}_{-0.009}$ is obtained.

The RENO experiment [32] measured $\bar{\nu}_e$s from six 2.8 GW_{th} reactors at Yonggwang Nuclear Power Plant in Korea with two identical detectors located at 294 m and 1383 m from the reactor array center. Initially with 229 days of running time, RENO reported [32] the ratio of the observed to expected number of $\bar{\nu}_e$s in the far detector of $R = 0.920 \pm 0.009 \pm 0.014$, and $\sin^2 2\theta_{13} = 0.113 \pm 0.013 \pm 0.019$ obtained from a rate-only analysis. This result excluded the no-oscillation hypothesis at the 4.9σ level. In September, 2013, RENO reported [37] a new result of $\sin^2 2\theta_{13} = 0.100 \pm 0.010 \pm 0.012$ from 403 live days of data, based on improved data analysis.

The Double Chooz experiment [30,33] measured $\bar{\nu}_e$s from two 4.25 GW_{th} reactors with a far detector at 1050 m from the two reactor cores. Double Chooz initially reported [30] $\sin^2 2\theta_{13} = 0.086 \pm 0.041 \pm 0.030$ with 101 days of data, and more recently [33] $\sin^2 2\theta_{13} = 0.109 \pm 0.030 \pm 0.025$ with 227.93 live days of running, by analyzing the rate and energy spectrum of prompt positrons using the reactor $\bar{\nu}_e$ spectrum of Ref. 160 and Ref. 156 and the Bugey4 rate measurement [148]. The latter data exclude the no-oscillation hypothesis at 2.9σ. Double Chooz also measured θ_{13} using inverse β-decay interactions with neutron capture on hydrogen (H-capture) [149], or from combined fit of Gd-capture and H-capture rate+spectrum, etc. [150], and consistent results are obtained. A near detector at 415 m from the cores will be operational in 2014.

In the accelerator neutrino oscillation experiments with conventional neutrino beams, θ_{13} can be measured using $\nu_\mu \to \nu_e$ appearance. By examining the expression for the probability of $\nu_\mu \to \nu_e$ oscillations in matter (given by Eq. (14.45)) it is understood that subleading terms could have rather large effects and the unknown CP-violating phase δ causes uncertainties in determining the value of θ_{13}. Actually, from the measurement of $\nu_\mu \to \nu_e$ appearance, θ_{13} is given as a function of δ for a given sign and value of Δm^2_{31}, and values of θ_{23}, Δm^2_{21} and θ_{12}. Therefore, a single experiment with a neutrino beam cannot determine the value of θ_{13}, although it is possible to establish a non-zero θ_{13}.

In 2011, experimental indications of $\nu_\mu \to \nu_e$ oscillations and a non-zero θ_{13} have been reported by the T2K [28] experiment. The T2K [28] Collaboration observed, with 1.43×10^{20} POT, six ν_e candidate events having all characteristics of being due to $\nu_\mu \to \nu_e$ oscillations, while the expectation for $\theta_{13} = 0$ is 1.5 ± 0.3 events. This result implies a non-zero θ_{13} with statistical significance of 2.5σ. In [34] T2K reported updated results. With 3.01×10^{20} POT, 11 ν_e candidates were observed, while the number of expected events for $\theta_{13} = 0$ is 3.3 ± 0.4, implying a non-zero θ_{13} with a significance of 3.1σ. For $\delta = 0$, $\sin^2 2\theta_{23} = 1$ and $\Delta m^2_A = 2.4 \times 10^{-3}$ eV^2, this result gives $\sin^2 2\theta_{13} = 0.088^{+0.049}_{-0.039}$. Recently, T2K announced [151] the observation of 28 ν_e appearance events with 4.92 ± 0.55 predicted background events. For $\sin^2 2\theta_{23} = 1$ and $\delta = 0$, this result means that $\theta_{13} = 0$ is excluded with a significance of 7.3σ. The probability relevant for the interpretation of this result of the T2K experiment is given in Eq. (14.45). For $\delta = 0$, $\sin^2 \theta_{23} = 0.5$ and $|\Delta m^2_{31(32)}| = 2.4 \times 10^{-3}$eV^2, the T2K collaborations finds in the case of $\Delta m^2_{31(32)} > 0$ ($\Delta m^2_{31(32)} < 0$): $\sin^2 2\theta_{13} = 0.140^{+0.038}_{-0.032}$ ($0.170^{+0.045}_{-0.037}$). Thus, the best fit value of $\sin^2 2\theta_{13}$ thus found in the T2K experiment is approximately by a factor of 1.6 (1.9) bigger than that found in the Daya Bay experiment [36]. This implies that the compatibility of the results of the two experiments on $\sin^2 2\theta_{13}$ requires, in particular, that $\delta \neq 0$ and/or $\sin^2 \theta_{23} \neq 0.5$. As we will see in Section 14.8, the indicated results will lead to a certain indication about the possible value of δ in the global analyses of the neutrino oscillation data.

The MINOS Collaboration [29] also searched for the $\nu_\mu \to \nu_e$

appearance signal. Though dependent on the definition of the signal, typically 62 candidate events are observed with an exposure of 8.2×10^{20} POT, while the expectation for $\theta_{13} = 0$ is $49.6 \pm 7.0 \pm 2.7$ events. The MINOS data disfavored the $\theta_{13} = 0$ hypothesis at the 89% CL [29]. Recently, MINOS has extended the analysis using 10.6×10^{20} POT ν-beam mode and 3.3×10^{20} POT $\bar{\nu}$-beam mode data [147]. Assuming $\Delta m^2_{\rm A} > 0$ ($\Delta m^2_{\rm A} < 0$), $\delta = 0$, and $\theta_{23} < \pi/4$, the results of this analysis imply that $0.01\ (0.03) < 2\ \sin^2\theta_{23}\ \sin^2 2\theta_{13} < 0.12\ (0.18)$ at the 90% CL, with the best fit value $2\ \sin^2\theta_{23}\ \sin^2 2\theta_{13} = 0.051^{+0.038}_{-0.030}\ (0.093^{+0.054}_{-0.049})$.

14.7. Search for Oscillations Involving Light Sterile Neutrinos

Although the mixing of the 3 flavour neutrino states has been experimentally well established, implying the existence of 3 light neutrinos ν_j having masses m_j not exceeding approximately 1 eV, there have been possible hints for the presence in the mixing of one or more additional neutrino states with masses at the eV scale. If these states exist, they must be related to the existence of one or more sterile neutrinos (sterile neutrino fields) which mix with the active flavour neutrinos (active flavour neutrino fields). The hints under discussion have been obtained: i) in the LSND $\bar{\nu}_\mu \to \bar{\nu}_e$ appearance experiment [152], in which a significant excess of events over the background is claimed to have been observed, ii) from the analysis of the $\bar{\nu}_\mu \to \bar{\nu}_e$ and $\nu_\mu \to \nu_e$ appearance data of the MiniBooNE experiment [153,154], iii) from the re-analyses of the short baseline (SBL) reactor neutrino oscillation data using newly calculated fluxes of reactor $\bar{\nu}_e$ [155,156], which show a possible "disappearance" of the reactor $\bar{\nu}_e$ ("reactor neutrino anomaly"), and iv) from the data of the radioactive source calibrations of the GALLEX [157] and SAGE [158] solar neutrino experiments.

The short baseline neutrino oscillation experiment MiniBooNE at Fermilab investigated ν_e and $\bar{\nu}_e$ appearance in ν_μ and $\bar{\nu}_\mu$ beams, respectively, with a detector containing 800 tons of mineral oil and located 541 m downstream of the production target. With the antineutrino running mode [153,154], a 2.8σ excess of events over the background was observed in the energy range of $200 < E_\nu < 1250$ MeV in the charged-current quasielastic data. Excess events were observed, in particular, in the interval of energies $200 < E_\nu < 475$ MeV, which corresponds to L/E range outside of that probed in the LSND experiment. The origin of this excess is not understood. Employing a simple 2-neutrino oscillation hypothesis and using the data from the entire neutrino energy interval $200 < E_\nu < 1250$ MeV used in the data analysis, this result, interpreted in terms of $\nu_\mu \to \nu_e$ oscillations, corresponds to an allowed region in the $\sin^2 2\theta - \Delta m^2$ plane, which overlaps with the allowed region obtained from the interpretation of the LSND data in terms of $\bar{\nu}_\mu \to \bar{\nu}_e$ oscillations. The overlap region at the 90% CL extends over $\Delta m^2 \sim$ a few $\times 10^{-2}$ eV^2 at $\sin^2 2\theta = 1$ to 1 eV^2 at $\sin^2 2\theta =$ a few $\times 10^{-3}$. The MiniBooNE Collaboration studied also the CP conjugate oscillation channel [154], $\nu_\mu \to \nu_e$, and observed a 3.4 σ excess of events in the same energy range. Most of the excess events lie in the interval $200 < E_\nu < 475$ MeV and are incompatible with the $\bar{\nu}_\mu \to \bar{\nu}_e$ oscillation interpretation of the LSND data. The energy spectra of the excess events observed in the ν_μ and $\bar{\nu}_\mu$ runs are only marginally compatible with each other and thus with the simple 2-neutrino oscillation hypothesis.

The reactor neutrino anomaly [155] is related to the results of a new and very detailed calculation of the reactor $\bar{\nu}_e$ fluxes [156] which were found to be by approximately 3.5% larger than the fluxes calculated in Ref. 159 and widely used in the past in the interpretation of the data of the SBL reactor $\bar{\nu}_e$ oscillation experiments. These data show indications for reactor $\bar{\nu}_e$ "disappearance" when analysed using the fluxes from [156]. It should be added that there are a number of uncertainties in the calculation of the fluxes under discussion (associated, *e.g.*, with the weak magnetism term contribution to the corresponding β-decay rates [160], the contribution of a relatively large number of "forbidden" β-decays [161], etc.) which can be of the order of the difference between the "old" and "new" fluxes.

Radioactive source calibrations of the GALLEX [157] and SAGE [158] experiments also showed a deficit of the measured fluxes compared to the expected fluxes ("Gallium anomaly"), and therefore might be interpreted as hints for ν_e disappearance.

Significant constraints on the parameters characterising the oscillations involving sterile neutrinos follow from the negative results of the searches for $\nu_\mu \to \nu_e$ and/or $\bar{\nu}_\mu \to \bar{\nu}_e$ oscillations in the KARMEN [162], NOMAD [163], ICARUS [164], and OPERA [165] experiments, and from the nonobservation of effects of oscillations into sterile neutrinos in the solar neutrino experiments and in the studies of ν_μ and/or $\bar{\nu}_\mu$ disappearance in the CDHSW [166], MINOS and SuperKamiokande experiments.

Two possible "minimal" phenomenological models (or schemes) with light sterile neutrinos are widely used in order to explain the data discussed in this section in terms of neutrino oscillations: the so-called "3 + 1" and "3 + 2" models. They contain respectively one and two sterile neutrinos (right-handed sterile neutrino fields). Thus, the "3 + 1" and "3 + 2" models have altogether 4 and 5 light massive neutrinos ν_j, which in the minimal versions of these models are Majorana particles. The additional neutrinos ν_4 and ν_4, ν_5 should have masses m_4 and m_4, m_5 at the eV scale (see below). It follows from the data that if ν_4 or ν_4, ν_5 exist, they couple to the electron and muon in the weak charged lepton current with couplings U_{ek} and $U_{\mu k}$, $k = 4;\ 4, 5$, which are approximately $|U_{ek}| \sim 0.1$ and $|U_{\mu k}| \sim 0.1$.

Global analysis of all the data (positive evidences and negative results) relevant for the test of the sterile neutrino hypothesis were performed recently in Ref. 167 and in Ref. 168. Analysing the data within the 3 + 1 scheme, the authors of Ref. 167 find for the best fit values of the parameters $|U_{e4}|^2$, $|U_{\mu 4}|^2$ and $\Delta m^2_{\rm SBL} \equiv m^2_4 - m^2_{min}$, where $m_{min} = \min(m_j)$, $j = 1, 2, 3$, characterising the active-sterile neutrino (antineutrino) oscillations:

$$|U_{e4}|^2 = 0.0225\,, \quad |U_{\mu 4}|^2 = 0.0289\,, \quad \Delta m^2_{\rm SBL} = 0.93\ {\rm eV}^2\,. \quad (14.75)$$

In contrast to Ref. 167, the authors of Ref. 168 reported also results within the 3 + 1 scheme without including in the data set used in their global analysis the MiniBooNE data at $E_\nu \leq 0.475$ GeV. As we have already mentioned, these data show an excess of events over the estimated background [154,169] whose nature is presently not well understood. For the best fit values of $|U_{e4}|^2$, $|U_{\mu 4}|^2$ and $\Delta m^2_{\rm SBL}$ in this case the authors of Ref. 168 find:

$$|U_{e4}|^2 = 0.03\,, \quad |U_{\mu 4}|^2 = 0.013\,, \quad \Delta m^2_{\rm SBL} = 1.60\ {\rm eV}^2\,. \quad (14.76)$$

The existence of light sterile neutrinos has cosmological implications the discussion of which lies outside the scope of the present article (for a discussion of the cosmological constraints on light sterile neutrinos see, e.g., [170,171]) .

The hypothesis of existence of light sterile neutrinos with eV scale masses and charged current couplings to the electron and muon quoted above will be tested in a number of experiments with reactor and accelerator neutrinos, and neutrinos from artificial sources, some of which are under preparation and planned to start taking data already this year (see, e.g., [172,173] for a detailed list and discussion of the planned experiments).

14.8. The three neutrino mixing

All existing compelling data on neutrino oscillations can be described assuming 3-flavour neutrino mixing in vacuum. This is the minimal neutrino mixing scheme which can account for the currently available data on the oscillations of the solar (ν_e), atmospheric (ν_μ and $\bar{\nu}_\mu$), reactor ($\bar{\nu}_e$) and accelerator (ν_μ) neutrinos. The (left-handed) fields of the flavour neutrinos ν_e, ν_μ and ν_τ in the expression for the weak charged lepton current in the CC weak interaction Lagrangian, are linear combinations of the LH components of the fields of three massive neutrinos ν_j:

$$\mathcal{L}_{\rm CC} = -\ \frac{g}{\sqrt{2}} \sum_{l=e,\mu,\tau} \overline{l_L}(x)\, \gamma_\alpha\, \nu_{lL}(x)\, W^{\alpha\dagger}(x) + h.c.\,,$$

$$\nu_{l\rm L}(x) = \sum_{j=1}^{3} U_{lj}\, \nu_{j\rm L}(x), \quad (14.77)$$

where U is the 3×3 unitary neutrino mixing matrix [4,5]. The mixing matrix U can be parameterized by 3 angles, and, depending on whether the massive neutrinos ν_j are Dirac or Majorana particles, by 1 or 3 CP violation phases [43,44]:

$$U = \begin{bmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13} \end{bmatrix} \times \mathrm{diag}(1,\ e^{i\frac{\alpha_{21}}{2}},\ e^{i\frac{\alpha_{31}}{2}}) \ . \quad (14.78)$$

where $c_{ij} = \cos\theta_{ij}$, $s_{ij} = \sin\theta_{ij}$, the angles $\theta_{ij} = [0, \pi/2]$, $\delta = [0, 2\pi]$ is the Dirac CP violation phase and α_{21}, α_{31} are two Majorana CP violation phases. Thus, in the case of massive Dirac neutrinos, the neutrino mixing matrix U is similar, in what concerns the number of mixing angles and CP violation phases, to the CKM quark mixing matrix. The presence of two additional physical CP violation phases in U if ν_j are Majorana particles is a consequence of the special properties of the latter (see, *e.g.*, Refs. [41,43]) .

As we see, the fundamental parameters characterizing the 3-neutrino mixing are: i) the 3 angles θ_{12}, θ_{23}, θ_{13}, ii) depending on the nature of massive neutrinos ν_j - 1 Dirac (δ), or 1 Dirac + 2 Majorana ($\delta, \alpha_{21}, \alpha_{31}$), CP violation phases, and iii) the 3 neutrino masses, m_1, m_2, m_3. Thus, depending on whether the massive neutrinos are Dirac or Majorana particles, this makes 7 or 9 additional parameters in the minimally extended Standard Model of particle interactions with massive neutrinos.

The neutrino oscillation probabilities depend (Section 14.2), in general, on the neutrino energy, E, the source-detector distance L, on the elements of U and, for relativistic neutrinos used in all neutrino experiments performed so far, on $\Delta m^2_{ij} \equiv (m^2_i - m^2_j)$, $i \neq j$. In the case of 3-neutrino mixing there are only two independent neutrino mass squared differences, say $\Delta m^2_{21} \neq 0$ and $\Delta m^2_{31} \neq 0$. The numbering of massive neutrinos ν_j is arbitrary. It proves convenient from the point of view of relating the mixing angles θ_{12}, θ_{23} and θ_{13} to observables, to identify $|\Delta m^2_{21}|$ with the smaller of the two neutrino mass squared differences, which, as it follows from the data, is responsible for the solar ν_e and, the observed by KamLAND, reactor $\bar{\nu}_e$ oscillations. We will number (just for convenience) the massive neutrinos in such a way that $m_1 < m_2$, so that $\Delta m^2_{21} > 0$. With these choices made, there are two possibilities: either $m_1 < m_2 < m_3$, or $m_3 < m_1 < m_2$. Then the larger neutrino mass square difference $|\Delta m^2_{31}|$ or $|\Delta m^2_{32}|$, can be associated with the experimentally observed oscillations of the atmospheric ν_μ and $\bar{\nu}_\mu$ and accelerator ν_μ. The effects of Δm^2_{31} or Δm^2_{32} in the oscillations of solar ν_e, and of Δm^2_{21} in the oscillations of atmospheric ν_μ and $\bar{\nu}_\mu$ and of accelerator ν_μ, are relatively small and subdominant as a consequence of the facts that i) L, E and L/E in the experiments with solar ν_e and with atmospheric ν_μ and $\bar{\nu}_\mu$ or accelerator ν_μ, are very different, ii) the conditions of production and propagation (on the way to the detector) of the solar ν_e and of the atmospheric ν_μ and $\bar{\nu}_\mu$ or accelerator ν_μ, are very different, and iii) $|\Delta m^2_{21}|$ and $|\Delta m^2_{31}|$ ($|\Delta m^2_{32}|$) in the case of $m_1 < m_2 < m_3$ ($m_3 < m_1 < m_2$), as it follows from the data, differ by approximately a factor of 30, $|\Delta m^2_{21}| \ll |\Delta m^2_{31(32)}|$, $|\Delta m^2_{21}|/|\Delta m^2_{31(32)}| \cong 0.03$. This implies that in both cases of $m_1 < m_2 < m_3$ and $m_3 < m_1 < m_2$ we have $\Delta m^2_{32} \cong \Delta m^2_{31}$ with $|\Delta m^2_{31} - \Delta m^2_{32}| = |\Delta m^2_{21}| \ll |\Delta m^2_{31,32}|$. Obviously, in the case of $m_1 < m_2 < m_3$ ($m_3 < m_1 < m_2$) we have $\Delta m^2_{31(32)} > 0$ ($\Delta m^2_{31(32)} < 0$).

It follows from the results of the CHOOZ experiment with reactor $\bar{\nu}_e$ [61] and from the more recent data of the Daya Bay, RENO, Double Chooz and T2K experiments, discussed in the preceding subsection, that, in the convention we use, in which $0 < \Delta m^2_{21} < |\Delta m^2_{31(32)}|$, the element $|U_{e3}| = \sin\theta_{13}$ of the neutrino mixing matrix U is relatively small. This makes it possible to identify the angles θ_{12} and θ_{23} as the neutrino mixing angles associated with the solar ν_e and the dominant atmospheric ν_μ (and $\bar{\nu}_\mu$) oscillations, respectively. The angles θ_{12} and θ_{23} are often called "solar" and "atmospheric" neutrino mixing angles, and are often denoted as $\theta_{12} = \theta_\odot$ and $\theta_{23} = \theta_{\rm A}$ (or $\theta_{\rm atm}$) while Δm^2_{21} and Δm^2_{31} are often referred to as the "solar" and "atmospheric" neutrino mass squared differences and are often denoted as $\Delta m^2_{21} \equiv \Delta m^2_\odot$, $\Delta m^2_{31} \equiv \Delta m^2_{\rm A}$ (or $\Delta m^2_{\rm atm}$).

The solar neutrino data tell us that $\Delta m^2_{21} \cos 2\theta_{12} > 0$. In the convention employed by us we have $\Delta m^2_{21} > 0$. Correspondingly, in this convention one must have $\cos 2\theta_{12} > 0$.

Global analyses of the neutrino oscillation data [174,175] available by the second half of 2013 and including, in particular, the latest Daya Bay [36], RENO [37] and T2K [151,23] and MINOS [143,147] data, allowed us to determine the 3-neutrino oscillation parameters Δm^2_{21}, θ_{12}, $|\Delta m^2_{31}|$ ($|\Delta m^2_{32}|$), θ_{23} and θ_{13} with a relatively high precision. We present in Table 14.7 the best fit values and the 99.73% CL allowed ranges of these parameters found in Ref. 174. The results obtained in Ref. 174 show, in particular, that in the case of $\Delta m^2_{31(32)} > 0$ (i.e., $m_1 < m_2 < m_3$), the best fit value of $\sin^2\theta_{23} = 0.425$ increased somewhat with respect to that found in the analyses of the 2012 data. At 2σ we now have: $0.376 \lesssim \sin^2\theta_{23} \lesssim 0.506$, i.e., the 2σ indication from 2012 data that θ_{23} lies in the first quadrant [176] is not confirmed by including the 2013 data. In both analyses [174,175] the authors find that the best fit value of $\delta \cong 3\pi/2$. The CP conserving values $\delta = 0$ (2π) and π ($\delta = 0$ (2π)) are disfavored at 1.6σ to 2.0σ (at 2.0σ) for $\Delta m^2_{31(32)} > 0$ ($\Delta m^2_{31(32)} < 0$). In the case of $\Delta m^2_{31(32)} < 0$, the value $\delta = \pi$ is statistically 1σ away from the best fit value $\delta \cong 3\pi/2$.

Table 14.7: The best-fit values and 3σ allowed ranges of the 3-neutrino oscillation parameters, derived from a global fit of the current neutrino oscillation data (from [174]) . The values (values in brackets) correspond to $m_1 < m_2 < m_3$ ($m_3 < m_1 < m_2$). The definition of Δm^2 used is: $\Delta m^2 = m^2_3 - (m^2_2 + m^2_1)/2$. Thus, $\Delta m^2 = \Delta m^2_{31} - \Delta m^2_{21}/2 > 0$, if $m_1 < m_2 < m_3$, and $\Delta m^2 = \Delta m^2_{32} + \Delta m^2_{21}/2 < 0$ for $m_3 < m_1 < m_2$.

Parameter	best-fit ($\pm 1\sigma$)	3σ
Δm^2_{21} [10^{-5} eV ^{2}]	$7.54^{+0.26}_{-0.22}$	$6.99 - 8.18$
$\lvert\Delta m^2\rvert$ [10^{-3} eV ^{2}]	2.43 ± 0.06 (2.38 ± 0.06)	$2.23 - 2.61$ ($2.19 - 2.56$)
$\sin^2\theta_{12}$	0.308 ± 0.017	$0.259 - 0.359$
$\sin^2\theta_{23}$, $\Delta m^2 > 0$	$0.437^{+0.033}_{-0.023}$	$0.374 - 0.628$
$\sin^2\theta_{23}$, $\Delta m^2 < 0$	$0.455^{+0.039}_{-0.031}$,	$0.380 - 0.641$
$\sin^2\theta_{13}$, $\Delta m^2 > 0$	$0.0234^{+0.0020}_{-0.0019}$	$0.0176 - 0.0295$
$\sin^2\theta_{13}$, $\Delta m^2 < 0$	$0.0240^{+0.0019}_{-0.0022}$	$0.0178 - 0.0298$
δ/π (2σ range quoted)	$1.39^{+0.38}_{-0.27}$ ($1.31^{+0.29}_{-0.33}$)	$(0.00 - 0.16) \oplus (0.86 - 2.00)$ $((0.00 - 0.02) \oplus (0.70 - 2.00))$

It follows from the results given in Table 14.7 that θ_{23} is close to, but can be different from, $\pi/4$, $\theta_{12} \cong \pi/5.4$ and that $\theta_{13} \cong \pi/20$. Correspondingly, the pattern of neutrino mixing is drastically different from the pattern of quark mixing.

Note also that Δm^2_{21}, $\sin^2\theta_{12}$, $|\Delta m^2_{31(32)}|$, $\sin^2\theta_{23}$ and $\sin^2\theta_{13}$ are determined from the data with a 1σ uncertainty (= 1/6 of the 3σ range) of approximately 2.6%, 5.4%, 2.6%, 9.6% and 8.5%,respectively.

The existing SK atmospheric neutrino, K2K and MINOS data do not allow to determine the sign of $\Delta m^2_{31(32)}$. Maximal solar neutrino mixing, *i.e.*, $\theta_{12} = \pi/4$, is ruled out at more than 6σ by the data. Correspondingly, one has $\cos 2\theta_{12} \geq 0.28$ (at 99.73% CL).

At present no experimental information on the Dirac and Majorana CP violation phases in the neutrino mixing matrix is available. Thus, the status of CP symmetry in the lepton sector is unknown. With $\theta_{13} \neq 0$, the Dirac phase δ can generate CP violation effects in neutrino oscillations [43,55,56]. The magnitude of CP violation in $\nu_l \to \nu_{l'}$ and $\bar{\nu}_l \to \bar{\nu}_{l'}$ oscillations, $l \neq l' = e, \mu, \tau$, is determined, as we have seen, by the rephasing invariant J_{CP} (see Eq. (14.19)), which in the "standard" parametrisation of the neutrino mixing matrix (Eq. (14.78)) has the form:

$$J_{CP} \equiv \mathrm{Im}\,(U_{\mu 3}\, U^*_{e3}\, U_{e2}\, U^*_{\mu 2}) = \frac{1}{8}\, \cos\theta_{13} \sin 2\theta_{12}\ \sin 2\theta_{23}\ \sin 2\theta_{13}\ \sin\delta \,. \quad (14.79)$$

Thus, given the fact that $\sin 2\theta_{12}$, $\sin 2\theta_{23}$ and $\sin 2\theta_{13}$ have been determined experimentally with a relatively good precision, the size of CP violation effects in neutrino oscillations depends essentially only on the magnitude of the currently not well determined value of the Dirac phase δ. The current data implies $|J_{CP}| \lesssim 0.040\,|\sin\delta|$, where we have used the 3σ ranges of $\sin^2\theta_{12}$, $\sin^2\theta_{23}$ and $\sin^2\theta_{13}$ given in Table 14.7. For the best fit values of $\sin^2\theta_{12}$, $\sin^2\theta_{23}$ and $\sin^2\theta_{13}$ and δ we find in the case of $\Delta m^2_{31(2)} > 0$ ($\Delta m^2_{31(2)} < 0$): $J_{CP} \cong -0.032$ (-0.029). Thus, if the indication that $\delta \cong 3\pi/2$ is confirmed by future more precise data, the CP violation effects in neutrino oscillations would be relatively large.

As we have indicated, the existing data do not allow one to determine the sign of $\Delta m^2_{\rm A} = \Delta m^2_{31(2)}$. In the case of 3-neutrino mixing, the two possible signs of $\Delta m^2_{31(2)}$ correspond to two types of neutrino mass spectrum. In the widely used conventions of numbering the neutrinos with definite mass in the two cases, the two spectra read:

– *i) spectrum with normal ordering (NO)*:

$$m_1 < m_2 < m_3,\ \Delta m^2_{\rm A} = \Delta m^2_{31} > 0,$$
$$\Delta m^2_{\odot} \equiv \Delta m^2_{21} > 0,\ m_{2(3)} = (m_1^2 + \Delta m^2_{21(31)})^{\frac{1}{2}};$$

– *ii) spectrum with inverted ordering (IO)*:

$$m_3 < m_1 < m_2,\ \Delta m^2_{\rm A} = \Delta m^2_{32} < 0,\ \Delta m^2_{\odot} \equiv \Delta m^2_{21} > 0,$$
$$m_2 = (m_3^2 + \Delta m^2_{23})^{\frac{1}{2}},\ m_1 = (m_3^2 + \Delta m^2_{23} - \Delta m^2_{21})^{\frac{1}{2}}.$$

Depending on the values of the lightest neutrino mass [177], $\min(m_j)$, the neutrino mass spectrum can also be:

– *Normal Hierarchical (NH)*:

$$m_1 \ll m_2 < m_3,\ m_2 \cong (\Delta m^2_{\odot})^{\frac{1}{2}} \cong 0.0087\ \text{eV},$$
$$m_3 \cong |\Delta m^2_{31}|^{\frac{1}{2}} \cong 0.050\ \text{eV};\ \text{or}$$

– *Inverted Hierarchical (IH)*:

$$m_3 \ll m_1 < m_2,\ \text{with}\ m_{1,2} \cong |\Delta m^2_{32}|^{\frac{1}{2}} \cong 0.049\ \text{eV};\ \text{or}$$

– *Quasi-Degenerate (QD)*:

$$m_1 \cong m_2 \cong m_3 \cong m_0,\ m_j^2 \gg |\Delta m^2_{\rm A}|,\ m_0 \gtrsim 0.10\ \text{eV}.$$

Sometimes the determination of the neutrino mass spectrum is referred to in the literature on the subject as determination of "neutrino mass hierarchy".

All three types of spectrum are compatible with the existing constraints on the absolute scale of neutrino masses m_j. Information about the latter can be obtained, *e.g.*, by measuring the spectrum of electrons near the end point in ^{3}H β-decay experiments [179–183] and from cosmological and astrophysical data. The most stringent upper bounds on the $\bar\nu_e$ mass were obtained in the Troitzk [183,180] experiment:

$$m_{\bar\nu_e} < 2.05\ \text{eV} \quad \text{at}\ 95\%\ \text{CL}. \tag{14.80}$$

Similar result was obtained in the Mainz experiment [181]: $m_{\bar\nu_e} < 2.3$ eV at 95% CL. We have $m_{\bar\nu_e} \cong m_{1,2,3}$ in the case of QD spectrum. The KATRIN experiment [182] is planned to reach sensitivity of $m_{\bar\nu_e} \sim 0.20$ eV, *i.e.*, it will probe the region of the QD spectrum.

The Cosmic Microwave Background (CMB) data of the WMAP experiment, combined with supernovae data and data on galaxy clustering can be used to obtain an upper limit on the sum of neutrinos masses (see review on Cosmological Parameters [171] and, *e.g.*, Ref. 184). Depending on the model complexity and the input data used one obtains [184]: $\sum_j m_j \lesssim (0.3 - 1.3)$ eV, 95% CL.

In March of 2013 the Planck Collaboration published their first constraints on $\sum_j m_j$ [185]. Assuming the existence of three massive neutrinos and the validity of the Λ CDM (Cold Dark Matter) model, and combining their data on the CMB temperature power spectrum with the WMAP polarisation low-multiple ($\ell \leq 23$) and ACT high-multiple ($\ell \geq 2500$) CMB data [186,187], the Planck Collaboration reported the following upper limit on the sum of the neutrino masses [185]:

$$\sum_j m_j < 0.66\ eV, \quad 95\%\ \text{CL}.$$

Adding the data on the Baryon Acoustic Oscillations (BAO) lowers significantly the limit [185]: $\sum_j m_j < (0.23$ eV), 95% CL. It follows from these data that neutrino masses are much smaller than the masses of charged leptons and quarks. If we take as an indicative upper limit $m_j \lesssim 0.5$ eV, we have $m_j/m_{l,q} \lesssim 10^{-6}$, $l = e, \mu, \tau$, $q = d, s, b, u, c, t$. It is natural to suppose that the remarkable smallness of neutrino masses is related to the existence of a new fundamental mass scale in particle physics, and thus to new physics beyond that predicted by the Standard Model.

14.8.1. *The see-saw mechanism and the baryon asymmetry of the Universe* :

A natural explanation of the smallness of neutrino masses is provided by the (type I) see-saw mechanism of neutrino mass generation [3]. An integral part of this rather simple mechanism [188] are the RH neutrinos ν_{lR} (RH neutrino fields $\nu_{lR}(x)$). The latter are assumed to possess a Majorana mass term as well as Yukawa type coupling $\mathcal{L}_{\rm Y}(x)$ with the Standard Model lepton and Higgs doublets, $\psi_{lL}(x)$ and $\Phi(x)$, respectively, $(\psi_{lL}(x))^T = (\nu^T_{lL}(x) \quad l^T_L(x))$, $l = e, \mu, \tau$, $(\Phi(x))^T = (\Phi^{(0)}(x) \ \ \Phi^{(-)}(x))$. In the basis in which the Majorana mass matrix of RH neutrinos is diagonal, we have:

$$\mathcal{L}_{\rm Y,M}(x) = \left(\lambda_{il}\,\overline{N_{iR}}(x)\,\Phi^\dagger(x)\,\psi_{lL}(x) + \text{h.c.}\right) - \frac{1}{2}\,M_i\,\overline{N_i}(x)\,N_i(x)\,, \tag{14.81}$$

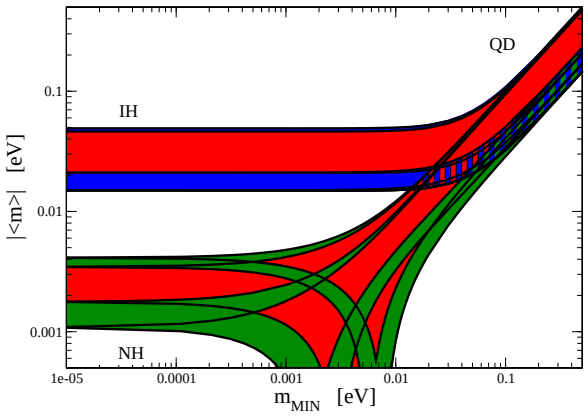
where λ_{il} is the matrix of neutrino Yukawa couplings and N_i ($N_i(x)$) is the heavy RH Majorana neutrino (field) possessing a mass $M_i > 0$. When the electroweak symmetry is broken spontaneously, the neutrino Yukawa coupling generates a Dirac mass term: $m^D_{il}\,\overline{N_{iR}}(x)\,\nu_{lL}(x) + \text{h.c.}$, with $m^D = v\lambda$, $v = 174$ GeV being the Higgs doublet v.e.v. In the case when the elements of m^D are much smaller than M_k, $|m^D_{il}| \ll M_k$, $i, k = 1, 2, 3$, $l = e, \mu, \tau$, the interplay between the Dirac mass term and the mass term of the heavy (RH) Majorana neutrinos N_i generates an effective Majorana mass (term) for the LH flavour neutrinos [3]: $m^{LL}_{l'l} \cong -(m^D)^T_{l'j} M_j^{-1} m^D_{jl}$. In grand unified theories, m^D is typically of the order of the charged fermion masses. In $SO(10)$ theories, for instance, m^D coincides with the up-quark mass matrix. Taking indicatively $m^{LL} \sim 0.1$ eV, $m^D \sim 100$ GeV, one finds $M \sim 10^{14}$ GeV, which is close to the scale of unification of the electroweak and strong interactions, $M_{GUT} \cong 2 \times 10^{16}$ GeV. In GUT theories with RH neutrinos one finds that indeed the heavy Majorana neutrinos N_j naturally obtain masses which are by few to several orders of magnitude smaller than M_{GUT}. Thus, the enormous disparity between the neutrino and charged fermion masses is explained in this approach by the huge difference between effectively the electroweak symmetry breaking scale and M_{GUT}.

An additional attractive feature of the see-saw scenario is that the generation and smallness of neutrino masses is related via the leptogenesis mechanism [2] to the generation of the baryon asymmetry of the Universe. The Yukawa coupling in Eq. (14.81), in general, is not CP conserving. Due to this CP-nonconserving coupling the heavy Majorana neutrinos undergo, *e.g.*, the decays $N_j \to l^+ + \Phi^{(-)}$, $N_j \to l^- + \Phi^{(+)}$, which have different rates: $\Gamma(N_j \to l^+ + \Phi^{(-)}) \neq \Gamma(N_j \to l^- + \Phi^{(+)})$. When these decays occur in the Early Universe at temperatures somewhat below the mass of, say, N_1, so that the latter are out of equilibrium with the rest of the particles present at that epoch, CP violating asymmetries in the individual lepton charges L_l, and in the total lepton charge L, of the Universe are generated. These lepton asymmetries are converted into a baryon asymmetry by $(B - L)$ conserving, but $(B + L)$ violating, sphaleron processes, which exist in the Standard Model and are effective at temperatures $T \sim (100 - 10^{12})$ GeV. If the heavy neutrinos N_j have hierarchical spectrum, $M_1 \ll M_2 \ll M_3$, the observed baryon asymmetry can be reproduced provided the mass of the lightest one satisfies $M_1 \gtrsim 10^9$ GeV [189]. Thus, in this scenario, the neutrino masses and mixing and the baryon asymmetry have the same origin - the neutrino Yukawa couplings and the existence of (at least two) heavy Majorana neutrinos. Moreover, quantitative studies based on recent advances in leptogenesis theory [190] have shown that the Dirac and/or Majorana phases in the neutrino mixing matrix U can provide the CP violation, necessary in leptogenesis for the generation of the

observed baryon asymmetry of the Universe [191]. This implies, in particular, that if the CP symmetry is established not to hold in the lepton sector due to U, at least some fraction (if not all) of the observed baryon asymmetry might be due to the Dirac and/or Majorana CP violation present in the neutrino mixing.

14.8.2. ***The nature of massive neutrinos*** :

The experiments studying flavour neutrino oscillations cannot provide information on the nature - Dirac or Majorana, of massive neutrinos [43,57]. Establishing whether the neutrinos with definite mass ν_j are Dirac fermions possessing distinct antiparticles, or Majorana fermions, i.e. spin 1/2 particles that are identical with their antiparticles, is of fundamental importance for understanding the origin of ν-masses and mixing and the underlying symmetries of particle interactions (see *e.g.*, Ref. 68). The neutrinos with definite mass ν_j will be Dirac fermions if the particle interactions conserve some additive lepton number, *e.g.*, the total lepton charge $L = L_e + L_\mu + L_\tau$. If no lepton charge is conserved, ν_j will be Majorana fermions (see *e.g.*, Ref. 41). The massive neutrinos are predicted to be of Majorana nature by the see-saw mechanism of neutrino mass generation [3]. The observed patterns of neutrino mixing and of neutrino mass squared differences can be related to Majorana massive neutrinos and the existence of an approximate flavour symmetry in the lepton sector (see, *e.g.*, Ref. 192). Determining the nature of massive neutrinos ν_j is one of the fundamental and most challenging problems in the future studies of neutrino mixing.



