KEYWORDS: bis-µ-oxo uranium complex, CO2 activation, magnetism, electronic structure

Abstract: In a multiple bond metathesis reaction, the tacn-anchored neopentyl (nP)-substituted tris-aryloxide U III complex [[{(nP,MeArO)3tacn}U III] (1) reacts with mesitylazide and CO2 to form mesitylisocyanate and the dinuclear bis-µ-oxo bridged U V/UV complex [{[(nP,MeArO)3tacn]UV}2(µ-O)2] (3). This reaction proceeds via the mononuclear U V imido intermediate [{[(nP,MeArO)3tacn]-U V(NMes)} (2), which has been synthesized and fully characterized independently. The dimeric UV oxo species shows rich redox behaviour: Complex 3 can be reduced by one and two electrons, respectively; thus, yielding the mixed-valent U IV/UV bis-µ-oxo [K(crypt)][{{(nP,MeArO)3tacn}U IV/V}2(µ-O)2] (7) and the U IV/UV bis-µ-oxo complex K2[{[(nP,MeArO)3tacn]U IV}2(µ-O)2] (6). In addition, complex 3 can be oxidized to provide the mononuclear uranium(VI) oxo complexes [{[(nP,MeArO)3tacn]U VI(O)(OTf)ax} (8) and [{[(nP,MeArO)3tacn]U VI(O)(pyridine)] (4) and [{[(nP,MeArO)3tacn]U VI(O)(O-NMe3)} (5) were synthesized and fully characterized. The magnetic study revealed an unusually strong antiferromagnetic exchange coupling between the two UV ions in 3. Examining the 18-O labeled bis-µ-oxo-bridged dinuclear complexes 3, 6, and 7 allowed – for the first time – the unambiguous assignment of the vibrational signature of the [U(µ-O)2] diamond core structural motif.
Although the uranyl unit \([O=U=O]\) is ubiquitous in uranium chemistry,\(^1\) few terminal mono oxo uranium complexes – and even fewer with a dinuclear \([O=U=O]\) motif – are reported in the literature.\(^2\) Uranium oxo complexes with the same coordination environment but different oxidation states are particularly rare.\(^3\) Therefore, our interests have focused on the role that the metal oxidation states play in structure, reactivity, and spectroscopic properties of a series of complexes with nearly identical core structures. From such a homologous structural series, we can draw new insights into the electronic structures and reactivity of uranium-oxo complexes, which may improve our fundamental understanding of the role \(f\)-orbitals play in uranium–ligand multiple bonding. While bonds in 4f-element complexes have generally been considered to be ionic,\(^4\) the ligand bonding in even fewer with a dinuclear \([O=U=O]\) motif – are reported in the literature.\(^2\) Uranium oxo complexes with the same coordination environment but different oxidation states are particularly rare.\(^3\) Therefore, our interests have focused on the role that the metal oxidation states play in structure, reactivity, and spectroscopic properties of a series of complexes with nearly identical core structures. From such a homologous structural series, we can draw new insights into the electronic structures and reactivity of uranium-oxo complexes, which may improve our fundamental understanding of the role \(f\)-orbitals play in uranium–ligand multiple bonding. While bonds in 4f-element complexes have generally been considered to be ionic,\(^4\) the degree of covalency in the M–L bond of 5f-element complexes, and uranium in particular, remains an important subject of debate.\(^5\)

The greater radial extension of the 5f valence orbitals of the early actinides can provide increased overlap with ligand orbitals, thereby enhancing the correlated magnetic behavior between bridged metal centers within a single unit, such as the structurally and electronically interesting diamond-core, \(M(M\rightarrow O)\_2M\). In the series of complexes presented here, considerably different magnetic behavior is observed depending on the oxidation state. Furthermore, the interplay between strong spin-orbit coupling and a low-symmetry crystal field may result in fascinating but intrinsically difficult to rationalize electronic properties, including magnetic exchange phenomena. Magnetic superexchange, while well-investigated and understood in transition metal coordination chemistry, is receiving increasing attention in actinide coordination and organometallic chemistry.\(^6\) Antiferromagnetic exchange interaction, for instance, has been observed for most transition metal and \(f\)-element compounds, and Néel temperatures \(T_N\), defined as the maximum in the magnetic susceptibility of an antiferromagnetically coupled system) up to 1145 K are known for transition metal oxides or alloys.\(^7\) While transition metal complexes exhibit Néel temperatures up to 270 K,\(^8\) only relatively small values have been observed for lanthanide and actinide complexes. This weak coupling is directly related to weak interactions and small covalent contributions to the metal – ligand bonding in \(f\)-element complexes. By far the highest value of \(T_N\), 110 K, for a uranium complex was published by Cummins et al. in 2000, for a toluene-bridged \(U^{III}/U^{II}\) complex.\(^6\) In a landmark publication, Andersen and Edelstein et al. reported a dinuclear \(U^V\) organoimide, which exhibits strong exchange coupling and a \(T_N\) of 20 K.\(^6\) Other \(U^V\) complexes exhibit \(T_N\) from 5 to 17 K.\(^6\) We now report the synthesis of three dinuclear uranium complexes bridged by two oxo ligands, which results in a diamond-shaped \([U(\mu-O)\_2U]\) structural motif. The principal complex, a dinuclear bis-\(\mu\)-oxo bridged \(U^V/U^V\) complex \([\{(\text{apMeArO})_3\text{tacn})U(V)\}]_2(\mu-O)\), possesses a remarkably high Néel temperature of approximately 70 K, suggesting unusually strong exchange inter-actions within the \([U^V(\mu-O)\_2U^V]\) core. In order to understand the magnetic properties of this compound – and for comparison – mononuclear uranium(V) imido, uranium(V) and uranium(VI) oxo complexes are presented as well. These new complexes have been characterized by a combination of single-crystal X-ray diffraction, \(^1\)H NMR spectroscopy, elemental analysis, mass spectrometry, cyclic voltammetry, UV/vis/NIR electronic absorption, and IR/Raman vibrational spectroscopy, including \(18\)-O isotope labeling experiments, electron paramagnetic resonance (EPR) spectroscopy, as well as variable-temperature magnetic susceptibility.

In order to synthesize high-valent oxo and imido complexes of \([\{(\text{apMeArO})_3\text{tacn})U^{III}\}]\, a solution of 1 in pyridine was treated with mesitylazide. The reaction lead to an immediate color change from red to black-brown with concomitant evolution of \(N_2\) gas to yield the \(U^V\) imido complex \([\{(\text{apMeArO})_3\text{tacn})U^{V}(\text{NMes})]\\) (2, Scheme 1) as analytically pure, dark-brown powder in moderate yield (42%). The addition of pyridine-N-oxide or trimethyl-N-oxide to a solution of 1 also results in a color change to orange-yellow to give the eight-coordinate, terminal \(U^V\) oxo complexes \([\{(\text{apMeArO})_3\text{tacn})U^{V}(\text{O})(\text{py-NO})]\] and \([\{(\text{apMeArO})_3\text{tacn})-U^V(\text{O})(\text{Me}_2\text{NO})]\) (4 and 5, Scheme 1) as analytically pure, bright yellow powders in moderate and good yields (for 4: 45% and 5: 68%). However, formation of a bis-\(\mu\)-oxo complex, analogous to \([\{(\text{AdMeArO})_3\text{N})U(\text{py-NO})\}]\, \(\mu\)-\(O\)\_2\([\{(\text{AdMeArO})_3\text{N})U]\] ), as observed in a similar reaction with the \(N\)-anchored system \([\{(\text{AdMeArO})_3\text{N})U^{III}\}]\, was not observed.\(^2\)