The effective Majorana mass $|<m>|$ (including a 2σ uncertainty), as a function of $\min(m_j)$. The figure is obtained using the best fit values and the 2σ ranges of allowed values of Δm^2_{21}, $\sin^2\theta_{12}$, and $|\Delta m^2_{31}| \cong |\Delta m^2_{32}|$ from Ref. 174. The phases $\alpha_{21,31}$ are varied in the interval $[0,\pi]$. The predictions for the NH, IH and QD spectra are indicated. The red regions correspond to at least one of the phases $\alpha_{21,31}$ and $(\alpha_{31} - \alpha_{21})$ having a CP violating value, while the blue and green areas correspond to $\alpha_{21,31}$ possessing CP conserving values. (Update by S. Pascoli of a figure from the last article quoted in Ref. 196.)

The Majorana nature of massive neutrinos ν_j manifests itself in the existence of processes in which the total lepton charge L changes by two units: $K^+ \to \pi^- + \mu^+ + \mu^+$, $\mu^- + (A,Z) \to \mu^+ + (A, Z-2)$, *etc.* Extensive studies have shown that the only feasible experiments having the potential of establishing that the massive neutrinos are Majorana particles are at present the experiments searching for $(\beta\beta)_{0\nu}$-decay: $(A,Z) \to (A, Z+2) + e^- + e^-$ (see *e.g.*, Ref. 193). The observation of $(\beta\beta)_{0\nu}$-decay and the measurement of the corresponding half-life with sufficient accuracy, would not only be a proof that the total lepton charge is not conserved, but might also provide unique information on the i) type of neutrino mass spectrum (see, *e.g.*, Ref. 194), ii) Majorana phases in U [178,195] and iii) the absolute scale of neutrino masses (for details see Ref. 193 to Ref. 196 and references quoted therein).

Under the assumptions of 3-ν mixing, of massive neutrinos ν_j being Majorana particles, and of $(\beta\beta)_{0\nu}$-decay generated only by the (V-A) charged current weak interaction via the exchange of the three Majorana neutrinos ν_j having masses $m_j \lesssim$ few MeV, the $(\beta\beta)_{0\nu}$-decay amplitude has the form (see, *e.g.*, Ref. 41 and Ref. 193): $A(\beta\beta)_{0\nu} \cong <m>\, M$, where M is the corresponding nuclear matrix element which does not depend on the neutrino mixing parameters, and

$$|<m>| = \left| m_1 U^2_{e1} + m_2 U^2_{e2} + m_3 U^2_{e3} \right| = \left| \left(m_1 c^2_{12} + m_2 s^2_{12} e^{i\alpha_{21}} \right) c^2_{13} + m_3 s^2_{13} e^{i(\alpha_{31} - 2\delta)} \right|, \quad (14.82)$$

is the effective Majorana mass in $(\beta\beta)_{0\nu}$-decay. In the case of CP-invariance one has [45], $\eta_{21} \equiv e^{i\alpha_{21}} = \pm 1$, $\eta_{31} \equiv e^{i\alpha_{31}} = \pm 1$, $e^{-i2\delta} = 1$. The three neutrino masses $m_{1,2,3}$ can be expressed in terms of the two measured Δm^2_{jk} and, *e.g.*, $\min(m_j)$. Thus, given the neutrino oscillation parameters Δm^2_{21}, $\sin^2\theta_{12}$, Δm^2_{31} and $\sin^2\theta_{13}$, $|<m>|$ is a function of the lightest neutrino mass $\min(m_j)$, the Majorana (and Dirac) CP violation phases in U and of the type of neutrino mass spectrum. In the case of NH, IH and QD spectrum we have (see, *e.g.*, Ref. 178 and Ref. 196):

$$|<m>| \cong \left| \sqrt{\Delta m^2_{21}}\, s^2_{12} c^2_{13} + \sqrt{\Delta m^2_{31}}\, s^2_{13} e^{i(\alpha_{31} - \alpha_{21} - 2\delta)} \right|, \quad \text{NH}, \quad (14.83)$$

$$|<m>| \cong \tilde{m} \left(1 - \sin^2 2\theta_{12} \sin^2 \frac{\alpha_{21}}{2} \right)^{\frac{1}{2}}, \quad \text{IH (IO) and QD}, \quad (14.84)$$

where $\tilde{m} \equiv \sqrt{\Delta m^2_{23} + m^2_3}$ and $\tilde{m} \equiv m_0$ for IH (IO) and QD spectrum, respectively. In Eq. (14.84) we have exploited the fact that $\sin^2\theta_{13} \ll \cos 2\theta_{12}$. The CP conserving values of the Majorana phases $(\alpha_{31} - \alpha_{21})$ and α_{21} determine the intervals of possible values of $|<m>|$, corresponding to the different types of neutrino mass spectrum. Using the 3σ ranges of the allowed values of the neutrino oscillation parameters Table 14.7 one finds that: i) 0.58×10^{-3} eV $\lesssim |<m>| \lesssim 4.22 \times 10^{-3}$ eV in the case of NH spectrum; ii) $\sqrt{\Delta m^2_{23}} \cos 2\theta_{12}\, c^2_{13} \lesssim |<m>| \lesssim \sqrt{\Delta m^2_{23}}\, c^2_{13}$, or 1.3×10^{-2} eV $\lesssim |<m>| \lesssim 5.0 \times 10^{-2}$ eV in the case of IH spectrum; iii) $m_0 \cos 2\theta_{12} \lesssim |<m>| \lesssim m_0$, or 2.8×10^{-2} eV $\lesssim |<m>| \lesssim m_0$ eV, $m_0 \gtrsim 0.10$ eV, in the case of QD spectrum. The difference in the ranges of $|<m>|$ in the cases of NH, IH and QD spectrum opens up the possibility to get information about the type of neutrino mass spectrum from a measurement of $|<m>|$ [194]. The predicted $(\beta\beta)_{0\nu}$-decay effective Majorana mass $|<m>|$ as a function of the lightest neutrino mass $\min(m_j)$ is shown in Fig. 14.10.

14.9. Outlook

After the spectacular experimental progress made in the studies of neutrino oscillations, further understanding of the pattern of neutrino masses and neutrino mixing, of their origins and of the status of CP symmetry in the lepton sector requires an extensive and challenging program of research. The main goals of such a research program, outlined in the 2010 PDG edition of the Review of Particle Physics, included:

- Determining the nature - Dirac or Majorana, of massive neutrinos ν_j. This is of fundamental importance for making progress in our understanding of the origin of neutrino masses and mixing and of the symmetries governing the lepton sector of particle interactions.
- Determination of the sign of $\Delta m^2_{\rm A}$ (Δm^2_{31}) and of the type of neutrino mass spectrum.
- Determining or obtaining significant constraints on the absolute scale of neutrino masses.
- Measurement of, or improving by at least a factor of (5 - 10) the existing upper limit on, the small neutrino mixing angle θ_{13}. Together with the Dirac CP-violating phase, the angle θ_{13}

determines the magnitude of CP-violation effects in neutrino oscillations.

- Determining the status of CP symmetry in the lepton sector.
- High precision measurement of Δm^2_{21}, θ_{12}, and $|\Delta m^2_{31}|$, θ_{23}.
- Understanding at a fundamental level the mechanism giving rise to neutrino masses and mixing and to L_l-non-conservation. This includes understanding the origin of the patterns of ν-mixing and ν-masses suggested by the data. Are the observed patterns of ν-mixing and of $\Delta m^2_{21,31}$ related to the existence of a new fundamental symmetry of particle interactions? Is there any relation between quark mixing and neutrino mixing, *e.g.*, does the relation $\theta_{12} + \theta_c = \pi/4$, where θ_c is the Cabibbo angle, hold? What is the physical origin of CP violation phases in the neutrino mixing matrix U? Is there any relation (correlation) between the (values of) CP violation phases and mixing angles in U? Progress in the theory of neutrino mixing might also lead to a better understanding of the mechanism of generation of baryon asymmetry of the Universe.

The successful realization of this research program, which would be a formidable task and would require many years, already began with the high precision measurement of the value of $\sin^2 2\theta_{13}$ in the Daya Bay experiment, and with the subsequent results on θ_{13} obtained by the RENO, Double Chooz and T2K collaborations. It follows from these measurements and from the global neutrino oscillation data that at 99.73% CL one has [174] $0.0177 \lesssim \sin^2\theta_{13} \lesssim 0.0297$ ($0.0171 \lesssim \sin^2\theta_{13} \lesssim 0.0315$) for NO (IO) neutrino mass spectrum. The data provide also a hint that the Dirac phase δ has a CP nonconserving value $\delta \cong 3\pi/2$, the CP conserving values $\delta = 0(2\pi), \pi$ [$0(2\pi)$] being disfavored at 1.6σ to 2σ [at 2σ] in the case of NO [IO] spectrum. For IO spectrum though, the value $\delta = \pi$ is statistically only 1σ away from the best fit value $\delta \cong 3\pi/2$.

The results on θ_{13} have far reaching implications. The measured relatively large value of θ_{13} opens up the possibilities, in particular,

i) for searching for CP violation effects in neutrino oscillation experiments with high intensity accelerator neutrino beams, like T2K, NOνA, etc. NOνA [65], an off-axis ν_e appearance experiment using the NuMI beam, is under construction and expected to be completed in 2014. The sensitivities of T2K and NOνA on CP violation in neutrino oscillations are discussed in, *e.g.*, Refs. [197,173].

ii) for determining the sign of Δm^2_{32}, and thus the type of neutrino mass spectrum in the long baseline neutrino oscillation experiments at accelerators (NOνA, etc.), in the experiments studying the oscillations of atmospheric neutrinos as well as in experiments with reactor antineutrinos [198](for a review see, *e.g.*, Ref. 199).

There are also long term plans extending beyond 2025 for seraches for CP violation and neutrino mass spectrum determination in long baseline neutrino oscillation experiments with accelerator neutrino beams (see, *e.g.*, Refs. [173,200]) .

A value of $|\sin\theta_{13}\sin\delta| \gtrsim 0.09$, and thus $\sin\theta_{13} \gtrsim 0.09$, is a necessary condition for a successful "flavoured" leptogenesis with hierarchical heavy Majorana neutrinos when the CP violation required for the generation of the matter-antimatter asymmetry of the Universe is provided entirely by the Dirac CP violating phase in the neutrino mixing matrix [191]. This condition is comfortably compatible both with the measured value of $\sin^2\theta_{13}$ and with the best fit value of $\delta \cong 3\pi/2$.

With the measurement of θ_{13}, the first steps on the long "road" leading to a comprehensive understanding of the patterns of neutrino masses and mixing, of their origin and implications, were made.

70. P. Langacker, J.P. Leveille, and J. Sheiman, Phys. Rev. **D27**, 1228 (1983).
71. The difference between the ν_μ and ν_τ indices of refraction arises at one-loop level and can be relevant for the $\nu_\mu - \nu_\tau$ oscillations in very dense media, like the core of supernovae, *etc.*; see F.J. Botella, C.S. Lim, and W.J. Marciano, Phys. Rev. **D35**, 896 (1987).
72. The relevant formulae for the oscillations between the ν_e and a sterile neutrino ν_s, $\nu_e \leftrightarrow \nu_s$, can be obtained from those derived for the case of $\nu_e \leftrightarrow \nu_{\mu(\tau)}$ oscillations by Refs. [57,70] replacing N_e with $(N_e - 1/2N_n)$, N_n being the neutron number density in matter.

98. S.T. Petcov and J. Rich, Phys. Lett. **B224**, 401 (1989).
99. An expression for the "jump" probability P' for N_e varying linearly along the neutrino path was derived in W.C. Haxton, Phys. Rev. Lett. **57**, 1271 (1986) and in Ref. 91 on the basis of the old Landau-Zener result: L.D. Landau, Phys. Z. USSR **1**, 426 (1932), C. Zener, Proc. R. Soc. A **137**, 696 (1932). An analytic description of the solar ν_e transitions based on the Landau-Zener jump probability was proposed in Ref. 91 and in W.C. Haxton, Phys. Rev. **D35**, 2352 (1987). The precision limitations of this description, which is less accurate than that based on the exponential density approximation, were discussed in S.T. Petcov, Phys. Lett. **B191**, 299 (1987) and in Ref. 93.

15. QUARK MODEL

Revised August 2013 by C. Amsler (University of Bern), T. DeGrand (University of Colorado, Boulder), and B. Krusche (University of Basel).

15.1. Quantum numbers of the quarks

Quantum chromodynamics (QCD) is the theory of the strong interactions. QCD is a quantum field theory and its constituents are a set of fermions, the quarks, and gauge bosons, the gluons. Strongly interacting particles, the hadrons, are bound states of quark and gluon fields. As gluons carry no intrinsic quantum numbers beyond color charge, and because color is believed to be permanently confined, most of the quantum numbers of strongly interacting particles are given by the quantum numbers of their constituent quarks and antiquarks. The description of hadronic properties which strongly emphasizes the role of the minimum-quark-content part of the wave function of a hadron is generically called the quark model. It exists on many levels: from the simple, almost dynamics-free picture of strongly interacting particles as bound states of quarks and antiquarks, to more detailed descriptions of dynamics, either through models or directly from QCD itself. The different sections of this review survey the many approaches to the spectroscopy of strongly interacting particles which fall under the umbrella of the quark model.

Table 15.1: Additive quantum numbers of the quarks.

	d	u	s	c	b	t
Q – electric charge	$-\frac{1}{3}$	$+\frac{2}{3}$	$-\frac{1}{3}$	$+\frac{2}{3}$	$-\frac{1}{3}$	$+\frac{2}{3}$
I – isospin	$\frac{1}{2}$	$\frac{1}{2}$	0	0	0	0
I_z – isospin z-component	$-\frac{1}{2}$	$+\frac{1}{2}$	0	0	0	0
S – strangeness	0	0	-1	0	0	0
C – charm	0	0	0	$+1$	0	0
B – bottomness	0	0	0	0	-1	0
T – topness	0	0	0	0	0	$+1$

Quarks are strongly interacting fermions with spin 1/2 and, by convention, positive parity. Antiquarks have negative parity. Quarks have the additive baryon number 1/3, antiquarks -1/3. Table 15.1 gives the other additive quantum numbers (flavors) for the three generations of quarks. They are related to the charge Q (in units of the elementary charge e) through the generalized Gell-Mann-Nishijima formula

$$\mathsf{Q} = \mathsf{I}_z + \frac{\mathcal{B} + \mathsf{S} + \mathsf{C} + \mathsf{B} + \mathsf{T}}{2} \ , \tag{15.1}$$

where $\mathcal{B}$ is the baryon number. The convention is that the *flavor* of a quark (I_z, S, C, B, or T) has the same sign as its *charge* Q. With this convention, any flavor carried by a charged meson has the same sign as its charge, *e.g.*, the strangeness of the K^+ is $+1$, the bottomness of the B^+ is $+1$, and the charm and strangeness of the D_s^- are each -1. Antiquarks have the opposite flavor signs.

The hypercharge is defined as

$$\mathsf{Y} = \mathcal{B} + \mathsf{S} - \frac{\mathsf{C} - \mathsf{B} + \mathsf{T}}{3} \ .$$

Thus Y is equal to $\frac{1}{3}$ for the u and d quarks, $-\frac{2}{3}$ for the s quark, and 0 for all other quarks.

15.2. Mesons

Mesons have baryon number $\mathcal{B} = 0$. In the quark model, they are $q\overline{q}'$ bound states of quarks q and antiquarks $\overline{q}'$ (the flavors of q and q' may be different). If the orbital angular momentum of the $q\overline{q}'$ state is ℓ, then the parity P is $(-1)^{\ell+1}$. The meson spin J is given by the usual relation $|\ell - s| \leq J \leq |\ell + s|$, where s is 0 (antiparallel quark spins) or 1 (parallel quark spins). The charge conjugation, or C-parity $C = (-1)^{\ell+s}$, is defined only for the $q\bar{q}$ states made of quarks and their own antiquarks. The C-parity can be generalized to the G-parity $G = (-1)^{I+\ell+s}$ for mesons made of quarks and their own antiquarks (isospin $\mathsf{I}_z = 0$), and for the charged $u\bar{d}$ and $d\bar{u}$ states (isospin $\mathsf{I} = 1$).

The mesons are classified in J^{PC} multiplets. The $\ell = 0$ states are the pseudoscalars (0^{-+}) and the vectors (1^{--}). The orbital excitations $\ell = 1$ are the scalars (0^{++}), the axial vectors (1^{++}) and (1^{+-}), and the tensors (2^{++}). Assignments for many of the known mesons are given in Tables 15.2 and 15.3. Radial excitations are denoted by the principal quantum number n. The very short lifetime of the t quark makes it likely that bound-state hadrons containing t quarks and/or antiquarks do not exist.

States in the natural spin-parity series $P = (-1)^J$ must, according to the above, have $s = 1$ and hence, $CP = +1$. Thus, mesons with natural spin-parity and $CP = -1$ (0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, *etc.*) are forbidden in the $q\bar{q}'$ model. The $J^{PC} = 0^{--}$ state is forbidden as well. Mesons with such *exotic* quantum numbers may exist, but would lie outside the $q\bar{q}'$ model (see section below on exotic mesons).

Following SU(3), the nine possible $q\bar{q}'$ combinations containing the light u, d, and s quarks are grouped into an octet and a singlet of light quark mesons:

$$\mathbf{3} \otimes \overline{\mathbf{3}} = \mathbf{8} \oplus \mathbf{1} \ . \tag{15.2}$$

A fourth quark such as charm c can be included by extending SU(3) to SU(4). However, SU(4) is badly broken owing to the much heavier c quark. Nevertheless, in an SU(4) classification, the sixteen mesons are grouped into a 15-plet and a singlet:

$$\mathbf{4} \otimes \overline{\mathbf{4}} = \mathbf{15} \oplus \mathbf{1} \ . \tag{15.3}$$

The *weight diagrams* for the ground-state pseudoscalar (0^{-+}) and vector (1^{--}) mesons are depicted in Fig. 15.1. The light quark mesons are members of nonets building the middle plane in Fig. 15.1(a) and (b).

Isoscalar states with the same J^{PC} will mix, but mixing between the two light quark isoscalar mesons, and the much heavier charmonium or bottomonium states, are generally assumed to be negligible. In the following, we shall use the generic names a for the $\mathsf{I} = 1$, K for the $\mathsf{I} = 1/2$, and f and f' for the $\mathsf{I} = 0$ members of the light quark nonets. Thus, the physical isoscalars are mixtures of the SU(3) wave function ψ_8 and ψ_1:

$$f' = \psi_8 \cos\theta - \psi_1 \sin\theta \ , \tag{15.4}$$

$$f = \psi_8 \sin\theta + \psi_1 \cos\theta \ , \tag{15.5}$$

where θ is the nonet mixing angle and

$$\psi_8 = \frac{1}{\sqrt{6}}(u\bar{u} + d\bar{d} - 2s\bar{s}) \ , \tag{15.6}$$

$$\psi_1 = \frac{1}{\sqrt{3}}(u\bar{u} + d\bar{d} + s\bar{s}) \ . \tag{15.7}$$

Table 15.2: Suggested $q\overline{q}$ quark-model assignments for some of the observed light mesons. Mesons in bold face are included in the Meson Summary Table. The wave functions f and f' are given in the text. The singlet-octet mixing angles from the quadratic and linear mass formulae are also given for the well established nonets. The classification of the 0^{++} mesons is tentative: The light scalars $a_0(980)$, $f_0(980)$, and $f_0(500)$ are often considered as meson-meson resonances or four-quark states, and are omitted from the table. Not shown either is the $f_0(1500)$ which is hard to accommodate in the nonet. The isoscalar 0^{++} mesons are expected to mix. See the "Note on Scalar Mesons" in the Meson Listings for details and alternative schemes.

† The masses of these states are considerably smaller than most theoretical predictions. They have also been considered as four-quark states The open flavor states in the 1^{+-} and 1^{++} rows are mixtures of the $1^{+\pm}$ states.

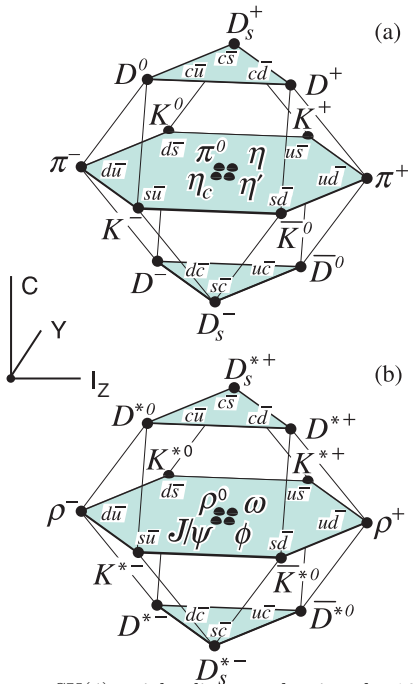

Figure 15.1: SU(4) weight diagram showing the 16-plets for the pseudoscalar (a) and vector mesons (b) made of the u, d, s, and c quarks as a function of isospin I_z, charm C, and hypercharge $\mathsf{Y} = \mathcal{B} + \mathsf{S} - \frac{\mathsf{C}}{3}$. The nonets of light mesons occupy the central planes to which the $c\bar{c}$ states have been added.

These mixing relations are often rewritten to exhibit the $u\bar{u} + d\bar{d}$ and $s\bar{s}$ components which decouple for the "ideal" mixing angle θ_i, such that $\tan\theta_i = 1/\sqrt{2}$ (or $\theta_i = 35.3°$). Defining $\alpha = \theta + 54.7°$, one obtains the physical isoscalar in the flavor basis

$$f' = \frac{1}{\sqrt{2}}(u\bar{u} + d\bar{d})\cos\alpha - s\bar{s}\ \sin\alpha\ , \tag{15.8}$$

and its orthogonal partner f (replace α by α –90°). Thus for ideal mixing ($\alpha_i = 90°$), the f' becomes pure $s\bar{s}$ and the f pure $u\bar{u} + d\bar{d}$. The mixing angle θ can be derived by diagonalizing the mass matrix

$$\begin{pmatrix} m_8 & m_{81} \\ m_{18} & m_1 \end{pmatrix}$$

The mass eigenvalues are $m_{f'}$ and m_f. The mixing angle is given by

$$\tan\theta = \frac{m_8 - m_{f'}}{m_{81}}\ .$$

Calculating m_8 and m_{81} from the wave functions Eq. (15.6) and Eq. (15.7), and expressing the quark masses as a function of the $\mathsf{I} = 1/2$ and $\mathsf{I} = 1$ meson masses, one obtains

$$\tan\theta = \frac{4m_K - m_a - 3m_{f'}}{2\sqrt{2}(m_a - m_K)}\ , \tag{15.9}$$

which also determines the sign of θ. Alternatively, one can express the mixing angle as a function of all nonet masses. The octet mass is given by

$$m_8 = m_{f'}\cos^2\theta + m_f \sin^2\theta$$

whence

$$\tan^2\theta = \frac{4m_K - m_a - 3m_{f'}}{-4m_K + m_a + 3m_f}\ . \tag{15.10}$$

Eliminating θ from Eq. (15.9) and Eq. (15.10) leads to the sum rule [1]

$$(m_f + m_{f'})(4m_K - m_a) - 3m_f m_{f'} = 8m_K^2 - 8m_K m_a + 3m_a^2. \tag{15.11}$$

This relation is verified for the ground-state vector mesons. We identify the $\phi(1020)$ with the f' and the $\omega(783)$ with the f. Thus

$$\phi(1020) = \psi_8\cos\theta_V - \psi_1\sin\theta_V\ , \tag{15.12}$$

$$\omega(782) = \psi_8\sin\theta_V + \psi_1\cos\theta_V\ , \tag{15.13}$$

with the vector mixing angle $\theta_V = 36.4°$ from Eq. (15.10), very close to ideal mixing. Thus $\phi(1020)$ is nearly pure $s\bar{s}$. For ideal mixing, Eq. (15.9) and Eq. (15.10) lead to the relations

$$m_K = \frac{m_f + m_{f'}}{2}\ ,\quad m_a = m_f\ , \tag{15.14}$$

which are satisfied for the vector mesons.

The situation for the pseudoscalar and scalar mesons is not so clear cut, either theoretically or experimentally. For the pseudoscalars, the mixing angle is small. This can be understood qualitatively via gluon-line counting of the mixing process. The size of the mixing process between the nonstrange and strange mass bases scales as α_s^2, not α_s^3, because of two rather than three gluon exchange as it does for the vector mesons. It may also be that the lightest isoscalar pseudoscalars mix more strongly with excited states or with states of substantial non-$\bar{q}q$ content, as will be discussed below.

A variety of analysis methods lead to similar results: First, for these states, Eq. (15.11) is satisfied only approximately. Then Eq. (15.9) and Eq. (15.10) lead to somewhat different values for the mixing angle. Identifying the η with the f' one gets

$$\eta = \psi_8\cos\theta_P - \psi_1\sin\theta_P\ , \tag{15.15}$$

$$\eta' = \psi_8\sin\theta_P + \psi_1\cos\theta_P\ . \tag{15.16}$$

Following chiral perturbation theory, the meson masses in the mass formulae (Eq. (15.9) and Eq. (15.10)) might be replaced by their squares. Table 15.2 lists the mixing angle $\theta_{\rm lin}$ from Eq. (15.10) (using the neutral members of the nonets) and the corresponding $\theta_{\rm quad}$ obtained by replacing the meson masses by their squares throughout.

The pseudoscalar mixing angle θ_P can also be measured by comparing the partial widths for radiative J/ψ decay into a vector and a pseudoscalar [2], radiative $\phi(1020)$ decay into η and η' [3], or $\bar{p}p$ annihilation at rest into a pair of vector and pseudoscalar or into two pseudoscalars [4,5]. One obtains a mixing angle between –10° and –20°. More recently, a lattice QCD simulation, Ref. [6], has successfully reproduced the masses of the η and η', and as a byproduct find a mixing angle $\theta_{lin} = -14.1(2.8)°$. We return to this point in Sec. 15.6.

The nonet mixing angles can be measured in $\gamma\gamma$ collisions, *e.g.*, for the 0^{-+}, 0^{++}, and 2^{++} nonets. In the quark model, the amplitude for the coupling of neutral mesons to two photons is proportional to $\sum_i Q_i^2$, where Q_i is the charge of the i-th quark. The 2γ partial width of an isoscalar meson with mass m is then given in terms of the mixing angle α by

$$\Gamma_{2\gamma} = C(5\cos\alpha - \sqrt{2}\sin\alpha)^2 m^3\ , \tag{15.17}$$

for f' and f ($\alpha \to \alpha$ – 90°). The coupling C may depend on the meson mass. It is often assumed to be a constant in the nonet. For the isovector a, one then finds $\Gamma_{2\gamma} = 9\ C\ m^3$. Thus the members of an ideally mixed nonet couple to 2γ with partial widths in the ratios $f : f' : a = 25 : 2 : 9$. For tensor mesons, one finds from the ratios of the measured 2γ partial widths for the $f_2(1270)$ and $f_2'(1525)$ mesons a mixing angle α_T of $(81\pm 1)°$, or $\theta_T = (27 \pm 1)°$, in accord with the linear mass formula. For the pseudoscalars, one finds from the ratios of partial widths $\Gamma(\eta' \to 2\gamma)/\Gamma(\eta \to 2\gamma)$ a mixing angle $\theta_P = (-18 \pm 2)°$, while the ratio $\Gamma(\eta' \to 2\gamma)/\Gamma(\pi^0 \to 2\gamma)$ leads to $\sim$ –24 °. SU(3) breaking effects for pseudoscalars are discussed in Ref. [7].

The partial width for the decay of a scalar or a tensor meson into a pair of pseudoscalar mesons is model-dependent. Following Ref. [8],

$$\Gamma = C \times \gamma^2 \times |F(q)|^2 \times q\ . \tag{15.18}$$

C is a nonet constant, q the momentum of the decay products, $F(q)$ a form factor, and γ^2 the SU(3) coupling. The model-dependent form factor may be written as

$$|F(q)|^2 = q^{2\ell} \times \exp(-\frac{q^2}{8\beta^2}), \tag{15.19}$$

where ℓ is the relative angular momentum between the decay products. The decay of a $q\bar{q}$ meson into a pair of mesons involves the creation of a $q\bar{q}$ pair from the vacuum, and SU(3) symmetry assumes that the matrix elements for the creation of $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ pairs are equal. The couplings γ^2 are given in Table 15.4, and their dependence upon the mixing angle α is shown in Fig. 15.2 for isoscalar decays. The generalization to unequal $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ couplings is given in Ref. [8]. An excellent fit to the tensor meson decay widths is obtained assuming SU(3) symmetry, with $\beta \simeq 0.5$ GeV/c, $\theta_V \simeq 26\,^\circ$ and $\theta_P \simeq -17\,^\circ$ [8].

Table 15.4: SU(3) couplings γ^2 for quarkonium decays as a function of nonet mixing angle α, up to a common multiplicative factor C ($\phi \equiv 54.7^\circ + \theta_P$).

Isospin	Decay channel	γ^2
0	$\pi\pi$	$3\cos^2\alpha$
	$K\overline{K}$	$(\cos\alpha - \sqrt{2}\sin\alpha)^2$
	$\eta\eta$	$(\cos\alpha\cos^2\phi - \sqrt{2}\sin\alpha\sin^2\phi)^2$
	$\eta\eta'$	$\frac{1}{2}\sin^2 2\phi\ (\cos\alpha + \sqrt{2}\sin\alpha)^2$
1	$\eta\pi$	$2\cos^2\phi$

15.3. Exotic mesons

The existence of a light nonet composed of four quarks with masses below 1 GeV was suggested a long time ago [9]. Coupling two triplets of light quarks u, d, and s, one obtains nine states, of which the six symmetric (uu, dd, ss, $ud+du$, $us+su$, $ds+sd$) form the six dimensional representation **6**, while the three antisymmetric ($ud-du$, $us-su$, $ds-sd$) form the three dimensional representation $\overline{\mathbf{3}}$ of SU(3):

$$\mathbf{3} \otimes \mathbf{3} = \mathbf{6} \oplus \overline{\mathbf{3}}\ . \tag{15.20}$$

Combining with spin and color and requiring antisymmetry, one finds that the most deeply bound diquark (and hence the lightest) is the one in the $\overline{\mathbf{3}}$ and spin singlet state. The combination of the diquark with an antidiquark in the **3** representation then gives a light nonet of four-quark scalar states. Letting the number of strange quarks determine the mass splitting, one obtains a mass inverted spectrum with a light isosinglet ($ud\bar{u}\bar{d}$), a medium heavy isodoublet (*e.g.*, $ud\bar{s}\bar{d}$) and a heavy isotriplet (*e.g.*, $ds\bar{u}\bar{s}$) + isosinglet (*e.g.*, $us\bar{u}\bar{s}$). It is then tempting to identify the lightest state with the $f_0(500)$, and the heaviest states with the $a_0(980)$, and $f_0(980)$. Then the meson with strangeness $\kappa(800)$ would lie in-between.

QCD predicts the existence of extra isoscalar mesons. In the pure gauge theory they contain only gluons, and are called the glueballs. The ground state glueball is predicted by lattice gauge theories to be 0^{++}, the first excited state 2^{++}. Errors on the mass predictions are large. From Ref. 10 one obtains 1750 (50) (80) MeV for the mass of the lightest 0^{++} glueball from quenched QCD. As an example for the glueball mass spectrum, we show in Fig. 15.3 a calculation from Ref. 11. A mass of 1710 MeV is predicted for the ground state, also with an error of about 100 MeV. Earlier work by other groups produced masses at 1650 MeV [12] and 1550 MeV [13] (see also [14]) . The first excited state has a mass of about 2.4 GeV, and the lightest glueball with exotic quantum numbers (2^{+-}) has a mass of about 4 GeV.

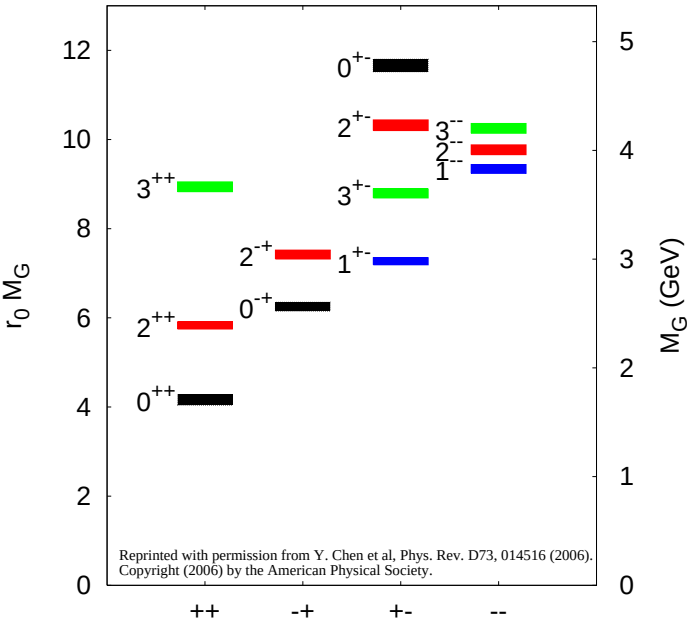

Figure 15.3: Predicted glueball mass spectrum from the lattice in quenched approximation (from Ref. 11)

These calculations are made in the so-called "quenched approximation" which neglects $q\bar{q}$ loops. However, both glue and $q\bar{q}$ states will couple to singlet scalar mesons. Therefore glueballs will mix with nearby $q\bar{q}$ states of the same quantum numbers. For example, the two isoscalar 0^{++} mesons around 1500 MeV will mix with the pure ground state glueball to generate the observed physical states $f_0(1370)$, $f_0(1500)$, and $f_0(1710)$ [8,15]. Lattice calculations are only beginning to include these effects. We return to a discussion of this point in Sec. 15.6.

The existence of three singlet scalar mesons around 1.5 GeV suggests additional degrees of freedom such as glue, since only two mesons are predicted in this mass range. The $f_0(1500)$ [8,15] or, alternatively, the $f_0(1710)$ [12], have been proposed as candidates for the scalar glueball, both states having considerable mixing also with the $f_0(1370)$. Other mixing schemes, in particular with the $f_0(500)$ and the $f_0(980)$, have also been proposed [16]. Details can be found in the "Note on Scalar Mesons" in the Meson Listings and in Ref. 17

Mesons made of $q\bar{q}$ pairs bound by excited gluons g, the hybrid states $q\bar{q}g$, are also predicted. They should lie in the 1.9 GeV mass region, according to gluon flux tube models [18]. Lattice QCD also predicts the lightest hybrid, an exotic 1^{-+}, at a mass of 1.8 to 1.9 GeV [19]. However, the bag model predicts four nonets, among them an exotic 1^{-+} around or above 1.4 GeV [20,21]. There are so far two candidates for exotic states with quantum numbers 1^{-+}, the $\pi_1(1400)$ and $\pi_1(1600)$, which could be hybrids or four-quark states (see the "Note on Non-$q\bar{q}$ Mesons" in the 2006 issue of this *Review* [22] and in Ref. 17)

15.4. Baryons: *qqq* states

Baryons are fermions with baryon number $\mathcal{B} = 1$, *i.e.*, in the most general case, they are composed of three quarks plus any number of quark - antiquark pairs. So far all established baryons are 3-quark (qqq) configurations. The color part of their state functions is an SU(3) singlet, a completely antisymmetric state of the three colors. Since the quarks are fermions, the state function must be antisymmetric under interchange of any two equal-mass quarks (up and down quarks in the limit of isospin symmetry). Thus it can be written as

$$|\,qqq\,\rangle_A = |\,\text{color}\,\rangle_A \times |\,\text{space, spin, flavor}\,\rangle_S\ , \tag{15.21}$$

where the subscripts S and A indicate symmetry or antisymmetry under interchange of any two equal-mass quarks. Note the contrast with the state function for the three nucleons in ^{3}H or ^{3}He:

$$|\,NNN\,\rangle_A = |\,\text{space, spin, isospin}\,\rangle_A\ . \tag{15.22}$$

This difference has major implications for internal structure, magnetic moments, *etc.* (For a nice discussion, see Ref. 23.)

The "ordinary" baryons are made up of u, d, and s quarks. The three flavors imply an approximate flavor SU(3), which requires that baryons made of these quarks belong to the multiplets on the right side of

$$\mathbf{3}\otimes\mathbf{3}\otimes\mathbf{3} = \mathbf{10}_S \oplus \mathbf{8}_M \oplus \mathbf{8}_M \oplus \mathbf{1}_A \tag{15.23}$$

(see Sec. 45, on "SU(n) Multiplets and Young Diagrams"). Here the subscripts indicate symmetric, mixed-symmetry, or antisymmetric states under interchange of any two quarks. The **1** is a uds state (Λ_1), and the octet contains a similar state (Λ_8). If these have the same spin and parity, they can mix. The mechanism is the same as for the mesons (see above). In the ground state multiplet, the SU(3) flavor singlet Λ_1 is forbidden by Fermi statistics. Section 44, on "SU(3) Isoscalar Factors and Representation Matrices," shows how relative decay rates in, say, $\mathbf{10} \to \mathbf{8}\otimes\mathbf{8}$ decays may be calculated.

The addition of the c quark to the light quarks extends the flavor symmetry to SU(4). However, due to the large mass of the c quark, this symmetry is much more strongly broken than the SU(3) of the three light quarks. Figures 15.4(a) and 15.4(b) show the SU(4) baryon multiplets that have as their bottom levels an SU(3) octet, such as the octet that includes the nucleon, or an SU(3) decuplet, such as the decuplet that includes the $\Delta(1232)$. All particles in a given SU(4) multiplet have the same spin and parity. The charmed baryons are discussed in more detail in the "Note on Charmed Baryons" in the Particle Listings. The addition of a b quark extends the flavor symmetry to SU(5); the existence of baryons with t-quarks is very unlikely due to the short lifetime of the t-quark.

For the "ordinary" baryons (no c or b quark), flavor and spin may be combined in an approximate flavor-spin SU(6), in which the six basic states are $d\uparrow$, $d\downarrow$, $\cdots$, $s\downarrow$ ($\uparrow$, $\downarrow$ = spin up, down). Then the baryons belong to the multiplets on the right side of

$$\mathbf{6}\otimes\mathbf{6}\otimes\mathbf{6} = \mathbf{56}_S \oplus \mathbf{70}_M \oplus \mathbf{70}_M \oplus \mathbf{20}_A\ . \tag{15.24}$$

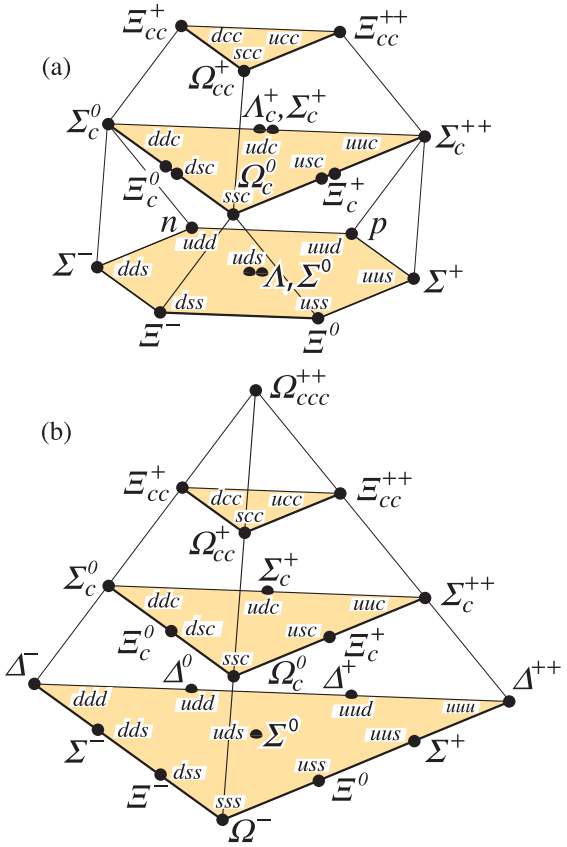

Figure 15.4: SU(4) multiplets of baryons made of u, d, s, and c quarks. (a) The 20-plet with an SU(3) octet. (b) The 20-plet with an SU(3) decuplet.

These SU(6) multiplets decompose into flavor SU(3) multiplets as follows:

$$\mathbf{56} = {}^4\mathbf{10} \oplus {}^2\mathbf{8} \tag{15.25a}$$

$$\mathbf{70} = {}^2\mathbf{10} \oplus {}^4\mathbf{8} \oplus {}^2\mathbf{8} \oplus {}^2\mathbf{1} \tag{15.25b}$$

$$\mathbf{20} = {}^2\mathbf{8} \oplus {}^4\mathbf{1}\ , \tag{15.25c}$$

where the superscript $(2S+1)$ gives the net spin S of the quarks for each particle in the SU(3) multiplet. The $J^P = 1/2^+$ octet containing the nucleon and the $J^P = 3/2^+$ decuplet containing the $\Delta(1232)$ together make up the "ground-state" 56-plet, in which the orbital angular momenta between the quark pairs are zero (so that the spatial part of the state function is trivially symmetric). The **70** and **20** require some excitation of the spatial part of the state function in order to make the overall state function symmetric. States with nonzero orbital angular momenta are classified in SU(6)$\otimes$O(3) supermultiplets.

It is useful to classify the baryons into bands that have the same number N of quanta of excitation. Each band consists of a number of supermultiplets, specified by (D, L_N^P), where D is the dimensionality of the SU(6) representation, L is the total quark orbital angular momentum, and P is the total parity. Supermultiplets contained in bands up to N = 12 are given in Ref. 24. The N = 0 band, which contains the nucleon and $\Delta(1232)$, consists only of the $(56,0_0^+)$ supermultiplet. The N = 1 band consists only of the $(70,1_1^-)$ multiplet and contains the negative-parity baryons with masses below about 1.9 GeV. The N = 2 band contains five supermultiplets: $(56,0_2^+)$, $(70,0_2^+)$, $(56,2_2^+)$, $(70,2_2^+)$, and $(20,1_2^+)$.

The wave functions of the non-strange baryons in the harmonic oscillator basis are often labeled by $|X^{2S+1}L_\pi J^P\rangle$, where S, L, J, P are as above, $X = N$ or Δ, and $\pi = S, M$ or A denotes the symmetry of the spatial wave function. The possible model states for the bands with N=0,1,2 are given in Table 15.5. The assignment of experimentally observed states is only complete and well established

up to the N=1 band. Some more tentative assignments for higher multiplets are suggested in Ref. 25.

In Table 15.6, quark-model assignments are given for many of the established baryons whose SU(6)⊗O(3) compositions are relatively unmixed. One must, however, keep in mind that apart from the mixing of the Λ singlet and octet states, states with same J^P but different L, S combinations can also mix. In the quark model with one-gluon exchange motivated interactions, the size of the mixing is determined by the relative strength of the tensor term with respect to the contact term (see below). The mixing is more important for the decay patterns of the states than for their positions. An example are the lowest lying $(70, 1^-_1)$ states with J^P=1/2$^-$ and 3/2$^-$. The physical states are:

$$|\, N(1535)1/2^-\rangle = \cos(\Theta_S)|N^2P_M1/2^-\rangle - \sin(\Theta_S)|N^4P_M1/2^-\rangle \quad (15.26)$$

$$|\, N(1520)3/2^-\rangle = \cos(\Theta_D)|N^2P_M3/2^-\rangle - \sin(\Theta)_D|N^4P_M3/2^-\rangle \quad (15.27)$$

and the orthogonal combinations for $N(1650)1/2^-$ and $N(1700)3/2^-$. The mixing is large for the J^P=1/2$^-$ states ($\Theta_S \approx$ -32^o), but small for the J^P=3/2$^-$ states ($\Theta_D \approx +6^o$) [26,27].

All baryons of the ground state multiplets are known. Many of their properties, in particular their masses, are in good agreement even with the most basic versions of the quark model, including harmonic (or linear) confinement and a spin-spin interaction, which is responsible for the octet - decuplet mass shifts. A consistent description of the ground-state electroweak properties, however, requires refined relativistic constituent quark models.

The situation for the excited states is much less clear. The assignment of some experimentally observed states with strange quarks to model configurations is only tentative and in many cases candidates are completely missing. Recently, Melde, Plessas and Sengl [28] have calculated baryon properties in relativistic constituent quark models, using one-gluon exchange and Goldstone-boson exchange for the modeling of the hyperfine interactions (see Sec. 15.5 on Dynamics). Both types of models give qualitatively comparable results, and underestimate in general experimentally observed decay widths. Nevertheless, in particular on the basis of the observed decay patterns, the authors have assigned some additional states with strangeness to the SU(3) multiplets and suggest re-assignments for a few others. Among the new assignments are states with weak experimental evidence (two or three star ratings) and partly without firm spin/parity assignments, so that further experimental efforts are necessary before final conclusions can be drawn. We have added their suggestions in Table 15.6.

In the non-strange sector there are two main problems which are illustrated in Fig. 15.5, where the experimentally observed excitation spectrum of the nucleon (N and Δ resonances) is compared to the results of a typical quark model calculation [29]. The lowest states from the N=2 band, the $N(1440)1/2^+$, and the $\Delta(1600)3/2^+$, appear lower than the negative parity states from the N=1 band (see Table 15.5) and much lower than predicted by most models. Also negative parity Δ states from the N=3 band ($\Delta(1900)1/2^-$, $\Delta(1940)3/2^-$, and $\Delta(1930)5/2-$) are too low in energy. Part of the problem could be experimental. Among the negative parity Δ states, only the $\Delta(1930)5/2^-$ has three stars and the uncertainty in the position of the $\Delta(1600)3/2^+$ is large (1550 - 1700 MeV).

Table 15.5: N and Δ states in the N=0,1,2 harmonic oscillator bands. L^P denotes angular momentum and parity, S the three-quark spin and 'sym'=A,S,M the symmetry of the spatial wave function. Only dominant components indicated. Assignments in the N=2 band are partly tentative.

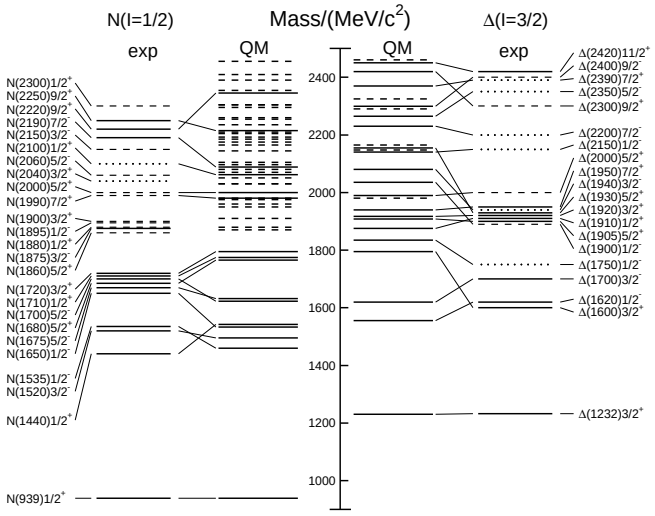

Figure 15.5: Excitation spectrum of the nucleon. Compared are the positions of the excited states identified in experiment, to those predicted by a relativized quark model calculation. Left hand side: isospin $I = 1/2$ N-states, right hand side: isospin $I = 3/2$ Δ-states. Experimental: (columns labeled 'exp'), three- and four-star states are indicated by full lines (two-star dashed lines, one-star dotted lines). At the very left and right of the figure, the spectroscopic notation of these states is given. Quark model [29]: (columns labeled 'QM'), all states for the N=1,2 bands, low-lying states for the N=3,4,5 bands. Full lines: at least tentative assignment to observed states, dashed lines: so far no observed counterparts. Many of the assignments between predicted and observed states are highly tentative.

Furthermore, many more states are predicted than observed. This has been known for a long time as the 'missing resonance' problem [26]. Up to an excitation energy of 2.4 GeV, about 45 N states are predicted, but only 14 are established (four- or three-star; see Note on N and Δ Resonances for the rating of the status of resonances) and 10 are tentative (two- or one-star). Even for the N=2 band, up to now only half of the predicted states have been observed. The most recent partial wave analysis of elastic pion scattering and charge exchange data by Arndt and collaborators [30] has made the situation even worse. They found no evidence for almost half of the states listed in this review (and included in Fig. 15.5). Such analyses are of course biased against resonances which couple only weakly to the $N\pi$ channel. Quark model predictions for the couplings to other hadronic channels and to photons are given in Ref. 29. A large experimental effort is ongoing at several electron accelerators to study the baryon resonance spectrum with real and virtual photon-induced meson production reactions. This includes the search for as-yet-unobserved states, as well as detailed studies of the properties of the low lying states (decay patterns, electromagnetic couplings, magnetic moments, *etc.*) (see Ref. 31 for recent reviews). This experimental effort has currently entered its final phase with the measurement of single and double polarization observables for many different meson production channels, so that a much better understanding of the experimental spectrum can be expected for the near future.

In quark models, the number of excited states is determined by the effective degrees of freedom, while their ordering and decay properties are related to the residual quark - quark interaction. An overview of quark models for baryons is given in Ref. 27, a recent discussion of baryon spectroscopy is given in Ref. 25. The effective degrees of freedom in the standard nonrelativistic quark model are three equivalent valence quarks with one-gluon exchange-motivated, flavor-independent color-magnetic interactions. A different class of models uses interactions which give rise to a quark - diquark clustering of the baryons (for a review see Ref. 32). If there is a tightly bound diquark, only two degrees of freedom are available at low energies, and thus *fewer* states are predicted. Furthermore, selection rules in the

Table 15.6: Quark-model assignments for some of the known baryons in terms of a flavor-spin SU(6) basis. Only the dominant representation is listed. Assignments for several states, especially for the $\Lambda(1810)$, $\Lambda(2350)$, $\Xi(1820)$, and $\Xi(2030)$, are merely educated guesses. † recent suggestions for assignments and re-assignments from Ref. [28]. For assignments of the charmed baryons, see the "Note on Charmed Baryons" in the Particle Listings.

decay pattern may arise from the quantum numbers of the diquark. *More* states are predicted by collective models of the baryon like the algebraic approach in Ref. 33. In this approach, the quantum numbers of the valence quarks are distributed over a Y-shaped string-like configuration, and additional states arise *e.g.*, from vibrations of the strings. *More* states are also predicted in the framework of flux-tube models (see Ref. 34), which are motivated by lattice QCD. In addition to the quark degrees of freedom, flux-tubes responsible for the confinement of the quarks are considered as degrees of freedom. These models include hybrid baryons containing explicit excitations of the gluon fields. However, since all half integral J^P quantum numbers are possible for ordinary baryons, such 'exotics' will be very hard to identify, and probably always mix with ordinary states. So far, the experimentally observed number of states is still far lower even than predicted by the quark–diquark models.

Recently, the influence of chiral symmetry on the excitation spectrum of the nucleon has been hotly debated from a somewhat new perspective. Chiral symmetry, the fundamental symmetry of QCD, is strongly broken for the low lying states, resulting in large mass differences of parity partners like the $J^P{=}1/2^+$ $N(938)1/2^+$ ground state and the $J^P{=}1/2^-$ $N(1535)1/2^-$ excitation. However, at higher excitation energies there is some evidence for parity doublets and even some very tentative suggestions for full chiral multiplets of N^* and Δ resonances. An effective restoration of chiral symmetry at high excitation energies due to a decoupling from the quark condensate of the vacuum has been discussed (see Ref. 35 for recent reviews) as a possible cause. In this case, the mass generating mechanisms

for low and high lying states would be essentially different. As a further consequence, the parity doublets would decouple from pions, so that experimental bias would be worse. However, parity doublets might also arise from the spin-orbital dynamics of the 3-quark system. Presently, the status of data does not allow final conclusions.

The most recent developments on the theory side are the first unquenched lattice calculations for the excitation spectrum discussed in Sec. 15.6. The results are basically consistent with the level counting of SU(6)⊗O(3) in the standard non-relativistic quark model and show no indication for quark-diquark structures or parity doubling. Consequently, there is as yet no indication from lattice that the mis-match between the excitation spectrum predicted by the standard quark model and experimental observations is due to inappropriate degrees of freedom in the quark model.

15.5. Dynamics

Quantum chromodynamics (QCD) is well-established as the theory for the strong interactions. As such, one of the goals of QCD is to predict the spectrum of strongly-interacting particles. To date, the only first-principles calculations of spectroscopy from QCD use lattice methods. These are the subject of Sec. 15.6. These calculations are difficult and unwieldy, and many interesting questions do not have a good lattice-based method of solution. Therefore, it is natural to build models, whose ingredients are abstracted from QCD, or from the low-energy limit of QCD (such as chiral Lagrangians) or from the data itself. The words "quark model" are a shorthand for such phenomenological models. Many specific quark models exist, but most contain a similar basic set of dynamical ingredients. These include:

i) A confining interaction, which is generally spin-independent (*e.g.*, harmonic oscillator or linear confinement);

ii) Different types of spin-dependent interactions:

a) commonly used is a color-magnetic flavor-independent interaction modeled after the effects of gluon exchange in QCD (see *e.g.*, Ref. 36) For example, in the S-wave states, there is a spin-spin hyperfine interaction of the form

$$H_{HF} = -\alpha_S M \sum_{i>j} (\overrightarrow{\sigma}\lambda_a)_i (\overrightarrow{\sigma}\lambda_a)_j \ , \tag{15.28}$$

where M is a constant with units of energy, λ_a $(a = 1, \cdots, 8,)$ is the set of SU(3) unitary spin matrices, defined in Sec. 44, on "SU(3) Isoscalar Factors and Representation Matrices," and the sum runs over constituent quarks or antiquarks. Spin-orbit interactions, although allowed, seem to be small in general, but a tensor term is responsible for the mixing of states with the same J^P but different L, S combinations.

b) other approaches include flavor-dependent short-range quark forces from instanton effects (see *e.g.*, Ref. 37) This interaction acts only on scalar, isoscalar pairs of quarks in a relative S-wave state:

$$\langle q^2; S, L, T|W|q^2; S, L, T\rangle = -4g\delta_{S,0}\delta_{L,0}\delta_{I,0}\mathcal{W} \tag{15.29}$$

where $\mathcal{W}$ is the radial matrix element of the contact interaction.

c) a rather different and controversially discussed approach is based on flavor-dependent spin-spin forces arising from one-boson exchange. The interaction term is of the form:

$$H_{HF} \propto \sum_{i<j} V(\overrightarrow{r}_{ij})\lambda_i^F \cdot \lambda_j^F \overrightarrow{\sigma}_i \cdot \overrightarrow{\sigma}_j \tag{15.30}$$

where the λ_i^F are in flavor space (see *e.g.*, Ref. 38).

iii) A strange quark mass somewhat larger than the up and down quark masses, in order to split the SU(3) multiplets;

iv) In the case of spin-spin interactions (iia,c), a flavor-symmetric interaction for mixing $q\overline{q}$ configurations of different flavors (*e.g.*, $u\overline{u} \leftrightarrow d\overline{d} \leftrightarrow s\overline{s}$), in isoscalar channels, so as to reproduce *e.g.*, the η - η' and ω - ϕ mesons.

These ingredients provide the basic mechanisms that determine the hadron spectrum in the standard quark model.

15.6. Lattice Calculations of Hadronic Spectroscopy

Lattice calculations are a major source of information about QCD masses and matrix elements. The necessary theoretical background is given in Sec. 18 of this *Review*. Here we confine ourselves to some general comments and illustrations of lattice calculations for spectroscopy.

In general, the cleanest lattice results come from computations of processes in which there is only one particle in the simulation volume. These quantities include masses of hadrons, simple decay constants, like pseudoscalar meson decay constants, and semileptonic form factors (such as the ones appropriate to $B \to Dl\nu$, $Kl\nu$, $\pi l\nu$). The cleanest predictions for masses are for states which have narrow decay widths and are far below any thresholds to open channels, since the effects of final state interactions are not yet under complete control on the lattice. As a simple corollary, the lightest state in a channel is easier to study than the heavier ones. "Difficult" states for the quark model (such as exotics) are also difficult for the lattice because of the lack of simple operators which couple well to them.

Good-quality modern lattice calculations will present multi-part error budgets with their predictions. A small part of the uncertainty is statistical, from sample size. Typically, the quoted statistical uncertainty includes uncertainty from a fit: it is rare that a simulation computes one global quantity which is the desired observable. Simulations which include virtual quark-antiquark pairs (also known as "dynamical quarks" or "sea quarks") are often done at up and down quark mass values heavier than the experimental ones, and it is then necessary to extrapolate in these quark masses. Simulations can work at the physical values of the heavier quarks' masses. They are always done at nonzero lattice spacing, and so it is necessary to extrapolate to zero lattice spacing. Some theoretical input is needed to do this. Much of the uncertainty in these extrapolations is systematic, from the choice of fitting function. Other systematics include the effect of finite simulation volume, the number of flavors of dynamical quarks actually simulated, and technical issues with how these dynamical quarks are included. The particular choice of a fiducial mass (to normalize other predictions) is not standardized; there are many possible choices, each with its own set of strengths and weaknesses, and determining it usually requires a second lattice simulation from that used to calculate the quantity under consideration.

A systematic error of major historical interest is the "quenched approximation," in which dynamical quarks are simply left out of the simulation. This was done because the addition of these virtual pairs presented an expensive computational problem. No generally-accepted methodology has ever allowed one to correct for quenching effects, short of redoing all calculations with dynamical quarks. Recent advances in algorithms and computer hardware have rendered it obsolete.

With these brief remarks, we turn to examples. The field of lattice QCD simulations is vast, and so it is not possible to give a comprehensive review of them in a small space. The history of lattice QCD simulations is a story of thirty years of incremental improvements in physical understanding, algorithm development, and ever faster computers, which have combined to bring the field to a present state where it is possible to carry out very high quality calculations. We present a few representative illustrations, to show the current state of the art.

By far, the major part of all lattice spectroscopy is concerned with that of the light hadrons, and so we illustrate results in Fig. 15.6, a comprehensive summary provided by A. Kronfeld [39].

Flavor singlet mesons are at the frontier of lattice QCD calculations, because one must include the effects of "annihilation graphs," for the valence q and $\bar{q}$. Recently, the RBC and UKQCD collaborations, Ref. 6, have reported a calculation of the η and η' mesons, finding masses of 573(6) and 947(142) MeV, respectively. The singlet-octet mixing angle (in the conventions of Table 15.2) is $\theta_{lin} = -14.1(2.8)°$.

The spectroscopy of mesons containing heavy quarks has become a truly high-precision endeavor. These simulations use Non-Relativistic QCD (NRQCD) or Heavy Quark Effective Theory (HQET), systematic

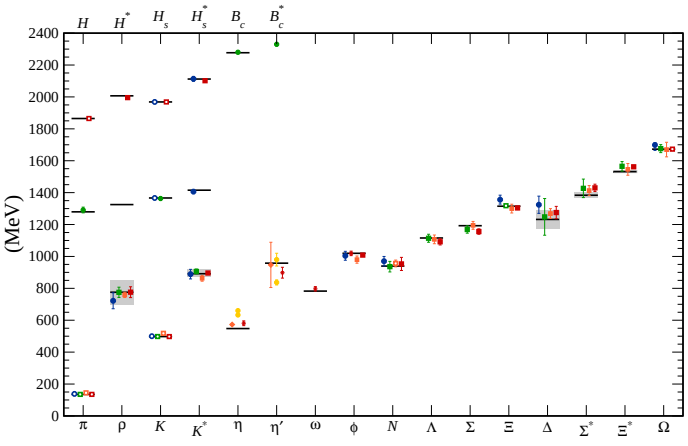

Figure 15.6: Lattice results for spectroscopy. The plot combines data for mesons and baryons from the MILC [40,41], PACS-CS [42], BMW [43] and QCDSF [44] collaborations. The results for the η and η' are from the RBC and UKQCD collaborations [6], the Hadron Spectrum collaboration (they also measured the ω) [45] and UKQCD [46]. Data for heavy-light hadrons comes from the Fermilab-MILC collaboration [47], HPQCD [48], and Mohler and Woloshyn [49]. Circles, squares, and diamonds represent different kinds of lattice discretizations for fermions: staggered, Wilson and chiral sea quarks. Asterisks show lattices with different spatial and temporal lattice spacings. Open symbols show the masses which were used to fix parameters. Red, orange, yellow, green, and blue stand for increasing numbers of ensembles (different lattice spacings and quark masses). Horizontal bands and gray boxes show experimentally measured masses and widths. The b-mesons are offset by about 4 GeV.

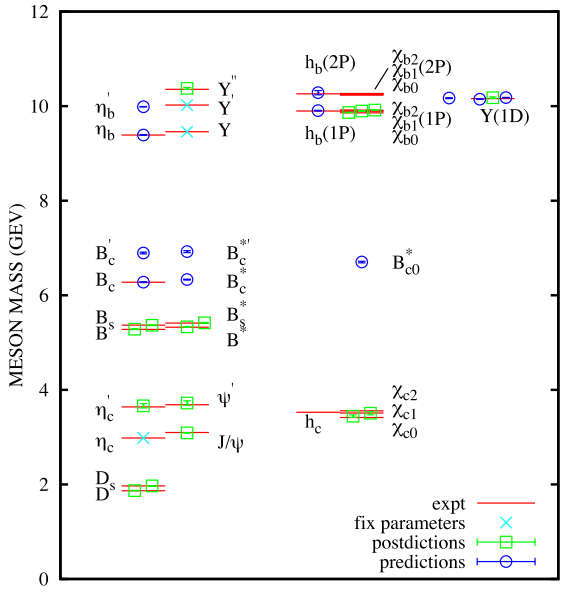

Figure 15.7: Spectroscopy for mesonic systems containing one or more heavy quarks (adapted from Ref. 50) Particles whose masses are used to fix lattice parameters are shown with crosses; the authors distinguish between "predictions" and "postdictions" of their calculation. Lines represent experiment.

expansions of the QCD Lagrangian in powers of the heavy quark velocity, or the heavy quark mass. Terms in the Lagrangian have obvious quark model analogs, but are derived directly from QCD. For example, the heavy quark potential is a derived quantity, extracted from simulations. Fig. 15.7 shows the mass spectrum for mesons containing at least one heavy (b or c) quark from Ref. 50 It also contains results from Refs. [51] and [52]. The calculations uses a discretization of nonrelativistic QCD for bottom quarks with charm and lighter quarks being handled with an improved relativistic action. Four flavors (u, d, s, c) of dynamical quarks are included.

Finally, Fig. 15.8 and Fig. 15.9 show recent lattice calculations of singly and double charmed baryons. These figures were provided by S. Collins and are based on ones in the review Ref. 53. Here we are at the forefront of theory and experiment.

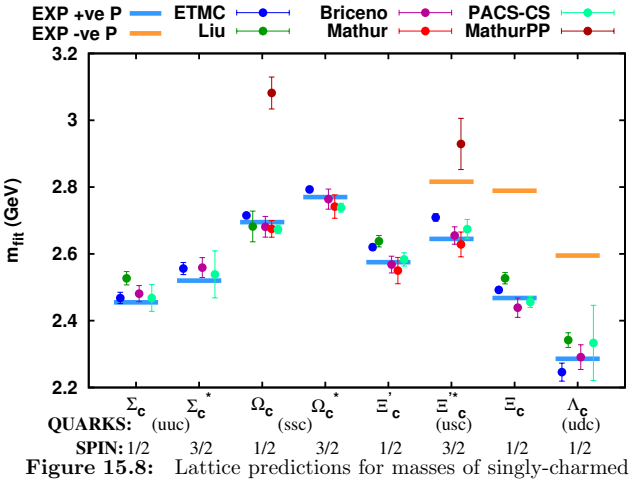

Figure 15.8: Lattice predictions for masses of singly-charmed baryons. Data are labeled ETMC, Ref. 54 Liu, Ref. 55; Briceno, Ref. 56; PACS-CS, Ref. 57; and Mathur and Mathur-PP, Ref. 58. Lines are from experiment (positive and negative parity states).

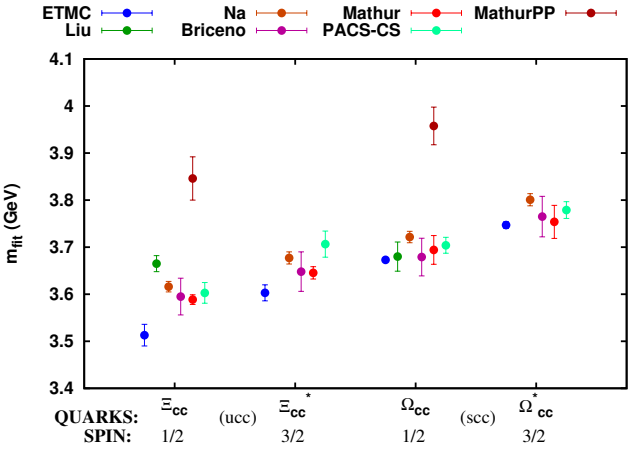

Figure 15.9: Lattice predictions for masses of doubly-charmed baryons. Data are ETMC, Ref. 54; Liu, Ref. 55; Briceno, Ref. 56; PACS-CS, Ref. 57; Mathur and Mathur-PP, Ref. 58. and Na, Ref. 59.

Recall that lattice calculations take operators which are interpolating fields with quantum numbers appropriate to the desired states, compute correlation functions of these operators, and fit the correlation functions to functional forms parametrized by a set of masses and matrix elements. As we move away from hadrons which can be created by the simplest quark model operators (appropriate to the lightest meson and baryon multiplets) we encounter a host of new problems: either no good interpolating fields, or too many possible interpolating fields, and many states with the same quantum numbers. Techniques for dealing with these interrelated problems vary from collaboration to collaboration, but all share common features: typically, correlation functions from many different interpolating fields are used, and the signal is extracted in what amounts to a variational calculation using the chosen operator basis. In addition to mass

spectra, wave function information can be garnered from the form of the best variational wave function. Of course, the same problems which are present in the spectroscopy of the lightest hadrons (the need to extrapolate to infinite volume, physical values of the light quark masses, and zero lattice spacing) are also present. We briefly touch on three different kinds of hadrons: excited states of baryons, glueballs, and hybrid mesons. The quality of the data is not as good as for the ground states, and so the results continue to evolve.

Ref. 60 is a good recent review of excited baryon spectroscopy. The interesting physics questions to be addressed are precisely those enumerated in the last section. An example of a recent calculation, due to Ref. 61 is shown in Fig. 15.10. Notice that the pion is not yet at its physical value. The lightest positive parity state is the nucleon, and the Roper resonance has not yet appeared as a light state.

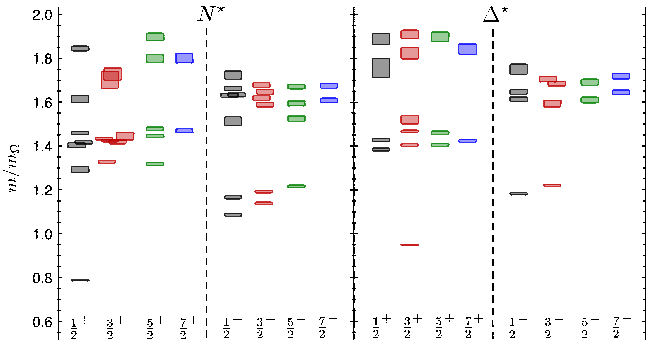

Figure 15.10: Spin-identified spectrum of nucleons and deltas, from lattices where $m_\pi = 396$ MeV, in units of the calculated Ω mass, from Ref. 61. The colors just correspond to the different J assignments: grey for $J = 1/2$, red for $J = 3/2$, green for 5/2, blue for $J = 7/2$.

Exotic mesons share the difficulties of ordinary excited states, and some recent calculations actually include both kinds of states in their combined fits. Ref. 62 provides a good summary of the theoretical and experimental situation regarding mesons with exotic quantum numbers, including a compilation of lattice data. The lightest exotics, the h_0, η_1, and h_2, have long been targets of lattice studies. Recently, the authors of Ref. 45 have presented new results for isoscalar and isovector meson spectroscopy, which observe the three states around 2 GeV. Again, the light quark masses in the simulations are higher than in nature; the pion is at 396 MeV.

In Fig. 15.3 we showed a figure from Ref. 11 showing a lattice prediction for the glueball mass spectrum in quenched approximation. A true QCD prediction of the glueball spectrum requires dynamical light quarks and (because glueball operators are intrinsically noisy) high statistics. Only recently have the first useful such calculations appeared. Fig. 15.11 shows results from Ref. 63, done with dynamical u, d and s quarks at two lattice spacings, 0.123 and 0.092 fm, along with comparisons to the quenched lattice calculation of Ref. 10 and to experimental isosinglet mesons. The dynamical simulation is, of course, not the last word on this subject, but it shows that the effects of quenching seem to be small.

Several other features of hadronic spectroscopy are also being studied on the lattice.

Electromagnetic mass splittings (such as the neutron - proton mass difference) are interesting but difficult. The mass difference has two origins: the first is that the up and down quarks have slightly different masses. The second is that the quarks have (different) charges, so electromagnetic interactions must be included in the simulations. This creates a host of technical issues. An important one is that electromagnetic interactions are long range, but lattice simulations are done in finite volumes. Two recent calculations, Refs. [64] and [65], find reasonable agreement with experiment. The situation is summarized in the review Ref. 66.

Most hadrons are resonances, and their widths are the last target of lattice simulations we will mention. The actual calculation is of the combined mass of two (or more) hadrons in a box of finite size.

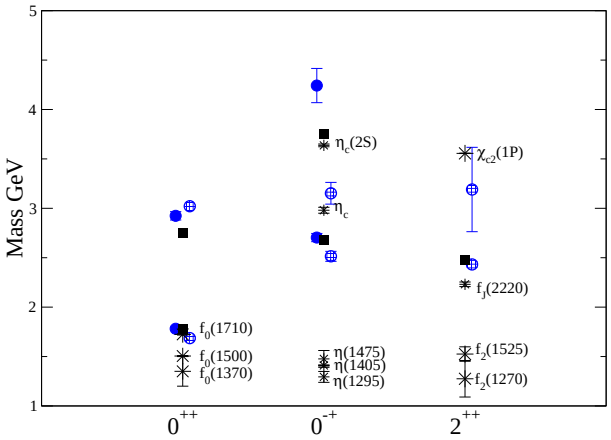

Figure 15.11: Lattice QCD predictions for glueball masses. The open and closed circles are the larger and smaller lattice spacing data of the full QCD calculation of glueball masses of Ref. 63. Squares are the quenched data for glueball masses of Ref. 10. The bursts labeled by particle names are experimental states with the appropriate quantum numbers.

The combined mass is shifted from being the sum of the individual masses because the finite box forces the hadrons to interact with each other. The volume-dependent mass shift yields the phase shift for the continuum scattering amplitude, which in turn can be used to extract the resonance mass and width, with some degree of modeling. So far only two-body resonances, the rho meson and a few others, have been well studied. This is an active research topic, and recent reviews, Ref. 67, summarize the situation.

16. GRAND UNIFIED THEORIES

Revised October 2011 by S. Raby (Ohio State University).

16.1. Grand Unification

16.1.1. *Standard Model : An Introduction* :

In spite of all the successes of the Standard Model [SM] it is unlikely to be the final theory. It leaves many unanswered questions. Why the local gauge interactions $SU(3)_C \times SU(2)_L \times U(1)_Y$ and why 3 families of quarks and leptons? Moreover why does one family consist of the states $[Q, u^c, d^c; L, e^c]$ transforming as $[(3,2,1/3), (\bar{3},1,-4/3), (\bar{3},1,2/3); (1,2,-1), (1,1,2)]$, where $Q = (u,d)$ and $L = (\nu, e)$ are $SU(2)_L$ doublets and u^c, d^c, e^c are charge conjugate $SU(2)_L$ singlet fields with the $U(1)_Y$ quantum numbers given? [We use the convention that electric charge $Q_{EM} = T_{3L} + Y/2$ and all fields are left handed Weyl spinors.] Note the SM gauge interactions of quarks and leptons are completely fixed by their gauge charges. Thus if we understood the origin of this charge quantization, we would also understand why there are no fractionally charged hadrons. Finally, what is the origin of quark and lepton masses or the apparent hierarchy of family masses and quark and leptonic mixing angles? Perhaps if we understood this, we would also know the origin of CP violation, the solution to the strong CP problem, the origin of the cosmological matter - antimatter asymmetry. In addition, it lacks an explanation for the observed dark matter and dark energy of the universe.

The SM has 19 arbitrary parameters; their values are chosen to fit the data. Three arbitrary gauge couplings: g_3, g, g' (where g, g' are the $SU(2)_L$, $U(1)_Y$ couplings, respectively) or equivalently $\alpha_s = (g_3^2/4\pi)$, $\alpha_{EM} = (e^2/4\pi)$ $(e = g \sin\theta_W)$ and $\sin^2\theta_W = (g')^2/(g^2 + (g')^2)$. In addition there are 13 parameters associated with the 9 charged fermion masses and the four mixing angles in the CKM matrix. The remaining 3 parameters are v, λ [the Higgs VEV and quartic coupling] (or equivalently M_Z, m_h^0) and the QCD θ parameter. In addition, data from neutrino oscillation experiments provide convincing evidence for neutrino masses. With 3 light Majorana neutrinos there are at least 9 additional parameters in the neutrino sector; 3 masses and 6 mixing angles and phases. In summary, the SM has too many arbitrary parameters and leaves open too many unresolved questions to be considered complete. These are the problems which grand unified theories hope to address.

16.1.2. *Charge Quantization* :

In the Standard Model, quarks and leptons are on an equal footing; both fundamental particles without substructure. It is now clear that they may be two faces of the same coin; unified, for example, by extending QCD (or $SU(3)_C$) to include leptons as the fourth color, $SU(4)_C$ [1]. The complete Pati-Salam gauge group is $SU(4)_C \times SU(2)_L \times SU(2)_R$ with the states of one family $[(Q,L),(Q^c,L^c)]$ transforming as $[(4,2,1), (\bar{4},1,\bar{2})]$ where $Q^c = (d^c, u^c)$, $L^c = (e^c, \nu^c)$ are doublets under $SU(2)_R$. Electric charge is now given by the relation $Q_{EM} = T_{3L} + T_{3R} + 1/2(B-L)$ and $SU(4)_C$ contains the subgroup $SU(3)_C \times (B-L)$ where B (L) is baryon (lepton) number. Note ν^c has no SM quantum numbers and is thus completely "sterile". It is introduced to complete the $SU(2)_R$ lepton doublet. This additional state is desirable when considering neutrino masses.

Although quarks and leptons are unified with the states of one family forming two irreducible representations of the gauge group; there are still 3 independent gauge couplings (two if one also imposes parity, i.e. $L \leftrightarrow R$ symmetry). As a result the three low energy gauge couplings are still independent arbitrary parameters. This difficulty is resolved by embedding the SM gauge group into the simple unified gauge group, Georgi-Glashow $SU(5)$, with one universal gauge coupling α_G defined at the grand unification scale M_G [2]. Quarks and leptons still sit in two irreducible representations, as before, with a $\mathbf{10} = [Q, u^c, e^c]$ and $\bar{\mathbf{5}} = [d^c, L]$. Nevertheless, the three low energy gauge couplings are now determined in terms of two independent parameters : α_G and M_G. Hence there is one prediction.

In order to break the electroweak symmetry at the weak scale and give mass to quarks and leptons, Higgs doublets are needed which can sit in either a $\mathbf{5_H}$ or $\bar{\mathbf{5}}_\mathbf{H}$. The additional 3 states are color triplet Higgs scalars. The couplings of these color triplets violate baryon and lepton number and nucleons decay via the exchange of a single color triplet Higgs scalar. Hence in order not to violently disagree with the non-observation of nucleon decay, their mass must be greater than $\sim 10^{11}$ GeV [3]. Moreover, in supersymmetric GUTs, in order to cancel anomalies as well as give mass to both up and down quarks, both Higgs multiplets $\mathbf{5_H}$, $\bar{\mathbf{5}}_\mathbf{H}$ are required. As we shall discuss later, nucleon decay now constrains the color triplet Higgs states in a SUSY GUT to have mass significantly greater than M_G.

Complete unification is possible with the symmetry group $SO(10)$ with one universal gauge coupling α_G and one family of quarks and leptons sitting in the 16 dimensional spinor representation $\mathbf{16} = [\mathbf{10} + \bar{\mathbf{5}} + \mathbf{1}]$ [4]. The $SU(5)$ singlet $\mathbf{1}$ is identified with ν^c. In Table 1 we present the states of one family of quarks and leptons, as they appear in the **16**. It is an amazing and perhaps even profound fact that all the states of a single family of quarks and leptons can be represented digitally as a set of 5 zeros and/or ones or equivalently as the tensor product of 5 "spin" 1/2 states with $\pm = |\pm\frac{1}{2}>$ and with the condition that we have an even number of $|+>$ spins. The first three "spins" correspond to $SU(3)_C$ color quantum numbers, while the last two are $SU(2)_L$ weak quantum numbers. In fact an $SU(3)_C$ rotation just raises one color index and lowers another, thereby changing colors $\{r,\ b,\ y\}$. Similarly an $SU(2)_L$ rotation raises one weak index and lowers another, thereby flipping the weak isospin from up to down or vice versa. In this representation weak hypercharge Y is given by the simple relation $Y = -2/3(\sum \text{ color spins}) + (\sum \text{ weak spins})$. $SU(5)$ rotations [in particular, the ones NOT in $SU(3)_C \times SU(2)_L \times U(1)_Y$] then raise (or lower) a color index, while at the same time lowering (or raising) a weak index. It is easy to see that such rotations can mix the states $\{Q,\ u^c,\ e^c\}$ and $\{d^c, L\}$ among themselves and ν^c is a singlet. The new $SO(10)$ rotations [not in $SU(5)$] are then given by either raising or lowering any two spins. For example, by raising the two weak indices ν^c rotates into e^c, etc.