Instead, the dinuclear \(U^V/U^V\) bis-\(\mu\)-oxo complex \([\{(\text{apMeArO})_3\text{tacn})U^V\}]_2(\mu-O)\] (3) was synthesized by forming \(2\) \(\text{in situ}\) and introducing \(\text{CO}_2\) under vigorous stirring. After cooling to \(-35\) °C, a microcrystalline precipitate formed, was filtered off, and dried \(\text{in vacuo}\) to give 3 (Scheme 1) as a dark-
purple, microcrystalline solid in moderate yield (42%). Although in poor yield, complex 3 has also been synthesized via reaction of 1 with SeO2, trimethylamine-N-oxide (in n-pentane and heat), TEMPO, and, interestingly, low concentrations of neat di-oxygen. For the dinuclear complex 3, the ESI-MS mass spectrometry shows a single molecular peak corresponding to the dimeric [3]+ complex with m/z = 1902. The EI+ mass spectrometry shows the molecular peak for the dimeric compound as well. These results indicate that complex 3 exists as a dimer in both solid state and solution. Reduction of 3 in benzene with excess KC8 results in a slow color change to green-brown and yields the doubly reduced U IV/U IV complex $K_2[\{(n^{\circ}{Me}{Ar}O)_{3}tacn\}U^{IV/IV}]_2(\mu-O)_2$ (6, Scheme 1) as analytically pure, pale-green powder in excellent yield (96%). Using only one equivalent of KC8, in the presence of equimolar amounts of 2.2.2-cryptand dissolved in THF, results in a fast color change to yellow-brown and formation of the mixed-valent U IV/U V complex, namely [K(2.2.2-crypt)][{(n^{\circ}{Me}{Ar}O)3 tacn}U^{V/IV}]2(\mu-O)2] (7, Scheme 1). Employing this synthetic protocol, 7 was isolated as a yellow-beige powder in good yield (56%). Interestingly, complete conversion to mixed-valent 7 can also be obtained by comproportionation of equimolar amounts of pentavalent 3 and tetravalent 6 in the presence of one equivalent of 2.2.2-cryptand. Noteworthy, the reduction of the terminal oxo complexes 4 and 5 with KC8 – in an attempt to prepare mononuclear tetravalent oxo species – shows no reaction. In light of the stability of the dinuclear U IV/U IV complex 6, as well as previous2g,11 isolation of U IV complexes with terminal oxo ligands, this result is all the more remarkable.

Finally, attempts to synthesize the oxidized, dinuclear U V/U VI and U IV/U V complexes with Ag-salts (AgBARf24, AgBF4, AgNTf2, AgI, AgNO2, AgO, Ag2O, Ag[Al(OC(CF3)3)4]), and various other oxidizing reagents (I2, NOBF4, CuSCN, CuCN, (NH4)2Ce(NO3)6, Au2S, [NMMe(C8H7)2][Au(C5S5)2], [Fe(Cp)2]PF6, Co(Cp)2, NO [Al(OC(CF3)3)3]), incorporating weakly or even non-coordinating anions, were unsuccessful. Instead, the oxidation of dimeric 3 with excess silver triflate or silver hexafluoroantimonate lead to the formation of black, monomeric terminal U VI oxo complexes, namely eight-coordinate $\{(n^{\circ}{Me}{Ar}O)_{3}tacn\}U(VI)(CF3SO3)$ (8) and seven-coordinate $\{(n^{\circ}{Me}{Ar}O)_{3}tacn\}U(VI)(O)[SbF6]$ (9) in good to excellent yields (for 8: 63 % and 9: 89 %). The reaction of 3 with exactly one equivalent of AgOTf or AgSbF6 results in conversion of half of the starting material to yield monomeric species 8 or 9, respectively, whereas the rest remains as the U IV/U IV dimer. To the best of our knowledge, no dinuclear, doubly-bridged U IV/U VI or U VI/U VI complexes are known except for those containing the uranyl moiety.12

All complexes shown in Scheme 1 have been isolated in moderate to excellent yields, and have been characterized by 1H NMR spectroscopy, single crystal X-ray diffraction, cyclic voltammetry, UV/vis/NIR absorption, and IR vibrational spectroscopy. The electronic structure and magnetic properties have been studied by X-band EPR spectroscopy and SQUID magnetization. The purity of the bulk material has been confirmed by CHN elemental analyses, except for fluoride-containing complexes 8 and 9, where possible formation of hazardous, volatile UF6 precluded elemental analysis. In addition to elemental analysis, title complex 3 has been characterized by mass spectrometry and vibrational spectroscopy (Raman and IR), including its 18-O labeled isotopomer.

Scheme 1. Reaction scheme for the synthesis of complexes 2 – 9; phenolate rings, including the neopentyl and methyl substituents, are omitted for clarity.

In general, the uranium ion in eight-coordinate complexes 2 – 8 is situated in a distorted trigonal dodecahedral coordination environment, with a neutral donor ligand occupying the axial position above a square plane formed by three aryloxides and the oxo/imido ligand; the uranium ion lies slightly below this square plane. The amine nitrogen atoms of the triazacyclononane (tacn) anchor form a trigonal plane opposite to the neutral donor ligand (pyridine N-oxide, trimethylamine N-oxide, pyridine). For complex 9, the uranium ion is seven-coordinated, with a similar ligand environment as described earlier but with a free axial coordination site. In dinuclear complexes 3, 6, and 7, two trigonal dodecahedral polyhedra are connected over two bridging oxygen atoms (one axial and one equatorial oxygen, see Figure 1B). While the coordination polyhedra are distorted trigonal dodecahedra, these complexes may also be viewed as distorted octahedra with the three amine nitrogen atoms of the tacn ligand occupying a single coordination site trans to the axial, neutral donor ligand, which is best illustrated in Figure 1C. The description of the coordination as distorted octahedral not only simplifies but fits the explanation of the electronic properties of these complexes (vide infra).

Multiple bond metathesis of CO₂ with ŨV imido complexes of the related adamantyl and tert-butyl functionalized tris(aryloxide) tacn system [(R,R'ArO)₃tacn]UV (NMes) (with R = t-Bu, Ad; and R' = t-Bu, Me) yielded mononuclear UV oxo complexes. In these complexes, as well as in the imido precursor, the terminal, strongly π-donating oxo/imido ligand is situated on the three-fold axes of the C₃ symmetric complex.

Figure 1. Trigonal dodecahedral environment for monomeric (A) and dinuclear complexes (B); Simplified distorted octahedral environment (C); View from the top (D) along the axial O–U bond, illustrating C₃ symmetry for 3, 4, 5, 6, 7, and 8 (blue: nitrogen, red: oxygen, magenta: uranium).

Figure 2. Diamond core structures of the dinuclear complexes 6 (left), 7 (middle), and 3 (right) with U–O bond distances. The aryloxide oxo ligands trans coordinated to the equatorial bridging oxo ligands are labeled in red.
Clearly, the most prominent structural aspect of the neopentyl-derivatized tacn system is the formation of the high-valent, dinuclear bis-µ-oxo bridged complex 3 with a diamond core structural motif, $[\text{U}^\text{V} (\mu-O)_{2} \text{U}^\text{V}]$, along with its one-electron reduced mixed-valent complex $[\text{U}^\text{IV} (\mu-O)_{2} \text{U}^\text{V}]$ (7) and doubly-reduced $[\text{U}^\text{IV} (\mu-O)_{3} \text{U}^\text{IV}]$ (6). In 7, the complex anion is isolated from the encrypted potassium cation, while in 6, both potassium ions interact with one of the two bridging oxo ligands. Despite these significant structural differences, especially for 6, the metrics within the diamond core of 3, 6, and 7 are remarkably similar (Figure 2, Figure 3, and Table 2). In all three complexes, each bridging oxo ligand occupies an axial site on one uranium center and an equatorial site on the other. For 3 and 7, the shorter, equatorially bound oxo is situated within the plane of the three aryloxide ligands; thus, forming a square plane with the longer, axial oxo ligand nearly perpendicular to this plane. For complex 6, however, one bridging oxo is equatorial to both uranium ions, while in the other bridging oxo ligand, which interacts with both potassium ions, occupies the axial positions. Complex 3 possess an inversion center in its diamond core; thus, the two equivalent uranium ions are perfectly in plane with the two bridging oxo ligands. The observed asymmetry of the U–O bond distances within the core is most distinct in $[\text{U}^\text{V} (\mu-O)_{3} \text{U}^\text{V}]$ with alternating short U–O$_{eq}$ bonds at 2.066(2) Å and longer U–O$_{ax}$ bonds at 2.206(2) Å. The core structure is further characterized by the O–U–O and U–O–U angles, which were determined to be 71.55° and 108.45°, respectively. This leads to a relatively short U–U distance of 3.422(3) Å, which compares well to the U–U separation of 3.3557(3) Å reported by Arnold and Love et al.\textsuperscript{6c}

Remarkably, upon reduction, the core structural motif remains largely unperturbed. The O–U–O and U–O–U angles are very similar at approx. 82° and 108°. While the $[\text{U} (\mu-O)_{3} \text{U}]$ moiety remains nearly planar (deviation from planarity: 2.23° in 6 and 0.9° in 7), the U–U distances in these complexes show a clear trend with the degree of reduction (Table 2). Accordingly, the shortest U–U distance is found in 3 (3.422(3) Å) and the longest in doubly-reduced 6 (3.509(4) Å), while the U–U distance in mixed-valent 7 was determined to be inbetween 3 and 6 at 3.465(5) Å. As one progresses from 3 to one- and two-electron reduced 7 and 6, the difference between short and long U–O bonds becomes less pronounced. Consequently, 6 possesses a nearly symmetric core with similar U–O bond distances of 2.166(3) and 2.179(3) Å. The latter observation is particularly surprising, since two potassium cations are bound to one of the two bridging oxo ligands of 6.