Table 16.1: The quantum numbers of the **16** dimensional representation of SO(10).

State	Y	Color	Weak
$\boldsymbol{\nu^c}$	0	$- - -$	$- -$
$\boldsymbol{e^c}$	2	$- - -$	$+ +$
$\boldsymbol{u}_r$	1/3	$+ - -$	$- +$
$\boldsymbol{d}_r$	1/3	$+ - -$	$+ -$
$\boldsymbol{u}_b$	1/3	$- + -$	$- +$
$\boldsymbol{d}_b$	1/3	$- + -$	$+ -$
$\boldsymbol{u}_y$	1/3	$- - +$	$- +$
$\boldsymbol{d}_y$	1/3	$- - +$	$+ -$
$\boldsymbol{u}_r^c$	$-4/3$	$- + +$	$- -$
$\boldsymbol{u}_b^c$	$-4/3$	$+ - +$	$- -$
$\boldsymbol{u}_y^c$	$-4/3$	$+ + -$	$- -$
$\boldsymbol{d}_r^c$	2/3	$- + +$	$+ +$
$\boldsymbol{d}_b^c$	2/3	$+ - +$	$+ +$
$\boldsymbol{d}_y^c$	2/3	$+ + -$	$+ +$
$\boldsymbol{\nu}$	-1	$+ + +$	$- +$
$\boldsymbol{e}$	-1	$+ + +$	$+ -$

$SO(10)$ has two inequivalent maximal breaking patterns. $SO(10) \to SU(5) \times U(1)_X$ and $SO(10) \to SU(4)_C \times SU(2)_L \times SU(2)_R$. In the first case we obtain Georgi-Glashow $SU(5)$ if Q_{EM} is given in terms of $SU(5)$ generators alone or so-called flipped $SU(5)$ [5] if Q_{EM} is partly in $U(1)_X$. In the latter case we have the Pati-Salam symmetry. If $SO(10)$ breaks directly to the SM at M_G, then we retain the prediction for gauge coupling unification. However more possibilities for breaking (hence more breaking scales and more parameters) are available in $SO(10)$. Nevertheless with one breaking pattern $SO(10) \to SU(5) \to$ SM, where the last breaking scale is M_G, the predictions from gauge coupling unification are preserved. The Higgs multiplets in

minimal $SO(10)$ are contained in the fundamental $\mathbf{10_H} = [\mathbf{5_H}, \bar{\mathbf{5}}_\mathbf{H}]$ representation. Note, only in $SO(10)$ does the gauge symmetry distinguish quark and lepton multiplets from Higgs multiplets.

Finally, larger symmetry groups have been considered. For example, $E(6)$ has a fundamental representation **27** which under $SO(10)$ transforms as a $[\mathbf{16} + \mathbf{10} + \mathbf{1}]$. The breaking pattern $E(6) \to SU(3)_C \times SU(3)_L \times SU(3)_R$ is also possible. With the additional permutation symmetry $Z(3)$ interchanging the three $SU(3)$s we obtain so-called "trinification" [6] with a universal gauge coupling. The latter breaking pattern has been used in phenomenological analyses of the heterotic string [7]. However, in larger symmetry groups, such as $E(6)$, $SU(6)$, etc., there are now many more states which have not been observed and must be removed from the effective low energy theory. In particular, three families of **27**s in $E(6)$ contain three Higgs type multiplets transforming as **10**s of $SO(10)$. This makes these larger symmetry groups unattractive starting points for model building.

16.1.3. *String Theory and Orbifold GUTs* :

Orbifold compactification of the heterotic string [8–10], and recent field theoretic constructions known as orbifold GUTs [11], contain grand unified symmetries realized in 5 and 6 dimensions. However, upon compactifying all but four of these extra dimensions, only the MSSM is recovered as a symmetry of the effective four dimensional field theory.[1] These theories can retain many of the nice features of four dimensional SUSY GUTs, such as charge quantization, gauge coupling unification and sometimes even Yukawa unification; while at the same time resolving some of the difficulties of 4d GUTs, in particular problems with unwieldy Higgs sectors necessary for spontaneously breaking the GUT symmetry, and problems with doublet-triplet Higgs splitting or rapid proton decay. We will comment further on the corrections to the four dimensional GUT picture due to orbifold GUTs in the following sections. Finally, recent progress has been made in finding MSSM-like theories in the string landscape. This success is made possible by incorporating SUSY GUTs at an intermediate step in the construction. For a brief discussion, see Sec. 16.1.

16.1.4. *Gauge coupling unification* :

The biggest paradox of grand unification is to understand how it is possible to have a universal gauge coupling g_G in a grand unified theory [GUT] and yet have three unequal gauge couplings at the weak scale with $g_3 > g > g'$. The solution is given in terms of the concept of an effective field theory [EFT] [18]. The GUT symmetry is spontaneously broken at the scale M_G and all particles not in the SM obtain mass of order M_G. When calculating Green's functions with external energies $E \gg M_G$, we can neglect the mass of all particles in the loop and hence all particles contribute to the renormalization group running of the universal gauge coupling. However, for $E \ll M_G$ one can consider an effective field theory

[1] Also, in recent years there has been a great deal of progress in constructing three and four family models in Type IIA string theory with intersecting D6 branes [12]. Although these models can incorporate SU(5) or a Pati-Salam symmetry group in four dimensions, they typically have problems with gauge coupling unification. In the former case this is due to charged exotics which affect the RG running, while in the latter case the $SU(4)\times SU(2)_L \times SU(2)_R$ symmetry never unifies. Local models, however, with D-branes at singularities have had some more success in obtaining gauge coupling unification [13]. Note, heterotic string theory models also exist whose low energy effective 4d field theory is a SUSY GUT [14]. These models have all the virtues and problems of 4d GUTs. Finally, many heterotic string models have been constructed with the standard model gauge symmetry in 4d and no intermediate GUT symmetry in less than 10d. Some minimal 3 family supersymmetric models have been constructed [15,16]. These theories may retain some of the symmetry relations of GUTs, however the unification scale would typically be the string scale, of order 5×10^{17} GeV, which is inconsistent with low energy data. A way out of this problem was discovered in the context of the strongly coupled heterotic string, defined in an effective 11 dimensions [17]. In this case the 4d Planck scale (which controls the value of the string scale) now unifies with the GUT scale.

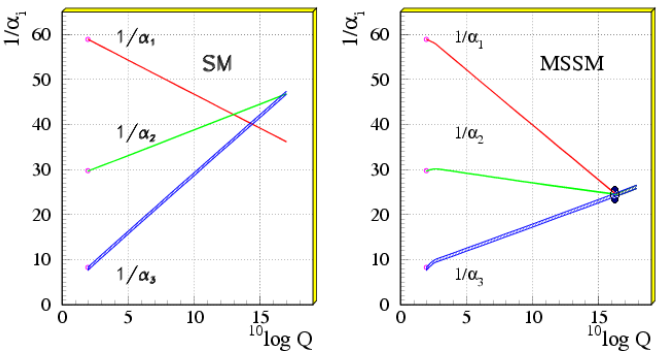

Figure 16.1: Gauge coupling unification in non-SUSY GUTs on the left vs. SUSY GUTs on the right using the LEP data as of 1991. Note, the difference in the running for SUSY is the inclusion of supersymmetric partners of standard model particles at scales of order a TeV (Fig. taken from Ref. 24). Given the present accurate measurements of the three low energy couplings, in particular $\alpha_s(M_Z)$, GUT scale threshold corrections are now needed to precisely fit the low energy data. The dark blob in the plot on the right represents these model dependent corrections.

including only the states with mass $< E \ll M_G$. The gauge symmetry of the EFT is $SU(3)_C \times SU(2)_L \times U(1)_Y$ and the three gauge couplings renormalize independently. The states of the EFT include only those of the SM; 12 gauge bosons, 3 families of quarks and leptons and one or more Higgs doublets. At M_G the two effective theories [the GUT itself is most likely the EFT of a more fundamental theory defined at a higher scale] must give identical results; hence we have the boundary conditions $g_3 = g_2 = g_1 \equiv g_G$ where at any scale $\mu < M_G$ we have $g_2 \equiv g$ and $g_1 = \sqrt{5/3}\, g'$. Then using two low energy couplings, such as $\alpha_s(M_Z)$, $\alpha_{EM}(M_Z)$, the two independent parameters α_G, M_G can be fixed. The third gauge coupling, $\sin^2\theta_W$ in this case, is then predicted. This was the procedure up until about 1991 [19,20]. Subsequently, the uncertainties in $\sin^2\theta_W$ were reduced ten fold. Since then, $\alpha_{EM}(M_Z)$, $\sin^2\theta_W$ have been used as input to predict α_G, M_G and $\alpha_s(M_Z)$ [21].

We emphasize that the above boundary condition is only valid when using one loop renormalization group [RG] running. With precision electroweak data, however, it is necessary to use two loop RG running. Hence one must include one loop threshold corrections to gauge coupling boundary conditions at both the weak and GUT scales. In this case it is always possible to define the GUT scale as the point where $\alpha_1(M_G) = \alpha_2(M_G) \equiv \tilde{\alpha}_G$ and $\alpha_3(M_G) = \tilde{\alpha}_G\,(1+\epsilon_3)$. The threshold correction ϵ_3 is a logarithmic function of all states with mass of order M_G and $\tilde{\alpha}_G = \alpha_G + \Delta$ where α_G is the GUT coupling constant above M_G and Δ is a one loop threshold correction. Note, the popular code "SOFTSUSY" [22] has defined the GUT scale in just this way. The value of ϵ_3 can be read off from the output data. To the extent that gauge coupling unification is perturbative, the GUT threshold corrections are small and calculable. This presumes that the GUT scale is sufficiently below the Planck scale or any other strong coupling extension of the GUT, such as a strongly coupled string theory.

Supersymmetric grand unified theories [SUSY GUTs] are an extension of non-SUSY GUTs [23]. The key difference between SUSY GUTs and non-SUSY GUTs is the low energy effective theory. The low energy effective field theory in a SUSY GUT is assumed to satisfy N=1 supersymmetry down to scales of order the weak scale in addition to the SM gauge symmetry. Hence the spectrum includes all the SM states plus their supersymmetric partners. It also includes one pair (or more) of Higgs doublets; one to give mass to up-type quarks and the other to down-type quarks and charged leptons. Two doublets with opposite hypercharge Y are also needed to cancel fermionic triangle anomalies. Finally, it is important to recognize that a low energy SUSY breaking scale (the scale at which the SUSY partners of SM particles obtain mass) is necessary to solve the gauge hierarchy problem.

Simple non-SUSY $SU(5)$ is ruled out; initially by the increased accuracy in the measurement of $\sin^2\theta_W$ and by early bounds on the proton lifetime (see below) [20]. However, by now LEP data [21] has conclusively shown that SUSY GUTs is the *new standard model*; by which we mean the theory used to guide the search for new physics beyond the present SM (see Fig. Fig. 16.1). SUSY extensions of the SM have the property that their effects decouple as the effective SUSY breaking scale is increased. Any theory beyond the SM must have this property simply because the SM works so well. However, the SUSY breaking scale cannot be increased with impunity, since this would reintroduce a gauge hierarchy problem. Unfortunately there is no clear-cut answer to the question, when is the SUSY breaking scale too high. A conservative bound would suggest that the third generation quarks and leptons must be lighter than about 1 TeV, in order that the one loop corrections to the Higgs mass from Yukawa interactions remains of order the Higgs mass bound itself.

At present gauge coupling unification within SUSY GUTs works extremely well. Exact unification at M_G, with two loop renormalization group running from M_G to M_Z, and one loop threshold corrections at the weak scale, fits to within 3 σ of the present precise low energy data. A small threshold correction at M_G ($\epsilon_3 \sim$ - 3% to - 4%) is sufficient to fit the low energy data precisely [25,26,27]. [2] This may be compared to non-SUSY GUTs where the fit misses by ~ 12 σ and a precise fit requires new weak scale states in incomplete GUT multiplets or multiple GUT breaking scales.[3]

Following the analysis of Ref. 27 let us try to understand the need for the GUT threshold correction and its order of magnitude. The renormalization group equations relate the low energy gauge coupling constants $\alpha_i(M_Z)$, $i = 1, 2, 3$ to the value of the unification scale Λ_U and the GUT coupling α_U by the expression

$$\frac{1}{\alpha_i(M_Z)} = \frac{1}{\alpha_U} + \frac{b_i}{2\pi}\log\left(\frac{\Lambda_U}{M_Z}\right) + \delta_i \qquad (16.1)$$

where Λ_U is the GUT scale evaluated at one loop and the threshold corrections, δ_i, are given by $\delta_i = \delta_i^{(2)} + \delta_i^{(l)} + \delta_i^{(g)}$ with $\delta_i^{(2)}$ representing two loop running effects, $\delta_i^{(l)}$ the light threshold corrections at the SUSY breaking scale and $\delta_i^{(g)} = \delta_i^{(h)} + \delta_i^{(b)}$ representing GUT scale threshold corrections. Note, in this analysis, the two loop RG running is treated on the same footing as weak and GUT scale threshold corrections. One then obtains the prediction

$$(\alpha_3(M_Z) - \alpha_3^{LO}(M_Z))/\alpha_3^{LO}(M_Z) = -\alpha_3^{LO}(M_Z)\ \delta_s \qquad (16.2)$$

where $\alpha_3^{LO}(M_Z)$ is the leading order one loop RG result and $\delta_s = \frac{1}{7}(5\delta_1 - 12\delta_2 + 7\delta_3)$ is the net threshold correction. [A similar formula applies at the GUT scale with the GUT threshold correction, ϵ_3, given by $\epsilon_3 = -\tilde{\alpha}_G\ \delta_s^{(g)}$.] Given the experimental inputs [31,32]:

$$\begin{aligned} \alpha_{em}^{-1}(M_Z) &= 127.916 \pm 0.015 \\ sin^2\theta_W(M_Z) &= 0.23116 \pm 0.00013 \\ \alpha_3(M_Z) &= 0.1184 \pm 0.0007 \end{aligned} \qquad (16.3)$$

and taking into account the light threshold corrections, assuming an ensemble of 10 SUSY spectra [27](corresponding to the Snowmass benchmark points), we have

$$\alpha_3^{LO}(M_Z) \approx 0.118 \qquad (16.4)$$

and

$$\begin{aligned} \delta_s^{(2)} &\approx -0.82 \\ \delta_s^{(l)} &\approx -0.50 + \frac{19}{28\pi}\log\frac{M_{SUSY}}{M_Z}. \end{aligned}$$

For $M_{SUSY} = 1$ TeV, we have $\delta_s^{(2)} + \delta_s^{(l)} \approx -0.80$. Since the one loop result $\alpha_3^{LO}(M_Z)$ is very close to the experimental value, we need $\delta_s \approx 0$ or equivalently, $\delta_s^{(g)} \approx 0.80$. This corresponds, at the GUT scale, to $\epsilon_3 \approx -3\%$. Note, this result depends implicitly on the assumption of universal soft SUSY breaking masses at the GUT scale, which directly affect the spectrum of SUSY particles at the weak scale. For example, if gaugino masses were not unified at M_G and, in particular, gluinos were lighter than winos at the weak scale, then it is possible that, due to weak scale threshold corrections, a much smaller or even slightly positive threshold correction at the GUT scale would be consistent with gauge coupling unification [34].

In four dimensional SUSY GUTs, the threshold correction ϵ_3 receives a positive contribution from Higgs doublets and triplets.[4] Thus a larger, negative contribution must come from the GUT breaking sector of the theory. This is certainly possible in specific SO(10) [35] or SU(5) [36] models, but it is clearly a significant constraint on the 4d GUT sector of the theory. In five or six dimensional orbifold GUTs, on the other hand, the "GUT scale" threshold correction comes from the Kaluza-Klein modes between the compactification scale, M_c, and the effective cutoff scale M_*.[5] Thus, in orbifold GUTs, gauge coupling unification at two loops is only consistent with the low energy data with a fixed value for M_c and M_*.[6] Typically, one finds $M_c < M_G = 3 \times 10^{16}$ GeV, where M_G is the 4d GUT scale. Since the grand unified gauge bosons, responsible for nucleon decay, get mass at the compactification scale, the result $M_c < M_G$ for orbifold GUTs has significant consequences for nucleon decay.

A few final comments are in order. We do not consider the scenario of split supersymmetry [39] in this review. In this scenario squarks and sleptons have mass at a scale $\tilde{m} \gg M_Z$, while gauginos and Higgsinos have mass of order the weak scale. Gauge coupling unification occurs at a scale of order 10^{16} GeV, *provided that the scale $\tilde{m}$ lies in the range* $10^3 - 10^{11}$ *GeV* [40]. A serious complaint concerning the split SUSY scenario is that it does not provide a solution to the gauge hierarchy problem. Moreover, it is only consistent with grand unification if it also postulates an "intermediate" scale, $\tilde{m}$, for scalar masses. In addition, it is in conflict with $b - \tau$ Yukawa unification, unless $\tan\beta$ is fine-tuned to be close to 1 [40]. [7]

[2] This result implicitly assumes universal GUT boundary conditions for soft SUSY breaking parameters at M_G. In the simplest case we have a universal gaugino mass $M_{1/2}$, a universal mass for squarks and sleptons m_{16} and a universal Higgs mass m_{10}, as motivated by $SO(10)$. In some cases, threshold corrections to gauge coupling unification can be exchanged for threshold corrections to soft SUSY parameters. See for example, Ref. 28 and references therein.

[3] Non-SUSY GUTs with a more complicated breaking pattern can still fit the data. For example, non-SUSY $SO(10) \to SU(4)_C \times SU(2)_L \times SU(2)_R \to SM$ with the second breaking scale of order an intermediate scale, determined by light neutrino masses using the see-saw mechanism, can fit the low energy data for gauge couplings [29] and at the same time survive nucleon decay bounds [30], discussed in the following section.

[4] Note, the Higgs contribution is given by $\epsilon_3 = \frac{3\tilde{\alpha}_G}{5\pi}\log|\frac{\tilde{M}_t\,\gamma}{M_G}|$ where $\tilde{M}_t$ is the effective color triplet Higgs mass (setting the scale for dimension 5 baryon and lepton number violating operators) and $\gamma = \lambda_b/\lambda_t$ at M_G. Since $\tilde{M}_t$ is necessarily greater than M_G, the Higgs contribution to ϵ_3 is positive.

[5] In string theory, the cutoff scale is the string scale.

[6] It is interesting to note that a ratio $M_*/M_c \sim 100$, needed for gauge coupling unification to work in orbifold GUTs is typically the maximum value for this ratio consistent with perturbativity [37]. In addition, in orbifold GUTs brane-localized gauge kinetic terms may destroy the successes of gauge coupling unification. However, for values of $M_*/M_c = M_*\pi R \gg 1$ the unified bulk gauge kinetic terms can dominate over the brane-localized terms [38].

[7] $b - \tau$ Yukawa unification only works for $\tilde{m} < 10^4$ for $\tan\beta \geq 1.5$. This is because the effective theory between the gaugino mass scale and $\tilde{m}$ includes only one Higgs doublet, as in the standard model. In this case, the large top quark Yukawa coupling tends to increase the ratio λ_b/λ_τ as one runs down in energy below $\tilde{m}$. This is opposite to what happens in MSSM where the large top quark Yukawa coupling decreases the ratio λ_b/λ_τ [41].

We have also neglected to discuss non-supersymmetric GUTs in four dimensions which still survive once one allows for several scales of GUT symmetry breaking [29]. Finally, it has been shown that non-supersymmetric GUTs in warped 5 dimensional orbifolds can be consistent with gauge coupling unification, assuming that the right-handed top quark and the Higgs doublets are composite-like objects with a compositeness scale of order a TeV [42]. However perturbative unification seems to fail.

16.1.5. ***Nucleon Decay*** :

Baryon number is necessarily violated in any GUT [43]. In $SU(5)$, nucleons decay via the exchange of gauge bosons with GUT scale masses, resulting in dimension 6 baryon number violating operators suppressed by $(1/M_G^2)$. The nucleon lifetime is calculable and given by $\tau_N \propto M_G^4/(\alpha_G^2\, m_p^5)$. The dominant decay mode of the proton (and the baryon violating decay mode of the neutron), via gauge exchange, is $p \to e^+\,\pi^0$ $(n \to e^+\,\pi^-)$. In any simple gauge symmetry, with one universal GUT coupling and scale $(\alpha_G,\ M_G)$, the nucleon lifetime from gauge exchange is calculable. Hence, the GUT scale may be directly observed via the extremely rare decay of the nucleon. Experimental searches for nucleon decay began with the Kolar Gold Mine, Homestake, Soudan, NUSEX, Frejus, HPW, and IMB detectors [19]. The present experimental bounds come from Super-Kamiokande and Soudan II. We discuss these results shortly. Non-SUSY GUTs are also ruled out by the non-observation of nucleon decay [20]. In SUSY GUTs, the GUT scale is of order 3×10^{16} GeV, as compared to the GUT scale in non-SUSY GUTs which is of order 10^{15} GeV. Hence the dimension 6 baryon violating operators are significantly suppressed in SUSY GUTs [23] with $\tau_p \sim 10^{34-38}$ yrs.

However, in SUSY GUTs there are additional sources for baryon number violation – dimension 4 and 5 operators [44]. Although our notation does not change, when discussing SUSY GUTs all fields are implicitly chiral superfields and the operators considered are the so-called F terms which contain two fermionic components and the rest scalars or products of scalars. Within the context of $SU(5)$ the dimension 4 and 5 operators have the form $(\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}}) \supset (u^c\ d^c\ d^c) + (Q\ L\ d^c) + (e^c\ L\ L)$ and $(\mathbf{10}\ \mathbf{10}\ \mathbf{10}\ \bar{\mathbf{5}}) \supset (Q\ Q\ Q\ L) + (u^c\ u^c\ d^c\ e^c) + B$ and L conserving terms, respectively. The dimension 4 operators are renormalizable with dimensionless couplings; similar to Yukawa couplings. On the other hand, the dimension 5 operators have a dimensionful coupling of order $(1/M_G)$.

The dimension 4 operators violate baryon number or lepton number, respectively, but not both. The nucleon lifetime is extremely short if both types of dimension 4 operators are present in the low energy theory. However both types can be eliminated by requiring R parity. In $SU(5)$ the Higgs doublets reside in a $\mathbf{5_H}$, $\bar{\mathbf{5}}_\mathbf{H}$ and R parity distinguishes the $\bar{\mathbf{5}}$ (quarks and leptons) from $\bar{\mathbf{5}}_\mathbf{H}$ (Higgs). R parity [45](or its cousin, family reflection symmetry (or *matter parity*) (see Dimopoulos and Georgi [23] and DRW [46]) takes $F \to -F$, $H \to H$ with $F = \{\mathbf{10},\ \bar{\mathbf{5}}\}$, $H = \{\bar{\mathbf{5}}_\mathbf{H},\ \mathbf{5_H}\}$. This forbids the dimension 4 operator $(\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}})$, but allows the Yukawa couplings of the form $(\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}}_\mathbf{H})$ and $(\mathbf{10}\ \mathbf{10}\ \mathbf{5_H})$. It also forbids the dimension 3, lepton number violating, operator $(\bar{\mathbf{5}}\ \mathbf{5_H}) \supset (L\ H_u)$ with a coefficient with dimensions of mass which, like the μ parameter, could be of order the weak scale and the dimension 5, baryon number violating, operator $(\mathbf{10}\ \mathbf{10}\ \mathbf{10}\ \bar{\mathbf{5}}_\mathbf{H}) \supset (Q\ Q\ Q\ H_d) + \cdots$.

Note, in the MSSM it is possible to retain R parity violating operators at low energy as long as they violate either baryon number or lepton number only but not both. Such schemes are natural if one assumes a low energy symmetry, such as lepton number, baryon number, baryon triality [47] or proton hexality [48]. However these symmetries cannot be embedded in a GUT. Thus, in a SUSY GUT, only R parity can prevent all the dimension three and four baryon and lepton number violating operators. This does not mean to say that R parity is guaranteed to be satisfied in any GUT. For example the authors of Refs. [51,52] use constrained matter content to selectively generate safe effective R parity violating operators in a GUT. For a review on R parity violating interactions, see [53]. In Ref. [52], the authors show how to obtain the effective R parity violating operator $O^{ijk} = (\bar{5}^j \cdot \bar{5}^k)_{\overline{15}} \cdot (10^i \cdot \Sigma)_{15}$ where Σ is an $SU(5)$ adjoint field and the subscripts $\overline{15}, 15$ indicate that the product of fields in parentheses have been projected into these $SU(5)$ directions. As a consequence the operator O^{ijk} is symmetric under interchange of the two $\bar{5}$ states, $O^{ijk} = O^{ikj}$, and out of $\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}}$ only the lepton number/R parity violating operator $QL\bar{D}$ survives.

Note also, R parity distinguishes Higgs multiplets from ordinary families. In $SU(5)$, Higgs and quark/lepton multiplets have identical quantum numbers; while in $E(6)$, Higgs and families are unified within the fundamental **27** representation. Only in SO(10) are Higgs and ordinary families distinguished by their gauge quantum numbers. Moreover the Z(4) center of SO(10) distinguishes **10**s from **16**s and can be associated with R parity [49].

Dimension 5 baryon number violating operators may be forbidden at tree level by symmetries in $SU(5)$, etc. These symmetries are typically broken however by the VEVs responsible for the color triplet Higgs masses. Consequently these dimension 5 operators are generically generated via color triplet Higgsino exchange. Hence, the color triplet partners of Higgs doublets must necessarily obtain mass of order the GUT scale. [It is also important to note that Planck or string scale physics may independently generate dimension 5 operators, even without a GUT. These contributions must be suppressed by some underlying symmetry; for example, the same flavor symmetry which may be responsible for hierarchical fermion Yukawa matrices.]

The dominant decay modes from dimension 5 operators are $p \to K^+\,\bar{\nu}$ $(n \to K^0\,\bar{\nu})$. This is due to a simple symmetry argument; the operators $(Q_i\ Q_j\ Q_k\ L_l)$, $(u_i^c\ u_j^c\ d_k^c\ e_l^c)$ (where $i,\ j,\ k,\ l = 1, 2, 3$ are family indices and color and weak indices are implicit) must be invariant under $SU(3)_C$ and $SU(2)_L$. As a result their color and weak doublet indices must be anti-symmetrized. However since these operators are given by bosonic superfields, they must be totally symmetric under interchange of all indices. Thus the first operator vanishes for $i = j = k$ and the second vanishes for $i = j$. Hence a second or third generation member must exist in the final state [46].

Recent Super-Kamiokande bounds on the proton lifetime severely constrain these dimension 6 and 5 operators with (172.8 kt-yr) of data they find $\tau_{(p\to e^+\pi^0)} > 1.0 \times 10^{34}$ yrs, $\tau_{(p\to K^+\bar{\nu})} > 3.3 \times 10^{33}$ yrs and $\tau_{(n\to e^+\pi^-)} > 2 \times 10^{33}$ yrs at (90% CL) [54]. These constraints are now sufficient to rule out minimal SUSY $SU(5)$ [55]. [8] Non-minimal Higgs sectors in $SU(5)$ or $SO(10)$ theories still survive [26,36]. The upper bound on the proton lifetime from these theories are approximately a factor of 10 above the experimental bounds. They are also being pushed to their theoretical limits. Hence if SUSY GUTs are correct, then nucleon decay must be seen soon.

Is there a way out of this conclusion? Orbifold GUTs and string theories, see Sec. 16.1, contain grand unified symmetries realized in higher dimensions. In the process of compactification and GUT symmetry breaking, color triplet Higgs states are removed (projected out of the massless sector of the theory). In addition, the same projections typically rearrange the quark and lepton states so that the massless states which survive emanate from different GUT multiplets. In these models, proton decay due to dimension 5 operators can be severely suppressed or eliminated completely. However, proton decay due to dimension 6 operators may be enhanced, since the gauge bosons mediating proton decay obtain mass at the compactification scale, M_c, which is typically less than the 4d GUT scale (see the discussion at the end of Sec. 16.1), or suppressed, if the states of one family come from different irreducible representations. Which effect dominates is a model dependent issue. In some complete 5d orbifold

[8] This conclusion relies on the mild assumption that the three-by-three matrices diagonalizing squark and slepton mass matrices are not so different from their fermionic partners. It has been shown that if this caveat is violated, then dimension five proton decay in minimal SUSY $SU(5)$ may not be ruled out [56]. This is however a very fine-tuned resolution of the problem. Another possible way out is to allow for a more complicated $SU(5)$ breaking Higgs sector in the otherwise minimal model [57]. I have also implicitly assumed a hierarchical structure for Yukawa matrices in this analysis. It is however possible to fine-tune a hierarchical structure for quarks and leptons which baffles the family structure. In this case it is possible to avoid the present constraints on minimal SUSY $SU(5)$, for example see [58].

GUT models [59,27] the lifetime for the decay $\tau(p \to e^+\pi^0)$ can be near the excluded bound of 1×10^{34} years with, however, large model dependent and/or theoretical uncertainties. In other cases, the modes $p \to K^+\bar{\nu}$ and $p \to K^0\mu^+$ may be dominant [27]. To summarize, in either 4d or orbifold string/field theories, nucleon decay remains a premier signature for SUSY GUTs. Moreover, the observation of nucleon decay may distinguish extra-dimensional orbifold GUTs from four dimensional ones.

As a final note, in orbifold GUTs or string theory new discrete symmetries consistent with SUSY GUTs can forbid all dimension 3 and 4 baryon [B] and lepton [L] number violating operators and even forbid the mu term and dimension 5 B and L violating operators to all orders in perturbation theory [50]. The mu term and dimension 5 B and L violating operators may then be generated, albeit sufficiently suppressed, via non-perturbative effects. The simplest example of this is a Z_4^R symmetry which is the unique discrete R symmetry consistent with SO(10) [50]. In this case, proton decay is completely dominated by dimension 6 operators.

Before concluding the topic of baryon number violation, consider the status of $\Delta B = 2$ neutron- anti-neutron oscillations. Generically the leading operator for this process is the dimension 9 six quark operator $G_{(\Delta B=2)}$ $(u^c\ d^c\ d^c\ u^c\ d^c\ d^c)$ with dimensionful coefficient $G_{(\Delta B=2)} \sim 1/M^5$. The present experimental bound $\tau_{n-\bar{n}} \geq 0.86 \times 10^8$ sec. at 90% CL [60] probes only up to the scale $M \leq 10^6$ GeV. For $M \sim M_G$, $n - \bar{n}$ oscillations appear to be unobservable for any GUT (for a recent discussion see [61]) .

16.1.6. *Yukawa coupling unification* :

16.1.6.1. *3rd generation, $b - \tau$ or $t - b - \tau$ unification:*

If quarks and leptons are two sides of the same coin, related by a new grand unified gauge symmetry, then that same symmetry relates the Yukawa couplings (and hence the masses) of quarks and leptons. In $SU(5)$, there are two independent renormalizable Yukawa interactions given by λ_t $(\mathbf{10\ 10\ 5_H}) + \lambda$ $(\mathbf{10\ \bar{5}\ \bar{5}_H})$. These contain the SM interactions λ_t $(\mathbf{Q\ u^c\ H_u}) + \lambda$ $(\mathbf{Q\ d^c\ H_d\ +\ e^c\ L\ H_d})$. Hence, at the GUT scale we have the tree level relation, $\lambda_b = \lambda_\tau \equiv \lambda$ [41]. In $SO(10)$ there is only one independent renormalizable Yukawa interaction given by λ $(\mathbf{16\ 16\ 10_H})$ which gives the tree level relation, $\lambda_t = \lambda_b = \lambda_\tau \equiv \lambda$ [62,63]. Note, in the discussion above we assume the minimal Higgs content with Higgs in $\mathbf{5}$, $\bar{\mathbf{5}}$ for $SU(5)$ and $\mathbf{10}$ for $SO(10)$. With Higgs in higher dimensional representations there are more possible Yukawa couplings [75,76,77].

In order to make contact with the data, one now renormalizes the top, bottom and τ Yukawa couplings, using two loop RG equations, from M_G to M_Z. One then obtains the running quark masses $m_t(M_Z) = \lambda_t(M_Z)\ v_u$, $m_b(M_Z) = \lambda_b(M_Z)\ v_d$ and $m_\tau(M_Z) = \lambda_\tau(M_Z)\ v_d$ where $< H_u^0 > \equiv v_u = \sin\beta\ v/\sqrt{2}$, $< H_d^0 > \equiv v_d = \cos\beta\ v/\sqrt{2}$, $v_u/v_d \equiv \tan\beta$ and $v \sim 246$ GeV is fixed by the Fermi constant, G_μ.

Including one loop threshold corrections at M_Z and additional RG running, one finds the top, bottom and τ pole masses. In SUSY, $b - \tau$ unification has two possible solutions with $\tan\beta \sim 1$ or $40 - 50$. The small $\tan\beta$ solution is now disfavored by the LEP limit, $\tan\beta > 2.4$ [64]. [9] The large $\tan\beta$ limit overlaps the $SO(10)$ symmetry relation.

When $\tan\beta$ is large there are significant weak scale threshold corrections to down quark and charged lepton masses from either gluino and/or chargino loops [66]. Yukawa unification (consistent with low energy data) is only possible in a restricted region of SUSY parameter space with important consequences for SUSY searches [67]. More recent analyses of Yukawa unification can be found in Refs. [68,69,70,71]. There seems to be at least four possible choices of soft SUSY breaking parameters which fit the data, possibly more. Each case then leads to a distinct sparticle spectrum and phenomenology for LHC and dark matter experiments. They correspond to:

- universal squark and slepton masses (m_{16}), universal A parameter (A_0) and gaugino masses ($M_{1/2}$), and non-universal Higgs masses ($m_{H_u},\ m_{H_d}$) with "just-so" splitting [67,68].
- a universal squark and slepton mass term for the first two families ($m_{16_{1,2}}$) which is larger than the universal scalar mass for the third family (m_{16_3}), universal A parameter (A_0) and gaugino masses ($M_{1/2}$) and universal Higgs mass term (m_{10}). However all scalar masses then receive a D-term contribution to their masses given by the $U(1)$ from $SO(10)$ which commutes with $SU(5)$. This is of the form

$$m_Q^2 = m_E^2 = m_U^2 = m_{16}^2 + M_D^2,$$
$$m_D^2 = m_L^2 = m_{16}^2 - 3M_D^2,$$
$$m_\nu^2 = m_{16}^2 + 5M_D^2,$$
$$m_{H_{u,d}}^2 = m_{10}^2 \mp 2M_D^2.$$

  This is the so-called "DR3 splitting" [69]. The R is associated with taking into account the renormalization group [RG] running of the right-handed neutrino from the GUT scale to the nominal value of its mass of order 10^{10-14} GeV, as indicated by light neutrino masses via the See-Saw mechanism. This RG running contributes to an additional splitting of the H_u and H_d masses [67].
- universal squark and slepton masses (m_0), split Higgs masses and non-universal gaugino masses satisfying ($M_1 = \frac{3}{5}M_2 + \frac{2}{5}M_3$), and $\mu, M_2 < 0$ [70], and
- universal squark and slepton mass term (m_{16}), A parameter (A_0), Higgs mass term (m_{10}). All scalar masses then receive a D-term contribution to their masses given by the $U(1)$ from $SO(10)$ which commutes with $SU(5)$, as above. Finally, non-universal gaugino masses satisfying ($M_3 : M_2 : M_1 = 2 : -3 : -1$) with $M_3 > 0$ and $\mu < 0$ [71].

16.1.6.2. *Three families:*

Simple Yukawa unification is not possible for the first two generations of quarks and leptons. Consider the $SU(5)$ GUT scale relation $\lambda_b = \lambda_\tau$. If extended to the first two generations one would have $\lambda_s = \lambda_\mu$, $\lambda_d = \lambda_e$ which gives $\lambda_s/\lambda_d = \lambda_\mu/\lambda_e$. The last relation is a renormalization group invariant and is thus satisfied at any scale. In particular, at the weak scale one obtains $m_s/m_d = m_\mu/m_e$ which is in serious disagreement with the data with $m_s/m_d \sim 20$ and $m_\mu/m_e \sim 200$. An elegant solution to this problem was given by Georgi and Jarlskog [72]. For a recent anaylsis in the context of supersymmetric GUTs, see Ref. [73]. Of course, a three family model must also give the observed CKM mixing in the quark sector. Note, although there are typically many more parameters in the GUT theory above M_G, it is possible to obtain effective low energy theories with many fewer parameters making strong predictions for quark and lepton masses.

Three family models which make significant predictions for low energy experiments have been constructed in the context of supersymmetric GUTs. It is important to note that grand unification alone is not sufficient to obtain predictive theories of fermion masses and mixing angles. Other ingredients are needed. In one approach additional global family symmetries are introduced (non-abelian family symmetries can significantly reduce the number of arbitrary parameters in the Yukawa matrices). These family symmetries constrain the set of effective higher dimensional fermion mass operators. In addition, sequential breaking of the family symmetry is correlated with the hierarchy of fermion masses. Three-family models exist which fit all the data, including neutrino masses and mixing [74]. In a completely separate approach for $SO(10)$ models, the Standard Model Higgs bosons are contained in the higher dimensional Higgs representations including the $\mathbf{10}$, $\overline{\mathbf{126}}$ and/or $\mathbf{120}$. Such theories have been shown to make predictions for neutrino masses and mixing angles [75–77]. A recent paper on this subject argues the necessity of split supersymmetry [78].

[9] However, this bound disappears if one takes $M_{SUSY} = 2$ TeV and $m_t = 180$ GeV [65]. This apparent loop hole is now inconsistent with the observed top quark mass.

16.1.7. ***Neutrino Masses*** :

Atmospheric and solar neutrino oscillations, along with long baseline accelerator and reactor experiments, require neutrino masses. Adding three "sterile" neutrinos ν^c with the Yukawa coupling λ_ν ($\nu^{\mathbf{c}}$ **L** $\mathbf{H_u}$), one easily obtains three massive Dirac neutrinos with mass $m_\nu = \lambda_\nu\ v_u$.[10] However in order to obtain a tau neutrino with mass of order 0.1 eV, one needs $\lambda_{\nu_\tau}/\lambda_\tau \leq 10^{-10}$. The see-saw mechanism, on the other hand, can naturally explain such small neutrino masses [79,80]. Since ν^c has no SM quantum numbers, there is no symmetry (other than global lepton number) which prevents the mass term $\frac{1}{2}\ \nu^c\ M\ \nu^c$. Moreover one might expect $M \sim M_G$. Heavy "sterile" neutrinos can be integrated out of the theory, defining an effective low energy theory with only light active Majorana neutrinos with the effective dimension 5 operator $\frac{1}{2}$ (**L** $\mathbf{H_u}$) $\lambda_\nu^T\ M^{-1}\ \lambda_\nu$ (**L** $\mathbf{H_u}$). This then leads to a 3×3 Majorana neutrino mass matrix $\mathbf{m} = m_\nu^T\ M^{-1}\ m_\nu$.

Atmospheric neutrino oscillations require neutrino masses with $\Delta m_\nu^2 \sim 3 \times 10^{-3}$ eV^2 with maximal mixing, in the simplest two neutrino scenario. With hierarchical neutrino masses $m_{\nu_\tau} = \sqrt{\Delta m_\nu^2} \sim 0.055$ eV. Moreover via the "see-saw" mechanism $m_{\nu_\tau} = m_t(m_t)^2/(3M)$. Hence one finds $M \sim 2 \times 10^{14}$ GeV; remarkably close to the GUT scale. Note we have related the neutrino Yukawa coupling to the top quark Yukawa coupling $\lambda_{\nu_\tau} = \lambda_t$ at M_G as given in $SO(10)$ or $SU(4) \times SU(2)_L \times SU(2)_R$. However at low energies they are no longer equal and we have estimated this RG effect by $\lambda_{\nu_\tau}(M_Z) \approx \lambda_t(M_Z)/\sqrt{3}$.

Neutrinos pose a special problem for SUSY GUTs. The question is why are the quark mixing angles in the CKM matrix small, while there are two large lepton mixing angles in the PMNS matrix. For a recent discussion of neutrino masses and mixing angles, see Refs. [81] and [82]. For SUSY GUT models which fit quark and lepton masses, see Ref. [74]. Finally, for a compilation of the range of SUSY GUT predictions for neutrino mixing, see [83].

16.1.8. ***Selected Topics*** :

16.1.8.1. *Magnetic Monopoles:*

In the broken phase of a GUT there are typically localized classical solutions carrying magnetic charge under an unbroken $U(1)$ symmetry [84]. These magnetic monopoles with mass of order M_G/α_G are produced during the GUT phase transition in the early universe. The flux of magnetic monopoles is experimentally found to be less than $\sim 10^{-16}$ cm^{-2} s^{-1} sr^{-1} [85]. Many more are however predicted, hence the GUT monopole problem. In fact, one of the original motivations for an inflationary universe is to solve the monopole problem by invoking an epoch of rapid inflation after the GUT phase transition [86]. This would have the effect of diluting the monopole density as long as the reheat temperature is sufficiently below M_G. Other possible solutions to the monopole problem include: sweeping them away by domain walls [87], U(1) electromagnetic symmetry breaking at high temperature [88] or GUT symmetry non-restoration [89]. Parenthetically, it was also shown that GUT monopoles can catalyze nucleon decay [90]. A significantly lower bound on the monopole flux can then be obtained by considering X-ray emission from radio pulsars due to monopole capture and the subsequent nucleon decay catalysis [91].

16.1.8.2. *Baryogenesis via Leptogenesis:*

Baryon number violating operators in $SU(5)$ or $SO(10)$ preserve the global symmetry $B - L$. Hence the value of the cosmological $B - L$ density is an initial condition of the theory and is typically assumed to be zero. On the other hand, anomalies of the electroweak symmetry violate $B + L$ while also preserving $B - L$. Hence thermal fluctations in the early universe, via so-called sphaleron processes, can drive $B + L$ to zero, washing out any net baryon number generated in the early universe at GUT temperatures.

One way out of this dilemma is to generate a net $B - L$ dynamically in the early universe. We have just seen that neutrino oscillations suggest a new scale of physics of order 10^{14} GeV. This scale is associated with heavy Majorana neutrinos with mass M. If in the early universe, the decay of the heavy neutrinos is out of equilibrium and violates both lepton number and CP, then a net lepton number may be generated. This lepton number will then be partially converted into baryon number via electroweak processes [92].

16.1.8.3. *GUT symmetry breaking:*

The grand unification symmetry is necessarily broken spontaneously. Scalar potentials (or superpotentials) exist whose vacua spontaneously break $SU(5)$ and $SO(10)$. These potentials are ad hoc (just like the Higgs potential in the SM) and therefore it is hoped that they may be replaced with better motivated sectors. Gauge coupling unification now tests GUT breaking sectors, since it is one of the two dominant corrections to the GUT threshold correction ϵ_3. The other dominant correction comes from the Higgs sector and doublet-triplet splitting. This latter contribution is always positive $\epsilon_3 \propto \ln(M_T/M_G)$ (where M_T is an effective color triplet Higgs mass), while the low energy data typically requires $\epsilon_3 < 0$. Hence the GUT breaking sector must provide a significant (of order -8%) contribution to ϵ_3 to be consistent with the Super-K bound on the proton lifetime [35,26,36,74].

In string theory (and GUTs in extra-dimensions), GUT breaking may occur due to boundary conditions in the compactified dimensions [8,11]. This is still ad hoc. The major benefit is that it does not require complicated GUT breaking sectors.

16.1.8.4. *Doublet-triplet splitting:*

The minimal supersymmetric standard model has a μ problem; why is the coefficient of the bilinear Higgs term in the superpotential μ ($\mathbf{H_u}$ $\mathbf{H_d}$) of order the weak scale when, since it violates no low energy symmetry, it could be as large as M_G. In a SUSY GUT, the μ problem is replaced by the problem of *doublet-triplet* splitting — giving mass of order M_G to the color triplet Higgs and mass μ to the Higgs doublets. Several mechanisms for natural doublet-triplet splitting have been suggested, such as the sliding singlet [93], missing partner or missing VEV [94], and pseudo-Nambu-Goldstone boson mechanisms. Particular examples of the missing partner mechanism for $SU(5)$ [36], the missing VEV mechanism for $SO(10)$ [74,26] and the pseudo-Nambu-Goldstone boson mechanism for $SU(6)$ [95] have been shown to be consistent with gauge coupling unification and proton decay. There are also several mechanisms for explaining why μ is of order the SUSY breaking scale [96]. Finally, for a recent review of the μ problem and some suggested solutions in SUSY GUTs and string theory, see Ref. [97,10,98,50] and references therein.

Once again, in string theory (and orbifold GUTs), the act of breaking the GUT symmetry via orbifolding projects certain states out of the theory. It has been shown that it is possible to remove the color triplet Higgs while retaining the Higgs doublets in this process. Hence the doublet-triplet splitting problem is finessed. As discussed earlier (see Sec. 16.1), this can have the effect of eliminating the contribution of dimension 5 operators to nucleon decay.

16.1.9. ***String theory*** :

String theory has made significant progress in locating the minimal supersymmetric standard model [MSSM] in the string landscape. Random searches for MSSM-like models have found some success, see for example Ref. 99. However, recently a solid leap forward has been made by imposing a supersymmetric GUT locally in the extra dimensions of the string. Many MSSM-like models have been found in $E(8) \times E(8)$ heterotic orbifold constructions [100–103] or more recently on smooth Calabi-Yau three-folds [104]. See also in F theory constructions [105–107]. There appear, however, to be some problems associated with large threshold corrections to gauge coupling unification in the F theory constructions which make use of a non-vanishing hypercharge field strength to break $SU(5)$ to $SU(3)_C \times SU(2)_L \times U(1)_Y$ [108]. Nevertheless, a SUSY GUT guarantees the correct particle content of the Standard Model and also allows for reasonable looking hierarchical Yukawa matrices. For a more detailed discussion, see [109].

[10] Note, these "sterile" neutrinos are quite naturally identified with the right-handed neutrinos necessarily contained in complete families of $SO(10)$ or Pati-Salam.

16.2. Conclusion

Grand unification of the strong and electroweak interactions requires that the three low energy gauge couplings unify (up to small threshold corrections) at a unique scale, M_G. Supersymmetric grand unified theories provide, by far, the most predictive and economical framework allowing for perturbative unification.

The three pillars of SUSY GUTs are:

- gauge coupling unification at $M_G \sim 3 \times 10^{16}$ GeV;
- low-energy supersymmetry [with a large SUSY desert], and
- nucleon decay.

The first prediction has already been verified (see Fig. Fig. 16.1). Perhaps the next two will soon appear. Whether or not Yukawa couplings unify is more model dependent. Nevertheless, the "digital" 16 dimensional representation of quarks and leptons in $SO(10)$ is very compelling and may yet lead to an understanding of fermion masses and mixing angles.

In any event, the experimental verification of the first three pillars of SUSY GUTs would forever change our view of Nature. Moreover, the concomitant evidence for a vast SUSY desert would expose a huge lever arm for discovery. For then it would become clear that experiments probing the TeV scale could reveal physics at the GUT scale and perhaps beyond. Of course, some questions will still remain: Why do we have three families of quarks and leptons? How is the grand unified symmetry and possible family symmetries chosen by Nature? At what scale might stringy physics become relevant? Etc.

17. HEAVY-QUARK AND SOFT-COLLINEAR EFFECTIVE THEORY

Updated September 2013 by C.W. Bauer (LBNL) and M. Neubert (U. Mainz).

17.1. Effective Field Theories

Quantum field theories represent the most precise computational tool for describing physics at the highest energies. One of their characteristic features is that they almost inevitably involve multiple length scales. When trying to determine the value of an observable, quantum field theory demands that all possible virtual states and hence all particles be included in the calculation. Since these particles have widely different masses, the final prediction is sensitive to many scales. This fact represents a formidable challenge from a practical point of view. No realistic quantum field theories can be solved exactly, so that one has to resort to approximation schemes; these, however, are typically most straightforward when only a single scale is involved at a time.

Effective field theories (EFTs) provide a general theoretical framework to deal with the multi-scale problems of realistic quantum field theories. This framework aims to reduce such problems to a combination of separate and simpler single-scale problems; simultaneously, however, it provides an organization scheme whereby the other scales are not omitted but allowed to play their role in a separate step of the computation. The philosophy and basic principles of this approach are very generic, and correspondingly EFTs represent a widely used method in many different areas of high-energy physics, from the low-energy scales of atomic and nuclear physics to the high-energy scales of (partly yet unknown) elementary particle physics. EFTs can play a role both within analytic perturbative computations and in the context of non-perturbative numerical simulations; see [1–3] for some early references. One of the simplest applications of EFTs to particle physics is to describe an underlying theory that is only probed at energy scales $E < \Lambda$. Any particle with mass $m > \Lambda$ cannot be produced as a real state and therefore only leads to short-distance virtual effects. Thus, one can construct an effective theory in which the quantum fluctuations of such heavy particles are "integrated out" from the generating functional integral for Green functions. This results in a simpler theory containing only those degrees of freedom that are relevant to the energy scales under consideration. In fact, the standard model of particle physics itself is widely viewed as an EFT of some yet unknown, more fundamental theory.

The development of any effective theory starts by identifying the degrees of freedom that are relevant to describe the physics at a given energy (or length) scale, and constructing the Lagrangian describing the interactions among these fields. Short-distance quantum fluctuations associated with much smaller length scales are absorbed into the coefficients of the various operators in the effective theory. These coefficients are determined in a matching procedure, by requiring that the EFT reproduces the matrix elements of the full theory up to power corrections. In many cases the effective Lagrangian exhibits enhanced symmetries compared with the fundamental theory, allowing for simple and sometimes striking predictions relating different observables.

17.2. Heavy-Quark Effective Theory

Heavy-quark systems provide prime examples for applications of the EFT technology, because the hierarchy $m_Q \gg \Lambda_{\rm QCD}$ (with $Q = b, c$) provides a natural separation of scales. Physics at the scale m_Q is of a short-distance nature and can be treated perturbatively, while for heavy-quark systems there is always also some hadronic physics governed by the confinement scale $\Lambda_{\rm QCD}$ of the strong interaction. Being able to separate the short-distance and long-distance effects associated with these two scales is crucial for any quantitative description in heavy-quark physics. For instance, if the long-distance hadronic matrix elements are obtained from lattice QCD, then it is necessary to analytically compute the short-distance effects, which come from short-wavelength modes that do not fit on present-day lattices. In many other instances, the long-distance hadronic physics can be encoded in a small number of universal parameters.

17.2.1. ***General idea & derivation of the effective Lagrangian*** : The simplest effective theory for heavy-quark systems is the heavy-quark effective theory (HQET) [4–7] (see [8,9] for detailed discussions). It provides a simplified description of the soft interactions of a single heavy quark interacting with soft, light partons. This includes the interactions that bind the heavy quark with other light partons inside heavy mesons (B, B^*, ...) and baryons (Λ_b, Σ_b, ...).

A softly interacting heavy quark is nearly on-shell. Its momentum may be decomposed as $p_Q = m_Q v + k$, where v is the 4-velocity of the hadron containing the heavy quark. The "residual momentum" k results from the soft interactions of the heavy quark with its environment and satisfies $v \cdot k \sim \Lambda_{\rm QCD}$ and $k^2 \sim \Lambda^2_{\rm QCD}$, which in the rest frame of the heavy hadron reduces to $k^\mu \sim \Lambda_{\rm QCD}$. In the limit $m_Q \gg \Lambda_{\rm QCD}$, the soft interactions do not change the 4-velocity of the heavy quark, which is therefore a conserved quantum number that is often used as a label on the effective heavy-quark fields. A nearly on-shell Dirac spinor has two large and two small components. We define

$$Q(x) = e^{-im_Q v\cdot x}\,[h_v(x) + H_v(x)]\,, \tag{17.1}$$

where

$$h_v(x) = e^{im_Q v\cdot x}\,\frac{1+\not v}{2}\,Q(x)\,, \qquad H_v(x) = e^{im_Q v\cdot x}\,\frac{1-\not v}{2}\,Q(x) \tag{17.2}$$

are the large ("upper") and small ("lower") components of the spinor field, respectively. The extraction of the phase factor in Eq. (17.1) implies that the fields h_v and H_v carry the residual momentum k. These fields obey the projection relations $\not v\, h_v = h_v$ and $\not v\, H_v = -H_v$. Inserting these definitions into the Dirac Lagrangian yields

$$\mathcal{L}_Q = \bar h_v\, iv\cdot D\, h_v + \bar H_v(-iv\cdot D - 2m_Q)H_v + \bar h_v\, i\vec{\not D}\, H_v + \bar H_v\, i\vec{\not D}\, h_v\,, \tag{17.3}$$

where $i\vec D^\mu = iD^\mu - v^\mu\, iv\cdot D$ is the "spatial" covariant derivative (note that $v^\mu = (1,\vec 0)$ in the heavy-hadron rest frame). The interpretation of Eq. (17.3) is that the field h_v describes a massless fermion, while H_v describes a heavy fermion with mass $2m_Q$. Both modes are coupled to each other via the last two terms. Soft interactions cannot excite the heavy fermion, so one can integrate it out from the generating functional of the theory. The light field which remains describes the fluctuations of the heavy quark about its mass shell. Solving the classical equation of motion for the field H_v yields

$$H_v = \frac{1}{2m_Q + iv\cdot D}\, i\vec{\not D}\, h_v = \frac{1}{2m_Q}\sum_{n=0}^{\infty}\left(-\frac{iv\cdot D}{2m_Q}\right)^n i\vec{\not D}\, h_v\,, \tag{17.4}$$

which implies $H_v = O(\Lambda_{\rm QCD}/m_Q)\, h_v$, provided the residual momenta are small. The effective Lagrangian of HQET is obtained by inserting this result into Eq. (17.3). At subleading order in $1/m_Q$ one finds

$$\mathcal{L}_{\rm HQET} = \bar h_v\, iv\cdot D_s\, h_v + \frac{1}{2m_Q}$$

$$\left[\bar h_v (i\vec D_s)^2 h_v + C_{\rm mag}(\mu)\,\frac{g}{2}\,\bar h_v\,\sigma_{\mu\nu}\,G_s^{\mu\nu} h_v\right] + \ldots\,. \tag{17.5}$$

Note that the covariant derivative $iD_s^\mu = i\partial^\mu + gA_s^\mu$ and the field strength $G_s^{\mu\nu}$ contain only the soft gluon field. Hard gluons have been integrated out, and their effects are contained in the Wilson coefficients of the various operators in the effective Lagrangian. From the leading operator one derives the Feynman rules of HQET. The new operators entering at subleading order are referred to as the "kinetic energy" and "chromo-magnetic interaction". The kinetic-energy operator corresponds to the first correction term in the Taylor expansion of the relativistic energy $E = m_Q + \vec p^{\,2}/2m_Q + \ldots$. Lorentz invariance, which is encoded as a reparametrization invariance of the effective Lagrangian [10], ensures that its Wilson coefficient is not renormalized ($C_{\rm kin} \equiv 1$). The coefficient of the chromo-magnetic operator, $C_{\rm mag}(\mu) = 1 + \mathcal{O}(\alpha_s)$, receives corrections starting at one-loop order.

17.2.2. ***Spin-flavor symmetry and applications in spectroscopy*** : The leading term in the HQET Lagrangian exhibits a global spin-flavor symmetry. Its physical meaning is that, in the infinite mass limit, the properties of hadronic systems containing a single heavy quark are insensitive to the spin and flavor of the heavy quark [11,12]. The spin symmetry results from the fact that there appear no Dirac matrices in the leading term of the effective Lagrangian in Eq. (17.5), implying that the interactions of the heavy quark with soft gluons leave its spin unchanged. The flavor symmetry arises since the mass of the heavy quark does not appear at leading order. When there are n_Q heavy quarks moving at the same velocity, one can simply extend Eq. (17.5) by summing over n_Q identical terms for heavy-quark fields h_v^i. The result is invariant under rotations in flavor space. When combined with the spin symmetry, the symmetry group becomes promoted to SU($2n_Q$). The flavor symmetry is broken by the operators arising at order $1/m_Q$ and higher. However, at first order only the chromo-magnetic operator breaks the spin symmetry.

The spin-flavor symmetry leads to many interesting relations between the properties of hadrons containing a heavy quark. The most direct consequences concern the spectroscopy of such states [13]. In the heavy-quark limit, the spin of the heavy quark and the total angular momentum j of the light degrees of freedom are separately conserved by the strong interactions. Because of heavy-quark symmetry, the dynamics is independent of the spin and mass of the heavy quark. Hadronic states can thus be classified by the quantum numbers (flavor, spin, parity, etc.) of the light degrees of freedom. The spin symmetry predicts that, for fixed $j \neq 0$, there is a doublet of degenerate states with total spin $J = j \pm 1/2$. The flavor symmetry relates the properties of states with different heavy-quark flavor. In the case of the ground-state mesons containing a heavy quark, the light degrees of freedom have the quantum numbers of an antiquark, and the degenerate states are the pseudoscalar ($J = 0$) and vector ($J = 1$) mesons. Their masses are split by hyperfine corrections of order $1/m_Q$, such that one expects $m_{B^*} - m_B = O(1/m_b)$ and $m_{D^*} - m_D = O(1/m_c)$. It follows that $m_{B^*}^2 - m_B^2 \simeq m_{D^*}^2 - m_D^2 \simeq$ const. The data are compatible with this result: $m_{B^*}^2 - m_B^2 \simeq 0.49\,\mathrm{GeV}^2$ and $m_{D^*}^2 - m_D^2 \simeq 0.55\,\mathrm{GeV}^2$.

17.2.3. ***Weak decay form factors*** : Of particular interest are the relations between the weak decay form factors of heavy mesons, which parametrize hadronic matrix elements of currents between two meson states containing a heavy quark. These relations have been derived by Isgur and Wise [12], generalizing ideas developed by Nussinov and Wetzel [14] and Voloshin and Shifman [15]. For the purpose of this discussion, it is convenient to work with a mass-independent normalization of meson states and use velocity rather than momentum variables.

Consider the elastic scattering of a pseudoscalar meson, $P(v) \to P(v')$, induced by an external vector current coupled to the heavy quark contained in P, which acts as a color source moving with the meson's velocity v. The action of the current is to replace instantaneously the color source by one moving at velocity v'. Soft gluons need to be exchanged in order to rearrange the light degrees of freedom and build the final state meson moving at velocity v'. This rearrangement leads to a form factor suppression. The important observation is that, in the $m_Q \to \infty$ limit, the form factor can only depend on the Lorentz boost $\gamma = v \cdot v'$ connecting the rest frames of the initial and final-state mesons (as long as $\gamma = \mathcal{O}(1)$). In the effective theory the hadronic matrix element describing the scattering process can be written as

$$\langle P(v')|\,\bar h_{v'}\gamma^\mu h_v\,|P(v)\rangle = \xi(v\cdot v')(v+v')^\mu, \tag{17.6}$$

with a form factor $\xi(v \cdot v')$ that is real and independent of m_Q. By flavor symmetry, the form factor remains identical when one replaces the heavy quark Q in one of the meson states by a heavy quark Q' of a different flavor, thereby turning P into another pseudoscalar meson P'. At the same time, the current becomes a flavor-changing vector current. This universal form factor is called the Isgur-Wise function [12]. For equal velocities the vector current $J^\mu = \bar h_v \gamma^\mu h_v$ is conserved in the effective theory, irrespective of the flavor of the heavy quarks. The corresponding conserved charges are the generators of the flavor symmetry. It follows that the Isgur-Wise function is normalized at the point of equal velocities: $\xi(1) = 1$. Since the recoil energy of the daughter meson P' in the rest frame of the parent meson P is $E_{\rm recoil} = m_{P'}\,(v \cdot v' - 1)$, the point $v \cdot v' = 1$ is referred to as the zero-recoil limit. The heavy-quark spin symmetry leads to additional relations among weak decay form factors. It can be used to relate matrix elements involving vector mesons to those involving pseudoscalar mesons, which once again can be described completely in terms of the universal Isgur-Wise function.

These form factor relations imposed by heavy-quark symmetry describe the semileptonic decay processes $\bar B \to D\,\ell\,\bar\nu$ and $\bar B \to D^*\ell\,\bar\nu$ in the limit of infinite heavy-quark masses. They are model-independent consequences of QCD. The known normalization of the Isgur-Wise function at zero recoil can be used to obtain a model-independent measurement of the element $|V_{cb}|$ of the Cabibbo-Kobayashi-Maskawa (CKM) matrix. The semileptonic decay $\bar B \to D^*\ell\,\bar\nu$ is ideally suited for this purpose [16]. Experimentally, this is a particularly clean mode, since the reconstruction of the D^* meson mass provides a powerful rejection against background. From the theoretical point of view, it is ideal since the decay rate at zero recoil is protected by Luke's theorem against first-order power corrections in $1/m_Q$ [17]. This is described in more detail in Section 12 of the PDG Book.

17.2.4. ***Decoupling transformation*** : At leading order in $1/m_Q$, the couplings of soft gluons to heavy quarks in the effective Lagrangian Eq. (17.5) can be removed by the field redefinition $h_v(x) = Y_v(x)\,h_v^{(0)}(x)$, where $Y_v(x)$ denotes a time-like soft Wilson line along the direction of v, extending from minus infinity to the point x. In terms of the new fields, the HQET Lagrangian becomes

$$\mathcal{L}_{\rm HQET} = \bar h_v^{(0)} iv\cdot\partial\, h_v^{(0)} + O(1/m_Q). \tag{17.7}$$

At leading order in $1/m_Q$, this is a free theory as far as the strong interactions of heavy quarks are concerned. However, the theory is nevertheless non-trivial in the presence of external sources. Consider, e.g., the case of a weak-interaction heavy-quark current

$$\bar h_{v'}\gamma^\mu(1-\gamma_5)h_v = \bar h_{v'}^{(0)}\gamma^\mu(1-\gamma_5)\,Y_{v'}^\dagger Y_v\,h_v^{(0)}, \tag{17.8}$$

where v and v' are the velocities of the heavy mesons containing the heavy quarks. Unless the two velocities are equal, corresponding to the zero-recoil limit discussed above, the object $Y_{v'}^\dagger Y_v$ is non-trivial, and hence the soft gluons do not decouple from the heavy quarks inside the current operator. One may interpret $Y_{v'}^\dagger Y_v$ as a Wilson loop with a cusp at the point x, where the two paths parallel to the different velocity vectors intersect. The presence of the cusp leads to non-trivial ultra-violet behavior (for $v \neq v'$), which is described by a cusp anomalous dimension $\Gamma_c(v \cdot v')$ that was calculated at two-loop order in Ref. 18. It coincides with the velocity-dependent anomalous dimension of heavy-quark currents, which was introduced in the context of HQET in [19]. The interpretation of heavy quarks as Wilson lines is a useful tool, which was put forward in some of the very first papers on the subject, e.g. Ref. 4. This technology will be useful in the study of the interactions of heavy quarks with collinear degrees of freedom discussed later in this review.

17.2.5. ***Heavy-quark expansion for inclusive decays*** : The theoretical description of inclusive decays of hadrons containing a heavy quark exploits two observations [20–24]: bound-state effects related to the initial state can be calculated using the heavy-quark expansion, and the fact that the final state consists of a sum over many hadronic channels eliminates the sensitivity to the properties of individual final-state hadrons. The second feature rests on the hypothesis of quark-hadron duality, i.e. the assumption that decay rates are calculable in QCD after a smearing procedure has been applied [25]. In semileptonic decays, the integration over the lepton spectrum provides a smearing over the invariant hadronic mass of the final state (global duality). For nonleptonic decays, where the total hadronic mass is fixed, the summation over many hadronic final states provides an averaging (local duality). Since global duality is a much weaker assumption, the theoretical control of inclusive semileptonic decays is on much firmer footing.

Using the optical theorem, the inclusive decay width of a hadron H_b containing a b quark can be written in the form

$$\Gamma(H_b) = \frac{1}{M_{H_b}} \,\mathrm{Im}\,\langle H_b|\, i \int \mathrm{d}^4x\, T\,\{\mathcal{H}_{\rm eff}(x), \mathcal{H}_{\rm eff}(0)\}\,|H_b\rangle\,. \qquad (17.9)$$

The effective weak Hamiltonian for b-quark decays consists of dimension-6 four-fermion operators and dipole operators [26]. It follows that the leading contributions to the inclusive decay rate in Eq. (17.9) arise from two-loop diagrams. Because of the large mass of the b quark, the momenta flowing through the internal propagators are large. It is thus possible to construct an operator-product expansion (OPE) for the time-ordered product in Eq. (17.9), in which it is represented as a series of local operators containing two b-quark fields. The operator with the lowest dimension is $\bar{b}b$. The next non-trivial operator has dimension 5 and contains the gluon field. It arises from diagrams in which a soft gluon is emitted from one of the internal lines of the two-loop diagrams. From dimension 6 on, an increasing number of operators contribute. For dimensional reasons, the matrix elements of higher-dimensional operators are suppressed by inverse powers of the b-quark mass. Thus, the total inclusive decay rate of a hadron H_b can be written as [21,22]

$$\Gamma(H_b) = \frac{G_F^2 m_b^5 |V_{cb}|^2}{192\pi^3} \times$$

$$\left\{ c_3\,\langle \bar{b}b\rangle + c_5\,\frac{\langle \bar{b}\, g\sigma_{\mu\nu}G^{\mu\nu} b\rangle}{m_b^2} + \sum_n c_6^{(n)}\,\frac{\langle O_6^{(n)}\rangle}{m_b^3} + \ldots \right\}, \qquad (17.10)$$

where the prefactor arises from the loop integrations, c_i are calculable coefficient functions, and $\langle O_i\rangle$ are the (normalized) forward matrix elements between H_b states. These matrix elements can be systematically expanded in powers of $1/m_b$ using HQET. The result is [21,22]

$$\langle \bar{b}b\rangle = 1 - \frac{\mu_\pi^2(H_b) - \mu_G^2(H_b)}{2m_b^2} + \ldots, \qquad \frac{\langle \bar{b}\, g\sigma_{\mu\nu}G^{\mu\nu} b\rangle}{m_b^2} = \frac{2\mu_G^2(H_b)}{m_b^2} + \ldots, \qquad (17.11)$$

where $\mu_\pi^2(H_b)$ and $\mu_G^2(H_b)$ are the matrix elements of the heavy-quark kinetic energy and chromomagnetic interaction inside the hadron H_b, respectively [27]. For the ground-state heavy mesons and baryons, one has $\mu_G^2(B) = 3(m_{B^*}^2 - m_B^2)/4 \simeq 0.36\,\mathrm{GeV}^2$ and $\mu_G^2(\Lambda_b) = 0$.

From the fully inclusive width Eq. (17.10) one can obtain the lifetime of a heavy hadron via $\tau(H_b) = 1/\Gamma(H_b)$. Due to the universality of the leading term in the heavy-quark expansion, lifetime ratios such as $\tau(B^-)/\tau(\bar{B}^0)$, $\tau(\bar{B}_s^0)/\tau(\bar{B}^0)$, and $\tau(\Lambda_b)/\tau(\bar{B}^0)$ are particularly sensitive to the hadronic parameters determining the power corrections in the expansion. In order to understand these ratios theoretically, it is necessary to include phase-space enhanced power corrections of order $(\Lambda_{\rm QCD}/m_b)^3$ as well as short-distance perturbative effects in the calculation [28,29].

A formula analogous to Eq. (17.10) can be derived for differential distributions in specific inclusive decay processes, assuming that these distributions are integrated over sufficiently large portions of phase space to ensure quark-hadron duality. Important examples are the distributions in lepton energy ($d\Gamma/dE_\ell$) or lepton invariant mass ($d\Gamma/dq^2$), as well as moments of the invariant hadronic mass distribution in the semileptonic processes $\bar{B} \to X_u\,\ell\,\bar{\nu}$ and $\bar{B} \to X_c\,\ell\,\bar{\nu}$, as well as the photon energy spectrum ($d\Gamma/dE_\gamma$) in the radiative process $\bar{B} \to X_s\gamma$. While the latter process is primarily used to test the Standard Model and search for hints of new physics, an analysis of decay distributions in the semileptonic processes can be employed to perform a global fit determining the CKM matrix elements $|V_{ub}|$ and $|V_{cb}|$ along with heavy-quark parameters such as the masses m_b, m_c and the hadronic parameters $\mu_\pi^2(B)$, $\mu_G^2(B)$. These determinations provide some of the most accurate values for these parameters [30].

17.2.6. ***Shape functions and non-local power corrections*** : In certain regions of phase space, in which the hadronic final state in an inclusive heavy-hadron decay is made up of light energetic partons, the local OPE for inclusive decays must be replaced by a more complicated expansion involving hadronic matrix elements of non-local light-ray operators [31,32]. Prominent examples are the radiative decay $\bar{B} \to X_s\gamma$ for large photon energy E_γ near $m_B/2$, and the semileptonic decay $\bar{B} \to X_u\,\ell\,\bar{\nu}$ at large lepton energy or small hadronic invariant mass. In these cases, the differential decay rates at leading order in the heavy-quark expansion can be written in the factorized form $d\Gamma \propto H\,J \otimes S$ [33], where the hard function H and the jet function J are calculable in perturbation theory. The characteristic scales for these functions are set by m_b and $(m_b\Lambda_{\rm QCD})^{1/2}$, respectively. The soft function

$$S(\omega) = \int \frac{dt}{4\pi}\, e^{-i\omega t}\,\langle \bar{B}(v)|\,\bar{h}_v(tn) Y_n(tn) Y_n^\dagger(0) h_v(0)|\bar{B}(v)\rangle \qquad (17.12)$$

is a genuinely non-perturbative object, called the shape function [31,32]. Here Y_n are soft Wilson lines along a light-like direction n aligned with the momentum of the hadronic final-state jet. The jet function and the shape function share a common variable $\omega \sim \Lambda_{\rm QCD}$, and the symbol $\otimes$ denotes a convolution in this variable.

While the hard function is different for the two decays, the jet and soft functions are identical at leading order in $\Lambda_{\rm QCD}/m_Q$. This is particularly important for the soft function. It is this shape function that introduces non-perturbative physics into the theoretical predictions for the cross sections of $\bar{B} \to X_s\gamma$ and $\bar{B} \to X_u\,\ell\bar{\nu}$ in the regions of experimental interest. The fact that both decays depend on the same non-perturbative function makes it possible to determine this non-perturbative information from the measured shape of the photon spectrum in $\bar{B} \to X_s\gamma$, allowing for a better understanding of the process used to determine the CKM element $|V_{ub}|$. In higher orders of the heavy-quark expansion, an increasing number of subleading jet and soft functions is required to describe the decay distributions [34]. These have been analyzed in detail at order $1/m_b$ [35–37]. In the case of $\bar{B} \to X_s\gamma$, some of these non-local effects survive in the total decay rate and give rise to irreducible hadronic uncertainties [38]. The technology for deriving the corresponding factorization theorems relies on SCET, which is discussed below.

17.3. Soft-Collinear Effective Theory

As discussed in the previous section, soft gluons that bind a heavy quark inside a heavy meson cannot change the virtuality of that heavy quark by a significant amount. The ratio of $\Lambda_{\rm QCD}/m_Q$ provided the expansion parameter in HQET, which is a small parameter since $m_Q \gg \Lambda_{\rm QCD}$. This obviously does not work when considering light quarks. However, if the energy Q of the quarks is large, the ratio $\Lambda_{\rm QCD}/Q$ provides a small parameter which can be used to construct an effective theory. One major difference to HQET is that light energetic quarks cannot only emit soft gluons, but they can also emit collinear gluons (an energetic gluon in the same direction as the original quark), without parametrically changing their virtuality. Thus, to fully reproduce the long-distance physics of energetic quarks requires that one includes their interactions with both soft and collinear particles. The resulting effective theory is therefore called soft-collinear effective theory (SCET) [39–41].

A single energetic particle can always be boosted to a frame where all momentum components have similar size, in which case there is no small expansion parameter. Thus the presence of energetic particles must refer to a reference frame defined by external kinematics. SCET has a wide range of applications, with examples being the production of energetic, light states in the decay of a heavy particle in its rest frame, the production of energetic jets in collider environments, and the scattering of energetic particles off a target at rest. In this brief review we will outline the main features of this effective theory and mention a few selected applications.

17.3.1. ***General idea of the expansion*** : Consider a quark with energy Q and virtuality $m \ll Q$, moving along the direction $\vec{n}$. It is convenient to parameterize the momentum p_n of this particle in terms of its light-cone components, defined by $(p_n^-, p_n^+, p_n^\perp) = (\bar{n}\cdot p_n, n\cdot p_n, p_n^\perp)$, where $n^\mu = (1,\vec{n})$ and $\bar{n}^\mu = (1,-\vec{n})$ are light-like 4-vectors, and $n\cdot p_\perp = \bar{n}\cdot p_\perp = 0$. A subscript n has been added to the momentum to identify it as a collinear particle in direction n (more precisely, a particle with energy much larger than its virtuality moving along a direction $\vec{n}$). In terms of these light-cone components, the virtuality satisfies $m^2 = p_n^+ p_n^- + p_n^{\perp 2}$. The individual components of the momentum satisfy

$$(p_n^-, p_n^+, p_n^\perp) \sim (Q, m^2/Q, m) \equiv Q(1,\lambda^2,\lambda), \tag{17.13}$$

where $\lambda = m/Q$ is the expansion parameter of SCET. The virtuality of such an energetic particle remains parametrically unchanged if it interacts with energetic particles in the same direction n, or with soft particles with momentum scaling as

$$(p_s^-, p_s^+, p_s^\perp) \sim Q(\lambda^2,\lambda^2,\lambda^2). \tag{17.14}$$

It is the interactions of collinear and soft degrees of freedom that give rise to the long-distance physics. SCET, which is constructed to reproduce this long-distance dynamics, is therefore an effective theory describing the interactions of collinear and soft particles.

The above power counting treats the soft momentum to be of order m^2/Q, where m denotes the invariant mass of a collinear system. If this mass is of order $\Lambda_{\rm QCD}$, as would be the case for a single energetic hadron, this power counting is no longer applicable, since $\Lambda_{\rm QCD}$ provides a natural cutoff to QCD and the soft momentum cannot be below this scale. To describe such systems requires a modified version of SCET, called $\rm SCET_{II}$, in which the scaling of the soft modes is $Q(\lambda,\lambda,\lambda)$. In this review we will focus mostly on SCET with the scaling discussed before, which is sometimes called $\rm SCET_I$. We will briefly comment on factorization theorems derived in the context of $\rm SCET_{II}$ in Section 17.3.7.

17.3.2. ***Leading-order Lagrangian*** : The derivation of the SCET Lagrangian follows similar steps as the derivation of the HQET Lagrangian in Section 17.2.1, but care needs to be taken to properly account for the interactions of collinear fields with one another. We begin by deriving the Lagrangian for a theory containing only a single collinear sector. We are interested in the interactions of fermion fields $q_n(x)$ with gluon fields $A_n(x)$, which have collinear momentum in the same light-like direction n. Similar to HQET, one can separate the full QCD field into two components, $q_n(x) = \psi_n(x) + \Xi_n(x)$, where (with $n\cdot\bar{n} = 2$)

$$\psi_n(x) = \frac{\not{n}\bar{\not{n}}}{4}\, q_n(x)\,, \qquad \Xi_n(x) = \frac{\bar{\not{n}}\not{n}}{4}\, q_n(x).$$

In terms of these fields, the massless QCD Lagrangian is

$$\begin{aligned}\mathcal{L}_n = {}& \bar\psi_n(x)\frac{\bar{\not{n}}}{2}\, in\cdot D_n\, \psi_n(x) + \bar\Xi_n(x)\frac{\not{n}}{2}\, i\bar{n}\cdot D_n\, \Xi_n(x) \\ & + \bar\psi_n(x) i\not{D}_n^\perp\, \Xi_n(x) + \bar\Xi_n(x) i\not{D}_n^\perp\, \psi_n(x),\end{aligned} \tag{17.15}$$

where we have defined the transverse derivative $D_n^{\perp\mu} = D_n^\mu - \frac{n^\mu}{2}\bar{n}\cdot D_n - \frac{\bar{n}^\mu}{2} n\cdot D_n$. Since $\bar{n}\cdot p_n \gg \Lambda_{\rm QCD}$ the degrees of freedom described by Ξ_n are far off shell. This is similar to the situation with the field H_v in Eq. (17.3). Ξ_n can therefore be eliminated using its equation of motion. Inserting this back into Eq. (17.15), one finds

$$\mathcal{L}_n = \bar\psi_n(x)\left[in\cdot D_n + i\not{D}_n^\perp \frac{1}{i\bar{n}\cdot D_n} i\not{D}_n^\perp\right]\frac{\bar{\not{n}}}{2}\,\psi_n(x). \tag{17.16}$$

While this Lagrangian leads to the correct Feynman rules of SCET, there is one feature that warrants extra discussion. In contrast to the Lagrangian of HQET given in Eq. (17.5), where the derivative scales like the residual momentum k of the heavy quark, the derivatives in Eq. (17.16) pick up both the large momentum components of order Q and $Q\lambda$, as well as the residual momentum of order $Q\lambda^2$. One can separate the large and residual momentum components using a procedure similar to the HQET case. Separating the collinear momentum into a "label" and a residual component, $p^\mu = P^\mu + k^\mu$, and performing a phase redefinition on the collinear fields $\psi_n(x) = e^{iP\cdot x}\,\xi_n(x)$, derivatives acting on the fields $\xi_n(x)$ now only pick out the residual momentum. Since the label momentum in SCET is not conserved as in HQET, one defines a label operator $\mathcal{P}^\mu$ acting as $\mathcal{P}^\mu\xi_n(x) = P^\mu\xi_n(x)$ [40], as well as a corresponding covariant label operator $i\mathcal{D}_n^\mu = \mathcal{P}^\mu + gA_n(x)$.