**Figure 3.** Molecular structures of the dinuclear uranium oxo complex: $\text{U}^\text{V}/\text{U}^\text{V}$ 3 in crystals of 3 • 4 $\text{C}_{4} \text{H}_{8}$. H-atoms and co-crystallized solvent molecules are omitted for clarity. Thermal ellipsoids are at 50 % probability.

Recently, we reported the synthesis of the bis-µ-oxo bridged diuranium species $[\{(\text{Ad,MeArO})_{3} \text{N})\text{py-NO}\text{U}\} (\mu-\text{O})_{2}\{((\text{Ad,MeArO})_{3})\text{N}\text{U}^{\text{III}}\}]$, obtained by treatment of $[\{(\text{Ad,MeArO})_{3} \text{N})\text{U}\}$, the single N-anchored tris-aryloxide derivative of 1, with pyridine-N-oxide. However, a similar treatment of 1 does not produce dimeric 3. Instead, oxidation of 1 with pyridine-N-oxide or trimethyl-amine N-oxide yields mononuclear $\text{U}^\text{V}$ complexes 4 and 5, $[\{(\text{Ad,MeArO})_{3} \text{N})\text{py}^{\text{III}}(\text{O}(\text{L}))\}]$ (with L = pyN-O, Me$_{3}$N-O). As mentioned before, all previously reported pentavalent uranium complexes of the tacn ligand systems with tert-butyl and adamantyl substituents in ortho position, namely $[\{(\text{Ad,MeArO})_{3} \text{N})\text{py}^{\text{III}}(\text{L})_{\text{ax}}\}]$ (with R = R$_{\text{ortho}}$ = t-Bu, Ad; R’ = R$_{\text{para}}$ = t-Bu, Me; L$_{\text{ax}}$ = O, NTMS, NMes) are seven-coordinate with the strongly $\pi$-donating oxo and imido ligands located on the three-fold axis of these $C_{3}$ symmetric complexes.\textsuperscript{14} Only upon oxidation to the hexavalent state, do oxo and imido $\text{U}^\text{VI}$ complexes of this ligand system display the inverse trans influence (ITI).\textsuperscript{21–15} Consequently, their molecular structures show approximate $C_{3}$ symmetry with the strongly $\pi$-donating ligand in the equatorial plane trans to a mutually enforced, strongly bound aryloxide ligand of the hexadentate chelate. In stark contrast, all monomeric, pentavalent uranium complexes of the new neopentyl-derivatized tacn system,
\[ \left[ \text{HMMeArO}_3 \text{tacn} \right] \text{UV}^\text{V} (\text{L}) \], have the terminal oxo and imido ligands in the equatorial plane along with the three aryloxide pendent arms of the hexadentate chelate. In the presence of the neutral, donor ligands, pyridine N-oxide, trimethylamine N-oxide, or pyridine, the coordination sphere of these complexes is completed by a usually weakly bound donor ligand in the axial position \textit{trans} to the tacn anchor. Regardless of these drastically different coordination environments, the U–O bond distances are almost the same with 1.856(2) and 1.850(2) Å for the two independent molecules in the structure of 4, and 1.860(2) Å for 5, in comparison to 1.848(4) and 1.848(8) Å for \[ \left[ \text{HMMeArO}_3 \text{tacn} \right] \text{UV}^\text{V} (\text{O}) \] (with \( R = \text{Ad}, \text{t-Bu}; R' = \text{t-Bu} \)), respectively, and other \text{UV}^\text{V} terminal oxo complexes.

Attempts to oxidize the dinuclear complexes 3, 6, and 7 to obtain the corresponding complexes with \[ \text{UVI}^\text{VI}(\mu_\text{O})_2 \text{UVI}^\text{VI} \] or \[ \text{UVI}^\text{VI}(\mu_\text{O}_2)\text{UVI}^\text{VI} \] core structures only lead to isolation of mononuclear \text{UVI}^\text{VI} complexes with terminal oxo ligands, \[ \left[ \text{HMMeArO}_3 \text{tacn} \right] \text{UVI}^\text{VI}(\text{O})_{\text{eq}} (\text{L}) \] (with L = \text{CF}_3\text{SO}_3, 8) and \[ \left[ \text{HMMeArO}_3 \text{tacn} \right] \text{UVI}^\text{VI}(\text{O})_{\text{eq}} [\text{A}] \] (with A = \text{SbF}_6, 9). \text{UVI}^\text{VI} complexes with a single terminal oxo ligand represent a rare class of complexes with few reported examples.

The monomeric \text{UVI}^\text{VI} terminal oxo complexes 8 and 9 possess similar coordination environments to 4 and 5 as well as to known complexes of the \textit{tert}-butyl and adamantyl-derivatized tacn systems (with complex 9 missing the axial ligand). As in 4 and 5, the terminal oxo ligand in 8 is in the equatorial position along with the three aryloxides, and the weakly coordinating triflate counter ion is bound in axial position \textit{trans} to the tacn anchor. The very short bond U–O_{\text{Oxida}} (1.794(2) in 8 vs. 1.811(2) Å for \[ \left[ \text{HMMeArO}_3 \text{tacn} \right] \text{UVI}^\text{VI}(\text{O})(\text{CF}_3\text{COO}) \] and 1.836(6) Å for \[ \left[ \text{HMMeArO}_3 \text{tacn} \right] \text{UVI}^\text{VI}(\text{O})[\text{SbF}_6] \]) is due to the coordination of the triflate counter ion.

(1) Distance of the aromatic ring to the carbon atom from the neopentyl group or the tacn ring, where a π-CH bond interaction is possible.
(2) Torsion angle
(3) O,, is the aryloxido arm cis to the terminal oxo/imido ligand

to the ITI and results from the mutually reinforced bonding within the near linear O_{ArO}−U−O_{oxo} arrangement (160.73(8)° in 8 vs. 159.67(6)° for [(\(\text{R,R'}\text{ArO})_3\text{tacn})\text{UV}(\text{NTMS})] (with R = \(\text{Bu, Me}\)), the neopentyl derivative, U V imido complexes. The average uranium aryloxide bond distances in complexes 2−9 are in the range of 2.1827 to 2.23 0.08 V and 1.53 V, respectively. A similar trend for the average U−N_{tacn} bond distances cannot be observed; the U−N_{nax} bond lengths vary from ~2.747 to ~2.867 Å for all complexes; and thus, are slightly longer than those found in other uranium complexes of the tacn chelate, which are in the range of 2.67 to 2.76 Å. Notevorthy, all new high-valent complexes, including the

imido species 2 and oxo complexes 3−9, feature the ITI.

Here, the strongly π-donating terminal imido and oxo ligand is in plane with the three aryloxide ligands. Within this plane, the uranium aryloxide bond trans to the terminal oxo/imido ligand is slightly shorter (~0.06 Å) than the two other cis U−O_{oxo} bonds. The ITI is observed in the di-nuclear as well as in the mononuclear complexes to the same extent. In addition to the ITI, the inverse is also observed: the longest M−L distances are coordinated trans to each other (the longest M−L distance is trans to tacn anchor).

Electrochemical data from cyclic, linear sweep, and square-wave voltammetry were collected for all uranium complexes in THF or acetonitrile solutions, with ~0.1 M [N(2,4,6-Br,Me)3][PF6] as electrolyte and the ferrocenium/ferrocene couple as internal standard. In addition, both the free (\(\text{R,R'}\text{ArOH})_3\text{tacn}\) ligand and 2.2.2-cryptand were investigated to demonstrate their redox-inactivity. A summary of experimentally determined half-step potentials is given in the ESI. In contrast to [(\(\text{R,R'}\text{ArO})_3\text{tacn})\text{UV}(\text{NTMS})] (with R = \(\text{Bu, Ad, dian}\), the neopentyl derivative, U V imido complex 2, shows no redox chemistry in the accessible electrochemical window. This might be due to the different geometries (C3 vs. C4) found in the tert-butyl and adamantyl complexes vs. the neopentyl system studied here. The dinuclear bis-μ-oxo bridged 3, however, shows a remarkable rich and unique electrochemistry, featuring two reversible redox events at half-wave potentials of E_{oxi} = −0.08 V and −1.53 V vs. the Fc/Fc⁺ couple (see Figure 4). The more cathodic redox wave can be unambiguously assigned to the one-electron reduction of the U V/UV species to the mixed-valent U V/UV complex.
This couple also appears in the cyclovoltammogram of 7 (\(E_{1/2} = -1.55\) V, see ESI), and similar reduction potentials for U\(^{V}/U\(^{IV}\) complexes are known (\(-1.25\) to \(-1.81\) V vs. Fc/Fc\(^+\)). The second redox wave at \(E_{1/2} = -0.08\) V is assigned to a one-electron oxidation to a U\(^{V}/U\(^{VI}\) complex, which is further confirmed by linear sweep. While the electrochemical reduction can be proved by a chemical reduction on a preparative scale, leading to isolable 7, the chemical oxidation of 3 to yield the hypothetical mixed-valent \([U\(^{V}\)(\(\mu\)-O)\(_2\)U\(^{VI}\)]\) species has not yet been accomplished. Attempts to oxidize 3 with a large variety of oxidants and different stoichiometries only lead to monomeric U\(^{VI}\) oxo complexes (vide supra). The large separation between the U\(^{V}/U\(^{IV}\), U\(^{IV}/U\(^{V}\), and U\(^{V}/U\(^{VI}\) redox couples allows the equilibrium constant for the disproportionation to the U\(^{IV}/U\(^{V}\) complex to be estimated. With \(\Delta E_{1/2} = 1.45\) V, \(K_c\) is approximately \(3.25 \times 10^{24}\), suggesting strong electronic communication between the uranium centers. It is likely that the highly covalent U–O bonds in the bis-\(\mu\)-oxo diamond core support this electronic coupling although short M–M distances (and their resulting M–M bonds) have also been implicated in remarkably strong interactions between two transition metal centers. The large value for \(K_c\) may further explain the unusual stability of 3, which is air-stable. Similar \(K_c\) values have been reported by Cummins et al. for the dinuclear nitrido-bridged U\(^{V}/U\(^{IV}\) complex (\(K_c \approx 5.6 \times 10^{17}\)), for which a wave separation of \(\Delta E_{1/2} = -1.05\) V between the U\(^{IV}/U\(^{IV}\), U\(^{IV}/U\(^{V}\), and U\(^{V}/U\(^{IV}\) redox couple has been reported.

Interestingly, while treatment of 3 with excess KC\(_8\) yields the doubly-reduced, U\(^{IV}/U\(^{IV}\) complex 6, the second reduction, the U\(^{IV}/U\(^{V}\) to U\(^{IV}/U\(^{IV}\) redox couple, is not observed in the CV of 3. Also, isolated complex 6 is electrochemically inert, showing neither reversible nor irreversible redox events in its CV.

Considering that in 6, two potassium cations are bound to one of the bridging oxo ligands and form multiple bonding interactions with the aryloxide pendant arms of each U\(^{IV}\) moiety, it is reasonable to assume that the chemically introduced potassium ions play a major role in the stabilization of 6, which may explain the different electrochemical and chemical behavior. While mononuclear U\(^{VI}\) oxo complexes 8 and 9 show no reversible redox chemistry in the accessible electrochemical window, complexes 4 and 5 show one reversible redox event centered at \(E_{1/2} = -0.18\) and \(-0.27\) V, respectively, consistent with reported redox potentials for the metal-centered U\(^{V}/U\(^{VI}\) redox-couple (\(-0.11\) to \(-0.19\) V vs. Fc/Fc\(^+\)). However, chemical oxidation of complex 4 with AgOTf resulted in ligand degradation and formation of a U\(^{VI}\) uranyl complex coordinated by two triflate and three pyridine-N-oxide ligands (see ESI).
Figure 4. Reversible reduction wave (left) and reversible oxidation wave (middle) of 3 at different scan rates. Linear sweep measurement (right) in ~0.1 M [N(n-Bu)₄][PF₆] in THF at room temperature. Scan was collected at 50 mV/s and with a step potential of 2 mV.

The UV/vis/NIR electronic absorption spectra of the dark brown imido complex 2, the yellow-orange terminal oxo complexes 4 and 5, the dark red-brown U⁵⁺–U⁷⁺ complex 3, the orange U⁵⁺/U⁷⁺ complex 7, the pale green U⁴⁺/U⁷⁺ complex 6, and the two black U⁶⁺ complexes 8 and 9 were measured in THF for different concentrations from 200 to 2500 nm at 25 °C. Figure 5A displays all collected spectra over the UV/vis spectral range and Figure 5B shows excerpts of characteristic f–f transitions in the NIR spectrum. Generally, the electronic absorption spectra of complexes 2–7 can be divided into two regions. The first region, between 200 and 550 nm, shows intense and broad charge-transfer bands (CT) characteristic of π→π* and π→nb₅f (nb = non-bonding), and metal-centered 5f→6d transitions above 40,000 cm⁻¹ with molar extinction coefficients of ε ~ 20×10³ – 70×10³ M⁻¹cm⁻¹ (Figure 5A).¹⁹ A second region between 500 and 2500 nm is dominated by metal-based f–f transitions with varying intensity and molar extinctions that vary from 10 to 600 M⁻¹cm⁻¹ (Figure 5B).

Black, mononuclear U⁶⁺ oxo complexes 8 and 9 strongly absorb over the entire spectral range from 220 to 1280 nm. In the UV region, most complexes exhibit two similar features at ~250 and 300 nm with molar extinction coefficients of ~20×10³ – 30×10³ M⁻¹cm⁻¹ per uranium. In addition, dinuclear 3 and 7 show strong absorption into the visible spectrum below 600 nm, with ε ~ 3,000 M⁻¹cm⁻¹ per uranium (at λ ~ 483 and 388 nm, respectively), whereas monomeric U⁵⁺ complexes display only weak absorption below 450 nm. The U⁶⁺ complexes 8 and 9 absorb strongly below 1400 nm, but as expected, no f–f transitions are observed.

Figure 5. A) UV/vis absorption spectra of 2 (purple), 3 (blue), 4 (dark blue), 5 (pink), 6 (green), 7 (orange), 8 (black), and 9 (dark green). B) NIR absorption spectra. Top: 3, 6, and 7. Bottom: 2, 4, and 5. Extinction coefficients are reported per one uranium center.

The metal-centered f–f transitions depend on the electronic configuration of the uranium ion. U⁵⁺ is simplest to understand since it possesses just one unpaired electron; hence, no electron-electron repulsion occurs. Absorptions with average molar extinction coefficients of ε = 50 M⁻¹cm⁻¹ per uranium, can be observed for the terminal oxo complexes 4 and 5, as well as for the dinuclear bis-µ-oxo complexes 3 and 7, and are
comparable to bands observed for the terminal oxo complexes 
[(Bu,t-BuArO)tacn]− and [(t-BuArO)tacn]−.13
Note that 7 displays both UIV and Uiso spectral features. The
wider range of 840 – 1670 nm for 4, compared to 880 – 1610
nm for 5, suggests a slightly stronger ligand field in 4, which
produces a larger splitting of the states. In stark contrast to the
Uiso oxo complexes, UIV imido compound 2 shows one broad
absorption band, spanning from ~750 – 1700 nm, with some
less-resolved superimposed features. The spectral shape and
intensity (ε ~ 70 – 580 M−1cm−1) is reminiscent to the spec-
trum of the [(‘Bu,t-BuArO)tacn]UIV (NMes) and [(‘Bu-
ArO)tacn]UV (NMes)] complexes,13 and to other reported
UIV imido complexes.17, 20
For the purposes of interpreting the NIR spectra, the UIV oxo
complexes may be viewed as distorted octahedral complexes
with the tacn anchor occupying a single coordination site as
earlier noted. Of these complexes, 7 has the least distorted
U2(μ-O)2 core with U-O distances of 2.11 and 2.17 Å; the U-
O-phenoxide distances are somewhat longer at 2.25 Å. Com-
plex 3 has a more distorted U2(μ-O)2 core with U-O distances
of 2.07 and 2.20 Å, and 4 and 5 are strongly distorted with a
short terminal oxo distances of 1.86 Å. These four complexes
form a series in which the relatively symmetric bridging oxo
groups in 7 begin to distort in 3 forming short U-O bond,
which becomes the terminal oxo group of 4 and 5.
The NIR spectra of pseudo-octahedral uranium complexes
have previously been described21 and the bonding has been
interpreted by using a crystal field model.22 Like 3 – 5, dian-
ionic [UOX]2− possesses a short U–O bond in a distorted
octahedral coordination environment. The other related com-
plex is the anion [U(O-τ-Bu)3]−, which displays very similar
U–OR bond lengths (2.05 Å to 2.24 Å) to that observed here.23
Therefore, the NIR spectrum of 7 should be expected to be
similar to that of [U(O-τ-Bu)3]−, and the spectra of 3-5 should
be related to 7 in the same way that [UOX]2− are related to
[UX3]−.
The splitting of the f−orbitals in a pseudo-octahedral f6−1 com-
plex can be described as shown in Figure 6, following the
scheme developed by Selbin and Sherrill.22 In contrast to the
complexes described by Selbin and Sherrill, the ξ−orbital
participates in bonding in 3 – 5 and 7 (primarily with the tacn
amine nitrogen atoms), so the A2u state is antibonding in 3 – 5
and 7 rather than non-bonding. Using the labels for octahedral
symmetry (Figure 6b), the NIR spectrum of 7 may be assigned
by reference to the spectrum of [U(O-τ-Bu)3]−. The sharp
feature at 1487 nm is the Γ7 → Γ6 transition (6725 cm−1),
the absorption bands at 984 nm and 1072 nm are the two branches
of the Γ7 → Γ6 transition (9745 cm−1) (this peak is always split
in the octahedral UIV complexes), and the shoulder at 795 nm
is assigned to the Γ7 → Γ6 transition (12580 cm−1).