The final step to complete the Lagrangian of SCET is to include the interactions of collinear fields with soft fields. At leading power, these interactions can be included by adding the soft gluons to the covariant derivatives, while preserving the power counting. This leads to the final SCET Lagrangian [40–42]

$$\mathcal{L}_n = \bar\xi_n(x)\left[in\cdot D_n + gn\cdot A_s + i\not{\mathcal{P}}_n^\perp \frac{1}{i\bar{n}\cdot\mathcal{D}_n} i\not{\mathcal{P}}_n^\perp\right]\frac{\bar{\not{n}}}{2}\,\xi_n(x) + \ldots, \tag{17.17}$$

where the ellipses represent higher-order interactions between soft and collinear particles. The Lagrangian describing collinear fields in different light-like directions is simply given by the sum of the Lagrangians for each direction n separately, i.e. $\mathcal{L} = \sum_n \mathcal{L}_n$. The soft gluons are the same in each individual Lagrangian. An alternative way to understand the separation between large and small momentum components is to derive the Lagrangian of SCET in position space. In this case no label operators are required to describe interactions in SCET, and the dependence on short-distance effects is contained in non-localities at short distances [43]. An important difference between SCET and HQET is that the SCET Lagrangian is not corrected by short distance fluctuations. The physical reason is that in the construction described above no high-momentum modes are integrated out (since no large invariants can be formed out of soft and collinear momenta). Such hard modes arise when different collinear sectors are coupled via some external current (e.g. in jet production at e^+e^- or hadron colliders), or when collinear particles are produced in the rest frame of a decaying heavy object (such as in B decays). Short-distance effects are then incorporated in the Wilson coefficients of the external source operators.

17.3.3. ***Collinear gauge invariance and Wilson lines*** : An important aspect of SCET is the gauge structure of the theory. Because the effective field operators in SCET describe modes with certain momentum scalings, the effective Lagrangian respects only residual gauge symmetries. One of them satisfies the collinear scaling

$$(\bar{n}\cdot\partial_n, n\cdot\partial_n, \partial_n^\perp)\, U_n(x) \sim Q(1,\lambda^2,\lambda)\, U_n(x), \tag{17.18}$$

and one the soft scaling

$$(\bar{n}\cdot\partial_n, n\cdot\partial_n, \partial_n^\perp)\, U_s(x) \sim Q(\lambda^2,\lambda^2,\lambda^2)\, U_s(x). \tag{17.19}$$

The fact that collinear fields in different directions do not transform under the same gauge transformations implies that each collinear sector, containing particles with large momenta along a certain direction, has to be separately gauge invariant. This requires the introduction of collinear Wilson lines [40]

$$W_n(x) = P\exp\left[-ig\int_{-\infty}^0 ds\, \bar{n}\cdot A_n(s\bar{n}+x)\right], \tag{17.20}$$

which transform under collinear gauge transformations according to $W_n \to U_n W_n$. Thus, the combination $\chi_n \equiv W_n^\dagger\,\psi_n$ is gauge invariant. In a similar manner, one can define the gauge-invariant gluon field $B_n^\mu = g^{-1} W_n^\dagger\, iD_n^\mu W_n$ [44]. Operators in SCET are typically constructed from such gauge-invariant collinear fields.

17.3.4. ***Decoupling of soft gluons*** : Soft gluons in SCET couple to collinear quarks only through the term $\bar{\xi}_n\, gn\cdot A_s\, \dfrac{\bar{n}\!\!\!/}{2}\,\xi_n$ in the effective Lagrangian in Eq. (17.17). This coupling is similar to the coupling of soft gluons to heavy quarks in HQET, and soft gluons in SCET can thus be decoupled from collinear fields, in analogy to the discussion in Section 17.2.4. Written in terms of the redefined fields

$$\psi_n(x) = Y_n(x)\psi_n^{(0)}(x)\,, \qquad A_n(x) = Y_n(x)A_n^{(0)}(x)Y_n^\dagger(x), \quad (17.21)$$

the soft gluons decouple from the SCET Lagrangian [41]. This fact greatly facilitates proofs of factorization theorems in SCET.

17.3.5. ***Factorization Theorems*** : One of the important applications of SCET is to understand how to factorize cross sections involving energetic particles in different directions into simpler pieces that can either be calculated perturbatively or determined from data. Factorization theorems have been around for much longer than SCET. For a review on the subject, see [45]. However, the effective theory allows for a conceptually simpler understanding of certain classes of factorization theorems [46], since most simplifications happen already at the level of the Lagrangian. The discussion in this section is valid to leading order in the power counting of the effective theory.

As discussed in the previous section, the Lagrangian of SCET does not involve any couplings between collinear degrees of freedom in different light-like directions, or between soft and collinear degrees of freedom after the field redefinition Eq. (17.21) has been performed. An operator describing the scattering and production of collinear partons at short distances can thus be written as (omitting color indices for simplicity)

$$\langle O(x)\rangle \simeq C_O(\mu)\left\langle \mathcal{C}_{n_a}^{(0)}(x)\mathcal{C}_{n_b}^{(0)}(x)\mathcal{C}_{n_1}^{(0)}(x)\ldots\mathcal{C}_{n_N}^{(0)}(x)\times \right.$$
$$\left. [\mathcal{Y}_{n_a}\mathcal{Y}_{n_b}\mathcal{Y}_{n_1}\ldots\mathcal{Y}_{n_N}](x)\right\rangle_\mu . \quad (17.22)$$

Here $\mathcal{C}_n(x)$ denotes a gauge-invariant combination of collinear fields (either quark or gluon fields) in the direction n, and the matching coefficient accounting for short-distance effects is denoted by C_O. The soft Wilson lines can either be in a color triplet or color octet representation, and are collectively denoted by $\mathcal{Y}_n$. Both the matrix elements and the coefficient C_O depend on the renormalization scale μ.

Having defined the operator mediating a given process, one can calculate the cross section by squaring the operator, taking the forward matrix element and integrating over the phase space of all final-state particles. The absence of interactions between collinear degrees of freedom moving along different directions or soft degrees of freedom implies that the forward matrix element of the operator can be factorized as

$$\begin{aligned}\left\langle \text{in}\left|O(x)O^\dagger(0)\right|\text{in}\right\rangle &= \left\langle \text{in}_a\left|\mathcal{C}_{n_a}(x)\mathcal{C}_{n_a}^\dagger(0)\right|\text{in}_a\right\rangle\left\langle \text{in}_b\left|\mathcal{C}_{n_b}(x)\mathcal{C}_{n_b}^\dagger(0)\right|\text{in}_b\right\rangle \\ &\times\left\langle 0\left|\mathcal{C}_{n_1}(x)\mathcal{C}_{n_1}^\dagger(0)\right|0\right\rangle\cdots\left\langle 0\left|\mathcal{C}_{n_N}(x)\mathcal{C}_{n_N}^\dagger(0)\right|0\right\rangle \\ &\times\left\langle 0\left|[\mathcal{Y}_{n_a}\ldots\mathcal{Y}_{n_N}](x)[\mathcal{Y}_{n_a}\ldots\mathcal{Y}_{n_N}]^\dagger(0)\right|0\right\rangle . \end{aligned} \quad (17.23)$$

Thus, the matrix element required for the differential cross section has factorized into a product of simpler structures, each of which can be evaluated separately.

For many applications the matrix elements of incoming collinear fields are non-perturbative objects given in terms of the well-known parton distribution functions, while the matrix elements of outgoing collinear fields are determined by perturbatively calculable jet functions $J_i(\mu)$. Finally, the vacuum matrix element of the soft Wilson lines defines a so-called soft function, commonly denoted by $S(\mu)$. The shared dependence on x in the above equation implies that in momentum space the various components of the factorization theorem are convoluted with one another. Deriving this convolution requires a careful treatment of the phase-space integration, in particular treating the large and residual components of each momentum appropriately.

Putting all information together, the differential cross section can be written as

$$\mathrm{d}\sigma \sim H(\mu)\otimes\left[f_{p_1/P}(\mu)f_{p_2/P}(\mu)\right]\otimes[J_1(\mu)\ldots J_N(\mu)]\otimes S(\mu). \quad (17.24)$$

The hard coefficient is equal to the square of the matching coefficient, $H(\mu) = |C_O(\mu)|^2$. It should be mentioned that the most difficult part of traditional factorization proofs involves showing that so-called Glauber gluons do not spoil the above factorization theorem [47]. This question has not yet been fully addressed in the context of SCET.

17.3.6. ***Resummation of large logarithms*** : SCET can be used to sum the large logarithmic terms that arise in perturbative calculations to all orders in the strong coupling constant α_s. In general, perturbation theory will generate a logarithmic dependence on any ratio of scales r in a problem, and for processes that involve initial or final states with energy much in excess of their mass, there are two powers of logarithms for every power of α_s. Thus, for widely separated scales these large logarithms can spoil the convergence of fixed-order perturbation theory. One thus needs to reorganize the expansion in such a way that $\alpha_s L = \mathcal{O}(1)$ is kept fixed, with $L = \ln r$. More precisely, a proper resummation requires summing logarithms of the form $\alpha_s^n L^m$ with $m \le n+1$ in the logarithm of a cross section, by writing $\ln\sigma \sim Lg_0(\alpha_s L) + g_1(\alpha_s L) + \alpha_s g_2(\alpha_s L) + \ldots$, with functions $g_n(x)$ that need to be determined.

The important ingredient in achieving this resummation is the fact that SCET factorizes a given cross section into simpler pieces, as discussed in the previous section. Each of the ingredients of the factorization theorem depends on a single physical scale, and the only dependence on that scale can arise through logarithms of its ratio with the renormalization scale μ. Thus, for each of the components in the factorization theorem one can choose a renormalization scale μ for which the large logarithmic terms are absent.

Of course, the factorization formula requires a common renormalization scale μ in all its components, and one therefore has to use the renormalization group (RG) to evolve the various component functions from their preferred scale to the common scale μ. For example, for the hard coefficient $H(\mu)$, the RG equation can be written as

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}H(\mu) = \gamma_H(\mu)H(\mu). \quad (17.25)$$

In general, the anomalous dimension is of the form $\gamma_H(\mu) = c_H\,\Gamma_{\text{cusp}}(\alpha_s)\log(Q/\mu) + \gamma(\alpha_s)$, where c_H is a process-dependent coefficient and Γ_{cusp} denotes the so-called cusp anomalous dimension [18,48]. The non-cusp part of the anomalous dimension γ is again process dependent. The presence of a logarithm of the hard scale Q in the anomalous dimension is characteristic of Sudakov problems and arises since the perturbative series contains double logarithms of scale ratios. The anomalous dimension γ_H is known at two-loop order for arbitrary n-parton amplitudes containing massless or massive external partons [49–52]. Solving the RG equation yields

$$H(\mu) = U_H(\mu,\mu_h)H(\mu_h)\,, \quad (17.26)$$

which can be used to write the hard function at a scale $\mu_h \sim Q$, where its perturbative expression does not contain any large logarithms, in terms of the common renormalization scale μ. The RG evolution factor $U_H(\mu,\mu_h)$ sums logarithms of the form μ/μ_h. By calculating the anomalous dimension $\gamma_H(\mu)$ to higher orders in perturbation theory, one can resum more logarithms in the evolution kernel. The RG equations for the jet and soft functions are more complicated, since they involve convolutions over the relevant momentum variables.

17.3.7. ***Factorization and resummation in*** $\mathrm{SCET_{II}}$:

The effective theory $\mathrm{SCET_{II}}$ contains collinear and soft particles with momenta scaling as $(p_n^-, p_n^+, p_n^\perp) \sim Q(1,\lambda^2,\lambda)$ and $(p_s^-, p_s^+, p_s^\perp) \sim Q(\lambda,\lambda,\lambda)$. They have the same small virtuality ($p_n^2 \sim p_s^2 \sim Q^2\lambda^2$) but differ in their rapidities. An important class of observables, for which this scaling is relevant, contains cross sections for processes in which the transverse momenta of particles are contrained by external kinematics. The prime example are the transverse-momentum

distributions of electroweak gauge bosons or Higgs bosons produced at hadron colliders. The parton transverse momenta are constrained by the fact that their vector sum must be equal and opposite to the transverse momentum q_T of the boson. Standard RG evolution in the effective theory controls the logarithms arising from the fact that the virtualities of the collinear and soft modes are much smaller than the hard scale Q in the process (the boson mass). However, additional large logarithms arise since the rapidities of collinear and soft modes are parametrically different, such that $e^{y_c - y_s} \sim 1/\lambda$. These logarithms need to be factorized in the cross section and resummed by other means.

Two equivalent approaches exist for how to deal with the additional rapidity logarithms. In the first approach, they are interpreted as a consequence of a "collinear anomaly" of the effective theory $\mathrm{SCET_{II}}$, resulting from the fact that a classical rescaling symmetry of the effective Lagrangian is broken by quantum effects [53]. The extra large logarithms can be resummed by means of simple differential equations, which typically state that (in an appropriate space) the logarithm of the cross section contains only a single logarithm of $\lambda \sim q_T/Q$, to all orders in perturbation theory. An alternative approach to resum the rapidity logarithms uses the "rapidity renormalization group", in which the relevant differential equations are obtained by considering a new type of scale variation in a parameter ν, which separates the phase space for collinear and soft particles along a hyperbola in the (p_-, p_+) plane [54]. In contrast to the standard RG, there is no physical coupling constant involved in the ν evolution, since the different contributions live at the same virtuality.

$\mathrm{SCET_{II}}$ also plays an important role in the study of factorization for nonleptonic and radiative decays of B mesons such as $\bar{B} \to \pi\pi$ and $\bar{B} \to K^*\gamma$, for which the virtualities of energetic (collinear) finals-state particles are of order $\Lambda_{\rm QCD}$, which is also the scale for the soft light degrees of freedom contained in the initial-state B meson.

17.3.8. ***Applications*** : Most of the applications of SCET are either in flavor physics, where the decay of a heavy B meson can give rise to energetic light partons, or in collider physics, where the presence of jets naturally leads to collimated sets of energetic particles. For several of these applications alternative approaches existed before the invention of SCET, but the effective theory has opened up alternative ways to understand the physics of these processes. There are, however, many examples for which SCET has allowed new insights that were not available or possible without the effective theory. In particular, it has provided a field-theoretic basis for the QCD factorization approach to exclusive, non-leptonic decays of B mesons [55]. Using SCET methods, proofs of factorization were derived for the color-allowed decay $\bar{B}^0 \to D^+\pi^-$ [56], the color-suppressed decay $\bar{B}^0 \to D^0\pi^0$ [57], and the radiative decay $\bar{B} \to K^*\gamma$ [58]. Further examples are factorization theorems and the resummation of endpoint logarithms for quarkonia production [59], factorization theorems for cross sections defined through jet algorithms [60], the resummation of large logarithmic terms for the thrust [61] and jet broadening [62] distributions in e^+e^- annihilation beyond NLL order, the development of new factorizable observables to veto extra jets [63], all-orders factorization theorems for processes containing electroweak Sudakov logarithms [64], as well as the resummation of threshold (soft gluon) logarithms for several important processes at hadron colliders [65–67]. Recently, there has been a lot of activity describing p_T based resummation at hadron colliders. Examples the transverse-momentum distributions of electroweak gauge bosons and Higgs bosons [53] and the resummation of jet-veto cross sections [68–70]. An active research area is the understanding of non-global logarithms arising in hadron collider processes with jets [71,72]. SCET-based fixed-order calculations has helped to shed light on the nature of these logarithms [73,74].

We now describe one of these applications in more detail. Event-shape distributions, in particular the thrust distribution, have been measured to high accuracy at LEP [75]. Comparing these data to precise theoretical predictions allows for a determination of the strong coupling constant α_s. For small values of $\tau \equiv 1 - T$, the distribution can be factorized into the form [76,77]

$$\frac{1}{Q\sigma_0}\frac{\mathrm{d}\sigma}{\mathrm{d}\tau} = H(\mu) \int \mathrm{d}s \int \mathrm{d}k\, J(s,\mu)\, S(Q\tau - s/Q - k, \mu). \qquad (17.27)$$

Here Q denotes the center-of-mass energy of the collision, σ_0 is the total hadronic cross section, and H, J and S are the hard, jet and soft functions in SCET. Large logarithms of the form $(\alpha_s^n \ln^{2n-1}\tau)/\tau$ become important and have to be resummed. Furthermore, for $\tau \sim \Lambda_{\rm QCD}/Q$ non-perturbative effects in the soft function become important. Using SCET the resummation of these large logarithms has been performed to $\mathrm{N^3LL}$ [61], which is two orders beyond what was previously available. The factorization in the effective theory has also allowed one to include the non-perturbative physics through a shape function, in analogy with the B-physics case discussed in Section 17.2.6. The known perturbative effects for large values of τ can be included by matching the SCET result to the known two-loop spectrum [78,79]. Comparing the predicted to the measured thrust distribution allows for a precise determination of the strong coupling constant α_s [80].

17.4. Open issues and perspectives

HQET has successfully passed many experimental tests, and there are not too many open questions that still need to be addressed. One issue that has not been derived from first principles is quark-hadron duality. The validity of global duality (at energies even lower than those relevant in B decays) has been tested experimentally using high-precision data on semileptonic B decays and on hadronic τ decays, and there has been good agreement between theory and data. However, assigning a theoretical uncertainty to possible duality violations is difficult. Another known issue is the that the measured value of the CKM element $|V_{cb}|$ is different depending of whether one uses inclusive or exclusive B decays to derive it (see the relevant section in the Particle Data Book). Both measurements rely on the heavy-quark limit, and the uncertainties quoted include the effects from power corrections arising from the finite b-quark mass.

SCET, on the other hand, is still an active field of research, and there are several open questions that need to be answered. There are still some open issues in how to properly formulate $\mathrm{SCET_{II}}$, which are under active investigation. They include the treatment of endpoint singularities of convolution integrals and double counting between overlapping momentum regions. This is important, for example, to describe exclusive decays of B mesons into light, energetic mesons. Glauber gluons are known to affect factorization theorems, but how to properly include them in SCET is still an open question.

18. LATTICE QUANTUM CHROMODYNAMICS

Updated September 2013 by S. Hashimoto (KEK), J. Laiho (Syracuse University), and S.R. Sharpe (University of Washington).

18.1. Lattice regularization of QCD

Gauge theories form the building blocks of the Standard Model. While the SU(2) and U(1) parts have weak couplings and can be studied accurately with perturbative methods, the SU(3) component—QCD—is only amenable to a perturbative treatment at high energies. The growth of the coupling constant in the infrared—the flip-side of asymptotic freedom—requires the use of non-perturbative methods to determine the low energy properties of QCD. Lattice gauge theory, proposed by K. Wilson in 1974 [1], provides such a method, for it gives a non-perturbative definition of vector-like gauge field theories like QCD. In lattice regularized QCD—commonly called lattice QCD or LQCD—Euclidean space-time is discretized, usually on a hypercubic lattice with lattice spacing a, with quark fields placed on sites and gauge fields on the links between sites. The lattice spacing plays the role of the ultraviolet regulator, rendering the quantum field theory finite. The continuum theory is recovered by taking the limit of vanishing lattice spacing, which can be reached by tuning the bare coupling constant to zero according to the renormalization group.

Unlike dimensional regularization, which is commonly used in continuum QCD calculations, the definition of LQCD does not rely on the perturbative expansion. Indeed, LQCD allows non-perturbative calculations by numerical evaluation of the path integral that defines the theory.

Practical LQCD calculations are limited by the availability of computational resources and the efficiency of algorithms. Because of this, LQCD results come with both statistical and systematic errors, the former arising from the use of Monte-Carlo integration, the latter, for example, from the use of non-zero values of a. There are also different ways in which the QCD action can be discretized, and all must give consistent results in the continuum limit, $a \to 0$. It is the purpose of this review to provide an outline of the methods of LQCD, with particular focus on applications to particle physics, and an overview of the various sources of error. This should allow the reader to better understand the LQCD results that are presented in other sections for a variety of quantities (quark masses, the hadron spectrum and several electroweak matrix elements). For more extensive explanations the reader should consult the available textbooks or lecture notes, the most up-to-date of which are Refs. [2–4].

18.1.1. *Gauge invariance, gluon fields and the gluon action* :

A key feature of the lattice formulation of QCD is that it preserves gauge invariance. This is in contrast to perturbative calculations, where gauge fixing is an essential step. The preservation of gauge invariance leads to considerable simplifications, e.g. restricting the form of operators that can mix under renormalization.

The gauge transformations of lattice quark fields are just as in the continuum: $q(x) \longrightarrow V(x)q(x)$ and $\bar{q}(x) \longrightarrow \bar{q}(x)V^\dagger(x)$, with $V(x)$ an arbitrary element of SU(3). The only difference is that the Euclidean space-time positions x are restricted to lie on the sites of the lattice, i.e. $x = a(n_1, n_2, n_3, n_4)$ for a hypercubic lattice, with the n_j being integers. Quark bilinears involving different lattice points can be made gauge invariant by introducing the gluon field $U_\mu(x)$. For example, for adjacent points the bilinear is $\bar{q}(x)U_\mu(x)q(x+a\hat{\mu})$, with $\hat{\mu}$ the unit vector in the μ'th direction. (This form is used in the construction of the lattice covariant derivative.) The gluon field (or "gauge link") is an element of the group, SU(3), in contrast to the continuum field A_μ which takes values in the Lie algebra. The bilinear is invariant if U_μ transforms as $U_\mu(x) \to V(x)U_\mu(x)V^\dagger(x+a\hat{\mu})$. The lattice gluon field is naturally associated with the link joining x and $x+a\hat{\mu}$, and corresponds in the continuum to a Wilson line connecting these two points, $P\exp(i\int_x^{x+a\hat{\mu}} dx_\mu A_\mu^{\rm cont}(x))$ (where P indicates a path-ordered integral, and the superscript on A_μ indicates that it is a continuum field). The trace of a product of the $U_\mu(x)$ around any closed loop is easily seen to be gauge invariant and is the lattice version of a Wilson loop.

The simplest possible gauge action, usually called the Wilson gauge action, is given by the product of gauge links around elementary plaquettes:

$$S_g = \beta \sum_{x,\mu,\nu} [1 - \frac{1}{3}{\rm ReTr}[U_\mu(x)U_\nu(x+a\hat{\mu})U_\mu^\dagger(x+a\hat{\nu})U_\nu^\dagger(x)]] \,. \quad (18.1)$$

For small a, assuming that the fields are slowly varying, one can expand the action in powers of a using $U_\mu(x) = \exp(iaA_\mu(x))$. Keeping only the leading non-vanishing term, and replacing the sum with an integral, one finds the continuum form,

$$S_g \longrightarrow \int d^4x \frac{1}{4g_{\rm lat}^2}{\rm Tr}[F_{\mu\nu}^2(x)] \,, \qquad (F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu]) \quad (18.2)$$

as long as one chooses $\beta = 6/g_{\rm lat}^2$ for the lattice coupling. In this expression, $g_{\rm lat}$ is the bare coupling constant in the lattice scheme, which can be related (by combining continuum and lattice perturbation theory) to a more conventional coupling constant such as that in the $\overline{\rm MS}$ scheme (see Sec. 18.3.4 below).

In practice, the lattice spacing a is non-zero, leading to discretization errors. In particular, the lattice breaks Euclidean rotational invariance (which is the Euclidean version of Lorentz invariance) down to a discrete hypercubic subgroup. One wants to reduce discretization errors as much as possible. A very useful tool for understanding and then reducing discretization errors is the Symanzik effective action: the interactions of quarks and gluons with momenta low compared to the lattice cutoff ($|p| \ll 1/a$) are described by a continuum action consisting of the standard continuum terms (e.g. the gauge action given in Eq. (18.2)) augmented by higher dimensional operators suppressed by powers of a [5]. For the Wilson lattice gauge action, the leading corrections come in at $\mathcal{O}(a^2)$. They take the form $\sum_j a^2 c_j O_6^{(j)}$, with the sum running over all dimension-six operators $O_6^{(j)}$ allowed by the *lattice* symmetries, and c_j unknown coefficients. Some of these operators violate Euclidean invariance, and all of them lead to discretization errors of the form $a^2\Lambda^2$, where Λ is a typical momentum scale for the quantity being calculated. These errors can, however, be reduced by adding corresponding operators to the lattice action and tuning their coefficients to eliminate the dimension-six operators in the effective action to a given order in perturbation theory or even non-perturbatively. This is the idea of the Symanzik improvement program [5]. In the case of the gauge action, one adds Wilson loops involving six gauge links (as opposed to the four links needed for the original plaquette action, Eq. (18.1)) to define the $\mathcal{O}(a^2)$ improved (or "Symanzik") action [6]. In practical implementations, the improvement is either at tree-level (so that residual errors are proportional to $\alpha_s a^2$, where the coupling is evaluated at a scale $\sim 1/a$), or at one loop order (errors proportional to $\alpha_s^2 a^2$). Another popular choice is motivated by studies of renormalization group (RG) flow. It has the same terms as the $\mathcal{O}(a^2)$ improved action but with different coefficients, and is called the RG-improved or "Iwasaki" action [7].

18.1.2. *Lattice fermions* :

Discretizing the fermion action turns out to involve subtle issues, and the range of actions being used is more extensive than for gauge fields. Recall that the continuum fermion action is $S_f = \int d^4x \bar{q}[iD_\mu\gamma_\mu + m_q]q$, where $D_\mu = \partial_\mu + iA_\mu$ is the gauge-covariant derivative. The simplest discretization replaces the derivative with a symmetric difference:

$$D_\mu q(x) \longrightarrow \frac{1}{2a}[U_\mu(x)q(x+a\hat{\mu}) - U_\mu(x-a\hat{\mu})^\dagger q(x-a\hat{\mu})] \,. \quad (18.3)$$

The factors of U_μ ensure that $D_\mu q(x)$ transforms under gauge transformations in the same way as $q(x)$, so that the discretized version of $\bar{q}(x)D_\mu\gamma_\mu q(x)$ is gauge invariant. The choice in Eq. (18.3) leads to the so-called naive fermion action. This, however, suffers from the fermion doubling problem—in d dimensions it describes 2^d equivalent fermion fields in the continuum limit . The appearance of the extra "doubler" fermions is related to the deeper theoretical problem of formulating chirally symmetric fermions on the lattice. This is encapsulated by the Nielsen-Ninomiya theorem [8]: one cannot define lattice fermions having exact, continuum-like chiral

symmetry without producing doublers. Naive lattice fermions do have chiral symmetry but at the cost of introducing 15 unwanted doublers (for $d = 4$).

There are a number of different strategies for dealing with the doubling problem, each with their own theoretical and computational advantages and disadvantages. Wilson fermions [1] add a term proportional to $a\bar{q}\Delta q$ to the fermion action (the "Wilson term"—in which Δ is a covariant lattice Laplacian). This gives a mass of $\mathcal{O}(1/a)$ to the doublers, so that they decouple in the continuum limit. The Wilson term, however, violates chiral symmetry, and also introduces discretization errors linear in a. A commonly used variant that eliminates the $\mathcal{O}(a)$ discretization error is the $\mathcal{O}(a)$-improved Wilson (or "clover") fermion [9]. In this application of Symanzik improvement, methods have been developed to remove $\mathcal{O}(a)$ terms non-perturbatively using auxiliary simulations to tune parameters [10]. Such "non-perturbative improvement" is of great practical importance as it brings the discretization error from the fermion action down to the same level as that from the gauge action. It is used by essentially all simulations using clover fermions.

The advantages of Wilson fermions are their theoretical simplicity and relatively low computational cost. Their main disadvantage is the lack of chiral symmetry, which makes them difficult to use in cases where mixing with wrong chirality operators can occur, particularly if this involves divergences proportional to powers of $1/a$. A related problem is the presence of potential numerical instabilities due to spurious near-zero modes of the lattice Dirac operator. Ongoing work has, however, been successful at ameliorating these problems and increasing the range of quantities for which Wilson fermions can be used [11,12].

Twisted-mass fermions [13] are a variant of Wilson fermions in which two flavors are treated together with an isospin-breaking mass term (the "twisted mass" term). The main advantage of this approach is that all errors linear in a are automatically removed (without the need for tuning of parameters) by a clever choice of twisted mass and operators [14]. A disadvantage is the presence of isospin breaking effects (such as a splitting between charged and neutral pion masses even when up and down quarks are degenerate), which, however, vanish as $a^2\Lambda^2$ in the continuum limit.

Staggered fermions are a reduced version of naive fermions in which there is only a single fermion Dirac component on each lattice site, with the full Dirac structure built up from neighboring sites [15]. They have the advantages of being somewhat faster to simulate than Wilson-like fermions, of preserving some chiral symmetry, and of having discretization errors of $\mathcal{O}(a^2)$. Their disadvantage is that they retain some of the doublers (3 for $d = 4$). The action thus describes four degenerate fermions in the continuum limit. These are usually called "tastes", to distinguish them from physical flavors, and the corresponding SU(4) symmetry is referred to as the "taste symmetry". The preserved chiral symmetry in this formulation has non-singlet taste. Practical applications usually introduce one staggered fermion for each physical flavor, and remove contributions from the unwanted tastes by taking the fourth-root of the fermion determinant appearing in the path integral. The validity of this "rooting" procedure is not obvious because taste symmetry is violated for non-zero lattice spacing. Theoretical arguments, supported by numerical evidence, suggest that the procedure is valid as long as one takes the continuum limit before approaching the light quark mass region [16]. Additional issues arise for the valence quarks (those appearing in quark propagators, as described in Sec. 18.2 below), where rooting is not possible, and one must remove the extra tastes by hand [17].

Just as for Wilson fermions, the staggered action can be improved, so as to reduce discretization errors. The widely used "asqtad" action [18] removes tree-level $\mathcal{O}(a^2)$ errors, and leads to substantial reduction in the breaking of taste symmetry. More recently, a highly improved staggered quark ("HISQ") action has been introduced [19], which further reduces discretization errors, both those which break taste symmetry and those which do not. It is tuned to reduce discretization errors for both light and heavier quarks, and is being used to directly simulate charm quarks.

There is an important class of lattice fermions, "Ginsparg-Wilsons fermions", that possess a continuum-like chiral symmetry without introducing unwanted doublers. The lattice Dirac operator D for these fermions satisfies the Ginsparg-Wilson relation $D\gamma_5 + \gamma_5 D = aD\gamma_5 D$ [20]. In the continuum, the right-hand-side vanishes due to chiral symmetry. On the lattice, it is non-vanishing, but with a particular form (with two factors of D) that restricts the violations of chiral symmetry in Ward-Takahashi identities to short-distance terms that do not contribute to physical matrix elements [21]. In fact, one can define a modified chiral transformation on the lattice (by including dependence on the gauge fields) such that Ginsparg-Wilson fermions have an exact chiral symmetry for on-shell quantities [22]. The net result is that such fermions essentially have the same properties under chiral transformations as do continuum fermions, including the index theorem [21]. Their leading discretization errors are of $\mathcal{O}(a^2)$.

Two types of Ginsparg-Wilson fermions are currently being used in large-scale numerical simulations. The first are Domain-wall fermions (DWF). These are defined on a five-dimensional space, in which the fifth dimension is fictitious [23]. The action is chosen so that the low-lying modes are chiral, with left- and right-handed modes localized on opposite four-dimensional surfaces. For an infinite fifth dimension, these fermions satisfy the Ginsparg-Wilson relation. In practice, the fifth dimension is kept finite, and there remains a small, controllable violation of chiral symmetry. The second type are Overlap fermions. These appeared from a completely different context and have an explicit form that exactly satisfies the Ginsparg-Wilson relation [24]. Their numerical implementation requires an approximation of the matrix sign function of a Wilson-like fermion operator, and various approaches are being used. In fact, it is possible to rewrite these approximations in terms of a five-dimensional formulation, showing that the DWF and Overlap approaches are essentially equivalent [25]. Numerically, the five-dimensional approach appears to be the most computationally efficient.

As noted above, each fermion formulation has its own advantages and disadvantages. For instance, domain-wall and overlap fermions are theoretically preferred as they have chiral symmetry without doublers, but their computational cost is at least an order of magnitude greater than for other choices. If the physics application of interest and the target precision do not require near-exact chiral symmetry, there is no strong motivation to use these expensive formulations. On the other hand, there is a class of applications (including the calculation of the $\Delta I = 1/2$ amplitude for $K \to \pi\pi$ decays and the S-parameter [26]) where chiral symmetry plays an essential role and for which the use of Ginsparg-Wilson fermions is strongly favored.

18.1.3. *Heavy quarks on the lattice* :

The fermion formulations described in the previous subsection can be used straightforwardly only for quarks whose masses are small compared to the lattice cutoff, $m_q \lesssim 1/a$. This is because there are discretization errors proportional to powers of am_q, and if $am_q \gtrsim 1$ these errors are large and uncontrolled. Present LQCD simulations typically have cutoffs in the range of $1/a = 2 - 4$ GeV (corresponding to $a \approx 0.1 - 0.05$ fm). Thus, while for the up, down and strange quarks one has $am_q \ll 1$, for bottom quarks (with $m_b \approx 4.5$ GeV) one must use alternative approaches. Charm quarks ($m_c \approx 1.5$ GeV) are an intermediate case, allowing simulations using both direct and alternative approaches.

For the charm quark, the straightforward approach is to simultaneously reduce the lattice spacing and to improve the fermion action so as to reduce the size of errors proportional to powers of am_c. This approach has, for example, been followed successfully using the HISQ and twisted-mass actions [19,27,28]. It is important to note, however, that reducing a increases the computational cost because an increased number of lattice points are needed for the same physical volume. One cannot reduce the spatial size below $2 - 3$ fm without introducing finite volume errors. Present lattices have sizes up to $\sim 96^3 \times 192$ (with the long direction being Euclidean time), and thus allow a lattice cutoff up to $1/a \sim 4$ GeV.

Alternative approaches for discretizing heavy quarks are motivated by effective field theories. For a bottom quark in heavy-light hadrons, one can use Heavy Quark Effective Theory (HQET) to expand about the infinite quark-mass limit. In this limit, the bottom quark is a static

color source, and one can straightforwardly write the corresponding lattice action [29]. Corrections, proportional to powers of $1/m_b$, can be introduced as operator insertions, with coefficients that can be determined non-perturbatively using existing techniques [30]. This method allows the continuum limit to be taken controlling all $1/m_b$ corrections.

Another way of introducing the $1/m_b$ corrections is to include the relevant terms in the effective action. This leads to a non-relativistic QCD (NRQCD) action, in which the heavy quark is described by a two-component spinor [31]. This approach has the advantage over HQET that it can also be used for heavy-heavy systems, such as the Upsilon states. A disadvantage is that some of the parameters in this effective theory are determined perturbatively (originally at tree-level, but more recently at one-loop), which limits the precision of the final results. Although discretization effects can be controlled with good numerical precision for a range of lattice spacings, at fine enough lattice spacing the NRQCD effective theory no longer applies since power divergent terms become important, and taking the continuum limit would require fine-tuning a large number of couplings non-perturbatively.

This problem can be avoided if one uses HQET power counting to analyze and reduce discretization effects for heavy quarks while using conventional fermion actions [32]. For instance, one can tune the parameters of an improved Wilson quark action so that the leading HQET corrections to the static quark limit are correctly accounted for. As the lattice spacing becomes finer, the action smoothly goes over to that of a light Wilson quark action, where the continuum limit can be taken as usual. In principle, one can improve the action in the heavy quark regime up to arbitrarily high orders using HQET, but so far large-scale simulations have typically used clover improved Wilson quarks, where tuning the parameters of the action corresponds to including all corrections through next-to-leading order in HQET. Three different methods for tuning the parameters of the clover action are being used: the Fermilab [32], Tsukuba [33] and Columbia [34] approaches. An advantage of this HQET approach is that the c and b quarks can be treated on the same footing. Parameter tuning has typically been done perturbatively, as in NRQCD, but recent work using the Columbia approach has used non-perturbative tuning [35].

18.1.4. *Basic inputs for lattice calculations* :

Since LQCD is nothing but a regularization of QCD, the renormalizability of QCD implies that the number of input parameters in LQCD is the same as for continuum QCD—the strong coupling constant $\alpha_s = g^2/(4\pi)$, the quark masses for each flavor, and the CP violating phase θ. The θ parameter is usually assumed to be zero, while the other parameters must be determined using experimental inputs.

18.1.4.1. *Lattice spacing:* In QCD, the coupling constant is a function of scale. With lattice regularization, this scale is the inverse lattice spacing $1/a$, and choosing the bare coupling constant is equivalent to fixing the lattice spacing.

In principle, a can be determined using any dimensionful quantity measured by experiments. For example, using the mass of hadron H one has $a = (am_H)^{\rm lat}/m_H^{\rm exp}$. (Of course, one must first tune the quark masses to their physical values, as discussed below.) In practice, one chooses quantities that can be calculated accurately on the lattice, and that are only weakly dependent on the light quark masses. The latter property minimizes errors from extrapolating or interpolating to the physical light quark masses or from mistuning of these masses. Commonly used choices are the spin-averaged 1S-1P or 1S-2S splittings in the Upsilon system, the mass of the Ω^- baryon, and the pion decay constant f_π. Ultimately, all choices must give the consistent results for a, and that this is the case provides a highly non-trivial check of both the calculational method and of QCD.

The determination of a using quantities involving light (up and down) quarks—such as f_π—involves particular challenges. Most current lattice simulations are done using light quark masses heavier than those in nature. One thus has to extrapolate the lattice data towards the physical quark masses. This "chiral extrapolation" is non-trivial because the quark mass dependence may involve non-analytic terms due to the loops of nearly massless pions, as predicted by Chiral Perturbation Theory (ChPT) [36].