**Figure 6.** Splitting of an f−1 system due to (a) O6 ligand field of
[UX6]−, (b) effect of spin-orbit coupling, (c) effect of replacing X
with a terminal oxo ligand. Diagram after Selbin and Sherrill.22
Going from 7 to 3 to 4 and 5, one bridging oxo ligand be-
comes the short terminal oxo ligand, which is analogous to
moving from [UX3]− to [UOX]2−. Consequently, the Γ6 state
in 7 increases in energy in 3 forming the shoulder at 750 cm−1
and is unobserved in 4 and 5 (it should be ~625 nm, but is
obscured by the CT bands). The Γ4′ feature around 1000 nm in
7 splits in 3-5 as the distortion increases forming a Γ6 peak
~1150 nm and a Γ7 peak ~900 nm. The energy of the Γ5′ is roughly
in the same in all complexes ~1450 cm−1. A new peak appears
in 4 and 5 ~1600 cm−1, which is presumably the Γ7 peak pro-
duced by splitting the Γ6 peak in 7, which is in the IR.
Using the assigned energies of the Γ7, Γ6, and Γ6 states of 7
and its average g-value (1.080), the crystal field of 7 may be
modeled as previously done for [U(O-τ-Bu)3]− (Table S23).
The fitting parameters are spin-orbit coupling, ζ, and two
splitting parameters θ and Δ, illustrated in Figure 6. ζ was
almost identical to that of [U(O-τ-Bu)3]−, which implies that
bonding is equally covalent in both complexes. Likewise, 0,
which is essentially the destabilization of the f-orbitals due to π-

\[ \text{UX}_6^- \quad \text{UOX}_5^{2-} \]
bonding, is much smaller in $7$ (2166 cm$^{-1}$) than in $[\text{U(O-Ot-Bu)}_6]^-$ (3779 cm$^{-1}$). This difference may be rationalized by noting that each $t$-butoxide ligand may form two $\pi$-interactions with the $U$ center, while the phenoxide and bridging oxo ligands may only form a single $\pi$-interaction with each uranium center. Overall, the electronic structure and bonding in $7$ are very similar to that of $[\text{U(O-Ot-Bu)}_6]^{-}$ with the exception that $\pi$-bonding is somewhat weaker in $7$.

Although the $f$-$f$ transitions in $2$ are significantly more intense ($\sim 10 \times$) than for the $U^{IV}$ complexes $4$ and $5$, the their CT transitions are equally intense, which is contrast to recent reports of Kiplinger et al.$^{24}$ The comparatively high molar extinction coefficients for these $U^{IV}$ complexes in contrast to other $U^{V}$ compounds, like pseudo-octahedral $U^{V}$ halide complexes ($\varepsilon = 5 - 22 \text{ M}^{-1}\text{cm}^{-1}$), may arise from the low $C_s$ symmetry, leading to a relaxation of the electric dipole selection rules. The same behavior was observed for Kiplinger’s complexes, having $\varepsilon$ values ranging from $\sim 100$ to $400 \text{ M}^{-1}\text{cm}^{-1}$. Also, the nature of the uranium-ligand bond significantly affects the intensities of the absorption bands. While simple $\sigma$-donor ligands typically lead to low intensities, more covalently bound $\pi$-donor ligands, such as complexes with terminal oxo and imido ligands, possess larger extinction coefficients due to orbital-mixing and relaxation of the Laporte’s rule ("intensity stealing").$^{26}$

The most salient feature in the spectrum of $6$ is the lack of the distinctive $U^{IV}$ transitions observed in $3$-$5$ and $7$. This is not only immediately indicative for the complete reduction of pentavalent $3$ and mixed-valent $7$ to fully tetravalent $6$ but is in good agreement with the structural observation of a symmetric $[\text{U}^{IV}(\mu-O)_3\text{U}^{IV}]$ core with relatively long but equal $U$–$O$ bond distances, indicating weaker $U$–$O$ bonds with little to no double-bond character. Instead, the spectrum of $6$ is reminiscent of “standard” $U^{IV}$ complexes of the tacn and single $N$-anchored tris(aryloxide) complexes, featuring a large number of low-intensity $f$-$f$ transitions over the entire spectral range. The $U^{IV}$ ion with its $5f^2$ electronic configuration experiences electrostatic repulsion of the two $f$-electrons as well as significant spin-orbit coupling, which leads to a large number of levels within $^3H_4$ the ground state. In addition, and depending on symmetry and crystal-field strength, the levels are further split into $(2J + 1)$ states. In $U^{IV}$, the crystal-field splitting is typically between 100 and 2000 cm$^{-1}$,$^{19}$ which is in the same order of magnitude as the spin-orbit coupling energy. This leads to a significant mixing of states; consequently, a large number of $f$-$f$ transitions in the visible to NIR region. Accordingly, $6$ possesses several unresolved bands from 450 to 1950 nm with low molar extinction coefficients of $\varepsilon \approx 10 - 50 \text{ M}^{-1}\text{cm}^{-1}$. $^{27}$

The nature of the $U$–$O_{\text{oxo}}$ bonds in complexes $3$ – $9$ was further probed by IR and Raman vibrational spectroscopy. It should be noted that employing $^{18}$O in the multiple bond metathesis reaction enabled the synthesis and isolation of the $^{18}$O labeled bis-$\mu$-oxo-bridged dinuclear complexes $3$, $6$, and $7$ and allowed – for the first time – the unambiguous assignment of the vibrational signature of the $[\text{U}(\mu-O)_{2}\text{U}]$ diamond core structural motif.

The IR spectra, performed on solid samples (KBr pellet, see ESI), are all dominated by the spectrum of the relatively complex hexadentate chelating ligand system in $[(\text{C}^3\text{MeArO})_3\text{tacn}]\text{U}(L)]$. Consequently, all complexes show very similar vibrational spectra, except for a single absorption band in the fingerprint region at 748 cm$^{-1}$ for $4$ and 741 cm$^{-1}$ for $5$, respectively (see ESI). This feature cannot be observed in complexes $2$, $3$, $6$ – $9$, and is therefore assigned to the terminal oxo–uranium stretching vibration, $\nu$(U=O). Although labeling studies were not performed on $4$ and $5$ (these complexes were not synthesized with $^{18}$O$_2$), the energy of the assigned $\nu$(U=O) peak is in good agreement with literature reports for this absorption band.$^{2c, 2h}$ Unambiguous identification of the metal-oxygen bond stretching frequencies in the $[\text{U}(\mu-O)_{2}\text{U}]$ diamond core of dinuclear complexes $3$, $6$, and $7$, as well as the U=O group in their mononuclear oxidation products $8$ and $9$, was achieved through the use of isotopic labeling with $^{18}$O (95 % enriched in 18-O). Thus, comparison of the parent complexes with their 18-O labeled isoto-pomers (18-O isotopomer denoted with $^{*}$) $3^{*}$, $6^{*}$, $7^{*}$, $8^{*}$, and $9^{*}$ (see ESI) revealed two strong isotope-sensitive bands between 500 and 648 cm$^{-1}$ (see ESI). These vibrational bands were assigned to the symmetric stretching and symmetric deformation vibrations. Similar values between 600 and 900 cm$^{-1}$ are reported for transition metal complexes containing the $[\text{M}(\mu-O)_{2}\text{M}]$ diamond core moieties ($\text{M} = \text{Mn, Co, Os}$).$^{28}$