18.1.4.2. *Light quark masses:* In LQCD simulations, the up, down and strange quarks are usually referred to as the light quarks, in the sense that $m_q < \Lambda_{\rm QCD}$. (The standard definition of $\Lambda_{\rm QCD}$ is given in the "Quantum Chromodynamics" review; in this review we are using it only to indicate the approximate non-perturbative scale of QCD.) This condition is stronger than that used above to distinguish quarks with small discretization errors, $m_q < 1/a$. Loop effects from light quarks must be included in the simulations to accurately represent QCD. At present, most simulations are done in the isospin symmetric limit $m_u = m_d \equiv m_\ell$, and are often referred to as "$N_f = 2+1$" simulations. (If, in addition, one includes the charm quark, this is denoted as an $N_f = 2+1+1$ simulation.) Precision is now reaching the point where isospin breaking effects, as well as those of electromagnetism (EM) must be included. This can be done approximately using ChPT and other theoretical input, but ultimately one needs to simulate directly with $m_u \neq m_d$ and including QED corrections. Such work is now beginning.

To tune m_ℓ and m_s to their physical values, the most commonly used quantities are, respectively, m_π and m_K. If the scale is being set by m_Ω, then one adjusts the lattice light quark masses until the ratios m_π/m_Ω and m_K/m_Ω take their physical values. At leading order in ChPT, one has the Gell-Mann-Oakes-Renner relations $m^2_{\pi^0} \propto (m_u + m_d)$ and $m^2_{K^0} \propto (m_d + m_s)$, which show the sensitivity of these quantities to the quark masses. In practice one uses higher order ChPT (or other fit functions) to extrapolate or interpolate the lattice results so as to match the desired ratios, correcting for the (small) effects of isospin breaking and electromagnetic corrections. Most present calculations need to extrapolate to the physical value of m_ℓ, while simulating directly at or near to the physical value of m_s.

18.1.4.3. *Heavy quark masses:* Heavy quarks (c and b) are usually treated only as valence quarks, with no loop effects included. The errors introduced by this approximation can be estimated to be $\sim \alpha_s(m_c)\Lambda^2_{\rm QCD}/m_c^2$ and are likely to be small. For high precision, however, dynamical charm quarks may be necessary, and simulations are beginning to include them.

The heavy quark masses can be tuned by setting heavy-heavy or heavy-light meson masses to their experimental values. For the charm quark, for example, one could use the J/ψ or the D_s meson. Consistency between these two determinations provides an important check that the determination of parameters in the heavy quark lattice formulations is being done correctly (see, e.g. Ref. 37).

18.1.5. *Sources of systematic error* :

Lattice results have statistical and systematic errors that must be quantified for any calculation in order for the result to be a useful input to phenomenology. The statistical error is due to the use of Monte Carlo importance sampling to evaluate the path integral (a method discussed below). There are, in addition, a number of systematic errors that are always present to some degree in lattice calculations, although the size of any given error depends on the particular quantity under consideration and the parameters of the ensembles being used. The most common lattice errors are reviewed below.

Although not strictly a systematic error, it is important to note that the presence of long autocorrelations in the sequence of lattice configurations generated by the Monte Carlo method can lead to uncertainty in the estimates of statistical errors. It is known that the global topological charge of the gauge fields decorrelates very slowly with certain algorithms [38]. This issue is particularly important for quantities, like the η' mass, which are sensitive to topology. It is an active area of research.

18.1.5.1. *Continuum limit:* Physical results are obtained in the limit that the lattice spacing a goes to zero. The Symanzik effective theory determines the scaling of lattice artefacts with a. Most lattice calculations use improved actions with leading discretizations errors of $\mathcal{O}(a^2\Lambda^2)$, $\mathcal{O}(\alpha_s a^2\Lambda^2)$, or $\mathcal{O}(\alpha_s a\Lambda)$, where Λ is a typical momentum scale in the system. Knowledge of the scaling of the leading discretization errors allows controlled extrapolation to $a = 0$ when multiple lattice spacings are available, as in current state-of-the-art calculations. Residual errors arise from the exclusion of subleading a dependence from the fits.

For many quantities the typical momentum scale in the system is $\sim \Lambda_{\rm QCD} \approx 300$ MeV. Discretization errors are expected to be larger for quantities involving larger scales, for example form factors or decays involving particles with momenta larger than $\Lambda_{\rm QCD}$.

18.1.5.2. *Infinite volume limit:* LQCD calculations are necessarily carried out in finite space-time boxes, leading to departures of physical quantities (masses, decay constants, etc.) from their measured, infinite volume values. These finite-volume shifts are an important systematic that must be estimated and minimized.

Typical lattices are asymmetric, with N_s points in the three spatial directions and N_t in the (Euclidean) temporal direction. The spatial and temporal sizes in physical units are thus $L_s = aN_s$ and $L_t = aN_t$, respectively. (Anisotropic lattice spacings are also sometimes used, as discussed below in Sec. 1.3.1.) Typically, $L_t \geq 2L_s$, a longer temporal direction being used to allow excited-state contributions to correlators to decay. This means that the dominant impact of using finite volume is from the presence of a finite spatial box.

At present, high-precision LQCD calculations are of quantities involving no more than a single particle in initial and final states. For such quantities, once the volume exceeds about 2 fm (so that the particle is not "squeezed"), the dominant finite-volume effect comes from virtual pions wrapping around the lattice in the spatial directions. This effect is exponentially suppressed as the volume becomes large, roughly as $\sim \exp(-m_\pi L_s)$, and has been estimated using ChPT [39] or other methods [40]. The estimates suggest that finite volume shifts are sub-percent effects when $m_\pi L_s \gtrsim 4$, and most large-scale simulations use lattices satisfying this condition. This becomes challenging as one approaches the physical pion mass, for which $L_s \gtrsim 5$ fm is required. At present, this can only be achieved by using relatively coarse lattices, $a \gtrsim 0.07$ fm.

Finite volume errors are usually determined by repeating the simulations on two or more different volumes (with other parameters fixed). If different volumes are not available, the ChPT estimate can be used, often inflated to account for the fact that the ChPT calculation is truncated at some order.

In the future, LQCD calculations involving more than a single hadron will become increasingly precise. Examples include the calculation of resonance parameters and $K \to \pi\pi$ amplitudes. Finite volume effects are much larger in these cases, with power-law terms (e.g. $1/L_s^3$) in addition to exponential dependence. Indeed, as will be discussed in Sec. 1.2.4., one can use the volume dependence to indirectly extract infinite-volume quantities such as scattering lengths. Doing so, however, requires a set of lattice volumes satisfying $m_\pi L_s \gtrsim 4$ and is thus more challenging than for single-particle quantities.

18.1.5.3. *Chiral extrapolation:* An important source of systematic error in most LQCD calculations is the need to extrapolate in m_u and m_d (or, equivalently, in m_π). To do this, one needs a functional form that is, at least approximately, valid for pion masses ranging from the unphysical values used in simulations down to the physical value. A theoretically favored choice is to use the predictions of SU(3) or SU(2) ChPT. This is a valid description of QCD for $m_q \ll \Lambda_{QCD}$ (or $m_\pi \ll m_\rho$), but the extent to which it applies at larger pion masses is not known *a priori*. This concern is exacerbated in practice since one must truncate the ChPT expressions, typically at one-loop or two-loop order. Experience to date suggests that one-loop expressions are not sufficiently accurate if $m_\pi \gtrsim 400$ MeV [41].

Another choice of fit function is based on the observation that one does not need to extrapolate to the chiral limit, but only to the physical, non-zero, value of m_π, and thus an analytic description might suffice. In practice, of course, one must truncate the analytic form at low order, and a concern is whether the curvature from known non-analytic terms is adequately reproduced.

Extrapolation errors are estimated by comparing fits based on ChPT to those using analytic fits, or by varying the fit function in some other way, and/or by varying the number of data points included. We also note that, in many calculations, additional input to the chiral extrapolation is obtained from "partially quenched" results in which the valence and sea-quark masses differ [42].

Recently, simulations with physical light quark masses (except that $m_u = m_d = (m_u^{\rm phys} + m_d^{\rm phys})/2$) have been undertaken [43], and are now becoming increasingly common [44]. This is a major step forward as it removes the need for chiral extrapolation. As noted above, such simulations require large boxes, and thus very large lattices, and to date the results have been used to compute a limited number of observables. In the future, however, such simulations will play an increasingly important role in the determination of physical quantities.

18.1.5.4. *Operator matching:* Many of the quantities that LQCD can precisely calculate involve hadronic matrix elements of operators from the electroweak Hamiltonian. Examples include the pion and kaon decay constants, semileptonic form factors and the kaon mixing parameter B_K (the latter defined in Eq. (18.13)). The operators in the lattice matrix elements are defined in the lattice regularization scheme. To be used in tests of the Standard Model, however, they must be matched to the continuum regularization scheme in which the corresponding Wilson coefficients have been calculated. The only case in which such matching is not needed is if the operator is a conserved or partially conserved current. Similar matching is also needed for the conversion of lattice bare quark masses to those in the continuum $\overline{\rm MS}$ scheme.

Three methods are used to calculate the matching factors: perturbation theory (usually to one- or two-loop order), non-perturbative renormalization (NPR) using Landau-gauge quark and gluon propagators [45], and NPR using gauge-invariant methods based on the Schrödinger functional [46]. The NPR methods replace truncation errors (which can only be approximately estimated) by statistical and systematic errors which can be determined reliably and systematically reduced.

A common issue that arises in many such calculations (e.g. for quark masses and B_K) is that, using NPR, one ends up with operators regularized in a MOM-like (or Schrödinger functional) scheme, rather than the $\overline{\rm MS}$ scheme mostly used for calculating the Wilson coefficients. To make contact with this scheme requires a purely continuum perturbative matching calculation. The resultant truncation error can, however, be minimized by pushing up the momentum scale at which the matching is done using step-scaling techniques as part of the NPR calculation [47]. It should also be noted that this final step in the conversion to the $\overline{\rm MS}$ scheme could be avoided if continuum calculations used a MOM-like scheme.

18.2. Methods and status

Once the lattice action is chosen, it is straightforward to define the quantum theory using the path integral formulation. The Euclidean-space partition function is

$$Z = \int [dU] \prod_f [dq_f][d\bar{q}_f] e^{-S_g[U] - \sum_f \bar{q}_f (D[U] + m_f) q_f} \,, \qquad (18.4)$$

where link variables are integrated over the SU(3) manifold, q_f and $\bar{q}_f$ are Grassmann (anticommuting) quark and antiquark fields of flavor f, and $D[U]$ is the chosen lattice Dirac operator with m_f the quark mass in lattice units. Integrating out the quark and antiquark fields, one arrives at a form suitable for simulation:

$$Z = \int [dU] e^{-S_g[U]} \prod_f \det(D[U] + m_f) \,. \qquad (18.5)$$

The building blocks for calculations are expectation values of multi-local gauge-invariant operators, also known as "correlation functions",

$$\langle \mathcal{O}(U,q,\bar{q})\rangle = (1/Z)\int [dU]\prod_f [dq_f][d\bar{q}_f]\mathcal{O}(U,q,\bar{q})e^{-S_g[U]-\sum_f \bar{q}_f(D[U]+m_f)q_f}\,. \tag{18.6}$$

If the operators depend on the (anti-)quark fields q_f and $\bar{q}_f$, then integrating these fields out leads not only to the fermion determinant but also, through Wick's theorem, to a series of quark "propagators", $(D[U]+m_f)^{-1}$, connecting the positions of the fields.

This set-up allows one to choose, by hand, the masses of the quarks in the determinant (the sea quarks) differently from those in the propagators (valence quarks). This is called "partial quenching", and, as noted above, is used by some calculations as a way of obtaining more data points from which to extrapolate both sea and valence quarks to their physical values.

18.2.1. *Monte-Carlo method* :

Since the number of integration variables U is huge ($N_s^3\times N_t\times 4\times 9$), direct numerical integration is impractical and one has to use Monte-Carlo techniques. In this method, one generates a Markov chain of gauge configurations (a "configuration" being the set of U's on all links) distributed according to the probability measure $[dU]e^{-S_g[U]}\prod_f \det(D[U]+m_f)$. Once the configurations are generated, expectation values $\langle\mathcal{O}(U,q,\bar{q})\rangle$ are calculated by averaging over those configurations. In this way the configurations can be used repeatedly for many different calculations, and there are several large collections of ensembles of configurations (with a range of values of a, lattice sizes and quark masses) that are publicly available through the International Lattice Data Grid (ILDG). As the number of the configurations, N, is increased, the error decreases as $1/\sqrt{N}$.

The most challenging part of the generation of gauge configurations is the need to include the fermion determinant. Direct evaluation of the determinant is not feasible, as it requires $\mathcal{O}((N_s^3\times N_t)^3)$ computations. Instead, one rewrites it in terms of "pseudofermion" fields ϕ (auxiliary fermion fields with bosonic statistics). For example, for two degenerate quarks one has

$$\det(D[U]+m_f)^2 = \int [d\phi]e^{-\phi^\dagger(D[U]+m_f)^{-2}\phi}\,. \tag{18.7}$$

By treating the pseudofermions as additional integration variables in the path integral, one obtains a totally bosonic representation. The price one pays is that the pseudofermion effective action is highly non-local since it includes the inverse Dirac operator $(D[U]+m_f)^{-1}$. Thus, the large sparse matrix $(D[U]+m)$ has to be inverted every time one needs an evaluation of the effective action.

Present simulations generate gauge configurations using the Hybrid Monte Carlo (HMC) algorithm [48], or variants thereof. This algorithm combines molecular dynamics (MD) evolution in a fictitious time (which is also discretized) with a Metropolis "accept-reject" step. It makes a global update of the configuration, and is made exact by the Metropolis step. In its original form it can be used only for two degenerate flavors, but extensions (particularly the rational HMC [49]) are available for single flavors. Considerable speed-up of the algorithms has been achieved over the last two decades using a variety of techniques.

All these algorithms spend the bulk of their computational time on the repeated inversion of $(D[U]+m)$ acting on a source (which is required at every step of the MD evolution). Inversions are done using a variety of iterative algorithms, *e.g.* the conjugate gradient algorithm. In this class of algorithms, computational cost is proportional to the condition number of the matrix, which is the ratio of maximum and minimum eigenvalues. For $(D[U]+m)$ the smallest eigenvalue is $\approx m$, so the condition number and cost are inversely proportional to the quark mass. This is a major reason why simulations at the physical quark mass are challenging. Recent algorithmic studies are making progress in significantly reducing this problem.

A practical concern is the inevitable presence of correlations between configurations in the Markov chain. These are characterized by an autocorrelation length in the fictitious MD time. One aims to use configurations separated in MD time by greater than this autocorrelation length. In practice, it is difficult to measure this length accurately, and this leads to some uncertainty in the resulting statistical errors, as well as the possibility of insufficient equilibration.

For most of the applications of LQCD discussed in this review, the cost of generating gauge configurations is larger than that of performing the "measurements" on those configurations. The computational cost of gauge generation grows with the lattice volume, $V_{\rm lat}=N_s^3N_t$, as $V_{\rm lat}^{1+\delta}$. Here $\delta=1/4$ for the HMC algorithm [50] and can be reduced slightly using modern variants. Such growth with $V_{\rm lat}$ provides a (time-dependent) limit on the largest lattice volumes that can be simulated. At present, the largest lattices being used have $N_s=96$ and $N_t=192$. Typically one aims to create an ensemble of $\sim 10^3$ statistically independent configurations at each choice of parameters (a, m_q and $V_{\rm lat}$). For most physical quantities of interest, this is sufficient to make the resulting statistical errors smaller than or comparable to the systematic errors.

18.2.2. *Two-point functions* :

One can extract properties of stable hadrons using two-point correlation functions, $\langle O_X(x)O_Y^\dagger(0)\rangle$. Here $O_{X,Y}(x)$ are operators that have non-zero overlaps with the hadronic state of interest $|H\rangle$, *i.e.* $\langle 0|O_{X,Y}(x)|H\rangle\neq 0$. One usually Fourier-transforms in the spatial directions and considers correlators as a function of Euclidean time:

$$C_{XY}(t;\vec{p}) = \sum_{\vec{x}}\langle O_X(t,\vec{x})O_Y^\dagger(0)\rangle e^{-i\vec{p}\cdot\vec{x}}. \tag{18.8}$$

(Here and throughout this section all quantities are expressed in dimensionless lattice units, so that, for example, $\vec{p}=a\vec{p}_{\rm phys}$.) By inserting a complete set of states having spatial momentum $\vec{p}$, the two-point function can be written as

$$C_{XY}(t;\vec{p}) = \sum_{i=0}^{\infty}\frac{1}{2E_i(\vec{p})}\langle 0|O_X(0)|H_i(\vec{p})\rangle\langle H_i(\vec{p})|O_Y^\dagger(0)|0\rangle e^{-E_i(\vec{p})t}, \tag{18.9}$$

where the energy of the i-th state $E_i(\vec{p})$ appears as an eigenvalue of the time evolution operator e^{-Ht} in the Euclidean time direction. The factor of $1/[2E_i(\vec{p})]$ is due to the relativistic normalization used for the states. For large enough t, the dominant contribution is that of the lowest energy state $|H_0(\vec{p})\rangle$:

$$C_{XY}(t)\overset{t\to\infty}{\longrightarrow}\frac{1}{2E_0(\vec{p})}\langle 0|O_X(0)|H_0(\vec{p})\rangle\langle H_0(\vec{p})|O_Y^\dagger(0)|0\rangle e^{-E_0(\vec{p})t}\,. \tag{18.10}$$

One can thus obtain the energy $E_0(\vec{p})$, which equals the hadron mass m_H when $\vec{p}=0$, and the product of matrix elements $\langle 0|O_X(0)|H_i(\vec{p})\rangle\langle H_i(\vec{p})|O_Y^\dagger(0)|0\rangle$.

This method can be used to determine the masses of all the stable mesons and baryons by making appropriate choices of operators. For example, if one uses the axial current, $O_X=O_Y=A_\mu=\bar{d}\gamma_\mu\gamma_5 u$, then one can determine m_{π^+} from the rate of exponential fall-off, and in addition the decay constant f_π from the coefficient of the exponential. A complication arises for states with high spins ($j\geq 4$ for bosons) because the spatial rotation group on the lattice is a discrete subgroup of the continuum group SO(3). This implies that lattice operators, even when chosen to lie in irreducible representations of the lattice rotation group, have overlap with states that have a number of values of j in the continuum limit [51]. For example $j=0$ operators can also create mesons with $j=4$. A method to overcome this problem has recently been introduced [52,53].

The expression given above for the correlator $C_{XY}(t;\vec{p})$ shows how, in principle, one can determine the energies of the excited hadron states having the same quantum numbers as the operators $O_{X,Y}$, by fitting the correlation function to a sum of exponentials. In practice, this usually requires using a large basis of operators and adopting the variational approach such as that of Ref. 54. One can also use an anisotropic lattice in which a_t, the lattice spacing in the time direction, is smaller than its spatial counterpart a_s. This allows better separation of the different exponentials. Using a combination of these and other technical improvements extensive excited-state spectra have recently been obtained [53,55,56](for a recent review, see Ref. 57).

18.2.3. ***Three-point functions*** :

Hadronic matrix elements needed to calculate semileptonic form factors and neutral meson mixing amplitudes can be computed from three-point correlation functions. We discuss here, as a representative example, the $D \to K$ amplitude. As in the case of two-point correlation functions one constructs operators O_D and O_K having overlap, respectively, with the D and K mesons. We are interested in calculating the matrix element $\langle K|V_\mu|D\rangle$, with $V_\mu = \bar{c}\gamma_\mu s$ the vector current. To obtain this, we use the three-point correlator

$$C_{KV_\mu D}(t_x, t_y; \vec{p}) = \sum_{\vec{x},\vec{y}} \langle O_K(t_x, \vec{x}) V_\mu(0) O_D^\dagger(t_y, \vec{y})\rangle e^{-i\vec{p}\cdot\vec{x}}\,, \quad (18.11)$$

and focus on the limit $t_x \to \infty$, $t_y \to -\infty$. In this example we set the D-meson at rest while the kaon carries three-momentum $\vec{p}$. Momentum conservation then implies that the weak operator V_μ inserts three-momentum $-\vec{p}$. Inserting a pair of complete sets of states between each pair of operators, we find

$$C_{KV_\mu D}(t_x, t_y; \vec{p}) = \sum_{i,j} \frac{1}{2m_{D_i} 2E_{K_j}(\vec{p})} e^{-m_{D_i} t_x - E_{K_j}(\vec{p})|t_y|} \times$$

$$\times \langle 0|O_K(t_x, \vec{x})|K_i(\vec{p})\rangle \langle K_i(\vec{p})|V_\mu(0)|D_j(\vec{0})\rangle \langle D_j(\vec{0})|O_D^\dagger(0)|0\rangle. \quad (18.12)$$

The matrix element $\langle K_i(\vec{p})|V_\mu(0)|D_j(\vec{0})\rangle$ can then be extracted, since all other quantities in this expression can be obtained from two-point correlation functions. Typically one is interested in the weak matrix elements of ground states, such as the lightest pseudoscalar mesons. In the limit of large separation between the three operators in Euclidean time, the three-point correlation function yields the weak matrix element of the transition between ground states.

18.2.4. ***Scattering amplitudes and resonances*** :

The methods described thus far yield matrix elements involving single, stable particles (where by stable here we mean absolutely stable to strong interaction decays). Most of the particles listed in the Review of Particle Properties are, however, unstable—they are resonances decaying into final states consisting of multiple strongly interacting particles. LQCD simulations cannot directly calculate resonance properties, but methods have been developed to do so indirectly for resonances coupled to two-particle final states in the elastic regime [58].

The difficulty faced by LQCD calculations is that, to obtain resonance properties, or, more generally, scattering phase-shifts, one must calculate multiparticle scattering amplitudes in momentum space and put the external particles on their mass-shells. This requires analytically continuing from Euclidean to Minkowski momenta. Although it is straightforward in LQCD to generalize the methods described above to calculate four- and higher-point correlation functions, one necessarily obtains them at a discrete and finite set of Euclidean momenta. Analytic continuation to $p_E^2 = -m^2$ is then an ill-posed and numerically unstable problem. The same problem arises for single-particle states, but can be largely overcome by picking out the exponential fall-off of the Euclidean correlator, as described above. With a multi-particle state, however, there is no corresponding trick, except for two particles at threshold [59].

What LQCD can calculate are the energies of the eigenstates of the QCD Hamiltonian in a finite box. The energies of states containing two stable particles, e.g. two pions, clearly depend on the interactions between the particles. It is possible to invert this dependence and, with plausible assumptions, determine the scattering phase-shifts at a discrete set of momenta from a calculation of the two-particle energy levels for a variety of spatial volumes [58]. This is a challenging calculation, but it has recently been carried through in several channels with quark masses approaching physical values. Channels studied include $\pi\pi$ (for $I = 2$, 1 and 0), $K\pi$, KD and DD^*. For recent reviews see Ref. 60. Extensions to nucleon interactions are also being actively studied [61]. The generalization of the formalism to the case of three particles is under active consideration [62].

It is also possible to extend the methodology to calculate electroweak decay amplitudes to two particles below the inelastic threshold, e.g. $\Gamma(K \to \pi\pi)$ [63]. Results for the $\Delta I = 3/2$ amplitude with physical quark masses have been obtained [64], and significant progress made toward a calculation of the $\Delta I = 1/2$ amplitude [65]. Partial extensions of the formalism above the elastic threshold have been worked out, in particular for the case of multiple two-particle channels [66]. An extension to decays with many multiparticle channels, e.g. hadronic B decays, has, however, yet to be formulated.

18.2.5. ***Status of LQCD simulations*** :

Until the 1990s, most large-scale lattice simulations were limited to the "quenched" approximation, wherein the fermion determinant is omitted from the path integral. While much of the basic methodology was developed in this era, the results obtained had uncontrolled systematic errors and were not suitable for use in placing precision constraints on the Standard Model. During the 1990s, more extensive simulations including the fermion determinant (also known as simulations with "dynamical" fermions) were begun, but with unphysically high light quark masses ($m_\ell \sim 50 - 100$ MeV), such that the extrapolation to the physical light quark masses was a source of large systematic errors [67]. In the last 5-10 years, advances in both algorithms and computers have allowed simulations to reach much smaller quark masses ($m_\ell \sim 10 - 20$ MeV) and even, as noted above, to work at the physical light quark mass. The net effect is that LQCD calculations of selected quantities now have all sources of error controlled and small, such that they can be used effectively in phenomenological analyses.

On a more qualitative level, analytic and numerical results from LQCD have demonstrated that QCD confines color and spontaneously breaks chiral symmetry. Confinement can be seen as a linearly rising potential between heavy quark and anti-quark in the absence of quark loops. Analytically, this can be shown in the strong coupling limit $g_{\rm lat} \to \infty$ [1]. At weaker couplings there are precise numerical calculations of the potential that clearly show that this behavior persists in the continuum limit [68–70].

Chiral symmetry breaking was also demonstrated in the strong coupling limit on the lattice [15,71], and there have been a number of numerical studies showing that this holds also in the continuum limit. The accumulation of low-lying modes of the Dirac operator, which is the analog of Cooper pair condensation in superconductors, has been observed, yielding a determination of the chiral condensate [72–74] Many relations among physical quantities that can be derived under the assumption of broken chiral symmetry have been confirmed by a number of lattice groups [75].

18.3. Physics applications

In this section we describe the main applications of LQCD that are both computationally mature and relevant for the determination of particle properties.

A general feature to keep in mind is that, since there are many different choices for lattice actions, all of which lead to the same continuum theory, a crucial test is that results for any given quantity are consistent. In many cases, different lattice calculations are completely independent and often have very different systematic errors. Thus final agreement, if found, is a highly non-trivial check, just as it is for different experimental measurements.

The number, variety and precision of the calculations has progressed to the point that an international "Flavour Lattice Averaging Group" (FLAG) has been formed. The main aims of FLAG include collecting all lattice results of relevance for a variety of phenomenologically interesting quantities and providing averages of those results which pass appropriate quality criteria. The averages attempt to account for possible correlations between results (which can arise, for example, if they use common gauge configurations). The quantities considered are those we discuss in this section, with the exception of the hadron spectrum. FLAG has recently completed their review [75], and we have made extensive use of it in preparing the following summary. We stress that the results we quote below are those obtained using the physical complement of light quarks (i.e. $N_f = 2 + 1$ or $2 + 1 + 1$ simulations).

18.3.1. *Spectrum* :

The most basic prediction of LQCD is of the hadron spectrum. Once the input parameters are fixed as described in Sec. 18.1.4, the masses or resonance parameters of all other states can be predicted. This includes hadrons composed of light (u, d and s) quarks, as well as heavy-light and heavy-heavy hadrons. It also includes quark-model exotics (e.g. $J^{PC} = 1^{-+}$ mesons) and glueballs. Thus, in principle, LQCD calculations should be able to reproduce many of the experimental results compiled in the Review of Particle Properties. Doing so would test both that the error budgets of LQCD calculations are accurate and that QCD indeed describes the strong interactions in the low-energy domain. The importance of the latter test can hardly be overstated.

What is the status of this fundamental test? As discussed in Sec. 1.2, LQCD calculations are most straightforward for stable, low-lying hadrons. Resonances which can decay into only two particles are more challenging, though substantial progress has been made. First theoretical work on decays to more than two particles has begun, but the methodology is not yet practical. It is also more technically challenging to calculate masses of flavor singlet states (which can annihilate into purely gluonic intermediate states) than those of flavor non-singlets, although again algorithmic and computational advances have made such calculations accessible in some cases. The present status for light hadrons is that fully controlled results are available for the masses of the octet light baryons, while results with less than complete control are available for the decuplet baryon resonances, the vector meson resonances and the η and η'. There are more extensive results for heavy-light (D and B systems) and heavy-heavy (J/ψ and Υ systems). All present results, which are discussed in the "Quark Model" review, are consistent with experimental values. For a recent extensive review of lattice results see also Ref. 76.

18.3.2. *Decay constants and bag parameters* :

The pseudoscalar decay constants can be determined from two point correlation functions involving the axial-vector current, as discussed in Sec. 18.2.2. The decay constant f_P of a meson P is extracted from the weak matrix element involving the axial-vector current using the relation $\langle 0|A_\mu(x)|P(\vec{p})\rangle = f_P p_\mu \exp(-ip\cdot x)$, where p_μ is the momentum of P and $A_\mu(x)$ is the axial-vector current. For the pion and kaon decay constants, this calculation is by now straightforward. The ratio f_K/f_π is especially important for the extraction of $|V_{us}|/|V_{ud}|$ from experiment, and many of the systematic errors in the lattice calculation cancel or are significantly reduced when forming the ratio [77]. A number of lattice groups have calculated this ratio with precision at the percent level or better; all the results are in good agreement, with sub-percent precision in the world average [78,79,75]. A summary is shown in Fig. 18.1. The most significant advance in the last two years is the addition of a calculation including dynamical charm quarks ("$N_f = 2+1+1$") [44], the result from which is in complete agreement with the average of results with $N_f = 2+1$.

The heavy-light decay constants f_D and f_{D_s} involve a charm valence quark, which can be simulated using various methods, as discussed in Sec. 18.1.3. The most accurate result uses the same HISQ action for the charm quark as for the light quarks, which means that the matching factor for the axial currents of interest are unity. This allows Ref. 83 to quote values for the charm decay constants with 1-1.5% errors. Calculations using alternative quark actions give consistent results, but with larger errors [84,85]. The FLAG averages are $f_D = 209(3)$ MeV, $f_{D_s} = 249(3)$ MeV, $f_{D_s}/f_D = 1.187(12)$.

The bottom meson decay constants f_B and f_{B_s} require a valence b quark. Lattice calculations of these quantities are available using the Fermilab formulation [84], NRQCD [86] or HQET [87] to treat the bottom quark or using an interpolation between results from around m_c to infinite quark mass [88,89]. Results have precisions ranging down to $\sim 2\%$. The FLAG averages are $f_B = 191(4)$ MeV, $f_{B_s} = 228(5)$ MeV, $f_{B_s}/f_B = 1.20(2)$.

The kaon bag parameter B_K is needed to turn the precise measurement of CP-violation in kaon mixing into a constraint on the Standard Model. It is defined by

$$\frac{8}{3} m_K^2 f_K^2 B_K(\mu) = \langle \overline{K}^0 | Q_{\Delta_S=2}(\mu) | K^0 \rangle, \qquad (18.13)$$

where m_K is the kaon mass, f_K is the kaon decay constant, $Q_{\Delta S=2} = \overline{s}\gamma_\mu(1-\gamma_5)d\overline{s}\gamma_\mu(1-\gamma_5)d$ is the four-quark operator of the effective electroweak Hamiltonian and μ is the renormalization scale. The short distance contribution to the electroweak Hamiltonian can be calculated perturbatively, but the hadronic matrix element parameterized by B_K must be computed using non-perturbative methods. In order to be of use to phenomenology, the renormalization factor of the four-quark operator must be matched to a continuum renormalization scheme, e.g. to $\overline{\rm MS}$, as described in Sec. 18.1.5.4. Determinations with percent-level precision using different fermion actions are now available with DWF [82], staggered fermions [90], DWF valence on staggered sea quarks [91], twisted mass fermions [92] and Wilson fermions [12]. The results are all consistent, and the FLAG average is $\hat{B}_K = 0.766(10)$.

The bag parameters for B and B_s meson mixing are defined analogously to that for kaon mixing. The B and B_s mesons contain a valence b-quark so that calculations of these quantities must use one of the methods for heavy quarks described above. Calculations have been done using NRQCD [93], the Fermilab formalism [94], the Columbia formalism [95] and twisted-mass fermions [96]. For $f_B\sqrt{B_B}$ and $f_{B_s}\sqrt{B_{B_s}}$ the averages are dominated by the HPQCD results [93]. The errors ($\sim 7\%$) are dominated by that from operator matching. For the ratio of these two quantities, ξ, the total error ($\sim 5\%$) is somewhat smaller due to cancelations: the dominant errors are due to chiral extrapolation and statistics. The FLAG averages are $f_B\sqrt{B_B} = 216(15)$ MeV, $f_{B_s}\sqrt{B_{B_s}} = 266(18)$ Mev and $\xi = 1.268(63)$.

The results discussed in this section are used in the reviews "The CKM Quark-Mixing Matrix," "V_{ud}, V_{us}, the Cabibbo Angle and CKM Unitarity," and "$B_0 - \bar{B}_0$ Mixing."

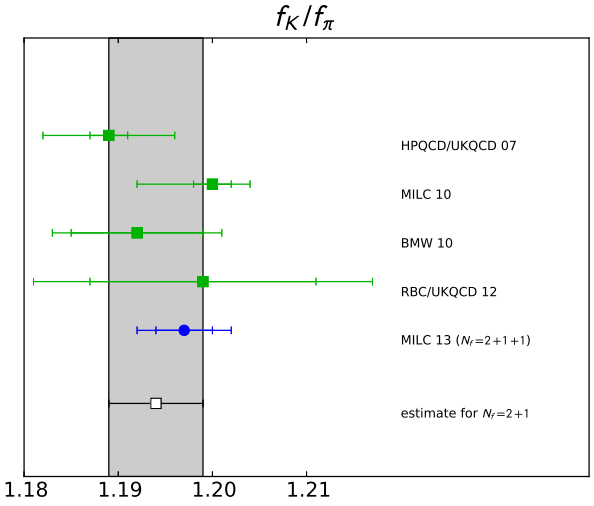

Figure 18.1: Results for f_K/f_π in the isospin limit from simulations with $N_f = 2+1$ and $N_f = 2+1+1$. These are from the HPQCD/UKQCD [37], BMW [80], MILC [81,44], and RBC/UKQCD collaborations [82]. The MILC collaboration results have been shifted upward (by $\sim 0.2\%$, following Ref. 75) since they were originally quoted for $m_u \neq m_d$. The FLAG average of the $N_f = 2+1$ results is 1.194 ± 0.005 [75].

18.3.3. ***Form factors ($K \to \pi\ell\nu$, $D \to K\ell\nu$, $B \to \pi\ell\nu$, $B \to D^{(*)}\ell\nu$)*** :

Semileptonic decay rates can be used to extract CKM matrix elements once the semileptonic form factors are known from lattice calculations. For example, the matrix element of a pseudoscalar meson P undergoing semileptonic decay to another pseudoscalar meson D is mediated by the vector current, and can be written in terms of form factors as

$$\langle D(p_D)|V_\mu|P(p_P)\rangle = f_+(q^2)(p_D + p_P - \Delta)_\mu + f_0(q^2)\Delta_\mu\,, \quad (18.14)$$

where $q = p_D - p_P$, $\Delta_\mu = (m_D^2 - m_P^2)q_\mu/q^2$ and V_μ is the quark vector current. The shape of the form factor is typically well determined by experiment, and the value of $f_+(q^2)$ at some reference value of q^2 is needed from the lattice in order to extract CKM matrix elements. Typically $f_+(q^2)$ dominates the decay rate, since the contribution from $f_0(q^2)$ is suppressed when the final state lepton is light.

The form factor $f_+(0)$ for $K \to \pi\ell\nu$ decays is highly constrained by the Ademollo-Gatto theorem [97] and chiral symmetry. Old estimates using chiral perturbation theory combined with quark models quote sub-percent precision [98], though they suffer from some model dependence. The lattice has now matched this precision while also eliminating the model dependence; good agreement with the old estimate is found [99–102]. The FLAG average is $f_+(0) = 0.967(4)$.

Charm meson semileptonic decays have been calculated by different groups using methods similar to those used for charm decay constants, and results are steadily improving in precision [103,104]. For semileptonic decays involving a bottom quark, one uses HQET or NRQCD to control the discretization errors of the bottom quark. The form factors for the semileptonic decay $B \to \pi\ell\nu$ have been calculated in unquenched lattice QCD by HPQCD [105] and Fermilab/MILC Collaborations [106]. These B semileptonic form factors are difficult to calculate at low q^2, *i.e.* when the mass of the B-meson must be balanced by a large pion momentum, in order to transfer a small momentum to the lepton pair. The low q^2 region has large discretization errors and very large statistical errors, while the high q^2 region is much more accessible to the lattice. For experiment, the opposite is true. To combine lattice and experimental results it has proved helpful to use the z-parameter expansion [107]. This provides a theoretically constrained parameterization of the entire q^2 range, and allows one to obtain $|V_{ub}|$ without model dependence [108,106].

The semileptonic decays $B \to D\ell\nu$ and $B \to D^*\ell\nu$ can be used to extract $|V_{cb}|$ once the corresponding form factors are known. At present only one unquenched calculation exists for the $B \to D^*\ell\nu$ form factor, where the Fermilab formulation of the heavy quark was adopted [109]. This calculation is done at zero-recoil because that is where the lattice systematic errors are smallest. Calculations of the necessary form factors for both processes at non-zero recoil have been done in the quenched approximation [110] using a step-scaling approach for the heavy quarks. Lattice calculations at non-zero recoil are needed in order to decrease the error associated with the extrapolation of the experimental data to the zero-recoil point.

The results discussed in this section are used in the reviews "The CKM Quark-Mixing Matrix," "V_{ud}, V_{us}, the Cabibbo Angle and CKM Unitarity," and "V_{cb} and V_{ub} CKM Matrix Elements."

18.3.4. ***Strong coupling constant*** :

As explained in Sec. 18.1.4.1, for a given lattice action, the choice of bare lattice coupling constant, $g_{\rm lat}$, determines the lattice spacing a. If one then calculates a as described in Sec. 18.1.4.1, one knows the strong coupling constant in the bare lattice scheme at the scale $1/a$, $\alpha_{\rm lat} = g_{\rm lat}^2/(4\pi)$. This is not, however, useful for comparing to results for α_s obtained from other inputs, such as deep inelastic scattering or jet shape variables. This is because the latter results give α_s in the $\overline{\rm MS}$ scheme, which is commonly used in such analyses, and the conversion factor between these two schemes is known to converge extremely poorly in perturbation theory. Instead one must use a method which directly determines α_s on the lattice in a scheme closer to $\overline{\rm MS}$.

Several such methods have been used, all following a similar strategy. One calculates a short-distance quantity K both perturbatively ($K^{\rm PT}$) and non-perturbatively ($K^{\rm NP}$) on the lattice, and requires equality: $K^{\rm NP} = K^{\rm PT} = \sum_{i=0}^{n} c_i \alpha_s^i$. Solving this equation one obtains α_s at a scale related to the quantity being used. Often, α_s thus obtained is not defined in the conventional $\overline{\rm MS}$ scheme, and one has to convert among the different schemes using perturbation theory. Unlike for the bare lattice scheme, the required conversion factors are reasonably convergent. As a final step, one uses the renormalization group to run the resulting coupling to a canonical scale (such as M_Z).