For the mononuclear $U^{VI}$ oxo complexes $8$ and $9$, a shift of one vibrational band from 829 to 818 cm$^{-1}$ and 826 to $822 \text{ cm}^{-1}$ for
the isotopomers \(8^*\) and \(9^*\) was observed. These values are comparable to those reported for the terminal \(U^{VI}\) oxo complexes \(\{(\text{Me}_5\text{Si})_2\text{N})\text{U}^{VI}\text{O}(X)\} (X = F, Cl, Br)\) re-reported by Schelter et al. \((\nu_{\text{v,o}} = 859 – 882 \text{ cm}^{-1})\). The results obtained from IR vibrational spectroscopy agree well with the ones obtained from X-ray crystallographic studies and verify that the overall \(U=O\) bond order is lowered from the terminal oxo \(U^{VI}\) (1.794 (2), 1.791(6) and 1.800(6) Å) to the terminal oxo \(U^{V}\) (1.8561(18), 1.8586(18) and 1.860(2) Å) to the dinuclear bis-\(\mu\)-oxo bridged complexes. Raman spectroscopy measurements for all labeled and unlabeled complexes were conducted in solid state at room temperature. Due to strong emissions for all complexes except for \(3\) and its 18-O isotopomer \(3^*\), no meaningful Raman spectra could be obtained. For \(3\) and \(3^*\), however, a set of features are evident in the spectra, but only one shift is sensitive to 18-O substitution moving from 622 cm\(^{-1}\) to 584 cm\(^{-1}\) (588 cm\(^{-1}\) calculated for a simple \(U=O\) harmonic oscillator) and is assigned to the “breathing mode” of the diamond core moiety (see ESI). Similar values and assignments can be found in the literature for \([\text{M}(\mu-O)_2\text{M}]\) complexes in transition metal complexes. For example, Tolman et al. synthesized \([\text{Cu}(\mu-O)_2\text{Cu}]\) complexes with Raman shifts from 604 – 647 cm\(^{-1}\) for the unlabeled and 570 – 624 cm\(^{-1}\) for the 18-O labeled complex. Further complexes show similar shifts for the unlabeled (700 – 590 cm\(^{-1}\)) and 18-O labeled (634 – 560 cm\(^{-1}\)) \([\text{M}(\mu-O)_2\text{M}]\) diamond core moiety with \(M = \text{Fe, Mn, Ni}\). Until recently, the magnetism of \(U^{V}\) compounds has not been extensively investigated due to the difficulty in preparing complexes in this oxidation state. This has been particularly true for coordination complexes of low symmetry and for magnetically coupled systems. More recently, the development of novel synthetic routes to stable \(U^{V}\) complexes has lead to an expansion in the studies of the magnetism of this oxidation state. Nevertheless, exchange coupled systems remain rare. Thus, the complexes described in this paper offer a unique opportunity to study the magnetic properties of this novel series of dinuclear uranium coordination complexes with similar uranium coordination environments. Reproducible temperature-dependent and field-dependent magnetization data were collected for several isolated and independently synthesized samples. Even in analytically pure samples, all complexes exhibit small amounts of an unidentified paramagnetic impurity. These ubiquitous impurities may occur from minute uncoupled impurities (for the dinuclear complexes), ferrites, especially magnetite, from stainless steel lab equipment, and/or defects at the surface of the micro-crystallites. The presence of impurities is mainly noticeable in the low temperature magnetic susceptibility of \(3\) and \(6\) since both of these complexes have very small magnetic moments at low temperature.

The magnetic susceptibilities of these complexes are best understood using the van Vleck equation (eq 1), where \(\chi_{\text{tot}}\) is the magnetic susceptibility of the complex, \(\chi\) is the magnetic susceptibility of a thermally occupied state at energy \(E\), the \(\alpha\) term is the temperature independent paramagnetism (TIP) due to low lying excited states, and the other symbols have their usual meanings. The magnetic susceptibility of a given complex is just the Boltzmann distribution of the susceptibilities of the energies of the excited states. In uranium complexes, some excited states are typically at low energy and become thermally populated below 300 K. In addition, the TIP term \(\alpha\) is often large in these systems due to the low energies of the excited states.

\[
\chi = \sum_{j} \frac{\chi_j e^{\frac{E_j}{kT}}}{\sum_{j} e^{\frac{E_j}{kT}}}, \quad \text{where } \chi_j = N \left( \frac{2\mu_B^2 S(S+1)}{3kT} - \alpha \right) \quad \text{with}
\]

\[
\alpha = \sum_{j \neq k} \frac{2|\langle \psi_k | \mathbf{I} | \psi_j \rangle |^2}{E_k - E_j}
\]

(eq 1)

When the magnetic susceptibility is plotted as \(\chi T\) vs. \(T\), the occupancy of the low-lying states is often discernable by the change in slope of \(\chi T\) vs. \(T\). At low temperatures, where only a single state is occupied, \(\chi T\) will be linear in \(T\). The TIP term can be determined from the slope, and the average value of \(g\) may be determined by extrapolating \(\chi T\) to zero \(K\) (\(\chi T\) at 0 K).

As the temperature increases and low-lying states become thermally populated, the slope of \(\chi T\) vs. \(T\) decreases (the TIP terms of the ground and excited states cancel), and the slope of \(\chi T\) vs. \(T\) changes (the plot curves) until the occupied states are again in thermal equilibrium, at which point \(\chi T\) vs. \(T\) is again linear. If the total splitting of the \(f\)-orbitals by the crystal field is significantly smaller than \(kT\) at room temperature, all of the states in the ground multiplet (e.g. \(\tilde{2}F_{3/2}\) for \(U^{V}\)) are in thermal...
equilibrium, and the magnetic moment may be compared to that of the free ion. Covalent interactions decrease the magnetic moment by reducing the orbital angular momentum of the complex, which decreases both g and α in eq 1.34 The strength of the crystal field has a large effect of the magnetic susceptibility of the complex. If the ligands create a crystal field that is large compared to kT at 300 K, only the lowest lying f-states will be occupied, and the magnetic susceptibility will be significantly different from that of the free ion. A plot of χT vs. T will be significantly temperature dependent at 300 K, if this is the case, due to TIP created by slightly higher lying excited states. A strong crystal field will also result in mixing of the lowest lying free-ion states (e.g. \( ^2F_{5/2} \) and \( ^2F_{7/2} \) for UIV), resulting in a further deviation of the magnetic moment from that of the free ion. Magnetic moments at room temperature and extrapolated to zero K are given in the ESI for . The magnetic susceptibilities at room temperature and extrapolated to magnetic moment from that of the free ion.

Magnetic moments of complexes 4 and 5 are typical of UIV complexes stabilized by oxo ligands (see ESI).2e, f, 13 In all of the complexes, the magnetic moment at 300 K is significantly reduced from the free ion moment of 2.54 \( \mu_B \) for \( ^2F_{5/2} \). Also, \( \chi_T \) has substantial temperature dependence at 300 K, which is consistent with the large crystal field splitting observed in the NIR. In 4, \( \chi_T \) is linear in T from 0 to 20 K, at which point the slope changes until \( \chi_T \) is again linear in T from 150 K to 300 K, which indicates that the first excited state is ~50 K (35 cm\(^{-1}\)) above the ground state and that no other low-lying excited states become populated below 300 K. In 5, on the other hand, \( \chi_T \) is linear in T from 5 to 300 K with a slight deviation below 5 K. In this case, the first excited state is either very low in energy and is in thermal equilibrium with the ground state at 5 K, or the first excited state does not become significantly populated below room temperature. Given the relatively large splitting of the f-orbitals observed in the NIR (>5000 cm\(^{-1}\)) relative to kT at 300 K (209 cm\(^{-1}\)), the latter explanation seems more likely.

The ground states of these complexes have similar magnetic moments to those of octahedral [UX\(_6\)] complexes, which vary from 0.63 \( \mu_B \) for [U(OR)\(_6\)] to 1.24 \( \mu_B \) for [UR\(_6\)] as determined from the g-values of their ground states.5a This similarity supports the analogy with octahedral f\(^{1}\) ions presented when discussing the electronic spectra and suggests that the half-occupied orbital is largely \( f_{3z^2} \) in character. The lack of low-lying states in 5 is also consistent with the picture. The three dinuclear complexes (3, 6, and 7) show remarkably different magnetic behavior, clearly observable in the plot \( \chi_T \) vs. T (see Figure 7). The \( \chi \) vs. T plot of complex 3 exhibits the magnetic behavior of an anti-ferromagnetically coupled dinuclear complex with a Néel temperature (T\(_N\)) of approximately 70 K. The (reproducible) upturn in susceptibility below 20 K is attributed to the presence of paramagnetic impurities.

At room temperature, 3 has a magnetic moment per U that is comparable to the other UIV complexes.2e, f, 13 Interestingly, the \( \chi_T \) vs. T plot of 3 is linear from 100 K to 300 K, which suggests that no further states become thermally populated over this range. The strong temperature dependence of \( \chi_T \) of 3 at 300 K suggests that only the lowest crystal field states of each ion – possibly only a single crystal field state – are populated below room temperature, which is consistent with the NIR spectrum of this ion. Magnetic exchange in this complex will be addressed below.

The magnetic susceptibility of the doubly-reduced complex 6, [UIV(\( \mu\)-O)\(_2\)UIV\(^{1}\)], shows no evidence of exchange coupling. Instead, 6 displays characteristic behavior for isolated tetravalent UIV complexes.2e,5b Specifically, \( \chi_T \) of 6 is linear to 70 K with \( \chi_T \) at zero K approximately equal to zero, which implies that the g-value of the ground state is zero. In addition, the \( \chi \) vs. T plot of 6 displays a plateau below 70 K, which is masked by the presence of paramagnetic impurities (vide supra). The free-ion ground state for UIV is \( ^{1}\text{H}_{4}^{\text{a}} \), which is split by the ligand field into three non-Kramers doublet states and one singlet state. The singlet state has a g value of zero and displays only TIP, which is consistent with the ground state magnetic susceptibility observed for 3. In octahedral crystal fields, UIV displays a singlet ground state,36 which further supports the postulate that these complexes may be viewed as distorted octahedra, at least from the perspective of their electronic structures. A singlet ground state in 6 is consistent with the observed lack of coupling in this molecule since singlet states have no net spin and thus do not display exchange coupling.

To estimate the energy gap between the ground and excited state, it is assumed that an excited state population of less than 5 % leads to no change in magnetic susceptibility.37 Applying the Boltzmann distribution, a state energy gap of ~125 cm\(^{-1}\) can be expected.37-38 As with the other complexes, \( \chi_T \) of 6 is
strongly temperature dependent at 300 K, which is consistent with the large crystal field splitting observed in its NIR spectrum.

Figure 7. Temperature-dependent magnetic susceptibility data for 3 (blue), 6 (green), and 7 (orange) shown as $\chi_T$ vs. $T$ (left) and $\chi$ vs. $T$ (right). For the $\chi$ vs. $T$ plot, the scale for 3 is on the left and the scale for 6 is on the right.

The mixed-valent U$^{IV}$/U$^{V}$ complex 7 shows magnetic behavior reminiscent of both U$^{IV}$ and U$^{V}$, which is in perfect agreement to its electronic absorption spectrum (vide supra). The product $\chi_T$ of 7 is linear in $T$ from 6 to 100 K with a small deviation below this value. Therefore, only a single state is (or two almost degenerate states are) thermally occupied over this range, which is consistent with both the behavior of 6 and with the monomeric U$^V$ species 5. At 300 K, as one might expect, the magnetic moment is intermediate between those of the U$^{IV}$ complex 6 and of the monomeric U$^V$ complexes. For 7, $\chi_T$ does not become linear at higher temperature, most likely due to the changing thermal populations of the low-lying states, which is similar to the behavior of 6. As with the other complexes, $\chi_T$ is strongly temperature dependent at 300 K, which suggests that only the lowest lying states are thermally occupied and is consistent with the large splitting of the $f$-states observed in the NIR.

The Néel temperature $T_N$ of 3 is considerably larger than typically observed for U$^V$ complexes. Only $T_N$ of the U$^{III}$ inverse sandwich complex described by Cummins et al. is larger at 110 K. Ideally, one would like to quantify the exchange coupling in this system; however, this goal is complicated by several factors. The contribution of the paramagnetic impurity must be accounted for, which is straightforward. Exchange coupling may be quantified in centrosymmetric systems, such as 3, if the magnetic anisotropy and magnetic susceptibility of an isolated magnetic ion (diamagnetic substitute) is available. In the case of 3, the ideal diamagnetic substitute would be the analogous complex with one of the uranium atoms replaced by protactinium, which is prohibitively difficult. The role of the diamagnetic substitute is to account for the effect of the crystal field on the magnetic susceptibility of the ions in the coupled pair. Therefore, a complex with a similar structure to 3 but without a neighboring magnetic ion would be useful. While 4 and 5 are similar to 3, the uranium terminal oxo distances in the mononuclear systems are considerably shorter than the short U–O bond in 3. On the other hand, the structure of 7 is quite similar to that of 3 and could be a useful diamagnetic substitute if one can account for the susceptibility of the U$^{IV}$ center. Since the U$^{IV}$ centers in 6 are not exchange coupled (at least their singlet ground states are not coupled), it is possible that this complex can be used to correct for the presence of the U$^{IV}$ center in 7 by simply subtracting half of the susceptibility of 6 from that of 7. This approach will fail if the U$^{V}$ and U$^{IV}$ centers in 7 are exchange coupled, which is unlikely given the singlet ground state of U$^{IV}$ in 6. As shown in Figure 8, this procedure does result in the typical magnetic susceptibility of a U$^{IV}$ ion. $\chi_T$ is linear over the entire temperature range, which is consistent with occupancy of only a single crystal field state below 300 K; as seen with mononuclear 5.

Figure 8. Magnetic susceptibility of 7 minus half of the magnetic susceptibility of 6.

In addition to the magnetic susceptibility of the diamagnetic substitute, its magnetic anisotropy is needed and may be obtained from the EPR spectrum. As shown in Figure 9, 7 displays the rhombic EPR spectrum of a low symmetry complex,
and its anisotropy, $\gamma$, is given by $\mu_{\text{nuc}}/\mu_{\text{max}} = 0.39$. The magnetic moment of the ground state may be determined from the EPR spectrum using $4\mu_{\text{eff}}^2 = (g_1^2 + g_2^2 + g_3^2)\mu_B^2$. The resulting value, $\mu_{\text{eff}} = 1.01 \mu_B$, may be compared with $\mu_{\text{eff}} (0 \text{ K})$ determined from a linear fit of the data shown in Figure 8 (1.00 $\mu_B$). The agreement between these values supports the notion that the magnetic susceptibility of the U(V) center in 7 may be modeled by subtracting half the susceptibility of 6 from that of 7.