In the work of the HPQCD collaboration [111], the short-distance quantities are Wilson loops of several sizes and their ratios. These quantities are perturbatively calculated to $\mathcal{O}(\alpha_s^3)$ using the V-scheme defined through the heavy quark potential. The coefficients of even higher orders are estimated using the data at various values of a.

Another choice of short-distance quantities is to use current-current correlators. Appropriate moments of these correlators are ultraviolet finite, and by matching lattice results to the *continuum* perturbative predictions, one can directly extract the $\overline{\rm MS}$ coupling. The JLQCD collaboration [112] uses this approach with light overlap fermions, while the HPQCD collaboration uses charm-quark correlators and HISQ fermions [113]. Yet another choice of short-distance quantity is the static-quark potential, where the lattice result for the potential is compared to perturbative calculations; this method was used to compute α_s within 2+1 flavor QCD [114]. The ETM Collaboration obtains α_s by a comparison of lattice data for the ghost-gluon coupling with that of perturbation theory [115], providing the first determination of α_s with 2+1+1 flavors of dynamical quarks.

With a definition of α_s given using the Schrödinger functional, one can non-perturbatively control the evolution of α_s to high-energy scales, such as 100 GeV, where the perturbative expansion converges very well. This method developed by the ALPHA collaboration [47] has been applied to 2+1-flavor QCD by the PACS-CS collaboration [116].

The various lattice methods for calculating α_s have significantly different sources of systematic error. Thus the good agreement between the approaches (which can be seen in the "Quantum Chromodynamics" review) provides a strong check on the final result.

18.3.5. ***Quark masses*** :

Once the quark mass parameters are tuned in the lattice action, the remaining task is to convert them to those of the conventional definition. Since the quarks do not appear as asymptotic states due to confinement, the pole mass of the quark propagator is not a physical quantity. Instead, one defines the quark mass after subtracting the ultra-violet divergences in some particular way. The conventional choice is again the $\overline{\rm MS}$ scheme at a canonical scale such as 2 or 3 GeV.

As discussed in Sec. 18.1.5.4, one must convert the lattice bare quark mass to that in the $\overline{\rm MS}$ scheme. The most common approaches used for doing so are perturbation theory and the NPR method, the latter using an RI/MOM intermediate scheme.

Alternatively, one can use a definition based on the Schrödinger functional, which allows one to evolve the quark mass to a high scale non-perturbatively [117]. In practice, one can reach scales as high as ∼100 GeV, at which matching to the $\overline{\rm MS}$ scheme can be reliably calculated in perturbation theory.

Another approach available for heavy quarks is to match current-current correlators at short distances calculated on the lattice to those obtained in continuum perturbation theory in the $\overline{\rm MS}$ scheme. This has allowed an accurate determination of $m_c(\overline{\rm MS})$ [118].

Results are summarized in the review of "Quark Masses".

18.3.6. ***Other applications*** :

In this review we have concentrated on applications of LQCD that are relevant to the quantities discussed in the Review of Particle Properties. We have not discussed at all several other applications which are being actively pursued by simulations. Here we list the major such applications. The reader can consult the texts [2,3,4] for further details, as well as the proceedings of recent lattice conferences [119].

LQCD can be used, in principle, to simulate QCD at non-zero temperature and density, and in particular to study how confinement and chiral-symmetry breaking are lost as T and μ (the chemical

potential) are increased. This is of relevance to heavy-ion collisions, the early Universe and neutron-star structure. In practice, finite temperature simulations are computationally tractable and relatively mature, while simulations at finite μ suffer from a "sign problem" and are at a rudimentary stage.

Another topic under active investigation is nucleon structure (generalized structure functions) and inter-nucleon interactions.

Finally, we note that there is much recent interest in studying QCD-like theories with more fermions, possibly in other representations of the gauge group. The main interest is to find nearly conformal theories which might be candidates for "walking technicolor" models.

18.4. Outlook

While LQCD calculations have made major strides in the last decade, and are now playing an important role in constraining the Standard Model, there are many calculations that could be done in principle but are not yet mature due to limitations in computational resources. As we move to exascale resources (e.g. 10^{18} floating point operations per second), the list of mature calculations will grow. Examples that we expect to mature in the next few years are results for excited hadrons, including quark-model exotics; $\langle N|\bar{s}s|N\rangle$ and related matrix elements (needed for dark-matter searches); results for moments of structure functions; $K \to \pi\pi$ amplitudes (allowing a prediction of ϵ'/ϵ from the Standard Model); $\bar{K} \leftrightarrow K$ and $\bar{B} \leftrightarrow B$ mixing amplitudes from operators arising in models of new physics (allowing one to constrain these models in a manner complementary to the direct searches at the LHC); hadronic vacuum polarization contributions to muon $g-2$, the running of $\alpha_{\rm EM}$ and α_s; $\pi \to \gamma\gamma$ and related amplitudes; and perhaps the long-distance contribution to $\overline{K} \leftrightarrow K$ mixing and the light-by-light contribution to muon $g-2$. There will also be steady improvement in the precision attained for the mature quantities discussed above. As already noted, this will ultimately require simulations with $m_u \neq m_d$ and including electromagnetic effects.

18.5. Acknowledgments

We are grateful to Jean-Francois Arguin, Christine Davies, Aida El-Khadra, Max Hansen, Tony Kennedy, Andreas Kronfeld, Laurent Lellouch, Vittorio Lubicz, Paul Mackenzie and Hartmut Wittig for comments.

19. STRUCTURE FUNCTIONS

Updated September 2013 by B. Foster (University of Hamburg/DESY), A.D. Martin (University of Durham), and M.G. Vincter (Carleton University).

19.1. Deep inelastic scattering

High-energy lepton-nucleon scattering (deep inelastic scattering) plays a key role in determining the partonic structure of the proton. The process $\ell N \to \ell' X$ is illustrated in Fig. 19.1. The filled circle in this figure represents the internal structure of the proton which can be expressed in terms of structure functions.

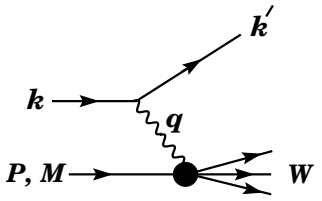

Figure 19.1: Kinematic quantities for the description of deep inelastic scattering. The quantities k and k' are the four-momenta of the incoming and outgoing leptons, P is the four-momentum of a nucleon with mass M, and W is the mass of the recoiling system X. The exchanged particle is a γ, $W^{\pm}$, or Z; it transfers four-momentum $q = k - k'$ to the nucleon.

Invariant quantities:

$\nu = \dfrac{q\cdot P}{M} = E - E'$ is the lepton's energy loss in the nucleon rest frame (in earlier literature sometimes $\nu = q\cdot P$). Here, E and E' are the initial and final lepton energies in the nucleon rest frame.

$Q^2 = -q^2 = 2(EE' - \vec{k}\cdot\vec{k}\,') - m_\ell^2 - m_{\ell'}^2$ where $m_\ell(m_{\ell'})$ is the initial (final) lepton mass. If $EE'\sin^2(\theta/2) \gg m_\ell^2,\, m_{\ell'}^2$, then

$\approx 4EE'\sin^2(\theta/2)$, where θ is the lepton's scattering angle with respect to the lepton beam direction.

$x = \dfrac{Q^2}{2M\nu}$ where, in the parton model, x is the fraction of the nucleon's momentum carried by the struck quark.

$y = \dfrac{q\cdot P}{k\cdot P} = \dfrac{\nu}{E}$ is the fraction of the lepton's energy lost in the nucleon rest frame.

$W^2 = (P+q)^2 = M^2 + 2M\nu - Q^2$ is the mass squared of the system X recoiling against the scattered lepton.

$s = (k+P)^2 = \dfrac{Q^2}{xy} + M^2 + m_\ell^2$ is the center-of-mass energy squared of the lepton-nucleon system.

The process in Fig. 19.1 is called deep ($Q^2 \gg M^2$) inelastic ($W^2 \gg M^2$) scattering (DIS). In what follows, the masses of the initial and scattered leptons, m_ℓ and $m_{\ell'}$, are neglected.

19.1.1. *DIS cross sections* :

The double-differential cross section for deep inelastic scattering can be expressed in terms of kinematic variables in several ways.

$$\frac{d^2\sigma}{dx\,dy} = x\,(s-M^2)\,\frac{d^2\sigma}{dx\,dQ^2} = \frac{2\pi\,M\nu}{E'}\frac{d^2\sigma}{d\Omega_{\rm Nrest}\,dE'}\,. \qquad (19.1)$$

In lowest-order perturbation theory, the cross section for the scattering of polarized leptons on polarized nucleons can be expressed in terms of the products of leptonic and hadronic tensors associated with the coupling of the exchanged bosons at the upper and lower vertices in Fig. 19.1 (see Refs. 1–4)

$$\frac{d^2\sigma}{dxdy} \;=\; \frac{2\pi y\alpha^2}{Q^4}\,\sum_j\,\eta_j\,L_j^{\mu\nu}\,W_{\mu\nu}^j\,. \qquad (19.2)$$

For neutral-current processes, the summation is over $j = \gamma, Z$ and γZ representing photon and Z exchange and the interference between them, whereas for charged-current interactions there is only W exchange, $j = W$. (For transverse nucleon polarization, there is a dependence on the azimuthal angle of the scattered lepton.) The lepton tensor $L_{\mu\nu}$ is associated with the coupling of the exchange boson to the leptons. For incoming leptons of charge $e = \pm 1$ and helicity $\lambda = \pm 1$,

$$\begin{aligned} L_{\mu\nu}^{\gamma} &= 2\left(k_\mu k'_\nu + k'_\mu k_\nu - (k\cdot k' - m_\ell^2)g_{\mu\nu} - i\lambda\varepsilon_{\mu\nu\alpha\beta}k^\alpha k'^\beta\right), \\ L_{\mu\nu}^{\gamma Z} &= (g_V^e + e\lambda g_A^e)\,L_{\mu\nu}^{\gamma}, \qquad L_{\mu\nu}^{Z} = (g_V^e + e\lambda g_A^e)^2\,L_{\mu\nu}^{\gamma}, \\ L_{\mu\nu}^{W} &= (1+e\lambda)^2\,L_{\mu\nu}^{\gamma}, \end{aligned} \qquad (19.3)$$

where $g_V^e = -\frac{1}{2} + 2\sin^2\theta_W, \qquad g_A^e = -\frac{1}{2}$.

Although here the helicity formalism is adopted, an alternative approach is to express the tensors in Eq. (19.3) in terms of the polarization of the lepton.

The factors η_j in Eq. (19.2) denote the ratios of the corresponding propagators and couplings to the photon propagator and coupling squared

$$\begin{aligned} \eta_\gamma \;&=\; 1 \quad ; \quad \eta_{\gamma Z} \;=\; \left(\frac{G_F M_Z^2}{2\sqrt{2}\pi\alpha}\right)\left(\frac{Q^2}{Q^2+M_Z^2}\right); \\ \eta_Z \;&=\; \eta_{\gamma Z}^2 \quad ; \quad \eta_W \;=\; \tfrac{1}{2}\left(\frac{G_F M_W^2}{4\pi\alpha}\,\frac{Q^2}{Q^2+M_W^2}\right)^2. \end{aligned} \qquad (19.4)$$

The hadronic tensor, which describes the interaction of the appropriate electroweak currents with the target nucleon, is given by

$$W_{\mu\nu} \;=\; \frac{1}{4\pi}\int d^4z\; e^{iq\cdot z}\,\left\langle P,S\left|\left[J_\mu^\dagger(z), J_\nu(0)\right]\right|\,P,S\right\rangle, \qquad (19.5)$$

where S denotes the nucleon-spin 4-vector, with $S^2 = -M^2$ and $S\cdot P = 0$.

19.2. Structure functions of the proton

The structure functions are defined in terms of the hadronic tensor (see Refs. 1–3)

$$\begin{aligned} W_{\mu\nu} = &\left(-g_{\mu\nu} + \frac{q_\mu q_\nu}{q^2}\right)\,F_1(x,Q^2) + \frac{\hat{P}_\mu\hat{P}_\nu}{P\cdot q}\,F_2(x,Q^2) \\ &- i\varepsilon_{\mu\nu\alpha\beta}\,\frac{q^\alpha P^\beta}{2P\cdot q}\,F_3(x,Q^2) \\ &+ i\varepsilon_{\mu\nu\alpha\beta}\,\frac{q^\alpha}{P\cdot q}\,\left[S^\beta g_1(x,Q^2) + \left(S^\beta - \frac{S\cdot q}{P\cdot q}\,P^\beta\right)\,g_2(x,Q^2)\right] \\ &+ \frac{1}{P\cdot q}\,\left[\tfrac{1}{2}\left(\hat{P}_\mu\hat{S}_\nu + \hat{S}_\mu\hat{P}_\nu\right) - \frac{S\cdot q}{P\cdot q}\,\hat{P}_\mu\hat{P}_\nu\right]\,g_3(x,Q^2) \\ &+ \frac{S\cdot q}{P\cdot q}\,\left[\frac{\hat{P}_\mu\hat{P}_\nu}{P\cdot q}\,g_4(x,Q^2) + \left(-g_{\mu\nu} + \frac{q_\mu q_\nu}{q^2}\right)\,g_5(x,Q^2)\right] \end{aligned} \qquad (19.6)$$

where

$$\hat{P}_\mu \;=\; P_\mu - \frac{P\cdot q}{q^2}\,q_\mu, \qquad \hat{S}_\mu \;=\; S_\mu - \frac{S\cdot q}{q^2}\,q_\mu\,. \qquad (19.7)$$

In Ref. 2, the definition of $W_{\mu\nu}$ with $\mu \leftrightarrow \nu$ is adopted, which changes the sign of the $\varepsilon_{\mu\nu\alpha\beta}$ terms in Eq. (19.6), although the formulae given below are unchanged. Ref. 1 tabulates the relation between the structure functions defined in Eq. (19.6) and other choices available in the literature.

The cross sections for neutral- and charged-current deep inelastic scattering on unpolarized nucleons can be written in terms of the structure functions in the generic form

$$\begin{aligned} \frac{d^2\sigma^i}{dxdy} \;=\; &\frac{4\pi\alpha^2}{xyQ^2}\,\eta^i\left\{\left(1 - y - \frac{x^2y^2M^2}{Q^2}\right)\,F_2^i\right. \\ &\left. + y^2xF_1^i \mp \left(y - \frac{y^2}{2}\right)\,xF_3^i\right\}, \end{aligned} \qquad (19.8)$$

where i = NC, CC corresponds to neutral-current ($eN \to eX$) or charged-current ($eN \to \nu X$ or $\nu N \to eX$) processes, respectively. For incoming neutrinos, $L^W_{\mu\nu}$ of Eq. (19.3) is still true, but with e, λ corresponding to the outgoing charged lepton. In the last term of Eq. (19.8), the $-$ sign is taken for an incoming e^+ or $\overline{\nu}$ and the $+$ sign for an incoming e^- or ν. The factor $\eta^{\rm NC} = 1$ for unpolarized $e^\pm$ beams, whereas*

$$\eta^{\rm CC} \;=\; (1 \pm \lambda)^2 \eta_W \tag{19.9}$$

with $\pm$ for $\ell^\pm$; and where λ is the helicity of the incoming lepton and η_W is defined in Eq. (19.4); for incoming neutrinos $\eta^{\rm CC} = 4\eta_W$. The CC structure functions, which derive exclusively from W exchange, are

$$F_1^{\rm CC} = F_1^W,\; F_2^{\rm CC} = F_2^W,\; xF_3^{\rm CC} = xF_3^W. \tag{19.10}$$

The NC structure functions $F_2^\gamma, F_2^{\gamma Z}, F_2^Z$ are, for $e^\pm N \to e^\pm X$, given by Ref. 5,

$$F_2^{\rm NC} \;=\; F_2^\gamma \;-\; (g_V^e \pm \lambda g_A^e)\eta_{\gamma Z} F_2^{\gamma Z} \;+\; (g_V^{e\,2} + g_A^{e\,2} \pm 2\lambda g_V^e g_A^e)\;\eta_Z F_2^Z \tag{19.11}$$

and similarly for $F_1^{\rm NC}$, whereas

$$xF_3^{\rm NC} = \; -(g_A^e \pm \lambda g_V^e)\eta_{\gamma Z} xF_3^{\gamma Z} + [2g_V^e g_A^e \pm \lambda(g_V^{e\,2} + g_A^{e\,2})]\eta_Z xF_3^Z \;. \tag{19.12}$$

The polarized cross-section difference

$$\Delta\sigma \;=\; \sigma(\lambda_n = -1, \lambda_\ell) \;-\; \sigma(\lambda_n = 1, \lambda_\ell) \;, \tag{19.13}$$

where λ_ℓ, λ_n are the helicities (± 1) of the incoming lepton and nucleon, respectively, may be expressed in terms of the five structure functions $g_{1,\ldots 5}(x, Q^2)$ of Eq. (19.6). Thus,

$$\begin{aligned}\frac{d^2\Delta\sigma^i}{dxdy} \;=\; & \frac{8\pi\alpha^2}{xyQ^2}\;\eta^i \left\{ -\lambda_\ell y \left(2 - y - 2x^2y^2\frac{M^2}{Q^2}\right)\; xg_1^i + \lambda_\ell 4x^3y^2\;\frac{M^2}{Q^2}\;g_2^i \right. \\ & +\; 2x^2 y \frac{M^2}{Q^2}\left(1 - y - x^2y^2\frac{M^2}{Q^2}\right)\; g_3^i \\ & \left. -\;\left(1 + 2x^2y\frac{M^2}{Q^2}\right)\left[\left(1 - y - x^2y^2\frac{M^2}{Q^2}\right)\; g_4^i + xy^2 g_5^i\right]\right\}\end{aligned} \tag{19.14}$$

with i = NC or CC as before. The Eq. (19.13) corresponds to the difference of antiparallel minus parallel spins of the incoming particles for e^- or ν initiated reactions, but the difference of parallel minus antiparallel for e^+ or $\overline{\nu}$ initiated processes. For longitudinal nucleon polarization, the contributions of g_2 and g_3 are suppressed by powers of M^2/Q^2. These structure functions give an unsuppressed contribution to the cross section for transverse polarization [1], but in this case the cross-section difference vanishes as $M/Q \to 0$.

Because the same tensor structure occurs in the spin-dependent and spin-independent parts of the hadronic tensor of Eq. (19.6) in the $M^2/Q^2 \to 0$ limit, the differential cross-section difference of Eq. (19.14) may be obtained from the differential cross section Eq. (19.8) by replacing

$$F_1 \;\to\; -g_5 \;, \quad F_2 \;\to\; -g_4 \;, \quad F_3 \;\to\; 2g_1 \;, \tag{19.15}$$

and multiplying by two, since the total cross section is the average over the initial-state polarizations. In this limit, Eq. (19.8) and Eq. (19.14) may be written in the form

$$\begin{aligned}\frac{d^2\sigma^i}{dxdy} &= \frac{2\pi\alpha^2}{xyQ^2}\;\eta^i \left[Y_+ F_2^i \mp Y_- xF_3^i - y^2 F_L^i\right], \\ \frac{d^2\Delta\sigma^i}{dxdy} &= \frac{4\pi\alpha^2}{xyQ^2}\;\eta^i \left[-Y_+ g_4^i \mp Y_- 2xg_1^i + y^2 g_L^i\right],\end{aligned} \tag{19.16}$$

with i = NC or CC, where $Y_\pm = 1 \pm (1-y)^2$ and

$$F_L^i \;=\; F_2^i \;-\; 2xF_1^i \;, \qquad g_L^i \;=\; g_4^i \;-\; 2xg_5^i \;. \tag{19.17}$$

In the naive quark-parton model, the analogy with the Callan-Gross relations [6] $F_L^i = 0$, are the Dicus relations [7] $g_L^i = 0$. Therefore, there are only two independent polarized structure functions: g_1 (parity conserving) and g_5 (parity violating), in analogy with the unpolarized structure functions F_1 and F_3.

19.2.1. *Structure functions in the quark-parton model* :

In the quark-parton model [8,9], contributions to the structure functions F^i and g^i can be expressed in terms of the quark distribution functions $q(x, Q^2)$ of the proton, where $q = u, \overline{u}, d, \overline{d}$ etc. The quantity $q(x, Q^2)dx$ is the number of quarks (or antiquarks) of designated flavor that carry a momentum fraction between x and $x + dx$ of the proton's momentum in a frame in which the proton momentum is large.

For the neutral-current processes $ep \to eX$,

$$\begin{aligned}\left[F_2^\gamma,\; F_2^{\gamma Z},\; F_2^Z\right] &= x\sum_q \left[e_q^2,\; 2e_q g_V^q,\; g_V^{q\,2} + g_A^{q\,2}\right]\;\; (q + \overline{q})\;, \\ \left[F_3^\gamma,\; F_3^{\gamma Z},\; F_3^Z\right] &= \sum_q \left[0,\; 2e_q g_A^q,\; 2g_V^q g_A^q\right]\;\; (q - \overline{q})\;, \\ \left[g_1^\gamma,\; g_1^{\gamma Z},\; g_1^Z\right] &= \tfrac{1}{2}\sum_q \left[e_q^2,\; 2e_q g_V^q,\; g_V^{q\,2} + g_A^{q\,2}\right]\;\; (\Delta q + \Delta\overline{q})\;, \\ \left[g_5^\gamma,\; g_5^{\gamma Z},\; g_5^Z\right] &= \sum_q \left[0,\; e_q g_A^q,\; g_V^q g_A^q\right]\;\; (\Delta q - \Delta\overline{q})\;,\end{aligned} \tag{19.18}$$

where $g_V^q = \pm\frac{1}{2} - 2e_q \sin^2\theta_W$ and $g_A^q = \pm\frac{1}{2}$, with $\pm$ according to whether q is a $u-$ or $d-$type quark respectively. The quantity Δq is the difference $q\uparrow - q\downarrow$ of the distributions with the quark spin parallel and antiparallel to the proton spin.

For the charged-current processes $e^- p \to \nu X$ and $\overline{\nu} p \to e^+ X$, the structure functions are:

$$\begin{aligned}F_2^{W^-} &= 2x(u + \overline{d} + \overline{s} + c\ldots)\;, \\ F_3^{W^-} &= 2(u - \overline{d} - \overline{s} + c\ldots)\;, \\ g_1^{W^-} &= (\Delta u + \Delta\overline{d} + \Delta\overline{s} + \Delta c\ldots)\;, \\ g_5^{W^-} &= (-\Delta u + \Delta\overline{d} + \Delta\overline{s} - \Delta c\ldots)\;,\end{aligned} \tag{19.19}$$

where only the active flavors have been kept and where CKM mixing has been neglected. For $e^+ p \to \overline{\nu} X$ and $\nu p \to e^- X$, the structure functions F^{W^+}, g^{W^+} are obtained by the flavor interchanges $d \leftrightarrow u, s \leftrightarrow c$ in the expressions for F^{W^-}, g^{W^-}. The structure functions for scattering on a neutron are obtained from those of the proton by the interchange $u \leftrightarrow d$. For both the neutral- and charged-current processes, the quark-parton model predicts $2xF_1^i = F_2^i$ and $g_4^i = 2xg_5^i$.

Neglecting masses, the structure functions g_2 and g_3 contribute only to scattering from transversely polarized nucleons (for which $S \cdot q = 0$), and have no simple interpretation in terms of the quark-parton model. They arise from off-diagonal matrix elements $\langle P, \lambda' | [J_\mu^\dagger(z), J_\nu(0)] | P, \lambda\rangle$, where the proton helicities satisfy $\lambda' \neq \lambda$. In fact, the leading-twist contributions to both g_2 and g_3 are both twist-2 and twist-3, which contribute at the same order of Q^2. The Wandzura-Wilczek relation [10] expresses the twist-2 part of g_2 in terms of g_1 as

$$g_2^i(x) \;=\; -g_1^i(x) \;+\; \int_x^1 \frac{dy}{y}\; g_1^i(y)\;. \tag{19.20}$$

However, the twist-3 component of g_2 is unknown. Similarly, there is a relation expressing the twist-2 part of g_3 in terms of g_4. A complete set of relations, including M^2/Q^2 effects, can be found in Ref. 11.

19.2.2. *Structure functions and QCD* :

One of the most striking predictions of the quark-parton model is that the structure functions F_i, g_i *scale*, i.e., $F_i(x, Q^2) \to F_i(x)$ in the Bjorken limit that Q^2 and $\nu \to \infty$ with x fixed [12]. This property is related to the assumption that the transverse momentum of the partons in the infinite-momentum frame of the proton is small. In QCD, however, the radiation of hard gluons from the quarks violates this assumption, leading to logarithmic scaling violations, which are particularly large at small x, see Fig. 19.2. The radiation of gluons produces the evolution of the structure functions. As Q^2 increases, more and more gluons are radiated, which in turn split into $q\overline{q}$ pairs. This process leads both to the softening of the initial quark momentum distributions and to the growth of the gluon density and the $q\overline{q}$ sea as x decreases.

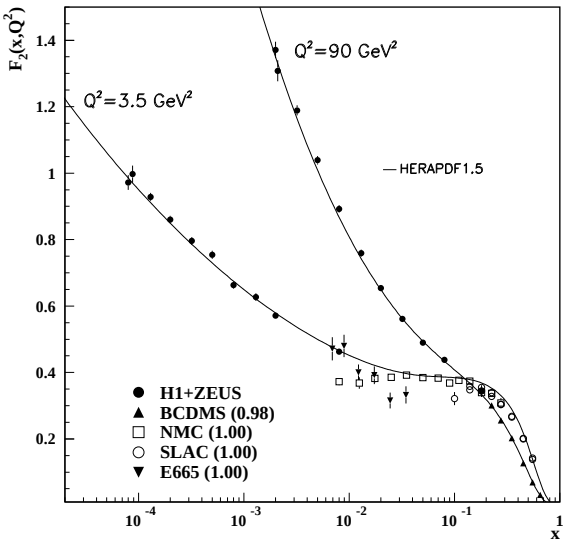

Figure 19.2: The proton structure function F_2^p given at two Q^2 values (3.5 GeV^2 and 90 GeV^2), which exhibit scaling at the 'pivot' point $x \sim 0.14$. See the captions in Fig. 19.8 and Fig. 19.10 for the references of the data. The various data sets have been renormalized by the factors shown in brackets in the key to the plot, which were globally determined in the full HERAPDF analysis [13]. In practice, data for the reduced cross section, $F_2(x,Q^2) - (y^2/Y_+)F_L(x,Q^2)$, are fitted, rather than F_2 and F_L separately.

In QCD, the above process is described in terms of scale-dependent parton distributions $f_a(x,\mu^2)$, where $a = g$ or q and, typically, μ is the scale of the probe Q. For $Q^2 \gg M^2$, the structure functions are of the form

$$F_i = \sum_a C_i^a \otimes f_a, \tag{19.21}$$

where $\otimes$ denotes the convolution integral

$$C \otimes f = \int_x^1 \frac{dy}{y}\, C(y)\, f\left(\frac{x}{y}\right) , \tag{19.22}$$

and where the coefficient functions C_i^a are given as a power series in α_s. The parton distribution f_a corresponds, at a given x, to the density of parton a in the proton integrated over transverse momentum k_t up to μ. Its evolution in μ is described in QCD by a DGLAP equation (see Refs. 14–17) which has the schematic form

$$\frac{\partial f_a}{\partial \ln \mu^2} \sim \frac{\alpha_s(\mu^2)}{2\pi} \sum_b (P_{ab} \otimes f_b) , \tag{19.23}$$

where the P_{ab}, which describe the parton splitting $b \to a$, are also given as a power series in α_s. Although perturbative QCD can predict, via Eq. (19.23), the evolution of the parton distribution functions from a particular scale, μ_0, these DGLAP equations cannot predict them *a priori* at any particular μ_0. Thus they must be measured at a starting point μ_0 before the predictions of QCD can be compared to the data at other scales, μ. In general, all observables involving a hard hadronic interaction (such as structure functions) can be expressed as a convolution of calculable, process-dependent coefficient functions and these universal parton distributions, e.g. Eq. (19.21).

It is often convenient to write the evolution equations in terms of the gluon, non-singlet (q^{NS}) and singlet (q^S) quark distributions, such that

$$q^{NS} = q_i - \overline{q}_i \quad (\text{or } q_i - q_j), \qquad q^S = \sum_i (q_i + \overline{q}_i) . \tag{19.24}$$

The non-singlet distributions have non-zero values of flavor quantum numbers, such as isospin and baryon number. The DGLAP evolution equations then take the form

$$\frac{\partial q^{NS}}{\partial \ln \mu^2} = \frac{\alpha_s(\mu^2)}{2\pi}\, P_{qq} \otimes q^{NS} ,$$

$$\frac{\partial}{\partial \ln \mu^2} \begin{pmatrix} q^S \\ g \end{pmatrix} = \frac{\alpha_s(\mu^2)}{2\pi} \begin{pmatrix} P_{qq} & 2n_f\, P_{qg} \\ P_{gq} & P_{gg} \end{pmatrix} \otimes \begin{pmatrix} q^S \\ g \end{pmatrix}, \tag{19.25}$$

where P are splitting functions that describe the probability of a given parton splitting into two others, and n_f is the number of (active) quark flavors. The leading-order Altarelli-Parisi [16] splitting functions are

$$P_{qq} = \frac{4}{3}\left[\frac{1+x^2}{(1-x)}\right]_+ = \frac{4}{3}\left[\frac{1+x^2}{(1-x)_+}\right] + 2\delta(1-x) , \tag{19.26}$$

$$P_{qg} = \frac{1}{2}\left[x^2 + (1-x)^2\right] , \tag{19.27}$$

$$P_{gq} = \frac{4}{3}\left[\frac{1+(1-x)^2}{x}\right] , \tag{19.28}$$

$$P_{gg} = 6\left[\frac{1-x}{x} + x(1-x) + \frac{x}{(1-x)_+}\right] + \left[\frac{11}{2} - \frac{n_f}{3}\right]\delta(1-x), \tag{19.29}$$

where the notation $[F(x)]_+$ defines a distribution such that for any sufficiently regular test function, $f(x)$,

$$\int_0^1 dx f(x)[F(x)]_+ = \int_0^1 dx\, (f(x) - f(1))F(x) . \tag{19.30}$$

In general, the splitting functions can be expressed as a power series in α_s. The series contains both terms proportional to $\ln \mu^2$ and to $\ln\ 1/x$. The leading-order DGLAP evolution sums up the $(\alpha_s \ln \mu^2)^n$ contributions, while at next-to-leading order (NLO) the sum over the $\alpha_s(\alpha_s \ln \mu^2)^{n-1}$ terms is included [18,19]. In fact, the NNLO contributions to the splitting functions and the DIS coefficient functions are now also all known [20–22].

In the kinematic region of very small x, it is essential to sum leading terms in $\ln\ 1/x$, independent of the value of $\ln \mu^2$. At leading order, LLx, this is done by the BFKL equation for the unintegrated distributions (see Refs. [23,24]). The leading-order $(\alpha_s \ln(1/x))^n$ terms result in a power-like growth, $x^{-\omega}$ with $\omega = (12\alpha_s \ln 2)/\pi$, at asymptotic values of $\ln\ 1/x$. More recently, the next-to-leading $\ln\ 1/x$ (NLLx) contributions have become available [25,26]. They are so large (and negative) that the result appears to be perturbatively unstable. Methods, based on a combination of collinear and small-x resummations, have been developed which reorganize the perturbative series into a more stable hierarchy [27–30]. There are indications that small-x resummations become necessary for sufficient precision for $x \lesssim 10^{-3}$ at low scales. On the other hand, there is no convincing indication for a 'non-linear' regime, for $Q^2 \gtrsim 2$ GeV^2, in which the gluon density would be so high that gluon-gluon recombination effects would become significant.

The precision of the experimental data demands that at least NLO, and preferably NNLO, DGLAP evolution be used in comparisons between QCD theory and experiment. Beyond the leading order, it is necessary to specify, and to use consistently, both a renormalization and a factorization scheme. The renormalization scheme used almost universally is the modified minimal subtraction ($\overline{\rm MS}$) scheme [31,32]. There are two popular choices for factorization scheme, in which the form of the correction for each structure function is different. The most-used factorization scheme is again $\overline{\rm MS}$ [33]. However, sometimes the DIS [34] scheme is adopted, in which there are no higher-order corrections to the F_2 structure function. The two schemes differ in how the non-divergent pieces are assimilated in the parton distribution functions.

The discussion above relates to the Q^2 behavior of leading-twist (twist-2) contributions to the structure functions. Higher-twist terms, which involve their own non-perturbative input, exist. These die off as powers of Q; specifically twist-n terms are damped by $1/Q^{n-2}$. Provided a cut, say $W^2 > 15$ GeV^2 is imposed, the higher-twist terms appear to be numerically unimportant for Q^2 above a few GeV^2, except for x close to 1 [35–37].

Table 19.1: The main processes relevant to global PDF analyses, ordered in three groups: fixed-target experiments, HERA and the $p\bar{p}$ Tevatron / pp LHC. For each process we give an indication of their dominant partonic subprocesses, the primary partons which are probed and the approximate range of x constrained by the data.

Process	Subprocess	Partons	x range
$\ell^\pm\{p,n\} \to \ell^\pm X$	$\gamma^* q \to q$	$q, \bar{q}, g$	$x \gtrsim 0.01$
$\ell^\pm n/p \to \ell^\pm X$	$\gamma^* d/u \to d/u$	d/u	$x \gtrsim 0.01$
$pp \to \mu^+\mu^- X$	$u\bar{u}, d\bar{d} \to \gamma^*$	$\bar{q}$	$0.015 \lesssim x \lesssim 0.35$
$pn/pp \to \mu^+\mu^- X$	$(u\bar{d})/(u\bar{u}) \to \gamma^*$	$\bar{d}/\bar{u}$	$0.015 \lesssim x \lesssim 0.35$
$\nu(\bar{\nu})\, N \to \mu^-(\mu^+)\, X$	$W^* q \to q'$	$q, \bar{q}$	$0.01 \lesssim x \lesssim 0.5$
$\nu\, N \to \mu^-\mu^+\, X$	$W^* s \to c$	s	$0.01 \lesssim x \lesssim 0.2$
$\bar{\nu}\, N \to \mu^+\mu^-\, X$	$W^* \bar{s} \to \bar{c}$	$\bar{s}$	$0.01 \lesssim x \lesssim 0.2$
$e^\pm p \to e^\pm X$	$\gamma^* q \to q$	$g, q, \bar{q}$	$10^{-4} \lesssim x \lesssim 0.1$
$e^+ p \to \bar{\nu}\, X$	$W^+\{d,s\} \to \{u,c\}$	d, s	$x \gtrsim 0.01$
$e^\pm p \to e^\pm c\bar{c}X, e^\pm b\bar{b}X$	$\gamma^* c \to c$, $\gamma^* g \to c\bar{c}$	c, b, g	$10^{-4} \lesssim x \lesssim 0.01$
$e^\pm p \to$ jet$+X$	$\gamma^* g \to q\bar{q}$	g	$0.01 \lesssim x \lesssim 0.1$
$p\bar{p}, pp \to$ jet$+X$	$gg, qg, qq \to 2j$	g, q	$0.005 \lesssim x \lesssim 0.5$
$p\bar{p} \to (W^\pm \to \ell^\pm\nu)\, X$	$ud \to W^+, \bar{u}\bar{d} \to W^-$	$u, d, \bar{u}, \bar{d}$	$x \gtrsim 0.05$
$pp \to (W^\pm \to \ell^\pm\nu)\, X$	$u\bar{d} \to W^+, d\bar{u} \to W^-$	$u, d, \bar{u}, \bar{d}, g$	$x \gtrsim 0.001$
$p\bar{p}(pp) \to (Z \to \ell^+\ell^-)X$	$uu, dd, ..(u\bar{u}, ..) \to Z$	$u, d, ..(g)$	$x \gtrsim 0.001$
$pp \to W^- c$, $W^+\bar{c}$	$gs \to W^- c$	$s, \bar{s}$	$x \sim 0.01$
$pp \to (\gamma^* \to \ell^+\ell^-)X$	$u\bar{u}, d\bar{d}, .. \to \gamma^*$	$\bar{q}, g$	$x \gtrsim 10^{-5}$
$pp \to b\bar{b}\, X$, $t\bar{t}X$	$gg \to b\bar{b}$, $t\bar{t}$	g	$x \gtrsim 10^{-5}, 10^{-2}$
$pp \to$ exclusive J/ψ, Υ	$\gamma^*(gg) \to J/\psi$, Υ	g	$x \gtrsim 10^{-5}, 10^{-4}$
$pp \to \gamma\, X$	$gq \to \gamma q$, $g\bar{q} \to \gamma\bar{q}$	g	$x \gtrsim 0.005$

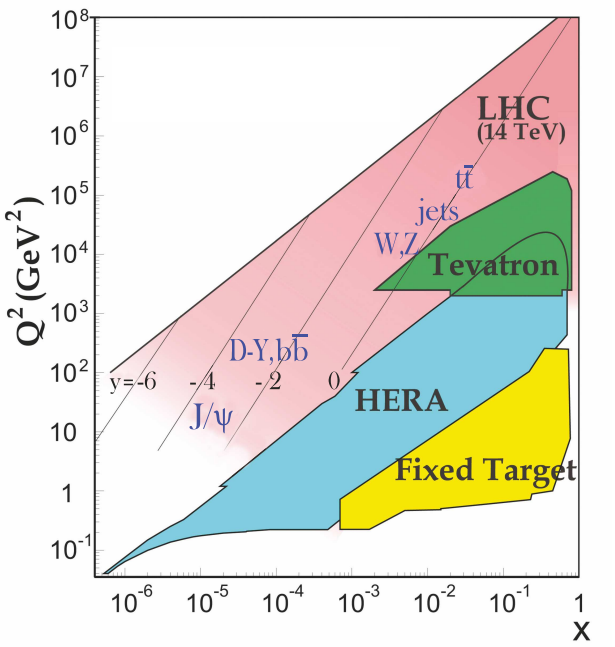

Figure 19.3: Kinematic domains in x and Q^2 probed by fixed-target and collider experiments. Some of the final states accessible at the LHC are indicated in the appropriate regions, where y is the rapidity. The incoming partons have $x_{1,2} = (M/14\ \text{TeV})e^{\pm y}$ with $Q = M$ where M is the mass of the state shown in blue in the figure. For example, exclusive J/ψ production at high $|y|$ at the LHC may probe the gluon PDF down to $x \sim 10^{-5}$.

19.3. Determination of parton distributions