**Figure 9.** X-band EPR spectrum of 7 and simulation. ($g_1 = 1.712$, $g_2 = 0.851$, $g_3 = 0.666$).

In 3, with strong, antiferromagnetic exchange, the standard Heisenberg-Dirac-van Vleck (HDVV) spin Hamiltonian can be applied to the spins, $\mathcal{H} = -2J\mathbf{S}_1 \cdot \mathbf{S}_2$, where $2J$ is the difference in energy between the singlet and triplet states, and $\mathbf{S}$ is the spin of the electron. In molecules such as 3 with unquenched orbital angular momentum, $\mathbf{L}$, and strong spin-orbit coupling, the total angular momentum, $\mathbf{J}$, rather than $\mathbf{S}$ is applicable, and the system is described using an effective spin, $\mathbf{S}$, which accounts for the degeneracy of the state and is related to the angular momentum by the g-values and Landé factor. Since the states of the individual U centers in 3 are Kramers doublets, $\mathbf{S} = 1/2$, the resulting effective spin Hamiltonian is anisotropic, $\hat{\mathcal{H}} = 4J\mathbf{S}_1 \mathbf{S}_2 + 2J_{||}\mathbf{S}_{||1}\mathbf{S}_{||2}$, where $J_{||} = (g_\parallel/g_\perp)^2(g_{J-1})^2\gamma$ and $\hat{J}_{||} = (g_\parallel/g_\perp)^2(g_{J-1})^2\gamma$, which leads to $\hat{J}_{||} = (g_\parallel/g_\perp)^2 J_{||}$. In other words, the magnetic anisotropy of the isolated ion produces highly anisotropic coupling of the effective spins. In contrast to the anisotropy, the paramagnetic impurity is easy to account for. In this case, the magnetic susceptibility of the three lowest data points was fit to the Curie-Weiss equation, $\chi = C/(T - \theta)$, to determine $\theta$, which was held constant. The value of C was allowed to vary in the fit to account for the paramagnetic impurity. In addition to the Curie constant of the impurity, the parameters used in the fit are $J$ (the HDVV coupling constant) and $w$ (a weighting factor applied to the susceptibility of the diamagnetic substitute to account for weighing errors). The fit of the susceptibility of 3 using this approach is shown in Figure 10. The value of $2J$ determined for 3 has no physical significance in and of itself because the large crystal field in this complex mixes the $^{5}F_{3/2}$ and $^{5}F_{5/2}$ states, so $g_\perp$ is not that of either state. The values of $J_{||}$ and $\hat{J}_{||}$ are still meaningful -- $2\hat{J}_{||}$ is the singlet-triplet gap when the magnetic field is parallel with the axis with $g_\parallel = 1.71$, and $2\hat{J}_{||}$ is the gap when the magnetic field is perpendicular. The small value of $\hat{J}_{||}$ results in an increase in the magnetic susceptibility of 3 at low temperature (~15 K); however, the increase is relatively small because $\chi$ is small ($\chi \propto g_\parallel$. The main effect is that $\chi$ decreases to zero less rapidly below $T_N$ than it would if $\hat{J}_{||} = 0$ (Ising coupling) or if $\hat{J}_{||} = 0$ (Heisenberg coupling).

**Figure 10.** Fitting of the temperature-dependent SQUID magnetization data of 3 with $\gamma = 0.39$ (from EPR), $C = 0.044$, $w = 0.92$, and $\hat{J}_{||} = 67 \text{ cm}^{-1}$ ($J_{||} = 15 \text{ cm}^{-1}$).

The $T_N$ of 70 K in 3 is the second highest reported for a uranium compound; only the 110 K $T_N$ observed in the arené-bridged $\text{U}^{\text{III}}$ dimer reported by Cummins et al. is greater. Only few solid-state materials, such as $\text{UCl}_3$ and $\text{UBr}_3$, with ordering temperatures of 22 and 15 K, respectively, have been studied. Few coordination complexes of $\text{U}^{\text{V}}$ are known that show $f^2-f^1$ coupling between the uranium centers via the bridging ligand. In 1989, Andersen and Edelstein et al. presented the first $\text{U}^{\text{V}}$ complex, [$(\text{MeC}_3\text{H}_4)_2\text{U}_{12-\text{(\text{1,4-N}_2\text{C}_6\text{H}_4})}$], showing antiferromagnetic coupling. In this case, the $\text{U}^{\text{V}}$ centers are bridged by 1,4-di-imidobenzene, which yields to a $T_N$ of ~20 K. In 2008, Mazzanti et al. reported the dimeric $\text{U}^{\text{V}}$ uranyl complex, [$\text{UO}_2(\text{dbm})_2\text{K}(18\text{C}_6)_2$], in which two uranyl–oxos acting as bridging ligands. Herein, the $T_N$ is ~5 K, suggesting relatively weak antiferromagnetic exchange coupling; stronger coupling was observed in a structurally
related trimeric complex with a $T_N$ of 10 K.\textsuperscript{39} Only recently, in 2012, Love, Arnold and co-workers studied the dinuclear complex [(Me$_3$SiO)$_2$O](L)], L = polypyrrolic macrocycle, and reported a strongly antiferromagnetic coupling, with an ordering temperature of 17 K.\textsuperscript{66} Ordering temperatures in a comparable temperature range to 3 (70 K) only occur in uranium solid state compounds, cf., UO$_2$ (28.7 K), UN (53 K) or UBi (285 K).\textsuperscript{44}

**CONCLUSIONS**

In 2008, we reported the synthesis of mononuclear \( U^V \) terminal oxo complexes \( \textit{via} \) multiple-bond metathesis of a high-valent \( U^V \) imido complex with CO$_2$.\textsuperscript{13} With the introduction of the neopentyl-derivatized tris(aryl oxide) tacn chelate, \((^{\text{apMe}}\text{ArO})_3\text{tacn}^3\), (instead of ortho tert-butyl or adamantanly substituents),\textsuperscript{10} the \( U^V \) imido \( \{(^{\text{apMe}}\text{ArO})_3\text{tacn}\\text{UV}^-\text{NMes}^\text{eq}(\text{py})\text{ax}\} \) not only shows an entirely different and surprising coordination mode but also leads to a ‘different’ reaction product when exposed to an atmosphere of CO$_2$. Multiple-bond metathesis reaction of the imido complex with CO$_2$ still eliminates isocyanate but the terminal oxo complex formed \( \textit{in situ} \) dimerizes to yield the principal dinuclear complex 3 with a diamond core \( U^V(\mu-O)_{2}U^V \) structural motif. This reaction selectivity is likely due to the more flexible neopentyl substituents and to additional $\pi$-C–H interactions of the phenolate rings and the neopentyl groups, which stabilize the dinuclear diamond-core.\textsuperscript{10} Complex 3 can be reduced by one or two electrons to yield the mixed-valent \( U^{IV/V} \) bis-$\mu$-oxo complex, \( [K(\text{crypt})]\{(^{\text{apMe}}\text{ArO})_3\text{tacn}\U^{IV/V} \text{UV}^-\text{UV}^-\}(\mu-O)_{2}\} \) (7), and the \( U^{IV/V} \) bis-$\mu$-oxo complex, \( K_2\{(^{\text{apMe}}\text{ArO})_3\text{tacn}\U^{IV/V} \text{UV}^-\text{UV}^-\}(\mu-O)_{2}\} \) (6), respectively. Due to the convenient synthesis \( \textit{via} \) U=NR/CO$_2$ multiple bond metathesis, access to the 18-O labeled iso-topomers is provided by the use of 18-O labeled C$_{18}$O$_2$. Thus, for the first time, the unambiguous assignment of the vibrational signature of the \( [U(\mu-O)_{2}U] \) diamond core structural motif in 3, 6, and 7 has been accomplished. Invariably oxidation of the dinuclear \( U^V/U^V \) complex gave mononuclear \( U^{VI} \) oxo complexes, independent of the coordination chemistry of the oxidant anion. Oxidation of 3 lead exclusively to formation of monomeric \( U^{VI} \) oxo complexes, with the counter ion either coordinated (triflate) or not (SbF$_6$), depending on the oxidizing agent. Additionally, two mononuclear \( U^{V} \) oxo complexes were synthesized independently. The UV/vis/NIR electronic absorption spectra of the pentavalent complexes 3–5 can be understood by considering the tacn anchor to be a single ligand. This assumption means that the coordination sphere of these complexes can be considered distorted octahedra. In this symmetry, the half-occu\-pied orbital is $f_{xy}$, and the $f-f$ transitions may be assigned by analogy to the simple and well-under-stood \( [UX^6]^- \) and \( [UOX^5]^2^- \) systems. The energies of the low-lying $f-f$ transitions show that the splitting of the $f$-orbitals due to their interactions with the ligands is large compared with kT at room temperature. Magnetic measurements of the paramagnetic complexes 2–7 are consistent with large splitting of the $f$-orbitals observed in the NMR. Specifically, only a single, occupied state is observed to relatively high temperature in most of these complexes and the values of $\mu_{eq}$ at 300 K are considerably smaller than that of the free ion. Most remarkable, in this series of bis-$\mu$-oxo diuranium complexes, the \( U^{IV/V} \) dimer, 3, displays unusually strong antiferromagnetic coupling with $T_N = 70$ K. The magnetic susceptibility was fit using the magnetic susceptibility of the \( U^V \) center in 7 to model the magnetic susceptibility of a magnetically isolated \( U^V \) center with the same crystal field as 3. The resulting effective spin coupling constants are $\tilde{J} = -66$ cm$^{-1}$ and $\tilde{J} = -7.7$ cm$^{-1}$, which implies that the magnetic anisotropy, $g_\perp/g_\parallel$, of the \( U^V \) center in 3 is 0.34. The value of $\tilde{J}$ is the largest reported for a \( U^V \) complex, while a larger value of $T_N$ has been observed in a $U^{VII}$ inverse sandwich complex, fitting the magnetic susceptibility of that complex to determine the coupling constant has not been possible.
